Metacognition has been investigated in various areas of psychology (developmental, educational, cognitive, social, brain/neuroscience, etc.). What functions and mechanisms of metacognition researchers believe is essential to elucidate and unveil and probably what methodology to employ, however, depends upon what theoretical approach they would take [3]. For example, cognitive psychologists analyze accuracy and bases of metacognitive judgments in memory and learning – where ►prospective monitoring and ►retrospective monitoring is involved (e.g., feeling of knowing (FOK), judgments of task difficulty and ease of learning (EOL), and judgments of learning (JOL)), and regulatory mechanisms of the cognitive processes that occur based upon those judgments. Educational psychologists investigate the role of metacognition as a tool for self-regulated learning of reading, writing, mathematics, and problem-solving in academic contexts (i.e., in what way metacognition is related with age, motivation, IQ, and academic achievement, and how

it can be cultivated so as to facilitate instruction and learning) [4,5]. Developmental psychologists study ontogeny of metacognition in a variety of areas, by examining individual- and group-differences in metacognitive knowledge, ability, strategies, etc. Brain scientists and cognitive neuropsychologists determine, with elders and patients suffering from brain function disorders, the area(s) that control(s) metacognition, and how those different areas interact.

Finally, the solution to the endlessly debated question of whether metacognition is conscious/explicit versus unconscious/implicit depends upon what metatheory researchers hold. We believe that "metacognition operates implicitly as long as problem-solving proceeds smoothly, but once problems emerge, it begins to function explicitly and solves them; the beneficial functions of metacognition, therefore, come into play whenever trouble-shooting is necessitated."

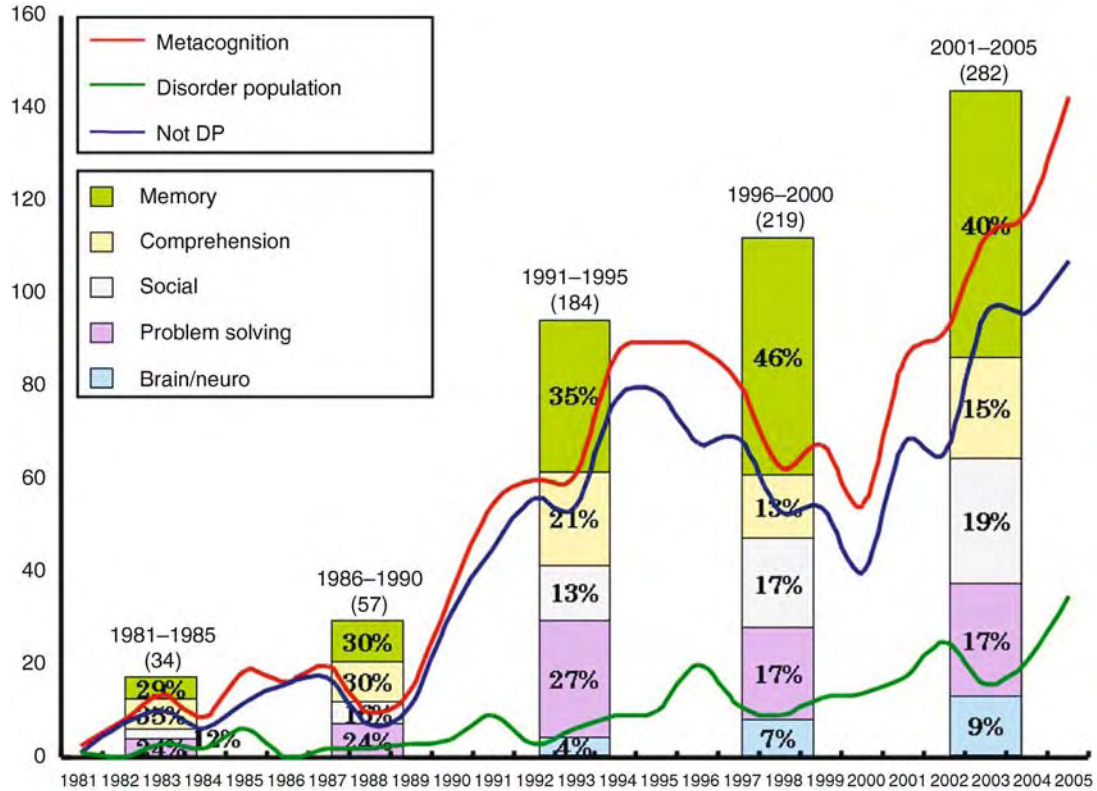
## New Directions in Metacognition Research

Figure 1 shows differentially increasing trends (the number of papers) in the five research areas from 1981 to 2005.

The following characteristics can be pointed out: (i) in the 1980s, most research focused on memory, comprehension, and problem-solving with normal children and adults; (ii) in the late 1980s, social metacognition research began to increase; (iii) in 1992, brain/neuroscience research began (the journal of "Consciousness and Cognition" started), and (iv) research with the populations suffering from psychiatric and brain function disorders increased, corresponding closely to the increment of brain/neuroscience research. In addition to those general trends, the following changes are particularly noteworthy.

### *Metacognition in Social Contexts*

A review on the previous research led to the realizations: (i) although online, or moment-to-moment, monitoring, control, and emotional reactions have been well investigated, implicit theories underlying society and culture were not paid much attention, and (ii) most research has put too much emphasis on metacognitive judgments within the individual, and, therefore, failed to put into perspective the role of metacognition on others and situations [4]. On the basis of those realizations,



**Metacognition. Figure 1** Trends in the five areas of metacognition research from 1981 to 2005. (a) 1358 articles in peer-reviewed journals were retrieved, by searching PsycInfo database with the keyword "metacognition." (b) Five bar graphs indicate the percentages for the total number of articles published during 5 years in the five areas. (c) Line graphs delineate the increasing trend of research in each area from 1981 to 2005.

M

social cognition researchers recently began to address the importance of metacognitive perspectives and accordingly to investigate theories of mind, stereotypes, naïve psychology, and even further critical thinking in discussion situations as well as decision-making processes. Especially, the processes in which creative thinking is generated through discussions with others deserve special attention because they require situational monitoring of grasping the situation and social metacognitive abilities of flexibly collaborating with others.

### Expertise and Metacognition

Metacognition facilitates the progress in expertise. Expertise can be categorized into routine and adaptive expertise [6]. Routine experts carry out a predetermined (or routinized) sequence of procedures accurately and quickly. Adaptive experts, on the other hand, not only carry out such procedures (or strategies) effectively, but because they deeply understand the utility and limitations of those procedures, they can also flexibly and appropriately adjust and modify them so as better to cope with incessantly changing demands of the situation. To become an adaptive expert, therefore, it is not sufficient just to be able to apply previously acquired declarative and procedural knowledge to the task, but one needs to expand expertise constantly, to attempt self-improvement, and to gain many experiences of reflective practice with conditional knowledge and strategies.

To facilitate the acquisition of adaptive expertise in students' learning, metacognitive tool (e.g., computers – which allow to externalize tacit thinking processes and monitor metacognitive strategies) and teachers' adaptive metacognition (e.g., knowledge of how to create social environments to support reflective discourse) are drawing attention from researchers [6,7].

### Frontal Lobe Dysfunction and Metacognition

In the last decade, researchers have attempted to identify the brain regions that control metacognitive functions, especially the executive function involving monitoring and control, using neuroimaging techniques (e.g., positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and magnetoencephalography (MEG)), by examining higher-level mental activities in the brain [8,9].

Patients who are in the pathological states involving the frontal lobes (e.g., traumatic brain injury, frontal strokes, dementia, schizophrenia, attention deficit disorder, Alzheimer's disease, Korsakoff's syndrome) suffer from disorders in cognitive monitoring (e.g., error detection, ►source monitoring in memory retrieval) and cognitive control (conflict resolution, error correction, inhibitory control, emotional regulation). They also suffer from disorders not only in executive functions but also in self-appraisal. However, they do not show disorders in implicit memory (e.g., routinized procedural knowledge), because it requires no active and conscious metacognitive monitoring functions.

The regions that control the error monitoring system are located in the medial areas of the frontal lobe. The fact that the task requiring cognitive and emotional controls activates its mid-frontal areas suggests that a common neuroanatomy underlying those executive controls might exist. For the time being, however, it is still unknown whether this neuroanatomy is a set of independent modules or an integrated cognitive-emotional system that is located in the midfrontal areas.

### Social Neuroscience and Metacognition

To live a social life, human beings need to figure out what the other person thinks, wants, and intends to do, and, at the same time, to make appropriate judgments on what actions should be taken accordingly.

Amodio and Frith [10] conducted meta-analyses on neuroscientific findings to determine in what regions of the brain are located the following functions of social cognition: (i) mentalizing, or theory of mind (TOM) (e.g., self-reflection, person perception, making inference about the other's thought and intent), (ii) outcome monitoring linked to the reward system (reward and punishment), and (iii) action monitoring. The analyses revealed that these functions are located in the medial prefrontal cortex (MPFC).

## Metalearning

►Metacognition

## Metalloproteinases

**Definition**

Metalloproteinases are a family of proteolytic enzymes, known as the metzincin superfamily, that depend on Zn as a co-factor for endopeptidase activity. Several different subfamilies exist, including matrix metalloproteinases (MMPs), A disintegrin and metalloproteinases (ADAMs) and astacins. They can proteolytically degrade extracellular matrix proteins as well as a number of bioactive molecules (e.g. cell surface receptors). In the nervous system, metalloproteinases are implicated in cancer biology and other pathologies, and more recently during development. Secreted, transmembrane and membrane associated forms exist.

## Metamorphosis

**Definition**

A radical change in body form and lifestyle between larval and adult stages of an organism

►The Phylogeny and Evolution of Amniotes

## Metarepresentation

**Definition**

A representation of a representation, e.g. a thought about a thought or a belief about a belief.

►Theory Theory (Simulation Theory, Theory of Mind)

## Metencephalon

**Definition**

Pons and cerebellum.

►General CNS

## Method of Adjustment

**Definition**

A psychophysical procedure in which an observer adjusts stimulus intensity: Increasing intensity until s/he just perceives (ascending trials), or decreasing a clearly perceptible intensity until s/he just fails to perceive the stimulus (descending trials).

►Psychophysics

M

## Method of Constant Stimuli

**Definition**

A psychophysical procedure in which each of a fixed set of stimuli (ranging near the threshold) is presented repeatedly in random order; the stimulus value yielding a detection response in 50 percent of the time is taken as the threshold.

►Psychophysics

## Method of Limits

**Definition**

A psychophysical procedure in which stimulus intensity is varied independently of the observer (by the experimenter or computer program) until the observer

just perceives (ascending trials), or just fails to perceive the stimulus (descending trials).

►Psychophysics

## Methylphenidate

### Definition

Methylphenidate is a stimulant drug that inhibits the noradrenaline and dopamine transporters. The drug is used in the treatment of patients with attention deficit hyperactivity disorder (ADHD).

►Attentional Disorder
►Stimulants

## 1-Methyl-4-phenyl-1,2,3, 6-tetrahydropyridine (MTPT)

### Definition

MTPT is a meperidine derivative that is used for experimental studies in a non-human primate model of ►Parkinson disease.

►Parkinson Disease

## Metric, Metric Space

### Definition

A coordinate system for measuring arbitrary spaces. Measurements and judgments about the similarity or relatedness of objects require an explicitly or implicitly defined metric by which to compare them. For example, a blue ball on the ground and another blue ball on the roof are similar if the metric is color or some quantification of shape, but are relatively dissimilar in terms of spatial location. Scale is of course a critical factor in such judgments – on a continental scale, for example, the two balls are in nearly identical locations. Objects can be located as points or regions within metric spaces according to their properties; e.g. with a color metric, our ball would be located at a point in the blue spectrum. The distance between two objects in the relevant metric space is a measure of their similarity; e.g. blue is more similar to green than it is to red.

## Meynert Cells

### Definition

Meynert (nineteenth century Austrian psychiatrist) cells make up the nucleus basalis neurons in the basal part of the forebrain. They are cholinergic and project widely to the cerebral cortex. The term Meynert cell is also an old term for large pyramidal cells found in occipital cortex near the calcarine fissure. Meynert also gave the first description of “association neurons.”

## Microaerobic

### Definition

Living, active, or occurring only in the presence of low concentrations of oxygen.

## Microampullary Organ

►Electroreceptor Organs

## Microarray, DNA Chip

### Definition

A technology that allows simultaneous measurement of the expression levels for up to tens of thousands of genes (genome-wide expression profiling) in various cells and tissues and under different conditions.

## Synonyms

Characterization of neuronal subtypes by microarrays; Microarray analysis using pure neuronal subpopulations; Identification of neuronal subtype-specific genes by microarrays

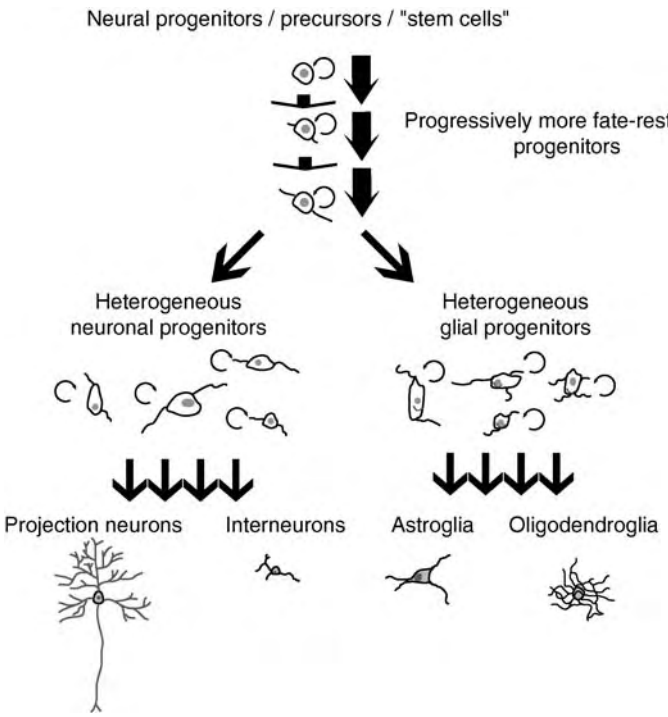
## Definition

Emergence of microarray technology is now enabling molecular-genetic analysis of developmental controls for neuronal subpopulations in the cellularly heterogeneous brain.

## Characteristics

### Cellular Heterogeneity in the CNS

The central nervous system (CNS) is composed of three major cell-types: neurons, astroglia, and oligodendroglia (Fig. 1), and these cell types are differentiated from neural progenitors/precursors/"stem cells," which have self-renewal capacity and multipotency (diverse populations of neural precursors are often termed "neural stem cells," though many types of data indicate that these are quite heterogeneous by region and developmental stage) [1]. Neurogenesis is a very involved process: unlike other tissues, there are hundreds of intermixed neuronal subtypes in the mammalian brain [2–4]. The mechanisms by which such a rich neuronal diversity is produced in the CNS are poorly



**Microarray Analysis of Molecular-Genetic Controls over Development of Neuronal Subtypes.**
**Figure 1** Diversity of neural lineage. There is progressive differentiation of early neural progenitors/precursors/"stem cells," by which they become more fate-restricted by regional type, neuron subtype, and neuronal-glial lineage. Subsequently, neural progenitors include heterogeneous neuronal and glial progenitors. Heterogeneous neuronal progenitors produce related groups of distinct mature neuronal subtypes. Morphologically and functionally, neurons are subdivided into two major classes, excitatory projection neurons that send axons long distances, and inhibitory and local interneurons.

understood. During the development of the CNS, neuronal progenitors undergo precise stepwise differentiation to ultimately produce the complex variety of neuronal subtypes that populate the mature brain. Morphologically, neurons are divided into two broad categories: (i) projection neurons, which extend axons to distant target areas, and (ii) interneurons, which make local connections. Projection neurons and interneurons are further subclassified by location, neurotransmitter production or sensitivity, electrophysiological characteristics, and axonal connectivity and neuronal circuits within which they send projections. Gene expression analysis in the brain is generally complicated by the coexistence of many different cell types, resulting in high background noise and the masking of small differences in cell type-specific gene expression.

The relative lack of approaches for efficient isolation of pure neuronal populations, and the difficulties involved with analysis of minute amounts of mRNA, have previously hampered progress toward understanding the molecular development of neuronal subtypes. However, the rapid emergence of microarray technologies, as well as development of approaches for isolation of neuronal subtypes have provided for a synergistic advance in the field. ►DNA microarrays (also known as gene chips or gene arrays) are a collection of DNA spots representing individual genes, arranged on a chip, and used for monitoring expression levels of thousands of genes simultaneously, thus allowing comparison of thousands of genes between different populations.

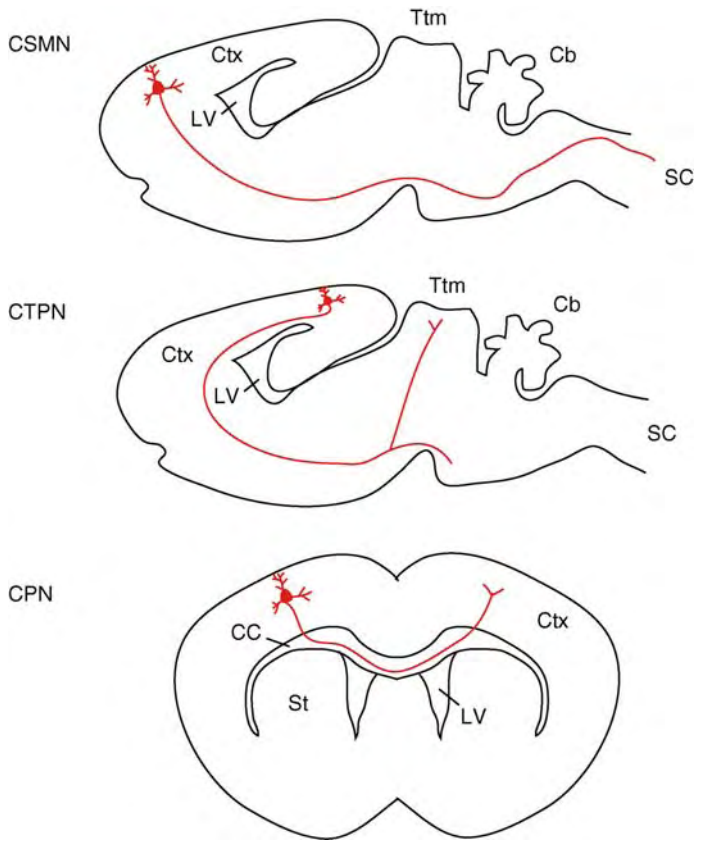
In this essay, we review three recent approaches using microarray analysis to investigate the molecular developmental controls and/or identity of specific brain neuronal subtypes.

## Molecular Controls over Development of Corticospinal Motor Neurons (CSMN) and Other Forebrain Neuronal Populations

Our laboratory has begun to uncover molecular controls over the development of corticospinal motor neurons (CSMN; upper motor neurons; residents of layer V of the cerebral cortex) and other forebrain projection neurons (Fig. 2). CSMN degeneration is a key component of motor neuron degenerative diseases, including amyotrophic lateral sclerosis (ALS), and CSMN injury contributes critically to the loss of motor function in spinal cord injury. The anatomical and morphological development of CSMN have been extensively characterized, but the genetic mechanisms that control their development were previously unknown. Importantly, understanding the molecular controls over CSMN circuitry development might enable future strategies for therapeutic repair or modulation in disease.

To uncover the gene regulation programs of mouse CSMN development and other forebrain projection neurons, our lab has developed and established approaches using comparative microarray analysis of stage-specific gene expression by CSMN purified by ►fluorescence-activated cell sorting (FACS) [5]. Like other forebrain projection neurons, there are no specific markers for CSMN that could be utilized to isolate them. However, CSMN extend axons to the spinal cord, so they can be retrogradely labeled by injecting an appropriate retrograde label in the spinal cord. We developed an approach to retrogradely label CSMN with fluorescent latex microspheres; dissociate labeled cortex; and isolate the labeled CSMN by FACS. In addition to CSMN, we also purified two distinct cortical projection neuron subtypes, callosal projection neurons (CPN) and corticotectal projection neurons (CTPN) (Fig. 2). CPN are interhemispheric callosal projection neurons, a subset of which share lamina V location with CSMN, offering insight into genes that are involved in cell type specification rather than lamina specification by comparing between CSMN and CPN. CTPN are subcerebral layer V projection neurons extending axons to the tectum instead of the spinal cord, likely sharing some overlapping early developmental gene regulation programs with CSMN. Comparison between CSMN and CTPN can allow the identification of genes unique to CSMN among other highly related layer V subcerebral projection neurons. Using these FACS-purified pure cell populations at multiple developmental stages, we performed microarray analyses, and identified genes specifically expressed in CSMN as well as genes that are expressed in other projection neurons, but not in CSMN. We classified those genes into one of six groups based on expression profiles suggestive of specific role in distinct aspects of CSMN development: (i) genes that are expressed at higher levels in CSMN at all stages of development and might be important for the establishment and maintenance of CSMN identity; (ii) genes that are highly expressed in CSMN early in development and may be important for early CSMN specification; (iii and iv) genes that exhibit increasing levels of expression as CSMN develop and might control intermediate (iii) or later aspects (iv) of CSMN differentiation; (v) genes that are expressed at higher levels in CSMN compared to the highly related population of CTPN and are representative of the small class of genes that differentiate CSMN from other subcerebral projection neurons of layer V; (vi) genes that are negative markers of CSMN but that are expressed in CPN or CTPN.

Thus, we identified a number of CSMN-specific genes, including *COUP-TF1 interacting protein 2* (*Ctip2*, also known as *Bcl11b*). *Ctip2* had very recently been identified by Kominami and colleagues to have a critical role in the immune system, controlling T cell subtype specification and survival in the developing thymus, but had not been investigated in the CNS. Ctip2 is expressed at high levels in layer V of cortex, and



**Microarray Analysis of Molecular-Genetic Controls over Development of Neuronal Subtypes.**
**Figure 2** Subtypes of cortical projection neurons. Arlotta et al. analyzed three distinct populations of cortical projection neurons [5]. CSMN (corticospinal projection neurons) are located in the sensorimotor area of the neocortex and maintain primary projections to the spinal cord. CTPN (corticotectal projection neurons) are located in the visual area of the neocortex and maintain primary projections to the superior colliculus of the tectum. CPN (callosal projection neurons) are primarily located in layers II/III, V and VI, and extend their axons across the corpus callosum to the contralateral hemisphere. Cb; cerebellum, CC; corpus callosum, Ctx: neocortex, LV: lateral ventricle, SC: spinal cord, St: Striatum, Ttm: tectum. (Adapted from Molyneaux, Arlotta et al. *Nat Rev Neurosci*, 2007 [2].)

expressed both in CSMN and CTPN, but not in CPN, indicating that Ctip2 is expressed at high levels in subcerebral projection neurons which extend axons to outside of the cortex. In *Ctip2* mutant mice, CSMN axons exhibit defects in fasciculation, outgrowth, and pathfinding, resulting in failure of CSMN to connect to the spinal cord [5]. Interestingly, Arlotta, Molyneaux and others in our lab have recently identified that *Ctip2* in the *Gsh2* developmental domain plays a totally different and critical role in the proper differentiation of striatal medium spiny neurons and the patch-matrix cytoarchitectural organization of the striatum.

Another CSMN-specific gene, *Forebrain embryonic zinc finger-like* (*Fezl*, recently renamed *Fezf2*) [6], is also expressed in CSMN and CTPN, like *Ctip2*. However, unlike *Ctip2*, *Fezl* is expressed in ventricular zone and subventricular zone progenitors of subcerebral neurons, in addition to subcerebral neurons themselves. *Fezl* is centrally involved in the birth and specification of CSMN. Importantly, in *Fezl* mutant mice, the entire population of both CSMN and CTPN is never born in the cortex. In addition, both anterograde and retrograde labels confirm the total absence of the corticospinal tract in *Fezl* mutant mice, indicating that no other neurons compensate to form such circuitry. Gain-of-function analysis using *in vivo* electroporation showed that overexpression of *Fezl* in cells that give rise to superficial layer neurons results in an accessory layer of *Ctip2*-expressing subcerebral neurons that send axons toward the spinal cord, further reinforcing that *Fezl* plays a critical role in the specification of subcerebral projection neurons.

As a third example of critical regulators of the development of CSMN and other corticofugal neurons, Lai, Jabaudon and others in our lab recently identified *Sox5* as regulating the sequential generation

of cortical projection neuron diversity [7]. It represses the onset of differentiation of CSMN, thereby allowing generation of the other corticofugal neuron types. *Ctip2*, *Fezl*, *Sox5*, and a larger program of molecular-genetic controls over CSMN differentiation all were identified by the original microarray analysis.

## Molecular Analysis of Excitatory and Inhibitory Neurons in the Adult Forebrain

Nelson and colleagues used microarray analysis to propose a molecular taxonomy of major neuronal classes in the adult forebrain [8]. They identified various neuronal subtypes by retrograde labeling with a fluorescent tracer, or using fluorescently labeled neurons from transgenic mice. In these transgenic mice, specific neuronal subtypes are visualized with green/yellow fluorescent protein (GFP and YFP, respectively) driven by the promoters *Thy1*, *Gad1*, and *Gad2*. Thy1 is an immunoglobulin superfamily member that is expressed by excitatory projection neurons in many parts of the nervous system, as well as by several nonneuronal cell types, including thymocytes. Gad1/2 are glutamic acid decarboxylase 1 or 2, and are expressed in distinct subpopulations of inhibitory GABAergic interneurons. Using these transgenic mice, they defined 12 neuronal populations characterized by neurotransmitters and electrophysiological properties, and analyzed gene expression profiles by microarray. Based on similarity of the gene expression, they classified these 12 populations, showing that this molecular taxonomy largely parallels the traditional classification criteria (e.g. GABAergic neurons vs. glutamatergic pyramidal neurons, neocortex vs. hippocampus vs. amygdala).

## Molecular Analysis of Striatal Projection Neuron Subtypes

Yang and colleagues analyzed differential gene expression between striatal projection neuron subtypes using FACS-purified cell populations from ►GENSAT project (Gene Expression Nervous System Atlas) BAC transgenic mice [9,10]. In the striatum, 95% of the neurons are projection neurons called medium spiny neurons (MSNs), and these neurons are subdivided into two morphologically indistinguishable neuronal subtypes: striatonigral MSNs and striatopallidial MSNs. Current understanding suggests that these two projection neuron pathways provide balanced but antagonistic influences on the basal ganglia output and behavior. It is thought that their functional imbalance is involved in movement disorders, such as Parkinson's and Huntington diseases, and psychiatric disorders including schizophrenia and depression.

Using FACS, Yang and colleagues isolated striatonigral MSNs and striatopallidial MSNs for microarray studies from mice containing cell type-specific regulatory elements that express enhanced green fluorescent protein (EGFP) specifically in MSN subtypes. Their analysis identified a new set of differentially expressed genes in addition to known MSN subtype-specific genes, such as *Penk1* and *Drd2*. They identified the transcription factors *Zfp521* and *Ebf1* as new striatonigral MSN-specific genes, which functionally interact with each other. Importantly, they showed that the number of striatonigral MSNs and their axonal projections to the substantia nigra are affected in *Ebf1* mutant mice, whereas striatopallidal MSNs are preserved, demonstrating that these striatonigral MSN-specific genes play a critical role in the development of striatonigral MSNs.

## Molecular Analysis of Neuronal Subtypes in the Future

Although developmental, precursor, and stem cell biology may enable future therapeutic approaches to some diseases of the nervous system, including neurodegenerative diseases, little is known about individual molecular and genetic characteristics of individual neuronal subtypes. Understanding regarding molecular controls over development of specific neuronal subtypes is still in its infancy. Recent microarray technologies have enabled analysis of broad gene expression profiles using smaller amounts of RNA (nanogram levels). New markers and control genes now enable dissection of neuronal diversity more and more deeply. Additionally, availability of genetic labeling using fluorescent proteins under neuronal subtype specific promoters has dramatically increased. These approaches will promote understanding of the molecular development and molecular anatomy, and functional analysis of individual neuronal subtypes, and reveal gene regulation underlying precise development and potentially regeneration of specific neuronal subtypes.

## Microarrays

### Definition

Microarrays consist of thousands of cDNAs printed on a glass slide. Alternatively, the GeneChip® arrays (Affymetrix, Santa Clara, CA, USA) consist of quartz chips on which up to 500,000 oligonucleotide probes can exist on an area of 1.28 cm2. Both are used to bind labelled cDNA derived from tissues or cells of interest. Differences in the intensity of binding between cDNA samples can be used to assess differences in RNA expression levels between experimental samples. This technology can pinpoint differences between normal and diseased tissues, identify genes crucial to certain disease processes, and generate gene expression profiles unique to individual tissue samples. Such "fingerprints" are proving useful in assignment of identity to samples and revealing relationships between them.

►Bioinformatics

## Microcephaly

### Definition

Developmental brain disorder characterized by a small-sized brain and skull, often associated with mental retardation.

►Endocrine Disorders of Development and Growth

## Microcircuits

Patterns of interaction between nerve cells which process information such as the odor patterns.

►The Proust Effect

## Microdialysis

### Definition

A technique for measuring extracellular concentrations of substances (e.g. neurotransmitters) in tissues, usually in vivo, by means of a small probe equipped with a semi-permeable membrane. Substances may also be introduced into the extracellular space through the membrane.

## Micro-electrode Array (MEA)

### Definition

Device for *in-vivo* or *in-vitro* multi-site, long-term recordings of the electrical activity of neuronal populations. MEAs may be passive (arrays of metal or silicon electrodes), or active (electrodes and amplifiers are integrated in the same chip). Since their introduction in the early 80's due to advancements in micro-fabrication technologies, these devices have enabled the experimental investigation of the collective dynamics and computational properties of large populations of neurons.

# Microfilament

## Definition

A thin (approximately 7 nm in diameter) cytoskeletal filament composed of a linear polymer of actin subunits.

# Microglia

## Definition

(Greek mikros, small; glia, glue) Small supporting cells of the central nervous system (CNS), serving as brain-resident phagocytes and antigen-presenting cells. They normally exist in a resting state, but a trigger (injury, illness) can activate them to support injured tissue. If their activation is not properly regulated, it can have devastating side effects, including neuroxicity.

►Microglia: Functions in Immune Mechanisms in the Central Nervous System

# Microglia: Functions in Immune Mechanisms in the Central Nervous System

Akio Suzumura
Department of Neuroimmunology, Research Institute of Environmental Medicine, Nagoya University, Nagoya, Japan

## Definition

Immune mechanisms are implicated in various pathological conditions in the central nervous system (CNS). Microglia are resident immune cells functioning as either antigen presenting cells or effector cells that destroy myelin or neurons. In contrast, they also produce a variety of neurotrophins to support neuronal survival. Microglia-derived cytokines induce proliferation of astrocytes, also suggesting their possible role in gliosis formation.

## Characteristics

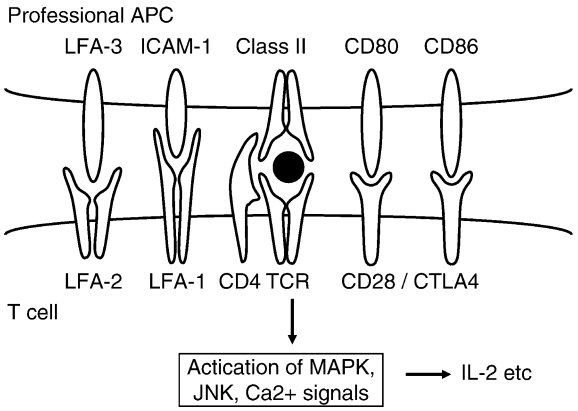
### Quantitative Description

Since ►microglia first appear in the early postnatal period in the brain parenchyma, they may play a role in the development of neural cells and/or neuronal network. Another important role of microglia is the function as immune cells in the CNS. Microglia provide a first line defense in either infection or injury of the brain. They express ►CD14 and a variety of ►toll-like receptors (TLR). Microglia express TLR1,2,3,4,6, which are upregulated in inflammatory lesions in the CNS. Microglia recognize lipopolysaccaride (LPS) or peptidoglycan on the bacterial membrane non-specifically via these receptors to produce ►cytokines, such as IL-1β, IL-6, TNFα, and other inflammatory mediators like nitric oxide (NO) or reactive oxygen species (ROS). Microglia are also activated through complement receptors and Fc receptors. This classical innate immunity had been considered to be only a defense mechanism in the CNS. The brain had long been considered as an immunological privileged site where specific immune responses do not occur. However, studies in the last three decades have clearly disclosed that this is no more the case. In acquired immunity, microglia play a critical role, either as antigen presenting cells (APC), or effector cells. Microglia, as other neural cells, do not usually express class II ►major histocompatibility complex (MHC) antigen that is essential for antigen presentation to T cells. However, in some pathological conditions, microglia are induced to express class II MHC antigens. Although astrocytes and endothelial cells can be class II MHC antigen-positive, the functional APC that express all other co-stimulatory molecules are microglia.

Microglia also function as effector cells in inflammation, demyelination, and gliosis via production of various inflammatory mediators. In addition, the recent studies have shown the involvement of immune and/or inflammatory mechanisms in neurodegenerative disorders such as Alzheimer's disease (AD), Parkinson's disease (PD) and Huntington disease (HD). Activated microglia are accumulated in or around degenerating neurons in these diseases, and have been shown to play a principal role in neuronal degeneration and regeneration.

### Microglia as Antigen Presenting Cells

The immune response is initiated when protein antigen is presented to T cells by APC. The APC process



**Microglia: Functions in Immune Mechanisms in the Central Nervous System. Figure 1** Molecules and signals in antigen presentation. Antigens (*black circle*) processed and expressed on class II MHC antigens by professional antigen presenting cells (APC) are recognized by T cell receptors (TCR), which activates MAP kinase (MAPK), JNK and $Ca^{2+}$-NFAT system. These signal cascades activate transcriptional regulation region to produce T cell activating factors including interleukin-2 (IL-2).

antigen, either foreign or self, by internalizing and digesting it into peptide fragments. The processed peptide fragments are then expressed on the surface of APC as a form of MHC-peptide complex. When the MHC-peptide complex interacts with T cell receptors (TCR), subsequent T cell activation occurs (Fig. 1). Class II MHC molecules present antigen to CD4-positive T cells, while class I MHC molecules present antigen to CD8-positive T cells. Binding of the MHC-peptide complex to the TCR is critical, but not sufficient, for activation of T cells. There should be several co-stimulatory molecules that interact with the ligands on T cells for sufficient activation. These co-stimulatory molecules include B7.1 (CD80), B7.2 (CD86), leukocyte function associated molecule-3 (LFA-3), intercellular adhesion molecule-1 (ICAM-1), ICAM-2 and ICAM-3. They bind to ligands on T cells to form ligand pairs such as B7.1-CD28/CTLA4, B7.2-CD28/CTLA4, LFA-3-CD2, ICAM-1, 2 or 3-LFA-1. Interaction of T cells and APC occurs in a MHC-restricted manner. The T cells recognize a foreign antigen only when the antigen forms a complex with self MHC molecules on APC. Therefore, the cells expressing class II MHC and co-stimulatory molecules constitutively are considered to be professional APC. Those include macrophages, B cells, dendritic cells, and Langerhans cells. Non-professional APC differs from the professional APC by expressing little or no MHC class II molecules constitutively, and by not having a complete set of co-stimulatory molecules. The candidates for the non-professional APC in the CNS are microglia, astrocytes and endothelial cells. They do not usually express class II MHC antigen constitutively. These cells, however, are induced to express class II MHC molecules with certain inflammatory cytokines, especially IFNγ [1], and also express some of the co-stimulatory molecules [2]. There are evidences that endothelial cells, astrocytes, and pericytes can process and present protein antigens to primed CD4-positive T cells in vitro, but the specific role of these cells as APC in vivo is still unclear. At least, astrocytes do not usually express class II MHC antigens in vivo, even in the presence of inflammatory cells. Since microglia have very similar characteristics to macrophages and are induced to express class II MHC antigens as discussed above, microglia are the most possible candidates for APC in the CNS. Microglia express co-stimulatory molecules, such as B7, ICAM, LFA3, but only some in astrocytes. It has been shown that human microglia, but not astrocytes, express both B7-1 and B7-2, suggesting that microglia is a much more suitable candidate for local APC in the CNS. In fact, microglia when stimulated with IFNγ can present antigen to antigen-specific T cells in vitro. Microglia have been shown to function as APC in pathological conditions in vivo [3]. In bone marrow chimera of experimental autoimmune encephalomyelitis (EAE)-susceptible and resistant animals, EAE lesions developed only when the perivascular microglia were replaced with an EAE-susceptible strain, suggesting that antigen presentation by perivascular microglia is critical for the development of EAE lesions.

Professional APC such as dendritic cells or macrophages produce IL-12 and IL-18. IL-12 and IL-18 are key cytokines in the development of autoimmune processes, regulating differentiation of naïve T cells into T helper 1 (Th1). To exert its activity, IL-12 needs to form a heterodimer of P35 and P40; homodimer of P40 suppresses the functional heterodimer. Immature IL-18 is cleaved by caspase-1 to become functionally mature IL-18 that induces differentiation of Th1 and cytotoxic activity of NK and T cells. Microglia produce a functional heterodimer of IL-12 upon stimulation. LPS-stimulated microglia have bioactivity of IL-18 to induce INFγ production by T cells in synergism with IL-12. This suggested that microglia also express caspase-1.

Another IL-12 family cytokine, IL-23, is a heterodimer of IL-12 p40 and p19. It has been shown recently that p35 knockout mice that cannot produce IL-12 develop EAE, while p40 knockout mice that cannot produce IL-12 and IL-23 do not, suggesting that IL-23, but not IL-12, is a critical cytokine for the Th-1 development [4]. IL-27 is also an IL-12 family member, and plays a role in the early stage of Th-1 development. Both IL-23 and IL-27 are produced by microglia upon activation [5]. Since all Th-1 inducing cytokines are produced by microglia in the CNS, while IL-4 that induces Th-2 response is not

produced, a Th-1 response occurs much more easily in the CNS than a Th-2 response.

The most potent stimulus to induce MHC class II antigen on neural cells is IFNγ. IFNγ has been considered to be produced exclusively by lymphoid cells, such as T cells or NK cells. However, microglia can produce IFNγ upon stimulation with IL-12 and/or IL-18 [6]. Thus, induction of MHC antigen expression on neural cells may occur without immune cell infiltration in the CNS.

## Immune Mechanisms in Neurodegenerative Disorders

Recent evidence suggests the presence of immune and/or inflammatory mechanisms in neurodegenerative disorders [7]. In AD, PD and HD, there is no obvious accumulation of activated immune cells. Nevertheless, potent inflammatory molecules such as cytokines, chemokines, free radicals and complement are detected in the cerebrospinal fluid and CNS lesions. Amyloid-β (Aβ) or tau protein reportedly activates microglia to produce neurotoxic substances to kill neurons. Visualizing microglial activation in vivo using positron emission tomography (PET) with activated microglial marker, PK11195, clearly demonstrated accumulation of activated microglia in the early stage of AD and HD. Therefore, microglia may play a critical role in neurodegeneration and prevention of the active inflammation may suppress disease process. A non steroidal anti-inflammatory drug (NSAID) was used for this purpose to prevent the progression of AD, and gave favorable results.

In contrast, microglia can also produce neurotrophic factors, such as nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), glial cell line-derived neurotrophic factor (GDNF) and neurotrophin-3, 4 (NT-3,4), suggesting neuroprotective functions of microglia. Taken altogether, immune and inflammatory mechanisms may be involved in neurodegeneration, where microglia play a critical role on both neuronal degeneration and regeneration. The mechanisms of how microglia exert the opposite effects on neurons are currently unknown. There may be distinct subpopulations of microglia, toxic versus protective. Alternatively, some specific ligand-receptor complex may decide the functions of microglia.

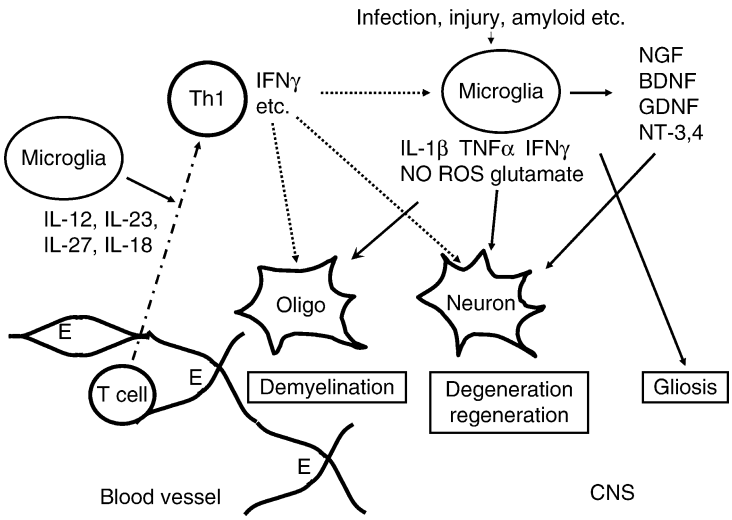
## Microglia as Effector Cells in Inflammation and Neuronal Degeneration

Microglia produce a variety of cytokines, such as IL-1, IL-5, IL-6, IL-8, IL-10, IL-12 family, TNFα, and M-CSF, in response to LPS and/or IFNγ. These stimuli also induce chemokines, nitric oxide (NO), superoxide ($O_2^-$) and glutamate. TNFα, NO, $O_2^-$ have been shown to destroy mylein and neuronal cells to induce demyelination and neuronal degeneration. Recently, it has been shown that the most neurotoxic factor from activated microglia is glutamate, which disturbs the mitochondrial respiratory chain to cause energy depletion in neurons [8]. TNFα was a candidate for neurotoxic factor from activated microglia. However, in our experimental conditions, TNFα did not kill neurons. Although TNFα by itself is not a potent neurotoxic factor, it induces glutamate production in microglia via upregulation of glutaminase. Interestingly, thus produced glutamate is released through the hemichannel of gap junctions but not through glutamate transporters [9]. Thus, microglia can act as effector cells in either inflammatory demyelination and neuronal degeneration. In addition, since IL-1β, TNFα and IFNγ induce proliferation of astrocytes in vitro, these microglia-derived cytokines may contribute to the formation of gliosis, a scar formation in the CNS (Fig. 2).

Recently, a great deal of attention has been focused on the relation between activated microglia through adenosine 5′-triphosphate (ATP) receptors and neuropathic pain [10]. Neuropathic pain is often a consequence of nerve injury through surgery, bone compression, diabetes, or infection. There is abundant evidence that extracellular ATP and microglia have an important role in neuropathic pain. The expression of the P2X4 receptor, a subtype of ATP receptors, is enhanced in spinal microglia after peripheral nerve injury model, and blocking pharmacologically and suppressing molecularly P2X4 receptors produces a reduction of the neuropathic pain. Several cytokines such as IL-1β, IL-6, and TNFα in the dorsal horn are increased after nerve lesion and have been implicated in contributing to nerve-injury pain, presumably by altering synaptic transmission in the CNS, including the spinal cord. Nerve injury also leads to persistent activation of p38 mitogen-activated protein kinase (MAPK) in microglia. An inhibitor of this enzyme reverses mechanical allodynia following spinal nerve ligation. ATP is able to activate MAPK, leading to the release of bioactive substances, including cytokines, from microglia. Thus, diffusible factors released from activated microglia by the stimulation of purinergic receptors may have an important role in the development of neuropathic pain.

## Suppression of Microglial Functions as Therapeutic Strategy

Inhibitory cytokines such as TGFβ and IL-10 suppress the IFNγ-induced class II MHC antigen expression and LPS-induced cytokine production by microglia. Therefore, suppression of microglial functions by TGFβ or IL-10 may result in suppression of the disease process. As expected, these inhibitory cytokines successfully suppressed the development of EAE. The cAMP-elevating agents, either phosphodiesterase inhibitor or adenylate cyclase activator, suppress TNFα and NO production by microglia. These drugs have also effectively suppressed the development of EAE and clinical relapse of multiple sclerosis (MS). Analysis of



**Microglia: Functions in Immune Mechanisms in the Central Nervous System. Figure 2** Functions of microglia in immune and inflammatory mechanisms in the CNS.Microglia produce a variety of neuroprotective and neurotoxic factors. These factors play a role on the development of demyelination, neuronal degeneration, regeneration, and gliosis. Infiltrating T cells, especially Th1 cells, activate microglia to function as effector cells in neuroinflammation. *Arrows* indicate functions of soluble factors from microglia, and *dotted lines* indicate functions of Th1-derived factors. E: endothelial cells, oligo: oligodendrocytes, other abbreviations are indicated in the text.

the cytokine profile in CD4-positive T cells during the treatment of MS shows that phosphodiesterase inhibitors induce a Th1 to Th2 shift. Since phosphodiesterase inhibitors upregulate IL-10 and down-regulate IL-12 production by microglia, this mechanism may be involved in the Th1 to Th2 shift to suppress MS relapse.

HMG Co-A reductase inhibitors (statins) may also be useful to suppress EAE via suppressing microglial activation, cytokine production and induction of MHC antigen. Statins are now the candidates for the treatment of MS, ischemic brain disease and neuronal degeneration.

As discussed above, neurotoxic glutamate is released from microglia via gap junctions. In addition, microglia produce glutamate by glutaminase using extracellular glutamine as a substrate. Thus, inhibitors for gap junction or glutaminase may be able to suppress glutamate from activating microglia without affecting physiological glutamate. These drugs are another candidate for the treatment of neurodegenerative disorders.

# Microglial Cell

## Definition

The microglial cell is the smallest of the neuroglial cells. It is of mesodermal origin and some can act as phagocytes absorbing and digesting up neuronal waste products and debris.

# Microglial Signaling Regulation by Neuropeptides

KYOUNGHO SUK
Department of Pharmacology, School of Medicine, Kyungpook National University, Daegu, Korea

## Definition

Neuropeptides are short-chain peptides found in brain tissue, with some functioning as neurotransmitters and others functioning as hormones. Recent studies indicated that neuropeptides may directly or indirectly regulate glial functions in the central nervous system (CNS). Described here are the effects of neuropeptides pituitary adenylate cyclase-activating polypeptide (PACAP) and corticotropin-releasing hormone (CRH) on inflammatory activation of microglia and intracellular signal transduction pathways associated with the microglial activation. As microglia are believed to function as the resident immune defense system of the brain and to participate in neuroinflammation in response to intrinsic or extrinsic stimuli, the neuropeptides may modulate immune and inflammatory responses in the CNS by influencing microglial signaling.

## Characteristics

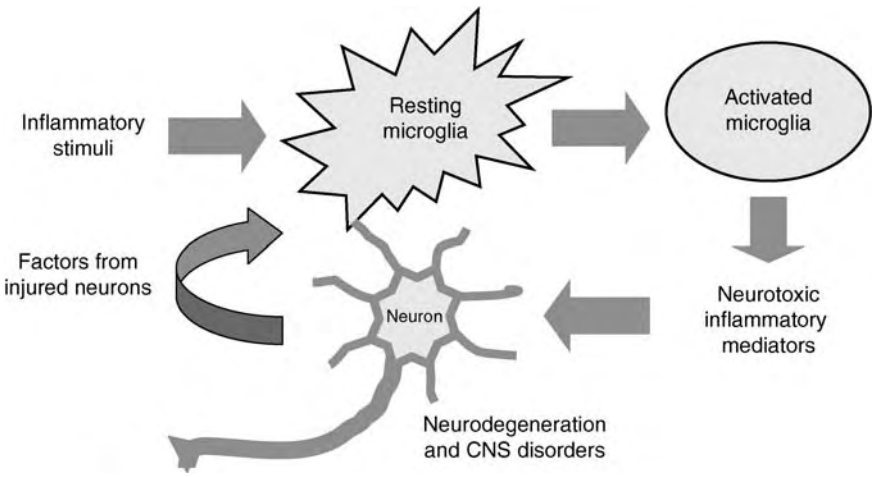
### Description of the Structure/Process/Conditions

#### *Microglia and Neuroinflammation*

The central nervous system (CNS) consists of neuron and neuroglia. Neuroglia were once merely thought of as a structural support for neurons in the CNS. Increasing evidence now indicates that neuroglial cells actively participate in brain functions by nurturing neurons and facilitating neuronal activity. Four different types of neuroglial cells – oligodendrocytes, ependymal cells, astrocytes, and ►microglia – fulfill distinct tasks. Oligodendrocytes are the myelin-forming cells of the CNS and they ensure rapid signal conduction in the white matter. Ependymal cells constitute the lining of cerebral ventricles. Astrocytes provide guiding structures during development and they represent important elements for controlling the composition of the extracellular space mediating signals between the brain endothelium and the neuronal membrane. Microglial cells are immunocompetent cells in the brain and their functional role is best defined as the first responsive elements during pathologic events in the CNS [1]. Microglial cells are ubiquitously distributed in the CNS and comprise of up to 20% of the total glial cell population in the brain [2]. Microglial cells function in a manner similar to monocytes/macrophages in the periphery. Microglia, as the CNS resident phagocytes, migrate to the area of injured nervous tissue, and they engulf and destroy microbes and cellular debris. In response to brain injury or infection, microglia are mobilized to secrete various soluble immune mediators such as cytokines and chemokines, and they function as immunocompetent cells expressing MHC class I and II molecules. Activated microglia also secrete neurotoxic inflammatory cytokines and mediators such as tumor necrosis factor (TNF)α and nitric oxide (NO), which may initiate or amplify the neuroinflammatory responses [3,4] (Fig. 1). The activation of microglial cells may initially be aimed at protecting neurons. Activation of microglial cells and inflammatory products derived from them, however, have also been implicated in neuronal destruction commonly observed in various neurodegenerative diseases [4] (Fig. 1). Recent studies indicated that brain inflammation is closely associated with the pathogenesis of neurodegenerative diseases. Compared with inflammation in peripheral tissue, inflammation in the brain appears to follow distinct pathways and time courses. The major immune cells that respond to and produce inflammatory stimuli in the brain are microglia. The inflammatory responses in microglia are coordinately regulated by the production of cytokines, chemokines, proteases, and reactive oxygen or nitrogen species. These molecules function in a synergistic and/or antagonistic manner, eventually leading to neurodegeneration via inflammatory cascades. The activation of microglia is regulated by signals from neurons and astrocytes as well as various systemic signals.

#### *Intracellular Signal Transductions of Microglial Activation*

Microglia exert both positive and negative effects on the nervous system. As the first line of defense, microglia protect neurons against toxic insults, while the chronic and excessive activation of microglia may play direct or indirect roles in various neuropathologies [5]. The signals that activate microglia or that are produced by activated microglia could be neutralized in order to suppress the negative effects of microglia. Alternatively, intracellular signal transduction pathways that are involved in microglial activation could be interrupted to block microglial activation. Many endogenous and



**Microglial Signaling Regulation by Neuropeptides. Figure 1** A role of microglial activation in neurodegeneration. Resting microglia (ramified type) can be activated by inflammatory stimuli such as LPS, IFNγ, and hypoxia. Activated microglia (amoeboid type) produce a variety of inflammatory mediators including nitric oxide, TNFα, and IL-1β, which in turn cause neuronal injury and neurodegeneration (and possibly other CNS disorders). Damaged neurons also act as a stimulus that induces neuroinflammation. This constitutes a vicious cycle by which the process of inflammation-mediated neurodegeneration is perpetuated.

exogenous agents have been demonstrated to influence the microglial signal transduction. Signal transduction pathways that have been shown to be associated with microglial activation include NF-κB, MAPKs, STAT/IRFs, and TLRs.

NF-κB constitutes a canonical pathway of microglial activation in neuroinflammation. NF-κB regulates a wide variety of inflammatory gene expressions in microglia, and its signaling pathways are well characterized. Upon the stimulation of microglia with a wide variety of inflammatory mediators, IκB kinase (IKK) is activated to phosphorylate IκB. Phosphorylated IκB triggers its degradation through the ubiquitin system, where the target molecule is masked by a chain of ubiquitins for degradation by the 26S proteasome. The free NF-κB can then translocate to the nucleus and activate the transcription of numerous inflammatory genes. NF-κB has been shown to mediate the transcriptional activation of CD40, inducible nitric oxide synthase (iNOS), cyclooxygenase (COX)-2, chemokines, TNFα, interleukin (IL)-1 and other cytokines upon the stimulation of microglia with lipopolysaccharide (LPS; endotoxin), transglutaminase 2, S100B, thrombin, gangliosides, plasminogen, advanced glycation endproducts (AGEs), and neuromelanin. NF-κB also plays an important role in a number of neuropathology occurring in neurodegenerative processes and neuronal cell death [6, 7]. NF-κB activation can prevent the death of neurons by inducing the production of anti-apoptotic proteins. Molecular pathways upstream and downstream of NF-κB in neurons are being elucidated and may provide novel targets for therapeutic intervention in various neurological disorders. MAPK pathways have been implicated in the inflammatory activation of glial cells. MAPKs consist of three subgroups: ▶p38 MAPK, extracellular signal regulated kinase (ERK), and c-Jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK). These kinases are activated by the phosphorylation of both tyrosine and threonine residues that is catalyzed by specific upstream MAPK kinase (MAPKK). Activated MAPKs phosphorylate their specific substrates on serine and/or threonine residues, thus ultimately leading to the activation of specific subsets of transcription factors. While ERKs are stimulated mainly by growth factors and tumor promoters, p38 MAPK and JNK/SAPK are activated by inflammatory stimuli and environmental stresses such as osmotic shock. In the CNS, ERKs and p38 MAPK have been shown to regulate the iNOS and TNFα gene expression in endotoxin-stimulated primary glial cultures. In addition, MAPKs play a crucial role in regulating the neurochemistry of N-methyl-D-aspartate receptors, their physiologic and biochemical/biophysical properties, and their potential role in pathophysiology [8]. JAK/STAT1 and IRF-1 constitute the main component of IFNγ signaling in microglia. IFNγ phosphorylates STAT1 through JAK and subsequently the IRF-1 expression is induced. As a transcription factor, these two gene products regulate the expression of numerous IFNγ-inducible genes, thereby playing a critical role in the cellular response to IFNγ. The specific inhibition of JAK by AG490 attenuated the IFNγ-induced NO production in microglia as well as in mixed glial cultures, thus demonstrating the critical role of JAK in IFNγ signaling in the glia. In contrast to the downstream

signaling events of microglial activation that have been partly elucidated, little is known about the early signaling events proximal to the plasma membrane. Toll-like receptors (TLRs) play a critical role in early innate immunity to invading pathogens by sensing microorganisms. TLRs are evolutionary conserved homologues of the Drosophila Toll gene, which recognize structural motifs that are only expressed on microbial pathogens called pathogen-associated molecular patterns (PAMPs). PAMPs include bacterial DNA, flagellin, and their cell wall components such as LPS, peptidoglycan, and lipopeptides. The stimulation of TLRs by these PAMPs initiates a signaling cascade that involves a number of Toll/IL-1 receptor (TIR) domain-containing adaptor proteins (MyD88, TIRAP/Mal, TRIF, TRAM), protein kinases (IRAK-1, IRAK-M, MAPK), and other signaling intermediates (TRAF6, Tollip). The TLR-initiated signaling pathways ultimately lead to the activation of NF-κB, PKR, STAT1, and IRFs. Some of these signaling pathways are involved in the microglial activation.

## Regulation of the Structure/Process/Conditions

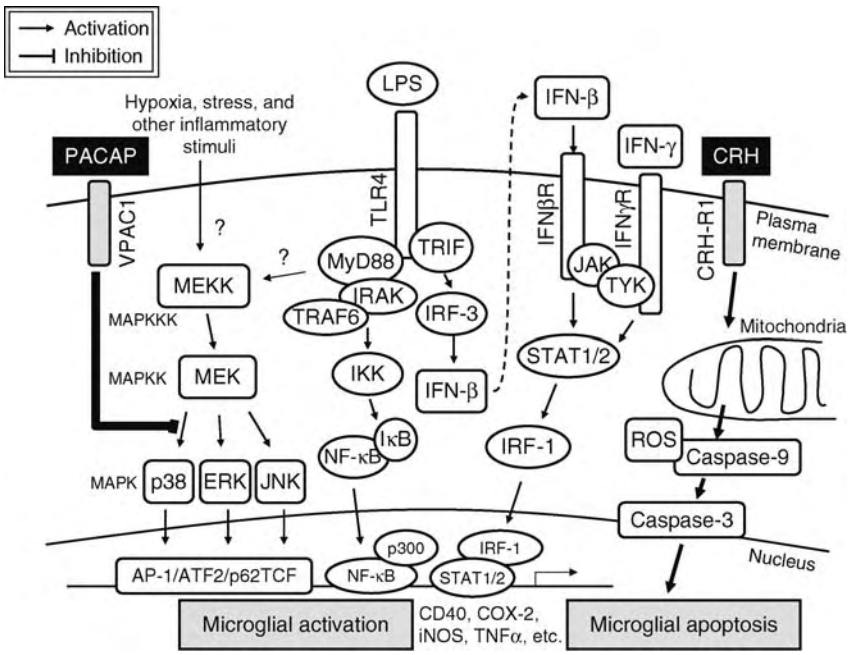
### *Regulation of Microglial Signal Transductions by Neuropeptides*

►Neuropeptides are short-chain peptides found in brain tissue, with some functioning as neurotransmitters and others functioning as hormones. Recent studies indicated that neuropeptides may directly or indirectly regulate glial functions in the CNS. Among many neuropeptides, this essay focused on the effects of PACAP and CRH on inflammatory activation of microglia and intracellular signal transduction pathways associated with microglial activation.

#### *Effect of PACAP*

Pituitary adenylate cyclase-activating polypeptide (PACAP) is a neuropeptide that was first identified as an activator of adenylate cyclase in rat anterior pituitary cells. PACAP is widely distributed in the brain and peripheral organs, notably in the endocrine pancreas, gonads, and respiratory and urogenital tracts. Consistent with its widespread distribution, PACAP exerts multiple actions in the CNS and periphery through three distinct receptor subtypes – PAC1, VPAC1, and VPAC2. In the CNS, PACAP is thought to act as a neurotrophic factor during development, whereas the neuropeptide seems to function as a neuroprotector against various insults in the adult brain [9]. PACAP also elicits a broad spectrum of biological effects on natural and acquired immunity [10]. PACAP has been shown to inhibit cytokine production and the proliferation of T cell, and to inhibit several macrophage functions, including phagocytosis, respiratory burst, chemotaxis, and cytokine production. It has also been shown that PACAP inhibits inflammatory activation of microglia through VPAC1 receptor. PACAP inhibited production of chemokines and CD40 expression from LPS-stimulated microglia. However, little information is available regarding the effect of PACAP on microglial signal transduction pathways. In one report, PACAP inhibited the JNK signaling pathway in endotoxin-activated microglia. PACAP inhibited TNFα production from rat microglia following spinal cord injury via a cAMP-dependent pathway. PACAP has also been reported to inhibit LPS-stimulated production of inflammatory mediators by inhibiting NF-κB activation. Moreover, PACAP inhibition of NF-κB-controlled gene expression was mediated via inhibition of CBP-NF-κB interaction. A recent study systematically evaluated the effect of PACAP on signal transduction of microglia initiated by various inflammatory stimuli, in an attempt to better understand how the neuropeptide PACAP influences CNS inflammation [11] (Fig. 2). In that study, the BV-2 mouse microglia cell line was utilized as a model system to determine the effect of PACAP on microglial signal transduction. The BV-2 cell line was originally established by oncogenic viral transformation of primary microglial cells derived from mouse brain. The cell line is known to exhibit morphological and functional properties that are similar to freshly isolated microglia, and has been widely used for the investigation of microglial activation. It has been shown that PACAP suppresses the inflammatory activation of BV-2 microglia via specific inhibition of LPS-induced p38 MAPK pathway (Fig. 2): (i) pretreatment of BV-2 cells with PACAP resulted in a significant decrease in LPS- or IFNγ-induced NO production as well as iNOS and IL-1β mRNA levels; (ii) the inhibitory effect of PACAP appeared to be mediated through an increase in intracellular cAMP; (iii) PACAP inhibition of LPS-induced NO production was accompanied by inhibition of p38 MAPK activation, but not ERK, JNK, or NF-κB; and (iv) IFNγ-induced STAT-1 activation or IRF-1 induction was not significantly influenced by PACAP [11].

As it has previously been shown that hypoxia induces inflammatory activation of cultured microglia and their inducible nitric oxide synthase induction via the p38 MAPK pathway [12], it was hypothesized that the neuropeptide may inhibit the hypoxic activation of microglia, and this may provide a neuroprotection against inflammation-induced neuronal injury. When this possibility was tested using cultured microglia and PC12 cells, it was found that PACAP attenuates inflammatory activation of microglia under hypoxic condition, and protects co-cultured PC12 cells from microglial neurotoxicity [13]. In addition, the neuropeptide reduced the hypoxia-induced activation of p38



**Microglial Signaling Regulation by Neuropeptides. Figure 2** Schematic diagram of microglial signal transduction following exposure to LPS, IFNγ, and other inflammatory or stress signals: the action sites of PACAP and CRH. After treatment of microglia with LPS, TLR4 signaling is initiated with the ensuing NF-κB activation and IFNβ production, which feeds back to evoke the secondary signaling. IFNγ induces STAT1 activation followed by IRF-1 induction. Hypoxia and stress signals initiate three subgroups of MAPK pathways. NF-κB, STAT/IRF, and MAPKs commonly induce the transcription of a wide variety of inflammatory genes. PACAP specifically inhibits p38 MAPK, while CRH induces apoptosis of microglia via mitochondrial pathway (ROS production and caspase-9 activation with subsequent caspase-3 activation).

MAPK, indicating that the p38 MAPK is also a molecular target of the PACAP action in microglia under the hypoxic condition. The neuroprotective effects of PACAP in animal models of cerebral hypoxia/ischemia may be partly due to its direct actions on brain microglia and neurotoxic inflammation.

### *Effect of CRH*

Corticotropin-releasing hormone (CRH) plays a pivotal role in stress responses as a key mediator of hypothalamic-pituitary-adrenocortical system [14]. CRH is released from the hypothalamus, and then carried to the pituitary gland, where it causes secretion of the adrenocorticotropic hormone (ACTH) that triggers cortisol secretion from the adrenal glands. The peptide hormone has also been implicated in the regulation of neuronal cell survival, exerting either neurotoxic or neuroprotective effects. Peripheral secretion of CRH is involved in the modulation of peripheral immune responses by acting at specific receptors on multiple populations of immune cells to produce a wide range of effects. Earlier works support a proinflammatory role of CRH: it induced activation of monocytes/macrophages, T cells, and mast cells. In the CNS, primary microglia cultures, microglial cell lines, and microglia in vivo have been shown to be a direct target of CRH action. Microglia express CRH receptor 1 (CRH-R1), and the ligation of this receptor by CRH induced TNFα release in cultured rat microglia, IL-18 and β-endorphin production in microglial cells, and cAMP accumulation in mouse microglia, respectively.

Proapoptotic activity of CRH has previously been reported in the PC12 rat pheochromocytoma cell line with neuronal characteristics, where CRH induced Fas ligand expression and ►apoptosis. CRH also increased the apoptosis of activated T cells through Fas ligand induction, suggesting a role for CRH in immunotolerance. Based on these proapoptotic activities of CRH, the effects of the neuropeptide on the survival or death of purified microglia have been investigated [15]. While vasoactive intestinal peptide, substance P, cholecystokinin, or neuropeptide Y did not affect microglial cell viability, CRH induced a classical apoptosis of mouse microglia in culture as evidenced by nuclear condensation and fragmentation, TUNEL staining, and cleavage of caspase-3 and poly (ADP-ribose) polymerase (PARP) protein (Fig. 2). CRH, however, did not influence nitric

oxide production or inflammatory gene expression including cytokines and chemokines, indicating that CRH did not affect the inflammatory activation of microglia. The CRH-induced microglial apoptosis appeared to involve a mitochondrial pathway and reactive oxygen species (Fig. 2). Taken together, these results indicate that the stress neuropeptide CRH may regulate neuroinflammation by inducing the apoptosis of microglia, the major cellular source of inflammatory mediators in the CNS.

## Function

### Regulation of Microglial Signaling by PACAP

PACAP has been proposed as a deactivator of innate immune responses. In the CNS, PACAP suppressed neuroinflammation by inhibiting inflammatory activation of microglia. Therefore, PACAP may act as a neuroprotector by inhibiting microglial activation under the conditions where inflammatory responses associated with microglial activation play an important pathogenic role in neuronal injury. In fact, the neuroprotective effect of PACAP has been well documented in a variety of experimental models in vivo as well as in vitro. PACAP has been reported to reduce brain damage after global and focal ischemia in vivo. Also, PACAP has been found to prevent neuronal cell death under various neurotoxic conditions in vitro: PACAP protected cerebellar granule neurons against oxidative stress- or ethanol-induced apoptosis; it reduced LPS-induced neurotoxicity in mixed cortical neuron/glia cultures; and it attenuated β-amyloid-induced toxicity in PC12 cells. Although some of these previous works have shown that PACAP may act on neurons directly to exert its neurotrophic or neuroprotective activities, it has also been suggested that inhibition of pathological activation of microglia may be another way that PACAP exerts its neuroprotective effects in vivo. The findings that PACAP specifically inhibits p38 MAPK activation thereby resulting in down-regulation of inflammatory activation of microglia enhance our understanding of the mechanistic basis of the neuroprotective action of PACAP. The cellular target of PACAP action in the CNS may be either microglia or neurons, and the molecular target of PACAP in microglia appears to be p38 MAPK.

During cerebral ischemia, hypoxia may not only impose the damage on neurons directly, but also promote neuronal injury indirectly via microglial activation. The neuroprotective PACAP also inhibited microglial activation under hypoxic conditions, thereby suggesting that PACAP may directly act on microglia to exert its neuroprotective effects against hypoxia/ischemia. In addition, using a co-culture of microglia and PC12 cells, it has been shown that PACAP is protective against microglial neurotoxicity. In the co-culture system, it was demonstrated that: (i) hypoxia could stimulate microglia to secrete neurotoxic molecules, which actually mediated PC12 cell death; and (ii) PACAP acted on microglia to block their activation under hypoxic condition, mitigating PC12 cell death [13]. The results corroborated the hypothesis that the PACAP inhibition of hypoxic activation of microglia is neuroprotective.

### Induction of Microglial Apoptosis by CRH

Activated microglia are believed to contribute to neuronal damages in neurodegenerative diseases or stroke through the excess release of proinflammatory and/or cytotoxic factors [4]. An apoptotic elimination of activated microglia has recently been suggested as one way of regulating the microglial activation in vitro as well as in vivo [15]. It has recently been reported that a stress neuropeptide CRH induces apoptosis of microglia, and reactive oxygen species (ROS) generation and mitochondrial pathways are involved in the CRH-induced microglial apoptosis. Ase microglia play a central role in inflammatory responses in the CNS, the current results indicate an important link between the stress response and the neuroinflammation, and may have a relevance to CNS pathologies under stress conditions. An abnormal production of CRH under stress conditions may deregulate the self-regulatory microglial apoptosis, thereby contributing to CNS diseases.

CRH may exert dual effects on microglia depending on their proliferative state. CRH seems to enhance proliferation of serum-starved microglia to some extent, while it may induce apoptosis of normally growing microglia (at the inflammatory sites in vivo). The CRH-induced proliferation was also observed in astrocytes cultured under serum-free conditions, while CRH inhibited proliferation of mouse melanoma cells that were actively progressing through the cell cycle. CRH did not affect the viability, proliferation, or apoptosis in astrocyte cultures that were maintained with 5% serum. Astrocytes have previously been reported to express CRH receptor. These results suggest that CRH exerts differential effects on cell proliferation or viability depending on the conditions under which the cells reside.

CRH mediates immunological, autonomic, and behavioral responses to stress. In the CNS, CRH has been shown to act on glia to exert either neurotoxic or neuroprotective effects depending on the experimental systems employed. In addition, the neuropeptide induced apoptosis of microglia, a cellular population that plays a pivotal role in neuroinflammation. As neuroinflammation is closely associated with neuronal injury and neurodegenerative diseases, the CRH induction of microglial apoptosis suggests an existence of the interconnection among stress responses, neuroinflammation, and CNS disorders. However, further study is required to precisely understand the in vivo relevance of the CRH-induced microglial apoptosis, and to determine the molecular mechanisms underlying the CRH-induced microglial apoptosis.

# Microgliosis

## Definition

Aggregation of microglia in the brain in response to hypoxia/ischemia or infection. Microglial activation involves increased recruitment of cells through mitosis of resident microglia and probably also from bone marrow derived precursors that infiltrate the central nervous system (CNS). Microglia phagocytose debris occurring as a result of injury, programmed cell death and possibly axonal and dendritic remodelling. Prolonged microglial activation in inflammation can release toxic substances including cytokines and cause cell death.

## Synonyms

Microelectrophoresis; Iontophoretic application; Pressure micro-ejection

## Definition

Microelectrophoresis: Ejection of charged molecules from a capillary microelectrode close to or within a nerve or muscle cell by electrical current.

Micro-pressure ejection: Ejection by pressure of a small liquid volume containing a chemical or drug from a micropipette in the vicinity of a cell or group of cells.

## Purpose

►Microiontophoresis and Micro-pressure Ejection are used to apply drugs or chemicals to nerve cells. The ejected agents bind to cell membrane binding sites (►receptors) or cross the cell membrane, altering the cell's excitability. The methods are also used to mark the location of cells in a region of the central nervous system.

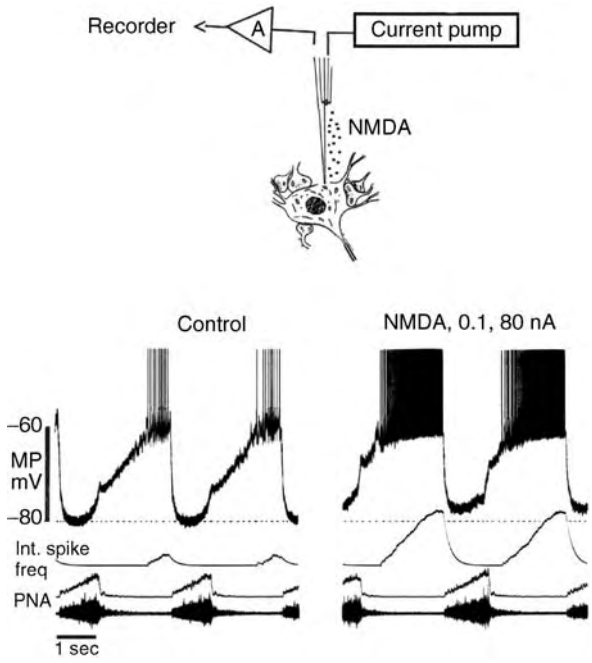
## Principles

### Microiontophoresis

Microiontophoresis involves the ejection of charged drugs or chemicals from a conductive electrolyte solution in a glass capillary micropipette into the extracellular milieu of cells or into a cell's cytoplasm. Direct current (d.c.), either negative or positive and ranging from nanoamperes to microamperes ($10^9$–$10^6$ amperes), is passed from a "current pump" through a fine silver wire to a micropipette solution containing positively- or negatively-charged molecules to be ejected. To eject the substance, current of a polarity identical to its charge is applied. Between ejections, applying current of opposite polarity retains the substance. Thus, for example, acetylcholine ($ACh^+$) would be ejected with positive current and retained by negative current.

Extracellular microiontophoresis is commonly used to test several substances on a neuron by ejecting them sequentially or simultaneously from a ►multibarrel microelectrode assembly (Fig. 1). Several ►neurotransmitters or analogs that bind to cell receptors and alter action potential discharges as well as substances that block the neurotransmitter's receptor sites can be tested on the same cell. After testing, a dye can be ejected to mark the location of the cell.

Present day microiontophoresis units typically consist of 6–7 constant current pumps, or channels. Each pump provides a separate, independent source of ejecting or retaining current that is passed through a silver wire to a current-conducting electrolyte solution, typically 165 mM NaCl solution containing the charged chemical. The current pump incorporates a high voltage



**Microiontophoresis and Micropressure Ejection. Figure 1** Intracellular recording of responses evoked from a respiratory neuron during extracellular s of an excitatory neurotransmitter analog. Upper panel: Recording and microiontophoresis arrangement The sharp tip of the recording micropipette penetrates the cell membrane and records membrane potential changes evoked during extracellular iontophoresis of *N*-methyl-D-aspartate (NMDA), an amino acid that binds to a subtype of receptor for the excitatory neurotransmitter glutamate. Iontophoresis of NMDA is accomplished by applying negative d.c. current from a current pump connected to a silver wire inserted in a pipette containing 0.1 M Sodium NMDA, a negatively charged compound. Lower panels: Responses to NMDA recorded intracellularly from a respiratory neuron in an anesthetized cat. Traces, top to bottom in each panel, are: Membrane potential (MP), the time integral of neuron action potential frequency, the time integral of action potential frequency recorded from the phrenic nerve and the electroneurogram of phrenic nerve activity (PNA) (Lalley and Bischoff, unpublished data).

►field effect transistor (FET) amplifier with plus or minus outputs in the nanoampere range (typically, up to ± 200 × $10^9$ amperes). Some units may have pumps capable of generating microampere currents for dye ejection. Channel output is measured and recorded by a ►galvanometer and can be operated manually, programmed for automatic sequential operation or controlled externally, e.g. by computer. A summing, or neutralizing channel applies a current that is the sum of all applied currents but of opposite polarity to a separate barrel of the array. The neutralizing current balances out ejecting and retaining currents that might otherwise pass through the extracellular fluid to alter excitability by direct electrical field effects on the cell membrane.

Intracellular microiontophoresis of a chemical allows nerve cells to be labeled for subsequent histological identification, or it can be used to study the actions of a substance that alters excitability through actions on intracellular signaling proteins. The ejecting current is most often delivered while recording with a conventional capillary microelectrode, or with ►theta glass capillary tubing (►theta tubing). On one side of the ►theta glass septum is the electrolyte and a fine Ag/AgCl wire connected to an amplifier to record bioelectric signals, and on the other side is the solution of molecules to be ejected and a silver wire connected to the current pump.

Extracellular microiontophoresis can be combined with intracellular recording to more thoroughly analyze effects of ejected substances on membrane potential (Fig. 1). A single glass capillary micropipette for intracellular recording is either glued side by side to a multibarrel microiontophoresis assembly, or a recording micropipette is inserted into the enlarged central orifice of a customized multibarrel array. In either case the tip of the recording pipette projects beyond the multibarrel tips, usually by 40–50 µM.

## Advantages and Disadvantages

### Advantages and Disadvantages of Microiontophoresis

Microiontophoresis has three principal advantages over other methods of drug and chemical delivery. (i) Diffusion barriers and breakdown by enzymes that impede access to neurons by parenteral administration can be avoided. (ii) Effects of neurotransmitters, their congeners, second messengers and receptor blockers can be analyzed on a single cell. (iii) Many cells can be tested in an experiment.

There are two major disadvantages. (i) Neuronal responses can be evoked with the applied electric current and interpreted as drug or chemical effects, however there are well-established control procedures [1] that minimize the potential for such current artifacts. (ii) The concentration of the ejected substance at the site of action is unknown, however there are procedures to determine relative potencies of test substances [2,3].

### Micro-Pressure Ejection

Pressure ejection is used to deliver uncharged or poorly charged substances to the vicinity of neurons. The technique is useful for in vivo and in vitro studies. In the in vitro slice preparation, separate recording and pressure-ejection pipettes are positioned close to the target neuron. In the in vivo preparation, ►micropressure ejection has been used in two general ways:

1. Single micropipettes with relatively large tips (10 µm or greater) have been used to inject nanoliter volumes for the purpose of altering the excitability of groups of neurons in a small area.
2. Volumes less than 1nl of neuroactive drugs and neuromodulators have been applied to single neurons from ►multibarrel assemblies during extracellular or intracellular recording [4].

Volumes of neuroactive substances are ejected from micropipettes connected by soft catheter tubing and high-pressure tubing to a source of compressed gas, usually nitrogen. A switch- or ►TTL pulse-controlled ►solonoid valve is used to deliver pulses of known pressure and duration.

The general procedure is to microscopically measure with a reticule the length (L) of fluid ejected under pressure from a pipette of known internal radius (r). Volume (V) can then be calculated from $V = \pi r^2 L$. From the known concentration of the pipette solution, the amount of substance ejected can be calculated. The volume ejected is linearly proportional to either the applied pressure with ejection duration held constant, or to ejection duration when pressure is constant [4].

Micropipettes with tip resistances between 1.0 and 1.4 MΩ resistance will usually eject uniform volumes for a given pressure and duration over long test periods. Pipettes with finer tips tend to plug in brain or spinal cord tissue, whereas larger tips (resistance less than 1.0 MΩ) produce variable results, and larger volumes are ejected that are more likely to produce volume-related response artifacts [4,5].

### Advantages and Disadvantages of Micro-Pressure Ejection

Pressure ejection has several advantages. (i) Uncharged drugs and chemicals that can be made soluble in an aqueous medium can be tested on neurons. (ii) As with microiontophoresis, diffusion barriers and enzymatic degradation outside the central nervous system are circumvented. (iii) There is no possibility for current artifacts, as with iontophoretic drug delivery. (iv) The essential equipment is relatively inexpensive.

Disadvantages include (i) Potential effects on neurons related to pH when substances are made soluble by pH values <5.5 and >8. (ii) Solution volume can produce injury discharges and changes of membrane potential, and can move nerve cells away from the recording and drug delivery assembly. (iii) Solvents other than water, such as ethanol or dimethylsulfoxide, can also alter neuron behavior. (iv) Solutions of high osmolarity can affect neuron responses through redistribution of cytoplasmic and extracellular water.

# Microneurography

## Definition

Technique developed by Karl–Erik Habarth and Åke Vallbo in Upsalla, Sweden, in which an insulated tungsten microelectrode is inserted percutaneously into an accessible peripheral (or cranial) nerve to record electrical signals from nerve fibers (axons) in awake human subjects. The technique is used to record from groups of axons or, usually, single type-identified axons such as muscle spindles, tendon organs and tactile afferents. Microneurography also allows one to record from single unmyelinated axons, such as afferent C fibers or sympathetic axons. The technique has contributed significantly to our understanding of sensorimotor control, pain and cardiovascular control.

## Microstimulation

### Definition

Low intensity (less than about 100 μA) electrical activation of a region of the brain through a microelectrode.

## Microtubule

### Definition

Microtubules form a major part of the cell's cytoskeleton and are found in most eukaryotic cells. Structurally, microtubules are hollow cylinders that are ~24 nm in diameter with a wall thickness of about 5 nm and with 13 protofilaments that consist of the dimeric protein α- and β-tubulin. Microtubules exhibit a structural and functional polarity with a minus (−) end and a plus (+) end. Microtubule-organizing centers nucleate the assembly of microtubules from their -end. In a process known as dynamic instability, microtubule plus ends undergo alternating phases of growth and shrinkage. Microtubules associate with a wide range of proteins (e.g., microtubule-associated proteins (MAPs) which contribute to the dynamism of the microtubule networks, and motor proteins involved with transport such as kinesin). Microtubules are involved in a number of cellular processes such as cell elongation, migration and maintenance of cell shape. Microtubules also serve as tracks for the movement of molecular cargo in cells; in neurons this is particularly important where material needs to be transported down the length of the axon (axonal transport).

## Micturition, Neurogenic Control

William C. de Groat
Department of Pharmacology, University of Pittsburgh Medical School, Pittsburgh, PA, USA

M

### Synonyms

Neural control of voiding; Neural control of the lower urinary tract; Urination

### Definition

#### Micturition

Storage and periodic elimination of urine are dependent on a complex neural control system that coordinates the activity of two functional units in the lower urinary tract: (i) a reservoir (the urinary bladder) and (ii) an outlet (consisting of the bladder neck, urethra, and striated muscles of the ►pelvic floor) [1–3]. During urine storage the bladder outlet is closed and the bladder is quiescent, thereby maintaining a low intravesical pressure over a wide range of bladder volumes. A low intravesical pressure is essential to allow urine flow from the kidney into the bladder. During micturition (►Bladder control (neural)), outlet resistance is reduced as a consequence of relaxation of the pelvic floor and periurethral striated muscles in conjunction with mechanical shortening of the urethra and opening of the bladder neck. These changes are followed in a few seconds by a bladder contraction and a rise in intravesical pressure, which is maintained until the bladder is empty. This reciprocal relationship between bladder and outlet is controlled by neural pathways

(►Urogenital reflex) that are organized in the brain and lumbosacral spinal cord.

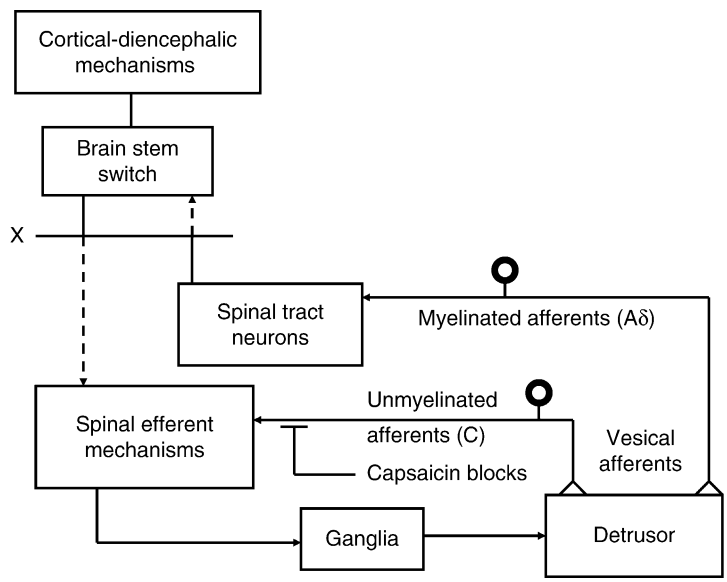
## Characteristics

During urine storage intravesical pressure is usually below 10 cm $H_2O$ and maximal pressure in the urethral outlet is high (70–100 cm $H_2O$) [1]. Cystometric studies in normal healthy women revealed that the first sensation of bladder filling and the first desire to void occur on average at mean bladder volumes of 160 and 320 ml, respectively. Voiding occurs at intravesical pressures ranging between 50 and 70 cm $H_2O$ and normal maximal urine flow rates range between 20 and 30 ml/min. Healthy women normally void 5–7 times per day at a mean volume of 300 ml.

### Peripheral Nervous System

The lower urinary tract is innervated by three sets of nerves arising at the lumbosacral level of the spinal cord [1–3]. Like other visceral organs, the bladder and urethra receive an innervation from both divisions of the autonomic nervous system. Parasympathetic preganglionic pathways, which arise from neurons in the intermediolateral region of the sacral spinal cord ($S_2$–$S_4$) travel in the ►pelvic nerve and provide an excitatory input to parasympathetic ganglion cells located in the pelvic plexus and in the wall of the organs. These cells in turn innervate the bladder and urethral smooth muscle. Sympathetic preganglionic pathways to the lower urinary tract which arise in the lumbar spinal segments ($L_1$–$L_4$) provide excitatory input to ganglion cells in the sympathetic chain ganglia as well as prevertebral ganglion cells in the hypogastric and pelvic plexus that in turn innervate bladder and urethral smooth muscle [3]. Periurethral striated muscles, which form the external urethral sphincter, and pelvic floor striated muscles are innervated by sacral motoneurons ($S_2$–$S_3$) that send axons into the ►pudendal nerves and levator ani nerves, respectively.

Afferent activity arising in the bladder is conveyed to the central nervous system via both sets of autonomic nerves [2,3]. The most important afferents for initiating micturition are those, which arise from neurons in the lumbosacral dorsal root ganglia and travel in the pelvic nerve to the sacral spinal cord. These afferents consist of small myelinated (A-δ) and unmyelinated (C) fibers (Fig. 1), which convey impulses from tension receptors and nociceptors in the bladder wall. Afferent activity arising in the urethra passes through the pelvic, hypogastric and pudendal nerves.



**Micturition, Neurogenic Control. Figure 1** Diagram showing the organization of the parasympathetic excitatory reflex pathway to the detrusor muscle. Scheme is based on electrophysiologic studies in cats. In animals with an intact spinal cord, micturition is initiated by a supraspinal reflex pathway passing through a center in the brain stem. The pathway is triggered by myelinated afferents (A δ fibers) that are connected to the tension receptors in the bladder wall. Injury to the spinal cord (indicated by X) above the sacral segments interrupts the connections between the brain and spinal autonomic centers and initially blocks micturition. However, over a period of several weeks following cord injury, a spinal reflex mechanism emerges, which is triggered by unmyelinated vesical afferents (C-fibers); the A-fiber afferent inputs are ineffective. The C-fiber reflex pathway is usually weak or undetectable in animals with an intact nervous system. Capsaicin (20–30 mg, subcutaneously) blocks the C-fiber reflex in chronic spinal cats, but does not block micturition reflexes in intact cats. Intravesical capsaicin also suppresses detrusor hyper-reflexia in patients with neurogenic bladder dysfunction.

### Central Nervous System

The central neural control of micturition depends on reflex pathways in the spinal cord and brain stem as well as circuitry in the forebrain that mediate the voluntary control of micturition [3,4]. Anatomical tracing and electrophysiological studies in animals have revealed that spinal reflex pathways are primarily polysynaptic and consist of at least three elements. Afferent neurons from the bladder and urethra send projections into Lissauer's tract from which collaterals extend laterally and medially around the surface of the dorsal horn into the region of the autonomic nuclei and the dorsal commissure. Afferent fibers terminate on interneurons. Interneurons in turn make synaptic connections with preganglionic neurons that send their axons into the periphery via the ventral roots. A similar circuitry controls the motoneurons innervating the urethral sphincter.

Electrophysiological and tracing studies in animals [2,3,5] and brain imaging experiments in humans [4,6] have been identified various populations of neurons at sites in the brain stem (periaqueductal grey, ►pontine micturition center (Barrington's nucleus), medullary raphe nucleus, locus ceruleus, A5 noradrenergic nucleus) and in the forebrain (paraventricular nucleus, medial preoptic nucleus, cingulate gyrus, prefrontal cortex, basal ganglia) that have a role in the regulation of micturition.

### Lower Level Components

The parasympathetic postganglionic innervation of the bladder is distributed throughout the base and dome of the bladder and each smooth muscle cell receives a neural input [2,3]. However the sympathetic innervation is concentrated in the base of the bladder and in the urethra. Afferent nerves are also heavily concentrated in the bladder base. A-δ afferent nerves are located in the smooth muscle layers; whereas C-fiber afferents (►C-fiber afferent nerves) are distributed within and below the epithelial layer (the urothelium) [1,3,7].

### Peripheral Nervous System

Parasympathetic nerves excite bladder smooth muscle via the release of acetylcholine and a noncholinergic transmitter (adenosine triphosphate, ATP). Acetylcholine acts on ►muscarinic receptors ($M_2$ and $M_3$); whereas ATP acts on P2X ►purinergic receptors [8–10]. Parasympathetic nerves also inhibit urethral smooth muscle via the release of nitric oxide. Sympathetic postganglionic nerves which release norepinephrine provide an excitatory input to the smooth muscle of the bladder neck and urethra and an inhibitory input to smooth muscle of the bladder dome. The excitatory effects of adrenergic nerves in the bladder and urethra are mediated by $\alpha_1$-adrenergic receptors, whereas the inhibitory effects in the bladder dome are mediated by $\beta_3$ adrenergic receptors [8,10]. Sympathetic nerves also inhibit transmission in bladder parasympathetic ganglia.

A-δ afferents respond to bladder distension and normally trigger the sensation of bladder fullness and initiate voiding [3]. C-fiber afferents are activated by bladder irritation or infection and can induce bladder hyperactivity. C-fiber afferents synthesize and release various transmitters including substance P, calcitonin-gene-related peptide, and ►glutamic acid and express multiple receptors, e.g., purinergic ($P2X_{2/3}$), neurokinin and capsaicin receptors (TRPV1) [3,9]. Although afferent nerves can respond directly to bladder distension or to chemicals present in the urine, it is also likely that they are affected indirectly by chemical transmitters released from the urothelial cells which line the bladder lumen and which receive an afferent innervation. Recent studies have revealed that urothelial cells release ATP and nitric oxide in response to stretch or chemical stimulation. Urothelial cells express ►TRPV1 receptors [7] as well as receptors for various transmitters including, muscarinic, nicotinic, adrenergic, purinergic and serotoninergic receptors [1,3]. It has been proposed that ATP and nitric oxide released by urothelial cells act on afferent nerves adjacent to and within the urothelium to influence afferent nerve firing. Thus urothelial cells exhibit "neuronal-like" properties and seem to play a role in sensory mechanisms in the bladder [7].

### Central Nervous System

Electrophysiological studies in animals indicate that the micturition reflex is mediated by a spinobulbospinal (SBS) reflex pathway that passes through a coordinating center (the pontine micturition center, PMC) in the rostral brain stem (Fig. 1). This pathway is activated by A-δ bladder afferents and is in turn subject to modulating influences from higher centers in the cerebral cortex and diencephalon, which are essential for the voluntary control of micturition. Axonal tracing studies in cats indicate that the ascending limb of the SBS micturition pathway consists of projections of spinal tract neurons in the sacral spinal cord to neurons in the periaqueductal gray that in turn send inputs to neurons in the PMC [4]. Projections from the PMC back to the sacral parasympathetic nucleus in the spinal cord complete the reflex circuit [3,4].

Pharmacological experiments in animals have revealed that glutamic acid is the principal excitatory transmitter in the spinal and supraspinal components of the micturition reflex pathway [2,3]. The effects of glutamic acid are mediated by NMDA and non-NMDA ►glutamatergic receptors. Other excitatory transmitters (substance P, dopamine, nitric oxide, vasoactive intestinal polypeptide, pituitary adenylate cyclase activating peptide and norepinephrine) appear to act by modulating glutamatergic transmission. Transmitters that are involved in inhibition of the micturition reflex include: gamma aminobutyric acid, glycine, opioid peptides, serotonin and dopamine [2,3].

## Function

Micturition is a visceral function that is under voluntary control. Storage and elimination of urine requires the coordinated activity of a number of smooth and striated muscles and is dependent upon the integrative properties of neural pathways at various levels of the neuraxis ranging from the cerebral cortex to the lumbosacral spinal cord and the peripheral autonomic ganglia. The central reflex mechanisms controlling lower urinary tract function seem to be organized as simple on-off switching circuits which maintain a reciprocal relationship between the bladder and urethral outlet. During urine storage a low level of activity in the sacral afferent pathways initiates reflex firing in the sympathetic and somatic efferent pathways to the urethral outlet, thereby contributing to the maintenance of urinary continence. At the same time, parasympathetic efferent pathways to the bladder are quiescent. The storage reflexes are organized in the lumbosacral spinal cord. During micturition a high level of sacral afferent activity from tension receptors in the bladder wall reverses the pattern of efferent outflow, resulting in firing in the parasympathetic excitatory pathways to the bladder and inhibition of the sympathetic and somatic inputs to the outlet. These reflexes occur in their simplest form in infants where micturition is purely an involuntary act. In adults the basic reflexes are integrated into a more complex voluntary control of micturition.

## Pathology

Damage to forebrain structures due to injury, tumors, cerebrovascular disease or neurological disorders such as Parkinson's disease or multiple sclerosis usually leads to an enhancement of micturition reflexes and symptoms of urinary urgency, frequency and incontinence; indicating that forebrain mechanisms mediate a predominant inhibitory control [2–4]. In these conditions the bladder usually exhibits involuntary contractions during storage leading to activation of mechano-sensitive afferent nerves and irritative sensations; however bladder-sphincter coordination is usually maintained. Similar symptoms (the overactive bladder syndrome) can also occur by unknown mechanisms in the absence of overt neural dysfunction particularly in the elderly population.

Damage to the bulbospinal pathways in patients with spinal cord injuries leads initially to urinary retention and complete loss of bladder function due to interruption of the supraspinal micturition reflex pathway. In most paraplegic patients, bladder reflexes slowly recover as a result of a reorganization of synaptic connections in the spinal cord and the emergence of sacral reflex mechanisms that initiate involuntary bladder contractions [3,5]. However, micturition in these patients is usually compromised due to a lack of coordination between bladder and sphincter activity (a condition termed detrusor-sphincter dyssynergia). This condition is characterized by simultaneous contractions of the bladder and the striated urethral sphincter causing incomplete emptying and urinary retention.

Experimental studies in animals and humans indicate that the emergence of involuntary voiding reflexes following spinal cord injury is due in part to plasticity in bladder afferent pathways and the unmasking of reflexes triggered by capsaicin-sensitive, C-fiber bladder afferent neurons (Fig. 1) [2,3,5]. C-fiber afferents have also been implicated in the bladder hyperactivity associated with other neurological disorders such as multiple sclerosis.

Damage to peripheral neural pathways to the lower urinary tract or to the lumbosacral spinal cord (i.e. a lower motoneuron lesion) causes a loss of bladder sensations as well as loss of voluntary and reflex voiding. Injury to muscles or the motor nerves of the urethral sphincter and pelvic floor can often occur during pregnancy and/or childbirth. This results in decreased urethral closure mechanisms and involuntary loss of urine (stress urinary incontinence) during increases in abdominal pressure that are associated with straining, sneezing or coughing.

## Therapy

Urinary frequency, urgency and urgency incontinence occurring in the absence of a neurological disorder (the overactive bladder syndrome) or as a result of central nervous system lesions are usually treated with antimuscarinic agents that reduce involuntary bladder contractions [1,3,10]. These drugs increase bladder capacity and reduce urgency sensations as well as incontinent episodes. However these agents are not effective against stress urinary incontinence which is caused by reduced urethral outlet resistance. A new drug (duloxetine) that blocks serotonin and norepinephrine reuptake mechanisms in the central nervous system and that enhances reflex activation of the urethral sphincter is effective in the treatment of stress urinary incontinence. Botulinum toxin is injected into the external urethral sphincter to suppress detrusor-sphincter-dyssynergia or injected into the wall of the urinary bladder to treat neurogenic or idiopathic overactive bladder conditions. Intravesical administration of capsaicin or resiniferatoxin, neurotoxins that desensitize C-fiber afferents, is also used to treat neurogenic bladder hyperactivity and incontinence [3,10].

## Midbrain

### Definition

Also known as the mesencephalon. The region of the brain between the hindbrain and the diencephalon. Its dorsal region is the tectum and its ventral region is the tegementum. Among its functions are aspects of vision and the control of eye movements and reflexes.

►Evolution of the Spinal Cord

## Middle Cerebellar Peduncle

### Synonyms

Pedunculus cerebellaris med

### Definition

Composed exclusively of afferent fibers which all come from the pontine nuclei, and account for the majority of cerebellar afferents and are designated collectively as the pontocerebellar tract. The fibers decussate before entering the peduncle of the contralateral side, giving off collaterals to the dentate nucleus and projecting to the cerebral cortex of the cerebellar hemispheres.

►Cerebellum

## Midline and Intralaminar Thalamic Nuclei

### Definition

A group of nuclei extending from the rostral to caudal pole of the thalamus in the midline and embedded within the internal medullary lamina. Midline nuclei include the parataenial, paraventricular, intermediodorsal, reuniens and rhomboid. Intralaminar nuclei are the central medial, paracentral, central lateral, parafascicular and subparafascicular. These nuclei are extensively connected to brainstem and diencephalic structures associated with the reticular formation, such as the pedunculopontine and laterodorsal tegmental nuclei and the lateral hypothalamus and also receive inputs from brainstem visceroceptive nuclei such as the nucleus of the tractus solitarius and parabrachial complex. Collectively, they project to the entire cerebral cortex and most of the deep telencephalic nuclei and are thought to be involved in processes associated with arousal and awareness.

►Thalamus

## Migraine

### Definition

A moderate to severe primary headache disorder which is usually unilateral with a pulsating quality, accompanied by nausea and/or vomiting, photophobia and phonophobia.

►Headache

## Migrating Motor Complex

### Definition

During fasting, several hours after the previous meal, the stomach and the small intestine exhibit a distinct pattern of behaviour characterized with bursts of intense activity, electrically and mechanically, with long silent intervals of 75–90 min in humans. This pattern is termed the migrating motor complex (MMC) or migrating myoelectric complex. Other terms used by different investigators are the intestinal housekeeper, the interdigestive migrating electric complex, and the interdigestive migrating motor complex.

## Miller Fisher's Syndrome

### Definition

A clinical syndrome consisting of ophtalmoplegia, areflexia and ataxia without significant limb weakness.

## Mind Body Problem

### Definition

The question of how mental states, such as beliefs and desires, are related to physical, actual brain states.

►Mental Models

## Mineralocorticoid Receptor (MR)

### Definition

Nuclear receptor with a 10 fold higher affinity than the GR for glucocorticoids and a high affinity for aldosteron. It is involved in mineral metabolism and is more restricted in its distribution than the GR, and e. g. found selectively in the hippocampus and the kidney.

►Hypothalamo-Pituitary-Adrenal Axis, ►Stress and Depression

## Minimum Convex Polygon

### Definition

A minimum polygon with no obtuse internal angles, drawn to enclose the points in a data-set.

►Evolution and Brain-Body Allometry

## Minimum-jerk Model

### Definition

This model makes the assumption that movement trajectories are smooth, i.e. that the square of jerk, which is the third derivative of position (or equivalently, jerk is the first derivative of acceleration), integrated over movement time, is minimal.

►Motor Control Models

## Minimum Torque-change Model

### Definition

This model makes the assumption that movements from one position to another with a particular movement time, are made under the constraint that the integral over movement time of the square of changes in torque is minimal.

►Motor Control Models

## Mint

### Definition

Together with CASK and Velis, a component of a conserved heterotrimeric synaptic scaffolding protein complex; also known to interact with Munc18. Also know as the X11 protein family.

►Synaptic Proteins and Regulated Exocytosis

## Miosis

### Definition

Pupillary constriction, particularly when the pupil is strongly constricted to approach its minimum diameter.

►Neural Regulation of the Pupil

## miRNA Profiling

### Definition

Refers to an in depth analysis of the miRNAs present in a biological sample, for example from a particular cell type or a developmental stage. A variety of experimental assays are now available for miRNA profiling (e.g. microarray technology, Real-Time PCR, deep sequencing, bead-based flow cytometry).

►miRNAs in Neurobiology

## miRNAs in Neurobiology

F. Gregory Wulczyn
Center for Anatomy, Institute for Cell and Neurobiology, Charité University Hospital, Berlin, Germany

### Synonyms

microRNA

### Definition

miRNA are ~21–22 nucleotide single-stranded RNAs that are encoded in the genome. The transcription units lie either in mRNA-poor genomic regions, or frequently within the introns of protein-encoding genes. In either case, they are generally transcribed by the same RNA polymerase as mRNAs, RNA polymerase II, and carry the standard features of a protein-encoding mRNA (5′ cap and a polyadenosine tail). The transcribed product undergoes nuclear and cytoplasmic processing events to generate the ~21–22 nucleotide single-stranded miRNA. The single-stranded miRNA is incorporated into a regulatory multi-protein complex, the miRNA-specific RNA induced silencing complex (miRISC), which scans mRNAs for short stretches of sequence complementarity to the miRNA. Although exceptions to the rule have recently been identified, in most cases recognition of the mRNA by the miRISC leads to a decrease in the translation of the mRNA. While a great deal remains to be learned about the miRNA/mRNA interaction, it is well established that miRNAs represent a widespread and fundamental level of control over the protein repertoires of individual cells.

### Characteristics

#### Putting miRNAs in Context

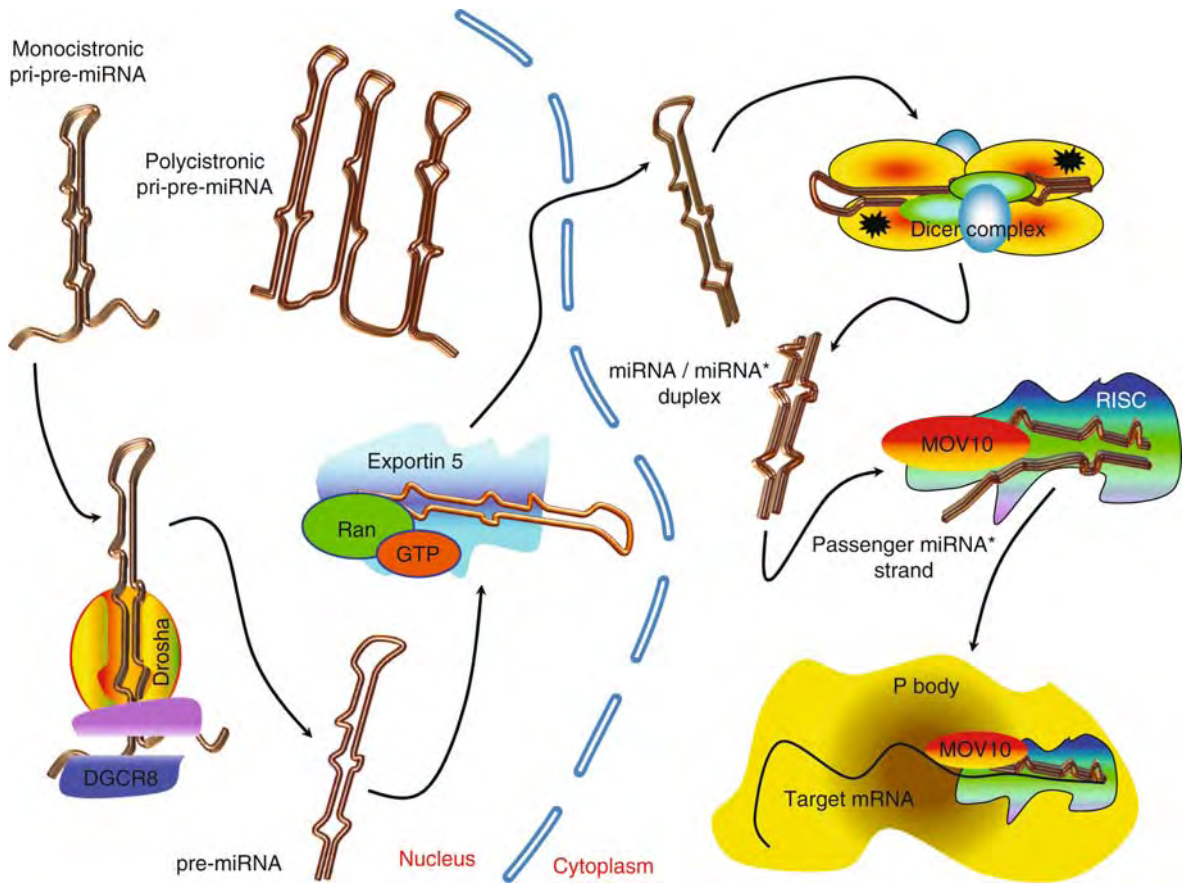
Most people are familiar with the allegory of the butterfly in Mexico beating its wings, and how the initial motion is successively amplified, and initiates a chain of events that ends in a typhoon sweeping ashore on a distant continent. The discovery of the first miRNA in 1993 is akin to the butterfly, and presently the winds in the scientific world are gathering. Indeed, in a recent review of progress in genomic biology in the scientific journal Nature, the discovery of miRNA was placed alongside the elucidation of the DNA double helix structure by Watson and Crick as one of the seminal discoveries. These analogies may, of course, prove overblown, and the purpose of this review is to summarize recent advances in our knowledge of miRNAs as they relate to nervous system development and function. But we will also attempt to provide some ideas about where this very new and promising field may be heading.

One of the reasons that miRNA are generating so much interest is because they are an unexpected challenge to one of the underpinnings of molecular genetics, the formulation of the one gene – one protein hypothesis by Beadle and Tatum in 1941. miRNA share many of the features of a conventional regulatory gene: they are encoded in the genome, are transcribed (most frequently) by the same RNA polymerase as mRNAs, RNA polymerase II, and often carry the standard features of a protein-encoding mRNA (5′ cap and a polyadenosine tail). Like mRNA for protein-coding genes, the primary miRNA transcript is first subjected to nuclear processing events that ready the transcript for export to the cytoplasm. However, the nuclear and cytoplasmic processing pathways for miRNA and mRNA differ, as will be discussed later. For miRNAs, the end result is an ~21–22 nucleotide single-stranded RNA. To date, the sole known function of miRNAs is to influence the efficiency of protein-encoding mRNA utilization. As such, miRNAs represent an additional level of control over the protein repertoire of individual cells that was essentially unrecognized until the year 2000. Indications are that the influence of miRNAs, in particular during development, is pervasive, as efforts to elucidate their myriad functions intensify.

Scientific reviews of the discovery of miRNAs can be found in [1], of miRNA biology in [2] and current knowledge of miRNA in neurobiology in [3–5]. There are many excellent reviews discussing miRNA, and more are published almost weekly, but these should give an overview and links to the entire miRNA literature.

## miRNA Biogenesis

Because one of the approaches to study the significance of miRNAs for neural development and function is to interfere with the pathway in which miRNAs are generated and then utilized, it is useful to briefly describe miRNA biogenesis. An overview of the pathway is also provided in Figure 1. miRNA genes can be transcribed either as independent transcription units from mRNA-poor genomic regions, or as part of mRNA transcripts with the mRNA positioned in an intron. One consistent feature shared by miRNA genes is that sequences immediately surrounding the mature miRNA form stable ►stem-loop structures of approximately ~60–70 nucleotides. In most cases, this structure serves as a recognition element for a nuclear processing complex comprised, at a minimum, of the ►ribonuclease (RNase) Drosha and its partner the DGCR8 (DiGeorge Candidate Region 8) protein (Some intronic miRNAs have recently been shown to bypass Drosha cleavage). Drosha cleavage releases the hairpin from surrounding sequences, generating the so-called miRNA precursor. The miRNA precursor is actively transported to the cytoplasm, where it is recognized by a second protein complex centered on the ribonuclease Dicer. The Dicer complex orients itself on the precursor stem and cleaves off a 21–22 nucleotide duplex RNA. What happens next is not understood in detail, but the



**miRNAs in Neurobiology. Figure 1** Overview of the miRNA pathway. Starting at the upper left, primary miRNA transcripts (either mono- or polycistronic) are seen. Pri-miRNA are engaged by the Microprocessor, a protein complex containing DGCR8 and Drosha. Drosha cleavage releases the miRNA precursor (Pre-miRNA). Exportin 5 mediates the energy dependent export of the pre-miRNA to the cytoplasm. Cytoplasmic processing is performed by thr Dicer ribonuclease, accompanied miniually by an Argonaute protein and TARBP2. Cleavage of the pre-miRNA yields a 22nt duplex RNA. One strand becomes integrated within a third protein complex, the miRISC, which mediates regulatory interactions between the miRNA and its target mRNAs. miRNAs, the miRISC as well as translationally suppressed mRNAs accumulate in P-bodies, cytoplasmic centers of RNA storage and metabolism.

duplex is subsequently unwound, with one strand destined for incorporation into a regulatory multiprotein complex we will refer to as the miRISC (for miRNA-specific RNA induced silencing complex). The miRNA-primed miRISC is a regulatory machine that scans mRNAs for short stretches of sequence complementarity to the miRNA. In almost all studies performed so far, recognition of an appropriate miRNA interaction site in an mRNA, referred to as a target mRNA, results in suppression of the target mRNA. Very recently, the group of Joan Steitz at Yale University found that under certain conditions (cell cycle arrest), the outcome may be reversed: that miRNA binding may activate translation. It is not yet clear how widespread miRNA-mediated activation may be, but this is a very exciting new insight.

At the moment, there is considerable controversy regarding the precise mechanism miRNA use to inhibit translation, and different targets may in fact interact with the miRISC in different ways. In general, however, the miRNA-miRISC-mRNA interaction appears to suppress the entry of the targeted mRNA into the translational cycle, leading to an inhibition of protein synthesis. Frequently, but not always, mRNA targeting also results in the destruction of the mRNA due to enhanced degradation.

Although the field is progressing rapidly, the genetic and biochemical analysis of the miRNA pathway is in its infancy. Mutational phenotypes of a number of genes in the pathway have been reported, whether in humans, mice or invertebrate model systems. In general, loss of Drosha, DGCR8, Dicer, or the Argonaute proteins of the miRISC is incompatible with embryonic development; in most cases nervous system development is also severely disrupted. From these results, it seems clear that the miRNA pathway plays a fundamental role in the developmental regulation of gene expression in the nervous system.

## Neural miRNA Genes

By intervening between the transcription and translation steps of mRNA utilization, miRNAs act to sculpt the raw information of the transcriptional output of the cell into temporal and tissue specific patterns of protein expression. This raises the inevitable question: "Who regulates the regulators." There is not yet a firm count of the number of miRNA genes, over 400 have been experimentally verified in mammalian genomes, with some estimates of the total number exceeding one thousand. Expression analysis of miRNAs initially relied on Northern blotting of individual sequences, this has now been supplanted by high-throughput sequencing of cloned miRNA libraries, miRNA-specific RT-PCR, chip-based miRNA microarrays, and ►deep sequencing. At the cellular level, the introduction of high affinity locked-nucleotide probes has allowed traditional in situ hybridization methods to be modified for detection of miRNAs (please refer to [2] for a description and references for these important innovations). The CNS has a particularly rich repertoire of miRNAs, with over 30% of the known miRNAs expressed in the brain. An increasing body of work applying these new methods is now providing a detailed look at miRNA expression patterns. One fundamental issue that was addressed early on is whether miRNA expression is specific for individual cells and tissues. As more and more miRNAs were discovered and characterized, it was shown that many miRNAs are expressed nearly ubiquitously with little preference for particular organs or tissues, but others show various degrees of tissue specificity. In a study headed by Todd Golub at the Broad Institute, tissue specificity was found to be characteristic enough to allow the tissue of origin of tumor samples to be predicted based on ►miRNA profiling. A recently published large scale compendium of miRNA expression patterns (headed by Thomas Tuschl at The Rockefeller University), however, identified less than a dozen miRNAs with strong overrepresentation in the human and mouse nervous systems. Within the brain, large scale efforts to define expression patterns in zebrafish, chicken, mouse and in primates have revealed regional as well as temporal specificity in expression patterns (again, refer to [2] for links to specific papers). These efforts provide an invaluable starting point for the investigation of the roles of individual miRNAs in both the development of the nervous system, and in the function of neural cell types in the brain.

## miRNA Functions in the CNS

### *The Sensory Nervous System of Caenorhabditis Elegans Leads the Way*

As discussed above, the complexity of neural miRNA populations appears to reflect the cellular and architectural complexity of the nervous system. Approximately 30% of the known miRNA genes are expressed in the CNS, however, their precise roles and functions remain for the most part enigmatic. In this section we will highlight groundbreaking studies that have revealed the involvement of miRNAs in developmental processes such as neuronal specification, and then turn to evidence for miRNAs as mediators of mature brain functions such as synaptic plasticity and memory.

Probably the most thoroughly characterized example of miRNA involvement in cell specification relates to the establishment of asymmetry in the nematode *Caenorhabditis elegans* as elaborated in a series of papers from Oliver Hobert's group at the Columbia University Medical Center. These studies evoke the classical molecular genetic investigations by Jacob and Monod of another binary fate choice, the decision between lysis and lysogeny by the bacteriophage λ. In

both cases, transcriptional and post-transcriptional regulatory mechanisms intertwine to stabilize genetic networks that discriminate between alternative cell states. In the gustatory system of *Caenorhabditis elegans,* two taste receptor neurons termed "ASE left" (ASEL) and "ASE right" (ASER) express distinct sets of ►chemoreceptors, an arrangement that allows the nematode to orient itself in relation to a source of food. The establishment of left/right asymmetry in gene expression from symmetric ►progenitors involves mutually exclusive ►feedback loops driven by miRNAs working in concert with ►transcription factors.

In ASEL cells, the transcription factor *die-1* and the miRNA *lsy-6* are expressed and together promote ASEL genes while suppressing ASER genes. Similarly, in ASER cells the transcription factor and miRNA pair *cog-1* and *miR-273* activate ASER specific genes and antagonize *die-1* and *lsy-6*. Although the initial trigger has not yet been defined, the results so far demonstrate how miRNAs can play integral roles in the establishment, reinforcement and maintenance of cell-specific ►gene expression patterns and therefore represent a model for the possible contribution of miRNAs to the myriad ►cell fate decisions required to construct the vertebrate brain. Whether or not miRNAs are also involved in the ►left/right asymmetry typical for the human brain is not yet clear, but very recently a study by Choi, Giraldez, and Schier implicated the zebrafish miRNA *mir-430* in left/right asymmetry, and the group of Tamas Dalmay at the University of East Anglia demonstrated strong asymmetry in the expression of mouse *mir-500*.

### *mir-124 – a Significant Actor in Neuronal Cell Identity*

Turning to studies of the vertebrate nervous system, *mir-124* has attracted a great deal of interest as a paradigm for tissue specific miRNAs. By sequencing small RNA libraries prepared from various mouse tissues, Thomas Tuschl's group, then at the Max-Planck-Institute in Martinsried, had originally discovered a remarkable property of miRNA expression. Whereas many miRNA were expressed across many tissues, others were highly restricted to individual tissues or organs. *mir-124* is a striking example of this principle, with expression restricted to neurons, where it accounts for over 25% of the total miRNA population. Very recently, Tom Maniatis' group at Harvard University found that *mir-124* promotes neuronal specification by regulating mRNA splicing factors. The end consequence is to allow a greater degree of flexibility in neuronal splicing. Although it is not yet clear what the relative advantage of greater diversity in splicing products for neurons compared to other somatic cell types might be, the conservation of *mir-124* across animal phyla suggests that neurons may have acquired this property early in the evolution of the nervous system.

### *miRNAs and Synaptic Plasticity and Learning*

So far, we have discussed examples of miRNAs that act at early stages in the establishment of neuronal identity. Michael Greenberg's laboratory, also at Harvard University, has shown that miRNAs influence neuronal connectivity. They were able to demonstrate that one neuronal miRNA, *mir-134*, is present in ►dendritic spines, structures that form the receiving end of synaptic communication between neurons. It is known that translational regulation is important in reinforcing connectivity at active synapses. *mir-134* was shown to target a mRNA, *limK1*, that encodes a kinase involved in determining the size of dendritic spines. Interestingly, both the levels of *mir-134* and its efficiency as a translational inhibitor were affected by synaptic activity. In their model, *mir-134* acts as a local inhibitor of dendritic maturation; at least in part by regulating *limK1*. Importantly, the inhibitory effect of *mir-134*, and by extension other synaptic miRNAs, was relieved after neuronal stimulation by brain derived neurotrophic factor (►BDNF). Because BDNF is released at active synapses, the result conforms to expectations for positive regulators of ►synaptic plasticity.

Taking advantage of the genetic power of *Drosophila melanogaster*, another group at Harvard University headed by Sam Kunes was able to go one step further and link the miRNA pathway to ►memory formation. The beauty of this study lies in their ability to monitor local translation at specific synapses as they respond to a learning task. Specifically, they examined the role of miRNA-mediated regulation of a key synaptic translation product: ►Calcium/Calmodulin-dependent Kinase II (CaMKII). Synapses participating in memory formation increase their synthesis of CaMKII. Flies carrying mutations that inactivate the miRISC express much higher levels of CaMKII, implying a regulatory network similar to that described above for LimK1 and *mir-134*. The Kunes group showed that increased synaptic activity resulted in the elimination of miRNA pathway proteins by protein degradation, suggesting a general role for the pathway in dampening responses in quiescent neurons.

### *The miRNA Pathway and the Maintenance of the Cerebellum*

In the near future, transgenic approaches can be expected to rapidly advance our understanding of miRNA functions in the brain. As a recent example, Paul Greengard's group at the Rockefeller University examined the effects of eliminating the Dicer protein in a single cell type within the ►cerebellum, the ►Purkinje neurons. Although the analysis was complicated by the gradual and uneven loss of the Purkinje miRNA population, the affected mice did not display an overt phenotype or detectable changes in the electrophysiological properties of the affected cells for several weeks. Thereafter, profound ►neurodegeneration set

in, beginning with the Purkinje cells and then spreading to the entire cerebellum. Although more work remains to be done, these results underscore a requirement of miRNAs for cellular viability. In contrast, they do not provide evidence for miRNA involvement in short term synaptic activity, at least in Purkinje neurons.

## The miRNA Pathway and Neurological Disease

Several protein components of the miRNA biogenesis pathway discussed in the previous sections are critical not only for CNS development but also are associated with neurological diseases. We will discuss some of the initial discoveries, including miRNA involvement in mental retardation syndromes, neurodegeneration, Tourette's Syndrome and cancer (Fig 1).

### *miRNAs and Mental Retardation*

The ►Fragile X Mental Retardation Protein (FMRP) is silenced in patients with Fragile X Syndrome, an inherited form of mental retardation. The gene responsible for Fragile X Syndrome, FMR1, is situated on the X chromosome and consequently contributes to the higher incidence of mental retardation observed in males. As a likely correlate of cognitive impairment, affected individuals also demonstrate altered dendritic spines, focusing attention on alterations of neuronal ►connectivity in the disease state. FMRP is an evolutionarily conserved protein that contains several RNA binding domains that mediate interactions with mRNAs. mRNA binding by FMRP leads to a suppression of protein translation. FMRP can be detected in synapses where it regulates local protein synthesis and thereby plays an important role in synaptic plasticity and dendritic development. The initial link to the miRNA pathway was forged by the groups of Scott Hammond at the Cold Spring Harbor Laboratory and Haruhiko Siomi at the University of Tokushima, who showed that the *Drosophila melanogaster* FMRP homolog, dFMR1, co-purified with miRNA pathway proteins. Stephen Warren's group at the Emory University School of Medicine extended these findings to the human protein, then returned to the *Drosophila melanogaster* system to show that dFMR1 acts together with the miRNA pathway protein dAgo1 in the regulation of synaptic plasticity. These studies provided the first demonstration that the miRNA pathway contributes to normal neuronal function, in addition to advancing our understanding of the Fragile X disease state.

### *miRNAs and Neurodegeneration*

The miRNA pathway has also been implicated in the pathogenesis of a complex of neurodegenerative diseases characterized by ►expansion of the trinucleotide CAG (poly-glutamine, or poly-Q, expansion). Using a genetic model designed in *Drosophila melanogaster*, a group headed by Nancy Bonini at the University of Pennsylvania designed a genetic test which showed that disruption of the miRNA biogenesis pathway exacerbated neurodegeneration induced in the fly retina by poly-Q proteins. The authors then extended the results to a human cell-based system, supporting the potential relevance for human disease. How miRNA's contribute to the observed neuroprotection remains to be determined.

### *miRNA Dysregulation and Tourette's Syndrome*

The Fragile X Mental Retardation and the Poly-Q Expansion Syndromes summarized above may reflect the consequences of widespread disruption of miRNA biogenesis or translational regulation. In the case of ►Tourette's Syndrome, a mutation that disrupts a single miRNA-mRNA interaction is linked to a neurological disorder. A team of scientists centered at the Yale University School of Medicine and headed by Matthew State identified ►*Slit and Trk-like 1* (SLITRK1) as the first candidate gene for Tourette's Syndrome, a prevalent neuropsychiatric disorder characterized by so-called ►tics. The term tic refers to repetitive, stereotyped and irresistible movements or vocalizations with considerable individual variability, ranging from sneezing or blinking to outbursts of profanity or complex series of movements. In two independent cases, point mutations were identified in the 3′UTR of the SLITRK1 gene. Remarkably, the mutations were shown to lie in a binding site for the miRNA *mir-189*, and had the affect of increasing the affinity of the miRNA for the mRNA, thus enhancing inhibition of SLITRK1. SLITRK1 is one of a family of transmembrane proteins with similarities to both the SLIT family of ►axon guidance factors and, with the exception of SLITRK1, ►neurotrophin receptors. So far, the SLITRK's have not been well-characterized functionally, but the State group was able to support the initial characterization of SLITRK1, by Aruga and Mikoshiba at the Riken Brain Science Institute, as a protein involved in dendritic ►outgrowth and morphology. Although the work to date depends primarily on correlation, it represents a breakthrough as the first example in which mutations in a miRNA binding site were shown to be causative for a human disease.

### *miRNAs and Cancer*

One of the most active current directions in miRNA research relates to their role in cellular growth control and apoptosis. A thorough discussion of this rapidly expanding field is beyond the scope of this review. In general terms, miRNAs have been implicated in the control of stem cell differentiation in a variety of contexts, and in the regulation of a number of well-studied genes and pathways commonly affected in human cancers (for example *bcl-2*, *c-myc*, *N-ras*, *p27* and *p53*). Given the likelihood that cancer stem cells are

the catalysts for each of the main forms of brain tumors (►medulloblastoma, ►glioblastoma and ►ependymoma), interest in the contribution of miRNA misregulation is high. In the case of glioblastoma, a number of investigators have catalogued characteristic changes in miRNA profiles, and begun to relate those changes to potential oncogenic target genes. miRNAs are attractive targets for pharmaceutical interventions, as they can at least in principle be specifically blocked or mimicked by small molecules, such as chemically modified antisense inhibitors.

### Conclusions and Outlook

It is impossible to introduce all of the interesting findings from dozens of new miRNA articles that appear each month. In this short overview, we have instead focused on a few of the groundbreaking discoveries that have illuminated the whole field. Going forward, it seems likely that miRNA research will be increasingly integrated into traditional research programs as outlined above (oncogenesis, ►cell specification, cortical development, learning and memory, etc). Continuing refinement in target mRNA predictions are facilitating the identification of gene networks under miRNA control, which can then be studied with a variety of new tools for manipulating miRNA expression. Genetic analysis will dissect the functions of miRNA pathway proteins and individual miRNAs at an increasingly fine scale, despite the challenge imposed by the considerable redundancy of miRNA genes. The pace of discovery in the field over the past 5 years has been bracing, we hope we have been able to communicate a sense of that excitement.

## Mirror Neuron

### Definition

A particular class of neurons, originally discovered in the ventral premotor cortex of macaque monkeys (area F5) and then observed in the inferior parietal lobule (PF/PFG), which code goal-related motor acts like grasping. They become activated both when the subject performs a particular action, e.g. a precision grip, and when the subject observes another individual performing a similar goal-related action. There is evidence for a similar system in the human brain.

►Action Representation
►Visual Space Representation for Reaching

## Mismatch Negativity (MMN)

### Definition

A sound-evoked event-related potential. A response to an acoustical change in two sounds. It is evoked by an occasional subtle stimulus change in a long train of repetitive stimuli. The difference may be in frequency, intensity, complexity, etc. A difference in the evoked response between the two stimulus types indicates that a detection of the difference has taken place.

►Auditory Evoked Potentials

## Missense Mutation

### Definition

A nucleotide substitution that causes the replacement of one amino acid by another in the polypeptide typically leading to a change in the function of the protein.

## Mitochondrial Disease

### Definition

Mitochondrial disease refers to a group of medical disorders in which the primary metabolic defect affects the respiratory train/electron transfer system producing ATP in the intracellular organelles called mitochondria.

Genetic disorders of mitochondrial dysfunction can be inherited as either single gene mendelian or primary mitochondrial traits. This is because the mitochondrial respiratory train enzymes are encoded by both nuclear and mitochondria DNA. The clinical syndromes often

include seizures, cognitive deficits, visual loss, hearing loss, myopathy and peripheral neuropathy.

►Seizures

## Mitochondrial Myopathies

### Definition

Consequences of ►mitochondrial diseases resulting from defects in the mitochondrial respiratory chain (in particular defects in nuclear DNA and mutations in tRNA genes of mitochondrial DNA), which compromise energy production. This may cause myalgia, cramps, exercise intolerance, recurrent ►myoglobinuria, or weakness, particularly in extraocular muscles leading to ptosis (drooping of eyelids) and progressive external ►ophthalmoplegia.

## Mitochondrial Uniporter

### Definition

A channel on the inner membrane of the mitochondria that transports cytosolic $Ca^{2+}$ into the mitochondrial matrix.

►Influence of $Ca^{2+}$ Homeostasis on Neurosecretion

## Mitogen-activated Protein Kinase (MAPK)

### Definition

MAPK cascades are signaling molecules that serve as important mediators of signal transduction from the cell surface to the nucleus.

## Mitral Cell

### Definition

Mitral cells are large glutamatergic neurons found in the olfactory bulb, which along with tufted cells, receive input from olfactory sensory neurons and project to central olfactory areas of the brain, including the anterior olfactory nucleus and piriform cortex. The primary dendrite of a mammalian mitral cell projects to a single olfactory glomerulus and thus receives information from olfactory sensory neurons expressing a single type of olfactory receptor. The extensive lateral dendrites of mitral cells mediate inhibitory interactions (via granule cell interneurons) with neighboring mitral cells that generates a bulb-wide spatio-temporal pattern of mitral cell activity in response to odor stimulation.

## Mixture Theory

### Definition

The branch of continuum mechanics that deals with the equations governing the motion of mixtures, that is, of material bodies each of whose spatial positions is occupied simultaneously by particles of two or more different materials.

►Mechanics

## MLF

### Definition

►Medial Longitudinal Fasciculus

## MMC

### Definition

►Migrating Motor Complex

## M-modes

►Postural Synergies

## Mnestic Block Syndrome

### Definition

A type of memory disorder characterized by a sudden onset of severe retrograde amnesia, usually without significant anterograde amnesia. It typically includes memory loss for personal identity and autobiographical memories, as well as a period of wandering. It is usually precipitated by severe psychological stress (e.g., marital discord, financial collapse). Episodes generally resolve over a short period of time, lasting from a few hours to a few days.

►Amnesia

## Modafinil

### Definition

Modafinil is a stimulant drug that is used clinically for the treatment of excessive sleepiness (narcolepsy). The mechanism of action of the drug is unknown.

►Narcolepsy
►Stimulants

## Modal Logic

### Definition

Modal logic studies reasoning that involve the use of the expressions "necessarily" and "possibly." However, the term "modal logic" "it is obligatory that" and "it is permitted that."

►Mental Models

## Modality

### Definition

Modalities refer to large classes of senses and the related sensory receptors, e.g. visual, auditory, olfactory, gustatory and tactile (the five classic senses) (Sensory Systems).

►Sensory Systems

## Modality-specific

### Definition

From a single sensory modality (i.e., unimodal). Used in two forms: (a) to categorize a neuron based on the stimuli to which it can respond (e.g., a neuron responsive only to light would be a modality-specific neuron), and (b) to categorize a particular neuronal response regardless of the type of neuron from which it is evoked (e.g., a response to light, even in a multisensory neuron, is a modality-specific response).

►Multimodal Integration

## Model-based View

### Definition

Characterization of a system in terms of a model. Data are referenced to the parameters and predictions of the model.

## Model Estimator

### Definition

A model estimator is a tool used to generate a mathematical model for a physical system. Typically, it consists of an assumed family of mathematical models and an algorithm. The algorithm uses available data (commonly, actions on the system – inputs, and measurements - outputs) to choose the "best" fit to the physical system.

[2]Department of Kinesiology, University of Maryland, MD, USA

## Synonyms

Modeling; control theory

## Definition

Mathematical models represent the interaction of control processes with underlying physiological subsystems to develop testable predictions of behavior associated with stable, flexible upright stance control.

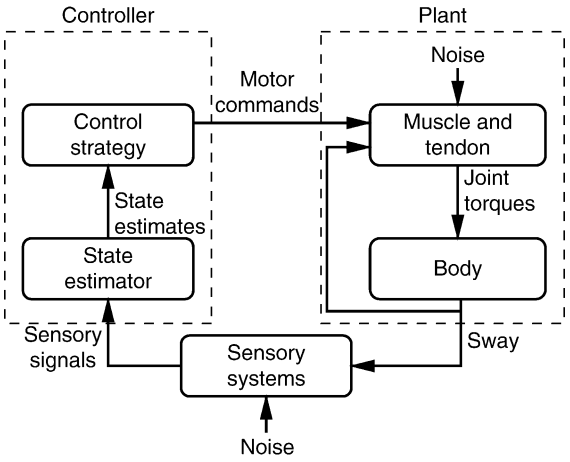
## Description of the Theory

Human upright stance is inherently unstable. The small, continuous displacements referred to as "sway" reflect a complex control process that counteracts the torque due to gravity, which continually accelerates the body away from vertical equilibrium. The end result of this control process is corrective joint torques that maintain the body upright. There is considerable controversy about how the nervous system generates these corrective torques. Here we illustrate the issues by starting with the simplest possible model, a single-joint negative feedback model, and progress to the current state of more complex models.

### The Control Theory Perspective

The predominant perspective for modeling postural control is based on principles of ▶control theory [1] In its most fundamental form, upright stance control has three elements a plant, sensory systems and a neural controller (see Fig. 1).

The plant is the mapping from motor commands to movement of the body and depends on musculotendon properties and the mechanics of the body. Sensory systems detect the body's position and movement and send related sensory signals to the neural controller. The neural controller then maps these incoming sensory signals into motor commands. Control theory addresses the question of how to design a controller based on the properties of the plant and sensory systems that is capable of producing the desired behavior of the plant, in this case maintenance of stable upright stance. The control theory perspective for postural control will be illustrated with simple plant and sensory models and a suitable neural controller.



**Modeling of Human Postural Control. Figure 1** A schematic representation of the postural control system from a control theory perspective.

### A Simple Plant Model

The body during "quiet stance" is often modeled as a single-joint inverted pendulum with the body bending only at the ankles and movement restricted to the sagittal plane [2,3]. "Quiet" means upright stance that is undisturbed externally by for example, a moving support surface. The motivation for the single-joint approximation is not only to simplify the control problem, but is also based on empirical results demonstrating that modulation of muscle activity during quiet stance is seen mostly for muscles of the lower legs, soleus and gastrocnemius. Since angular deviations of the body from vertical during quiet stance are small, the body model can be further simplified by linearizing its dynamics around vertical. In addition to simplifying body dynamics, musculotendon properties are often trivialized by assuming that the motor command is directly mapped into ankle torque. These simplifications result in the plant model

$$J\ddot{\theta}(t) = mgh\,\theta(t) + u(t) + \sigma\xi(t), \qquad (1)$$

where $t$ is time, $\theta(t)$ is the angular deviation of the body from vertical, $\ddot{\theta}(t)$ is the body's angular acceleration, $u(t)$ (the motor command) is the net forward ankle-muscle torque specified by the neural controller and $\xi(t)$ is a white noise. The noise in the model is meant to account for the fact that the actual torque produced by ankle muscle will not be exactly equal to the torque specified by the motor command. The model parameters are: $J$, the body's moment of inertia around the ankle joint; $m$, the mass of the body; $h$, the height of the body's center of mass above the ankle joint ($J$, $m$ and $h$ do not include the mass of the feet); $g$, the acceleration due to gravity; and $\sigma$, the noise level.

M

Although the plant model (1) is highly simplified, it contains essential features of the control problem the nervous system must solve. Most importantly, the plant is unstable. If the control signal $u$ is zero (or constant), the body will quickly deviate from vertical due to continual disturbances, both internal (e.g., physiological tremor) and external (e.g., uneven support surface, moving visual environment, etc.). Engineered devices, such as cars and robots, solve the stability problem by having a wide base of support and/or concentrating the bulk of their weight lower down. However, the human body has evolved with more than just upright stability as a constraint, with most of its mass concentrated higher up in the trunk, making it inherently unstable and prone to falls. Thus, the evolutionary development of bipedal stance, which freed the hands from locomotion and is considered the fundamental distinction between humans and our closest relatives, requires a sophisticated feedback control process to detect deviations from vertical and generate motor commands for a corrective torque to keep the body upright.

## A Simple Sensory Measurement Model

There are two common approaches to modeling sensory feedback. In models that focus on sensory integration, sensory signals are often assumed to be noisy versions of plant variables such as the body's position and velocity, because biological sensors are inherently noisy. Models that focus on biomechanics often assume that the neural controller has access to the true values of all relevant plant variables. For simplicity, the second approach is illustrated. If the plant is assumed to be a single-joint inverted pendulum, as in (1) it is completely described by two variables, the angular position and velocity of the body. Therefore, we assume that the neural controller has access to these two sensory signals:

$$z_1(t) = \theta(t), \quad z_2(t) = \dot{\theta}(t). \tag{2}$$

Although the sensory model is not usually explicitly presented when it is this simple, here it paves the way for the discussion of more complicated sensory models below.

## A Simple Neural Controller

It is well known from control theory that stabilization of an inverted pendulum requires that the control signal (corrective ankle torque) depends on both body position and velocity:

$$u(t) = -K_P\theta(t) - K_D\dot{\theta}(t). \tag{3}$$

This is an example of proportional-derivative (PD) control, where $K_\mathrm{P}$ and $K_\mathrm{D}$ are the proportional and derivative gains, which are assumed to be positive. Because of the negative signs, (2) describes *negative* feedback control. For example, if the body's position is forward and is moving forward, ankle torque will act to accelerate the body in the backward direction. If the body's position is forward but already moving backward toward vertical, the direction of the correcting ankle torque depends on the relative size of the proportional and derivative feedback gains.

## A Simple Posture Model

Combining the plant model (1), the sensory measurement model (2) and the controller model (3) results in the postural control model

$$J\ddot{\theta}(t) = (mgh - K_\mathrm{P})\,\theta(t) - K_\mathrm{D}\,\dot{\theta}(t) + \sigma\xi(t). \tag{4}$$

There are two criteria for this model to stabilize the upright orientation of the body. First, the proportional gain $K_\mathrm{P}$ must be greater than $mgh$, so that ankle torque produced by muscles is greater than the torque produced by gravity. Such position feedback by itself turns the inverted pendulum of the uncontrolled body into a controlled system that is mathematically equivalent to a frictionless non-inverted pendulum. Thus, position feedback turns an unstable system, which actively moves away from equilibrium, into a neutrally stable system whose oscillations neither grow nor decay. For example, a large perturbation would lead to a large oscillation that never decays. Adding velocity feedback is like adding friction to the pendulum. Any movement is counteracted by a torque in the opposite direction leading to a damped oscillation. Because of noise in the model, the damped oscillation does not decay completely to zero. Instead the body's orientation fluctuates around vertical, providing a simple model of sway during quiet stance.

## Current Models

Although model (4) provides insight into some of the essential features of postural control, such as the use of feedback control to stabilize upright stance, it is too simple to address other important features. Current research focuses on developing sophisticated models that explicitly represent features of the plant, feedback and control that allow for more complex behavior. For example, there is a long history of studying and modeling multi-joint postural control. When the support surface is translated backwards under standing subjects and they are instructed not to step, two patterns (or their combination) emerge. For small disturbances, the segments remain aligned in an ankle strategy, rotating predominantly around the ankle joint. Larger disturbances produce a hip strategy, a counter-rotation of the trunk relative to the legs [4]. A plant model with at least two joints, ankle and hip, are necessary to model the hip strategy.

Plant models may also include musculotendon dynamics so that muscle torques are no longer an instantaneous function of the motor commands (Fig. 1).

Musculotendon dynamics have been modeled using Hill type models, (e.g., [5]), or more simply as a time delay between the motor command and the generation of muscle torque. Time delays have also been added to sensory models. The inclusion of time delays in plant and sensory models are of interest because they tend to increase postural sway and can destabilize upright stance (e.g., [3]). Sensory integration models may also include dynamics specific to each sensory modality. For example, the vestibular dynamics is modeled as a low pass filter of the head's acceleration. At low frequencies, the vestibular signal that the neural controller receives is proportional to acceleration, whereas at higher frequencies it is proportional to velocity. Explicit modeling of sensory subsystems allows testing of model predictions that may help to identify important aspects of postural control in neurologically impaired populations such as individuals with loss of vestibular function [6,7]. Moreover, an open question is how to model ►adaptive control processes (e.g., sensory reweighting) that enable stability as environmental conditions change [6,7,8].

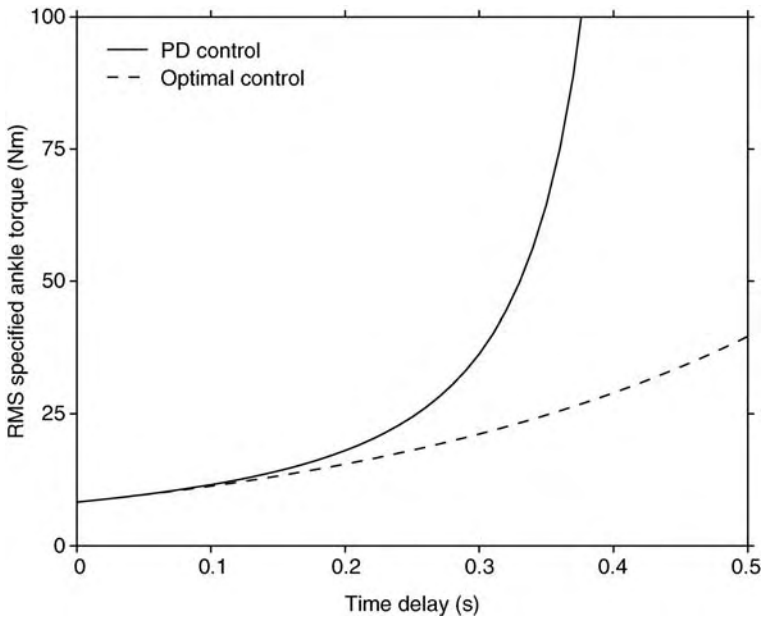
## Optimal Control Models

When considering specific features of the plant and sensory systems, the great challenge is to determine whether the neural control strategy takes these features into account. One approach to this question is to study ►optimal control models. Such models contain neural controllers that are optimally designed for the specific features of the plant and sensory systems included in the model, such as multi-joint, musculotendon and sensory dynamics. For example, the human nervous system has well known time delays associated with processing sensory information and generation of muscle force. Do time delays influence the appropriate type of controller to stabilize posture? Adding a time delay to the plant and the sensory systems (same delay for all modalities) and using the same PD control strategy, the posture model (4) becomes

$$J\ddot{\theta}(t) = mgh\theta(t) - K_{\mathrm{P}}\,\theta(t-\tau) - K_{\mathrm{D}}\,\dot{\theta}(t-\tau) + \sigma\xi(t), \qquad (5)$$

where $\tau$ is the sum of the plant delay and the sensory delay. For larger values of $\tau$ more torque from ankle muscles is necessary to stabilize upright stance (solid line in Fig. 2).

The question is how much of this additional muscle activity is necessary. An optimal control model provides this answer (dashed line in Fig. 2). For time delays of about 100 ms or less, the PD control model is near optimal. However, for longer time delays, a control strategy other than PD control offers a substantial advantage. This result does not, by itself,



**Modeling of Human Postural Control. Figure 2** The root mean square ankle torque specified by the neural controller as a function of time delay. For the PD control model (5), the proportional and derivative gains are adjusted to minimize ankle torque for each time delay. The optimal control model minimizes ankle torque across all possible controllers. The plant is characterized by the parameter $mgh/J = 9.83\ \mathrm{s}^{-2}$.

answer the question of which control strategy the nervous system uses, but it does provide insight into the challenge to postural control caused by time delays and how the nervous system *might* address this challenge.

As this example illustrates, optimal control theory provides a systematic method to generate a hypothesis about the control strategy the nervous system might use account for any (linear) feature of the plant or sensory systems. Determining the optimal control strategy requires three things, a model of the plant, a measurement model describing how sensory signals are related to plant variables, and a performance index. Models as in (1 and 2) above are examples of plant and measurement models respectively. Both plant and measurement models may contain noise terms. Also, there is no requirement that there be one measurement for every plant variable. An optimal control model uses an optimal state estimator, called a ►Kalman filter, to estimate the values of all plant variables, even those that are not directly measured (Fig. 1). The performance index is a quadratic function that describes the relative importance of minimizing the individual plant variables and control signals. Minimizing plant variables would include for example minimizing the deviations from vertical of body segments. Minimizing control signals involves minimizing the amount of motor neuron activity, which is related to the metabolic cost of muscle activity.

Optimal control models have addressed a variety of issues in postural control. For example, an optimal control model has been used to investigate how the performance index affects multi-joint coordination [9]. Appropriate choices of the performance index result in coordination patterns such as the ankle and hip strategies. Optimal control, or more specifically optimal state estimation, has also been used to investigate issues related to multi-sensory integration [2,10]. Incorporating a state estimator, such as a Kalman filter, into a model provides a potential solution to how non-comparable sensory signals such as position, velocity and acceleration signals can be fused to generate state estimates. For example, a Kalman filter in a posture model can estimate position and velocity based only on velocity signals.

Models with state estimation may also provide insight into underlying sources of sway variability. State estimation adds additional variables (there is one estimate for every plant variable) to a posture model and can therefore add dynamical components with additional time scales that increase sway variance. For example, it has been hypothesized that the slow dynamics observed in postural sway, which account for most of sway variance, are due to errors in state estimation [2]. This suggests that swaying is not due to errors of motor execution but because motor commands are based on inaccurate – estimates of self-motion.

## Summary

Human postural control has historically been modeled within a control theory framework using simple approximations of the plant (single-joint inverted pendulum) and the controller (proportional-derivative). While these classical engineering models have been useful to investigate fundamental problems of upright stance control such as its inherent instability, current models use techniques such as optimal control to generate testable hypotheses about neural control schemes based upon specific features of the postural control system. The focus is now to investigate properties of multi-joint, musculotendon and sensory dynamics to promote a more biologically motivated understanding of human postural control.

### Synonyms

Projection neurons; modulatory inputs; command neurons

### Definition

Broadly defined, projection neurons are neurons whose axons extend from the neuronal cell body within the central nervous system (CNS) to one or more distant regions of the CNS. ►Modulatory projection neurons are the subclass of these neurons which have modulatory (generally synonymous with ►metabotropic) actions on their target neurons usually in addition to having classical (i.e., ►ionotropic) actions. Such neurons are likely to be essential to neuronal integration for all sensory, associative and motor systems, but to date they are most extensively studied and understood at the cellular-level in terms of their regulation of rhythmically active motor circuits. To more readily obtain a cellular-level understanding of their function, studies of modulatory projection neurons on these motor circuits are generally performed in the isolated CNS. The value of using the isolated CNS is enhanced by the fact that the projection neurons can be stimulated in a manner that mimics their in vivo activity. Moreover, their motor circuit targets continue to generate neuronal activity patterns that are similar to those that they generate in vivo [1–6].

### Characteristics

Rhythmically active motor circuits, often called central pattern generators (CPGs), are small populations of CNS neurons that generate rhythmic neuronal output in response to non-rhythmic input, even in the isolated CNS. This type of circuit construct underlies all studied rhythmic motor behaviors, including various forms of locomotion, respiration, chewing and scratching [2–3,5]. CPGs are ►multifunctional circuits, each of which generates multiple neuronal activity patterns. These different activity patterns can be variations on a common pattern or else be quite distinct from one another [3–5,7].

The ability of CPGs to be multifunctional largely results from the presence of metabotropic (modulatory) receptors on the membranes of the individual circuit neurons [2–3,5,8]. Activation of this type of receptor elicits long-lasting biochemical cascades in the target neurons, which lead to changes in the intrinsic electrophysiological and synaptic properties of these neurons. Changes in these properties lead to changes in the related circuit activity.

In all systems studied, each different ►neuromodulator applied to the region of an isolated CNS that contains a CPG elicits a distinct activity pattern from that circuit [3,5]. Using applied neuromodulators to document the functional flexibility of CPG circuits led to the original paradigm shift in our understanding that neuronal circuits are in fact functionally flexible constructs. The ability of a tonically present neuromodulator to evoke a reproducible and stable change in the rhythmic output of a neuronal circuit results from the fact that these substances alter neuronal excitability by acting primarily on ►voltage-sensitive ion channels [8]. As their descriptor suggests, this class of ion channels is not open at all membrane potentials so that, despite changing the excitability of a neuron, the opening and closing of these channels can still be regulated by sufficiently strong synaptic inputs between the circuit neurons [3,5,8].

Modulatory projection neurons are a major source of metabotropic influence to CPG circuits [2–5,7]. These neurons typically reside in higher centers, from which they project to the region of the CNS where the relevant CPG is located. For example, the vertebrate locomotor CPG network in the spinal cord receives considerable input from projection neurons whose somata are located in the brainstem [2,5]. Similarly, CPGs in invertebrate ganglia are generally influenced by projection neurons that originate in higher-order ganglia [1,3–4,6–7].

In many small motor systems, individual projection neurons are physiologically and often neurochemically identified [4–5,7,9]. Consequently, these ►identified neurons are studied repeatedly in different preparations, allowing for the acquisition of considerable information about their function. The ability to work with identified neurons is facilitating the development of basic concepts regarding how these neurons are incorporated into larger network constructs [1,4,6–7].

Experimental activation of single projection neurons is sufficient for activating an entire CPG in small motor systems [4–7]. A comparable situation appears to occur for single populations of projection neurons in larger motor systems [2,9]. In the intact animal, however, sets of distinct projection neurons are more likely to be coactivated to drive a particular motor output [2,10]. Discerning the rules by which such populations are coactivated by natural stimuli, and determining their consequences for motor activity, is an active area of research.

## Quantitative Description

The parameters most commonly used to assess the state of a modulatory projection neuron are its pattern and intensity of activity. Thus far, data from different projection neurons indicate that some are silent unless activated, while others are spontaneously active [1–2, 4–7,9]. The latter subset is readily separated both by whether their spontaneous activity is tonic or rhythmic, and whether that activity is sufficiently strong to influence the target circuit(s). Each of these conditions has been documented to occur for different identified projection neurons including, in some cases, different projection neurons in the same system. Additionally, some projection neurons impose their own rhythmic activity pattern onto the target circuit, while others exhibit the rhythmic pattern generated by the target circuit as a result of synaptic feedback from that circuit [1,6–7]. The intensity of projection neuron activity is commonly described either by its instantaneous firing frequency or its mean intraburst firing frequency.

The consequences of projection neuron activity are determined by characterizing the ►motor pattern generated by the target CPG circuit(s). The standard set of criteria used for this purpose include determining changes in: (i) speed (cycle frequency) of the resulting motor pattern; (ii) the activity level (burst duration, number of spikes and intraburst spike frequency) of each circuit neuron; (iii) the relative timing of activity (phase) of each circuit neuron; (iv) the duration of these changes; and (v) the interactions between separate CPGs [1,3,5–6,9].

## Higher Level Structures

Modulatory projection neurons that influence the same neuronal network are often clustered into the same region of the CNS (e.g., brainstem, higher-order invertebrate ganglion). These projection neurons are not completely independent, parallel pathways whose actions only converge at the level of their shared targets. Instead, these neurons also interact to either facilitate or prevent their coactivation [2,4,7]. However, the extent to which there are well defined circuits among such populations of projection neurons remains to be determined. Further, although stimulation of an individual modulatory projection neuron is often sufficient to elicit or modulate an entire motor pattern, it appears likely that subsets of these neurons are normally coactivated by particular sensory or higher-order inputs [1–2,10].

## Lower Level Components

The influence of modulatory projection neurons can reach every level of a motor system. These neurons commonly synapse directly with CPG neurons and thereby activate, terminate or alter circuit output [2–5, 8–9]. These synapses often include both ionotropic and metabotropic components, so there are generally both short-term and long-term actions. As indicated above, there are also synapses between different projection neurons. In parallel, projection neurons also directly influence the same motor neurons whose activity is driven by the CPG, thereby modifying the motor neuron response to CPG activity. Finally, some projection neurons also project to the periphery, where they regulate transmitter release from motor neuron terminals at their neuromuscular junctions as well as directly altering muscle fiber properties [3,5,8].

## Structural Regulation

Focused sensory stimuli clearly activate modulatory projection neurons and thereby influence CPG activity [1–2,5,9]. Furthermore, any such focal sensory pathway stimulation appears to target subsets of the population of projection neurons relevant to any particular motor act [1,10]. However, the general organizing principles underlying this level of operation are yet to be determined. Thus far, the data set is small, but distinct sensory inputs are as likely to elicit distinct motor programs from the same CPG because they activate different or the same subset of modulatory projection neurons [1,10].

There is also feedback regulation from the target CPG(s) to the projection neurons. This often results in the projection neuron exhibiting a rhythmic activity pattern that is time-locked to that of the CPG [2,5–6]. The function of this feedback regulation remains obscure in most systems, although some recent work has documented a role for this feedback in enabling one CPG to regulate the activity of a distinct but related CPG circuit [6].

This general schema for sensorimotor organization implies a hierarchical organization for motor control. However, as we learn more about the cellular-level details at each level of organization, the lines between them have begun to blur. For example, some projection neurons also satisfy the criterion to be CPG members and some CPG members, when directly activated, can turn on the entire CPG [1,3–6].

## Higher Level Processes

The basic organizational features represented by the population of modulatory projection neurons that influence different CPGs seem comparable, but there are few data sets available for comparison. It is clear that such populations include subsets that use different sets of co-transmitters [2–3]. Furthermore, selective activation of some individual projection neurons is sufficient to orchestrate complete activation or termination of a CPG in small motor systems in invertebrates and non-mammalian vertebrates [2,4–5,9]. However, it appears likely that behaviorally-relevant activation of projection neurons in all motor systems involves the coactivation of subpopulations of these neurons [1–2,10]. The current issues being addressed that relate to this organization include determining: (i) how any single population of distinct but functionally related projection neurons are influenced by distinct sensory and higher-order inputs, and (ii) the extent to which inter-projection neuron interactions sculpt the influence of these neurons on their CPG targets. It is also important to expand to additional systems an understanding of the function of rhythmic CPG feedback onto these projection neurons.

## Lower Level Processes

Many of the concepts now known to be relevant to modulatory projection neurons were first established by studies in which neuromodulators were bath-applied to the isolated nervous system, as a model system for how modulatory neurons influence CPG activity [2–5,7–8]. Included among these now well-established concepts is that: (i) Neuromodulation alters CPG output, quantitatively and sometimes qualitatively, by changing the cellular and synaptic properties of the circuit neurons. (ii) Modulation works at multiple levels, often also altering the properties of pre-CPG interneurons and post-CPG targets, such as motor neurons and muscles. (iii) These modulatory consequences result from both convergence and divergence of modulator action. For example, different neuromodulators can evoke different motor patterns from the same CPG and yet have convergent actions on the same second messenger system(s) and/or ion channel(s). In such situations, the different motor patterns result at least partly from different CPG neurons having overlapping but distinct sets of receptors for the different modulators. There are also examples whereby a single modulator influences a CPG by altering the activity of a set of different ion channels, but the subset that it influences is distinct in each CPG neuron. (iv) Not all CPG neurons need be direct targets of any single modulator. (v) To completely understand modulation of a circuit, it is equally important to identify which CPG neurons are not targets and are targets of a modulator, because the synaptic actions of non-targets often alter the activity of the target neurons.

Studies using direct, intracellular recording and manipulation of individual projection neurons have revealed that, like bath-applying different modulators, stimulating different projection neurons elicits distinct outputs from the same CPG [3–5,7]. In addition to confirming the results of bath-applying neuromodulators, stimulating single projection neurons has revealed additional degrees of freedom available to these systems. For example, (i) many projection neurons contain co-transmitters, but each target neuron in a CPG does not necessarily contain receptors for all of the co-transmitters released by any single projection neuron; (ii) different projection neurons with the same co-transmitter complement can elicit different outputs from the same CPG; (iii) consistent with the belief that projection neurons provide no timing cues to the CPG, some projection neurons modulate CPG output by providing a non-rhythmic input to their target CPG; and (iv) the ability of a projection neuron to activate/modulate a CPG output cannot always be mimicked by bath application of its co-transmitters. This last point may be due to the difficulty in mimicking the temporal nature of the ionotropic actions of the projection neuron with either focal or bath application, or because of local regulation of transmitter release (see below).

## Process Regulation

There is both biochemical and synaptic regulation of the actions of projection neurons. Regarding biochemical regulation, despite the general belief that neurally-released peptides freely diffuse, many of them are locally inactivated by extracellular peptidase activity [7]. Such focal regulation of released neuropeptide can enable different projection neurons to elicit distinct CPG outputs despite releasing the same peptide.

At the so-called lower levels, synaptic regulation of projection neuron activity originates from both sensory feedback and CPG feedback [1–7]. Various sensory systems either trigger, terminate or modify projection neuron actions onto CPGs. Triggering and terminating tends to occur at the level of the projection neuron dendrites/soma, thereby influencing the ability of the neuron to generate action potentials. In contrast, the modifying actions of a sensory input can occur either at that same location or via axo-axonic synapses,

thereby having focal actions on specific transmitter release sites of the affected neuron.

The activity of some projection neurons is time-locked to that of their target CPG [5–6]. This rhythmic projection neuron activity is generally a consequence of synaptic feedback from the CPG activated by that projection neuron. The feedback can either globally or focally affect projection neuron activity, depending on the site of the synapse [4–7]. In most such cases, the function of this rhythmic projection neuron feedback is not known. In one recently documented example, its function is to enable one CPG to regulate the activity of a behaviorally related CPG [6].

### Function

Modulatory projection neurons integrate inputs from sensory and higher-order centers and, when activated, provide persistent drive to one or more rhythmically active motor circuits (CPGs). Different subsets of these projection neurons share the ability to activate a particular CPG, but their distinct actions enable them to generate different neuronal output patterns from that circuit. These distinct actions lead to the generation of particular coordinated rhythmic movements, such as walking, running or swimming from the spinal locomotor CPG. The collective influence of modulatory projection neurons appears to be necessary to enable CPGs to express their full potential. Their complete elimination may prevent the expression of any natural versions of the behaviors generated by that CPG.

### Therapy

The loss of input from modulatory projection neurons, such as might occur for the vertebrate locomotor CPG after spinal cord injury, either eliminates or severely limits the ability to activate that CPG [2–3,6]. Thus, understanding the detailed cellular-level influences of these neurons on their CPG targets will be pivotal to understanding how to circumvent or replace their loss after injury or disease.

## Module

### Definition

In neuroscience, "module" refers to a functional component of the brain, describable in terms of neurological structures, e.g. cells, columns, layers. In cognitive science, module refers to a specialized mental device that operates on specific types of information (domain-specificity), provides predetermined outputs for predetermined inputs (mandatory operation), has no access to information in mental systems except its own subsystems or dedicated input devices (informational encapsulation), delivers output restricted to relatively simple concepts (shallow output) and is subject to characteristic patterns of breakdown. The operations of a mental module are also fast and inaccessible to attention processes or consciousness.

►Theory Theory (Simulation Theory; Theory of Mind)

## Module in Central Pattern Generator

### Definition

A population of neurons within a central pattern generator (CPG) that acts in concert. Neurons in the module are active during a specific phase of a behavior and are quiet during other phases of the behavior. The unit-burst-generator and the half-center are examples of modules.

# Molecular and Cellular Biomechanics

Walter Herzog
Professor, Faculty of Kinesiology, University of Calgary, Canada

## Definition

Molecular and cellular biomechanics is the branch of biomechanics that deals with single molecules, molecular interactions, or cells as the system of interest. It deals with the effects that the mechanical environment has on gene expression, mRNA and protein production in cells, and transport and assembly of proteins in extracellular matrices, and further deals with the mechanical properties of isolated molecules or the interaction of proteins, specifically those that make up ►molecular motors that produce essential functions in living systems.

## Characteristics

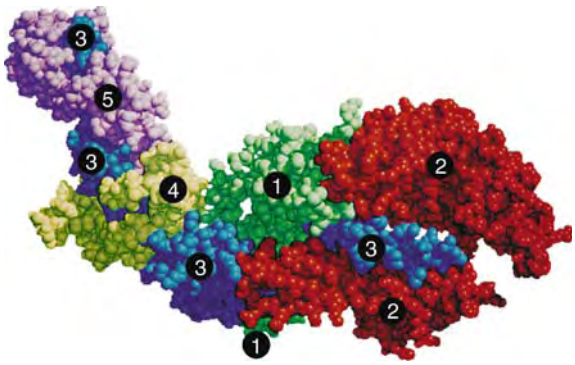
Molecular and cellular biomechanics is a relatively new branch of biomechanics. It was made possible by technological developments and by the interest of scientists to understand phenomena of tissue growth and adaptation, transport phenomena involving molecular motors, and material properties of isolated molecules, to name just a few of the emerging fields of research. Here, selected approaches are highlighted to provide insight into the field of molecular and cellular biomechanics, and to give specific examples of applications.

The first example will deal with the mechanisms of muscle contraction involving the molecular motor composed of ►myosin II and ►actin; the second example will deal with the giant molecular spring ►titin, which plays an important role in passive force production in skeletal and cardiac muscle.

### Myosin-Actin Interactions and the Molecular Mechanisms of Contraction

In order to deal with molecular interactions, it is important to have a detailed structural description of the proteins that are considered. In the case of myosin II, Rayment et al. [1] described the portion of that molecule that is referred to as the subfragment 1, S1. This part of the molecule contains the actin and nucleotide binding sites, as well as the regulatory and essential light chains (Fig. 1).

The structure of the S1 was determined by x-ray diffraction in a two-step procedure: first, the positions of the metal binding sites were determined using x-ray data sets with a 4.5 Å resolution, and then these data were filled in with Synchroton radiation results to produce a 2.8 Å resolution. In a companion study, Rayment et al. [2] revealed the structure of the actin binding site, and they speculated on the interaction of S1 with the actin attachment site that produces muscle contraction.

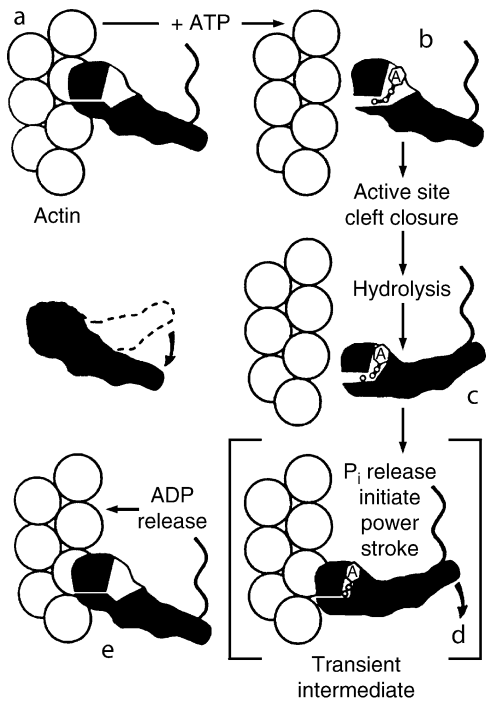


**Molecular and Cellular Biomechanics. Figure 1** Space-filling representation of all atoms in the myosin subfragment 1 model. Segments labeled 1, 2, and 3 represent parts of the heavy chains, while those labeled 4 and 5 show the essential and regulatory light chains, respectively. The proposed actin binding site is located at the lower right-hand corner (2). The active nucleotide site is on the opposite side from the proposed actin binding surface; segment 1 (Reprinted with permission from Rayment et al. [1]. Copyright 1993 American Association for the Advancement of Science).

Starting from the rigor confirmation, Rayment et al. [2] suggested that the narrow cleft that splits the 50 kD segments of the myosin heavy chain into two domains is closed (Fig. 2a and e, horizontal gap, perpendicular to the actin filament axis).

The addition of ATP and initial ATP binding to myosin at the active site causes an opening of the narrow cleft between the upper and lower domains of the 50 kD segment. This in turn disrupts the strong binding between actin and myosin but still allows for a weak attachment (Fig. 2b). The final ATP binding to myosin causes a closure of the nucleotide binding pocket and a corresponding configurational change of the myosin molecule. ATP is now hydrolyzed (Fig. 2c). Rebinding of myosin to actin can occur, presumably in multiple steps. The gap between the upper and lower domain closes in this process to produce strong binding, and phosphate, P, is released. This event starts the so-called power stroke, the myosin molecule reverses its conformational change induced by ATP binding, and the active site pocket is reopened, establishing the ►rigor configuration (Fig. 2e). The cross-bridge cycle can then start all over again.

The studies by Rayment et al. [1,2] suggested the possible mechanism of contraction from a structural point of view. However, the actual movement produced by actin myosin interactions, the corresponding forces, and the relationship of the mechanical events with



**Molecular and Cellular Biomechanics. Figure 2**
Proposed molecular mechanism of contraction. (a) Rigor conformation. The narrow cleft that splits the 50-kD segments of the myosin heavy-chain sequence into two domains is closed (horizontal gap, perpendicular to the actin filament axis). (b) Addition of ATP, and initial binding of ATP to the active site, causes an opening of the narrow cleft and disrupts the strong binding between actin and myosin, but still allows for weak binding. The actin and myosin dissociate. (c) The final binding of ATP to myosin causes a closure of the nucleotide binding pocket and a corresponding configurational change of the myosin molecule. ATP is now hydrolyzed. (d) Myosin can now reattach to actin, presumably in multiple steps. The narrow cleft closes to produce strong binding. Phosphate, P, is released, and the power stroke starts. (e) During the power stroke, the myosin molecule reverses its conformation change induced by ATP binding, and the active site pocket is reopened, establishing the rigor conformation. The cross-bridge cycle can now start all over again (Reprinted with permission from Rayment et al. [2]. Copyright 1993 American Association for the Advancement of Science).

the corresponding biochemical steps cannot be determined using x-ray diffraction. In 1994, Finer et al. [3] showed the first results of forces produced by the interaction of a single cross-bridge with an actin filament using a double beam ►laser trap approach.

## Single Myosin Mechanics

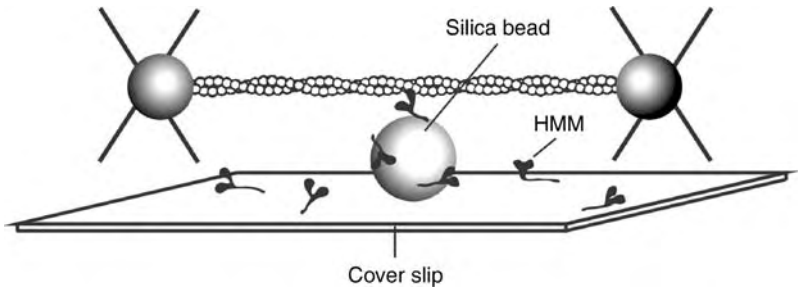
Finer et al. [3] attached silica beads to a microscope cover slip. The cover slip was coated with skeletal muscle heavy meromyosin (HMM) at a low density to allow for single attachments of cross-bridges to actin. Polystyrene beads coated with N-ethylmaleimide (NEM)-treated HMM were attached to actin filaments. An actin filament with two beads attached near its end was then caught and suspended in two optical traps (Fig. 3).

The image of one of the beads was projected to a photodiode detector for position detection. The actin filament was then pulled taut (with a force of about 2 pN) and was lowered to the silica bead with the HMM. Now, a single HMM molecule could interact and attach to the actin filament. When a cross-bridge head attached to the actin, a rapid transient movement of the silica bead along the axis of actin was observed. Consistent displacement traces were observed by keeping the stiffness of the optical traps high enough to decrease the noise caused by ►Brownian motion (i.e. about 0.02 pN/nm per trap), but small enough that a myosin molecule could produce a full displacement. The average size found for single myosin cross-bridge steps was about 11 ± 2.4 nm, independent of the ATP concentration (1μM–2mM ATP) and independent of the total trap stiffness (0.014–0.08 pN/nm).

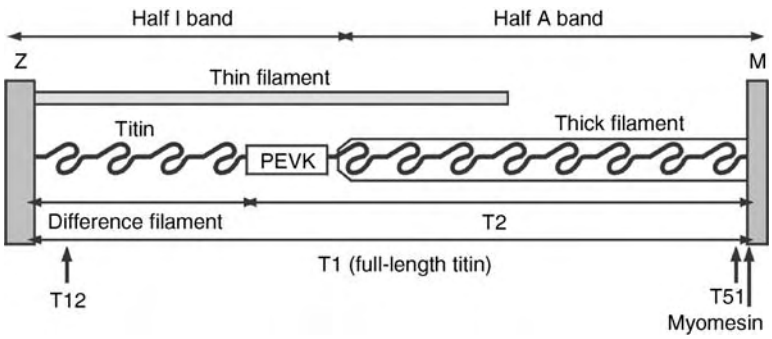
In order to measure the forces produced by single HMM molecules, the stiffness of the optical trap was increased to 6 pN/nm. Movements of the bead from the centre of the optical trap were proportional to the force applied on the actin filament. For the force measurements, movements of the bead were prevented by a feedback position system, which moved the optical trap (when force was applied to the bead) by the exact amount required to keep the bead stationary. Therefore, the displacement of the trap became a measure of the applied force. The magnitude of forces measured by single HMM interactions with actin were 1–7 pN, and they averaged 3.4 ± 1.2 pN. The force magnitudes were not affected by ATP concentration.

One of the limitations of the study by Finer et al. [3] was that it could not be determined with confidence whether a given mechanical event was produced by one or more HMM molecules or by one or both heads of the HMM molecule. Molloy et al. [4] addressed this issue using two optical traps in essentially the same way as Finer et al. [3], and measured the interactions of HMM molecules (two-headed cross-bridges) and myosin subfragment 1 (S1, single-headed cross-bridges) with actin. Molloy et al. [4] found that the average working strokes of S1 and HMM were comparable (about 4 nm) and were much smaller than those found by Finer et al. [3] for HMM (about 11 nm). Also, the average force values for both S1 and HMM interactions with actin were low (about 1.7 pN) compared to those measured by Finer et al. [3].

Muscle contraction with the myosin II-actin motor is just one example that could have been chosen to present



**Molecular and Cellular Biomechanics. Figure 3** Schematic illustration of single heavy meromyosin, HMM, interaction with an actin filament. The silica bead on the cover slip is coated with skeletal muscle heavy meromyosin (HMM). Coated polystyrene beads are attached to the ends of actin. The actin filament with its two beads is caught and suspended in two optical traps. The suspended actin filament is then lowered to the silica bead, and single HMM interactions with the actin filament are now possible (Reprinted by permission from *Nature*, Finer et al. [3]. Copyright 1994 Macmillan Magazines Ltd).



**Molecular and Cellular Biomechanics. Figure 4** Schematic illustration of titin and its association with other structures within a half-sarcomere. Titin spans from the Z-line to the M-band. It consists of about 300 immunoglobulin and fibronectin type III repeats and a proline (P), glutamate (E), valine (V), and lysine (K)-rich (PEVK) domain (Reproduced from Kellermayer et al. [8], with the permission of the American Association for the Advancement of Science).

some of the measuring techniques and approaches in molecular biomechanics. Excellent reviews describing the function of molecular motors are available (e.g. [5–7]).

## Molecular Springs

Here, we would like to discuss the function and action of titin, a molecular spring that is particularly important in skeletal and cardiac muscle where it is thought to provide a big portion of the passive forces, and to play an important role in providing longitudinal stability of the myosin filament in sarcomeres. Titin, sometimes referred to as connectin, is a giant filamentous polypeptide, consisting primarily of about 300 immunoglobulin (Ig) and related fibronectin type III (FNIII) repeats, and a unique proline (P), glutamate (E), valine (V), and lysine (K)-rich (PEVK) domain. Titin spans each half-sarcomere and is anchored to the Z-line and the thick filament reaching all the way to the M-band (Fig. 4). Titin is thought to play a basic role in maintaining ►sarcomere structural integrity and producing passive force when muscle sarcomeres are stretched. Titin is also believed to provide a molecular scaffold for thick filament formation.

It has been argued that titin stabilizes the thick filament in the centre of the sarcomere when, upon contraction, small asymmetries in pulling forces are produced on the two halves of the thick filament. Furthermore, titin is assumed to produce passive force in muscles. Such passive forces might help stabilize what has been labelled the unstable [9], or softening, behavior of active muscle force on the descending limb of the force-length relationship. Finally, once a sarcomere is stretched beyond thick and thin filament overlap, cross-bridge attachments become impossible, and the forces required to re-establish myofilament overlap are thought to come primarily from the passive elastic forces of the highly stretched titin.

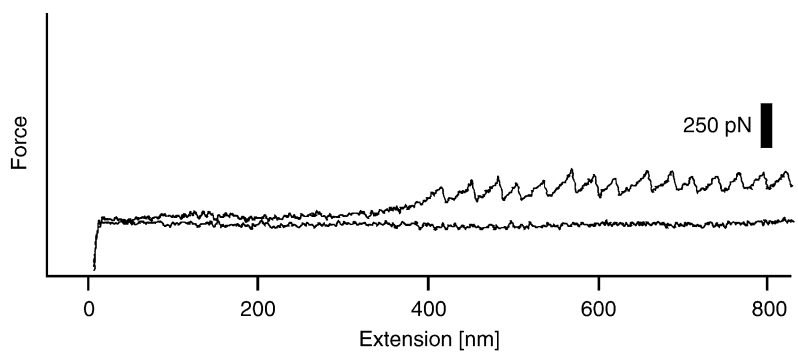
Despite the apparent importance of titin, the way it accomplishes its functional role has not been fully

resolved. If titin really provides most of the passive force in a stretched muscle, it should have several distinct characteristics: first, for centring the thick filament upon contraction, it should provide a low-level stiffness. The stiffness needs to be low because the asymmetries in active force acting on the thick filaments would presumably not be large, and the muscle (sarcomere) should still be stretchable without much resistance within its normal physiological range. Second, at some point titin should become stiff at a very fast rate in order to prevent large stretches of muscle against external forces that might cause injury. Finally, titin must accomplish its passive force at different lengths in different muscles, as the passive forces measured in different muscles occur at distinctly different sarcomere lengths. For example, in cardiac muscle, passive force is known to be high at about optimal sarcomere length, whereas in many skeletal muscles, passive force is negligible at optimal sarcomere length.

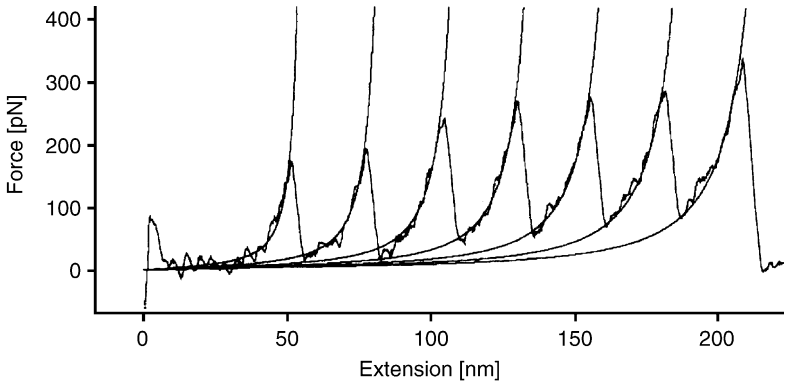
Rief et al. [10] used ►atomic force microscopy to study the mechanical properties of titin. Single titin molecules were stretched, and molecular elongation and the corresponding forces were recorded simultaneously. Rief et al. [10] found force-extension curves for titin that showed a sawtooth-type pattern (Fig. 5) that was typically preceded by a "smooth" increase in force of variable length. The periodicity of the force peaks was in the range of 25–28 nm, i.e. close to the expected full length of an Ig domain, and the force peaks varied from about 150–300 pN.

In order to test whether the peaks of the sawtooth pattern indeed reflect an unraveling of the Ig domains, two model recombinant titin fragments were constructed, consisting of either four (Ig4) or eight (Ig8) Ig segments in the I-band region (the flexible region) of titin. All traces obtained with these Ig segments showed a strict 25 nm periodicity. Furthermore, the force peaks were found to increase from the first to the last (Fig. 6), but stiffness was found to decrease from one force peak to the next (Fig. 6). Finally, when these Ig segments were released to one-half of their fully stretched length (but not to their resting length) and then pulled again, the sawtooth force-extension curve was not apparent. The sawtooth pattern was only fully recovered after complete relaxation of the titin to its resting length.

Based on their results, Rief et al. [10] concluded that each sawtooth pattern corresponded to an unfolding of one Ig domain: the force on the ascending part reflecting the molecular forces that must be overcome to produce the unfolding, the force decrease following the peak reflecting the fact that the molecular spring was now "abruptly" elongated by about 25 nm. The increasing peak forces with each subsequent sawtooth pattern were assumed to reflect increasingly stronger molecular bonds of the folded Ig domains; therefore, the "weakest" domain was unfolded first, followed by increasingly "stronger" Ig domains. The relative "smooth" increase in force preceding the sawtooth patterns was associated with a different molecular mechanism, possibly an elongation of the PEVK region, although this assumption was not rigorously tested. Finally, it took a full shortening of titin before a sawtooth pattern force-extension curve could be observed after the molecule had been stretched. Partial shortening did not produce partial sawtooth patterns, therefore it appears that a refolding of the Ig domains only occurs at or near titin's "resting" length or, in terms of force, at very low titin forces.



**Molecular and Cellular Biomechanics. Figure 5** Force-extension curve of a single titin molecule obtained using atomic force microscopy. The force-extension curve shows a sawtooth-type pattern that is preceded by a smooth increase in force. The periodicity for the force peaks is about 25–28 nm, and the force peak magnitudes were in the range of 150–300 pN. The smooth increase in force preceding the sawtooth pattern was associated with an elongation of the PEVK region. The sawtooth pattern was associated with an unfolding of the Ig domains (Reproduced from Rief et al. [10], with the permission of the American Association for the Advancement of Science).



**Molecular and Cellular Biomechanics. Figure 6** Force-extension curve of a recombinant titin fragment consisting of eight Ig segments. The curve shows a strict 25 nm periodicity. Force peaks increase from the first to the last sawtooth pattern, but the stiffness decreases. The force and stiffness on the ascending part of the sawtooth pattern likely reflect the molecular forces that must be overcome to produce unfolding of one Ig domain. The force decrease following the peak, reflects the sudden 25 nm elongation of the molecule once the molecular unfolding forces have been overcome (Reproduced from Rief et al. [10], with the permission of the American Association for the Advancement of Science).

Here we described the molecular motor myosin II-actin and the molecular spring titin as two examples of biomechanical investigation on the molecular level. Many other examples could have been advanced. However, these two covered some of the new technologies that are available today for performing mechanical experiments on the micro-scale level. We neglected a great number of studies relating to cell biomechanics. Many of these deal with the mechanical loading and the corresponding biological responses of cells, and tissue engineering. Regarding these issues, we would like to recommend the book by Mow et al. [11] for people with an interest in musculoskeletal tissues, and the book by Fung [12] for additional discussions on the cardiovascular system.

# Molecular Cues

Signals in the extracellular environment that instruct the axon which way to grow during pathfinding.

# Molecular Features in Odors

## Definition

Based on the assessment of odor similarity in relation to the molecular structure, two different but overlapping

categories of odorant molecular characteristics have been identified. One category is a polar functional group that contains an oxygen, or a nitrogen, or a sulfur atom. The other category is the molecular profile that is formed mainly by the overall molecular shape. Polar functional groups and molecular profiles strongly influence the perceived odor quality.

►Odor Maps

## Molecular Motors

### Definition

Molecular motors are engines made up of individual molecules. There are a series of well-studied molecular motors that perform life essential functions in the human body. For example, the myosin II-actin motor is responsible for muscle contraction, kinesin and dynein transport organelles or vesicles from one location of a cell along polar and periodic tracks (actin and microtubules), and membrane bound motor proteins transport ions against chemical concentration gradients.

## Monoaminergic Cell Groups

### Definition

These are cell groups that use monoamines as neurotransmitters. The monoamines include the catecholamines (dopamine, norepinephrine, and epinephrine) and the indoleamine serotonin (5-hydroxytryptamine). The catecholamines are derivatives of the amino acid tyrosine. Serotonin is a derivative of the amino acid tryptophan. The major cell groups that use dopamine are the substantia nigra and the ventral tegmental area in the midbrain. A major cell group that uses norepinephrine is the locus ceruleus (Latin for blue spot) in the dorsal pons. There are few if any epinephrine neurons in the brain. Epinephrine is secreted into the blood by the adrenal gland near the kidney. The major cell groups that use serotonin are the raphe (Greek for ridge or seam – refers to nuclei near the midline) nuclei which scattered from the caudal pons to the medulla.

## Monoamines

### Definition

Brain monoamine synaptic transmitters consist of an aromatic ring and amino group attached by a two carbon chain (-CH2-CH2-). Monoamines are further classified as catecholamines or indolamines depending on the specfic essential aromatic amino acid, phenylalanine or tryptophan respectively, from which they are derived. Dopamine and norepinephrine (noradrenaline) are derived from L-tyrosine first by the action of the enzyme tyrosine hydoxylase to form L-Dopa which is subsequently decarboxylated by aromatic amino acid decarboxylase to form dopamine. Norepinephrine is synthesized following the β–oxidation of dopamine by dopamine beta hydroxylase, with the co-factor ascorbate serving as an electron doner. Epinephrine is synthesized from norepinephrine in a restricted group of neurons in the brain-stem by phenylethanolomine N-methyltransferace. Serotonin is synthetized from Ltryptophan in two enzymatic steps involving tryptophan hydroxylase and aromatic amino acid decarboxylase. The discovery by Falk and Hilarp of histochemical fluorescence enabled the visualization of catecholamines and serotonin within specific nuclei and efferent neural pathways, which could then be lesioned by specific neurotoxins. Preclinical experiments employing this lesion technique helped to identify the function of specific brain monoamines in

many aspects of behavior ranging from motor control to emotional and cognitive processes. Monoamine transmitters influence post-synaptic neurons via specific receptor sub-types and synaptic levels are determined mainly by the action of selective uptake mechanisms. These sites have served as targets for the development of highly effective drugs for the treatment of neuropsychiatric disorders, including the SSRI's (serotonin-selective reuptake inhibitors) and neuroleptic drugs for the treatment of schizophrenia.

# Morning/Evening Oscillators

Michael N. Nitabach
Department of Cellular and Molecular Physiology, Yale School of Medicine, New Haven, CT, USA

## Definition

Morning ("M") and evening ("E") oscillators are distinct circadian oscillators that control the peaks of activity of twilight-active animals that occur during the morning and evening twilight.

## Characteristics

### Theoretical and Descriptive Analysis of M and E Oscillators

In animals, the circadian clocks that control the timing of rest and activity are embodied in groups of ►circadian pacemaker neurons in the central nervous system. Many animals are crepuscular – i.e. twilight-active – and thus concentrate their activity around dawn and dusk. It was theorized in the 1970s that crepuscular rodent activity rhythms are controlled by independent, but coupled, ►Morning and Evening (M and E) oscillators [1]. Later measurements of circadian rhythms of pacemaker neuron firing in the rodent ►suprachiasmatic nucleus (SCN) revealed two distinct subpopulations of neurons whose firing rhythms were out of phase, suggesting that these could be the M and E oscillators [2]. However, it has not been possible to experimentally test the hypothesis that a particular subset of rodent pacemaker neurons does indeed function as an M or E ►oscillator. This would require functionally inactivating the subset of pacemaker neurons constituting a putative M or E, followed by measurement of the effect of this inactivation on the morning and evening peaks of activity.

### Experimental Demonstration of M and E Oscillators

Like many rodents, *Drosophila melanogaster* fruit flies are crepuscular, exhibiting peaks of activity centered on the transitions from night to day and from day to night. And unlike in rodents, readily available techniques exist for functionally inactivating defined subsets of pacemaker neurons. In one study, flies were generated that lacked either the lateral–ventral anatomical subset of pacemaker neurons or several dorsal anatomical subsets of pacemaker neurons [3]. Flies lacking the lateral–ventral subset lost the morning peak of activity, but retained the evening peak. Flies lacking the dorsal subgroups lost the evening peak of activity, but retained the morning peak. In a different study, flies were generated that had functional ►cellular clocks either only in the lateral–ventral subgroup, or in both the lateral-ventral and dorsal subgroups [4]. Flies with functional cellular clocks solely in the lateral-ventral subgroup exhibit only the morning peak of activity, while flies with functional cellular clocks in both subgroups exhibit both the morning and evening peaks of activity. These findings demonstrate that the fly M and E oscillators reside in the lateral-ventral and dorsal pacemaker neurons, respectively.

### Communication of Phase Information Between M and E Oscillators

Those experiments were performed in 12 h:12 h light: dark (LD) conditions, where both M and E oscillators

can be independently synchronized to the environment and thereby maintain a constant phase relationship. When flies are synchronized to LD and then released into constant darkness (►constant conditions, DD), the morning and evening peaks still occur – although they ►free-run and gradually drift out of phase with the rotation of the Earth. But even in free-running conditions, the morning and evening peaks maintain a constant phase relationship with each other. So there must be some mechanism for keeping that relationship constant in free-running DD conditions even in the absence of any environmental cues.

One possible mechanism for maintaining constant phase between M and E oscillators is a ►master–slave relationship, so-called because one of the oscillators controls the other. To test this hypothesis, flies were genetically modified so that the M and E oscillators run with intrinsic periods that differ by 3–4 h [5]. Under ►free-running DD conditions, the period of the behavioral rhythm of locomotor activity is always determined by the intrinsic period of the M oscillator, suggesting both that there is a master–slave relationship and that M is the master. Furthermore, the period of oscillation of the cellular clock in the E cells is determined by that of M, and not by the intrinsic period of the E cells themselves. These results demonstrate that M cells send a signal to the E cells that controls the oscillation of their cellular clocks. A good potential candidate for this signal is a neuropeptide produced and secreted by the lateral-ventral M pacemaker neurons and known to be important for circadian function [6].

## Definition

In the development of organisms the organization of cells into tissues is a major achievement. Precursor cells or undifferentiated cells have to be organized in a spatial pattern that allows their differentiation to distinct cell types. To this end, positional information has to be transferred to cells. The term morphogen describes such positional signals that are secreted by a source, and therefore form a gradient emanating from this source by mechanisms that are still unclear (see below). Cells responsive to a particular morphogen will then sense their position in response to the concentration of the morphogen. Thus, ►morphogens are capable of specifying body axes or give polarity to tissues, in other words are responsible for the patterning of the

embryo. In vertebrates, morphogens include members of the Hedgehog, the ►Wnt, the FGF (Fibroblast Growth Factor), and the TGF-β (Transforming Growth Factor-β) families. In human there are three Hedgehogs (Sonic, Indian, and Desert Hedgehog), 19 Wnts (Wnt1 – Wnt16), and 22 FGFs. The TGF-β family is subdivided into several subfamilies, the TGF-βs, activin, and the bone morphogenetic proteins (BMPs). For the developing nervous system, the BMP subfamily is most relevant. In Drosophila, where development starts in a ►syncytium, transcription factors, e.g. bicoid, have also been identified as morphogens. In this essay I will concentrate on vertebrate morphogens, however.

## Characteristics

Neural development starts with neural induction and neurulation giving rise to the neural tube, which will form the central nervous system, and to the ►neural crest, from where cells will delaminate to form the peripheral nervous system. A hallmark of neural development is the considerable distances that cells migrate to reach their final destination from where they send out their long processes, ►axons and ►dendrites, to connect to their target cells. This is particularly true for the brain. The migratory routes are much shorter and less complicated in the caudal neural tube, the ►spinal cord. Therefore, early events of neural development, ►neurogenesis, ►cell differentiation, and patterning have been studied extensively in the spinal cord. Cell migration has been studied predominantly in the brain. Morphogens are involved in all steps of neural development from neural induction to axon guidance and ►synaptogenesis, the final step in neural circuit formation.

## Methods to Study Morphogen Function

Common to all morphogens is their involvement in the regulation of ►cell proliferation, differentiation, and patterning. Because all morphogens are involved not only in spatially distinct but also in temporally distinct processes, their functional analysis has to take time into account. This is quite difficult to achieve with classical genetic tools, as they allow only for the analysis of gene function in the first window of activity. Analysis of later events is often prevented by aberrant development due to the absence of gene activity during early time windows or even early embryonic lethality. Inducible knockout strategies or ►RNAi approaches have opened new possibilities in temporal control of gene expression and are therefore better suited for functional analyses of morphogens [1].

## Morphogens in Early Neural Development

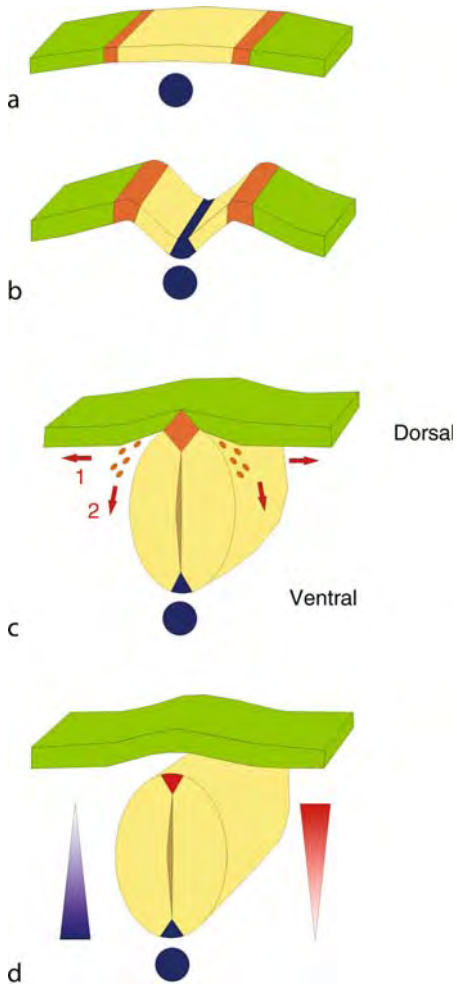
Neural induction starts with or even before gastrulation: Cells of the ►ectoderm are set aside to become neural ectoderm [2]. This process requires blocking the activity of ►bone morphogenetic proteins (BMPs), a subfamily of the TGF-β family of morphogens. BMPs drive differentiation to epidermis, thus, neural ectoderm will be formed only where this activity can be blocked by Chordin, Noggin, and Follistatin, three BMP inhibitors originally identified in Xenopus. In addition to BMPs, members of the FGF, and the Wnt family of morphogens have also been implicated in neural induction [2]. Once the neural epithelium has been defined it starts to undergo changes in shape, i.e. it folds up in a process called neurulation (Fig. 1).

## Morphogens and Neural Crest Formation

►Neural crest cells give rise to cells of the peripheral nervous system, pigment cells (melanocytes), and skeletal elements of the head. Neural crest cells arise from the border between the neural and the non-neural ectoderm and depend on the presence of BMPs (Fig. 1). The requirement for BMP signaling in neural crest cell formation was demonstrated for instance in zebrafish mutants (for references see [3]). In addition to BMPs, other morphogens, such as Wnts and FGFs were also implicated in neural crest induction and proliferation. Because neural crest specification cannot be separated from cell migration along distinct pathways, roles of morphogens in neural crest migration have also been demonstrated (reviewed by [3]).

## Morphogens in Differentiation and Patterning

The newly formed neural tube is specified from the beginning with respect to the antero-posterior and the dorso-ventral orientation. At the anterior end of the neural tube, the brain will form, the caudal neural tube will develop into the spinal cord. The ►notochord, a mesodermal structure underlying the neural plate, specifies the ventral midline of the neural tube, called the ►floor plate (Fig. 1). The roof plate originates during the closure of the neural tube and marks the dorsal midline of the spinal cord. Both the floor plate and the roof plate are important signaling centers, as they are the source of morphogens [4]. BMPs are produced in the roof plate, ►Sonic hedgehog (►Shh) is produced by the floor plate. Wnts are also expressed in the roof plate and in the adjacent dorsal neural tube. Under the influence of these morphogens ►neuroepithelial cells differentiate to distinct types of cells. In the dorsal neural tube, cells are predominantly under the dorsalizing effect of the BMPs, whereas cells in the ventral neural tube turn into ventral interneurons or motoneurons depending on the concentration of Shh [4]. High concentrations of Shh will induce V3 interneurons and motoneurons, successively lower concentrations will give rise to V2, V1, and V0 interneurons, respectively. These broad domains are distinguished by their characteristic expression of transcription factors used as markers. These transcription factors regulate



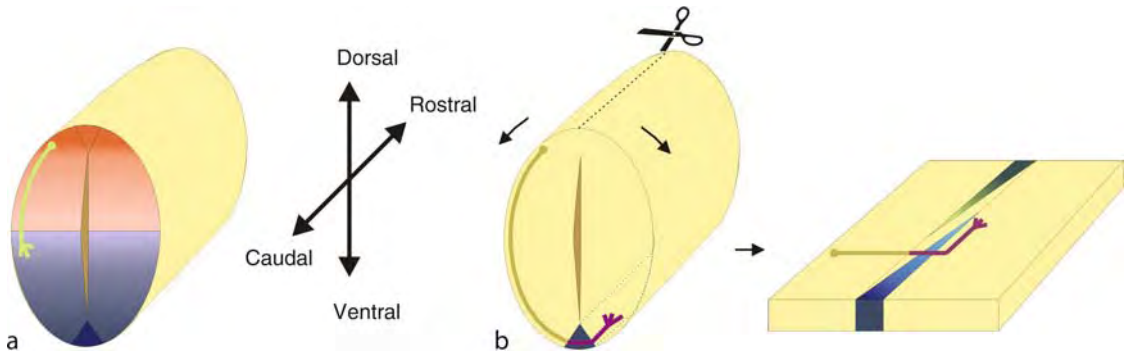
**Morphogens and Neural Development.**
**Figure 1** During neural induction ectodermal cells that are under the influence of BMP inhibitors develop into neural ectoderm (yellow in (a)). The remaining ectoderm (green) develops into epidermis. The notochord, a mesodermal structure underlying the neural ectoderm (blue), acts as an organizer for the neural tube. It expresses high levels of Shh and is responsible for the differentiation of the ventral midline cells of the developing neural tube into floor-plate cells (blue in (b)). The border between the neural and the non-neural ectoderm expresses BMPs and Wnts (orange) that are responsible for the delamination of neural crest cells during the closure of the neural tube (c). Neural crest cells migrate along a dorsal route (1) to turn into melanocytes and along a ventral route (2) to turn into cells of the peripheral nervous system. The fusion of the neural tube results in the formation of the roof plate (red triangle in (d)). Thus, the newly formed neural tube contains two organizing centers, the floor plate (blue triangle in (c) and (d)), the source of Shh with ventralizing activity, and the roof plate, the source of BMPs with dorsalizing activity. Cells along the dorsoventral axis adopt different cell fates depending on the concentration of BMPs and Shh that they experience (d).

specific gene expression patterns. The segregation of cells driven by selective cell-cell adhesion concludes the formation of the final classes of neurons along the dorso-ventral axis of the spinal cord. Similar processes are thought to occur in the brain but due to the increased complexity of the anterior neural tube the specific interactions and molecular processes are less well understood. In contrast, patterning of the anteroposterior axis of the neural tube has been studied in more detail in the brain [5]. The anterior end of the neural tube is subdivided into forebrain, midbrain, and hindbrain. The hindbrain and the borders between the individual segments of the hindbrain, the ►rhombomeres, are thought to be local signaling centers for the anteroposterior axis. The mid-hindbrain boundary, or isthmus, is the source of FGFs, in particular FGF8 that was shown to be most important for the organization of the midbrain and the ►cerebellum [6]. In addition to their role in differentiation and patterning morphogens regulate cell proliferation in the neural tube and thus define not only cell type but also cell number [7].

## Morphogens in Axon Guidance

More recently, a function of morphogens in axon guidance has been found [8–10]. First evidence for a role in ►axonal pathfinding was obtained in the visual system for FGFs in frog [6] and Shh in chicken embryos [9]. BMPs expressed by the roof plate were shown to act as axon guidance cues by repelling dorsolateral ►commissural axons (Fig. 2).

At the same time, these axons are attracted by ►Netrin-1, the first ►chemoattractant that was identified. Interestingly, the attractive effect of Netrin is supported by Shh that is expressed by the floor plate, as is Netrin. The activity of Shh is much weaker than the activity of the classical axon guidance cue, Netrin-1. Therefore, the attractive effect of Shh on commissural axons could only be detected in the absence of Netrin-1. More recently, Shh was identified as a ►repellent for the same commissural axons once they have crossed the ventral midline [9]. Interestingly, the repellent effect of Shh on postcommissural axons did not depend on the same receptor and the same signaling mechanism that was responsible for the patterning and axon guidance activities of Shh during earlier stages of development. Shh was shown to act as repellent for postcommissural axons that expressed Hedgehog-interacting protein (Hip). While the axon guidance function of Shh on postcommissural axons was detected in chicken embryos in vivo, a similar function was found for Wnt4 in mouse using in vitro assays. However, Wnt4 was shown to act as an attractant in accordance with its graded expression in the floor plate, with high levels rostrally and low levels caudally. Interestingly, Wnts were also found to act as repellents in longitudinal axon guidance in the corticospinal tract, where Ryk



**Morphogens and Neural Development. Figure 2** Commissural neurons located in the dorsolateral spinal cord (green in (a)) send out their axon under the repellent influence of BMPs emanating from the roof plate (red) and the attractive effect of Netrin-1 and Shh (blue). Patched and Smoothened expressed by commissural neurons mediate the attractive effect of Shh. When commissural axons reach the floor plate (blue triangle in (b)) they express Hedgehog-interacting protein (Hip; purple). Cells that express Hip no longer perceive Shh as attractive, and instead respond with repulsion. Thus, postcommissural axons are directed rostrally along the contralateral border of the floor plate in response to the decreasing Shh gradient, with high levels caudally and low levels rostrally. At the same time, a Wnt gradient with high levels rostrally and low levels caudally attracts postcommissural axons (see text and references [8–10] for details).

is involved as a co-receptor with the Wnt receptor Frizzled.

## Morphogens in Topographic Mapping

Axons reaching their target area have to select individual cells to form a ►synapse. In the visual system ►topographic mapping, i.e. the connection between the retinal ganglion cell (RGC) axons with the appropriate target cell in the tectum, has been studied for decades. Two coordinate systems, with perpendicular orientation to each other, specify the target for each incoming RGC axon. ►Eph-Ephrin interactions are responsible for both the antero-posterior and the medial-lateral orientation [10]. Recent studies have now added a Wnt gradient for medial-lateral retinal axon mapping, another example where a morphogen acts in parallel to a classical axon guidance cue (see above), in this case EphrinB1.

## Morphogens in Synaptogenesis

Finally, morphogens have also been implicated in the last step of neural circuit formation, synaptogenesis [7]. In the spinal cord, Wnt3 expressed by motoneurons was shown to play a role in the formation of terminal branches of proprioceptive neurons that contact dendrites of motoneurons in the ventral spinal cord. Similarly, in the cerebellum, ►mossy fibers that form a special type of nerve ending called rosettes with dendrites of ►granule cells undergo morphological changes that depend on the presence of Wnt7a in granule cells. In the absence of Wnt7a, axonal remodeling is perturbed and appropriate presynaptic structures fail to form [7].

## Morphogen Transport

The mechanism of morphogen gradient formation is not well understood, as morphogens are not freely diffusible due to ►posttranslational modifications, such as palmitoylation in the case of Wnt and Shh, or the covalent attachment of a cholesterol molecule in the case of Shh. Models for morphogen transport and gradient formation include transcytosis, i.e. the repeated endocytosis and release of morphogen molecules, or their transport in form of lipoprotein particles or argosomes. Furthermore, facilitated diffusion by binding to cell surface heparan sulfate ►proteoglycans has also been suggested for Wnt, Shh, and FGFs.

## Morphogen Signaling

In general, signaling by morphogens results in the activation of gene expression in the nucleus. Signaling by BMPs and FGFs has obtained a lot less attention than Wnt and Shh signaling. FGFs bind to one of four FGF receptors that are single-pass transmembrane receptor tyrosine kinases [6]. Heparan sulfate proteoglycans are co-factors for the activation of FGF receptors by FGFs. BMPs bind to a receptor complex consisting of type I and type II serine/threonine kinases. Receptor activation results in ►phosphorylation of SMAD family members [3]. Common to signaling of the Wnt and Shh families are structural features of the surface receptors. Both use seven-pass transmembrane receptors, Frizzleds in the case of Wnts and Smoothened in the case of Hedgehogs. It is important to note, however, that Hedgehogs do not bind to Smoothened directly but rather to the twelve-pass transmembrane receptor Patched. Upon binding of Hedgehogs, Patched

de-represses Smoothened activity. The mechanism of Patched/Smoothened interaction is not yet known.

Intracellular components of both the Hedgehog and the Wnt signaling cascade are multiprotein complexes containing a ►scaffold protein and kinases. These complexes phosphorylate and stabilize β-catenin downstream of Wnts, and control levels of Gli repressor and Gli activators downstream of Shh.

Wnt signaling includes three different pathways, the canonical and the non-canonical pathway with the latter being subdivided into planar cell polarity (PCP) and $Ca^{2+}$ pathways. The canonical pathway involves the stabilization of β-catenin. In the absence of Wnt, β-catenin is recruited to a multi-component complex consisting of the scaffold protein Axin, the tumor suppressor APC and two kinase families, CK1 and GSK. Subsequent ►ubiquitination results in degradation of β-catenin. If Wnt binds to the surface receptor Frizzled and co-receptors, such as Lrp5/6, phosphorylation of β-catenin is suppressed. Thus, β-catenin accumulates and can be transported to the nucleus, where it activates transcription by binding to LEF/TCF transcription factors.

In general signaling downstream of morphogens has only been studied in detail during early stages of development, including neural induction, differentiation and patterning. Signaling involved in later stages of development, such as axon guidance or synaptogenesis is not well understood. In axon guidance along the longitudinal axis of the spinal cord, the receptor for Shh is Hedgehog-interacting protein and no longer Patched [9,10]. Wnts appear to use Frizzled receptors for both axon guidance and earlier functions, but the intracellular signaling pathways have not been identified and do not seem to be identical to any of the well-known pathways (see above). In contrast to the classical roles of morphogens in tissue patterning, their role in axon guidance does most likely not involve changes in gene transcription but is restricted to more rapid changes in signaling affecting directly the cytoskeleton of growth cones.

# Mosaic Analysis with a Repressible Cell Marker

Veronica G. Rodriguez Moncalvo, Ana R. Campos
Department of Biology, McMaster University, Hamilton, ON, Canada

M

## Synonyms

MARCM

## Definition

Mosaic Analysis with a Repressible Cell Marker or MARCM is a set of genetic tools developed in the fruitfly *Drosophila melanogaster* for the positive labeling of individual cells or groups of cells derived from the same lineage. In addition, labeled cells may be generated that are homozygous mutant for genes of interest or that express constructs that modulate gene expression and/or function. This system was created by Liqun Luo and Tzumin Lee [1] and has been used extensively in this model organism for the analysis of neuronal differentiation, cell lineage and other biological processes outside of the nervous system.

## Characteristics

### Overview

The nervous system is arguably one of the most complex tissues in the animal kingdom. Even in the simplest of the model organisms, its assembly requires not only the generation of a large number of diverse cell types but also the complex wiring of these cells. Therefore, the study of nervous system development and function is aided by the identification and genetic manipulation of a small number of neurons. Genetic tools unique to the *Drosophila* model system have

greatly facilitated the analysis of the molecular mechanisms underlying neuronal pattern formation by providing investigators with exquisite spatial and temporal control of gene expression and function. In this context, mobile DNA elements (►P-elements), carrying heterologous transcription factors (e.g. *GAL4*) under the regulation of *Drosophila*-specific promoters have been used extensively for the targeted expression of reporter molecules, genetically modified alleles or more recently constructs capable of mediating gene silencing via RNA interference (►RNAi).

The ability to induce, isolate and characterize the phenotypic consequence of single gene mutations has been fundamental to our current understanding of nervous system development and function in *Drosophila* and other model organisms. Relevant genes are for the most part expressed in a temporal and spatial complex pattern, which is reflected in the pleiotropic phenotype displayed by mutant organisms. Moreover, homozygous mutant animals may not survive to adulthood making it difficult to study the consequence of lack of gene function beyond a certain stage. In order to overcome these limitations, developmental biologists have relied on genetic ►mosaic organisms in which homozygous mutant clones are generated in an otherwise wild type and heterozygous background. This approach has been used extensively in *Drosophila melanogaster* as well as in mice and *C. elegans*, to investigate the stage-specific cell autonomous requirement of gene function. Recent improvements to this system include the ability to generate small homozygous clones at specific times during development and to unambiguously identify individual homozygous mutant clones such that the cellular phenotype can be studied appropriately.

## Mechanism

Traditionally, genetic mosaics in *Drosophila* have been generated through chromosomal loss (e.g. ring X chromosome) or X-ray induced mitotic recombination. More recently, sequence-specific recombination systems (FLP/FRT or Cre/LoxP) have been introduced allowing efficient gene-specific mitotic recombination. While the generation of genetically distinct somatic clones is technically straightforward, a reliable way to unambiguously label specific cell types within mutant clones has been missing. In the past, external markers have been used to infer the genotype of internal tissue. An improvement on this approach was the introduction of reporter constructs whose loss would mark the presence of homozygous clones in an otherwise heterozygous-labeled organism. The shortcoming of this method was that mutant clones still remained unlabelled and thus not available to detailed morphological analysis.

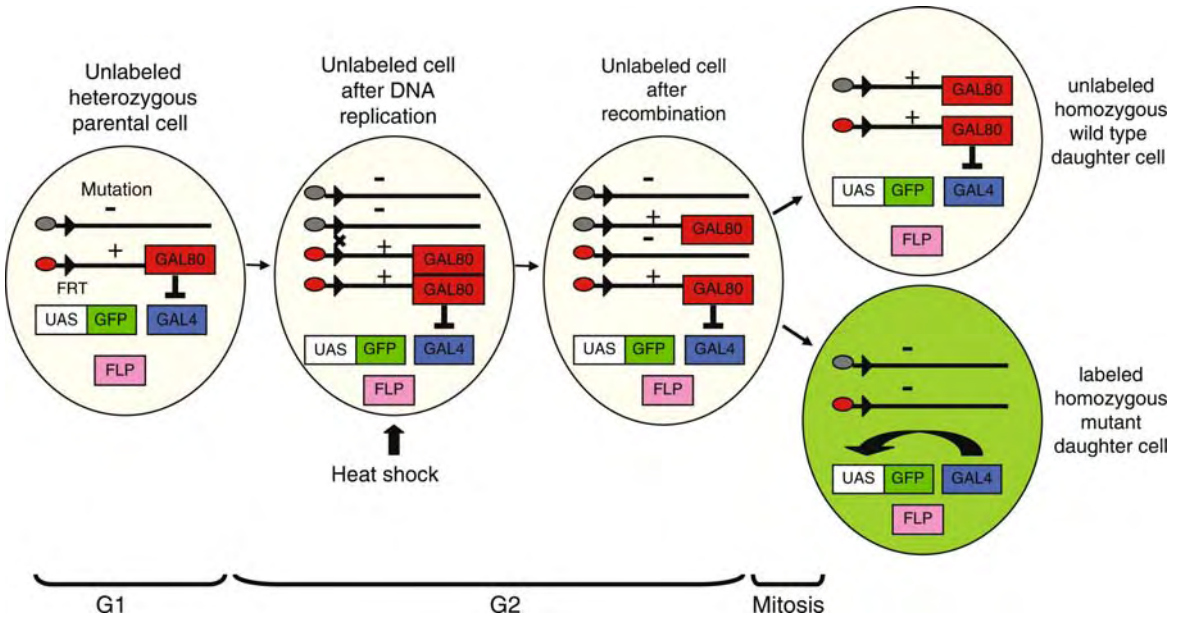
MARCM is a major advance because it combines the ability to positively label small numbers of cells with the FLP-FRT recombination system previously used to generate genetic mosaics (Fig. 1). This was made possible by the introduction of a repressible cell marker. In MARCM, the expression of reporter genes such as ►GFP, driven by a tissue-specific *GAL4* construct, is repressed due to the ubiquitous expression of a *GAL4* inhibitor, *GAL80*. The *GAL80* gene is inserted in the same chromosomal arm as the wild type allele of a gene of interest *X*. The homologous chromosome carries a mutant allele of the gene *X* and no copy of *GAL80*. Mitotic recombination generates two daughter cells that differ from the parental cell regarding the genotype of the *FRT*-bearing chromosome in that they are homozygous for one or the other homologous chromosome. Therefore, the mitotic recombination event not only yields homozygous mutant cells but also relieves in these cells the repression of the *GAL4* construct through the loss of *GAL80* ►transgene. The outcome is the generation of flies carrying single or multiple cells derived from a single progenitor that are homozygous mutant for a gene of interest. Specific cell types within the mutant clone will be positively labeled by the expression of a reporter construct that facilitates their morphological analysis. The size of the labeled clone depends upon the timing of FLP expression (refer to [2] for a detailed protocol). Moreover, as illustrated below, MARCM can be used to label clones of specific neurons without manipulating gene function. In this context, MARCM has been employed to investigate the developmental architecture – pattern of projection and clonal relationship – of specific neurons (see Fig. 2 for examples of MARCM generated clones).

The caveat is that, while labeling is found only in cells homozygous for the mutant chromosome (not carrying the *GAL80* repressor), not all mutant cells are labeled. Labeling of mutant cells is restricted to the cell types in which *GAL4* driver is expressed. Modifications to this method introduced recently address this issue but have not yet been used as extensively as MARCM [3].

## Components

All constructs described below are found within P-element vectors and were inserted into the *Drosophila* genome via ►P-element mediated transformation.

1. *GAL4* is a yeast transcription factor that binds to specific DNA elements known as upstream activating sequence (*UAS*) and activates RNA transcription of reporter genes. It is often referred to as a "driver element." In *Drosophila*, expression of GAL4 under the control of tissue-specific regulatory sequences has been employed to activate the expression of reporter genes such as *GFP* or *β-Galactosidase* in specific cell types. Alternatively, one can increase the expression of a target gene (up-regulation), by introducing a full-length cDNA downstream from the *UAS* or silence a gene



**Mosaic Analysis with a Repressible Cell Marker. Figure 1** Schematic representation of the MARCM system. MARCM requires two *FRT* sites (™) situated at the same location and one copy of the *GAL80* gene downstream to one of the *FRT* sites. The genes encoding Flipase (FLP) recombinase, the tissue-specific *GAL4* driver, and the *UAS-GFP* may be located anywhere in the genome. Additionally, the *FRT*-bearing, non-*GAL80* chromosome may carry a mutation (−) distal to the *FRT* site. A brief heat shock induces *FLP* expression. At the *FRT* sites, FLP recombines the wild type (+) *GAL80*-containing chromosome with its homologous mutant (−) chromosome. The resulting wild type (+/+) daughter cell will carry two copies of *GAL80*, which suppresses GAL4-dependent expression of the *UAS-GFP* (unlabeled cell). In the other daughter cell, which may be homozygous mutant for a gene of interest (−/−), the absence of GAL80 allows for GAL4-mediated expression of the GFP (labeled cell). (Adapted from [2]).

(knock-down), by introducing a construct capable of mediating RNA interference (RNAi).

2. *UAS-mCD8-GFP* This construct encodes a *GAL4* responsive reporter gene. In this case, the reporter is the green fluorescent protein (GFP), which has been fused to the transmembrane mouse lymphocyte marker CD8. This allows for targeting of GFP to the cell surface.
3. Flipase (FLP) recombinase. FLP recombinase is a yeast enzyme that catalyzes mitotic recombination at FRT sites. *Drosophila* strains have been created carrying the FLP gene under the regulation of a ubiquitous promoter, such as the *tubulin* gene promoter (*tubP*), or a conditional promoter such as that of the *Heat Shock Protein 70* gene (*HSP70*).
4. *FRT* sites. *FRT* sites are DNA sequences recognized by FLP recombinase. High frequency mitotic recombination is catalyzed by FLP at these sites. In flies heterozygous for a recessive allele of a gene of interest (+/−) in which FRT sequences are also present in the same chromosome, mitotic recombination at these sites yields homozygous mutant clones (−/−) as well as homozygous wild type twin clones (+/+). The latter are indistinguishable from the wild type heterozygous background (+/−).
5. *tubP-GAL80*- GAL80 is a yeast protein that represses GAL4 function as a transcription factor. In MARCM, the *GAL80* gene is under the control of the *tubulin* promoter (*tubP*) thereby providing ubiquitous repression of GAL4 function. Mitotic recombination at *FRT* sites catalyzed by the *FLP* gene product eliminates the *GAL80* gene from one of the daughter cells thereby relieving GAL4 from GAL80 repression while at the same time inducing a loss of heterozygosity event in the same chromosome.

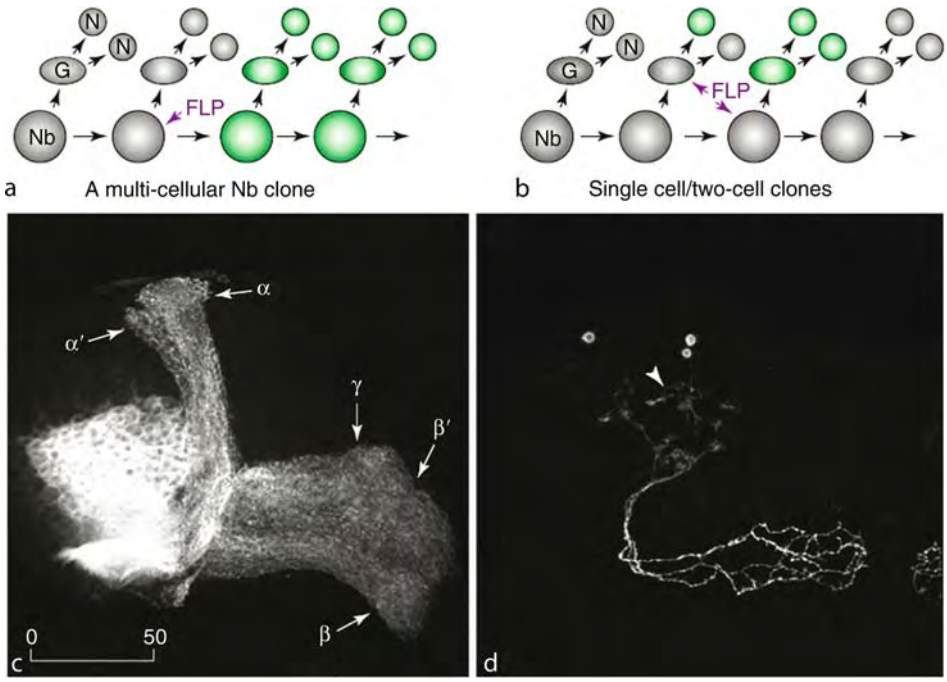
## Uses of MARCM

Since it was first published, MARCM has been used extensively. It has become an essential component of the ever-expanding *Drosophila* genetics toolbox. Below we describe briefly a few examples in which the use of MARCM system played an essential role in the genetic analysis of nervous system development.

### *Neuronal Morphogenesis*

MARCM has been effective in the investigation of axonal and dendritic branching patterns as well as neuronal wiring and circuitry formation. For instance, Grueber and colleagues employed MARCM to study dendrite

M



**Mosaic Analysis with a Repressible Cell Marker. Figure 2** MARCM clones in *Drosophila* mushroom bodies (MB). A neuroblast (Nb) generates a series of ganglion mother cells (GMC, G in Fig.). Each GMC generates two post-mitotic neurons (N). (a) A GAL80-negative Nb (GAL80–) gives rise to a multi-cellular clone. (b) If a GMC loses GAL80, a two-neuron labeled clone is generated. If mitotic recombination occurs in a dividing GMC, only one of the two post-mitotic neurons will be labeled. (c) and (d) Confocal images of MARCM clones of MB neurons. (c) A MB Nb clone produced by an early mitotic recombination event consists of hundreds of neurons at the adult stage visualized by mCD8-GFP expression. There are five axon bundles in the adult MB: γ, β′ and β projecting towards the midline and α′ and α projecting dorsally. (d) Single cell labeling shows that each cell body extends a single process from which dendrites (*arrowhead*) branch out. (Modified with permission from Lee T, Luo L (2001) Trends Neurosci 24(5):251–254).

branching morphology and the establishment of dendritic territories of specific neurons of the *Drosophila* third instar larva peripheral nervous system [4]. They focused their studies on the dendritic arborization neurons (da), which spread their dendrites in a two-dimensional coverage of the larval epidermis. By examining single cell clones generated using MARCM and labeled by the expression of a pan-neuronal driver (*elav-GAL4*), da neurons were grouped into four morphological classes (I-IV) according to differences in dendrite branching complexity. Most importantly, these authors reported that neurons of the same class show dendritic exclusion or heteroneuronal tiling whereas those in different classes show extensive overlap of their dendritic fields. These pioneer studies set the stage for further investigations addressing the molecular genetic mechanisms underlying dendritic branching and tiling briefly discussed below.

### Gene Function Requirement

The MARCM system has been successfully employed to assess the role of candidate genes in different biological processes. Of particular note are recent findings that further elucidate the role of *Down's syndrome cell adhesion molecule* (*Dscam*) in dendrite self-avoidance or isoneuronal tiling. The *Drosophila Dscam* gene shows a remarkable degree of alternative splicing with the potential to generate more than 38,000 different isoforms and has been implicated in axonal and dendritic patterning. Using MARCM, three different groups addressed the cell autonomous requirement for *DsCam* gene in the patterning of the larval epidermis da sensory neurons [5,6,7]. These workers showed that *Dscam* mediates isoform-specific homophilic interactions required for self-avoidance within a single sensory neuron arbor. Interestingly, heteroneuronal tiling such as that of class II and IV sensory neurons is not affected by *Dscam* mutations suggesting the existence of an additional pathway. Thus, the current view of the molecular underpinnings of dendrite morphogenesis in *Drosophila* has been made possible by the high level of resolution afforded by single cell labeling and genetic manipulation unique to the MARCM system.

### Mosaic Genetic Screens

Mutant screens constitute a powerful tool in the identification of genes essential for diverse biological processes. A forward genetic approach can be combined with the MARCM system, thereby bypassing pleiotropic

effect of mutations (i.e. early lethality) and increasing the sensitivity of the phenotype analysis. This strategy is well illustrated in the report of Reuter et al. [8]. These investigators carried out a genetic screen aimed at identifying genes that play a role in the morphogenesis of the larval MB neurons. To that end, homozygous mutant clones generated by MARCM were examined by virtue of expression of MB-specific *GAL4* drivers, which in turn activated the transcription of target reporter constructs (*UAS- mCD8-GFP*). In order to increase the frequency of MB clones, FLP expression was heat- induced in newly hatched larvae. At that time, the only dividing neuroblasts are those giving rise to the MB neurons. Nearly 20% of the genome was sampled by this approach. Larvae bearing mutant clones showing abnormal distribution of GFP, large cells, defective axonal transport and abnormal axon and dendrite morphogenesis were isolated. Further characterization of these mutations led to identification of new genes that play a role in neuronal morphogenesis as well as discovery of new functions of previously identified genes.

### *Cell Lineage Analysis*

The ability to induce mitotic recombination at different times during development makes MARCM particularly well suited for cell lineage analysis. Several investigators have taken advantage of these properties to investigate clonal relationships in the olfactory glomeruli and the mushroom body (MB), the area of the insect brain involved in olfaction-mediated learning and memory. As one of the earliest contributions of MARCM system, Lee et al. [9] showed that, in the *Drosophila* CNS, a single identified neuroblast sequentially gives rise to at least three distinct types of neurons. More interestingly, their projection into different MB lobes depends upon their birth order [9]. Similar strategy when applied to clonal relationship of projecting neurons of the *Drosophila* olfactory system demonstrated that their dendritic arborizations in the antennal lobe and thus odour representation, depends upon their birth order (reviewed in [10]).

M

# MOSAIC Model

## Definition

Modular selection and identification control (MOSAIC) model, proposed for solving a large-scale sensorimotor problem using multiple pairs of a forward (estimation) model and an inverse (control) model. An important ingredient in the model is how well a forward model predicts movement outcome or reward, defined as a responsibility signal. Those responsibility signals in turn determine which controllers will be used for a particular movement and which internal models will be updated accordingly. The MOSAIC model attempts to decompose a large-scale sensorimotor problem automatically by making each module specialized for a particular situation or task.

►Theories on Motor Learning

# Mossy Fibers

## Definition

Most afferents from the brainstem or spinal cord to the cerebellum terminate in the granule cell layer of the

cerebellar cortex as "mossy fibers". They are so named because of the appearance of their terminals under the microscope. Mossy fibers carry almost all the information to the cerebellar cortex that affects the short-term firing rates of granule cells and other cells in the cerebellum. Mossy fibers terminate bilaterally in discrete areas of the vermis and of the hemispheres, evidencing a partial somatotopic arrangement. They are differentiated from "climbing fibers" that originate only in the inferior olive, terminate on Purkinje cells, and affect the firing rate of cerebellar neurons over the long-term.

# Motion Aftereffect

## Definition

A visual motion illusion that occurs as a negative aftereffect of adaptation to motion. Often called the waterfall illusion after Robert Addams' description of his experience when viewing the Falls of Foyers in Inverness, Scotland. The effect is produced by adapting to a stimulus that moves in a particular direction for a prolonged period. On subsequent viewing of a stationary object, e.g., the rocks beside the waterfall, results in their appearing to move in the opposite direction. Addams (1834) commented: "I saw the rocky surface as if in motion upwards, and with an apparent velocity equal to that of the descending water, which the moment before had prepared my eyes to behold this singular deception."

# Motion Analysis

Stephen J. Piazza
Department of Kinesiology, The Pennsylvania State University, University Park, PA, USA

## Definition

For the purposes of this essay, "motion analysis" is defined as the recording of the three-dimensional movements of human body segments, and the subsequent computation of meaningful parameters that describe the movement from raw kinematic data. The collection of motion data may be accompanied by measurements of external forces acting on the body. In such cases, ►inverse dynamic analysis may be performed to estimate joint forces and moments internal to the body.

## Purpose

It is often necessary to track the motions of the human body in three dimensions in order to answer questions about the biomechanics and neural control of movement. Examples of such investigations include studies of posture, gait, movement perturbation, and reaching. Motion analysis is applied on a routine basis in ►clinical gait analysis, for the purpose of gathering data that is used to inform surgical decision-making for patients with gait abnormalities secondary to neurological conditions such as cerebral palsy and stroke.

## Principles

### *Motion Analysis Systems: Image-Based*

Three-dimensional image-based motion analysis involves the use of two or more cameras to track markers applied to the skin of a subject. Markers are usually spherical and covered with reflective tape in order to maximize the reflection of either visible or infrared light. Image-based motion analysis came of age in the 1970s, when sufficient computing power became available to rapidly transform two-dimensional camera views into three-dimensional marker coordinates. Making this transformation requires information about the position and orientation of each camera, as well as camera-specific corrections to account for optical distortion. The process of determining these parameters is known as ►camera calibration. One widely-used calibration procedure is called the ►direct linear transformation [1], and involves linear least-squares determination of camera parameters given a set of control points whose locations within the laboratory are known. Today, most commercially available systems use a two-step calibration process consisting of a static calibration followed by a dynamic calibration, with the correction for lens distortion handled separately. The static calibration establishes a laboratory-fixed coordinate system and involves the placement of stationary markers that define this coordinate system in view of all cameras. In the dynamic calibration, a rigid rod fitted with two markers is waved in front of the cameras, and parameters defining the position and orientation of the cameras are determined by iteratively minimizing deviations in the intermarker distance throughout the motion. In a process called ►reconstruction, camera parameters determined during the calibration procedure are used to compute three-dimensional marker locations following actual motion trials.

To establish the position and orientation of a body segment within the laboratory coordinate system, it

is necessary to locate a minimum of three markers attached to that segment during each timeframe. If these three markers are placed on bony landmarks, they may be used to define both an ►anatomical coordinate system and a 4 × 4 matrix specifying a ►homogeneous transformation [2] between the laboratory coordinate system and the anatomical coordinate system. Alternatively, a cluster of three or more markers not located on landmarks may be tracked. If the segment-fixed locations of the cluster markers within the anatomical coordinate system are known, it is possible to determine the homogeneous transformation between the laboratory and segment anatomical coordinate systems using a least-squares approach [3].

### Motion Analysis Systems: Magnetic

Motions may also be tracked in three dimensions using magnetic tracking devices. Such devices consist of a transmitter unit, which broadcasts three superimposed electromagnetic fields in the volume of interest, and one or more sensors that are applied to body segments. Each sensor contains three mutually-orthogonal passive antenna coils. Measurement of the currents induced in the sensor coils permits computation of the homogeneous transformations between the transmitter and each sensor.

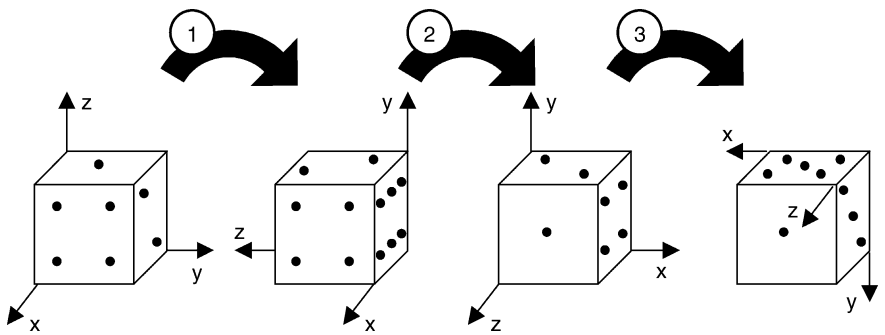
### Measurement of Ground Reaction Force

Measurements of human movement are often accompanied by determination of the ground reaction force carried out using a force plate. A force plate is a flat steel plate supported at each of its four corners by a pillar instrumented for measurements of triaxial force (gauges affixed to these pillars actually measure strain) [4]. Forces measured at the four corners are summed to obtain the three-dimensional ground reaction force vector. A force plate gives no information about the distribution of ground reaction force underfoot, but forces measured at the individual pillars can be used to locate the ►center of pressure, the point at which the resultant ground reaction force could be assumed to act if it acted at a single point. The motion of the center of pressure during standing is a commonly-used indicator of postural stability.

### Computation and Reporting of Joint Angles

Once laboratory-to-anatomical homogeneous transformations have been determined, it is possible to compute from them the transformations between the anatomical coordinate systems of adjacent segments. These transformations may then be decomposed in a variety of ways to arrive at the joint angles that are often of experimental or clinical interest. For example, we might use a motion analysis system to establish the locations of the thigh and shank anatomical coordinate systems, and then decompose the transformation between those two coordinate systems to the flexion-extension, abduction-adduction, and internal-external rotation angles of the knee joint. The most commonly used technique for obtaining joint angles is ►Euler/Cardan angle decomposition (Fig. 1).

A set of Euler/Cardan angles describes the three-dimensional rotation of one coordinate system into another, by starting with the coordinate systems initially aligned and applying a series of three rotations about the axes of one of the coordinate systems [2]. These rotations may occur about the axes of the coordinate system considered to be moving (resulting in "body-fixed" rotations) or about the axes of the fixed coordinate system ("ground-fixed" rotations). Rotation sequences must be specified (e.g. X-Y-Z) when reporting joint angles, as their selection will influence the angles computed [5], and a sequence may include two rotations about the same axis (e.g., Z-X-Z). Care must be taken when choosing a rotation sequence to avoid selecting one that will result in singularities that will prevent decomposition of the transformation matrix. A widely-used convention for reporting human knee joint angles [6] has been adapted for use at other joints and involves rotation of the tibia first about the



**Motion Analysis. Figure 1** Example of an Euler/Cardan rotation sequence of the type often used to describe three-dimensional joint rotations. In this example, the first rotation is 90° about the *x*-axis and is followed by a second rotation of 90° about the new *y*-axis. The third rotation is 180° about the twice-rotated *z*-axis. This is an example of an X-Y-Z body-fixed rotation sequence.

M

flexion axis (shared by femur and tibia), then about a tibia-fixed abduction-adduction axis, and finally about a tibia-fixed internal-external rotation axis. An alternative method for quantifying the relative rotations between body segments is ►helical axis decomposition [5]. It is always possible to describe the transformation from one coordinate system into another using a single rotation about an axis fixed in both coordinate systems coupled with a translation along that axis. Scaling the unit vector along the rotation axis by the magnitude of the rotation gives three components of the rotation that are analogous to joint angles. A second alternative to Euler/Cardan angles for reporting three-dimensional rotations involves the use of Euler parameters (or quaternions), a singularity-free method that is more robust computationally though less intuitively appealing.

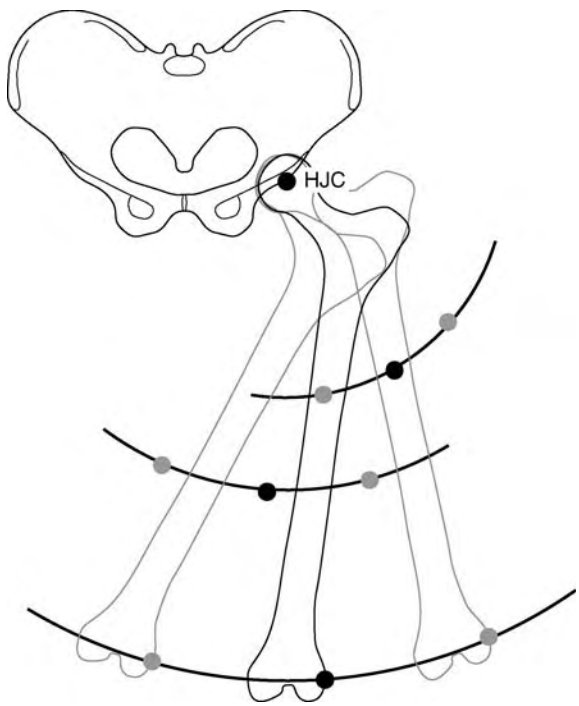
### *Inverse Dynamic Analysis*

The direct measurement of muscle forces is too invasive to perform on a routine basis, but muscle actions are often estimated from motion and force data in inverse dynamic analysis. This procedure involves computing the internal joint reaction forces and moments acting at the proximal end of a body segment for which the external force acting at the distal end is known. The external force may be measured (using a force plate in the case of a foot on the ground) or assumed to be zero (when the distal segment does not contact the ground). The Newton-Euler equations are used to compute proximal forces and moments from external forces and the position, velocity, and acceleration of the segment. Masses and moments of inertia that appear in the Newton-Euler equations must be determined using anthropometric estimation techniques. The forces and moments computed for the most distal segment are then used to compute the forces and moments at the next most proximal joint, and so on. The joint moments computed in this manner do not give information about the actions of individual muscles, but muscle forces are often obtained from these moments by applying optimization theory. Joint moments may be combined with measurements of the rate of joint rotation to compute the joint power, the rate at which energy is generated or absorbed by the muscles crossing a given joint.

## Advantages and Disadvantages

Modern motion analysis systems are capable of highly accurate measurements of the locations of individual markers. Marker location errors are typically less than 1 mm for image-based systems that use digital cameras. These systems permit image processing to occur at the individual cameras rather than at a central processor, and thus permit increased resolution and capture rates. Despite this high degree of marker location accuracy, significant methodological barriers remain to the accurate measurement of joint kinematics. As markers cannot be mounted on bones, movements of skin and other soft tissues contribute to errors in measured motion. Attempts to reduce these errors have included the identification of locations on body segments that are less susceptible to skin movement [7], and mathematical weighting techniques that correct for soft tissue deformation [8].

The reliable establishment of anatomical coordinate systems is sometimes difficult in practice. When coordinate systems are not created properly, one potential consequence is "kinematic crosstalk," which is the misinterpretation of motion about one joint axis as motion about another axis [9]. For example, if the knee flexion axis is misidentified, then pure knee flexion may be taken to be a combination of flexion and abduction. The accurate location of joint centers is important for the creation of anatomical coordinate systems, and for effectively carrying out inverse dynamic analyses, but some joint centers, such as that of the hip are deep, and thus difficult to locate from bony landmarks. This issue



**Motion Analysis. Figure 2** Illustration of the basis for functional location of the hip joint center. Markers affixed to the thigh trace out paths on spheres whose shared center is the hip joint center. Measurement of the motions of these markers and subsequent sphere-fitting permits location of the hip joint center, which does not rely upon location of bony landmarks near the joint center. Similar techniques have been employed to establish the joint centers or joint axes of all the joints of the upper and lower extremities.

has been addressed by the development of "functional" methods for fitting joint centers and joint axes to measured motions [10] rather than predicting their locations from the locations of bony prominences (Fig. 2).

Conventional motion analysis methods serve well when used to track the motions of large body segments, but fall short when they are employed to measure motions of less well-defined segments. Motion analysis of the foot, for example, is problematic because it contains joints, such as the subtalar and tarsometatarsal joints, which join body segments not easily tracked with external markers.

## Motion and Direction Sensitivity in Cutaneous Mechanosensation

### Definition

Motion and direction sensitivity is studied using air jets, brushes and probes applied to different body regions. Its functional significance relates to both manual dexterity and postural control. The capacity for human subjects to identify the direction of stimulus motion on the skin is dependent on stimulus velocity, contact force and length of movement. It also varies in proportion to the innervation density of the fast and slowly adapting type I mechanoreceptive afferents.

## Definition

The ability to perceive movement.

# Motion Sickness

Bill J. Yates
Department of Otolaryngology, University of Pittsburgh, School of Medicine, Eye & Ear Institute Building, Pittsburgh, PA, USA

## Definition

Motion sickness is a malady triggered by movement or perceived movement in the environment. In humans it is characterized by the presence of nausea and vomiting, pallor, cold sweating and a large increase in the circulating levels of the hormone arginine vasopressin.

## Characteristics

### Conditions that Produce Motion Sickness

Typically, motion sickness is elicited during conditions where multiple sensory inputs are present that provide contradictory information regarding body position in space [1]. Often, the sensory mismatch involves the vestibular and visual systems, as well as the somatosensory system. For example, when an individual is traveling within a boat or aircraft, there may be no tangible visual cues indicating the presence of movement, whereas vestibular receptors and proprioceptors signal that movement is taking place. Moving visual scenes, such as those generated by virtual reality devices, can also induce motion sickness, as the visual system indicates that the individual is moving whereas the vestibular system indicates that the head is stationary. However, other mismatched sensory inputs can also induce motion sickness. For example, many astronauts experience "space motion sickness" after entry into zero gravity, which is presumably triggered during head movements because the semicircular canals provide inputs indicating that the head is rotating, but the vestibular otolith organs (which are no longer subjected to gravitational forces, and thus do not signal the presence of head tilts) fail to indicate that head position has been altered [2].

The most critical signals required for the generation of motion sickness come from the vestibular system, as evidenced by that fact that this malady cannot be induced in individuals with bilateral vestibular dysfunction by stimuli that are typically highly provocative [3]. Furthermore, diseases that affect the vestibular system, such as inner ear infections, often produce signs and symptoms that are similar to those that occur during motion sickness. Fortunately, the vestibular system is very plastic and rapid adaptation occurs during conditions involving the disruption of the normal pattern of inputs from the inner ear to the brainstem. Such plasticity in the vestibular system probably explains why space motion sickness resolves after a few days of spaceflight. Visual inputs are not essential for producing motion sickness, since blind individuals have normal sensitivity for this condition (see [4] for a review).

Minimizing sensory conflict can often reduce the susceptibility for motion sickness. For example, motion sickness is less prevalent in drivers of automobiles, who are attending to visual cues reflecting the presence of movement, than in passengers who may be minimizing visually related movement cues by focusing their eyes on objects within the vehicle. Furthermore, repeated exposure to a provocative environment reduces the incidence and severity of motion sickness when that environment is experienced again. For instance, space motion sickness is less prevalent in veteran astronauts than individuals experiencing their first space flight [2]. Nonetheless, there are considerable individual differences in susceptibility to motion sickness that probably have a complex etiology and are not well understood.

### Physiological Manifestations of Motion Sickness

Motion sickness in humans is typically associated with several prominent symptoms and signs, including nausea and vomiting, pallor and cold sweating. Another physiological manifestation of the malady is a large increase in the levels of the posterior pituitary hormone arginine vasopressin circulating in the blood [1]. However, these indicators are not present in all species. For example, many animals, including rodents and lagomorphs (i.e. rabbits and hares), lack the ability to vomit and thus do not exhibit this hallmark sign of motion sickness. Non-emetic species often will ingest non-nutritive substances such as clay after exposure to stimuli that would produce vomiting in humans Animals that lack the capacity to vomit exhibit increases in the posterior pituitary hormone oxytocin rather than vasopressin, after exposure to nauseogenic stimuli (see [4] for discussion).

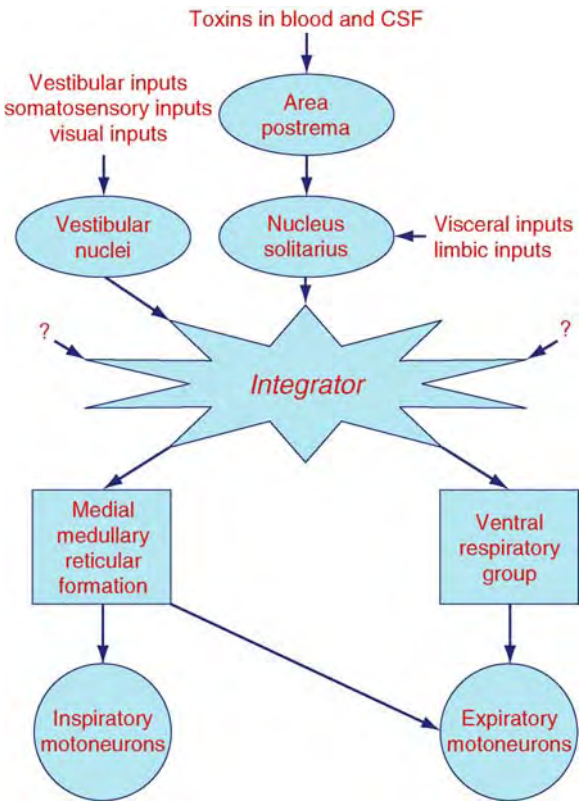
### Neural Mechanisms that Produce the Physiological Manifestations of Motion Sickness

Retching and vomiting are mainly the result of the coordinated contractions of the major respiratory

muscles and upper airway muscles [5]. The pattern of contraction of these muscles differs during breathing and emesis. During breathing, inspiratory muscles such as the diaphragm and expiratory muscles such as the abdominal muscles contract out of phase, to generate the forces that move air into and out of the lungs. In contrast, the diaphragm and abdominal muscles contract together during retching and vomiting to place considerable pressure on the stomach, thereby pushing the gastric contents towards the mouth. The autonomic nervous system contributes to generating vomiting by producing marked reductions in gastric tone and motility, changes in gastric myoelectric activity and a retrograde giant contraction that moves contents from the upper part of the small intestine back into the stomach before expulsion. Furthermore, a longitudinal contraction of the esophagus occurs that pulls open the relaxed gastroesophageal junction and thus forms a funnel that facilitates free flow of gastric contents to the esophagus.

It is generally believed that a common neural circuitry mediates vomiting, elicited by a variety of triggering signals, including motion-related inputs relayed to the vestibular nuclei, circulating toxins detected by the area postrema, visceral signals conveyed to the nucleus solitarius and even psychological perceptions (e.g. thought of a disgusting situation) processed through the limbic system. Figure 1 provides a synopsis of current information regarding the neural circuitry that produces the contractions of inspiratory and expiratory respiratory muscles that generate retching and vomiting.

The rhythmic contractions of the diaphragm and expiratory muscles during breathing are controlled by neurons located in the dorsal and ventral respiratory groups in the brainstem. However, the firing of many of these respiratory group neurons, particularly neurons with inspiratory-related activity, is inhibited during vomiting. This suggests that separate pattern generators coordinate the contractions of respiratory muscles during breathing and emesis. Recent anatomical [6] and physiological [7] evidence suggests that some of the neurons that are part of the vomiting pattern generator are located within the medial reticular formation of the medulla. Presumably, a neural integrator processes trigger signals for vomiting and when appropriate activates the pattern generator that produces this response. The identity of this neural integrator is unknown, although there is evidence that the neurons that form the integrator are located in the medulla. Vomiting can be produced in a reduced animal preparation in which all parts of the nervous system except the medulla and spinal cord are removed, indicating that the essential neural circuitry for producing emesis is confined to these regions [8].



**Motion Sickness. Figure 1** Neural pathways that produce vomiting. A common circuit produces vomiting in response to a number of triggering signals, including conflicting motion information, toxins in the blood or visceral inputs. This circuit includes an integrator that processes the triggering signals and a pattern generator that mediates the contractions of respiratory muscles that produce vomiting. The pattern generator is comprised in part of neurons located in the medial medullary reticular formation and the ventral respiratory group.

The neural pathways that produce nausea have remained elusive, but almost certainly are distinct from the pathways that generate vomiting (i.e. although nausea and vomiting are frequently triggered together, distinct circuits coordinate each response). The level of nausea is typically correlated with the concentration of the hormone vasopressin circulating in the blood, although this hormone does not appear to be critical for the production of nausea and is released as part of a parallel physiological response [4].

As noted above, conflicting sensory information regarding the position of the body in space is believed to be the primary trigger for motion sickness-related nausea and vomiting. Stimulation of the vestibular nerve can produce vomiting in animal preparations lacking the cerebellum, suggesting that the cerebellum is not a necessary component of the circuitry

that produces motion sickness. Nonetheless, there is evidence to suggest that regions of the cerebellum particularly the nodulus and uvula are typically engaged in generating the signs and symptoms of motion sickness.

## Pharmacological Agents that Suppress Motion Sickness

Drugs employed to treat motion sickness fall into two categories: (i) those that are only effective in alleviating motion-related nausea and vomiting and not the symptoms produced by other emetic triggers and (ii) those that serve as broad-spectrum anti-emetic drugs and suppress nausea and vomiting despite the trigger. Drugs in the former category presumably affect receptors in the vestibular nuclei and central vestibular system, whereas those in the latter category probably act on receptors of cells that form the central integrator responsible for producing nausea and vomiting [4].

Anticholinergic drugs that act on muscarinic receptors are the most effective agents in clinical use for treating motion sickness, but have limited efficacy in ameliorating nausea and vomiting elicited by other trigger signals. Scopolamine, which blocks all five subtypes of muscarinic receptors, is the most commonly employed anticholinergic drug for treating motion sickness. Scopolamine has a number of significant side effects, including sedation and dry mouth and is only available by prescription in most countries.

Antihistamines form another class of drugs that have some efficacy in reducing the symptoms of motion sickness, but not nausea and vomiting elicited by triggers such as toxins and visceral signals. Most "over the counter" anti-motion sickness drugs, such as dimenhydrinate (marketed under the brand names Dramamine and Gravol) and meclizine (Antivert, Bonine), belong to this drug class. Antihistamines are less effective than anticholinergics in combating motion sickness, but have a longer duration of action and are considerably safer and thus are used more frequently. Nonetheless, antihistamines do produce some drowsiness and dizziness.

A third type of drug employed to treat motion sickness has mixed antimuscarinic and antihistamine actions. An example of such a drug is promethazine (Phenergan), which is employed by NASA to treat space motion sickness in astronauts. The side effects of promethazine are similar to those of anticholinergics and antihistamines and include drowsiness.

Drugs that increase the release of norepinephrine in the central nervous system (sympathomimetics) also have efficacy in treating motion sickness. Drugs in this class include amphetamine and ephedrine. Sympathomimetics do not produce drowsiness, a side effect shared by anticholinergics and antihistamines, and thus have been used by individuals who must perform work while in an environment that may induce motion sickness. However, amphetamine is addictive and some states and countries have forbidden the use of this drug to treat motion sickness. Similarly, benzodiazepines such as diazepam (Valium) have some effectiveness in treating motion sickness, but are not commonly used for this purpose due to the risk of addiction and the occurrence of side effects when minimal required doses are delivered.

Several drugs are broad-spectrum anti-emetics and have promise in reducing the nausea and vomiting elicited by any trigger. Amongst these drugs are agonists for the serotonin 5-$HT_{1A}$ or 5-$HT_2$ receptors, antagonists of n-methyl-d-aspartate (NMDA) or neurokinin type 1 (NK-1) receptors and some calcium channel blockers.

## Evolutionary Significance of Motion Sickness

Since all individuals with an intact vestibular system have some predisposition for developing motion sickness, it is tempting to speculate that this condition has evolutionary significance. Treisman [9] hypothesized that motion sickness is a poison response in that toxins could affect the processing of visual and vestibular inputs and induce the sensory conflict that elicits nausea and emesis. In other words, modern circumstances such as space and air travel that result in conflicting sensory information regarding body position in space can trigger mechanisms that evolved to prevent poisoning. However, there is little experimental evidence to support Treisman's theory. It is now well established that the vestibular system provides influences on the brainstem circuitry that regulates blood pressure and respiration and elicits the changes in blood distribution in the body and alterations in respiratory muscle activity that are needed during movement and changes in posture [10]. It is thus feasible that the signs and symptoms of motion sickness are due to an aberrant activation of neural circuits that typically function to maintain homeostasis. Such a notion is impossible to test experimentally, but it raises the possibility that motion sickness has no evolutionary significance and is in fact a "mistake" that was never corrected because the circumstances that generate the condition (e.g. travel in airplanes and boats) have only become commonplace in the modern world.

## Motivation

### Definition

Motivation is a theoretical construct employed by experimental psychologists and philosophers when they seek to explain specific patterns of behavior. This term also refers to processes by which behavior is activated and directed. Physiological psychologists postulated that homeostatic imbalance within specific regulatory systems such as those responsible for energy, fluid or thermoregulation, gave rise to specify "drive" states. Reduction of a specific "drive" state by consumption of food or water reduced motivation to seek these stimuli and also provided reinforcement to repeat action patterns that brought the organism into contact with these natural reward stimuli.

►Learning and Motivation

## Motoneuron

### Definition

Motoneurons are neurons whose cell bodies lie in motor nuclei of cranial nerves in the brainstem or in the anterior horn of the spinal cord and whose efferent axons leave the central nervous system (CNS) to innervate muscle fibers. There are three classes of motoneurons. Large motoneurons with extensive dendritic trees and fairly thick myelinated axons and high action potential conduction velocity innervate skeletal muscle fibers and may thus be called skeleto-motoneurons. Among these, one class innervates skeletal muscle fibers only and is called α-motoneuron. A second class innervates skeletal muscle fibers and intrafusal muscle fibers of muscle spindles and is called β-motoneuron. The third class of smaller motoneurons with thinner myelinated axons innervates intrafusal muscle fibers of muscle spindles only and is called γ-motoneuron (or fusimotor neuron).

## Motor Control

Uwe Windhorst
Göttingen, Germany

### Introduction

In order to live, grow, survive and reproduce, organisms must be capable of at least two things. Firstly, they must be able to move because movement is the very prerequisite of life, even at the molecular level. Secondly, they must be able to ►control this movement in relation to relevant aspects of their natural environment, which in turn implies that they must be able to detect, categorize, recognize, and act on, aspects of their environment. The term "motor control" encompasses all these aspects. This overview article concentrates on some general aspects and principles of motor control.

As an introductory concrete example, consider the cat's, dog's or turtle's scratch "reflex" (►Scratching). In cats or dogs, the scratch reflex is "switched on" by a stimulus to a defined skin area on the upper forelimbs, neck, pinnas and adjacent skin areas (for review see [1]). The reflex consists of several components. Since an ipsilateral hindlimb needs to be flexed for scratching and, hence, taken off the ground, the posture (►Postural control) of the body must be changed and equilibrium re-stabilized by the other three limbs. The flexed hindlimb is then brought into a "postural" position for aiming at the stimulus. Subsequently, the scratching limb falls into a sequence of oscillations with long flexor and short extensor phases.

This example suggests that the system organizing the scratch reflex is composed of several subsystems executing particular tasks:

- ►*Sensory systems*, that are adequately tuned to detect, locate and identify the stimulus as well as the positions of the body parts throughout the sequence of events, involving cutaneous mechanoreceptive and proprioceptive senses, in particular.
- *Motor system* with
  - Central control system that organizes the goal-directed movement.
  - Executive system (skeleton, ►muscles etc.).
- *Interfaces* connecting the sensory and motor systems.

At a closer look, this simplified scheme can be elaborated by including

- ►*Information systems*, that select, represent, transfer, process, store and retrieve pertinent information (see ►Sensory systems).
- ►*Central pattern generators* (CPGs), which generate the rhythmical components of movement, and other generators of goal-oriented movements.
- *Coordinate transformations*, here from a sensory frame of reference into a motor frame of reference (►Sensory Systems). Such transformations are required because the sensory and motor frames are different. For example, cutaneous receptors are distributed across a 2D surface intricately folded in 3D space, while scratching movements are executed in multi-dimensional joint space, with certain restrictions such as exclusion of the own body.

- *Body schema*, i.e., a neural representation of the body's anatomical (spatial) configuration, which allows the localization of sensory stimuli and motor events with respect to the body, and integrates and aligns various reference frames (see ►Sensory systems).
- *Adaptability* of neuronal connections to particular circumstances, conditions and contexts.

## Classes of Movement

A cat's or dog's scratch reflex is composed of several components. We may suspect that these components are organized by different neural sub-systems. In order to explore this idea further, we will start by provisionally classifying movements into the following categories, with subsequent qualifications:

- ►*Rhythmic movements* (e.g., over-ground ►locomotion, ►swimming, ►flying, scratching, ►mastication, ►Respiration – neural control).
- ►*Reflexes*: Reflexes provide an appropriate response closely coupled to a sensory input of some sort.
- *Motor activity to maintain equilibrium and posture* (►Postural control).
- *Free, goal-oriented movements*, such as reaching, grasping and object manipulation (►Voluntary movement; ►Reaching movements).

Actually, most movements involve aspects of more than one of these classes, as evidenced by the above scratch reflex. All movements in some way require posture as a basis to work on. In terrestrial vertebrates, whose bodies are maintained above the ground by legs, posture depends on some basic excitatory "tone" of anti-gravity muscle groups as well as on reflexes. Also, rhythmic and free goal-oriented movements may be modulated by, or make use of, reflexes. Conversely, reflexes may incorporate rhythmic components, or can be modulated by free goal-oriented or other activities of the organism. However, these classes may still be useful guidelines to unveil neuronal networks and their operations underlying movements.

## Rhythmic Movements

Generally, movements should be as easy to generate, efficient and economic as possible. This "design principle" is readily apparent in rhythmic movements. Even unicellular organisms such as *Paramecium* easily move by rhythmic beats of flagellae. The ease in generating rhythmic movements is likely due to the repetitive succession of similar movement components and patterns. While, in multi-cellular organisms, the actual movement pattern is of course profoundly co-determined by the mechanics of the body components (to include invertebrates) and the environment, the driving and organizing control signals must be delivered by the nervous system. Conceptually, this task can be divided into two components:

- *Clock* (*oscillator*): There should be a mechanism providing the basic rhythm.
- *Pattern generator*: Additionally, the specific ►coordination of muscle activations required for a particular movement must be orchestrated in detail.

### Central Pattern Generators

In order to produce these features, the central nervous system (CNS) contains complex networks of neurons, which are generally called ►central pattern generators (CPGs) (e.g., [2–5]). In such CPGs or their constituent nerve cells, the two tasks defined above (clock (oscillator) and pattern generation) may or may not be identifiable as separate components (for respiration see [6]). In the first case, there are potential ►pacemaker neurons, which oscillate spontaneously due to intrinsic properties of their membranes and then impose their intrinsic rhythmic activity onto the network [7]. In the second case, the entire network may oscillate without any single inherent neuron being able to oscillate on its own, the rhythm thus being an emergent network property. In many invertebrates, CPGs have been identified and analyzed, and much progress has been made in this respect in lower vertebrates (i.e., lamprey), but not so in higher vertebrates such as mammals [2,4,5]. This applies to locomotion (swimming, walking, running, flying), mastication, feeding and breathing, respiration being a special case in that in many animals it goes on uninterrupted throughout life, as does the heart beat.

Neuronal networks generating rhythmic motor activities almost constantly reorganize and reconfigure themselves according to the task at hand and the context in which they operate. In fact, the operation of CPGs must be adaptable to various extrinsic circumstances and conditions:

- *Peripheral conditions* monitored by sensory signals.
- *Higher-level influences such as* ►*motivation, visual guidance etc.*
- *Internal conditions of the CNS.*

### Role of Sensory Inputs

Since rhythmic movements occur in complex and changing environments, it is obvious that they must adapt. For example, an uneven ground must be taken into account while walking on it, which in turn necessitates sensory inputs. In other words, CPGs must be amenable to, and change their properties and activities in response to, sensory inputs, to the extent that some of these inputs are able to reset the rhythm. In particular, the switch between different locomotor phases, e.g., the transition from stance to swing of a limb, depends on certain states of sensory inputs

or combinations thereof. Thus, rather than regulating motor output variables in an analog way, sensory inputs are often used to make discrete choices between motor alternatives, akin to technical finite-state systems [8]. These systems work using "if-then" rules as follows. The general rule is: IF sensory state 1 AND sensory state 2, THEN perform this particular action. For example, for slow forward gait of a cat: IF in a hindleg the extensor force is low AND the hip is extended AND the contralateral leg is loaded, THEN flex the ipsilateral leg. Or, for backward gait: IF the extensor force is low AND the hip is flexed AND the contralateral leg is loaded, THEN flex the ankle and knee and extend the hip. This description in terms of rules is likely to be heuristic and does not say anything about how the nervous system really performs this action [8].

Conversely, sensory inputs and their processing must be weighted according to the prevalent tasks in different phases of a rhythmic movement. For example, in human walking, the leg currently supporting the body weight must extend and should not easily yield to a flexor reflex initiated by a noxious stimulus to the foot (see below), while the situation is not that pressing in the other leg flexing anyway. This calls for a *CPG-dependent modulation of reflex effects*.

This discussion underscores the notion that classes of movement, in this case reflexes and rhythmic movements, are not absolutely separated, but depend on each other. Although rhythmic activities in the scratch reflex may be triggered by sensory stimuli, the CPGs do not depend on somatosensory ►feedback to maintain their activity. The CPG generating the scratch reflex is probably different from that generating locomotion [9].

### Descending Control

In vertebrates, the spinal CPGs provide the basic rhythm and pattern-generating networks for locomotion, scratching and paw shakes. However, left on its own, e.g., in spinalized cats, the spinal cord has problems providing sufficient locomotor vigor and speed, ensuring lateral stability, and dealing with foreseeable obstacles. To do so, the spinal cord needs sensory feedback for timing, support and adaptive functions. In addition, it needs signals from supraspinal neural sources, such as [10–12]:

- *General activating systems* arousing the animal to new and unexpected stimuli and initiating appropriate actions. For example, sudden attack by a predator must alert the animal to make an immediate decision about *fight, flight* or *play dead*, in all cases implicating changes in posture and locomotion.
- *Motivational drive*. Locomotion mostly serves a purpose in being directed towards a goal. The pursuit of goals is in part determined by motivational brain systems, in particular the ►limbic system.
- *Supraspinal locomotor drive* provides energizing sources for posture and for "stirring up" the CPGs.
- *Adaptive fine-tuning of locomotor functions*, in particular anticipatory reactions to upcoming events, whose detection and processing need higher-level senses.

Many different supraspinal structures are involved in various sub-functions, including the brainstem, basal ganglia, cerebellum, and cerebral cortex. These structures exert their influences directly or indirectly via various descending tracts to several brainstem and spinal targets.

### Neuromodulation of Central Pattern Generators

An important influence on locomotion and supporting posture is exerted by a variety of ►neurotransmitters and ►neuromodulators. These can (i) tonically facilitate or depress motor patterns; (ii) initiate motor activity and/or prime neuronal networks to more strongly respond to other inputs; (iii) modify cellular and synaptic properties [4]. Among the known neuromodulators are amino acids, ►neuropeptides, ►histamine, ►serotonin, ►catecholamines, and purinergic substances [13].

Neuromodulators generate temporal variability in many of the cellular, synaptic and network properties of CPGs. Neuromodulators may also change the properties of short-term ►synaptic plasticity, which in turn co-determine how networks operate in a task-and context-dependent way [14]. The effects of neuromodulators on network properties make each particular network a versatile instrument that is able to perform or contribute to a number of different motor tasks. On the other hand, similar tasks can actually be carried out by different types of network configurations [4].

## Reflexes

The term "reflex" traces back to René Descartes ("Traité de l'homme" 1680) who lived in a time when research on optics surged. Ever since, a reflex has often been defined as a stereotypic motor response tightly coupled to a sensory stimulus. However, the term is now used in a wider sense. Consider a few examples.

### Withdrawal Reflex

Reflex responses must occasionally be fast, for example, in emergency situations when potentially noxious stimuli must be avoided or evaded. The basic concept seems best exemplified by the withdrawal reflex, which was discussed by Descartes himself. The withdrawal reflex [15] is the motor response to a noxious stimulus to a body part, e.g., the withdrawal of the hand from a hot plate inadvertently touched. At first glimpse, this reflex seems to be the "simplest possible" response in that it appears generated by an causal chain

of events leading from a stimulus to a motor reaction, and represented, in technical terms, by a ►feedforward system. However, while there are true feedforward reflexes (e.g., the ►vestibulo-ocular reflex), in which the motor response (output) does not have a feedback effect on the stimulus (input), things usually are a bit more complicated. Many reflexes have a feedback effect, such that the motor (or other) response influences the stimulus. For instance, the withdrawal and scratch reflexes eliminate the original stimulus, thereby reverting the organism to the initial non-stimulated situation. Thus, for proper evaluation of many reflexes, the environment and its relation to the body must be taken into account. This latter factor may also force the withdrawal reflex to include more complicated actions. For instance, if during bipedal quiet upright stance, a human being is hit by a noxious stimulus to one foot, he or she will withdraw the injured leg by flexing the leg joints (►flexion reflex); but in order to secure upright stance and equilibrium, the extensor muscles of the contralateral leg must be activated (crossed extension reflex) so that the body mass can be shifted to the contralateral side. Finally, and most importantly, even the "simple" withdrawal reflex depends on the context. For example, during walking, a human may withdraw (flex) his swinging leg a bit further when the foot is hit by a noxious stimulus, but withdrawal of the stance leg would be counterproductive. This implies that *reflexes must be, and are, context-dependent in that their magnitude and at times their sign (excitatory or inhibitory) can be modulated, for example as a function of the phase of the locomotor cycle*.

### Stretch Reflex

Feedback action is also exerted by the so-called ►stretch reflex. When a physician uses his reflex hammer to hit, say, the Achilles tendon, the calf muscles contract after some short delay (in this narrow paradigm, the reflex is also called "tendon reflex"). What happens here is that the hammer indents the tendon and thereby slightly and transiently stretches the attached (calf) muscle fibers (►Muscle; ►Skeletal muscle architecture). Dispersed among these muscle fibers are ►muscle spindles, sensory receptors, which are excited by the stretch. The excitation is conveyed to the spinal cord by afferent nerve fibers that innervate the sensory receptors of the muscle spindles, where it activates skeleto-►motoneurons that in turn activate muscle fibers to contract. Note that the stretch stimulus is, at least partially, counteracted by the reflex contraction. It thus looks as if the reflex would serve to control muscle length by keeping it fairly constant.

The notion of "►control" resonates with that of ►feedback systems conceived to regulate the actual value of a control variable so as to keep it close to some *set value* or *reference value*. Regulation is often achieved by negative feedback systems (►Negative feedback control), which are capable of suppressing effects of disturbances. An inanimate example is the thermostatic control of room temperature by a heating or air conditioning system, and a biological example is the regulation of core temperature in warm-blooded animals. Other output variables can be made to change with time and, if these changes are also effected by negative feedback systems for the sake of disturbance suppression, the control process is called a ►servomechanism (see ►Computational motor control). An inanimate example is power steering in cars. A biological example is, again, the stretch reflex. As a matter of fact, skeleto-motoneurons receive inputs other than those from muscle spindles. After all, muscles should not just be kept at approximately constant length, but shorten and lengthen in movements of different sorts. There must therefore be time-variable reference signals that are handled by the muscle stretch reflex to yield the output. However, the situation is a bit more complicated in the case of the stretch reflex (►Feedback control of movement).

### Multiple-Loop Feedback Systems

Most often, several loops are meshed to control single or several variables, which in turn may act on single or several controllers. Indeed, even a closer look at the muscle stretch reflex reveals a complicated picture.

Firstly, the sensory fibers emanating from muscle spindles in a particular muscle exert actions on motoneurons other than those innervating the muscle of origin. Conversely, motoneurons innervating a particular muscle receive convergent inputs from spindle fibers originating in different muscles (e.g., [16]). This is the structure of a multiple input-multiple output system, which couples muscle activities via sensory feedback.

Secondly, muscle contraction is regulated by more than one type of feedback system. For simplicity, just one more system is mentioned here. In addition to muscle spindles, there are other receptors in the muscle, among which so-called ►Golgi tendon organs play an important role. These receptors lie at the transition from muscle to tendon fibers and are stretched and excited whenever the muscle fibers produce force. Their afferent nerve fibers exert widely divergent reflex effects, via ►interneurons, on many different motoneuron pools, such that the sign and distribution of these effects depend on the instantaneous motor task. Under rest conditions, the nerve fibers emanating from Golgi tendon organs have inhibitory effects (via inhibitory interneurons) on the motoneurons of their muscles of origin (particularly extensors), so that increases in muscle force reduce motoneuron activation. This would constitute another negative feedback circuit, but with muscle force being the controlled variable. It is still not

clear why two systems based on muscle spindles and Golgi tendon organs are needed to control muscle contraction [17]. This picture is still very simplified and needs qualification. An important one is task-dependency based on modulation of reflex magnitude and sign. For instance, during the stance phase of normal walking (e.g., in cats), sensory afferents from Golgi tendon organs in hindlimb extensor muscles exert not inhibitory but excitatory effects on extensor motoneurons, thus inverting the sign from rest and creating a positive feedback system [18,19], with its own problems of stability [20].

### Complexity of Reflexes

Today, the term "reflex" has lost its original connotation of simplicity and stereotypy, except for a few examples, such as the artificial tendon reflex. There are several major reasons that make reflexes complex.

- *Composition*. Today, the notion of "reflex" subsumes complicated sequences of events, such as the scratch reflex of the cat or dog, or the frog's wiping reflex [1,21–23]. The wiping, scratch and similar reflexes are intricate behaviors involving sequences of postural, goal-oriented and rhythmic components triggered by sensory input.
- *Modulation*. Reflexes are not stereotyped and hard-wired, as is often maintained even today, but flexible and modifiable. Firstly, reflexes are task- and context-dependent. Examples have been given above. Secondly, the magnitude and sign of reflexes often vary throughout a movement, e.g., during locomotion (e.g., [24]).
- *Sensory-motor transformations*. The complex effects of sensory inputs on muscle activities via skeleto-motoneurons involve transformations, of two basic kinds:
  - *Spatial transformations*. Vectors of spatially distributed sensory signals are converted into vectors of spatially distributed muscle actions. For example, in the scratch or wiping reflex, the 2D array of cutaneous receptors must be transformed into 3D space of limb movement [23].
  - ►*Kinematic*-to-►*kinetic transformations*. Sensory inputs are, at least to some extent, cast in kinematic terms related to movement, while muscle activities also express kinetic (dynamic) variables related to forces. This requires kinematic-to-kinetic transformations ([23]; see below).
- *Plasticity*. Reflexes are not fixed in time, but subject to "adaptation" and "learning" (see ►Learning and memory; ►Motor learning, and Computational motor control), such as gain adaptation (spinal reflexes: [25]; vestibulo-ocular reflex: [26], ►habituation, ►sensitization and others [27]). Hence, reflexes are very versatile instruments indeed.

## Posture and Equilibrium

When an animal performs a movement, it changes the coordinates of body parts in relation to each other and to the surrounding world. It is reasonable to assume that this change should not end up in chaos, but in some other ordered state. To define this order requires references and constraints, in regard to the outside world and the own body.

- *Outside-world references* are needed and used for orientation and ordered movement in the outer world. One important reference is up and down, where ►gravity supplies a convenient potential signal (►Graviception). In fact, gravity is not only a load acting on the body and its appendages, but is also used by the CNS as a dynamic orienting reference for the organization of movement [28]. Some animals may use other fields as reference, such as electromagnetic fields (sunlight, earth magnetism (►Vision; ►Magnetic and electric senses)). For many sea and terrestrial animals, the proper alignment of one of their body axes with the up-down axis is essential for organizing movement. This is particularly evident for terrestrial animals standing and moving on legs with the trunk suspended above the ground. These animals, including humans, need to maintain equilibrium and must therefore have sensory-motor mechanisms to do so.
- *Own-body references* are needed to define a framework, within which one body part (e.g., a limb) moves with respect to the rest of the body. Such a framework is usually called a body schema (see ►Sensory systems). The geometric relation of body parts to each other are subsumed under the rubric of posture. Posture is subject to constraints imposed by anatomical means such as ►joints and ►ligaments.
- *Statics and dynamics*. Whereas the above distinctions are valid for both static and dynamic conditions, dynamic movements pose another important problem resulting from acceleration. For instance, when a limb is accelerated, the generating force is counteracted by a reaction force that affects the rest of the body. There must be neuromuscular mechanisms accounting for these effects in order to prevent disturbances of equilibrium.

Thus, an essential basis and frame for the execution of dynamic movements, whether rhythmic, reflexive or freely goal-oriented, are equilibrium and posture. The two closely related aspects of equilibrium and posture (often simply referred to as posture) may be considered as reference values, which must be maintained against internal or external disturbances [29].

### Reference Values

The reference value of equilibrium is, in humans under static conditions, the projection of the body's center of

gravity (►Center of mass (CoM)) onto the supporting surface defined as the area of contact of the feet or other body parts with the ground. Reference values of posture are the positions of certain body segments, e.g., the arm, leg, trunk or head. Dynamic movements of some body parts interfere with these reference values, and appropriate compensations must therefore be pre-programmed in parallel with them. This ►anticipatory compensation, though highly significant, is often not easily recognizable. Massion [29] wrote that "in fact, the motor act might be compared to an iceberg, the apparent being the movement and the hidden part, which is often the most important, being the maintenance of reference values" (p. 36). Such anticipatory compensatory adjustments are generated in an open-loop (feedforward) fashion in parallel with the movement command.

### *Learning Anticipatory Adjustments*

Such anticipatory adjustments are mostly learned from experience, many of them in early childhood. Apparently, the postural disturbance is first corrected for in a feedback mode which is then transformed into a feedforward mode by modification of some as yet unknown adaptive network building up an internal representation of the disturbance to be minimized or the control signal used to cancel it [29].

## Free Goal-Oriented Movements

There is a class of movements that appear freer and less restricted than reflexes and locomotion and typically include reaching, grasping and object manipulation. Still, they may make use of reflexes and CPGs as subsidiary devices. And, as a matter of fact, they require postural adjustments. These skilled forearm movements may have their evolutionary precursors in food-handling behavior, dating back to early tetrapods [30], and are expressed in mammals (e.g., cats) in precision walking on complex ground, where accurate foot placement is of essence, and in arboreal locomotion of monkeys, which requires precise reaching for, and grasping of, tree branches [31]. They usually require excellent visuomotor coordination at cerebro-cortical level (►Viscomotor integration).

Many of the processes involved in organizing free goal-oriented reaching/grasping movements can be inferred from one's insight, experience and common sense. Others, however, must be hypothesized from a careful analysis of human and animal movements, often using conceptual frameworks borrowed from robotics and computational motor control [32,33].

For the purpose of discussion, suppose a monkey is hungry and in search for food. He moves close to an orange, tennisball-sized object. What neural processes need to take place to make the monkey reach out and successfully grasp the object? The following is a conceptual account that does not imply that the processes are run in a series of distinct steps.

- *Target perception*: Obviously, the object (possible target) must first be noticed and then visually perceived and recognized, in terms of its physical properties (size, shape, color), and location and orientation (►Vision).
- *Evaluation:* Once perceived, the object's physical properties must be evaluated in relation to the monkey's ►attention, drive and motivation, and to ►procedural memories (internal representations) of previous experiences with the present or similar objects.
- *Decision*: Once the object has been recognized as edible, desirable and attainable, a decision must be taken whether or not a movement should be made towards that object.
- *Planning*: If the decision is positive, the reaching/grasping movement must be planned, which involves several sub-processes, some of which take place in the posterior parietal cortex and premotor cortex [34,35].
- *Sensory-motor transformations*.
- *Selection processes*: A number of selections must be made, initially as reasonable guesses in a predictive feedforward mode, based on previous experience:
  - *Particular among equivalent motor acts*. Since there are many ways of moving the hand to a target, one among the possible ways must be selected.
  - *Adequate postural adjustments*. By intersegmental mechanical interactions, movement of the arm alters the equilibrium conditions of the whole body, which requires the selection of adequate compensatory postural adjustments executed in anticipation of, and in parallel with, the arm movement.
  - ►*Kinematic* and ►*kinetic parameters*. Reaching/grasping requires anticipatory, initially tentative, parameter settings based on internal representations of the object and on ►internal models of the own motor apparatus.
  - *Grip force*. Before contact, grip forces must be selected tentatively, small enough so as not to squeeze the object and large enough so as not to drop it.
  - *Expected feedback signals* must be estimated, using internal models, in order to be able to compare them with the actual feedback generated during the motor act.
- *Execution*: The desired hand path thus planned must be transformed into appropriate muscle activation patterns by some poorly understood implementation process composed of many sub-processes involving essentially the entire neuraxis.

- *Sensory update*: During the ongoing movement, the central selections listed above are updated by sensory feedback from various sensory systems, including visual and cutaneous receptors and proprioceptors. The sensory feedback serves for:
  - *Fast error correction*.
  - *Triggering of successive steps* in the movement sequence.
  - *Revision and updating of the internal model* of body and limb [32,36].
- *Memory*: The role of memory systems in the above processes cannot be overestimated. In fact, they dynamically interface sensory systems with motor commands. In addition to providing the basis for ►motor learning (see below), memory systems serve to retrieve pertinent object properties based on visual, haptic or olfactory information, identification of task features and the initial state of the skeleto-motor system and of sensory events during task progress [37].

## Degrees of Freedom and Constraints

The diversity, speed, accuracy and elegance of animal movements provide the overwhelming impression of freedom. However, these qualities can be fully appreciated only when due consideration is given to the delicate interplays between freedom and its constraints, which give rise to problems as well as to solutions.

Although musculo-skeletal assemblies may vary widely, their basic structures appear to be more consistent than body shape itself. Still, these elements have adapted by specializing to the particular demands of particular organisms. While these specifications open certain options to an organism, they also constrain it. Internal constraints have a mechanical component in that the peripheral instruments or tools that an organism uses to move not only enable movement, but also limit its extent, speed etc., by their specific properties. These also have to be taken into account by the nervous system when controlling and thereby using these tools [38].

### Problems and Constraints

Moving organisms meet many problems and constraints, which, on the one hand, arise in the organism's environment and, on the other, in its internal structure.

#### *External Problems and Constraints*

External problems and constraints arise from properties of the world, in which the organism lives and moves. The main properties are:

- *Mechanics*. Movement in the external world is subject to its mechanical properties, the most important ones being (►Classical mechanics; ►Mechanics):
  - *Newtonian mechanics*, defining the movements of bodies in space and including *inertia* and *gravity*. Gravity is, however, of different importance in different habitats.
  - *Material nature of habitat(s)*. Movements meet with different resistances and dynamics in gaseous (air), liquid (water), or solid (soil) media and have to be adequately adjusted and controlled.

#### *Internal Problems and Constraints*

Internal problems and constraints arise from the very means that have been developed by organisms to move under conditions on earth. The materials used, and their combinations, could not, and cannot, be chosen entirely freely. Skeletons (►Bone), ►joints, ►articular cartilages, capsules, ►ligaments, ►tendons and ►muscles have properties that, on the one hand, provide opportunities for movement, but on the other hand impose constraints (e.g., [39,40]. Opening new opportunities by solving one problem may in parallel open new problems calling for new solutions. In the end, the solutions must and will be provided by the nervous system that controls the actions of muscles and, in so doing, must take into account the properties of its peripheral instruments in addition to those of the external world [38]. It comes as no surprise that ►proprioception (see ►Sensory systems), in particular, appears well suited to contribute to the solution of problems resulting from the mechanics of the musculo-skeletal system. It has been proposed [17,38] that proprioception contributes to: (i) ►linearization of (correction for) nonlinear muscle properties; (ii) compensation for a muscle's lever-arm variations at joints; (iii) correction of interjoint interaction effects (see below).

### Degrees of Freedom

The vertebrate skeleton immediately unveils the fundamental principles of construction and the potentials afforded. It is a multi-segmented structure made up of hundreds of bones linked at joints. This construction principle should provide for a multitude of options for moving the segments relative to each other and through space. The options are commonly referred to as "degrees of freedom" (DOFs).

Degrees of freedom (DOFs) are the number of variables (coordinates) needed to describe a body's motion in space [41,42]. The DOF of a system of rigid segments is obtained by the general relationship:

$$\mathrm{DOC} = (\text{number of generalized coordinates}) - (\text{number of constraints})$$

The DOFs can change during a motor act, as easily seen when a human being lands from a jump. In the sagittal plane, the number of DOFs decreases by 2 when the toes make contact with the ground and by 1 more when the sole is flat on the ground. In vertical jumping, this sequence is reversed, with the number of DOFs increasing [42].

## Bernstein's Problem

Upon closer examination, the multi-segmented skeleton poses serious problems (see ►Coordination).

Dependent upon the type of joint, the distal segment (bone) can be moved in up to three DOFs with respect to the proximal segment. For example, in a ball-and-socket joint, such as the human shoulder joint, there are two dimensions for, say, extension-flexion and abduction-adduction, and one for rotation. This allows the humerus to be aimed at any point in almost half a sphere. Assembling bones into limbs with several joints increases the number of DOFs. This leads to the effect that, for instance, some desired position of the index finger in external 3D space could principally be realized by an infinite number of different combinations of joint angles. This problem arises whenever the combined number of directions, into which joints of multi-joint limbs can move, exceeds the three-dimensionality of external space. For example, the position of the hand (wrist) can be specified by three coordinates in external space, but it is defined by four joint angles (elevation and yaw of both the shoulder and the elbow; [43]). This ►redundancy of degrees of freedom (see ►Coordination) holds for many postures and movements. Hence, theoretically, there should be an infinite number of possible movement trajectories to reach the same target. Nonetheless, most arm and hand movements do not take advantage of the theoretical redundancy afforded, but are performed in fairly stereotyped manners, suggesting that there must be solutions for reducing the redundancy. The problem of providing such solutions has been clearly highlighted by Bernstein [44].

The query for solutions to ►Bernstein's problem has to be conducted at various levels. A rough distinction can be made between mechanical constraints deriving from specifics of the musculo-skeletal system itself and the nervous system dealing with the peripheral system.

## Constraining Freedom

Consider the cat hindlimb with its three large joints: hip, knee and ankle joint. If, in a first approximation, each of these joints is assumed to be a hinge joint of one DOF, the limb would be a 3-DOF assembly of segments, allowing for 2D movement of the limb endpoint in the parasagittal plane. Hence, despite the possibility of movements about three joints, the end-point movements are confined to two dimensions, implying a reduction in DOFs. How is this implemented? One possibility is to restrict the independence of movements in the different joints, i.e., to tightly couple changes in the three joint angles. This is indeed what happens during both passive and active hindlimb movements. That is, the relationship among the three joint angles shows a planar or 2D co-variation over a large range of limb positions [23,45].

►*Biomechanics*. In the passive limb, the mechanism underlying the joint-angle coupling is presumably of biomechanical nature, as indicated by post-mortem assessment. For example, biarticular muscles spanning two joints as well as passive structures such as joint shapes, joint capsules and ligaments may play a role in coupling different joints. During movements, inertial intersegmental interaction forces (see below) may contribute to couple the movements of limb segments [45].

*Neural Control Mechanisms*. In addition to passive biomechanical factors, neural control mechanisms may come into play. Awake cats trained to maintain quiet upright stance on a tilting support platform also show a linear co-variation of hindlimb joint angles. This pattern of joint-angle covariance is, however, different from that in the passive limb. Firstly, the coupling is tighter, suggesting that neural control may actually further reduce any independent motion in the individual limb segments. Secondly, the co-variance plane has a different orientation in 3D joint space, due mostly to a sign inversion of the relationship between the hip and ankle angles [23,45]. The difference between the passive state and the active state shows that the CNS should determine the particular form of joint angle co-variation (the orientation of the plane in joint space). Similarly, in human reaching movements, segment excursions are coupled, and so are joint torques [46].

## Exploiting Freedom

While there are mechanical and neural mechanisms that constrain the freedom of movement, the redundancy in DOFs also has advantages. Indeed, it allows for flexibility, stability and accuracy. Again taking the example of fingertip localization, arm orientation at the shoulder joint is usually less precise than fingertip location, such that more distal joints can compensate for errors committed by more proximal joints [47]. Therefore, redundancy can also be considered a virtue to be exploited rather than a problem that should be solved. One method to exploit the redundancy is to represent all the possible solutions by means of a multiple controller [48]. Another approach is to exploit redundancy in order to minimize the variance by means of optimal control [49]. Yet another recent approach has hypothesized a "principle of abundance," stating that no DOF is ever eliminated or frozen, but instead all DOFs always participate in all the tasks, thereby assuring both flexibility and stability of performance ([50,51]; see also ►Coordination).

## Representations of Space

Since movements take place in space and time, a basic requirement for any meaningful action based on perception and orientation is the construction by

the CNS of spatial frames of reference and their transformations (►Sensory Systems). This involves:

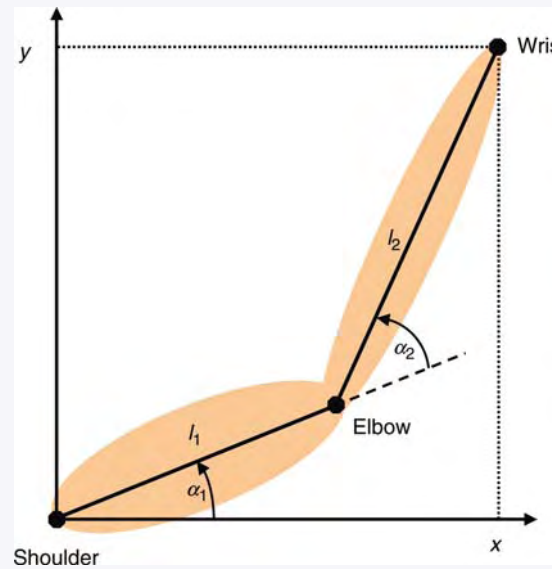
- *Spatial orientation,* depending on the perception of the position, orientation and motion of external objects and that of an animal's own body parts within reference frames. There is more than one frame that the nervous system makes use of. The particular subjective reference frame that an observer takes as stationary is called "rest frame." It is selected according to availability of sensory cues, convenience and circumstances. For example, on earth, astronauts choose a rest frame based primarily on gravity and visual scene polarity, while in microgravity (in a spaceship), the rest frame is based on visual scene polarity cues from the spaceship interiors and other crew members as well as on the internal head and body *z*-axes (ideotropic vector). It appears as if astronauts switch between rest frames depending on variables such as the task being performed [52].
- *Multiple representations of sensory spaces and muscle spaces*. The representations of the position, orientation and motion of external objects and those of an animal's own body parts are based on different sensory signals, which are coded in different frames of reference. For instance, reaching and grasping require the localization of the object in peripersonal space as well as the localization of the initial position of arm and hand. Object location is coded predominantly by ►vision (and/or hearing audition), arm/hand position by vision and/or proprioception, which each possesses its own reference frame (see ►Sensory systems). Finally, spatial aspects of muscle actions are coded in their own frame. All this calls for:
- *Sensory-motor transformations* characterized by several aspects [34,53,54]:
  - *Multi-sensory integration (►Mutimodal integration)*: Signals from different senses must be integrated and thus converge onto common neurons. This also applies to other senses such as hearing (for sound-emitting objects) and touch (for tactile shape perception after contact with the object).
  - *Construction of a unified sensory frame of reference*. The different sensory reference frames must be put in register and thus unified; for arm (►Voluntary movement) and eye movements (►Neural control of eye movement) this appears to be an eye-centered (oculocentric) frame established in the posterior parietal cortex.
  - *Sensory-motor coordinate transformation*: The sensory coordinate frame must be transformed into the motor frame.

## Kinematics

The spatio-temporal representations that the nervous system needs have several aspects and dimensions. The first important distinction to be made is between kinematic and kinetic (dynamic) descriptions, which nonetheless are closely related. The kinematic description simply deals with the spatio-temporal paths or trajectories of objects (head, eyes, limbs etc.). For this purpose, the kinematic description requires reference frames or coordinate systems to relate a moving object to for quantification. The dynamic aspect deals with the forces involved in, and required to drive, movements. Since forces are spatially directed and hence vectors, their description, too, involves spatial coordinate systems. Another connection between kinematic and dynamic descriptions is Newtonian dynamics.

### Extrinsic and Intrinsic Coordinate Systems

As exemplified in Fig. 1, the position (and movement) of the hand (wrist) can be described with respect to two coordinate systems. For simplicity, the right arm is here supposed to be held in a horizontal plane, and the arm is viewed from above (direction of the *z*-axis). The hand position can be given in terms of an extrinsic, rectangular Cartesian coordinate system, where the *x*-axis is in a parafrontal and the *y*-axis in a parasagittal plane through the right shoulder. (Alternatively, it could be described in *polar coordinates* as the direction and distance of the hand from the shoulder.) A second



**Motor Control. Figure 1** Representation of hand (wrist) position in two frames of reference. For simplicity, the right arm is supposed to be held in a horizontal plane, and the arm is viewed from above (direction of the *z*-axis). The hand position can then be given in terms of a rectangular Cartesian coordinate system, where the *x*-axis is in a parafrontal plane through the shoulders, and the *y*-axis in a parasagittal plane through the right shoulder, or in terms of segment lengths, $l_1$ and $l_2$, and joint angles, $a_1$ and $a_2$.

way of determining hand position with respect to the shoulder is by segment lengths, $l_1$ and $l_2$, and joint angles, $a_1$ and $a_2$, establishing an intrinsic system based on body geometry (see ►Arm trajectory formation).

## Coordinate Transformations

The existence of different coordinate systems requires the nervous system to continuously transform the positions of limbs and their trajectories during movements from one system into the other. For example, consider the transformation from joint angles to Cartesian coordinates (Fig. 1), which is given by the trigonometric relations:

$$x = l_1 cos(a_1) + l_2 cos(a_1 + a_2) \qquad (1a)$$

$$y = l_1 sin(a_1) + l_2 sin(a_1 + a_2). \qquad (1b)$$

This transformation is referred to as forward or direct kinematics [55]. It is called forward because it describes the natural causal flow of events from muscle activations, which determine muscle lengths, which determine joint angles, which finally determine hand position in relation to the body.

There is also the *inverse transformation* from extrinsic to intrinsic coordinates, which is obtained by solving (1a and b) for the joint angles $a_1$ and $a_2$, each of which will be a function of both $x$ and $y$ [55]. This transformation is called *inverse kinematics*. At first glimpse, it does not appear to have a natural counterpart as does the forward kinematics. However, it has been suggested that, at the highest stages of movement planning, the final hand position or the movement towards it is planned in extrinsic coordinates, $x$ and $y$ [23], from which the related set of joint angles would have to be obtained by an inverse transformation (however, there are other suggestions; see below). It merits emphasis that, in this case, there is a unique solution only because we consider the relation between two extrinsic and two intrinsic coordinates in a plane. In 3D space, three external coordinates and four joint angles are needed to specify hand position, leading to the well-known redundancy problem without a unique solution, as discussed above.

Another important implication can also be drawn from (1a,b). Any neuronal network to implement one or the other of the above transformations would have to incorporate neural elements, which would receive convergent input signals from the independent variables. This requirement may be one of the reasons for the widespread existence of *convergence* of many inputs onto many central neurons. Conversely, the inputs may affect more than one output, which in neural terms accounts for *divergence* of neural signals to affect more than one output. In general, of course, transformations between coordinate systems involve many more than just sets of two variables as in Fig. 1; they therefore become exquisitely complex.

## Algorithms for Inverse Transformations

In principle, there are several possibilities of performing inverse transformations, as illustrated here for inverse kinematics [55].

- *Computer program*: In robotics, inverse kinematics can be solved by a computer program. Obviously, the CNS cannot do it exactly this way, although the term "program" is being used in the field of biological motor control in a loose analogous way. Its use may be misleading, though, and has been criticized [56].
- *Lookup table*: Another possibility is that the CNS could use is a lookup table, which contains entries associating particular pairs $(x,y)$ and $(a_1,a_2)$. In general, these tables can come as "computational maps" [57,58], which map values of a particular sensory and/or motor variable along at least one spatial dimension of nervous tissue. Such maps indeed exist in several places in the CNS. For example, the ►superior colliculus (tectum opticum in lower vertebrates) contains maps of spatial sensory information as well as motor maps of the amplitude and direction of orienting movements of the eye (gaze), head, pinna and vibrissae [59–61]. These maps are dynamically maintained or altered according to experience during development, but also in adults. Sensory and motor maps have to be aligned, with early visual experience being highly important in doing so [59].
- *Internal model*: The equations describing the inverse kinematics could also be solved by special analog circuits representing an internal model. For limb and trunk motor control, such models would certainly be much more complicated than that which has been considered to be at work in certain ► eye movements, because as compared to the latter systems, the former ones have to deal with varying loads including those resulting from gravity. Yet, internal models probably exist, at least for certain purposes [33,36,62–64].

## Kinetics (Dynamics)

The kinetic (dynamic) aspect of movement organization results from the fact that the body or its parts have visco-elastic and inertial properties and are suspended in a gravitational field (albeit to very different extents in different species living in different habitats). Hence, their movement requires forces in order to counteract visco-elastic forces or achieve acceleration against inertial and gravitational forces. The description in terms of forces or torques at joints is by kinetic (or dynamic) variables [55].

## Muscles and Intersegmental Interactions

However, dynamics play a role not only in the interactions of the body and its segments with the environment, but also in the interactions between the different body

segments themselves. Since body segments are movably coupled at the joints, motion of one segment acts on those of other segments. This implies that any individual muscle not only accelerates the segments that it originates from and inserts on, but also remote segments via intersegmental dynamic interactions, which in addition depend in complicated ways on the joint angles and angular velocities [38]. These interactions in turn yield new insights into the functions of individual muscles and into how many muscles must be coordinated in order to serve movement goals (e.g., [65]). Consider a few examples.

### Swinging a Leg during Walking and Running

During human walking, stance and swing phases follow each other in each leg. From a naive standpoint, we might assume that, in order to lift and clear the swing leg from the ground and move it forward, all joints should be flexed, with the flexions to be initiated by concomitant activation of hip, knee and ankle flexor muscles. However, simple mechanics suggests another possibility. If the hip flexors alone were activated, then the thigh would be accelerated forward relative to the trunk and, due to inertia, the shank would lag behind, resulting in (passive) knee flexion. This indeed plays a major role in the hindlimb of cats during gallop, where knee flexion is sustained by inertial torques related to linear hip and angular leg acceleration, rendering activation of the knee-flexor semitendinosus muscle unnecessary. By contrast, at lower gait speeds, this muscle shows two bursts of activity during the movement cycle [66]. Conversely, the extension of the knee at the end of the swing phase is assisted by a whip-like forward movement of the lower leg while the upper limb is already decelerating. In human walking, there is only one problem concerning the ankle. If joint motions during the initial swing phase were sustained by hip flexor activation only, the foot would also remain behind due to its inertia, thus extending the ankle. This would be too little to clear the foot from and above the ground during swing. Hence, ankle dorsi-flexor activity (mainly in the tibialis anterior muscle) is also required. This is evident in patients suffering from paralysis of the nerve innervating the tibialis anterior, which leads to dragging of the foot in the swinging leg. In any case, intersegmental mechanics clearly contribute to dynamic motor acts, which must be taken into account by the nervous system in organizing the coordinated muscle activations.

### Paw Shake

During the cat's oscillatory paw shake elicited by an irritant stimulus to the paw, the hip, knee and ankle joints undergo rhythmic angle changes at ca. 11–12 Hz, with a proximo-to-distal increase in amplitude. At the ankle joint, interactive and gravitational torques do not contribute significantly to net joint torques, whereas at the knee joint they do. Here, torques related to the angular acceleration of the paw dominate over interactive contributions to the knee torque. At the ankle, the torques produced by ankle muscle activation account for much of the net joint torque and thus directly determine the paw segment dynamics. In contrast, knee muscles produce torques, which rather compensate for interactive torques, thus controlling intersegmental dynamics between paw and shank [67].

### Pedaling

A deeper insight into muscle functions during complex motor acts is provided by dynamical simulations of seated pedaling of humans. Seated pedaling is mechanically simpler than walking because it has fewer mechanical DOFs, the hips being essentially stationary and the foot path being constrained by the pedal trajectory [65]. The important points can be summarized as follows.

(i) The intersegmental interactions depend in a complicated way on joint angles and velocities, and the dynamics are different at different joints. If these interactions were to be described by sets of dynamic equations, different sets of equations would have to be set up for different situations. (ii) To understand the role of muscles in the above processes, deriving their function from their anatomical position, knowing just their origins and insertions alone, is insufficient. (iii) In fact, a muscle's function depends on the configuration of the body and its parts and on their interaction with external objects such as the ground or obstacles; it can thus vary with motor task and within a motor task [42]. (iv) Since muscle activations depend on peripheral circumstances, in order to organize their activations properly, the CNS needs information on these circumstances, that is, sensory feedback [38].

## Forward Dynamics

Consider the causal sequence of events in the musculoskeletal periphery, say an arm, referred to as *forward or direct dynamics* [76]. In this system, motoneuron activity provides the inputs, and body motions are the outputs. Thus, if there are $m$ muscles, their inputs are reflected in the electromyographic signals, $EMG^1 \ldots EMG^m$ (►Electromyography (EMG)). These activation signals are transformed into the set of muscle forces, $F^1 \ldots F^m$. These in turn are converted, depending on musculo-tendon dynamics and moment arms $R(F's)$, into a set of muscle torques at $n$ joints, $T_1^{mus} \ldots T_n^{mus}$. These torques finally are transformed into sets of joint angles $\Theta_1 \ldots \Theta_n$, their velocities and accelerations, which ultimately result in the motion of the limb endpoint. Note that there are some ►feedback loops because, for example, joint angles determine muscle lengths and these in turn co-determine muscle forces. On the whole, however, this is a feedforward scheme,

which indicates that the input signals should be precisely tuned to achieve the correct output.

### Inverse Dynamics

It has been suggested that the CNS plans reaching/grasping movements in terms of extrinsic coordinates, say of hand position and/or trajectory in extrapersonal space (e.g., [23]). Although other suggestions have been put forward (e.g., planning in terms of kinetic variables such as joint torques; [46]), it is instructive to consider the consequences of the kinematic model. The CNS must perform a number of transformations in order to provide the appropriate muscle activation patterns. The sequence of transformations is as follows:

*Desired trajectory* (*assumed to be coded in kinematic extrinsic coordinates*) → *joint angles* → *joint torques* → *muscle forces* → *muscle activation patterns*.

If the CNS used this approach, it would have to take into account the forward dynamics discussed in the preceding section by "inverting" them. That is, in order to achieve the desired movement trajectory, the planned trajectory must be implemented by a process compensating for the forward dynamics described above. Thus, from the desired end-point movement in extrinsic coordinates, intrinsic joint angles (muscle lengths) and their first two time derivatives must be derived via an "*inverse kinematics*" algorithm. Through an "*inverse dynamics*" algorithm, joint angles and their first two time derivatives would determine the net muscle torques needed to achieve them, and subsequently the muscle forces needed to generate the torques, and then the excitations needed to generate the forces. The desired excitations thus computed from the desired trajectory could serve as the template of motoneuronal activations.

However, this approach would raise formidable problems. The computation of such inverse dynamics is complex and often requires non-unique transformations. For example, individual muscle forces are not uniquely determined by net muscle torques, i.e., the torques can be achieved with many combinations of muscle forces. Also, the neuromuscular periphery has complex nonlinear properties. Furthermore, the different segments in multi-joint limbs exert mutual interaction forces on each other (intersegmental interactions). These complexities results in myriads of equations of motion, all of which would be task-dependent. In order to solve the problems, then, the CNS would have to "know" these equations as well as precise estimates of the initial and boundary conditions and parameters involved, such as the masses, locations of the centers of mass, principal axes of inertia, moments of inertia (see [68–70]). Moreover, the computation itself would have to be extremely accurate because even small errors, or small mis-estimates of initial and boundary conditions, would lead to large movement errors. Because of the complex computational capacity required, the inverse-dynamics computations have usually been thought to be performed, if at all, by the cerebral cortex or cerebellum, although the vertebrate spinal cord might also contribute its share [23]. Still, completely precise inverse-dynamics computations do not appear feasible.

The above considerations are based on the presumption that the inverse-dynamics calculations are performed in a feedforward (open-loop) fashion, i.e., without the CNS receiving feedback on the results of its actions, which could be used to correct for errors. Incorporating such feedback would alleviate some of the problems. However, this would raise new problems. First, in the neuro-muscular system, sensory feedback occurs with considerable delays (for visual or proprioceptive processing). Therefore, fast (ballistic) movements, precisely those movements posing the most severe dynamic problems, would have to do without it, at least initially. (However, CNS-internal feedback based on an ►efference copy of the motor command and sensory information as well as an internal model of peripheral dynamics could make early corrections to the unfolding motor plan; [62]). Second, the gains in feedback systems are usually low because high gains with long delays run the risk of instability (e.g., [71,72]). Perhaps this is one reason for ballistic movements being more imprecise than slow movements, unless well learned.

## Motor Control Schemes

### Equilibrium-Point Hypothesis

A concept purported to dispose of all the dynamic issues and thus provide a simpler solution than the inverse-dynamics approach is the so-called ►equilibrium-point hypothesis (EPH) [21,68,69,73,74]. The basic ideas are:

- Passive and active muscles have (nonlinear) spring-like properties (like rubber bands).
- At each moment of time, the relative levels of activity in the sets of agonist and antagonist muscles and the resulting muscle forces (or joint torques) specify a virtual position of each joint, at which all the torques, including those deriving from external loads, are in equilibrium, i.e., the net torque is zero.
- Following its dynamics, the limb moves to this equilibrium position unless some obstacle interferes with it.

The important point is the concept of the virtual equilibrium position because this is the "attractor" pulling on the limb. Movement comes about by a smooth and continuous change in virtual equilibrium position, which has to be specified by the CNS in terms of appropriate muscle activation patterns. Once the brain has acquired the ability to represent and control equilibrium positions, it can master movements as temporal

sequences of such positions [68]. The adherents of this hypothesis claim that the inverse-dynamics problem is simplified (or even obviated) because explicit representations of inertial, viscous, gravitational and other opposing forces are unnecessary.

One of the merits of this hypothesis is that it has stimulated attempts at taking into account real neuronal networks. This has been tried by both groups of its major proponents [73,75]. Feldman et al. [73] original approach is more explicit in dealing with particular networks including the stretch reflex, ►reciprocal inhibition and ►recurrent inhibition. However, it suffers from the weaknesses outlined above as to sensory feedback [71].

### Adaptable Internal Models

Another solution is to revert to the inverse model concept, but conceive of these models as *adaptable.* Such a model would then represent some properties of the musculo-skeletal periphery, and well so, by adapting to them through learning (see ►Computational Motor Control; ►Adaptive control). In this scheme, sensory feedback (e.g., vision and proprioception) attains a novel significance by being used to update internal models before the event rather than correcting for movement errors in real time.

Depending on the requirements, inverse models can also be combined with forward models that represent the forward dynamics of the "plant" (i.e., the physical system to be controlled; see ►Control). If plant and forward model are fed with the same motor command, the difference in outputs will tell how well the model represents the plant. This output can be used in various ways, one way being as an error signal teaching the model to adapt optimally. The keywords then are adaptation and learning.

### Neural Networks

The distinction between kinematic and dynamic aspects of movement control can be avoided in neural network models. In such networks, kinematics could be encoded by sensory receptors at the input level and dynamics by effectors at the output level, so that kinematics or dynamics, or both, or neither, are encoded anywhere in the brain [76].

## Plasticity and Sensory-Motor Learning

The CNS must adapt its actions to changing conditions of its environment, including the body, and learn from their effects, at very different levels of organization and time scales. This requires its neuronal networks to be not rigid, but plastic. The terms plasticity, learning and memory are not precisely defined, but are commonly applied to a diversity of processes. In a narrow ►behavioral sense, motor learning implies the acquisition of new behaviors or skills by practice [77]. But the term is often used with wider connotations including processes and mechanisms at much lower levels of complexity (►Learning and memory; ►Motor learning). The structures subject to plasticity are manifold and distributed throughout the neuraxis, even extending to the neuromuscular junction [78].

There are a number of different processes and mechanisms that contribute to learning (in the wide sense), such as axonal sprouting or pruning and modifiability of synaptic efficacy. The establishment of the proper neuronal connections and topographical maps at some critical stage of ontogenetic development in part relies on such processes, as does the adaptive change in such maps in adult life. Many of the basic events underlying learning, information storage (memory) and retrieval are thought to take place at a molecular level, in particular at ►synapses. Synaptic transmission is vastly flexible or plastic, at time scales ranging from the order of milliseconds to probably life-long.

### Acknowledgment

# Motor Control Hierarchy

## Definition

The motor systems are organized in both a hierarchical and parallel fashion. For example, cortical motor areas stand above motor neurons in the spinal cord in a hierarchical fashion, and can command lower motor neurons to activate. However, there are multiple routes from cortical and brainstem motor areas to lower motor neurons, also allowing a parallel control. Aspects of motor planning are also hierarchically organized. At the top of the hierarchy seem to be invariant properties of movements that are independent of the particular patterns of muscle activations used to achieve a motor goal.

# Motor Control Models

Stan C. A. M. Gielen
Department of Biophysics, Radboud University Nijmegen, Nijmegen, The Netherlands

## Definition

The aim of models in motor control is to reproduce experimental data and to make predictions for new experiments, where different models make different predictions so as to discriminate between various models for human movement control. Typically, models have been developed for different levels of motor control: for specific parts of the neuromuscular system as well as for neural feedback and feedforward control mechanisms. For each model, the modeller has to specify (i) the

family of admissible control signals, (ii) the characteristics of the neuromusculo-skeletal model, and (iii) a quantitative definition of task performance.

## Characteristics

### Introduction

A pointing or reaching movement to a target in three-dimensional space defines a redundant task at the geometric, kinematic and dynamic level of control. An infinite number of possible hand trajectories can be selected for moving the hand to the target, leading to an infinite set of possible arm postures for every hand location in 3D space. In this perspective, it is remarkable that human movements are quite reproducible and that the variability of movements starting from the same beginning position towards the same end position is relatively small. This observation has been considered to reflect some underlying principles, which reduce the number of degrees of freedom.

Several models have been proposed to explain the characteristics of human movements. The aim of these models is not only to see whether they can reproduce the experimental observations, but also to make predictions about movement characteristics for movements in new, complex situations, which have not been studied so far. The use of models to predict the behavior for complex movements is important to test and validate models and to suggest new experiments to discriminate between models.

### Kinematics

One of the influential theories in movement control, was the equilibrium-point (EP) hypothesis [1]. This theory assumes that the neuromuscular system has (nonlinear) elastic properties. For a linear spring force F depends on the stiffness K and the excursion from the equilibrium point $x_0$: $F = K(x-x_0)$. The EP-model postulates that the position of a limb corresponds to the position, where the external force (e.g. gravity, weight of objects) is equal (but opposite) to the force exerted by the muscles. Therefore, kinematics should follow directly from the elastic properties of the neuro-muscular system and the properties of external loads.

In general, the position of an end effector, like the finger tip, can be obtained by multiple postures of the arm. Yet, the variability of postures for the same position of the end effector is small. This reproducibility of postures has often been described as Donders' law, which states that limb postures for a given finger, eye, or head position are invariably the same for the same pointing or gaze direction, respectively. This law is certainly not trivial since it is well known that rotations in 3 dimensions do not commute. This implies that the orientation of an object after two rotations along different rotation axes, depends on the order of rotations. Eye movements perfectly obey Donders' law. The specific relation between direction of gaze and eye orientation is known as Listing's law [2]. However, Donders' law is not valid for limb postures. Experimental results by Soechting et al. [3] revealed consistent variations of postures for the same position of the index finger depending on the history of previous finger positions. These authors suggested that the history-dependence of limb postures could be explained by the minimal-work model, which assumes that movements are made under the constraint of minimal work (see below). This is consistent with the observation that final posture after a movement does not depend on ►movement velocity [4].

### Dynamics

In general ►point-to-point movements, which start and end at rest, follow a more or less straight path and have a bell-shaped velocity profile (►Bell-shaped speed profile), in agreement with predictions by the minimum jerk-model (see Fig. 1).

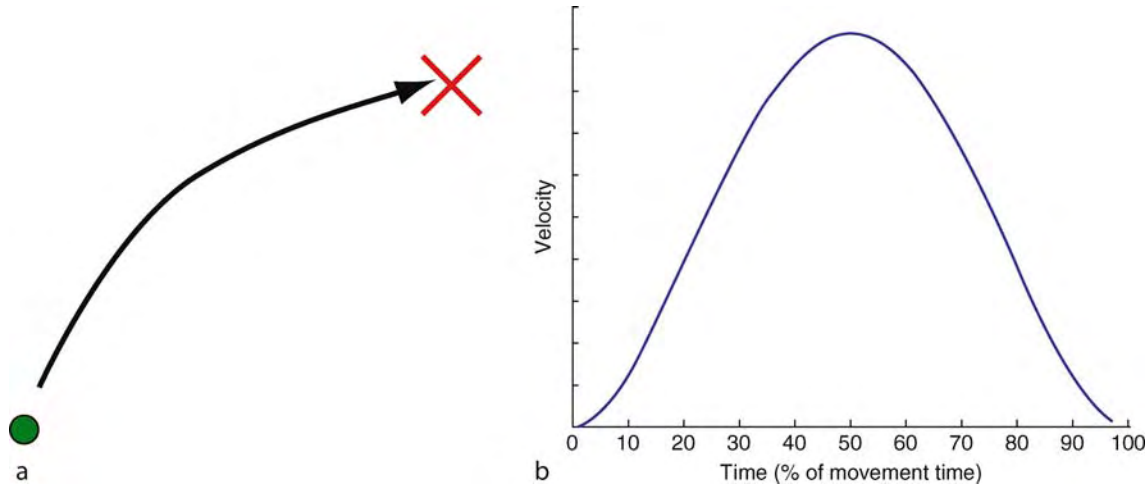
However, movement paths may differ depending on the instruction to the subject or depending on movement task. When subjects are instructed to make point-to-point movements in the dark, the movement trajectory is curved. This curved path has been interpreted as the result of movement planning in joint space, where joint rotations may give rise to curved movement paths of the end effector. However, when subjects are instructed to move an object (for example a cursor or mouse) between the same to positions with vision, the movement path is straight, suggesting that movement planning is in external work space. This illustrates that the movement trajectory is task-dependent, presumably because movement planning takes place in different frames of reference (e.g. joint space versus work space).

### Models to Explain Human Movements

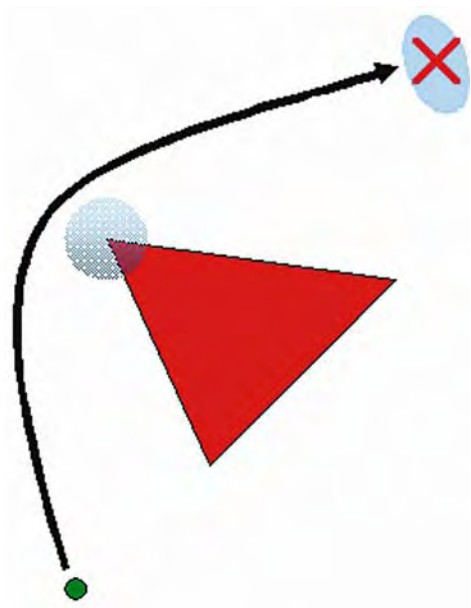
In general, models to explain human movement control belong to the general class of ►optimal control models [5]. Optimal control assumes that movements are made based on some ►optimization principle. Optimal control seeks to find the control (i.e. the muscle activation pattern), which optimizes the time-integral of some cost. This cost might be related to extrinsic features, such as e.g. end-point variability, smoothness of movement, and collision avoidance (see Fig. 2).

However, the cost should also include the properties (e.g. noise) in afferent sensory signals and in neuronal feedforward and feedback signals. The cost may be different for different types of movements. For example, movements, which have to be as fast as possible, require that movement time is minimal, whereas accurate movements require that the variability at the end of the movement is as small as possible.

Most models in the literature to explain properties of human movements focus on a single optimization principle. The most well-known models are



**Motor Control Models. Figure 1** For a typical movement (start position at the green circle) to target (red cross, Fig. 1a) the corresponding velocity profile (Fig. 1b) has a bell-shaped profile.

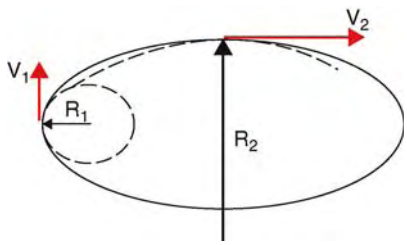


**Motor Control Models. Figure 2** For a movement from the green circle to the red cross the movement path should keep a sufficiently large distance from the triangle to avoid collision. Given the intrinsic noise of action potential firing and force generation in muscle, this requires that the movement path should remain outside a circle centered at the corner of the triangle. It should also reach the target with a particular accuracy (indicated by elliptic shape). For optimal control, there are several cost criteria, depending e.g. on the internal noise of the motor system, on target accuracy of the movement, on movement time. The total cost C, which should be minimized, is a weighed summation of the various cost criteria $C_i$ involved ($C = \sum w_i C_i$), where the weighting coefficients $w_i$ depend on the relative importance of the cost criterion $C_i$.

- Minimum jerk model. Jerk is the third derivative of position. Minimization of jerk assumes that movements are smooth and predicts that movement velocity profiles are bell-shaped [6].
- ►Minimum torque-change model [7]. This assumes that changes in joint torque are minimized. A variation on the minimum-torque-change model is the minimum force-change model, which assumes that movements are made under the constraint that changes in muscle force are minimized. Since torque is the product of force and lever arm, the predictions by the minimum-torque change and minimum force-change models are very similar.
- Minimum-work model [3] assumes that work is minimized. This is equivalent to assuming that kinetic energy at peak velocity is minimized.
- Minimum variance model [8] uses the fact that muscle noise increases proportionally with muscle force and assumes that those forces are selected that minimize variance at the end of the movement.

Advanced mathematical analyses make it possible to calculate the best control given an optimality criterion in the absence of noise. However, the human motor system has to deal with internal noise [8] and movements are made in an environment, which may change in an unpredictable way. The theoretical framework for these cases (called "stochastic optimal control") is far from complete and is an important topic for further research.

Quite surprisingly, many models make the same predictions for planar movements but differ greatly in their predictions for movements in three dimensions [9]. Because of the complexity of simulating models for 3D movements and of analyzing and interpreting movements in three dimensions, a thorough comparison



**Motor Control Models. Figure 3** For periodic movements along an elliptic path, the relation between radius R of the movement path and tangential velocity v is given by $V = CR^{1/3}$. The dashed and dashed-dotted lines are local fits of a circle segment to the ellipse. For a high curvature (small radius $R_1$) the corresponding tangential velocity $V_1$ is smaller than the tangential velocity $V_2$ for the less curved part of the ellipsoid. The ratio $V_1/V_2$ is equal to $\sqrt[3]{R_1/R_2}$.

between predictions of various models and experimental data for movements in 3 dimensions has not been made yet.

### Two-Third Power Law

It is a well-known phenomenological observation that velocity of curved movements is tightly related to the curvature of the movement. This relation has been referred to as the ►two-third power law, since angular velocity $\omega$ appears to be related to curvature $\kappa$ of the movement path by the exponential relation $\omega = Ck^{2/3}$. Since for circular movements tangential velocity $v$ is related to angular velocity $\omega$ by the radius R of the movement ($v = R\omega$) with R equal to the inverse of curvature $\kappa$, the two-third power law can also be written as $v = CR^{\beta}$, where the exponent $\beta$ equals 1/3 (see Fig. 3).

This relation can be derived mathematically when it is assumed that planar movements, such as elliptic movements, are made by a superposition of two orthogonal components with a sinusoidal and cosine modulation in time. As an alternative to the explanation that movements are built up by sine- and cosine modulated orthogonal components, Richardson and Flash [10] demonstrated that the two-third power law also follows from the smoothness constraint that underlies the ►minimum-jerk model.

## Motor Cortex

M

### Definition

A general term that historically has been used to refer to primary motor cortex. This term is now also used in a more general way to refer collectively to primary and secondary motor areas of the frontal lobe.

►Motor Cortex – Hand Movements and Plasticity
►Motor Cortex - Output Properties and Organization
►Primary Motor Cortex (M1)

## Motor Cortex – Hand Movements and Plasticity

Marc H. Schieber
Departments of Neurology and of Neurobiology and Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

### Definition

The primary motor cortex, in primates located just anterior to the central sulcus, plays a crucial role in control of fine hand and finger movements. The organization of movement representations in the motor cortex undergoes

plastic changes in response to altered internal and external requirements for finger movements.

## Characteristics

### Voluntary Use of the Hand and Fingers

►Grasping an object is the most frequent voluntary use of the hand. Depending on the object and goal, humans use a wide variety of grasps – from precision (►Grip – precision grip) pinch between the tip of the thumb and index finger as used in picking a raspberry, to power grip (►Grip – power grip) as used in holding a hammer [1]. As the hand is transported toward an object by the reaching movement of the arm, the fingers open and form into a shape that approximates the shape of the object to be grasped. Such visually guided pre-shaping of the hand is mediated by a flow of information from the anterior intraparietal area (AIP) to the ventral premotor cortex (PMv) to the primary motor cortex (M1) [2]. As the fingers close on the object, forces at the contact surfaces on the fingers and palm must be balanced to provide a stable grip that does not rotate or crush the object unintentionally.

Less frequently the hand is used to perform delicate manipulation or even such specialized acts as typing on a keyboard, or playing a musical instrument. Although one often has the impression that during such movements each finger is moved independently, recordings show considerable correlated motion of adjacent fingers [3]. Even when normal humans are asked to exert flexion force with one finger only, force is produced in adjacent digits, a phenomenon referred to as ►enslavement of the adjacent digits. Similarly, when asked to move only one finger, motion appears in other fingers as well. In part, this incomplete ►individuation results from biomechanical coupling of the digits, and in part it reflects control from the nervous system as well.

For both grasping and fine manipulation, use of the right versus left hand is not necessarily random. Hand preference has three levels: (i) individual subjects tend to use the same hand repeatedly for a given task; (ii) individual subjects prefer to use the same hand for many different tasks; and (iii) most individuals in a population tend to prefer the same hand. Whereas non-human primates systematically show only the first level of hand preference, humans show all three levels. Approximately 80% of any human population is right-handed. In general, right-handed people prefer to use the right hand for delicate tasks that require precise control of dynamically changing forces, while the left hand may perform better in tasks requiring accurate control of static position [4].

### Control of the Fingers From the Motor Cortex

Control of such relatively independent finger movements relies heavily on the hand representation in the primary motor cortex, and its corticospinal projection (►Motor cortex – output properties and organization 06078). When lesions affect this pathway, individuated finger movements are the first and most severely affected, and the last to recover. In macaque monkeys, a central core of Brodmann's area 4 representing hand movements and muscles is surrounded by a horseshoe-shaped band representing the more proximal upper extremity. This entire upper extremity representation lies between the representations of the face laterally and the lower extremity medially.

Throughout the M1 hand representation, neurons in cortical layer V send corticospinal axons to the lower cervical enlargement to control the motoneurons of hand muscles. Corticomotoneuronal (CM) cells that make monosynaptic connections to hand motoneurons are restricted to the posterior part of the hand representation, which in macaque monkeys lies in the anterior bank of the central sulcus [5]. CM cells are thought to be particularly important in the fine control of relatively independent finger movements. The firing rate of single neurons in the M1 hand representation – including corticospinal neurons and CM cells – varies depending on which type of grasp is used, or depending on which finger is moved. Although single neurons only rarely discharge selectively for a particular type of grasp, or for movement of a particular finger, the discharge of a large population of M1 neurons transmits information that specifies the hand or finger movement being made.

The M1 hand area classically was thought to contain an orderly somatotopic representation of the digits, with the thumb most lateral and the little finger most medial, but the representation of each digit now is known to be more widely distributed. This results from a number of structural features [6]. First, the cortical territory from which corticospinal axons converge on the motoneurons of a given hand muscle occupies several square millimeters. Given the number of hand muscles, these territories are so large that they overlap extensively with one another. Second, single cortical neurons often provide monosynaptic output connections to the spinal motoneuron pools of multiple muscles. Single cortical neurons thus may provide output to muscles acting on multiple digits, and even on the wrist, elbow and shoulder as well. Third, the entire M1 upper extremity representation is interconnected by horizontal axon collaterals that interlink not only the central digit core, but also the surrounding representation of more proximal muscles. As a consequence of this convergence, divergence and horizontal interconnectivity, neuronal activity appears throughout the hand representation during voluntary movement of even a single finger. In addition to this widely distributed base of activation, in humans a somatotopic gradient is superimposed, with more activation laterally during thumb movements, and more activation medially during movements of the little finger.

### Plastic Changes in Cortical Finger Movement Representations

The widely distributed organization provided by convergence, divergence and horizontal connectivity in the pathway from the primary motor cortex to spinal ►motor neuron pools also provides a flexible substrate that can undergo plastic reorganization. Some plastic changes are mediated very rapidly by altered patterns of intracortical inhibition. The hetero-synaptic processes of long-term potentiation and depression also contribute to plastic reorganization. As time passes, some existing synapses are pruned away and new synaptic connections form. All these underlying processing contribute to reorganization of ►motor maps.

Plastic reorganization occurs during motor learning (►Motor learning) in normal subjects [7]. Repeated practice of particular hand and finger movements expands the representation of the practiced movements and of the muscles involved in producing them. Reorganization also occurs after injury [8]. After amputation of the hand, stimulation of the M1 hand representation evokes larger than normal contractions of the remaining proximal muscles. Voluntary attempts to move the phantom hand result in contractions of proximal muscles that would not normally contract during hand movements [9]. Reorganization of the motor map occurs as well after damage to the primary motor cortex [10]. If damage to the hand representation is partial and the subject is made to use the affected hand, some cortical territory that previously had represented proximal movements changes to represent distal movements. If damage to the primary motor cortex hand representation is complete, representation of finger movements in other cortical motor areas expands. Plastic reorganization of finger movement representations thus underlies both normal motor learning and recovery from nervous system injury.

## Definition

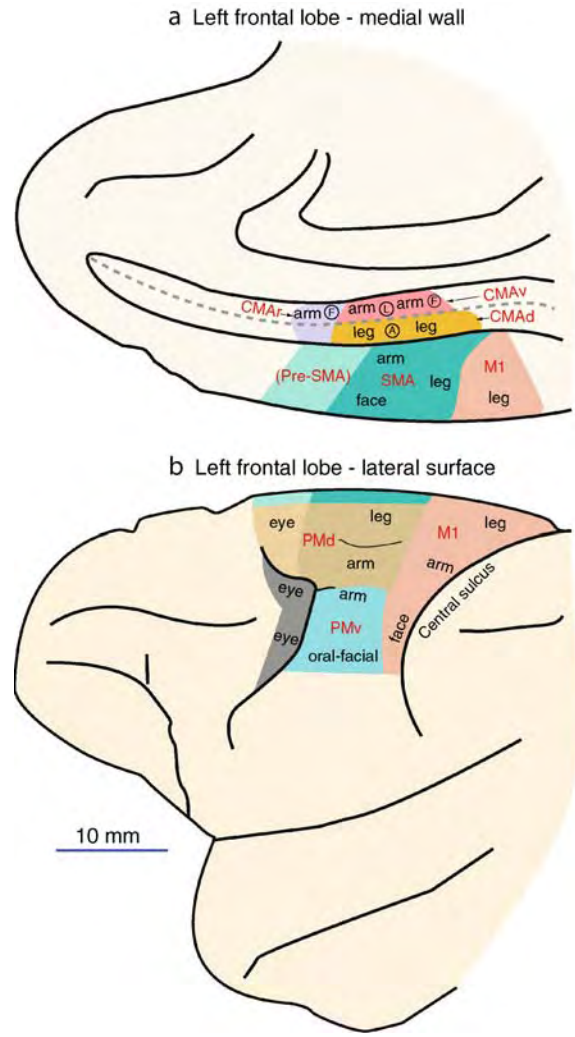
Movement planning and execution are the products of distributed neural processing involving many areas of the brain. This essay focuses on the role of motor areas of cerebral cortex, particularly primary motor cortex, in movement execution. Cortical motor areas are identified and their output capability is summarized in terms of the movements evoked by electrical stimulation. The synaptic organization of ►corticospinal neurons with motoneurons in the spinal cord is explained in terms of the selection of muscle synergies needed for producing coordinated limb movements.

## Characteristics

### Identification and Somatotopic Organization of Cortical Motor Areas

The cerebral cortex of mammals can be categorized into a number of specialized sensory, motor and association areas. In primates, these areas are particularly well developed and large. The motor areas of cerebral cortex are contained within the frontal lobe and include primary motor cortex or M1 located in the precentral gyrus just anterior to the central sulcus as well as several ►secondary motor areas. Six secondary motor areas have been identified in primates including the ►SMA (supplementary motor area) medial and anterior to primary motor cortex, dorsal and ventral ►premotor areas (PMd and PMv) on the lateral surface of the frontal lobe anterior to M1 and three ►cingulate motor areas located ventral to SMA in the cingulate gyrus [1,2]. The location of the primary and secondary motor areas is shown in Fig. 1 for a rhesus monkey cerebral hemisphere. Analogous areas have been identified in the human brain.

Primary motor cortex was first identified in the 19th century by applying electrical currents to the cerebral cortex of anesthetized animals. It was discovered that this electrical current evoked movements of specific body parts and that the representation followed an orderly pattern paralleling the anatomy of major body parts. The neuronal representation of motor and sensory functions associated with specific body parts is termed ►somatotopic organization and is a distinctive feature of cortical motor areas. The discovery of a somatotopic organization of electrically evoked movements in the cerebral cortex was strong evidence for localization of function in the brain. Cortical areas from which movement could be evoked were referred to as "electrically excitable". Electrical excitability or the ability to evoke movements with electrical stimulation is used as a means of identifying motor areas of the cerebral cortex. Movements can be evoked from both primary and secondary cortical motor areas, although significantly higher currents are required for secondary motor areas.



**Motor Cortex: Output Properties and Organization.**
**Figure 1** Location and general somatotopic organization of cortical motor areas of the macaque monkey brain based on ICMS evoked movements. (a) Motor areas on the medial wall of the left frontal lobe. (b) Motor areas on the lateral surface of the left frontal lobe. Motor areas are labeled in *red* and include primary motor cortex (*M1*), supplementary motor area (*SMA*), cingulate motor areas (*CMA*) and lateral premotor areas (*PMd* and *PMv*). The cingulate gyrus has been "unfolded" and represented as a two dimensional map. The *dotted line* represents the fundus (bottom) of the sulcus. The *small-circled letters* in the cingulate motor areas are included to show that in addition to the principal representation indicated, small patches of representation of the face (*F*), arm (*A*) and leg (*L*) also exist. (Modified from [3]).

Primary and secondary cortical motor areas can also be identified on the basis of their distinctive histological appearance including the thickness of various layers and the size of various cell types. This approach is

referred to as cytoarchitectonics. Based on this type of analysis, the cerebral cortex has been divided into numerous separable regions. An important principle of cortical organization is that areas of cerebral cortex identified on the basis of these anatomical criteria are often found to align closely with regions identified by functional criteria. For example, primary motor cortex corresponds with Broadman's cytoarchitectonic area 4.

Another identifying feature of cortical motor areas is the presence of corticospinal neurons. These are neurons that have a cell body contained within the cortex and an axon that projects to the spinal cord for the control of limb and trunk musculature. Similar neurons for control of facial and tongue muscles are called corticobulbar neurons because their axons terminate in the brainstem where motoneurons of these muscles are located. In primates, some corticospinal neurons, referred to as corticomotoneuronal cells, make monosynaptic connections directly with motoneurons and these connections are thought to be an important neural substrate underlying skilled use of the distal extremities, particularly the ability to make independent finger movements. Corticospinal neurons are found throughout primary motor cortex and secondary cortical motor areas, although the number of neurons is smaller for secondary cortical areas because the size of these areas is much smaller than primary motor cortex [1,2].

Electrical stimulation of cerebral cortex has been a highly informative approach to understanding cortical motor output organization. The classical early studies in humans by Penfield [4] and in non-human primates by Woolsey established the major features of body somatotopic organization that can be found today in nearly every textbook of neuroscience. Penfield and Woolsey summarized the general pattern of evoked movements from cortical stimulation by drawing a body surface representation, superimposed on the cortical surface and distorted in size to reflect the amount of cortex devoted to movements of each body part. These body surface representations, referred to as homunculi and simunculi for humans and monkeys respectively, indicate the location along the precentral gyrus where movements of different body parts can be evoked by electrical stimulation. The major features of the somatotopic organization of motor output from ►primary motor cortex (M1) are (i) largely separate areas devoted to the representation of the lower extremity, trunk, upper extremity, face and tongue with the lower extremity located medially and the tongue most laterally along the precentral gyrus, (ii) the representation is contralateral except for tongue, jaw and upper facial muscles and (iii) there is preferential representation of distal muscles, particularly muscles of the hand, face and tongue. These are the muscles most heavily involved in skilled movements and require the highest degree of fractionation in the patterns of activity across different muscles.

While the basic body plan of somatotopic organization revealed by the early stimulation studies is universally accepted, the degree to which a consistent and orderly somatotopic organization exists for muscles/movements within a major body segment has only been addressed in more recent studies [5]. Some of these studies have used cortical microstimulation in monkeys to identify activated muscles of the forelimb. Microstimulation consists of applying weak current pulses through a recording microelectrode. Using this approach, a consistent representation of forelimb muscles has been identified, consisting of a core representation of distal muscles (wrist and digit), a peripheral zone of proximal muscle (shoulder and elbow) representation and a large zone representing combinations of distal and proximal muscles separating the pure distal and pure proximal representations [6]. This pattern of forelimb representation is also supported by anatomical studies in which distal and proximal forelimb corticospinal neurons have been labeled with tracers and identified histologically [1,2]. Does the existence of a consistent somatotopic organization extend to movements of the hand including the wrist and individual digits? The homunculi and simunculi drawings based on early work would suggest this but the answer to this question is clearly no. Neurons involved in motor responses of the wrist and individual digits are completely overlapping within primary motor cortex [5]. In part this is due to the fact that the simplest movement of an individual digit actually involves the activation of a large number of distal muscles, not just the muscles of the digit to be moved but also muscles involved in stabilizing the other digits. Another factor is that individual corticospinal neurons rarely make synaptic connections with motoneurons of just one muscle. Rather these neurons activate combinations of muscles as functional synergies [7].

Cortical mapping using repetitive microstimulation of the cortex has typically involved applying brief (30 ms) trains of high frequency stimuli (330 Hz) to evoke twitch like movements. This has been and continues to be a very useful approach to cortical output mapping. However, if the stimulus train duration is lengthened from 30 ms to 500 ms, more complete movements can be evoked. These movements more closely resemble the time course, trajectory and velocity profile of normal voluntary movements. Graziano and colleagues [8] have exploited this approach to map the movements evoked from primary motor cortex and premotor areas on the lateral surface of the hemisphere (PMd and PMv). An important feature of these movements is that long duration repetitive stimulation brings the hand to the same end point in space regardless of the starting position. The cortical map

obtained using this approach contains four subregions from which different, seemingly purposeful movement responses can be elicited. Long duration stimulation of one subregion tends to bring the contralateral hand to locations in space in front of the chest. Stimulation within this part of the map also evokes a variety of hand postures similar to ones observed during object manipulation behavior including (i) grip with the thumb against the forefinger, (ii) fist formation, (iii) opening of the hand with all digits splayed, (iv) various rotations of the wrist and (v) pronation and supination of the forearm. The cortex from which these movements can be evoked corresponds to the forelimb representation of primary motor cortex, an area that has long been known to emphasize the control of manual dexterity. A second subregion corresponds to hand locations at the mouth and stimulation within this region produces a grip posture with movement of the hand to the mouth and often opening of the mouth. This area corresponds to a part of area PMv known to be involved in the cortical representation of grasp postures and interactions between the hand and mouth. A third subregion termed PZ or polysensory zone contains neurons that respond to tactile stimuli on the face and arms and visual stimuli near the face and arms. Stimulation of sites in the polysensory zone evokes apparent defensive movements. This is a multimodal subregion that is also largely within area PMv. The fourth subregion is contained with PMd. Stimulation within this subregion produces reaching movements in which the wrist straightens, the fingers open as if to prepare for grasp and the arm extends outward from the body.

## Organization of Corticospinal Output

Historically, a major controversy has existed over the issue of what is represented by the corticospinal neurons that constitute primary motor cortex output. Is it muscles that are represented or movements? To some extent, this controversy has lingered on because terms have not been adequately defined, but also because there is a genuine and important issue to be resolved. Obviously muscles are represented in the sense that corticospinal neurons make synaptic connections with motoneurons and activate muscles. However, the real issue might be redefined in terms of the way in which muscles are represented and its possible significance. For example, what would be implication of an output representation in which small pieces of motor cortex, like pieces of a mosaic or keys of a piano, were devoted to the representation of single muscles? This would constitute a muscle representation in the most extreme sense. In this case, the central motor program, containing information about the movement to be produced would select the appropriate keys (muscles) of the motor cortex keyboard to produce the desired movement. The role of motor cortex output would then simply be to devote a piece of tissue and corresponding corticospinal neurons to each individual muscle and give appropriate parts of the brain access to these muscle specific representations. It is now known that this is not the way motor cortex output is organized. In large part, individual corticospinal neurons do not have synaptic contacts confined to motoneurons of individual muscles. Rather, individual corticospinal neurons make synaptic contacts with motoneurons of multiple muscles representing functional muscle synergies [7,9–11]. The set of muscles influenced by a corticospinal neuron are referred to as its ►muscle field. Corticospinal neurons have a clustered organization in layer V of primary motor cortex and there is evidence that the individual neurons within a cluster have similar muscle fields. The set of corticospinal cells selected for activation by the central motor program is obviously dependent on the desired movement. Simple isolated movements of the wrist involve coactivation of forearm, wrist and digit synergist muscles and the corticospinal neurons activated for this task tend to have only distal muscle fields. Most importantly, single neurons engaged in isolated wrist movements do not act upon single muscles; rather, these neurons activate combinations of wrist and digit synergist muscles. Many of the same corticospinal neurons that facilitate motoneurons of multiple agonist muscles also simultaneously inhibit motoneurons of multiple antagonist muscles. To aid with the movement, the activity of the antagonist muscles must be suppressed as the agonist muscles contract and shorten. This combination of multiple facilitated agonist muscles and suppressed antagonist muscles constitutes a simple functional synergy for movement about a single joint. The representation of such functional muscle synergies goes beyond a simple muscle representation – it is the representation of a set of muscles for a particular movement. Hence, it can be argued that movements are, in fact, represented in the synaptic output organization of primary motor cortex. The corticospinal representation of functional muscle synergies also extends to more complex multi-joint movements. Reaching to grasp an object requires coactivation of muscles at multiple proximal and distal joints. Many corticospinal neurons involved in such reaching tasks make synaptic connections with motoneurons of both distal and proximal muscles [7]. These muscle combinations represent multi-joint functional synergies involved in reaching. To conclude, the output organization of primary motor cortex can be viewed in terms of the functional muscle synergies represented in the synaptic connections of corticospinal neurons with motoneurons. These muscle synergies and their combinations are the cortical building blocks the central motor program must work with to produce the diversity of skilled movements characteristic of primates.

# Motor Disorders

### Definition

Motor disorders may be neurologically classified as (i) paralysis due to dysfunctions of ►skeletal muscle, ►neuromuscular junction, ►brainstem or spinal skeleto-►motoneurons; (ii) paralysis due to damage to the ►corticospinal tract, ►corticobulbar tracts, or fibers descending from the brainstem (see ►spasticity); (iii) non-paralytic and ►apraxic dysfunctions of purposive movements resulting from lesions of the ►cerebral hemispheres; (iv) disorders of the ►basal ganglia (see ►Parkinson disease, Huntington's disease; Tourette's syndrome); (v) dysfunctions of coordination (►ataxia) resulting from lesions of the ►cerebellum and its inputs and outputs.

►Basal Ganglia
►Cerebellar Functions
►Corticospinal Tract
►Huntington's Disease
►Neuromuscular Junction
►Parkinson Disease
►Spasticity
►Tourette's Syndrome

# Motor Efference

### Definition

The motor commands from the brain leading to movement.

►Large-Fiber Sensory Neuropathy
►Effect on Proprioception

# Motor Equivalence

### Definition

Motor equivalence implies that the same movement or motor program can be executed by different muscle and/or joint assemblies.

►Motor Control Models

# Motor Error

### Definition

The difference between the present location of an effector (e.g., the hand or the eye) and its desired location. Neural correlates of motor error have been described in a variety of brain centers.

►Movement Sequences
►Eye-Hand Coordination

## Motor Evoked Potential (MEP)

### Definition

Electrical potential recorded over a muscle, evoked by electrical or magnetic stimulation of the nervous system.

►Transcranial Magnetic Stimulation

## Motor Fluctuations in Parkinson Disease

### Definition

Fluctuations in the severity of motor symptoms of Parkinson disease several times per day, related to the long term use of levodopa and disease progression

►Parkinson Disease
►Structures/Processes/Conditions: Parkinson Disease

## Motor Imagery

### Definition

The ability to mentally simulate a particular movement without actual execution. Neuroimaging studies have shown the involvement of several motor brain areas during motor imagery.

►Action Representation

## Motor Invariant

### Definition

An invariant is a quantity that remains unchanged under a set of transformations. For example, the curvature of a curved hand movement trajectory is invariant under the transformations of rotation and translation.

►Arm Trajectory Formation

## Motor Learning

Vlastislav Bracha, James R. Bloedel
Department of Biomedical Sciences, Iowa State University, Ames, IA, USA

### Definition

►Motor learning is the process of acquiring new motor skills. Common examples of motor learning are learning to ride a bicycle or to play tennis. Motor learning is essential for success under novel or changing environmental contexts and is thus ubiquitous. It participates in speech acquisition, in learning to use tools and machines, in the acquisition of artistic and athletic skills, in tuning motor performance during development and aging, and in compensating for movement deficits associated with a bodily injury.

### Characteristics

In the current literature, the term motor learning has been applied to a heterogeneous group of adaptive phenomena and as such it defies a simple definition. In general, motor learning pertains to processes of adaptively modifying the spatio-temporal structure of movements, of forming new or adjusting existing sensori-motor transformations and of forming new movement sequences.

Motor learning is distinct from other forms of learning, such as learning the spatial structure of the environment, remembering events and temporal associations between events, learning symbols and concepts, or autobiographical memory. The outcome of motor learning is an acquired modification of sensori-motor processing resulting in meaningful changes in motor performance that achieves a desired behavioral goal in specific environmental and motivational circumstances. A typical property of motor learning is that it progresses through a series of trial and error performances. Motor learning usually requires a large number of repetitions to achieve an asymptotic performance. The ►motor error, which is derived from the difference between the expected and actual results of movement, is a pivotal notion in conceptual and computational models of motor learning.

Similar to other forms of learning and memory, motor learning is thought to have explicit and implicit components or phases. When learning a new motor skill, successful movement generation frequently requires involvement of attention and awareness. At this stage, the movements are under an explicit, i.e., conscious and verbally describable control. As the learning progresses, movements become smoother, faster and automated. Eventually, well-trained movements become implicit, i.e. fully automatic, requiring

little or no conscious effort. However, some types of motor learning, such as the adaptation of hand movements to altered visual feedback or the classical conditioning of eyeblink responses, can occur exclusively in the implicit domain, with the subject either being unaware of the learning or being unable to report on the relevant details of learning.

Motor learning in natural conditions involves the complex coordination of a number of motor subsystems. For example, an efficient tennis stroke requires hitting the incoming ball at a precise time and place relative to the tennis player's body with a tennis racquet having precise speed, orientation and trajectory of movement. To achieve this, the player has to learn to observe the ball and extrapolate its trajectory, to run to the anticipated place of stroke execution, assume the appropriate posture and execute a complex and precisely timed kinetic chain of leg, torso and arm movements. These movements are synchronized with eye and head movements and with respiration, and they have to be adapted to the physical properties of the court, ball and the tennis racquet. To reduce this complexity to a level amenable to scientific analysis, motor learning is studied in simplified motor learning models.

## Models of Motor Learning

The neural substrates of motor learning are investigated in experimental models that focus on its specific aspects in specific motor sub-systems. The motor learning paradigms are usually designed to control the learning environment, to provide reliable measurements of executed movements and access to measurements or manipulations of the nervous system. The most common learning paradigms fit in one of the following categories.

### *Adaptive Modifications of the Vestibulo-ocular Reflex*

The purpose of the vestibulo-ocular reflex (VOR) is to stabilize images on the retina during head movements. Head movements stimulate the vestibular apparatus and the resulting sensory information is processed in VOR neural circuits to produce compensatory eye movements that stabilize the visual field. The VOR is under strong visual control. Inadequate VOR operation produces slip of the visual image on the retina, and this visual error signal drives adaptive VOR modifications. To induce VOR adaptation, experimenters usually introduce an artificial visual error by moving the subject's surroundings or by placing reversing or magnifying optical devices in the visual path. By using these tools, the VOR could be canceled, its direction reversed or its amplitude changed. VOR adaptation is one of the oldest models of motor learning, and it has yielded an advanced understanding of cerebellar and brainstem circuits controlling this adaptive process. This knowledge makes the VOR model well suited for studies at the neural network and cellular levels [1].

### *Classical Conditioning of Withdrawal Reflexes*

Withdrawal reflexes protect body parts from injury by withdrawing them from aversive stimuli. Withdrawal reflexes, such as an eyeblink response or a limb withdrawal, can be classically conditioned. In classical conditioning, subjects are presented with an initially irrelevant stimulus (conditioned stimulus) that is followed by the withdrawal-eliciting aversive stimulus (unconditioned stimulus). During repeated pairings of these stimuli, the subject learns to respond to the conditioned stimulus before the unconditioned stimulus reaches the body surface. The learned anticipatory response is called the conditioned response. Although eyeblink conditioning was originally studied in the context of associative learning, more recently it has also been categorized as a form of motor learning, most likely because of its dependence on the cerebellum and because it results in the formation of new, well timed motor response. Similar to the VOR, researchers employing the eyeblink conditioning model have been extremely successful in delineating involved neural circuits and in developing experimental strategies that address the nature and location of underlying plastic changes [2,3]. It has been shown that a simple form of eyeblink conditioning, known as ►delay eyeblink conditioning, is controlled predominantly by cerebellar, mesencephalic, pontine and medullar neural circuits. The more complex forms of conditioning, such as ►trace eyeblink conditioning, recruit additional CNS components, such as the hippocampus.

### *Learning New and Optimizing Existing Visuo-motor Skills*

This broad category of motor learning paradigms incorporates movements executed under visual feedback. An example of visuo-motor skill adaptation is learning to trace two-dimensional objects by hand or learning to reach for visually detected objects. In a typical tracing task the subject traces repeatedly a two-dimensional object with a pen. It has been shown that with training, tracing movements become faster, smoother and more accurate. The tracing task can be experimentally manipulated by altering the visual feedback. This can be achieved by asking the subject to trace the image reflected in a mirror, which reverses the normal relationship between directions of the eye and hand movements. Another common variant of this task involves tracing objects on a computer screen with an input device such as a computer mouse or tablet. The relationship between the direction and amplitude of the hand and cursor (and therefore the eye) movements can be manipulated with appropriate software. Since tracing tasks require close coupling between eye and hand movements, disrupting their normal relationship

leads to motor errors that drive a powerful and surprisingly fast motor learning.

Visuo-motor learning attracted large attention following the discovery that amnesiac subjects with injuries of the medial temporal lobe and hippocampus can learn the mirror tracing task despite being severely deficient in explicit memory tasks. This observation led to the modern concept of relatively independent explicit and implicit memory systems. It should be noted, however, that although motor learning is frequently considered to be a form of implicit memory, many motor learning tasks have explicit components or could be affected by explicit factors.

### Adaptation to Movement Perturbations

Models in this category utilize external forces to interfere with ongoing movements. Some paradigms perturb movements with continuously applied mechanical loads that are attached to moving body parts or with robotic devices that can apply arbitrary force fields to the moving limb. Other paradigms in this category use temporary interference of the movement, such as a sudden presentation of an obstacle in the movement trajectory, a sudden change of the speed of a treadmill on which the subject walks, or a sudden movement of a platform on which the subject stands. The motor learning in these tasks results in formation of various task-dependent anticipatory feedforward strategies and feedback adjustments that counter the effects of the interference and improve task performance.

### Learning of Movement Sequences

This popular category of motor learning paradigms requires subjects to learn sequences of movements [4]. Common variants are the serial reaction time task (SRT) and the 2xN task. In the SRT task subjects are presented with a series of targets that appear, one by one, on the computer screen in one of several possible positions. Subjects are required to press as fast as possible a key that corresponds to the presented target position. The repeated presentation of a specific sequence of targets leads to motor learning as evidenced by a significant decrease in key press reaction time. The 2xN task was originally developed to make sequence learning amenable for studies in primates. In this task, subjects are presented with a sequence of N (5 or 10) pairs of lighted keys on a $5 \times 5$ or $10 \times 10$ keypad. The subject is required to press the keys in each pair in the correct order (initially unbeknown to the subject). Once the subject determines by trial and error the correct order in the first pair, the next pair of keys in the sequence is presented. Any error resets the sequence, and the sequence presentation starts with the first pair of keys again. The presentation of the sequence continues until the correct order in each pair is mastered and the movement sequence is learned.

Sequence learning tasks are popular among neuropsychologists, who use them to address questions such as the participation of awareness in motor learning or the role of explicit and implicit memory systems.

### Rodent Motor Learning Paradigms

Advancements in motor learning research will depend on a thorough knowledge of how the underlying neural circuits become modified during learning and what are the cellular and molecular mechanisms of this process. For studies at the cellular and molecular levels, developing motor learning models in rodents will be necessary. Much progress has already been made in exploring neuronal function using genetically modified rodent models (e.g. knockout mice). Traditional models of motor learning in rodents are learning of the skilled forelimb reaching movement, modifications and conditioning of licking movements and learning acrobatic tasks, such as maintaining balance on a rotating horizontal cylinder. More recently, the eyeblink conditioning paradigm and the adaptation of the VOR were successfully implemented in rodents.

## Neural Substrates of Motor Learning

Motor learning depends on motor circuits that generate the movement to be learned and on associated components of sensory systems. Since the sensory and motor systems are organized in a modality-specific and somatotopic manner, circuits for specific forms of motor learning should be at least partially segregated based on involved parts of the motor system and on the type of sensory information utilized.

Research on motor learning involves several stages of analysis. At the first stage, an adequate model of motor learning is developed and its behavioral properties are characterized. Next, circuits that are involved in and essential for the studied form of motor learning are identified. This second stage involves a variety of methods, such as the recording of brain activity, lesions or pharmacological manipulations of individual circuit components, and neuroanatomical tracing techniques. At the third stage, the operating mechanism of the circuit that produces and modifies the behavior is addressed to reveal components that likely undergo plastic changes resulting in motor adaptation. At this stage, a combination of brain activity recording, brain stimulation and neuropharmacological techniques is most relevant. By the fourth stage, the techniques of cellular and molecular biology are deployed to reveal the cellular mechanisms of plasticity in brain regions identified during the previous stage of investigation.

The more complex forms of motor learning, such as learning of motor sequences, now are mostly at stages one and two where their properties and the underlying circuits are being identified. Because a large portion of these studies are being done in human subjects, most of

them focus on testing patients with brain pathologies and on using non-invasive brain imaging methods, such as functional MRI. A common conclusion from several paradigms is that at higher levels, the complex forms of motor learning are executed by circuits that include motor, sensory and associative areas of the cerebral cortex, basal ganglia and cerebellum [5,6]. This lively area of research produced important insights into the roles of awareness and explicit and implicit processes in movement sequence learning [4]. In another interesting development, circuits participating in movement sequence learning and in perturbation adaptation were shown to change over the course of learning, with some structures being more active at initial stages of learning and less involved during the recall of consolidated memory traces [7,8].

Research on simple forms of motor learning, such as VOR adaptation and eyeblink conditioning, has reached the more advanced stages. Their underlying circuits have been described in large detail, and although not all important issues pertinent to circuit operation have been resolved, some investigators are pursuing possible molecular mechanisms of neural plasticity. This research is driven mostly by the cerebellar learning hypothesis, which proposed the cerebellar cortex as a likely place of motor learning plasticity [1,9]. One intriguing feature of these models is that the underlying learning most likely occurs within circuits that generate the learned or modified response. Consequently, most attempts to interfere with learning at the circuit level also affect response execution. This produces uncertainty in whether the failure to learn was related to the animal's incapacity to execute the behavior properly (a performance deficit) or to the disruption of learning mechanisms. This dilemma, the conflicting of learning and performance hypotheses, has been partially overcome in the eyeblink conditioning model using techniques of temporary inactivation during response acquisition or consolidation. This is uniquely possible in eyeblink conditioning because the animal does not need to generate responses in order to learn them.

One major challenge in neuronal circuit level studies of eyeblink conditioning is that the underlying neuronal networks are comprised of mutually interconnected structures with an abundance of feedback connections. In networks of this kind, contributions of individual nodes to properties of the behavior or learning are difficult to discriminate, because neuronal activity patterns at a particular node of the network are usually influenced by a set of both up-stream and down-stream structures, and because effects of manipulations of individual parts of the circuit can propagate to much larger areas of the network via non-specific tonic interactions [10]. Such network properties of motor learning circuits will have to be accounted for during cellular and molecular studies. Ultimately, a full understanding of motor learning will include the synthesis of multi-paradigm hierarchical knowledge acquired at the behavioral, neural network and cellular levels.

## Motor Pattern

### Definition
The rhythmic, repeating sequence of motor neuron activity produced during an actual or fictive motor act.

## Motor Pattern Generator

### Definition
Motor pattern generator in neuroscience is sometimes called "central pattern generator," which can be defined as neural networks that can endogenously, without rhythmic sensory or central input, produce rhythmic patterned outputs or as neural circuits that generate periodic motor commands for rhythmic movements such as locomotion. Central pattern generator produces rhythmic outputs even in isolation from motor and sensory feedback from limbs and other muscle targets.

►Central Pattern Generator (CPG)
►Rhythmic Movements

## Motor Primitive

### Definition
A building component of body movements, usually consisting of coordinated kinematic variables (i.e., joint angles) or dynamic variables (i.e., muscle activations). In animal locomotion, for example, motor primitives are coordinated hip, knee, and ankle angles that operate cooperatively either inphase or antiphase. Motor primitives are believed to be a neural mechanism that realizes coordinated body movements, without handling all individual degrees of freedom in body movements independently.

►Degrees of Freedom
►Rhythmic Movements

## Motor Responsiveness

►Sleep – Motor Changes

## Motor Schema

### Definition
Set of non-conscious programmes and habits underpinning skilled automatic movements. These involve both sensory input to coordinate and motor output to effect.

►Large-Fiber Sensory Neuropathy
►Effect on Proprioception

## Motor Set

### Definition
The process by which the central nervous system optimizes the capacity to perform a movement prior to movement onset. This is achieved by invoking predictive or feed forward control mechanisms usually derived based on previous, related experience under the same behavioral conditions.

## Motor Stereotypies

### Definition
Motor stereotypy refers to repetitive motor behaviors that do not produce tissue damage, such as the same movement occurring multiple times in a short time period like arm-waving, body-rocking, leg-kicking, and head-nodding. Stereotypic motor behavior is a widespread phenomenon of many neurologic and psychiatric disorders. Studies on the mechanisms controlling motor stereotypies have suggested roles of nigrostriatal dopamine and an enhanced activation of neurons located in the striosomal compartment in the striatum.

►Dopamine
►Sensorimotor Learning and the Basal Ganglia
►Striatum

## Motor Strategy

### Definition
A specific way of performing a behavior. Examples of choices between different motor strategies are forward walk vs. backward walk, trot vs. gallop, and rostral scratch vs. caudal scratch.

►Scratching

## Motor Synergy

### Definition
Effective reduction of degrees of freedom in body movements by coordination and regulation of kinematic (i.e., joint angles) or dynamic (i.e., muscle tensions) variables.

►Degrees of Freedom
►Theories on Motor Learning

## Motor Threshold

### Definition
The minimal intensity of magnetic or electrical stimuli, which evokes muscle activation. Note that when stimulation is applied over the scalp, the motor threshold corresponds to the cortical threshold and can be taken as an estimate of the global excitability of the motor pathway.

►Transcranial Magnetic Stimulation

## Motor Unit

### Definition
The motor unit is a single motoneuron plus the number of muscle fibers it innervates. In fine movements made by, for example, the small muscles of the hand or the eye muscles, there are only a few muscle fibers per motor unit, whereas in large muscles like the gastrocnemius, a muscle used in walking, there are 2,000 muscle fibers per unit.

## Motor Unit Action Potential

### Definition
Extracellular potential detected when all of the muscle fibers in a single motor unit are stimulated.

►Electromyography

## Motor Unit Enlargement

### Definition
When some of the nerve supply to a skeletal muscle is disconnected to partially denervate the skeletal muscle, the nerve fibers or axons that have intact connections with muscle fibers can sprout axons to reinnervate denervated muscle fibers. Thereby each motor unit will include more muscle fibers than normal – motor unit enlargement.

►Axonal Sprouting in Health and Disease

## Motor Units

Robert E. Burke
Laboratory of Neural Control, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD, USA

### Definition
First defined by Sherrington in 1925, the ►motor unit is the combination of an ►alpha motoneuron or a ►beta motoneuron (or motor neuron) and the set of extrafusal striated muscle fibers (called the ►muscle unit portion) that are innervated by it. ►Gamma motoneurons that exclusively innervate specialized muscle fibers in muscle spindle stretch receptor organs do not form conventional motor units. In normal limb and trunk

muscles, each muscle fiber in a muscle unit receives a synaptic contact, or ►neuromuscular junction, from the same motoneuron and no other. The motoneurons that innervate muscle units in a given muscle are arranged within the spinal cord or brain stem in localized groupings called "motor nuclei," which occur in predictable locations in the ventral horn of the spinal cord. From a functional standpoint, muscles are simply populations, or "pools," of muscle units arranged more or less in parallel to generate force.

## Characteristics

### Quantitative Description

Muscles vary widely in size and function, from tiny muscles that move the eyeball and eardrum, to relatively huge masses that control limbs and trunk movements. Motor unit populations exhibit an equivalent range of characteristics that represent important functional specializations. In limbs and trunk, the number of muscle units in a given muscle (or motoneurons in its ►motor nucleus) is usually larger in more massive muscles than in small ones, varying from dozens in small intrinsic finger muscles to hundreds in knee extensors in man. In normal muscles, the fibers in an individual muscle unit are intermingled with those of dozens of other units, such that few fibers of a given unit are contiguous. The average number of muscle fibers in a given muscle unit ("►innervation ratio") also varies in a similar pattern, i.e., generally larger in large muscles than in small ones. These generalizations do not apply to small, specialized muscles innervated by cranial nerves (e.g., extraocular muscles), which can contain many hundreds of individual muscle units, many of which receive innervation from more than one motoneuron.

### Higher Level Structures

Motor units are the final elements in the control of body movements by the central nervous system. Motoneurons integrate synaptic information delivered by peripheral sensory afferents, local neural circuits within the spinal cord itself, and control signals descending from the brainstem and higher centers in the brain, to produce trains of action potentials that activate muscle units that generate output force. These control systems are organized to produce coordinated patterns of action by multiple motor nuclei.

### Lower Level Structures

The motor units in virtually all mammalian muscles can be divided into two broad groups, called slow twitch or fast twitch, based on the mechanical, morphological, and biochemical properties of their muscle unit fibers (►muscle fiber types). In general, all fibers in a muscle unit display the same muscle fiber type. Slow twitch muscle units (called type S) contract relatively slowly because of the molecular forms of contractile and regulatory proteins that they contain. Type S generally produces relative small forces, but they exhibit great resistance to mechanical fatigue during prolonged activation because they contain a high proportion of enzymes and mitochondria that provide energy by efficient oxidative, or aerobic, metabolism. Fast twitch units obviously contract more rapidly because they have a different complement of contractile and regulatory proteins, and they exhibit a wide range of resistance to mechanical fatigue. In many muscles, the fast motor units fall into two subgroups, one (called type FR) that is much more resistant to fatigue than the other (called type FF). Although the FR and FF muscle units have slightly different molecular species of contractile proteins, the major difference between them is that FR units have higher concentrations of oxidative enzymes and mitochondria than the FF units. However, both FR and FF units have a relatively high abundance of enzymes that can metabolize substrates like glycogen anaerobically, while type S units have much less anaerobic capacity. Both FR and FF fibers contain large stores of glycogen, a polymerized sugar that represents a stored source of energy that enables them to function during short bursts of forceful activity. In contrast, type S fibers have relatively little glycogen and anaerobic enzymes. These differences have important functional consequences. In general, type S motor units produce the smallest force output, type FF units are the largest forces, and type FR units are intermediate. These differences are related to the numbers of muscle fibers in the respective muscle units (FF > FR > S), by differences in the cross-sectional areas of the individual fibers (FF ≥ FR > S), and, to a lesser degree, by the specific force that can be generated by each fiber (FF = FR > S).

### Structural Regulation

Motoneurons differentiate early during embryonic spinal cord formation and migrate to the ventral part of the gray matter. The motoneuron axons that will innervate a specific muscle leave the spinal cord via the ventral roots and find their way to the primordial muscle, where they branch repeatedly to make neuromuscular synaptic junctions on the newly formed muscle fibers. During fetal and early postnatal life, immature muscle fibers receive innervation from multiple motoneurons. However, this polyneuronal innervation subsequently disappears during a competitive process that leaves only one motoneuron per muscle fiber in the mature muscle. At the same time, muscle fibers differentiate into the three major types described above. There is evidence for a strong element of genetic pre-specification of both motoneurons and muscle fibers, which results in the relative proportions of the different ►motor unit types found in various muscles.

## Higher Level Processes

Increasing and decreasing the number of motor units active in a given muscle (►recruitment and de-recruitment, respectively) is the major mechanism by which the central nervous system adjusts muscle force. The identities (i.e., types) of the active motor units are also critical to this process. Under many conditions, units in a given muscle (a motor unit pool) are recruited in a predictable sequence starting with type S, progressing to include type FR, and ending with type FF units as more and more force is required. De-recruitment ordinarily follows the reverse sequence. This sequence is often referred to as the "size principle," because the first units (type S) recorded generally produce small forces, while the largest force (type FF) units are normally activated only when maximum force is demanded. Simultaneous activation of an entire motor unit pool can occur in sudden, ballistic movements. In unusual situations, such as rapid alternating movements, there may be selective recruitment of the larger, fast twitch units. A second mechanism for force control, often called "rate coding," involves highly non-linear relations between the frequency and pattern of motoneuron firing and the force output from its muscle unit. Orderly recruitment sequences and rate coding both depend on interactions between intrinsic properties of the motoneurons themselves and the organization of synaptic input to them.

## Lower Level Processes

The motoneurons of type S motor units exhibit greater intrinsic excitability than those of the fast twitch units because of a complex interaction between their smaller size, the higher density of certain synaptic input systems, and the influence of active membrane conductance channels that promote repetitive firing. Certain voltage-sensitive conductances (including calcium and persistent sodium channels), located mainly in motoneuron dendrites, can produce self-sustained depolarization ("plateau potentials") and firing under certain conditions, particularly in the presence of neuromodulator substances such as serotonin. Specialized membrane conductances activated by action potentials produce after hyperpolarizations that limit the maximum frequencies at which motoneurons can fire, which are lower in slow than in fast twitch cells. These features of motoneurons fit the properties of their muscle units. Type S units attain their maximum force output at lower frequencies than fast twitch units. The pattern of motoneuron firing also affects force output, because insertion of short intervals in a train can generate sustained, non-linear enhancement of output force.

## Process Regulation

The properties of muscle units are malleable to some extent by usage. For example, endurance exercise training (e.g., distance running) can greatly enhance the oxidative capacity of muscle fibers, as well as their blood supply. Muscle fibers shrink somewhat, facilitating oxygen and substrate entry, which increases their resistance to fatigue at the price of some loss of overall force capacity. On the other hand, resistance training (e.g., weight lifting or sprint running) favors growth of muscle fiber diameter (hypertrophy), particularly among the fast twitch fibers, greatly enhancing force production but with little change in oxidative capacity or fatigue resistance. Neither form of exercise training produces significant change in the molecular nature of the contractile or regulatory proteins in muscle fibers (i.e., fiber types remain basically unaltered).

## Function

Motor units are the quantum elements in all movements. Type S motor units are ideally suited to maintain posture, which requires sustained activity without fatigue but generally small forces. Precise postural adjustments can be made by recruitment and de-recruitment of the small force type S units. Movements that are more vigorous like walking and running require more rapid contraction with moderate forces, with considerable resistance to fatigue. Such actions can be generated by recruitment of the type FR units. Greater force demands, such as during jumping and lifting heavy weights, are intermittent actions that need power but little fatigue resistance. Recruitment of the large force but fatigue-sensitive type FF motor units occurs mainly during this type of activity. The proportions of S, FR, and FF motor units in different limb and trunk muscles accurately reflect differences in the way muscles are used in different mammals. Muscle units with greater oxidative capacities exert a relatively high cost on metabolic maintenance, so their proportions are adjusted quite precisely to fit lifestyle demand.

## Pathology

The most common cause of motor unit dysfunction is trauma to peripheral nerves. Motoneurons usually survive damage to their axons unless the site is very close to the spinal cord. ►Motor axons have considerable ability to re-grow to reinnervate muscles, although the specificity found in the original process during embryonic life is largely lost in adult animals. Muscle fibers that are reinnervated after nerve damage are re-specified to the type dictated by the motoneuron, but there is eventually some return to the coordinated properties described above. Motoneurons are especially susceptible to viral infection in poliomyelitis, which can cause cell death and permanent disability. There are several neurodegenerative diseases that cause motoneuron death, the most well known being amyotrophic lateral sclerosis (ALS). In most victims, these dreadful diseases progress inexorably to complete motor disability.

### Therapy

Prompt surgical repair to injured peripheral nerves can result in good recovery of motor functions, although the process is slow. Happily, thanks to vaccination programs, poliomyelitis has almost disappeared in industrialized countries. Unhappily, the cause of motoneuron degeneration in ALS and allied disorders remains unknown, and there are no effective therapies for them.

## Movement Direction

### Definition

The line or course pursued by a moving body part (e.g. the hand). If the position in space of the body part, at a given instant, is represented by a vector (i.e. a triple of coordinates in a specific reference frame), its motion is described by a vector-valued function of time (movement trajectory). The time derivative of this function, the movement velocity, is a vector-valued function. At each instant, this vector is tangent to the trajectory and describes the instantaneous direction of movement as well as the instantaneous rate of change of the distance traveled along the trajectory (speed or tangential velocity).

►Reaching Movements

## Movement Discrimination

►Proprioception and Orthopedics

## Movement Field (of a Neuron)

### Definition

The region of space that will elicit a discharge in a motor-related neuron when movements are directed to the region. In particular, for eye movements, movement fields are regions of visual space for which saccade-related neurons will discharge when the saccade terminates in the region.

►Saccade, Saccadic Eye Movement
►SC – Motor Map terminates in the region

## Movement Field (of Saccade-related Neurons)

### Definition

The oculomotor space occupied by saccades accompanied by the discharges of the neuron in question (often defined in retinotopic coordinates but other coordinate systems are sometimes used).

►Saccade, Saccadic Eye Movement
►SC – Tectal Long-Lead Burst Neurons

## Movement (or Motor) Planning

### Definition

Processes whereby the global goal of the action is strategically defined, and the sequence of elementary

movements between intermediate goals is organized. These processes are based on the use of a large set of sensory and memorized information about the subject's environment, as well as on the subject's motivational drive resulting from the behavioral value of the anticipated outcome of the upcoming action.

►Eye-Hand Coordination

## Movement (or Motor) Programming

### Definition

The motor program comprises all information necessary to send to the motor apparatus the motor commands to execute a movement. Whereas movement planning processes specify how the global action will be implemented, motor programming processes are invoked for the detailed preparation of each individual movement (localization of the target, choice of a desired final posture and/or trajectory, and of response duration or speed, …). The result of this pre-movement programming phase is a set of motor commands which, when launched will activate the motor apparatus in a proper way to bring the effector close to its desired position (even accurately programmed movements require additional online control to reach optimal accuracy).

►Eye-Hand Coordination

## Movement Sense

Janet L. Taylor
Prince of Wales Medical Research Institute and University of New South Wales, Sydney, NSW, Australia

### Synonyms

Kinesthesia; Proprioception

### Definition

Movement sense is the process by which movements of parts of the body relative to one another are perceived. The sense includes detection of movements as well as sensations that convey the timing, distance and velocity of such movements. Examples of such movements include movements about a single joint e.g. bending the elbow, simple movements about multiple joints e.g. turning the head and complex movements about multiple joints e.g. closing the hand. Both passive movements, which are imposed on body parts by an external force while the muscles remain relaxed and active movements, which are made by the contraction of muscles, can be perceived. It is difficult to separate movement sense from position sense. A movement is a change of position and a position can only be reached by a movement. However, if a change of position is imposed extremely slowly, then no sensation of movement arises. This implies that joint position and movement can be sensed separately.

### Characteristics

#### Quantitative Description

Movement sense can be tested by determining the smallest imposed movement that subjects can detect with the muscles relaxed [1]. Such testing has been performed for movements about most joints in the limbs and for movements of the neck and trunk. For all joints, faster movements can be detected more easily than slower movements. At velocities >1°/s, movements of 0.1–0.5° are commonly reported as detectable at limb joints and for rotation of the neck and trunk. At slower velocities (down to 0.1°/s) larger amplitudes (∼1–3°) are needed for movements to be detected. At even slower velocities (<∼0.1°/s), the threshold amplitude for detection no longer depends on velocity and subjects have no sensation of movement. Here, subjects detect change of position. The movement velocity is below that required to engage the movement sense. At the interphalangeal joints of the fingers and toes, much larger movements are needed for detection. The big toe has the largest reported detection thresholds (∼2° for velocities >10°/s and ∼20° at 1°/s) [2]. Movements can also be imposed during muscle contraction. It is not clear whether detection of movement is improved or impaired by active contractions as both results have been reported.

Movement sense includes the perception of velocity of movement. Discrimination between velocities of imposed movement has been tested at the finger, elbow and shoulder joints. Subjects are able to detect smaller differences in velocity when the reference velocity is slower. For movements of ∼50°/s, differences of ∼10°/s can be discriminated. For movements of 15°/s, differences of ∼4°/s can be discriminated at the elbow. At the shoulder, differences as small as 2°/s can be detected. When subjects match the velocity of an imposed movement with a movement of the other limb they are accurate to within ±5°/s over a range of velocities from 15°/s to 78°/s [3].

## Higher Level Structures

Movement sense is one of the components of the sense of proprioception, which allows perception of events intrinsic to the body. The other senses of vision, hearing, touch, taste and smell allow perception of events outside the body. Of all the senses, proprioception is most closely connected with the control of voluntary movement. Explicit knowledge about the body can be used to plan and direct movements. In addition, neural signals that contribute to the sense of proprioception can act directly at different levels of the motor system to influence muscle contractions.

## Lower Level Components

Perception of movements of parts of the body involves sensory receptors in the muscles, in the skin and in the joints. Muscle spindle primary endings are activated dynamically by stretching of the muscle. They respond to the velocity and acceleration of muscle stretch. Slowly adapting type II endings respond to the skin stretch that accompanies joint movements. Receptors located in joint capsules and ligaments respond to stretch of these structures. All of these sensory receptors are at the termination of fast conducting afferent neurons, which have cell bodies in the dorsal root ganglia. Signals from the receptors are mostly conveyed via these neurons directly to the medulla, although signals from the muscle receptors in the legs pass through a synapse in the spinal cord. From the medulla, signals are conveyed via the thalamus to the contralateral primary somatosensory cortex. The signals also go to other areas of the brain including the secondary somatosensory cortex, motor cortical areas and the cerebellum.

## Higher Level Processes

### *Central Nervous System*

Signals from muscle, joint and skin receptors are all conveyed to the contralateral primary somatosensory cortex. Imaging studies show that a number of other cortical areas are also activated when movements are imposed on a limb or when illusions of movement are generated by tendon vibration. These include the secondary somatosensory cortex, primary motor cortex, supplementary motor area, supplementary somatosensory area and the primary and associative auditory cortex [4]. The specific functions of the different cortical areas in perceiving movements are not known. However, the activation of the primary motor cortex appears to be strongly related to the perception of illusions of movement [5]. The cerebellum and basal ganglia are also activated by passive movements. Additional areas of the brain are activated during voluntary movements. One of these areas, the superior parietal lobe, may aid in matching internal knowledge about the production of the movement with the afferent signals that the movement generates [6].

## Lower Level Processes

### *Sensory Receptors*

Sensory receptors in the muscles, joints and skin respond both when movements are imposed on parts of the body and during movements made through active contraction of muscles.

#### *Muscle Spindles*

Muscles on one side of a joint lengthen with a movement while those on the other side shorten. Muscle spindles lie in parallel with muscle fibers and respond to lengthening of muscles. They contain two types of sensory endings, primary and secondary muscle spindle endings. While both types of endings increase their firing with stretch of a muscle, the primary endings have a larger dynamic response. They respond to the velocity of a stretch and to its acceleration, as well as to the change in length. Primary muscle spindle endings are major contributors to the sense of movement. Activation of these endings by vibration over the tendon of a muscle can generate an illusion of movement [7]. For example, when vibration is applied over the tendon of the biceps brachii, subjects feel that the arm is moving into extension. Higher frequencies of tendon vibration generate faster illusory movements. This implies that the velocity of movement is encoded by the frequency of firing of the muscle spindle endings.

Muscle spindles are under the control of the nervous system. In actively contracting muscles, muscle spindles fire in response to output from the nervous system as well as to any stretch of the muscle. Despite this complication, signals from the contracting muscle are still interpreted as movements.

#### *Joint Receptors*

Joint receptors are located in joint capsules and ligaments and respond to stretch of these tissues. Although most joint receptors fire near the ends of joint range, occasional receptors signal joint angle across the range of movement and could contribute to a sense of joint movement. When the axons of individual joint afferents are stimulated in humans, sensations of joint movement including twisting are reported. Muscle contraction can increase the stress on joints and ligaments and can increase signals from joint receptors.

#### *Skin Receptors*

Some areas of skin are stretched during movement of parts of the body. For example, in the leg, when the knee is bent, the skin over the kneecap is stretched while that behind the knee is compressed. Slowly adapting type II

(SAII) receptors in the skin fire in response to the direction, speed and extent of stretch and are therefore likely to contribute to the sense of movement. Illusions of movement of the fingers can be generated by pulling on the skin over the joints to mimic the stretch and compression of the skin that usually accompanies joint movement.

## Function

### *Sensory*

Movement sense allows detection of movements imposed on parts of the body and perception of the velocity and timing of such movements. It also allows perception of the velocity and timing of movements made by active muscle contractions and of movements to which external forces and muscle contractions both contribute. Perception of movements imposed by external forces including gravity allows reaction to such perturbations to prevent injury. Ongoing knowledge of where and how the parts of the body are moving is crucial for motor control.

Movement signals can be processed in conjunction with various other proprioceptive signals.

1. Perception of the current position of the parts of the body has contributions from movement sense, position sense and sensations of muscle force and effort. Limb positions are most accurately detected immediately after movement to a new position.
2. Judgment of weight combines sensations of muscle force and effort with movement sense. If an object does not move when force is applied, its weight cannot be judged.
3. Judgment of stiffness also relies on sensations of muscle force and effort combined with movement sense.
4. Perception of the orientation and movement of the trunk relative to the outside world combines vestibular sensations, which signal position and movement of the head relative to the world, with sensations of movement and position from the neck.

Together with other senses, like vision and touch, proprioceptive sensations including movement sense generate a body image and awareness of self. If illusions of arm movement are generated by activating muscle spindles with tendon vibration while a person touches a finger to their own nose, remarkable changes in body image can occur, e.g. the nose may seem to grow or may feel like it is pushed into the face.

### *Motor Control*

Apart from providing perceptions, the signals that convey sensations of movement as well as other proprioceptive signals are integrated into the motor system. Movement sense provides feedback for the control of movement. Even common movements like lifting a cup to the lips, do not always require the same muscle activity. When the cup is full it is heavier and the movement requires more muscle activity than when the cup is empty. Feedback of the results of motor output is crucial to guide the muscle activity. Even if an action is too fast to allow ongoing correction, the sensations of movement can be used to adjust motor output in subsequent attempts, i.e. movement sense is used when learning motor tasks through repetition.

Coordination of muscle actions about different joints also relies on movement signals. For example, if a ball is thrown to hit a target, the hand must be opened when the velocity and direction imparted by shoulder, wrist and elbow movements are appropriate [8].

## Pathology

Impairment of movement sense can occur with non-pathological occurrences like muscle fatigue as well as in a range of pathological conditions. These include:

1. Musculoskeletal disease or injury including sprains, ligament damage, osteoarthritis, back pain, whiplash
   Impairment can result from change in the mechanical properties of the tissues around the sensory receptors. Pain without tissue changes can also impair movement detection. This may occur through a reduction in muscle spindle sensitivity or through interactions in the central nervous system.
2. Peripheral nerve injury or peripheral neuropathy
   Whether it occurs through disease or injury, damage to the neurons that carry the movement signals from the periphery to the spinal cord, will impair movement sense in the affected region.
3. Lesions or pathology in the central nervous system
   Lesions anywhere in the sensory pathway to the cortex, e.g. in the spinal cord, brainstem or thalamus
   i. *Basal ganglia lesions.* Patients with Parkinson's disease have a reduced ability to detect passive movements.
   ii. *Cerebellar lesions.* Patients with cerebellar pathology have a normal ability to detect passive movements but have impaired discrimination of velocity and duration.
   iii. *Cortical lesions.* Lesions of the primary somatosensory cortex can lead to loss of movement sense. Lesions of somatosensory association areas can impair kinesthesia [9]. Lesions of other areas (e.g. secondary somatosensory cortex, superior parietal lobule) may disrupt the perception of active movements.

# Movement Sequences

John F. Soechting
Department of Neuroscience, University of Minnesota, Minneapolis, MN, USA

## Definition

It has long been hypothesized that complex movements are generated by concatenating simpler, elementary movements in a serial order. This hypothesis seems intuitively obvious for motor behaviors such as speech, handwriting and typing, the elementary movements in these instances being the vocalization of phonemes, the generation of individual letters or strokes and the production of targeted keypresses. However, the hypothesis has been extended more generally to skilled motor tasks. With respect to this hypothesis several questions (that have been addressed experimentally to varying degrees) arise: (i) How is the proper serial order of elements in a sequence established? (ii) To what extent is there overlap between the expression of elements in the sequence and to what extent does the expression of one element depend on the preceding and succeeding movement in a sequence? and (iii) What are the properties of elemental movements?

## Characteristics

The strongest evidence that complex movements are generated by serially ordering simpler movements arises from motor deficits following damage to the frontal lobe in human subjects [1]. For example, Luria [2], in patients with damage to the premotor region, described the phenomenon of ►perseveration of movement, which he defined as the "continuation of a voluntary movement once it has started." On simple tasks such as drawing a circle, this deficit was expressed as the repeated production of the same circle. However, on more complex tasks, such as drawing a human figure, only some individual elements such as the fingers or the legs were drawn repeatedly. Additional evidence in favor of this hypothesis is provided by spontaneous errors in normal subjects, especially in speech and typing. In such behaviors, errors in serial ordering are not uncommon; most typically, they involve the transposition of adjacent phonemes or keystrokes.

### Serial Ordering

The question of how a proper serial ordering of elements in a sequence would be established was taken up in an influential work by Lashley [3] in 1951. He considered two alternative processes according to which serial order of a movement sequence could be established. In one, the associative chaining theory, each element in a sequence would trigger the generation of the succeeding element. For example, a sensory event signaling the completion of one element could trigger the initiation of the next one. Based primarily on spontaneous errors in speech and typing, Lashley argued against this hypothesis in favor of an alternative, in which all elements of a sequence are prepared in parallel. He left open the problem of how one particular element would be selected at the proper time. One possibility would be that the element that was most strongly represented in neural activity at any point in time would be translated into action, and that representations for individual elements could mutually inhibit each other.

The question is still largely unresolved. However, recently Averbeck et al. [4] have provided electrophysiological evidence in support of Lashley's proposition. They recorded activity of prefrontal cortical neurons while monkeys performed a task that required them to copy geometric figures such as squares and triangles by moving a joystick to control the motion of a cursor on a screen. They used standard criteria (minima in speed, see below) to determine the extent of each

segment. Distinct patterns of activity of neural ensembles (obtained from averages over each of the segments) were used to determine classifiers for each of the segments, using discriminant analysis. They then used these classifiers to determine the extent to which each of the segments was represented at different intervals during a trial. Their main result is presented in Fig. 1, which shows the average over all ensembles when the monkey drew a square, consisting of five segments. The fact that the strength of the representation for a particular segment is maximal when that segment is drawn is not remarkable, since that was the basis for constructing the classification scheme.

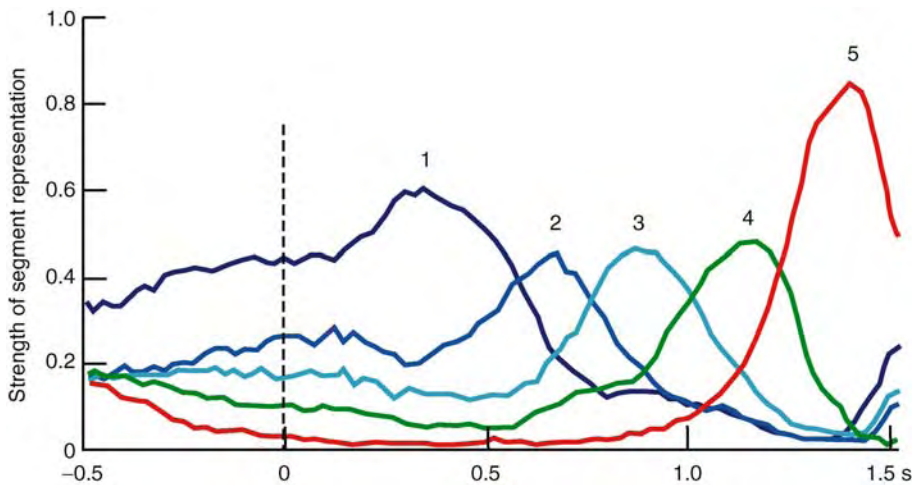
However, it is remarkable that the strength of representation throughout the trial, and in particular prior to the onset of the drawing at time 0, reflects the temporal order in which the segments were drawn.

## Serial Execution

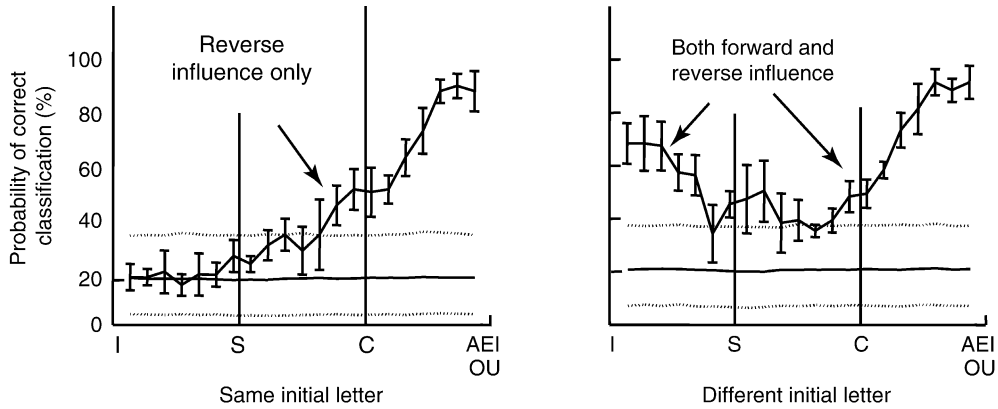
Assuming all of the segments of a movement sequence are planned in parallel, this still leaves open the question of how they are executed. Specifically, parallel planning would still be consistent with the possibility that each of the segments is executed in strict sequential order, without overlap. Such a possibility would imply that the kinematics of each segment would be identical to the kinematics if that segment were executed in isolation. This question has been addressed most extensively in speech, where it is known that the acoustic quality of a given phoneme can depend on the phonemes that precede and follow it, a phenomenon known as coarticulation [5]. The motions of the articulators responsible for sound production are difficult to measure, thus little is known about exactly how they are modified in generating words from individual phonemes.

The evidence from studies in limb motions suggests that, in that case, there is a preference to produce segments in a strictly serial fashion. Thus in typing [6], it was found that the finger and hand movements to generate a particular keypress did not depend on the preceding or subsequent keypress. Anticipatory modification of hand movements was observed in some instances in piano playing, for example in executing the thumb-under maneuver as a pianist played an ascending scale [7]. The clearest evidence for the equivalent of coarticulation was provided by a study of fingerspelling by signers fluent in American Sign Language [8]. In that study, signers spelled a set of words, all containing the same set of three letters (e.g., "*isc*") but with different vowels following the trigram. In one set of trials, the letter preceding the trigram was always the same, whereas in another set, each terminal vowel was associated with a different initial letter (Fig. 2).

Hand and finger movements were recorded as the signers spelled the words, and discriminant analysis was used to determine the time at which the final vowel could be predicted from the handshape. As is shown in Fig. 2, there was an anticipatory modification of the handshape about 1.5 letters prior to the generation of the vowel (reverse influence, beginning between the "*s*" and the "*c*"). A particular letter also influenced subsequent handshapes (forward influence in right panel of Fig. 2).



**Movement Sequences. Figure 1** Strength of representation of movement segments in the activity of prefrontal cortical neurons as a function of time. The drawn shape (a square) consisted of five segments and the traces depict the proportion of neuronal ensembles whose pattern of activity encoded a specific segment at a given time. Note that the relative strength of representation encodes the serial order in which the segments were drawn. Adapted from [4].



**Movement Sequences. Figure 2** Probability of correctly predicting the vowel following the trigram "*isc*" from the shape of the hand during fingerspelling in American Sign Language. The letters at the bottom of each panel denote the time at which handshape was static; intervening points denote the transition from one handshape to another. The solid horizontal line at 20% indicates chance performance, and the dotted lines indicate 95% confidence limits. In the left panel, the letter preceding the "*i*" was always the same; in the right panel it was different for each of the vowels following the "*c*." Adapted from [8].

The modifications of the finger movements during signing could take two different forms: a "dissimilation" in which differences between the handshapes for subsequent signs were emphasized, and an "assimilation" in which the motion at a joint was minimized during the transition from one handshape to the next one. Assimilation and dissimilation were found to occur, at different joints, in the same movement sequence, suggesting a sophisticated level of control of the execution as well as the planning of serial movements.

### Defining Segments in a Movement Sequence

This topic has received relatively little attention and the question is largely unresolved. Investigators have typically assumed that each segment of a sequence would have the same kinematic characteristics as a simple movement executed in isolation. Since such simple movements typically demonstrate a "bell-shaped" speed profile, kinematic landmarks such as local minima in speed have been used to demarcate individual segments. In other instances, abrupt changes in the plane of limb motion have been observed [9], and they have been assumed to denote transitions from one segment to another. Neurons in the supplementary and presupplementary motor area (SMA) have been shown to encode the transition from one segment to another while other neurons encoded the rank order of a particular movement [10]. Thus it appears possible to answer this question more definitively on the basis of neural activity.

### Definition

Messenger RNA is the intermediate between information encoded on the DNA and the ribosomes that translate this information into proteins. DNA is transcribed into mRNA after which ribosomes read the information encoded on triplets of the RNA bases, and translate it into a polypeptide chain.

## mRNA Targeting: Growth Cone Guidance

Barbara Lom
Biology Department and Program in Neuroscience, Davidson College, Davidson, NC, USA

### Synonyms

Local protein synthesis; Axonal RNA translation; Translational regulation; Local translation; Extrasomatic translation; Compartmentalized protein synthesis; Cytoplasmic mRNA localization; RNA localization

### Definition

Growing axons are tipped by highly dynamic and motile growth cones that navigate through the brain by detecting and responding to guidance molecules. When a growth cone reaches its target location it transforms into a presynaptic terminal. Thus, accurate growth cone guidance is critical in establishing functional brain circuitry. Messenger RNA (mRNA) targeting to growth cones refers to the selective transport of specific mRNAs along an axon out to the growth cone so translation of these mRNAs can occur locally within the growth cone, away from the soma. Growth cones contain protein synthetic machinery including ribosomes, translation factors, and specific mRNAs. Previously it had been thought that proteins were synthesized in the cell body then transported to specific regions of the neuron, but evidence now indicates that some mRNAs can be translated into proteins locally within the growth cone and this local translation is required for growth cones to respond to a variety of guidance cues. mRNA targeting allows new protein supplies to be rapidly and regionally mobilized that change growth cone motility via ►cytoskeletal alterations and change growth cone sensitivity to guidance cues by up- or down-regulating receptor expression.

### Characteristics

#### Growth Cones

Neurons are extremely polarized cells with axons that extend long distances from the cell body. Most proteins are thought to be synthesized and modified in the cell body then transported along the axon via fast and slow axonal transport mechanisms. The growth cone region has autonomous local navigation and steering mechanisms because growth cones can navigate accurately *in vitro* and *in vivo* even after being separated from their somas. A variety of guidance molecules (including extracellular matrix components, secreted factors, and molecules associated with the membranes of other cells) steer growth cones by signaling through specific

receptors expressed on the growth cone. When a growth cone detects an attractive or repulsive guidance cue (or combination of cues) the growth cone's shape, trajectory, and/or motility are altered to steer it toward its appropriate target and/or away from inappropriate regions. Specific guidance molecules are located at precise locations along a growth cone's route and the growth cone's responsiveness to these guidance cues can change dramatically as the expression of specific receptors are up- or down-regulated *en route*. Rapid changes in ►cytoskeletal structure underlie a growth cone's remarkable motility. A growth cone's ►cytoskeleton contains both microfilaments and microtubules, with actin-based microfilaments occupying the growth cone's particularly dynamic finger-like filopodia that sample the molecular terrain and steer the axon's growth. Guidance cues trigger changes in growth cone trajectories by inducing asymmetric filopodial extension and/or collapsing particular regions of a growth cone. Translation of mRNAs targeted to the growth cone can cause rapid and localized changes in protein composition that are necessary for accurate growth cone navigation.

## Protein Synthetic Machinery Localized to Growth Cones

Growth cones are equipped to synthesize proteins locally. Essential components of protein synthetic machinery including polyadenylated mRNAs, polyribosomes, ribosomal RNA, and factors that regulate translation such as elongation factors, ►ZBP, and ►RNA interference (RNAi) have been observed within vertebrate growth cones [1,2]. Functional evidence for local translation comes from experiments that separated growth cones from their cell bodies and measured the synthesis of new proteins in isolated growth cones [3]. The ability of isolated growth cones to navigate properly without contributions from somatic protein synthesis suggests that the cellular machinery to detect and respond to guidance cues is contained within the growth cone. Guidance molecules can functionally alter translation factors within growth cones. For example, the guidance cues netrin-1 and semaphorin 3A (Sema3A) cause a rapid rise phosphorylation of eIF-4PB1, which liberates the translation initiation factor eIF-4E [3]. The identities of mRNAs targeted to growth cones have not yet been thoroughly cataloged, but many of the mRNAs identified thus far code for proteins that comprise, influence, and/or associate with the cytoskeleton [4]. As an example, β-actin mRNA has been observed in association with microtubules in growth cones and has been implicated as a key player in protein synthesis dependent growth cone guidance [2,5].

## Growth Cone Responses to Guidance Cues Require Local Protein Synthesis

In just the past few years it has become apparent that local protein synthesis is involved in several distinct and important aspects of growth cone responsiveness to molecular guidance cues: directed movement, ►cytoskeletal organization, receptor expression, and sensitization. For example, neurotrophin-3 (NT-3) can stimulate axon elongation and act as a guidance cue for growth cones that express the appropriate neurotrophin receptor(s). Within minutes, NT-3 application causes β-actin mRNA to localize to growth cones *in vitro* in a cAMP-dependent manner [6]. NT-3-regulated β-actin mRNA localization to the growth cone requires interaction of the ►zipcode sequence in β-actin mRNA's ►3′ untranslated region (UTR) with ►zipcode binding protein 1 (ZBP1) to form ribonucleoprotein particles (RNPs). RNPs are heterogeneous complexes of translational components that can include ribosomes, mRNA binding proteins, elongation factors, and mRNAs. RNPs are thought to be transported by motor proteins to targeted subcellular locations where they become tethered to the ►cytoskeleton and translation regulators then allow precisely localized translation of targeted mRNAs. The identities of specific mRNA ►zipcode sequences and the ways they interact with other molecules to form RNPs are currently being elucidated. Experimentally disrupting interactions between β-actin mRNA's ►zipcode region and ►ZBP1 revealed that zipcode-ZBP1 binding is essential to the mRNA localization, protein levels, and growth cone mobility [6].

Several well-characterized guidance cues stimulate local translation within growth cones. Normally growth cones change their trajectory dramatically toward a netrin-1 gradient and turn away or collapse when they encounter Sema3A. When the ability to synthesize new proteins is pharmacologically inhibited, isolated growth cones cannot respond to either the attractive netrin-1 or the repulsive Sema3A guidance cues [3]. Other guidance cues including Slit2 and BDNF (brain-derived neurotrophic factor) also require protein synthesis to guide growth cones [2,4]. Thus, local protein translation is critical to a growth cone's ability to respond to a variety of guidance molecules in its pathway.

Translation of mRNAs within the growth cone also plays a critical role in regulating a growth cone's ►cytoskeleton. Evidence comes from observations of asymmetrical β-actin translation in growth cones orienting in response to netrin-1 gradients [5] and BDNF gradients [2]. When netrin-1 is presented on one side of a growth cone, a homolog of ZBP1 rapidly translocates into filopodia and both the translation initiation regulator 4EBP and β-actin translation become rapidly enhanced on the side nearest the netrin-1 source. These translational asymmetries within the growth cone are observed even before growth cones physically turn toward an attractive netrin source, indicating a netrin-induced mechanism can bias actin polymerization to steer growth cones. In another example of local translation affecting growth cone ►cytoskeleton and motility, the

repulsive guidance molecule Sema3A induced localized translation of RhoA, a member of the Rho family of small GTPases that are widely implicated in regulating actin alterations underlying filopodial dynamics [7]. RhoA transcripts localize to growth cones via targeting sequences with their ►3′ UTR and localized RhoA translation is necessary for Sema3A-induced growth cone collapse. In addition, the repulsive cue Slit2 initiates both a protein synthesis dependent decrease in growth cone F-actin and an increase in the actin depolymerizing protein cofilin within growth cones [4]. Taken together, these studies indicate that local translation of proteins that compose or influence the ►cytoskeleton can play critical roles in steering growth cones toward attractive cues and in collapsing in response to repulsive cues.

Local translation also alters a growth cone's responsiveness to guidance cues. Evidence for this role emerged from experiments that examined local translation in the distal regions of developing spinal axons as they crossed the midline of the spinal cord. These axons are initially attracted to the midline but after they have reached and crossed the midline their responsiveness to guidance cues expressed at the midline changes, presumably to prevent the axon from getting trapped at this intermediate target and/or to allow the axon to respond to subsequent cues that will guide it to its ultimate target. The EphA2 receptor is normally expressed in the distal regions of some spinal commissural axons after they have crossed the midline. When RNA containing a sequence in the ►3′ UTR of the EphA2 receptor fused with a green fluorescent protein (GFP) reporter construct was introduced into these neurons, GFP was expressed within growth cones only after crossing the midline, spatially and temporally similar to EphA2 expression [8]. Moreover, growth cones separated from their cell bodies demonstrated similar upregulation of gene expression, indicating that growth cones are capable of local protein synthesis. While this study did not demonstrate the existence of endogenous EphA2 mRNAs in growth cones, it suggests a plausible mechanism by which local translation could rapidly alter the expression receptors on a growth cone. In addition to changes in growth cone receptor expression, growth cones can adapt to persistent guidance cues, demonstrating desensitization and resensitization behaviors *in vitro*. Local protein synthesis is required for the resensitization phase of adaptation in netrin-1, BDNF, or Sema3A gradients [9]. Thus, changing a growth cone's responsiveness to guidance cues uses a protein synthesis-dependent mechanism.

## Signal Transduction Mechanisms and Translational Regulation

How do extracellular guidance cues stimulate protein synthesis within the growth cone cytoplasm? The intracellular signaling cascades that transduce guidance cue signals into local translation are only beginning to be elucidated, but it is clear that different guidance cues enlist different signaling molecules to regulate translation within growth cones. Caspase-3, TOR (target of rapamycin), p38 MAPK (mitogen activated protein kinase), and p42/44 MAPK have been differentially implicated in protein synthesis stimulated by the distinct guidance molecules Sema3A and netrin-1 [10]. By mobilizing distinct intracellular signaling cascades, different guidance cues could elicit the translation of target mRNAs into the proteins necessary for a growth cone's response. Translational regulators are likely the targets of signal transduction cascades stimulated by receptor activation. Mechanisms that regulate targeted translation of mRNAs within growth cones are just beginning to be identified. ►RNAi, which can repress translation or trigger degeneration of specific mRNAs, has recently been implicated in Sema3A-induced growth cone collapse [1].

## Proteolysis in the Growth Cone

In order to regulate the protein composition of a subcellular structure such as a growth cone, cells must coordinate protein synthesis and protein degradation. Both processes occur within growth cones, though proteolytic contributions to growth cone guidance mechanisms are not as well characterized. Proteolysis machinery such as proteosomes, signalosomes, ubiquitin, and the ubiquitin-activating enzyme E2 have been detected within growth cones [3]. Functionally, netrin-1 can induce rapid, local increases in ubiquitin-protein conjugates within growth cones and inhibiting proteolysis can abolish an isolated growth cone's ability to respond to the cue netrin-1 [3]. Sema3A, however, does not rely on proteolysis in the same way as netrin-1 in guiding growth cones, further suggesting that individual guidance cues regulate protein synthesis and degradation within the growth cone by distinct signaling mechanisms.

## Localized Protein Synthesis Elsewhere in the Nervous System

While the roles of localized protein synthesis are just becoming established in embryonic growth cones, it is becoming evident that regenerating axons also require localized protein synthesis when reestablishing neuronal connections. Moreover, the ability to translate specific mRNAs locally is not unique to growth cones. Spatially regulated translation within dendrites plays an important role in facilitating synaptic plasticity and insights into mechanisms of targeted dendritic translation have great potential to inform future studies of growth cone translation. Thus, it is becoming clear that neurons use localized protein synthesis as a rapid mechanism to reconfigure regional protein

composition in response to stimuli for navigation, repair, and memory.

## Multiform Layer

### Definition

The multiform layer of the cerebral cortex is layer VI. It has this name because it contains neurons of a wide variety of sizes and shapes. Projection neurons in layer VI send their axons to terminate in other parts of the cerebral cortex and to the thalamus.

## Multilayer Networks

### Definition

Neural networks composed of multiple layers, namely the input layer and the output layer with or without hidden layers between them.

►Neural Networks

## Multimerization (of Ion Channels)

### Definition

Multimerization is the process in which individual subunits (monomers) aggregate to form a functional ion channel. For example, voltage-gated potassium channels and glutamate receptors form tetramers of four subunits, the Cys-loop channel family (acetylcholine (Ach), GABA, glycine) consist of five subunit pentamers. These multimers may be derived from a single gene subunit (homomultimer) or from many different genes (heteromultimers).

### Synonyms

Crossmodal integration; Multisensory integration; Intermodal; Heteromodal; Polymodal; Supramodal

### Definition

Multimodal (or ►multisensory) integration refers to the neural integration or combination of information from different sensory modalities (the classic five senses of vision, hearing, touch, taste, and smell, and, perhaps less obviously, proprioception, kinesthesis, pain, and the vestibular senses), which gives rise to changes in behavior associated with the perception of and reaction to those stimuli [1,2]. Information is typically integrated across sensory modalities when the sensory inputs share certain common features. For example, although vision is concerned with a certain frequency band of the electromagnetic energy spectrum, and hearing is concerned with changes in pressure at the ears, stimulus features such as spatial location, movement, intensity, timing, and duration, as well as other higher-order features such as meaning and identity can apply equally to information from several (or all) sensory modalities. ►Crossmodal integration is often used synonymously with multimodal integration, however the latter term has various other associations in different disciplines, including in describing the use of more than one measuring system. The former term, crossmodal, may therefore be preferable.

Multimodal integration is more often used to refer to integrative processes operating at the systems level, and studied most commonly using brain imaging techniques alongside behavioral and perceptual measurements. ►Multisensory integration on the other hand, tends to refer to the combinatorial effects of stimulation of two or more senses on the activity of single neurons, measured electrophysiologically in experimental animals. Since multisensory integration is more commonly used in the context of single-cell recordings, often made under anesthetised recording conditions, causal relationships to the behavioral outcomes of multisensory integration are less certain, although this is currently an area attracting considerable research interest.

## Characteristics

### Upstream Events/Conditions

An extensive body of experimental research has shown that many cognitive systems operate in a multimodal manner. Such systems include those responsible for selective attention and orientation to external stimuli, along with both more elementary perceptual effects, and higher-level cognitive systems such as memory. For example, the familiar experience of both hearing another person speak in natural conversation, and seeing the speaker's lip movements while they speak, is an everyday example of multimodal integration involving both low-level perceptual features, such as detecting sounds and lip movements, as well as higher-level linguistic and semantic factors [3].

In a typical experiment designed to study multimodal attentional orienting, participants may be asked to pay attention and respond only to tactile stimuli presented to a certain hand (e.g., their left hand), and to ignore both tactile stimuli presented to the other hand (i.e., the right hand) or visual stimuli presented to either hand. Typically, visual stimuli presented close to the attended hand result in larger activation (as measured, for example, using electroencephalographic (EEG) or functional magnetic resonance (fMRI) techniques) than for visual stimuli presented to the unattended side. This is true even though the visual stimuli were not relevant to the participants' task. These, and many other similar results, suggest that the mechanisms of spatial attention may operate in a multimodal or supramodal fashion, facilitating the detection and discrimination of stimuli from a given location regardless of the stimulus modality. The behavioral and neurophysiological effects of attending to a primary modality on the response to the secondary modality, however, are usually smaller than the effects in the primary modality itself. This latter result suggests that both unimodal and multimodal perceptual and attentional mechanisms operate in concert.

### Downstream Events/Conditions

In order for multisensory or multimodal integration to occur, information must have been processed initially within the component unimodal sensory systems. The level and extent of this prior unimodal processing, however, depends on the system under study. In the superior colliculus (SC), for example, visual and auditory inputs are integrated very early on, after transmission along only several synapses following sensory transduction at the periphery. The retina sends visual projections directly onto the SC, while auditory inputs reach the SC only several neural synapses after initial sensory transduction at the cochlea. Conversely, those stimuli that are involved in multisensory integration in the cerebral cortex may undergo substantial unimodal processing prior to integration, lasting many tens or even hundreds of milliseconds. Recent research, on the other hand, is beginning to detail the extent to which different sensory processing streams interact at very early stages of processing – as early as 45 ms in the example of visual and auditory processing. This physiological evidence is supported by the existence of distinct anatomical connections between the primary sensory areas of several different sensory systems. More and more it appears that multimodal integration and interaction is the rule, not the exception, at all levels of processing.

### Involved Structures

Following many years of detailed study on the integration of multisensory inputs in neurons of the superior colliculus, several guiding principles of multisensory integration have emerged [4]. These principles have later been applied in order to determine whether a particular brain region is involved specifically in multisensory integration, both at the level of single-cells, in neurophysiology, and the whole-brain, in neuroimaging.

First, inputs to any given neuron or any given brain area must typically arrive at that area at the same time in order to be integrated and to have significant behavioral consequences. Depending on the specific brain area, "at the same time" typically refers to a "temporal window for multisensory integration." The width of the temporal window, that is, the maximum temporal delay between the arrivals of inputs from different sensory modalities, may be on the order of 100–300 ms.

Second, in many brain areas, particularly those concerned with spatial representations of visual, tactile, and auditory stimuli, multisensory integration is enhanced for those stimuli that arise from the same external spatial location as compared to different locations. The "same" location in the case of audio-visual speech integration, for example, would be the speaker's mouth, from which both visual and auditory signals arise. In the case of visual and tactile stimuli, the same location might refer, for instance, to the lower left portion of the visual field, and to the animals' front left leg, or the lower-left side of the organism's face.

Third, one important aspect of multisensory integration at the neural level relates to the relative strength of inputs from different sensory modalities and the relative amplification that occurs in the process of multisensory integration. This "principle of ▶inverse effectiveness" thus states that the relative enhancement due to multisensory integration is larger for those stimuli that produce weak sensory effects on their own, and is smaller for stimuli that cause strong activations at the neural level.

The *Superior Colliculus* in the midbrain integrates visual, somatosensory, and auditory inputs in the

generation and control of spatial orienting behaviors, particularly those concerning eye and head movements. The SC has been studied intensively as a potential model system for multisensory integration in animals. More recent research has examined the extent to which the ►spatial rule of multisensory integration and ►temporal rule of multisensory integration as measured in the SC also apply to higher-order behaviors and cognition.

The *posterior parietal cortex* contains multiple cortical regions, which respond in a variety of ways to visual, somatosensory, auditory, proprioceptive, and vestibular inputs, such as Brodmann's areas 5 and 7 (or the superior and inferior parietal lobules, respectively), and the multiple, heterogeneous areas within the intraparietal sulcus (e.g., ventral, anterior, and medial intraparietal areas). Somatosensory information is processed initially in Brodmann's areas 3 and 1, the primary somatosensory cortices. Somatosensory processing then proceeds posteriorly through areas 2 and 5, into the anterior or medial bank of the intraparietal sulcus. Visual stimuli are processed initially in the primary and secondary visual cortices, proceeding along the dorsal and ventral visual streams. In the intraparietal sulcus (IPS), the dorsal visual stream meets the somatosensory processing stream. Neurons in area 5 have been shown to integrate proprioceptive stimuli with visual information in the representation and updating of postural information.

At the *fundus of the intraparietal sulcus*, the *ventral intraparietal area* (VIP) contains a variety of neurons with responses ranging from purely somatosensory to purely visual. The *lateral intraparietal area* (LIP), on the posterior or lateral bank of the intraparietal sulcus is thought to be involved in the planning, generation, and control of eye movements. This area, dubbed the "parietal eye field" because of its close functional association with the frontal eye fields, integrates multisensory information in generating eye movements to expected, current, and remembered target locations originally specified in a variety of different possible sensory modalities. Other areas in the intraparietal sulcus display a variety of multisensory responses. The *anterior intraparietal area* (AIP) integrates visual and somatosensory information in planning and generating object-related movements such as grasping, while the *medial intraparietal area* (MIP), as part of the *parietal reach region* (PRR) is involved in the generation and control of reaching movements.

Neurons in the *superior temporal sulcus* in macaques and humans, and the *anterior ectosylvian gyrus* in cats respond to stimulation in a number of sensory modalities, but have been studied particularly in connection with audiovisual speech and vocalizations, in both monkeys and man. This area is often activated in studies that pair both audible and visual (lip movements) speech.

The *premotor cortex* in the frontal lobe is thought to integrate multisensory information involved in the planning and execution of movements. A small portion of the *ventral premotor cortex*, known as the *polysensory zone*, responds to somatosensory, visual, and auditory inputs, and seems to be involved in representing multisensory "peripersonal space" – the space immediately surrounding certain parts of our bodies, particularly the hands and face. This area is connected to functionally similar areas in the posterior parietal cortex such as the ventral intraparietal area. Neurons in the polysensory zone of the premotor cortex respond both to objects approaching a certain portion of the animal's skin (i.e., a visual receptive field surrounding the neuron's corresponding somatosensory receptive field), and to the generation of defensive or avoidance movements in response to these objects.

Certain areas of the orbitofrontal cortex also respond to multisensory stimuli, particularly those concerned with appetitive rewards, such as food, flavors, tastes, and aromas, along with emotionally salient multisensory signals.

Multiple feedforward and feedback connections between the frontal and parietal cortices subserving the processing of multisensory information, and the planning, and execution of movements following multisensory stimulation probably constitute a network of multimodal perception-action or attentional systems. Neural studies of multimodal integration, at least in recent years, have been based largely on the findings of multisensory integration in the SC concerning the generation of orientation movements. Since these early studies, however, research has unveiled numerous brain areas that process and integrate information from a number of sensory systems. Each of these areas seems to be specialized for particular domains of environmental stimuli, or for particular forms of action. Underlying the various approaches to the study of multisensory integration is the hope that general rules of multisensory integration can be discovered that apply to a wide range of behavioral situations, and across a variety of distinct brain regions.

## Methods to Measure this Event/Condition

Multisensory integration is typically measured via single-unit recordings in cats, ferrets, barn owls, or macaque monkeys. Both anesthetized and awake behaving preparations have been used, often in conjunction with behavioral studies in the same species and under similar stimulus conditions, or with human studies under similar experimental conditions.

A variety of neuroanatomical and neurophysiological techniques have been used in the model system of the SC,

including single-unit recording and stimulation, lesion studies, tract-tracing, cooling and other forms of inactivation and deactivation of the colliculi themselves, or of brain regions projecting to or receiving from the SC [4]. These studies have shown, for example, that selective lesions or deactivation of the SC abolishes the integration of auditory and visual information arising in those regions of space that the affected portion of the SC represented. Multisensory integration in those parts of the SC left intact was unaffected. Early work on the SC focused on the developmental time-course of multisensory integration, the temporal and spatial characteristics of the stimuli required for effective multisensory integration, the spatial arrangement of the different multisensory representations in the SC, and the ways in which this particular organization came about. (i.e., in part genetically determined, but influenced very strongly by visual and multisensory experience throughout development).

A number of behavioral methods are available to measure multimodal integration in human participants, including reaction-time measures, threshold determination, two (or more)-alternative-forced-choice measures (speeded or unspeeded) and signal detection analyses, which have been used on studies of sensory modalities in isolation for many years. The variety of experimental techniques now available for studying multimodal integration in healthy human participants as well as in brain-damaged neuropsychological patients is now considerable, and an adequate summary is beyond the scope of this article. However, certain important recent trends can be highlighted.

Modern neuroimaging techniques, such as fMRI, positron emission tomography (PET), and magnetoencephalography (MEG), are increasingly being used to address questions concerning multisensory integration. Such experiments often require the development of new stimulation equipment that can be brought into the scanner environment itself. Studying the effects of tactile, olfactory, and gustatory stimulation in the scanner has involved overcoming some difficult technical problems, due to the very strong electromagnetic fields involved in fMRI, and to the very sensitive equipment required to detect small changes in electrical (EEG) or magnetic (MEG) fields over the scalps of human participants. But it is now possible to present stimuli in a number of sensory modalities simultaneously to participants lying in the scanner while they perform simple behavioral tasks. This line of research will provide much-needed theoretical and empirical links between the neurophysiological literature derived from experimental animals, typically macaque monkeys, cats, or ferrets on the one hand, and the human behavioral, psychophysical, and neuropsychological literature on the other hand. It will be crucial to know, for example, to what extent the principles and properties of multisensory integration at the single-neuron level measured in experimental animals can be related to the principles and properties derived from human behavioral studies. In short, do those behaviors that reflect multimodal integration depend directly on cells displaying multisensory integration?

There has been much interest in the effects of a variety of brain lesions in adult humans on multimodal integration and associated behaviors. Several neuropsychological syndromes that have traditionally been studied as if they were unimodal deficits, such as tactile ►extinction and unilateral visuospatial neglect, have, upon closer inspection, been found to be multisensory in nature (►crossmodal extinction). For example, many patients with unilateral visuospatial neglect often have deficits in the detection of auditory and tactile stimuli that occur on their affected side, in addition to visual impairments. Similarly, patients suffering from tactile extinction (a condition where contralesional tactile stimuli are easily detected in isolation, but when two stimuli are presented together on opposite sides of the body, the detection of the contralesional stimulus is impaired), may also have impairments in detecting tactile stimuli on the contralesional hand, for example, when a simultaneous *visual* stimulus is presented near to the ipsilesional hand. The discovery of deficits that cut across the senses in disorders that have typically been thought of as being confined to a single sensory modality, suggests that disorders such as neglect and extinction may also be characterized as disorders of supramodal functions and processes such as spatial perception, and attention, rather than as impairments of a more sensory-specific (►modality-specific) perceptual nature.

Another important line of research involving human participants involves examining the multimodal consequences of sensory-specific impairments, for example in blind and deaf adults and children [5]. Such work has shown that impairments in a single modality have rather intriguing consequences for other sensory systems. In neuroimaging experiments, for example, it has been shown that, when blind participants read Braille, their visual cortex is activated suggesting a functional role for "visual" cortex in complex tactile spatial discrimination. Such visual activations are not observed when participants with unimpaired vision read Braille, nor in people who lose their sight late in life (i.e., after puberty). This neural activation was shown to be functionally relevant to the Braille reading task by the significant disruptive effects of transcranial magnetic stimulation (TMS) over the *occipital* cortex of the same volunteers that exhibited visual activations during Braille reading. Additionally, and perhaps more strikingly, it has recently been shown that normal participants, when completely blindfolded for 5 days while learning to recognize Braille characters, also show activation in the visual cortex, along with an

improved ability to learn the Braille task. These changes were not seen in normal participants who were blindfolded only during the learning and testing phases of the experiment, suggesting that this form of neural plasticity may take several days to take effect. Several different forms of ►crossmodal plasticity seem to be operating – one that occurs only in those patients who lose their sight before puberty, and another that results from the short-term recruitment of visual cortex following temporary blindfolding. Further research is needed to understand what neural mechanisms underpin these physiological changes.

The consequences of such findings for our views of the functional organization of the brain could hardly be more important: the assignment of visual cortex as strictly visually responsive may be rather premature. Rather, the visual cortex may be specialized for processing detailed spatial information in order to make complex spatial discriminations (e.g., in reading Braille). In normal circumstances, visual inputs are functionally the most useful for such spatial discrimination tasks, but in the absence of input from the eyes, inputs from the tactile and auditory receptors may help to perform such tasks. A similar line of research on the multimodal consequences of hearing impairments has reached analogous conclusions.

Finally, and quite recently, multimodal integration is now being approached from a mathematical modeling perspective, particularly with regard to modeling the precision and reliability of information arising from different sensory modalities [6]. Bayesian and maximum-likelihood methodologies have been used to model a variety of phenomena in multimodal integration. Such work suggests that the central nervous system integrates information from the different sensory modalities in an optimal fashion, based on the variability of responses under increasingly noisy stimulus conditions. This relates well to the foregoing conclusions of the work in blind and deaf people – the brain is a highly interconnected network dealing with vast quantities of information, and different neural subsystems are able to share that information effectively to the best advantage of the organism. The visual cortex will receive and process auditory and tactile inputs given a certain amount of visual deprivation, in order to process the relevant information and complete the designated task. Under less extreme conditions of visual deprivation, where the quality of the visual signal is degraded (e.g., on a misty day, or when we remove correcting lenses), information from other modalities may be weighted more strongly in the performance of certain cognitive tasks.

In conclusion, multimodal integration is an exciting and rapidly developing field of enquiry that spans numerous academic disciplines, from basic neuroscience, to medicine, physiology, psychology, cognitive science, and mathematical modeling. From each of these disciplines, multiple well-developed methodological approaches are now available to facilitate the study of the multimodal brain. By progressively questioning the assumption that we are born with only five senses, and that, throughout life, these five senses are both anatomically and phenomenologically distinct, the study of multimodal integration is beginning to provide intriguing answers to historically difficult questions.

# Multi-Oscillator System

Eric L. Bittman[1], Tanya L. Leise[2]
[1]Department of Biology, University of Massachusetts, Amherst, MA, USA
[2]Department of Mathematics, Amherst College, Amherst, MA, USA

## Definition

A multi-oscillator system is composed of potentially dissociable but normally coordinated rhythmic mechanisms which exist within the same organism, and may fall into mutual or hierarchical coupling arrangements.

## Characteristics

### Organization of Multi-Oscillator Circadian Systems

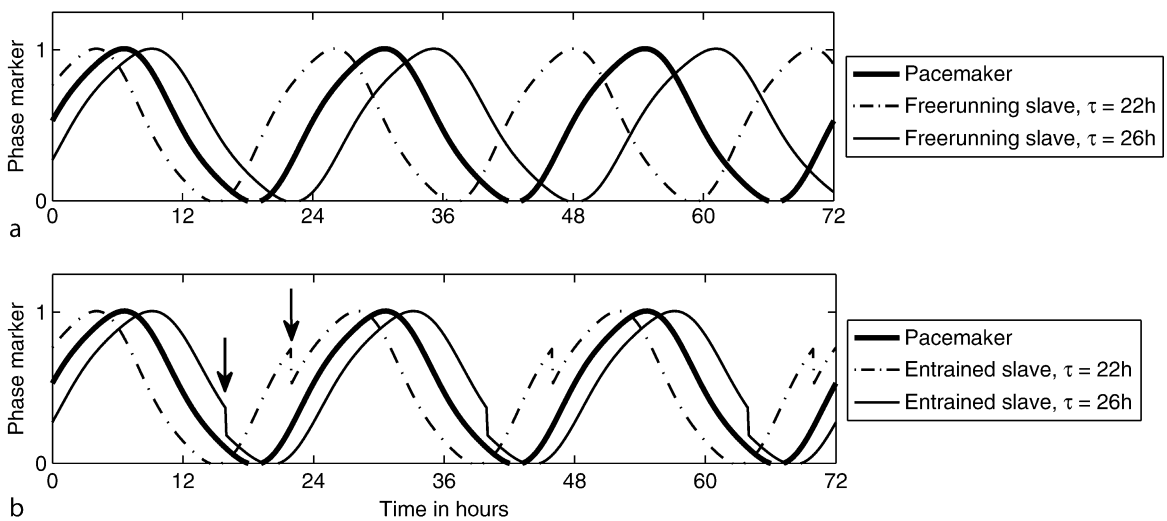
Many physiological functions are intrinsically rhythmic, and oscillations underlie the operation not only of organs, but also of individual cells. Sensory neurons fire action potentials in bursts, the frequency of which carries biological information such as the coding of stimulus intensity. Circadian oscillations provide another excellent example of physiological encoding of information, in this case, time of day. Multiple circadian ►oscillators occur in many different organisms, forming a complex network of internal clocks that increase the ability to coordinate internal functions and

execute them at appropriate times with respect to the environment.

The organization of circadian multi-oscillatory systems can take different forms and involve multiple levels of clock interactions. However, there is a common thread underlying all such systems: the constituent oscillators entrain, i.e, they match periods and maintain a steady relative phase (Fig. 1). This communication between oscillators does not require that they be synchronous. In other words, they often do not have the same phase; some components may even be antiphase to others so that incompatible processes occur at diametrically different times of day. In order for a set of heterogeneous oscillators (differing in period and other properties) to become mutually entrained, components with shorter periods must experience a ►phase delay each cycle (to lengthen the effective period), while components with longer periods must experience a ►phase advance (to shorten the effective period). The coupled components respond to coupling signals with appropriate delays and advances at specific phases (i.e., manifest a phase response curve) in order to achieve hierarchical or mutual ►entrainment. This coupling along with the intrinsic period of each component determines the phase differences between the components.

In multi-oscillator systems that are organized in a hierarchical manner, the ►pacemaker entrains "slave" oscillators. Some slaves may not be capable of sustaining oscillations in the absence of the pacemaker, i.e., they are damped oscillators. The pacemaker is often entrainable by an external signal, e.g., the 24 h light-dark cycle, and the pacemaker in turn entrains the rest of the circadian system. The nature of the signal from pacemaker to slave determines the entrained phase of the slave, just as the photic ►phase response curve of a pacemaker determines its entrained phase relative to dawn and/or dusk. The phase of an entrained slave oscillator can be either earlier than (leading) or later than (lagging) the phase of the pacemaker. For example, the ►suprachiasmatic nucleus (SCN) of mammals acts as a pacemaker that is believed to entrain circadian oscillators in peripheral tissues. The system is probably not strictly hierarchical, as the peripheral tissue clocks may in turn generate signals that influence the phase, amplitude, or ►period of the pacemaker. Other circadian systems are composed of autonomous oscillators which couple as a network through mutual interactions, with no dominant pacemaker involved.

Oscillatory tissues contain cells that generate circadian rhythms via a molecular clock mechanism that is composed of multiple loops in which rhythmic transcription of genes is achieved through feedback effects of the proteins they encode. In some circadian systems however, post–transcriptional events may play a predominant role in the clock mechanism. The roles of



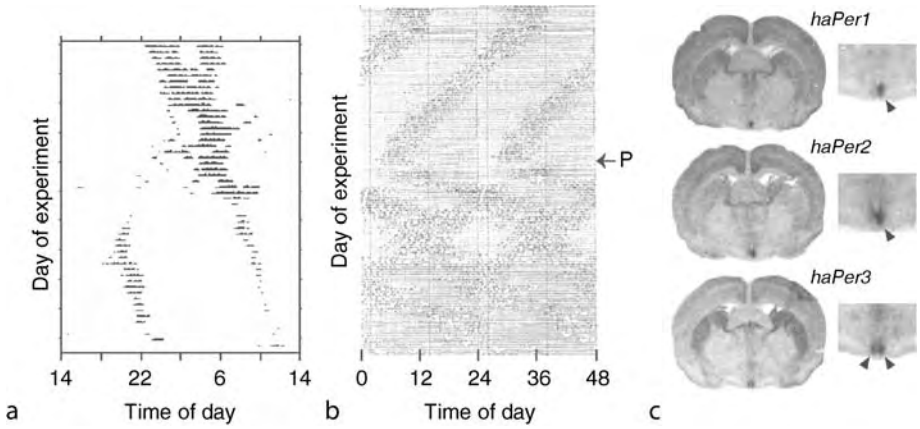
**Multi-Oscillator System. Figure 1** (a) Three oscillations that are not coupled are depicted. Note that the phase difference between the ►pacemaker and each "slave" increases over time. The "phase marker" may be an mRNA or protein level resulting from rhythmic expression of a clock gene, for example. Sinusoidal waveforms are indicated for simplicity, but need not be reflected in a biological system. (b) Appropriate signals from the pacemaker can entrain the slave oscillators, resulting in steady phase angles. Note that the two slaves take different phase angles to the pacemaker. A pacemaker signal reset the phase of the short period slave with a pulse at time 22 (and every 24 h thereafter) to correct for the difference in oscillator periods. This achieves a delay of 2 h, so that the slave repeats a 2 h portion of its cycle. The pacemaker entrains the long period slave with a pulse that falls at time 16 (and every 24 h thereafter) to advance its phase by 2 h, so that the slave skips 2 h of its cycle.

specific genes may differ between tissues, leading to qualitatively different clocks in the pacemaker and the peripheral tissues. Multi-oscillatory systems can be quite complex, spanning cell, tissue, and organismal levels. Furthermore, groups of organisms can act as multi-oscillatory circadian systems where mutual coupling is achieved through social cues.

## Evidence for Multi-Oscillatory Circadian Systems

The idea that independent oscillators couple to achieve a common period with a specific phase relationship may be traced to the Dutch astronomer Christian Huygens, who observed such phenomena in mechanical clocks. In the biological realm, Erwin Bunning proposed that individual organs including segments of gut were capable of sustained circadian oscillations when isolated from the whole animal. It was Colin Pittendrigh, however, who first established that circadian systems are comprised of multiple oscillators. Pittendrigh applied entrainment theory to model inter-oscillator coupling. He showed that although pupal eclosion of Drosophila is driven by a temperature-compensated circadian ("A") pacemaker, the phase of emergence depends upon temperature. Pittendrigh offered as an explanation the existence of slave ("B") oscillators that have circadian properties but are not temperature-compensated. The slave oscillators are thought to most directly control hormone release, motor patterns, etc., that lead to emergence of the adult fly. As environmental temperature changes, the intrinsic period of the slave changes, but not that of the pacemaker. Thus whether the slave must advance or delay its phase in order to adopt the period of the master pacemaker depends upon temperature. This implies that the entrained phase of the slave relative to the pacemaker must change as the temperature changes. Determination of this phase difference by temperature through the differential sensitivity of master and slave oscillators may serve an adaptive purpose, because the optimal time of emergence relative to sunrise depends upon season and relative humidity.

Pittendrigh extended the idea of multiple circadian oscillators to the phenomenon of splitting, which takes place upon exposure of hamsters to constant light. A high percentage of animals maintained in such conditions show bimodal activity rhythms, with two components free running with different circadian periods until they couple in an antiphase relationship (Fig. 2a). Pittendrigh argued that the capacity of an organism to sustain multiple



**Multi-Oscillator System. Figure 2** Activity rhythms can dissociate to reflect multioscillatory circadian organization, and pacemaker anatomy reflects dissociation among cell populations. (a) Splitting of activity rhythms (►split rhythm) in a golden hamster. Actogram represents locomotor activity of an animal maintained in constant light. Each horizontal line represents 24 h of wheel running behavior; successive days are represented one below the other. After about 30 days, two circadian components dissociate and free run with different periods before coupling in an antiphase relationship. (b) Pinealectomy of a Texas spiny lizard (*Sceloporus olivaceus*) induces dissociation of circadian components of locomotor activity. The animal was held in constant light for the duration of the record. After about 2 months, during which the animal showed a free running period of less than 24 h, the pineal was surgically removed (P). It was necessary to also remove the parietal eye in order to gain access to the pineal, but other experiments indicate that parietalectomy by itself has no consistent effect on circadian rhythms. Note that rhythmic components free ran with different periods and did not couple in the months following the surgery. From [1], reprinted with permission from AAAS (c) Splitting in constant light is accompanied by lateralization of clock gene expression in hamster SCN. Film autoradiograms illustrate expression of the clock genes *Per1, Per2*, and *Per3*, as assessed by *in situ* hybridization, in coronal sections of the brains of hamsters sacrificed 3 h before the anticipated onset of activity. Insets show that expression of *Per1* and *Per2* in the SCN (arrows), which normally peaks during subjective day, is laterally asymmetrical in split animals. Expression of *Per3* is not altered. From [2], reprinted with permission from AAAS.

periods, at least transiently, indicates the existence of dissociable, and hence multiple, oscillators. He subsequently developed the idea of a "temporal program" whereby the multi-oscillatory organization of the circadian system would lead to complex, seasonally changing scheduling of physiological events and might explain phenomena such as ►jet lag and ►photoperiodism [3].

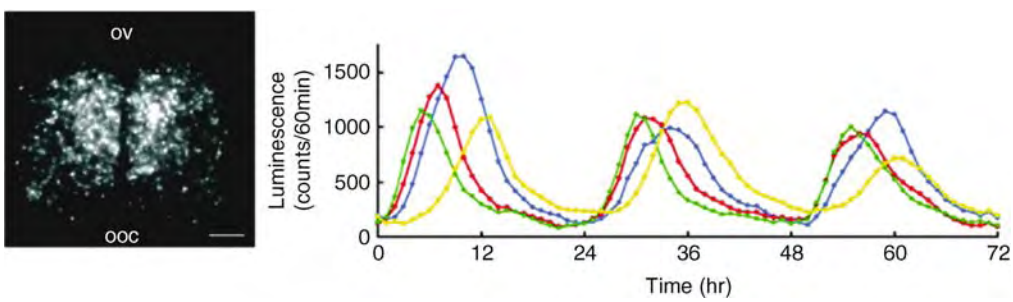
Multi-oscillatory models of circadian organization are supported by studies in a variety of species. For instance, Page [4] discovered that removal of the optic lobes of cockroaches eliminates circadian rhythms of locomotor behavior. The powerful technique of transplantation of optic lobes between animals with different circadian periods established that the period of the rhythm reinstated by the transplant was that of the donor. This proved that the optic lobe contains a pacemaker, rather than acting merely to permit expression of rhythmicity by a clock located elsewhere in the organism. Since the insect has bilateral optic lobes, it follows that there must be at least two circadian oscillators in the organism. Page further showed that the period of the intact animal is shorter than that of either optic lobe alone, arguing for coupling between the bilaterally paired pacemakers.

Other experiments in which circadian oscillators were localized to particular structures facilitated further insight into the multi-oscillatory structure of the circadian system. Electrophysiological recordings in the gastropod mollusks *Aplysia californicus* and *Bulla gouldiana* demonstrated that retinal neurons show circadian oscillations in action potential frequency. Dissociation of basal retinal neurons demonstrated their capacity to oscillate independently, proving the existence of multiple cellular oscillators. Among vertebrates, the ►avian pineal gland provided further evidence of multiple circadian oscillators. Not only do individual pinealocytes oscillate in their synthesis and secretion of ►melatonin, but in some species removal of the ►pineal gland causes a gradual decay of circadian rhythms of locomotor behavior. This argues for the existence of damping circadian oscillators whose coherence is normally maintained by the pacemaker. Using lizards, Underwood [1] showed that pinealectomy can lead to dissociation of circadian rhythms that free run with different periods (Fig. 2b). This not only indicates the multi-oscillatory structure of the circadian system, but also suggests a role for the pineal in maintaining coupling relationships between oscillators.

The suprachiasmatic nucleus (SCN) of mammals contains a set of neurons that can each generate a ~24 h rhythm via an intracellular molecular clock mechanism. While this group of oscillatory SCN neurons collectively forms the mammalian pacemaker, subpopulations can dissociate from each other. Antiphase patterns of gene expression have been observed in the left and right SCN of hamsters induced to split their circadian activity patterns by constant light ([2]; Fig. 2c). Ventral and dorsal regions of the rat SCN appear to dissociate when driven to the limits of entrainment. When SCN neurons interact synaptically, a consensus period emerges and neurons fall into phase-grouped populations (Fig. 3; [5]). Deficiency of vasoactive intestinal polypeptide (VIP) or the VPAC2 receptor compromises synchrony of both cellular oscillations and behavioral circadian rhythms. This suggests a role for these molecules in coupling between SCN neurons.

## Cellular Oscillators: Molecular Mechanisms

Demonstrations that individual basal retinal neurons of snails, suprachiasmatic neurons of rodents, and pinealocytes of chicks can sustain circadian oscillations not only force the conclusion that multiple oscillators exist within tissues, but also raise the question of whether individual cells may contain more than one oscillator.

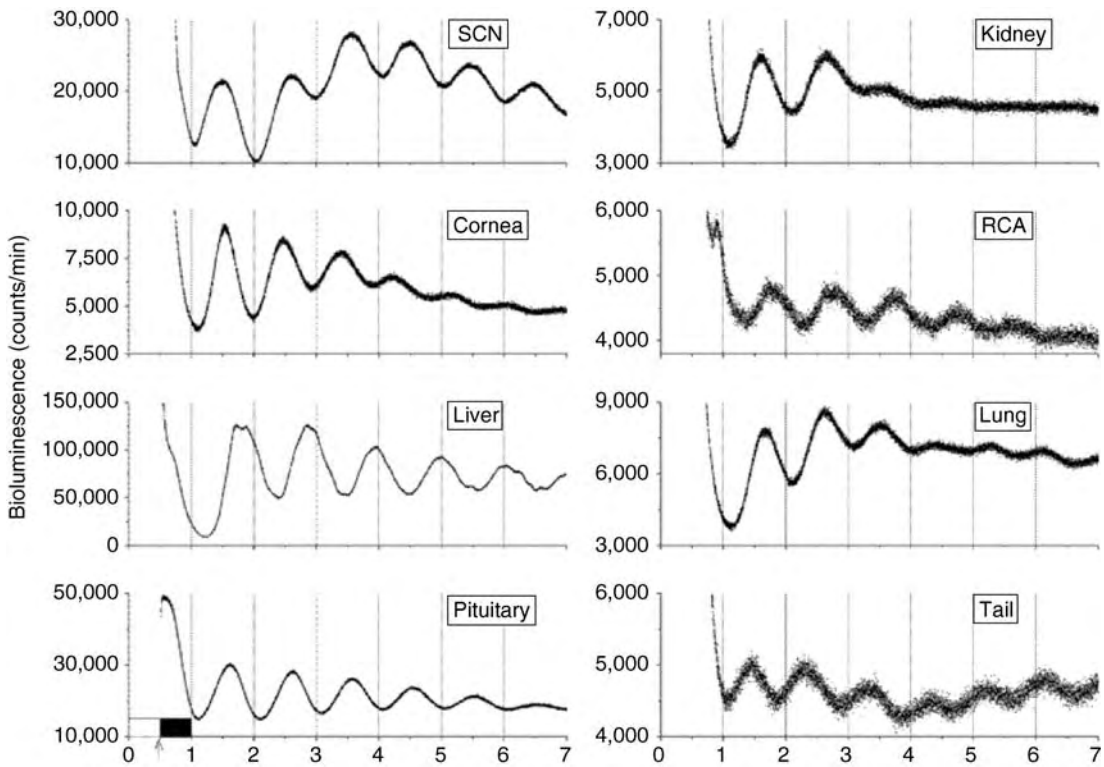


**Multi-Oscillator System. Figure 3** Expression of core circadian clock genes can be visualized in organotypic slices of the SCN, and in individual SCN neurons in culture. (a) Photomicrograph of an SCN slice prepared from a transgenic mouse carrying a Per1::Luciferase reporter construct. Ooc, optic chiasm; ov, third ventricle. Scale bar, 10 μm. (b) Luminescence due to reporter expression, reflecting PER concentrations, in four individual neurons visualized in the slice over a 3-day interval in culture. Note that individual neurons exhibit circadian periodicity of bioluminescence, but that the neurons depicted in blue and yellow peak at a phase later than the main cluster shown in green and red. From [5], reprinted with permission from AAAS.

Hastings and Sweeney found that the alga *Gonyaulax polyedra* expresses at least three distinct circadian oscillations: the intensity of bioluminescent glow, the frequency of flashing rate, and vertical migration in the water column. When these events occur with the same period, even in constant conditions and different phases, it remains possible that all are driven by a common oscillator mechanism. Under some lighting conditions, however, these three rhythms dissociate so that they free run with different periods. This argues for the existence of multiple oscillators within a single cell.

The modern era of study of multioscillator circadian systems began with characterization of molecular mechanisms that generate rhythmicity. In Drosophila the protein products of the ►Period, Timeless and ►*Cryptochrome* loci are engaged in a reciprocal interacting feedback loop with those of ►Cycle and ►Clock. Elegant studies utilizing a fluorescent reporter demonstrated not only that *Per* expression oscillates in individual isolated organs of the fly, but that these separate peripheral oscillators may be entrained by light in culture. With the discovery that several orthologs of Period are expressed in vertebrates, it became possible to investigate the multioscillatory organization of mammalian tissues and to study circadian rhythms in cell lines. Balsalobre et al. [6] demonstrated that a serum shock initiates an oscillation in cultures of immortalized cells and in primary hepatocytes. They proposed that the damping of cyclic *Per* expression that occurs after a few cycles reflects differences in period of individual cell oscillations leading to loss of phase coherence. This speculation has been validated through microscopic visualization of Period or ►*Bmal1*-driven luminescent reporters [7,8]. A mammalian organization similar to that of Drosophila, in which circadian oscillations persist in isolated organs, has now been demonstrated in mice ([9]; Fig. 4).

Not only do such studies establish that individual cells are oscillators, but they recall Pittendrigh's models of how a central neural pacemaker may coordinate and control the phasing of circadian rhythms throughout the body. According to the current model, entraining signals that originate in the pacemaker are relayed through appropriate pathways in order to set the phase and determine the period of peripheral oscillators. This communication may occur through innervation: the SCN in mammals communicates with paraventricular neurons that drive sympathetic output and thus may



**Multi-Oscillator System. Figure 4** Circadian rhythms of expression of *mPer2*, a core clock gene whose protein levels are reflected by bioluminescence in a mouse reporter strain, persist after isolation of brain regions (SCN, RCA: retrochiasmatic area) and peripheral organs (cornea, kidney, liver, lung, pituitary, tail) *in vitro*. The light:dark cycle experienced by the mouse prior to sacrifice and organ removal is depicted at the lower left. From [9]; copyright (2004) National Academy of Sciences, USA.

regulate the autonomic control of peripheral organs. Indeed, trans-synaptic retrograde tracing indicates the existence of multisynaptic pathways that connect the SCN with multiple visceral organs [10]. Furthermore, removal of vagal input interferes with rhythmicity of clock gene expression in the lung. On the other hand, humoral signals may carry SCN signals to the periphery. Secretion of a variety of pituitary hormones is clearly under circadian control, and glucocorticoids can set the phase of clock gene expression in liver and kidney. Importantly, cultured fibroblasts show a high amplitude phase resetting response to dexamethasone, a glucocorticoid analog [8]. Furthermore, circadian rhythms of fibroblasts fall under central control soon after their implantation to subcutaneous sites that lack innervation. Also among time cues that may serve to regulate peripheral circadian oscillators are those that arise from meal patterns. These could include carbohydrates, fats, and amino acids absorbed from the gut, or other food-associated signals. Fluctuations in temperature that may result from feeding or activity, whose rhythmicity may be pacemaker-regulated, can also regulate clock gene expression and thus potentially set the phase of peripheral oscillations. Cues arising from social signals may also play an important role in vertebrates. Regulation of clock gene expression by any of these signals – or perhaps more likely, by several in combination – may fit the definition of entrainment. It remains to be determined whether any such cues set the phase of ►peripheral oscillators in a physiological situation. It is also possible that physiological cues (such as hormones) that influence the period or amplitude of slave oscillators in the periphery alter temporal programs by determining the phase they take to signals from the pacemaker.

# Multiple Innervation

## Definition

The excess number of axonal innervations converging on a single target cell in the immature brain. The redundant inputs are eliminated through the process of synapse elimination and axon retraction during development.

►Synaptic Elimination

# Multiple Realization

## Definition

The thesis in the philosophy of mind that a given mental property, state or event is realized by different physical properties, states or events, which share no significant description at the physical level. Functionally defined kinds can be realized in a variety of physical states and processes, e.g. the kind "clock" can be multiply realized by a sun dial, a water clock, a mechanical mechanism or a silicon chip. If mental states like belief or pain are characterized functionally, i.e. in terms of their causalinferential relations to sensory input, to other mental states and to behavioral output, then they can in principle be realized by a variety of physical states and properties, e.g. by neural states in human beings and by silicon in Martians. The prospect of multiple realization

has served as an argument against the mind-body identity theory, which claims that types of mental states are identical to types of physical states, and against the reduction of the mental to the physical more generally.

Sylvia Lucas
Department of Neurology, University of Washington Medical Center, Seattle, WA, USA

## Synonyms

MS; Variants of MS include acute disseminated encephalomyelitis (ADEM), neuromyelitis optica (NMO or Devic's disease) and Balo's concentric sclerosis

## Definition

Multiple sclerosis (MS) is an inflammatory, demyelinating disease of the central nervous system characterized by a clinical course of neurologic dysfunction (relapses), periods of improvement (remissions) and for most patients a loss of functional capability which may be physical as well as cognitive. Focal demyelinated lesions or plaques are found in the white matter of the brain and spinal cord. Recent evidence [1] has shown that MS may include demyelination in the cortex and deep gray matter nuclei and diffuse axonal injury in normal-appearing white matter.

## Characteristics

### Epidemiology

MS affects approximately 350,000–400,000 Americans and 1.1 million patients world wide. It is second only to trauma as the most disabling neurologic condition in young adults. There is a female to male ratio which may be increasing and has been reported as high as 4:1. Though the clinical onset of the disease is uncommon under age 15 and over 45, it is most often diagnosed in young women of reproductive age in the 20's or 30's. A latitudinal prevalence exists which is lowest at the equator and increases above 40° north latitude and below 40° south latitude [2].

Besides environmental risk, there appears to be a genetic susceptibility as well, with a family history of MS in 15–20% of patients. The risk of a second sibling developing MS if one sibling has it is 3–5% with concordance in monozygotic twins of 31% compared to dizygotic twins.

Polygenic inheritance is likely and the major histocompatibility complex (MHC) on chromosome 6p21 encoding antigen-presenting proteins to T cells is an important susceptibility region. HLA-DR2 is associated with a three to four-fold increased risk of sporadic and familial cases of MS [3].

### Clinical Features

The onset of MS can be insidious without clinical symptoms (as evident on MRI obtained for other reasons) or abrupt and rapidly progressive. MS presenting symptoms are extremely varied and depend on lesion location in the brain or spinal cord (Table 1). An initial clinical event is known as clinically isolated syndrome (CIS) with a recurrent or second event (in time and space) defining clinically definite MS (CDMS). Any MS event may be monosymptomatic, involving a single clinical symptom with focal nervous system involvement, or polysymptomatic indicative of involvement of multiple areas of the nervous system.

Signs or symptoms of MS are non-specific and include all symptoms resulting from injury to any part of the brain or spinal cord. Approximately 85% of patients will have a relapsing-remitting course (RRMS) at disease onset. Acute attacks (the relapse) evolve over

**Multiple Sclerosis. Table 1** Initial symptoms of MS

| Symptom | Percent of cases | Symptom | Percent of cases |
|---|---|---|---|
| Sensory Loss | 37 | Lhermitte | 3 |
| Optic neuritis | 36 | Pain | 3 |
| Weakness | 35 | Dementia | 2 |
| Paresthesia | 24 | Visual Loss | 2 |
| Diplopia | 15 | Facial Palsy | 1 |
| Ataxia | 11 | Impotence | 1 |
| Vertigo | 6 | Myokymia | 1 |
| Paroxysmal Attacks | 4 | Seizures | 1 |
| Bladder | 4 | Falling | 1 |

Source: After WB Matthews et al. (1991) McAlpine's multiple sclerosis, New York, Churchill Livingstone

several days to weeks followed by stabilization and spontaneous recovery of symptoms (the remission). Between attacks patients are neurologically stable. As the disease progresses, however, attacks may become less frequent but MS patients may experience a steady deterioration in neurological function and accumulate disability (secondary progressive MS; SPMS). Prior to the advent of disease-modifying therapies, approximately 50% of MS patients with RRMS would develop SPMS after 15 years [4]. SPMS represents a late evolution of MS and is likely associated with axonal loss and loss of compensatory mechanisms (Fig. 1).

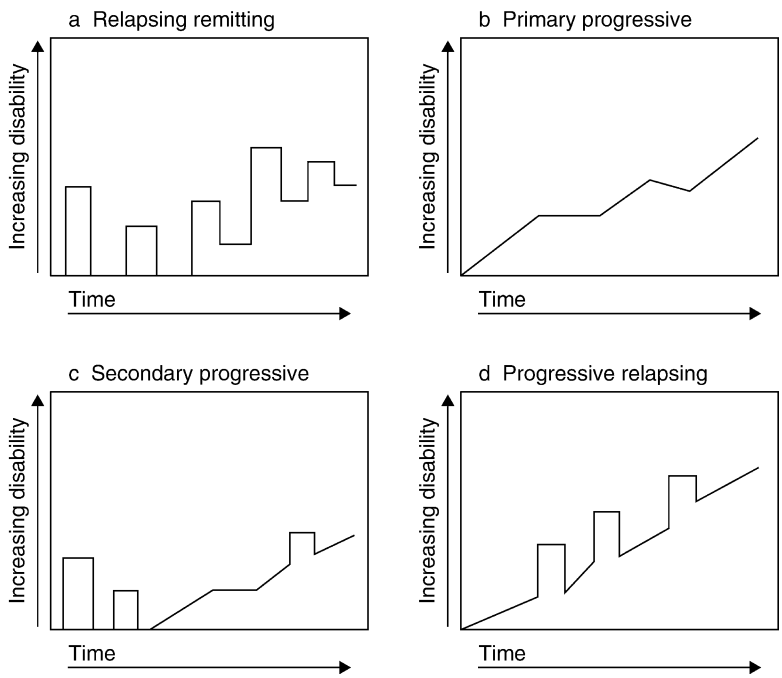
Because MS is thought to be predominantly a disease of white matter, inflammation and demyelination of myelinated tracts lead to common symptoms of sensory disturbances (paresthesias, numbness, dysesthesias), optic neuritis (usually unilateral), pyramidal symptoms, cerebellar symptoms (e.g. ataxia), or brainstem involvement (e.g. internuclear opthalmoplegia). Less common presentations are Lhermitte's sign (►Lhermitte's Symptom) (flexion of the neck produces electrical sensations or paresthesias along the spine or extremities), cortical symptoms or extrapyramidal syndromes. Bladder and bowel involvement is common (Table 1).

Symptoms which may also cause significant disability are fatigue, ►Uhthoff's phenomenon (symptoms exacerbated by increasing body temperature), primary pain syndromes (e.g. trigeminal neuralgia, flexor and extensor spasms, optic neuritis), spasticity, dementia, and mood disorders. Secondary pain syndromes may also occur such as hip or back pain from postural or gait abnormalities, decubital ulcers from skin breakdown, or compression palsies.

Attempts have been made to quantify neurologic impairment in MS to provide a current clinical description of the disease status of a patient as well as to follow disease course over time. The ►EDSS (Kurtzke Expanded Disability Status Score) and the Functional Status (FS) Score are used most commonly. Patients with EDSS scores <3.5 usually have RRMS and walk normally. Patients with EDSS scores >5.5 have symptom evolution indicative of progressive MS (SPMS or PPMS), are gait impaired and may be disabled [5].

## Diagnosis

There is no single definitive test for MS. The diagnosis is based on clinical and paraclinical criteria of "dissemination in time and space." CDMS requires documentation of two or more distinct episodes of symptoms lasting at least 24 h and two or more exam signs indicative of neurologic dysfunction in different white matter tracts of the CNS. Paraclinical studies used



**Multiple Sclerosis. Figure 1** Clinical course of MS. (a) Relapsing-remitting MS (RRMS) is characterized by acute attacks with full recovery or by a residual deficit after recovery. Times between relapses have no disease progression. (b) Primary progressive MS (PPMS) is characterized by progression of disease from the onset without periods of remission and no improvement in function. (c) Secondary progressive MS (SPMS) begins with an initial relapsing-remitting course followed by progression with or without relapses. (d) Progressive relapsing MS (PRMS) shows progression from the onset with superimposed relapses.

to diagnose MS include MRI, CSF findings and ►evoked potentials (EP) and may be useful to indicate disease activity even in the absence of any clinical activity.

MRI is 90–97% sensitive with typical lesions seen in periventricular white matter, corpus callosum, and juxtacortical white matter. Lesions are hyperintense on FLAIR and T2-weighted imaging (more useful than FLAIR for posterior fossa lesions), and may enhance with Gadolinium representing blood-brain barrier breakdown in acute disease activity. Chronic lesions may become hypointense on T1-weighted images (black holes) and other MRI findings of progressive disease are whole-brain atrophy, thinning of the corpus callosum and ex-vacuo dilation of the ventricles which correlate with cognitive impairment ([6]; Fig. 2).

CSF examination usually has a normal cell count or mild lymphocytosis, normal or slightly increased protein, and the presence of ►oligoclonal bands (OCBs) is highly sensitive (90–95%) for diagnosis, though they are not always present initially. There may be an increased IgG synthesis rate, IgG index and the presence of myelin basic protein [7].

Evoked potentials are most useful in patients with a history of optic neuritis and are abnormal in 90% of these patients. Visual, sensory or brainstem auditory evoked potentials are less sensitive (65–85%) and are usually unnecessary with the use of modern MRI imaging.

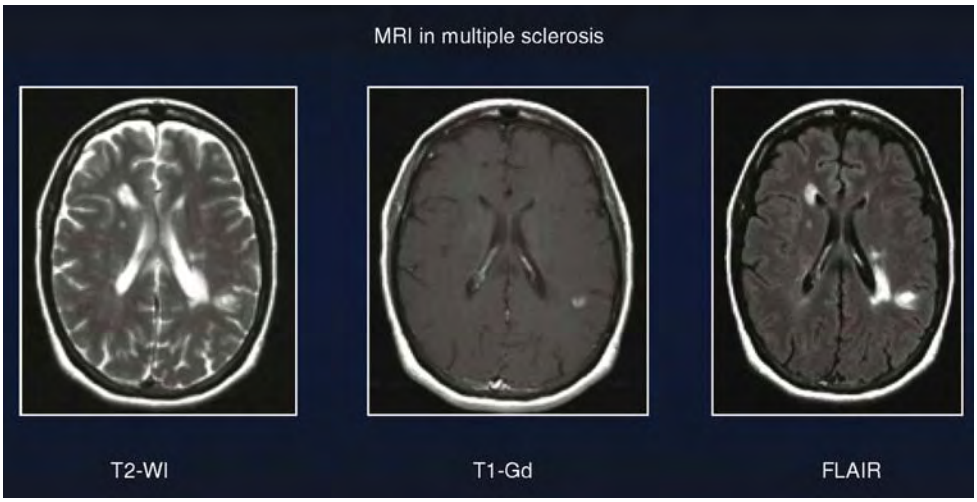
## Pathophysiology

In the autoimmune hypothesis of MS, T lymphocytes become "activated" expressing receptors for myelin components in the central nervous system. They enter the CNS through the specialized endothelial blood-brain barrier, attacking target antigens and triggering an inflammatory cascade.

The entry of activated T lymphocytes is mediated by chemotactic cytokines and cell adhesion molecules (e.g., VCAM-1) displayed on the inner surface of CNS microvascular endothelial cells. Interaction between VLA-4 (integrin molecules expressed on T cell lymphocytes) and Vcam-1 leads to T cell production and secretion of gelatinases, which break up perivascular basal lamina and allow entry into CNS interstitial spaces.

In a process similar to immune surveillance, these auto-reactive T lymphocytes find their specific antigen and start the inflammatory process. There are two roles for these T cells, one as Th1 cells producing proinflammatory cytokines such as IFN-gamma and TNF alpha. Th2 cells produce anti-inflammatory cytokoines (IL-4, IL-5, IL10 and are regarded as having a role in downregulation of brain inflammation and may lead to myelin repair and/or oligodendrocyte precursor activation.

Evidence in favor of the autoimmune hypothesis comes from lesion pathology [8]. Early active lesions are characterized by perivascular round cell inflammation, and are similar to inflammatory pathology seen in models of experimentally induced autoimmune encephalomyelitis (EAE). Additionally, disease susceptibility is associated with the polymorphic major histocompatibility complex (MHC) genes whose class II products are required for antigen presentation by the T lymphocytes.



**Multiple Sclerosis. Figure 2** MRI findings in a patient with relapsing-remitting multiple sclerosis. T2-weighted imaging (*left*) and FLAIR (*right*) imaging show several lesions in the periventricular white matter and juxtacortical areas. The T1 Gad image (*middle*) shows the left posterior lateral ventricular lesion enhancing with gadolinium indicative of an acute or active lesion.

The current working model of pathogenesis is based on evidence from human disease, EAE and other animal models of demyelination. This is a heterogeneous disorder with varying patterns of immune pathogenesis. In neuropathologic studies of MS lesions [9] four major patterns of demyelination are described. All patterns of these active MS lesions contain T lymphocytes and macrophages and though lesion patterns differ between patients, a given patient has a single lesion type. Patterns I and II (seen in 15% and 58% of patients, respectively) are characterized by oligodendrocyte survival and remyelination, with myelin appearing to be the principal target. Pattern I demyelination is probably mediated by macrophage toxins, whereas pattern II finds antibody deposition (Ig) and activated complement at sites of myelin destruction. Patterns III and IV (26 and 1% of patients, respectively) are characterized by oligodendrocyte loss and apoptosis with limited remyelination; oligodendrocytes appear to be the target of injury. Pattern III lesions show degeneration of distal oligodendrocyte processes with selective loss of myelin associated glycoprotein (MAG) and apoptosis. Pattern IV shows extensive oligodendrocyte degeneration in a small rim of periplacque white matter and no MAG loss or complement activation is present.

## Treatment of Multiple Sclerosis

There is no cure for MS. However, the results of controlled clinical trials with immunomodulatory and immunosuppressive therapy suggest that the natural course of MS may be modified. Additionally, it is important that diligence in the recognition and satisfactory treatment of symptoms of MS may dramatically improve a patient's quality of life.

Treatment of MS falls into three categories: (i) treatment for the acute attacks or relapses of MS, (ii) disease-modifying therapies that may change the natural course and long-term disability of MS and (iii) treatment of the symptoms of MS.

High dose corticosteroid therapy is used to manage either an initial attack or an acute relapse (breakthrough disease). It may provide a short-term benefit by shortening an attack and decreasing its severity though it is generally thought not to affect the long-term outcome of the disease. Typical treatment for relapses is a 3–5 day course of intravenous methylprednisolone at 1 g/day which may be followed by a tapering dose of oral corticosteroids for 1–2 weeks. Plasma exchange may be useful in patients with severe attacks refractory to corticosteroid treatment.

Immunomodulatory treatment is available for the treatment of CIS and RRMS with interferons and glatiramer acetate which may be self-injected, and natalizumab which is delivered by intravenous infusion. Interferon beta-1A and interferon beta-1B have been shown to decrease relapse rate, accumulation of lesion volume, and to decrease the number of enhancing lesions on MRI compared to placebo treatment. Though mechanism of action is not well understood, interferons are thought to reduce cell trafficking through the blood-brain barrier, shift T-cell response from Th1 to Th2, increase IL-10 and IL-4 production, and decrease antigen presentation and T-cell proliferation. Glatiramer acetate (a random polymer mixture of four amino acids) may shift T-cell response from Th-1 to Th-2, induce antigen-specific suppressor T cells, and compete with myelin basic protein on MHC II sites. It has effects similar to the beta-interferons on exacerbation frequency, however effects on MRI lesions or disability progression are less well established. These therapies were studied in 2- or 3-year clinical trials and long-term benefit is still unknown [10].

Natalizumab is a humanized monoclonal antibody which binds to alpha/4-beta 1 integrin on T-cells preventing association with VCAM-1 receptors on CNS endothelium and inhibits trafficking of T-cells into the CNS. It is delivered by intravenous infusion every 30 days has been approved for treatment of relapsing forms of MS. Though not directly compared to the interferons or glatiramer acetate in head-to-head trials, it may be more effective than prior approved therapies in reducing relapses and MRI activity. Close attention to safety issues via a specialized educational and reporting process was instituted following two cases of progressive multifocal leukoencephalopthy (PML) seen in the clinical trial setting with long-term use of natalizumab in combination with an interferon.

Treatment with the immunosuppressant mitoxantrone has been approved for SPMS and worsening RRMS. Mitoxantrone inhibits T cell, B cell, and macrophage proliferation, antigen presentation, and increases T cell suppressor activity. Mitoxantrone is an analogue of doxorubicin and has a cumulative dose ceiling to limit risk of cardiotoxicity. Delivery is by intravenous route every 3 months. Echocardiograms or other tests of cardiac function are recommended prior to each dose.

The aim of symptomatic therapy is to give relief from symptoms which have negative impact on function or quality of life. For example, bladder dysfunction in MS is common. Most often seen is the condition of a neurogenic bladder, with urgency, frequency and occasional incontinence. This and other bladder dysfunction such as detrusor/sphincter dyssynergia may be evaluated with urodynamic testing. Medication such as oxybutinin, hyoscamine, tolteridine, solifenacin, or trospium is usually helpful.

Depression may be seen in up to 50% of patients with MS and can be treated with medication or psychotherapy. The selective serotonin reuptake inhibitors (e.g. fluoxetine), selective serotonin reuptake/

norepinephrine reuptake inhibitors (e.g. duloxetine), or bupropion are most often used.

Fatigue may be dramatic and is the symptom most often causing disability in the workplace. Besides behavioral strategies to conserve energy, medication such as amantadine, modafinil and CNS stimulants (methylphenidate or amphetamines) usually help.

Constipation is the most common bowel problem in MS. A bowel program is often necessary and may consist of high-fiber diet, fluid intake, and laxatives administered orally or by suppository.

Spasticity is often seen with brainstem or spinal cord involvement in MS. Disinhibition of motor systems can manifest as tone changes, jerking or twitching, or a stiff-legged spastic gait. Stretching and exercise may help, and baclofen, tizanidine or diazepam are often helpful, though may cause sedation. For severe spasticity, intrathecal pump delivery of baclofen has improved function.

Pain symptoms are under-recognized in MS and can be due to a primary central pain syndrome (neuropathic pain) or secondary to other causes such as decubital ulcers, poor biomechanics, or osteoporosis. Central pain syndromes may respond to anticonvulsant medication, tricyclic antidepressants (e.g. amitriptyline), or selective serotonin/norepinephrine reuptake inhibitors. The addition of nonsteroidal anti-inflammatories and opioids may be of benefit.

### Prognosis

The clinical pattern or course of the disease is difficult to predict for an individual patient at disease onset. Certain patterns of disease are associated with slower progression and less disability. Optic neuritis or sensory symptoms at diagnosis, complete recovery between attacks, women and patients with one or two relapses in the first year of their MS will probably do better than those without these features. A progressive course has a worse prognosis for disability. Some patients have a more benign variant of MS and never develop disability. Mortality as a direct consequence of MS is highly uncommon. MRI has shown new or active lesions even in the absence of clinical disease. Known as "clinically silent lesions," these expressions of MS progression make it imperative that MS patients are followed with serial imaging studies as well as with office visits for clinical examination. If there is evidence of either clinical or radiological disease progression, more aggressive treatment to slow the course is likely to be of benefit. A comprehensive care approach to the treatment of MS by a caring, experienced physician can improve the quality of life for MS patients.

## Multiple Sclerosis: Macrophages and Axonal Loss

Elly J. F. Vereyken, Christine D. Dijkstra, Charlotte E. Teunissen
Department of Molecular Cell Biology and Immunology, VUMC, Amsterdam, The Netherlands

### Definition

►Multiple sclerosis is a disease of the central nervous system in which a progressive destruction of ►myelin, a fatty layer surrounding neurons, and transaction of neurons takes place. The mechanisms causing this destruction are largely unknown. ►Macrophages are thought to play a major role in the neuronal damage that occurs, through the release of inflammatory substances like ROS, ►cytokines and glutamate. Macrophages are not only detrimental in this disorder, but can also

be involved in axonal repair, e.g. by production of neutrophic factors.

## Characteristics

Multiple Sclerosis (MS) is a chronic inflammatory autoimmune disease of the central nervous system (CNS) and the most common cause of neurological disability among young adults. The prevalence of MS is approximately 1.5 million people worldwide and women are affected more often compared to men [1]. Three major clinical courses are recognized: the relapsing-remitting (RR-MS), the secondary-progressive (SP-MS) and primary progressive (PP-MS) subtype. Approximately 80% of the cases start with the RR subtype, which is characterized by clinical attacks that are followed by a clinically silent period with almost complete recovery. After a period of 10–15 years most cases of the RR-MS subtype develop progressive neurological deterioration without apparent remission, the SP-MS subtype. The last subtype, PP-MS, is less common and is characterized by progressive neurological impairment without relapses or remissions.

The major neuropathological hallmarks of MS are demyelinating lesions associated with perivascular infiltrates containing macrophages and lymphocytes. Most lesions also have some degree of astrogliosis, which is hypertrophy of and an abnormal increase in the number of ►astrocytes. The animal model that is most often used to study MS is ►experimental allergic encephalomyelitis (EAE). EAE is an inflammatory demyelinating autoimmune disease. The symptoms of EAE can be characterized as either acute or chronic-relapsing. To induce EAE animals are injected with CNS homogenate, myelin proteins or parts of these myelin proteins in adjuvant. Adoptive transfer of autoreactive $CD4^+$ T-cells or autoantibodies can also induce EAE passively.

Historically, MS has been viewed as a primary demyelinating disease with relative axonal sparing, although early papers did describe axonal damage and loss [2]. However, the view that axonal damage is important in MS pathology is now being widely accepted.

## Axonal Damage in MS

Demyelination has long been considered the main cause of disability in MS. However, more recent reports suggest that axonal injury is the correlate of irreversible clinical disability in MS patients. Early axonal damage may be either compensated for and/or repaired, but the continuous progression of axonal loss could ultimately lead to irreversible clinical dysfunction. A current hypothesis is that the transition from the RR to the SP subtype takes place once the loss of a critical number of ►axons is exceeded [2].

An indication that axonal damage might be important in MS pathology was that axonal transections are common in MS lesions, even in the periplaque white matter. It was most extensive in areas of active demyelination and inflammation. In chronic MS patients, axonal density was significantly decreased in both normal appearing white matter (NAWM) and lesions in the cervical spinal cord compared to controls. The decrease in axonal density was more extensive inside most lesions compared to the adjacent NAWM [2]. A marker for axonal injury is the amyloid precursor protein (APP). During acute injury anterograde axonal transport is interrupted causing APP to accumulate. In lesions with active demyelination APP accumulation was found, suggesting that axonal damage is a feature of early pathology and possibly associated with inflammation. In inactive lesions significant, though low-level axonal damage was observed associated with residual inflammation.

Magnetic resonance imaging (MRI) and spectroscopy (MRS) were used to visualize neuronal damage in living patients. Progressive brain atrophy was found to correlate with a decline in EDSS in MS patients. These findings suggest that brain atrophy leads to functional impairment. A more specific marker for axonal damage in MS is *N*-acetylaspartate (NAA), which can be detected *in vivo* in the brain using MRS. NAA is a mitochondrial amino acid that is primarily localized in neurons and neuronal processes, which means that a change in NAA signal reflects axonal injury and/or neuronal loss [2]. A relationship was observed between the decrease in NAA levels measured by MRS in MS lesions and the decrease in axonal density in corresponding biopsy specimens [2].

Changes in cerebrospinal fluid (CSF) concentrations of axon specific markers also point to a role of axonal damage in MS pathology and progression. In CSF of MS patients the NAA concentration was found to correlate with EDSS, a lower brain volume and a higher lesion load [3]. Other biomarkers for axonal damage in the CSF, as reviewed by our group, are proteins like Tau and neurofilament. The autoantibody index for the neurofilament-light chain has been found to correlate with atrophy [4].

All these data confirm the importance of axonal damage in MS pathology, which can already be observed early in the disease course. The mechanisms causing this damage are largely unknown. A hypothesis is that infiltrating macrophages might play a crucial role in axonal damage.

## Macrophages in Axonal Damage

It is generally accepted that macrophages/►microglia are involved in the pathogenesis of MS and EAE, for example through the removal of myelin debris by phagocytosis. Some indirect evidence has been found supporting a role for macrophages in axonal damage. Several studies have found correlations between

macrophages and axonal damage in MS lesions. The first example is the correlation observed between the location of axonal damage and cellular infiltrates in both MS and EAE [2]. Secondly, a correlation between the number of infiltrating macrophages and axonal damage, as viewed with both APP and axonal transections, was observed. Finally, the elimination of infiltrating macrophages or resident microglia in the CNS has a suppressive effect on the clinical signs of EAE, indicating a direct effect of macrophages on axonal function [1].

Macrophage and microglial activation are associated with an upregulation of a plethora of inflammatory mediators that could mediate the acute damage seen in the axons. Many studies have shown increased concentrations of markers for oxidative stress, like oxidized proteins, lipids and DNA [1]. These markers have been found in the CNS of EAE animals and sera of MS patients. This oxidative stress is caused by both ROS, like superoxide and hydrogen peroxide, and nitric oxide (NO). Treatment with ROS scavengers and antioxidants reduced inflammation and axonal damage in acute EAE [1]. By activating nuclear transcription factor-kappa B, ROS can induce the transcription of many genes involved in the pathogenesis of EAE and MS such as tumor necrosis factor-alpha (TNF-α), inducible nitric oxide synthase and intracellular adhesion molecule 1 [5]. The contribution of this pathway to the axonal damage in MS has not been investigated. ROS and NO could also lead to axonal damage by inducing oxidative stress in mitochondria. Axons are metabolically very active, especially due to impulse conduction and axonal transport. Mitochondria produce this energy and are therefore an intracellular source of ►reactive oxygen species (ROS). This makes them especially sensitive to exposure to extracellular ROS from macrophages. Mitochondrial dysfunction, due to the oxidative stress, leads to energy deficiency and can thereby lead to impairment of axonal transport and accumulation of APP. Impairment of axonal transport has been observed in many neurodegenerative disorders, like MS and Wallerian degeneration, indicating it plays an important role in axonal loss [6]. The precise mechanism behind decreased transport leading to axonal degeneration is not known. Reduced energy levels also cause increased sodium leakage into the axon and thereby reversal of the operation of the sodium-calcium exchanger and axonal swelling. This reversal of operation leads to increased intracellular calcium concentrations, bringing about the induction of apoptosis [6].

In CSF, blood and urine of MS-patients increased concentrations of markers of NO production, like peroxynitrite and 3-nitrotyrosine, have been observed. Peroxynitrite, which correlates with disease severity, is toxic and can damage both axons and myelin [1]. NO can induce a reversible conduction block in axons exposed to low frequency stimulation, while exposure to NO during higher frequency stimulation leads to axonal degeneration [7].

Both pro- and anti-inflammatory cytokines are upregulated, seemingly simultaneously as they are all detected in serum, CSF, and cultured mononuclear cells of MS patients. Cytokines have many different functions and in a complex disorder like MS it is not always clear whether they are beneficial or detrimental. For example moderate overexpression of TNF-α can lead to demyelination and axonal damage, very similar to that observed in EAE and MS [1]. However, no correlation was observed between axonal damage in MS patients and TNF-α expression in the CNS or serum levels, nor is treatment with TNF-α antibodies beneficial in MS. The same holds true for Interleukin-6 (IL-6), which has been implicated in induction of ►excitotoxicity, but also has been reported to have neuroprotective effects [1].

Glutamate is the most common excitatory neurotransmitter in the CNS. However, excessive concentrations of glutamate lead to excitotoxicity. Excitotoxicity is thought to play a role in MS since increased concentrations of glutamate have been observed in CSF of MS patients and this increase was found to be associated with the severity and course of the disease [1]. Treatment of EAE mice with an AMPA/kainate antagonist led to significant decrease in clinical scores, which corresponded pathologically to a reduction in axonal damage and oligodendrocyte loss [1].

## Macrophages in CNS Regeneration and Repair

Recently, evidence has been found pointing to not only a detrimental but also a beneficial role of macrophages in axonal regeneration/repair. Several studies have found macrophages to be involved in axonal regenerative processes at different locations. At these different locations different macrophage derived mediators were implicated. For example, it was found that increased brain derived neurotrophic factor (BDNF) expression by macrophages could lead to locomoter recovery and axonal outgrowth [8]. Four weeks after a spinal cord compression injury, causing paraplegia in rats, an injection of granulocyte macrophages-colony stimulating factor (GM-CSF) promoted increased expression of BDNF by macrophages at the lesion site and thereby axonal regeneration. Also *in vitro* microglia activated by GM-CSF produced more BDNF, causing co-cultured neurons to generate more neurites. This effect could be blocked by anti-BDNF antibodies.

After optical nerve crush, lens injury induced pro-regenerative effects due to an influx of macrophages. Macrophage infiltration corresponded with an upregulation in growth-associated protein (GAP)-43 expression levels. GAP-43 is a marker for axonal growth and

synaptogenesis. Intraocular Zymosan injection, which also results in massive macrophage infiltration, led to increased GAP-43 expression and axonal regeneration in absence of lens injury. In vitro, medium from Zymosan stimulated macrophages was able to enhance axon regeneration, with the axon-promoting effects being mediated by oncomodulin [9].

Finally, macrophages could be positively involved in axonal outgrowth through expression of the axon guidance molecule EphrinB3 [10]. Macrophages recruited to the site of nerve crush express this axon guidance molecule EphrinB3, while injured retinal ganglion cells express the receptor for EphrinB3. This was further confirmed by the fact that a reduction of EphrinB3 function led to a greatly decreased retinal ganglion cell axon re-extension or sprouting, after optic nerve injury in EphrinB3 heterozygous and homozygous null mutants.

## Subtypes of Macrophages

A current hypothesis poses that different activational subtypes of macrophages exist. These different macrophages have different functions in the immuneresponse and tissue repair. Interesting for the CNS could be the difference in their contribution to repair. The three main subtypes are: (i) the classically activated macrophages (CA-MΦ, also called M1), induced by IFN-γ and LPS; (ii) type II activated macrophages (MΦ-II), produced by exposure to IFN-γ in the presence of immunoglobulin G immunecomplexes; and the alternatively activated macrophages (AA-MΦ, also called M2), stimulated by IL-4 and/or glucocorticoids. The CA-MΦ is cytotoxic and secretes high amounts of NO and IL-12. The MΦ-II induces a Th2 response, through its release of IL-10. Finally, the AA-MΦ seems to be involved in immunosuppression and tissue repair, due to production of neurotrophic factors, extracellular matrix components and failure to produce NO [11]. Markers for the different types of macrophages are presented in Table 1. The most common used distinctive marker for AA-MΦ, in mice, is the higher expression and activity of arginase, leading to release of neurotrophic factors and extracellular matrix molecules [11]. Both CA-MΦ and MΦ-II are efficient antigen presenting cells, while AA-MΦ are not [11]. Until now, little research has been done about the presence and function of these different subsets of macrophages in neurodegenerative diseases like MS.

## Macrophages and Axonal Repair in MS

Removal of myelin debris by macrophages is thought to be important for axonal repair/regrowth, since myelin debris have been found to be growth inhibiting. In MS lesions activated macrophages/microglia are a source of growth factors, neurotrophins and their receptors that actively promote axonal regrowth, such as BDNF and the receptor for NGF [30]. It has been shown that both *in vivo* and *in vitro* macrophages/microglia in the CNS express nerve growth factor, neurotrophin-3 and BDNF [30]. Furthermore, macrophages could contribute to the resolution of the inflammation in MS thereby inhibiting further injury to the axons. It was found that myelin-laden foamy macrophages in active lesions expressed anti-inflammatory molecules, with the exact molecules expressed depending on the precise location in the lesions, while pro-inflammatory molecules were not expressed in any of the lesion locations [31]. *In vitro*, myelin ingestion induced foamy macrophage morphology and expression of anti-inflammatory molecules and inhibited the response to pro-inflammatory stimuli. This indicated a strong immunosuppressive function for foamy macrophages [31]. These foamy macrophages displayed functions and activities that might put them in the category of AA-MΦ. Another study also indicated that foamy macrophages in MS lesions might be AA-MΦ, since they express CD163, although the expression of mannose receptor is low in these cells [32]. Furthermore, periventricular macrophages, which are located at the blood brain barrier, have an AA-MΦ phenotype, since they do express both CD163 and mannose receptor. This could be important since their location at the blood brain barrier means they occupy a strategic position to control innate and adaptive immune responses in the brain [32].

Another indication that macrophages could be involved in axonal repair was found in our studies showing that activated macrophages are present in the areas of increased GAP-43 expression [33]. Levels of GAP-43 were higher around lesions. Although no correlation was found between the intensity of GAP-43 staining and macrophage presence, their presence was consistently observed in areas of increased GAP-43 expression. Macrophages producing neurotrophic factors, like neurotrophic growth factor and BDNF could induce the increase in GAP-43 expression [33]. We are planning to investigate the phenotype of the macrophages present in the areas of GAP-43 expression.

## Future Perspectives

Our hypothesis is that alternatively activated macrophages and classically activated macrophages may be different phenotypic forms of macrophages during different phases of MS pathology. This is schematically represented in Fig. 1. Classically activated macrophages could play an important role in causing axonal damage early in lesion development, through the release of soluble mediators like NO, ROS and glutamate. When lesions develop further and macrophages are present in the tissue longer, our idea is that the classically activated macrophages change into alternatively activated macrophages. Alternatively activated macrophages can play a role in the resolution of inflammation due to their anti-inflammatory nature

**Multiple Sclerosis: Macrophages and Axonal Loss. Figure 1** Hypothesis of macrophage activation in MS lesions. As the macrophages enter the lesion site, they are classically activated due to the local inflammation. These classically activated macrophages induce axonal damage due to secreted factors like NO, pro- inflammatory cytokines and glutamate. The macrophages at the lesion site spent time in the CNS tissue. Slowly the surrounding tissue starts to affect the activational phenotype of the macrophages. Due to IL-12 secreted by astrocytes and ingestion of myelin, the macrophages take on an alternatively activated phenotype. These macrophages are involved in axonal repair due to the expression of growth factors, induction of GAP-43 expression in neurons and secretion of anti-inflammatory cytokines.

and axonal repair/regeneration through the release of neurotrophic factors.

It has been shown that classically activated macrophages can still become alternatively activated and vice versa [34]. The activational subtype of the macrophage is therefore not fixed and could be influenced by the surrounding environment, such as CNS cells like astrocytes. For example, the ingestion of myelin, which makes macrophages foamy, could induce an alternative phenotype in macrophages [31]. In Gaucher disease glycolipids also accumulate inside macrophages, which subsequently show an alternatively activated phenotype. This seems to implicate that glycolipids could induce alternative activation. It might be that accumulation of glycolipid constituents of myelin directs macrophage gene transcription to induce the alternatively activated phenotype in MS. However, it is still a question whether foamy macrophages, which have been shown to be anti-inflammatory [31], can be really characterized as alternatively activated. Another question is whether foamy macrophages are able to directly induce GAP-43 expression in axons and whether this also leads to functional repair. Furthermore, it has been shown that astrocytes secrete IL-12, which could influence the macrophage activational subtype and skew it more to the alternative side.

Future therapeutic interventions should aim at reducing activation of classically activated macrophages during early phases of lesion development, while stimulating the formation of alternatively activated macrophages. Since axonal damage occurs early during disease course, perhaps specifically blocking the activity of classically activated macrophages could be a candidate therapy. It may also be a good option to treat patients early during disease course with substances able to induce the alternative phenotype, thus reducing inflammation, axonal damage and consequently clinical dysfunction.

## Multiple Sleep Latency Test

### Definition

A standardized, objective, clinical and research tool used to assess physiologic sleepiness. The test is based on the idea that the sleepiness can be measured by the speed of falling asleep under controlled environmental conditions of lying in bed with the lights off. Polysomnographic recordings of electroencephalogram (EEG), electrocardiogram (EKG), chin electromyogram (EMG), and eye movements are analyzed for four to five 20-min nap opportunities provided every 2 h across the day (e.g., naps at 1000, 1200, 1400, 1600, 1800 h). The average time that it takes to fall asleep across naps is calculated. Average sleep latency below 5 min is considered to be indicative of pathological or excessive sleepiness. Average latencies of between 5 and 10 min are considered to be in the grey zone and average sleep latency above 10 min is considered to indicate a normal or low level of physiological sleepiness.

►Parkinsonism

## Multipolar Neuron/Cellular

### Definition

A multipolar neuron is a neuron with many processes and a variety of shapes. Common example is the motoneuron and stellate cells.

## Multipotency

### Definition

Multipotency is a word describing the ability of a progenitor cell or tissue stem cells to give rise to a limited number of cell types. If a progenitor cell of the central nervous system is capable of turning only into neurons, astrocytes, and oligodendrocytes, for example, the cell is said to be “multipotent.”

## Multisensory

### Definition

Refers to neurons that are capable of responding to stimuli from more than a single sensory modality and to the neural processes associated with these responses (e.g., multisensory integration).

►Multimodal Integration

## Multisensory (Convergence, Integration)

### Definition

Many neurons of the central nervous system outside the specific sensory nuclei respond to peripheral stimuli of more than one modality, e.g., visual, auditory, somatic. They display thus a property of multisensory convergence.

When presented simultaneously, stimuli of different modalities can produce stronger or weaker responses, as compared to the sum of responses to separate presentations of unimodal stimuli. Because interaction of modalities at the level of single neurons is far more complex than a simple summation, it is described by the term "multisensory integration." An example of multisensory integration is given by tectoreticulospinal neurons (TRSNs) which transmit motor command for a gaze shift and display, at the same time, a multisensory convergence.

►Multimodal Integration
►SC-Tectoreticulospinal neurons (TRSNs)

## Multi-Track Disposition

### Definition

A disposition whose manifestations can widely vary. e.g. the softness of an object can manifest itself in uncountable ways, whereas water-solubility is a single-track disposition which can only manifest itself by dissolving in water.

►Behaviorism
►Logical

## Multi-Unit Recording

### Definition

Simultaneous recording from multiple nerve, glia or muscle cells (units) by means of a single electrode or pair of electrodes.

►Extracellular Recording

## Muscarinic Receptors

### Definition

Muscarinic receptors are G-protein coupled receptors that respond to acetylcholine and muscarine, and that are blocked by atropine and related anti-muscarinic agents. They occur in five subtypes. Muscarinic M3 receptors have been considered to be an effector cell receptor, M1 a ganglionic, and M2 a presynaptic inhibitory one. In the peripheral nervous system, more than one type of the excitatory muscarinic M1, M3 and M5 receptors and of the inhibitory muscarinic M2 and M4 receptors may however co-occur on effector cells as well as on nerve fibers.

These receptors are expressed in smooth muscle, cardiac muscle and glands as well as in the peripheral and central nervous system. Muscarinic receptors mediate the excitatory effects of parasympathetic nerves in the urinary bladder.

### Introduction

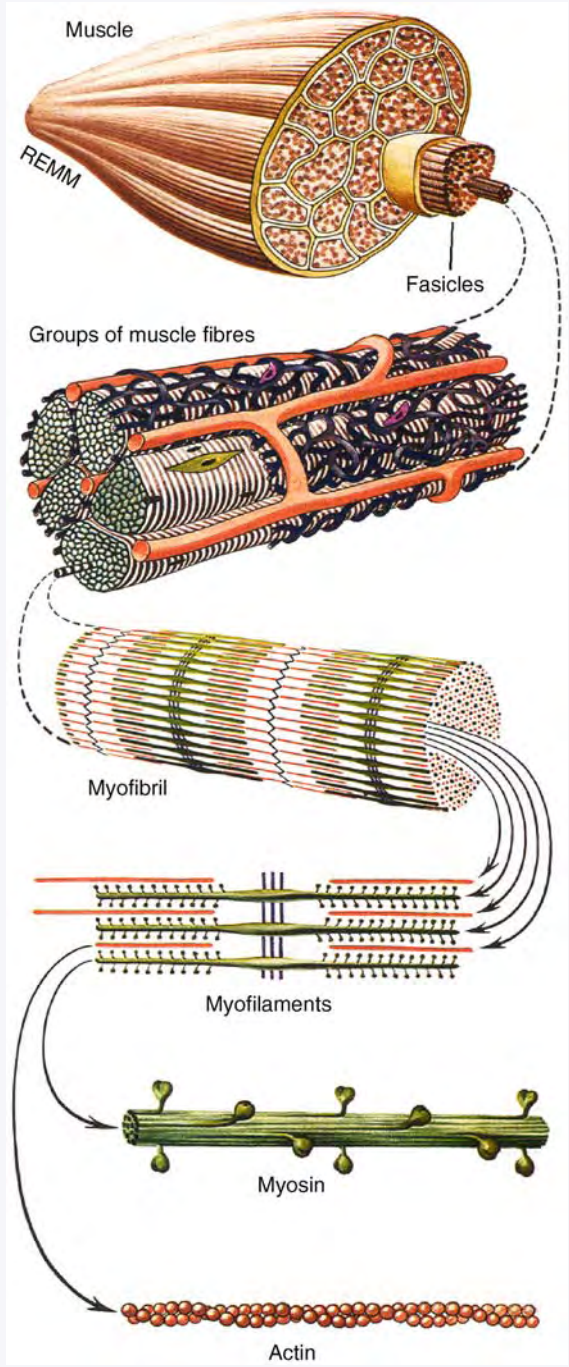
Skeletal muscle is the actuator for all vertebrate movements. As such, it has been the focus of scientific inquiry since the time of Erasistratus in the third century BC. While the earliest studies of muscle function focused on whole muscle properties, more recent investigations have been performed at levels ranging from mechanics within functional muscle groups down to the molecular interactions responsible for the active modulation of these mechanics. In accordance with the goals of this Encyclopedia, this section will focus on the role of muscle properties in the neural control of posture and movement. Hence, an emphasis will be

placed on the properties and control of individual motor units, the fundamental element of neural control, and how these units contribute to the regulation of whole muscle properties relevant to normal movement conditions. However, we also provide an overview of seminal findings across the spectrum of muscle research, from the molecular level to whole muscle behavior.

## Muscle Structure

The macroscopic properties of muscle relevant to the neural control of movement arise from the underlying microstructure and corresponding molecular interactions involved in the chemical to mechanical energy conversion process known as muscle contraction. Each whole muscle is composed of many long thin cells, or muscle fibers, arranged parallel to each other (Fig. 1). Most fibers terminate in microtendons, which merge to form the aponeurosis and tendon that connect to the skeleton. Because of this parallel organization, the total force a muscle can produce is proportional to the summed cross-sectional area of all the fibers. The fibers are, in turn, composed of several thousand parallel myofibrils. Each myofibril is composed of repeating microscopic units (2–3 μm in length) called sarcomeres, which are the basic contractile units of muscle. Since sarcomeres within a fiber are linked in series and contract together, many key muscle properties, such as the maximum speed at which a muscle can shorten, are proportional to the length of the fiber. For this reason, muscle contractile properties are often normalized by both the muscle cross-sectional area and the fiber length (see essay ►Muscle: Tendon, Intramuscular Force Transmission).

The sarcomere is the basic contractile element (Fig. 1). It is composed of two sets of interdigitating protein filaments, called thin and thick filaments, which can slide by each other. The sarcomere is held together by large molecules that form the Z lines at each end and by the giant protein titin, which forms a spring between Z line and thick filament. Titin helps to maintain sarcomere shape as well as transmit force from the contractile proteins to the Z lines [1]. Each thick filament consists of a few hundred myosin molecules; the helix part of the myosin molecules aggregate to form the dominant part of the thick filament. A portion of the helix for each molecule extends out from the thick filament to form the myosin head, which has the capacity to swing up and attach to actin on the thin filament [2]. The myosin head and the portion of its helix that protrudes from the thick filament is known as a crossbridge. The thin filament is dominated by actin, but also includes the proteins tropomyosin and troponin, which regulate the interaction between actin and myosin. Actin monomers are connected end to end to form two fibrous strands that are wrapped around each other in a helical form. Tropomyosin is a chain structure that lies in the groove between the strands of actin, whereas troponin is a globular complex that binds to tropomyosin periodically (see essays ►Sarcomere structural proteins).



**Muscle. Figure 1** Muscle structure. Diagram shows the organization of an idealized muscle. (from Gray's Anatomy, Warwick and Williams).

Muscle contraction occurs when calcium ($Ca^{2+}$) binds to troponin and causes a shift in the position of tropomyosin, uncovering binding sites for the myosin heads on actin. Depolarization of the muscle fiber via an action potential causes $Ca^{2+}$ release from the sarcoplasmic reticulum where it is sequestered at rest (see below). Large populations of crossbridges on the thick filaments interact with receptor sites on the actin, to produce force and relative motion between the two sets of filaments. Adenosine triphosphate (ATP) is the energy source and is needed to detach the bridges and maintain movement. Several different substrates (e.g. glycogen, fat) are broken down via different biochemical pathways to provide the ATP for cross-bridge cycling. The forces thus produced between the two filaments are in a direction to cause each sarcomere to shorten. The actin and myosin filaments are approximately inextensible, and sarcomere shortening occurs because of the relative sliding of the filaments past each other (sliding filament theory) [3] (see essay ►Muscle: the molecular motor, ►Energy sensing and signal transduction in skeletal muscle).

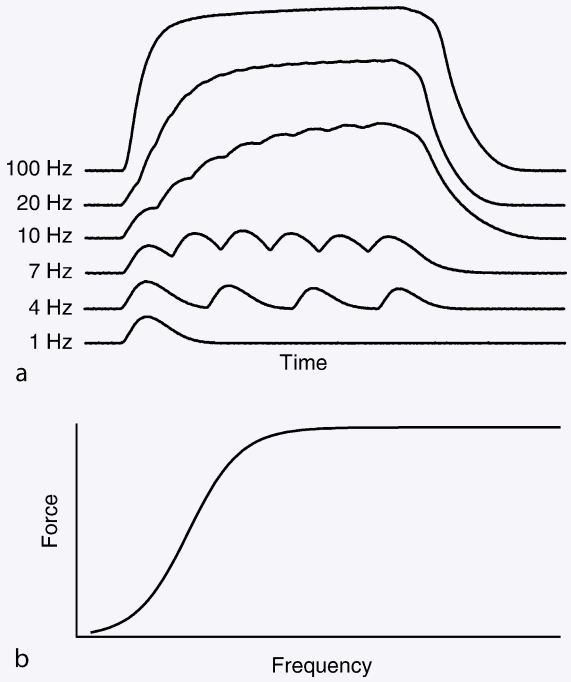
Muscle has specialized structures to allow a quick contraction following an action potential in the motor neuron. This complex process includes the following steps: release of acetylcholine at the neuromuscular junction in a response to the action potential, generation of a muscle fiber action potential, depolarization of the t-tubules that protrude into the muscle fiber, activation of ryanodine receptors, and release of $Ca^{2+}$ from the sarcoplasmic reticulum. Pumps on the sarcoplasmic reticulum rapidly re-sequester $Ca^{2+}$, so that each action potential produces only a single pulse of $Ca^{2+}$ and a single muscle twitch (see 1 Hz trace, Fig. 2a). The rate at which action potentials arrive at the muscle determine the sarcoplasmic level of $Ca^{2+}$, and hence, the strength of the contraction. This complete process is referred to as excitation contraction coupling (see essay ►Excitation Contraction Coupling).

## Basic Muscle Properties

Muscle has four basic properties that are essential for understanding its control by the CNS (Figs. 2–4). These are: the force-frequency (F-f) relationship, the force-velocity (F-V) relationship, the length-tension (L-T) relationship, and muscle stiffness. Each will be discussed in the following paragraphs. Their fundamentals have been understood since the 1950s, but the details about the interaction between these properties, how they are used in normal movement, and how they relate to the properties of single motor units, are still incomplete.

## Force-Frequency

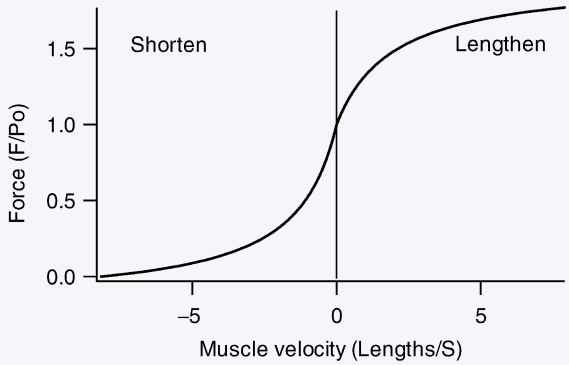
In general, a single muscle action potential does not produce full muscle force; rather, most actions require a sequence of action potentials. Summarizing the relation between an action potential train and the resulting muscle force has proven difficult. However, a useful steady state relationship can be determined by plotting action potential frequency against muscle force (Fig. 2). As the frequency is increased, single muscle twitches fuse and force increases (Fig. 2a). At high enough stimulus rates, which is dependent on the motor unit composition (see below), force is smooth. A further increase in action potential rate does not produce more force. This sigmoidal relation is shown in Fig. 2b. Stimulations rates and the details of the temporal pattern have important implications for the study of muscle function and its restoration following trauma or disease (see essay ►Force-Frequency; Muscle).



**Muscle. Figure 2** Force-Frequency characteristics of a muscle (cat soleus). (a) shows the force waveforms produces when a muscle is held isometrically and stimulated at different frequencies (action potentials per second). (b) Sigmodial curve obtained when the mean force is plotted against the stimulation frequency. This relationship is, at best, a rough approximation and depends strongly on the exact experimental procedures to measure it.

## Force-Velocity

The relationship between force and velocity is of fundamental importance when considering the power output and work performed by a muscle. Basically, when an active muscle shortens, it produces less force compared to that produced when it is held isometrically. A plot of the steady state relationship between

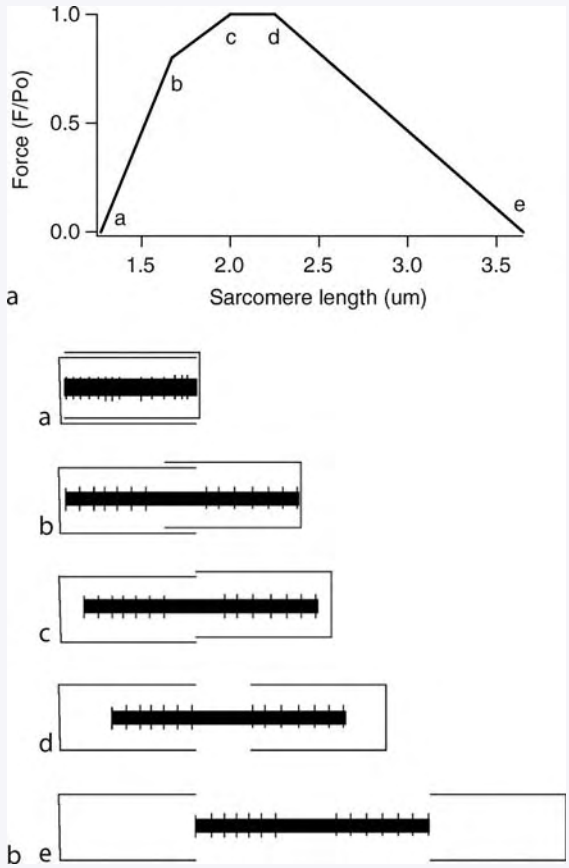


**Muscle. Figure 3** Force-Velocity Relationship. When a muscle is activated and allowed to shorten against a load, it reaches a steady state velocity. When this relationship is plotted for different loads Hill's hyperbolic relationship is obtained (left side of plot). Similar measurements can be made using loads large enough to stretch the muscle (right side of plot). However, a true steady state is not reached during stretch and different results are obtained depending on whether a constant load or constant velocity is imposed on the muscle.

shortening velocity and muscle force results in a characteristic hyperbolic curve [4] that has been demonstrated in all skeletal muscles tested (Fig. 3). The maximum shortening velocity, Vmax, is the point where the muscle can no longer produce any force. Peak power is obtained from a muscle at a velocity between zero and Vmax. Huxley [3] showed this relationship can be explained using a probabilistic model of crossbridge dynamics. The relationship between force and velocity is more complex during lengthening contractions. A steady state relationship is never really achieved. The muscle may also be damaged by active stretch. An approximate relationship between stretch velocity and force shows force initially increases but soon a plateau is reached at moderate lengthening velocities [5] (see essay ►Force-Velocity Relationship of Skeletal Muscle).

## Length-Tension

Muscle force is strongly affected by its length. During maximal stimulation the length-tension relationship (Fig. 4a) has a characteristic shape with an ascending limb, a plateau region of optimal force generation (defining an optimal length, $L_O$) and a descending limb. During tetanic stimulation the relationship is nicely explained by changing filament overlap within the sarcomere (Fig. 4b) [6]. However, the high frequencies used to induce a tetanic contraction in the laboratory are unlikely to be encountered during the physiological activation of motor units. At lower rates of activation, the length-tension relationship changes such that the peak shifts to longer lengths [7] (see essay ►Length-Tension).



**Muscle. Figure 4** Active Length-Tension relationship during tetanic activation. Idealized length tension relationship (top) and the sarcomere position (bottom) believed to produce it. (Redrawn from [6]). Force from passive muscle structures are also important. They are not shown in this figure.

## Muscle Stiffness

The CNS not only has to give commands to muscle to produce movement, but must also deal with stability of muscle in response to perturbations from the environment. The response of muscle to a perturbation, either lengthening or shortening, defines its stiffness (here we use "stiffness" in its most general form, to include all resistance to externally imposed displacements). For short perturbations muscle has a very linear spring-like response due to the spring-like behavior of the crossbridges. For larger perturbations, the response becomes complex and is determined by the L-T and F-V properties of sarcomeres. The passive structures within a muscle are also very important. The tendon and aponeurosis are connected in series with the muscle fibers and thus provide a series-elastic element (SEC). At long lengths, the passive molecules like titin that maintain the structure of the sarcomere also contribute substantially to total muscle stiffness [1]. These structures are in parallel with the force generated by

crossbridges and thus form the parallel elastic element (PEC). The PEC also includes the connective tissue surrounding muscle fibers as well as structures like the muscle fiber cell membrane. While the crossbridge dependent properties (L-T, F-V) are important determinants of stiffness at all lengths, tendon and other connective tissues are usually slack at short muscle lengths and the PEC does not contribute until muscle is stretched beyond its optimal length (see essays ►Muscular Stiffness, Tendon).

## Muscle Models

Many different models of muscle force generation have been constructed. Perhaps the most widely used for the purposes of motor control is the Hill model. Originally, the Hill model contractile element consisted solely of the F-V function during shortening, which was placed in series with a spring representing tendon (i.e. the SEC) and in parallel with a spring representing the PEC. Recent models typically add the lengthening F-V function and use the L-T and F-f relationships to scale the F-V curve in order to account for more realistic behavior [8]. Also important are models based on crossbridge dynamics. Such a model was initially developed by Huxley [3] and models of this type are usually referred to as Huxley-type models or crossbridge models. These models can be modified to include reasonably detailed mathematical descriptions of $Ca^{2+}$ dynamics to provide activation functions [9]. Muscle models face many tough challenges, primarily because the behavior of muscle is complicated. Thus far, we have only considered the "classic" muscle properties. Even these relatively simple muscle behaviors constitute a rather complicated mechanical interface: muscle force varies not only as a function of its neural activation but also as a function of its length and velocity. However, few studies have addressed the role of these and other complex properties in the neural control of movement. Recent studies attempting to assess muscle properties during normal movement conditions, including the use of advanced imaging techniques, hold much promise for both understanding muscle function and validating the models used to describe and predict that function (see essays ►Muscle Modeling; Muscle Imaging, Techniques: Computerized tomography, Magnetic resonance imaging, Ultrasound).

## Complex Muscle Mechanical Behaviors

As mentioned above, attached crossbridges exhibit a spring-like response to small stretches, known as short range stiffness (SRS). For stretches greater than approximately 1–2% of fiber length, the attached crossbridges are broken causing a sudden drop in stiffness known as yielding [10]. Yielding is most pronounced in slow twitch muscle fibers because of their slow re-attachment rates. Although SRS varies with muscle fiber type, these differences do not appear to play a significant role at the whole muscle level [11]. The participation of crossbridges in the SRS means that it varies as a function of muscle activation: increased activation results in more attached crossbridges, higher muscle force and increased SRS. In addition, tendon itself exhibits increasing stiffness with increasing applied force.

Activation also plays a pivotal role in regulating F-V and L-T properties. This occurs in two ways. First, there exist interactions between the F-f, L-T and F-V functions. Perhaps the most important interaction is that between the F-f and L-T functions. [7] showed that as stimulation rate is reduced below that needed to achieve maximal force, the $L_O$ point of the L-T function progressively shifts to longer lengths. Thus, the L-T function at low stimulation rates is not simply a scaled-down version of that at high rates. Interactions between the F-V and F-f functions are also important, especially during lengthening where, for example, yielding is greater at low stimulation rates [5]. There also exists an L-T/F-V interaction. At longer lengths, stretching at a given velocity produces more force [5]. A second important form of activation dependence is that F-V properties are very different in muscle fibers of different contraction speeds. These differences reflect both differences in the myosin ATPase on crossbridge heads and in the $Ca^{2+}$ release system [12]. Thus as motor units of different speeds are recruited as force increases, F-V behavior changes (see the section on "Motor Units" below). Finally, it is important to realize that the activation of muscle in itself is affected by movement. That is, the $Ca^{2+}$ system for control of crossbridge interactions is sensitive to both length and velocity [13]. Thus one reason that $L_O$ shifts to longer lengths at lower stimulus rates is that $Ca^{2+}$ release is length-dependent. In addition, movement may enhance $Ca^{2+}$ release and thus speed the decay of force in a velocity dependent manner [14] (see essays ►Muscle Stiffness, ►Length-Tension, ►Force-Velocity Relationship of Skeletal Muscle, ►Force Potentiation in Skeletal Muscle).

Muscle also exhibits a number of behaviors that can be thought of as being history dependent, in that their occurrence depends on a particular sequence of events. Perhaps the F-f function is most influenced by muscle history because its shape is highly sensitive to the measurement protocol [15]. A simple change as reversing the order of the test frequencies has a profound effect. In addition, in isometric conditions, muscle force can be strongly potentiated by a brief high frequency activation (post-tetanic potentiation) or even by a single pair of closely spaced stimuli (doublet potentiation) [16]. Of course, if stimulation is prolonged, fatigue ensues. Fatigue is a complex

phenomenon acting at multiple locations within the muscle. These mechanisms are not yet fully understood, but it plays a key role in motor function. For example, the normal activation pattern of motor units appears to be designed to minimize the impact of fatigue (see below). Movement history also strongly influences muscle function. For example, muscle generates a greater isometric force (force enhancement) when it has been stretched during activation compared to when it has been stretched passively and then activated [17]. The converse phenomenon is also often seen: less isometric force following shortening of an active muscle (force depression) (see essays ►History-Dependent Properties of Skeletal Muscle).

## Muscle Architecture

Provided the sarcomeres in a muscle are identical, and provided the fibers in a muscle are the same length and parallel to each other, the whole muscle can be viewed as a scaled version of the sarcomere. Few, if any, mammalian muscles fit the idealized profile above. Muscles come in a vast array of sizes and shapes and complex architecture is more the rule than the exception. Muscle fibers often lie at an angle to the direction in which the entire muscle changes length. This angle, called the angle of pennation, allows more muscle fibers to be arranged in parallel thus increase the force to weight ratio. Assuming the pennate fibers are attached to two bony surfaces that slide by, but do not approach each other, muscle force and length can be calculated by scaling fiber force and length by the cosine of the angle of pennation. This is the correction most models use to compensate for pennation. The true effects of pennation are more complex when the fibers are attached to connective tissue sheets, called aponeurosis, that show local deformation. Furthermore, connective tissues link adjacent muscles and, as a consequence, deformations in one muscle may influence force generation in another [18] (see essays ►Skeletal Muscle Architecture, ►Epimuscular Myofascial Force Transmission and Intermuscular).

Muscles are often composed of fibers of different lengths to accommodate for skeletal dimensions. Longer muscle fibers increase the maximum velocity of shortening by increasing the number of sarcomeres in-series. Recent studies have shown many seemingly long fibered muscles do not have fibers that run the length of the muscle (from tendon insertion to the tendon of origin), but rather are composed of fibers connected serially [19]. A portion of the force from these nonspanning muscle fibers must be transmitted to the tendon via myofascial pathways [20]. Serial fibers likely add to muscle compliance (see essays ►Intramuscular Myofascial Force Transmission, ►Epimuscular Myofascial Force Transmission and Intermuscular, ►Skeletal Muscle Architecture).

## Motor Unit Types

The CNS controls not individual muscle fibers but motor units, which are the quantal elements of motor control. The motor unit consists of a motor neuron in the ventral horn of the spinal cord, its axon, and the muscle fibers that the axon innervates [21]. The muscle fibers belonging to a single motor unit are often termed the muscle unit. There exist a very wide range in both the electrical properties of motoneurons (see essay Motoneurons) and in the mechanical properties of their muscle units [21]. Slow twitch motor units exhibit not only slow contraction speeds but also low maximum forces and very high fatigue resistances. At the other end of the spectrum, the fastest contracting motor units generate the highest forces and have very little fatigue resistance. In between are fast contracting units with moderate forces and moderate fatigue resistances. These differences have been used to divide motor units into three or more types (S for slow, FR for fast fatigue resistant and FF for fast fatigable) [21], but it should be kept in mind that there is a more or less continuous distribution of contraction speeds, forces and fatigue resistances (see essay ►Motor Unit Types).

For the usage pattern of motor units, the most important factor is that the amount of synaptic current required to bring the motoneuron to threshold covaries with the mechanical properties of its muscle unit (see the Motoneuron section). Thus, the activation (recruitment) of motor units always begins with the small, slow twitch, low force units followed by recruitment of progressively faster and higher force units (i.e. S > FR > FF). As a result, overall contraction speed of the muscle increases as its activation level rises while fatigue resistance decreases. This recruitment-dependent behavior is rarely considered in muscle models.

## Electromyography

Normally, a motoneuron action potential produces a corresponding action potential in each of the fibers of its muscle unit. Hence motoneuron firing patterns can be measured from muscle motor units in both humans and animals. Single fiber or single motor unit action potentials directly assess motoneuron firing patterns (motoneurons are the only CNS cells whose firing pattern can be individually measured in human subjects). Less selective electrodes measure the summed electrical activity of many motor units, the electromyogram (EMG). Both single fiber and whole muscle EMGs are valuable tools for assessing muscle and CNS function in normal and disease states (see essay ►Electromyography, ►Neuromuscular Junction).

## Muscle Plasticity and Disease

Muscle is likely the most plastic tissue in the body. To support the metabolic costs of the protein synthesis

required for this adaptability, muscle fibers are multinucleate. In fact, small animal fibers of only 1–2 cm length have approximately 2000–5000 nuclei [22]. All of the major components of muscle fibers, including contractile machinery of the sarcomere, mitochondria, enyzmes for anaerobic energy production, and connective tissue, exhibit adaptations to exercise, disuse and injury. Thus motor units can adapt for either greater strength or fatigue resistance, but in exercise, the pattern of these adaptations are set by the orderly recruitment sequence mentioned in the previous section. For example, only types S motor units will exhibit increases in mitochondria in response to low intensity endurance training, while all motor units, S, FR, and FF, will exhibit hypertrophy in response to high resistance training.

Plasticity is also a hallmark of many muscle diseases and age related changes. There are a broad range of muscle diseases, or myopathies, many of which lead to or arise from structural and metabolic changes in the muscle such as fiber degeneration, mitochondrial dysfunction, fibrosis, nuclear abnormalities, fiber type reorganization and changes in fiber architecture to name a few. Muscle diseases can be acquired or inherited and can be classified broadly into primary diseases of the muscle or secondary diseases brought about via injury or dysfunction to the neural systems mediating muscle activity. Examples of the former include Myasthenia Gravis and the various forms of muscular dystrophy and myositis, while those of the latter include amyotrophic lateral sclerosis and other diseases or conditions that result in motorneuron damage and dysfunction (see essays ►Muscle: Duchenne Muscular Dystrophy, ►Muscle: Age Related Changes).

## Which Muscle Properties are Most Important in Normal Movements?

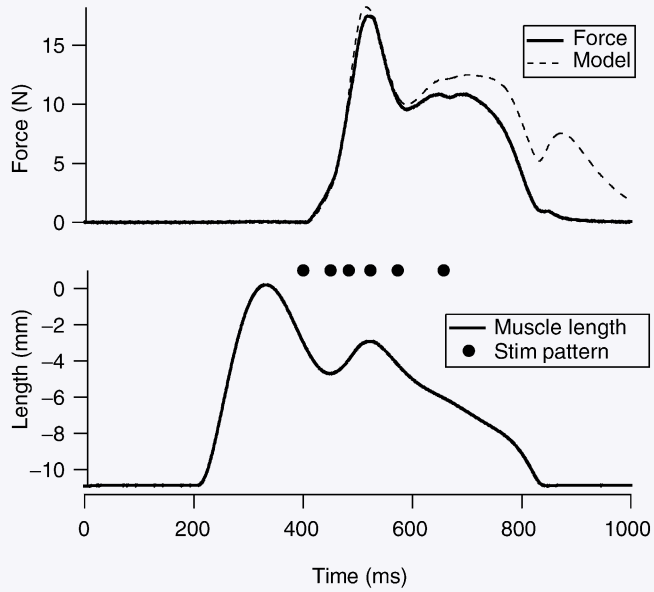
Although muscle exhibits an impressive array of properties in laboratory settings, the tightly controlled conditions so desirable for isolating specific properties often bear little relation to the highly dynamic conditions of normal movements. Consider first the normal neural activation pattern. Increasing neural activation produces a complex overlapping pattern of recruitment and rate modulation of a large population of motor units with very heterogeneous properties. This natural activation pattern stands in marked contrast to the usual techniques in the lab, such as activation of a single skinned muscle fiber via $Ca^{2+}$ or stimulation of an entire muscle by electrical pulses applied to its nerve. At the same time, the muscle is often experiencing mechanical conditions that are highly dynamic. The primary measurement of muscle dynamics in the lab, the F-V relationship, is measured during constant activation and constant velocity conditions. In contrast, in a natural movement such as locomotion, both activation and velocity undergo dramatic and continuous variations [23].

The question of how muscle is used in normal movements has received considerable attention in the past 10–20 years. One fundamentally important issue is to identify the operating range for the basic properties of the F-f, L-T and F-V relations in normal movements. For the F-f relation, the fundamental question concerns the firing patterns of individual motor units. Studies in humans indicate that low threshold units (likely S) are not only recruited before high threshold (FR, FF) but also tend to exhibit higher firing rates (e.g. [24]). Presumably, at the highest forces, rates for FR and FF units eventually exceed those of S units [25], because the high contraction speeds of these units require higher firing rates to reach fusion [26]. Few studies have measured firing rate in dynamically moving muscles, but the same pattern of higher firing rates for lower threshold units does appear to occur [27].

Some animal studies suggest that muscle lengths remain near $L_O$ [28]. However, other studies suggest that substantial force generation often occurs on either side of $L_O$ - that is to say, on either the ascending or descending limbs of the L-T function. For example, the positions of the cat ankle extensor L-T functions in relation to the physiological range of motion is skewed, such that $L_O$ occurs at a relatively long length [29]. While the peak force occurs during the stretch at the onset of the stance phase and is thus at a relatively long length near $L_O$, after this point, the ankle extensors exert substantial forces while rapidly shortening and most of this occurs on the ascending limb of the L-T function. In addition, studies of L-T functions in the hindlimbs of frogs suggest that much of the normal range of motion for thigh muscles can occur on the descending limb [30]. Finally, some specialized muscles operate over a very small range of the L-T function, serving primarily to transmit force and energy to the tendons connecting the muscle to the skeleton [31] (see ►Muscle and Tendon Energy Storage).

For the F-V functions, muscle velocities during locomotion have been estimated by inverse calculation from video records in numerous species (e.g. [32]) and from direct measurement in cats [33]. Clearly, even at the modest locomotor speeds associated with walking or slow running, the velocities reach peak values that result in substantial modulation of force due to the F-V relationship.

An approach that has great potential for delineating the role of various muscle properties in movement is to replicate the conditions of normal movements in isolated preparations, where the high degree of experimental control is highly advantageous for identifying the effect of each muscle property. An example from this type of experiment are shown in Fig. 5 [34]. A locomotor like movement was imposed on a cat



**Muscle. Figure 5** Performance of a Hill model during a simulated locomotor movement in cat soleus. The experimentally measured force, and the force predicted by a Hill type model are shown in the top plot. The onset of the stance phase approximately corresponds with the onset of force generation. The lower plot shows the length imposed on the muscle and the time of the stimulus pulses. Note the largest error occurs during muscle relaxation.

ankle extensor muscle while it was stimulated with a locomotor-like frequency pattern. The resulting force was then compared to the output of a Hill-type model, which included both F-V and L-T effects as well as an accurate estimate of the activation function obtained during isometric conditions. The model prediction was remarkably good during the initial stance phase, but greatly overestimated force during the decay phase. In fact, the model predicted that force would last long after the push-off ended. Similar studies were carried out using random patterns of length changes and stimulation patterns [35]. The Hill-type model did a reasonable job predicting force at high activation levels with electrical stimulation but an extremely poor job during natural activation via a reflex, which generates relatively modest motor unit firing rates. Increasing muscle velocity also increased errors. In both the locomotor and random cases, it is likely that the model errors were due to the Hill model's inability to account for the coupling between muscle activation and force-velocity-length properties. Thus this coupling may be the most important factor to add to muscle models.

## Summary

Muscle is a complex and adaptable organ. While great strides have been made toward understanding the molecular processes underlying muscle contraction, whole muscle function and its role in the neural control of movement remain an active and important area of research. New approaches that strive to link muscle ultrastructure to the whole muscle properties that emerge during the normal control of movement hold great promise for advancing our understanding of muscle and how it impacts the actions of the CNS controlling its function.

## Synonyms

Sarcopenia

## Definition

Age-related changes are those attributed primarily to increasing age. These changes are quantitative as well as qualitative and affect all parts of the ►motor unit, from the ►alpha motor neuron to the ►muscle fibers and various sub-cellular structures (►Muscle – ultrastructure and proteins). The main effects of increasing age are reductions in muscle mass and muscle strength and

alterations in the quality of the remaining muscle tissue, all referred to as sarcopenia. Sarcopenia leads to reduced functional capacity for the older individual, with an increased risk of falls, fractures, and dependency. The underlying mechanisms of these age-related changes are multifactorial (Fig. 1) and only partly known. Progressive ►resistance training (heavy-resistance strength training) (►Muscle: exercise adaptations) has become the most effective therapy to counteract the age-related changes in the skeletal muscle.

## Characteristics

### Higher Level Processes

The reduction in muscle volume and muscle cross-sectional area is one of the most noticeable age-related muscle changes. With modern imaging techniques (►Muscle imaging), such as ultrasonography, computed tomography (CT) and magnetic resonance imaging (MRI), muscle mass and muscle cross-sectional area can be assessed. With ultrasonography, a 25–35% reduction in the cross-sectional area of the quadriceps muscle in older compared to younger men and women has been found. CT has shown similar age-related reductions in the cross-sectional area of the psoas major and sacrospinalis muscles, the quadriceps muscle the brachial biceps and triceps muscles, and the plantarflexors. These CT studies have also shown increases in fat and connective tissue within the older muscle. MRI has confirmed these earlier studies, and also shown an age-related reduction in muscle cross-sectional area and an increase in non-contractile tissue, i.e. fat and connective tissue (Fig. 2), which can be more than twofold [1].

Direct assessments of the muscle cross-sectional area have been very limited, mainly due to the technical limitations in such analysis. Large cryomicrotomes and modified morphometric procedures have made it possible to study cross-sections of whole human (autopsied) muscles. The vastus lateralis of previously healthy men between 15 and 83 years of age have been analyzed [2], and the average reduction in muscle area between 20 and 80 years was 40% (Fig. 3).

The reduction began as early as 25 years of age. By the age of 50 years, ~10% of the muscle area was lost, and thereafter the reduction accelerated. A majority

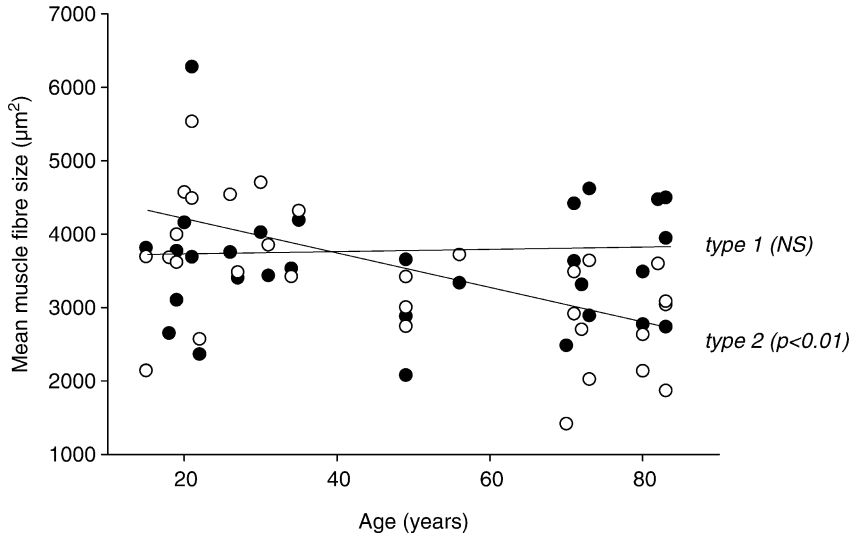
**Muscle: Age-related Changes. Figure 4** Relationship between age and total numbers of fibers.

of studies on muscle mass have been performed on men, but data implies that increasing age affects muscle mass in women in a similar way.

Muscle biopsy studies of the vastus lateralis of the quadriceps muscle, and of the biceps brachii and the anterior tibial muscles, have consistently shown that the ►type II (fast-twitch) fiber size is reduced with increasing age, while the size of ►type I (slow-twitch) fibers are much less affected [3]. With techniques allowing assessments of whole muscles, it has been shown that the total number of fibers is significantly reduced with increasing age [2]. The reduction in muscle cross-sectional area of the vastus lateralis muscle was caused mainly by a loss of fibers and to a smaller extent by a reduction in the size of fibers, mainly of type 2 (Figs. 4 and 5).

This loss of fibers began as early as 25 years of age and thereafter accelerated. The age-related reduction in fiber number, at least in the vastus lateralis muscle, affected both types to the same extent. Overall, there is a decrease in the relative amount of type II fiber tissue, due to the combined reduction in the number and size of type II fibers [3]. Muscles other than the vastus lateralis have not been studied in any detail, nor have muscle biopsies from older individuals with different physical activity levels been compared.

As a result of the reduced muscle mass, increasing age leads to a significant decrease in muscle strength.



**Muscle: Age-related Changes. Figure 5** Relationship between age and mean area of type 1 and type 2 fibers.

Studies of both upper and lower limb muscles have been compared between groups of young, middle-aged and older adults, showing that decreases in voluntary strength do not become readily apparent until after the age of 60 [4]. Small variations exist from muscle to muscle, but for all muscles in both men and women, the age-related reduction in strength tends to be curvilinear, with a relative plateau through the third, fourth and fifth decades. Most frequently studied has been the quadriceps femoris muscle group, measured extensively in test conditions involving all three actions of muscles: isometric, concentric and eccentric (►Isometric force; ►Contraction-concentric; ►Contraction-eccentric). Healthy people in the seventh and eighth decades score on average 20–40% less during isometric and concentric strength tests than young adults, and the very old show an even greater (50% or more) reduction. Differences between young and older groups of men and women are less for the eccentric type of muscle action than during either isometric or concentric.

With regard to the volitional component of maximal strength tests, healthy older individuals are able to recruit and activate all their available motor units (►Motor unit – usage patterns) maximally or near maximal, indicating that the age-related declines in strength in healthy older people is due mainly to a decreased excitable muscle mass.

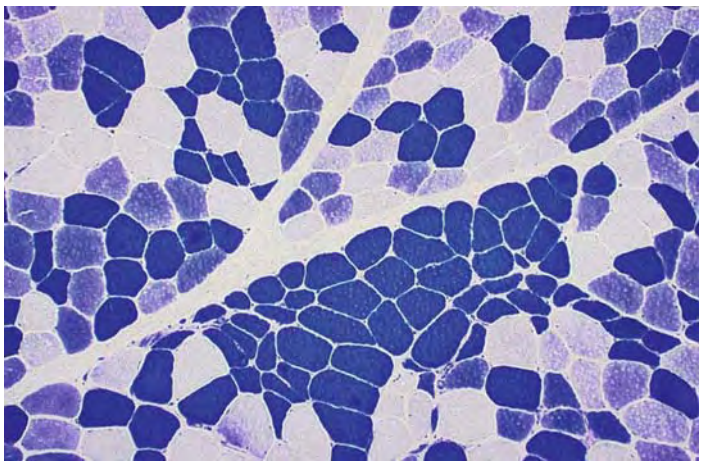
Tests of voluntary muscular effort, with variations in submaximal versus maximal contractions, and sustained versus intermittent efforts, have not found any age-related increase or decrease in ►muscle fatigue [5]. Despite the relatively greater proportion of type I fibers available, fatigue-resistance of aged muscle is not significantly enhanced.

One of the factors leading to sarcopenia in old age is a progressive degeneration of the nervous system, particularly after the age of 60 years [6]. Studies have shown an age-related reduction in the number of functioning motor units with an increase in the size of remaining/surviving motor units, suggesting cycles of denervation followed by reinnervation that ultimately stems from death of motor neurons in the spinal cord and from irreparable damage to peripheral nerve axons. As a consequence, the muscle fibers innervated by these neurons will also be affected, which leads to changes in the function of aging muscles.

Quantitative ►electromyography (EMG) has shown changes in both duration and amplitude of motor unit action potentials (MUAP) with increasing age. It has also been shown that the axonal conduction velocity (CV) is slower with aging, an effect that could reflect a variety of changes in the nerve fibers, such as a dropout of the largest fibers, a segmental demyelination and a reduced internodal length. Assessment of the number of motor units have shown a reduced number of functioning motor units with increasing age, mainly after the age of 60 years. The estimated reduction in the number of motor units of older individuals has been reported to be as large as 50%, and this loss also seems to be greatest among the largest and fastest motor units, i.e. ►type II (fast) motor units.

Studies of the muscle fiber population have shown evidence of neuropathic changes, such as small angulated fibers and grouped atrophy, of old/very old individuals (Fig. 6). ►Fiber type grouping has also been found in muscles from individuals above the age of 70 years (Fig. 7). Macro EMG has confirmed these studies and shown an increase in motor unit size in the vastus lateralis, the tibialis anterior and the biceps

Type 1 (slow-twitch) fibers are darkly stained whereas type 2 (fast-twitch) fibers are lightly stained. Note the variability in fiber and the increase in angulated fibers.



**Muscle: Age-related Changes. Figure 7** Small part of a muscle biopsy from a healthy man, age 73 years. The biopsy is stained for toluidine blue mATPase. Type 1 (slow-twitch) fibers are darkly stained whereas type 2 (fast-twitch) fibers are lightly stained. Note the increased occurrence of grouping of type 1 fibers.

brachii from subjects above the age of 60 years, indirectly indicating an increased number of muscle fibers per motor unit.

### Lower Level Processes

Several other factors contribute to the age-related changes in muscle structure and function (cf. Fig. 1). Muscle biopsy studies of the tibialis anterior muscle has shown a reduction (40%) of muscle ►satellite cells [7]. As satellite cells are also considered to be skeletal muscle stem cells, they can generate daughter cells that become new satellite cells following myotrauma or exercise. It is possible that this age-related reduction in the satellite cell pool may impair the regenerative capacity of skeletal muscles, but evidence so far is insufficient to support this.

Studies of single muscle fibers from the vastus lateralis of older men and women have found a significant age-related reduction in shortening velocity of both type I and IIA fibers [8], which also contribute to the reduced muscle function in older individuals.

Several studies have found decreases in four major anabolic hormones – testosterone, growth hormone (GH), insulin-like growth hormone (IGF-1) and dehydroepiandrosterone (DHEA) – with increasing age [9]. The exact implications of these decreases and whether hormone supplementation is a feasible therapeutic strategy and prevention of sarcopenia remain to be

determined. So far, the long-term risks have not been well defined and the side-effects have been significant. Muscle protein synthesis rates have also been shown to decline with increasing age, whereas muscle protein breakdown seem to be less affected [9], which may contribute to the age-related loss of muscle mass.

### Therapy

As a reduced neuromuscular capacity is related to limitations in activities of daily living, an important question has been whether muscles of older individuals can increase in size in response to resistance training, and to what extent resistance training can lead to motor learning or neural adaptations.

In 1988, Frontera and colleagues [10] presented strength and muscle biopsy results from a heavy-resistance training study in older men, and reported striking improvements in leg muscle strength, as well as significant increases in muscle fiber sizes. Since then, an increasing number of studies have documented the benefits of resistance training for older men and women, even above the age of 90 years [4]. Studies involving low intensity training in older adults report strength increases <20%, whereas high intensity training (>70% of one ►repetition maximum (RM)) has resulted in increases of up to 227% in one RM. Men are generally stronger than women, but there seems to be a remarkable similarity in their response to training. Moreover, ethnicity and previous experience of physical exercise do not seem to limit the response to heavy-resistance training; studies from North America and Scandinavia have yielded similar results.

Strength gains following heavy-resistance training in both young and older people may be explained by several factors. These include changes in muscle morphology, muscle/connective tissue biomechanics, central nervous system activation, motor skill coordination and motivation. Varying degrees of ►hypertrophy of both type 1 and type 2 fibers have been demonstrated following both short- and long-term heavy-resistance training in older individuals. When changes in fiber areas are minor and non-significant, they are consistent with small strength gains. Increases in fiber size as a result of strength training are generally small in comparison with the improvements in strength. Thus, the response to heavy-resistance training in older people can be mediated to some extent through hypertrophy of both fiber types, although the main part of the strength improvement, at least during the first 3 months of training, is caused by nervous system adaptation.

## Muscle and Tendon Energy Storage

Andrew A. Biewener
Concord Field Station, Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA, USA

### Synonyms

Elastic energy savings; Muscle-tendon elasticity

### Definition

Muscle and tendon energy storage refers to strain energy that is stored and elastically recovered within a muscle-tendon complex during each contractile cycle of a muscle.

### Characteristics

#### Quantitative Description

Muscle and tendon energy storage represents the strain energy that is stored within a muscle-tendon complex as a muscle and tendon are stretched by the force developed by the muscle when it contracts. This energy may be subsequently recovered elastically when the muscle relaxes. The elastic elements of a muscle-tendon

complex are generally divided into "*parallel*" and "*series*" elastic elements, based on their role in force transmission relative to the muscle's force-generating cross-bridge elements. The interaction between a muscle's contractile elements – the cross-bridges formed between myosin and actin filaments – and its parallel and ►series elastic elements, determines the relationship between a muscle's force development and length change, as well as its elastic energy storage [1]. For parallel-fibered muscles that have little or no tendon in series with the muscle's fibers, elastic energy storage is limited to parallel and series elastic elements within the muscle, which include the cross-bridges themselves. For pinnate-fibered muscles that have a substantial tendon, considerably more energy is stored and recovered elastically within the tendon that is in series with the muscle's fibers. Consequently, elastic energy savings is greatest in pinnate muscles that attach to the skeleton via long tendons [2].

### Mechanical Properties of Elastic and Viscoelastic Materials

Elastic materials are those that exhibit spring-like properties. When elastic materials are loaded, they store strain energy via deformation of their molecular bonds in combination with conformational changes in the protein's tertiary or quaternary structure. In the case of tendons and ligaments, this primarily results from the stretching of collagen. In the case of muscles, this involves additional elastic proteins, such as those within the cross-bridges (myosin I) and within the sarcomeres (titin), in addition to collagen. These proteins constitute the parallel and series elastic elements within a muscle, which are linked to a muscle's tendon as an external series elastic element [1]. During unloading, the stored strain energy is released and may be recovered to assist in mechanical movements of the body or limb segment, reducing the amount of work that the muscles must perform. The work performed by a muscle is the product of its force and its net length change (muscle shortening by definition corresponds to positive muscle work, whereas muscle lengthening corresponds to negative muscle work, or energy absorption). For pure elastic elements, all of the energy that is stored during loading is returned during unloading. However, most biological materials are non-linearly elastic and exhibit some degree of inelastic or viscous energy dissipation, which is ultimately lost as heat (Fig. 1c).

Due to this, materials like tendon are referred to as being "viscoelastic." The amount of strain energy that is elastically recovered relative to the amount of energy that is stored defines a material's resiliency. The resiliency of collagenous tendons is in the range of 90–94%, indicating that only 6–10% of the stored strain energy in a tendon is lost as heat during each contraction cycle of a muscle.

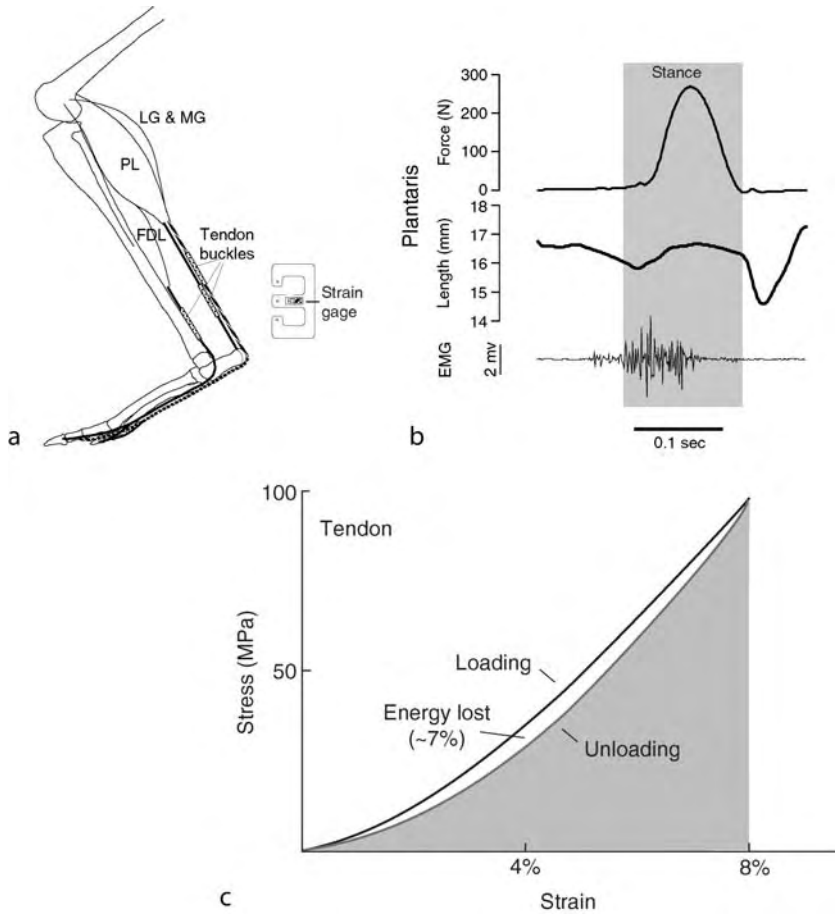
### Elastic Energy Storage in Relation to the Force-Length Properties of a Muscle

The force that a muscle develops depends on its length, which specifically reflects the amount of overlap between its myosin (thick) and actin (thin) filaments [1]. This is most often measured as the isometric force that a muscle can develop when it is stimulated to contract at different lengths. The force that is measured can be separated into two components: the active force that is developed by the cross-bridges formed between myosin and actin, and the passive force that is developed when the muscle is stretched to longer lengths without being stimulated (Fig. 2).

The slope of a muscle's passive force versus length curve defines its ►passive stiffness. A muscle's passive stiffness increases as it is stretched to longer lengths, typically beyond the length that a muscle develops its maximal isometric force. Elastic energy that can be stored within a muscle when it contracts is generally associated with its passive force-length properties, because these depend on the amount of non-contractile connective tissue within the muscle. Muscles that are pinnate typically have more titin and collagenous connective tissue than parallel-fibered muscles and, as a result, display greater passive force when they are stretched. Consequently, pinnate muscles store more strain energy than parallel fibered muscles when force developed by cross-bridges is transmitted to the parallel and series elastic elements of the muscle. However, even for pinnate muscles, the strain energy stored in a muscle's tendon greatly exceeds that in the muscle's fibers [2,4].

### Muscle-Tendon Design in Relation to Elastic Energy Storage

Muscle-tendon units with long thin tendons are most favorably designed for elastic energy savings. This is because strain energy varies with the square of tendon stress (force/area). Consequently, for a given muscle-tendon force, strain energy storage per unit mass (or volume) of tendon varies inversely in proportion to the square of the tendon's area ($\alpha\ 1/A^2$). The advantage of having slender tendons is evident in animals, such as antelope, horses and kangaroos, which have evolved particularly economical modes of locomotor transport [2]. The distal limb muscle-tendon units of these animals are often comprised of muscles with very short fibers and long tendons. The length of some tendons can exceed their muscle's fiber lengths by tenfold or more. As a result, the length change of the tendon, as it is stretched, may exceed the fibers' lengths in the muscle. The role of these muscle-tendon units, therefore, is mainly to facilitate elastic energy storage and recovery and to generate force economically, and not to do substantial mechanical work [5]. Even though the muscle's fibers may not perform much

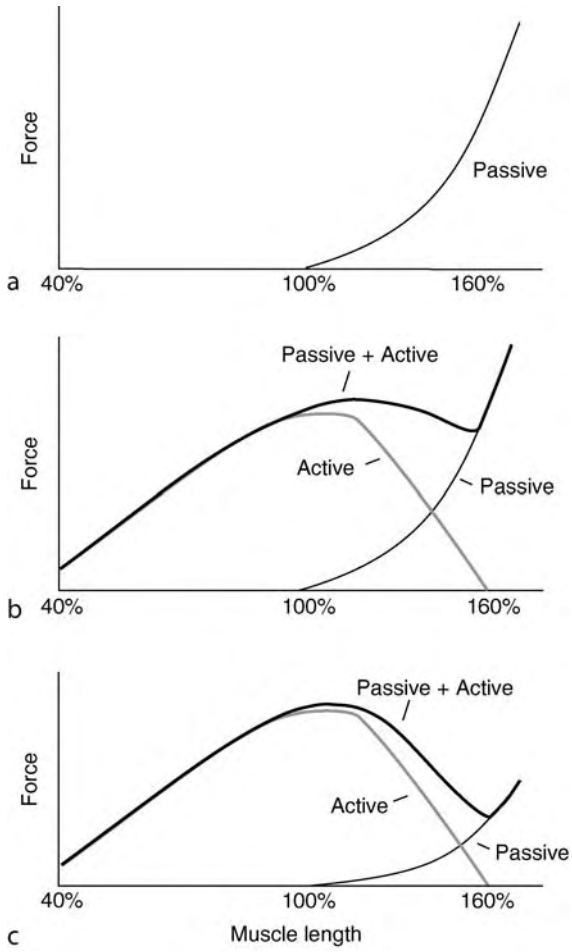


**Muscle and Tendon Energy Storage. Figure 1** (a) Schematic drawing of the hind limb muscle-tendon units of a wallaby, comprising the lateral and medial gastrocnemius (LG + MG), the plantaris (PL), and the flexor digitorum longus (FDL). "E"-shaped force buckles are shown attached to the tendons of these three muscles, and were used in [3] to record in vivo muscle-tendon forces in relation to muscle fascicle length change and indwelling electromyographic (EMG) activation of the muscles. (b) Representative in vivo recordings of muscle-tendon force, muscle fascicle length change from sonomicrometry, and EMG of the plantaris muscle-tendon are shown for one hopping cycle. (c) Tendon stress-strain curve used to calculate the elastic energy storage and recovery within the tendon over a cycle of loading and unloading.

useful work, they may provide a means for dissipating energy associated with unwanted vibrations in the limb when it impacts the ground [6].

## Measuring Elastic Energy Storage

Measurements of elastic energy storage and recovery depend on measurements of the material properties of muscle and tendon in combination with measurements of their structural dimensions and the forces that a muscle-tendon complex transmits during a given activity. Isolated in vitro or in situ force-length measurements allow the elastic and viscoelastic properties of a muscle and its tendon to be determined. The force-length properties of the muscle and tendon can then be normalized to muscle-tendon stress and strain (defined as their change in length/resting length). This allows a muscle's stiffness and a tendon's stiffness (ratio of force/length change) to be defined in terms of their elastic modulus (stress/strain). Whereas the (passive) force-length or stress-strain behavior of a muscle depends strongly on a muscle's architecture (i.e. whether or not a muscle is parallel- or more pinnate-fibered), the stress-strain behavior of various tendons in vertebrate animals is fairly uniform [2,4]. Consequently, the stress-strain behavior and elastic modulus of tendon can be generally characterized and used to



**Muscle and Tendon Energy Storage. Figure 2** (a) Representative passive force-length properties of a pinnate muscle. (b) Active isometric force-length properties of the muscle when stimulated to generate force over different percentages of its resting length (100%) in relation to passive properties shown in A, yielding the overall active + passive properties of the muscle. (c) Representative comparison of passive and overall force-length properties of a parallel-fibered muscle that has similar normalized active properties, but exhibits less passive stiffness than the pinnate muscle shown in (b).

calculate the elastic strain energy that is stored in a tendon of a given size and shape.

To determine the amount of elastic energy stored and recovered in a muscle-tendon complex, the force that muscle and its tendon transmit and their structural dimensions must be known. It is generally difficult to determine with accuracy the amount of strain energy stored within a muscle and its aponeurosis versus that in its external tendon. Consequently, unless direct measurements are obtained, it is usually assumed that the large majority of elastic energy is stored within the in-series elastic elements of a muscle-tendon complex [4]. Nevertheless, it is likely that significant elastic energy is stored and recovered from the aponeurosis and internal elastic elements of pinnate muscles, such as the quadriceps, which act to extend the knee. Muscle-tendon forces can be either calculated indirectly based on kinetic analyses of limb and joint forces and moments [7], or measured directly using tendon buckle transducers [3,8] (Fig. 1a, b).

Indirect measurements of muscle-tendon forces are derived from measurements of external ground reaction forces, applied to the limb using a force platform in combination with a free-body analysis of joint forces and joint moments [2,7]. This approach depends on assumptions of muscle force distribution among muscle agonists in cases where more than one muscle-tendon unit transmits force across a joint, and when bi-articular muscles play a role in force and energy transmission between joints. This is typical of many limb muscles involved in elastic energy storage. Direct measurements of muscle-tendon forces depend on the tendon being sufficiently long to attach the transducer without disrupting normal function of the muscle-tendon unit and the animal (Fig. 1a). This approach is, therefore, generally limited to more distal muscle-tendon units in the limbs of animals.

The force transmitted by a muscle-tendon unit that is determined directly or indirectly can then be used to calculate the tendon's stress and resulting strain, based on the elastic modulus and resiliency of the tendon over the range of strain that the tendon operates. Knowing the structural dimensions of the tendon (overall length – L, average cross-sectional area – A, and total volume – V) allows the total strain energy stored and recovered in the tendon to be calculated for the level of force (F) that it transmits. As tendon is non-linearly elastic, this formally involves integrating over the stress-strain curve of the tendon and multiplying by the tendon's volume. However, in most cases, an average elastic modulus ($E_{avg}$) characteristic of the functional stress-strain range of the tendon can be used to simplify the equation for calculating tendon strain energy:

$$U_{elas} = 0.5\sigma\varepsilon VR = 0.5F\Delta LR$$

where σ is the tendon stress (= F/A), ε is tendon strain (=σ /$E_{avg}$), V is tendon volume, and R is the tendon's resiliency (typically 0.9–0.95), which equals the product of tendon force and total tendon length change (ΔL = ε L).

M

### Role of Elastic Energy Storage in Locomotion and Movement Control

Elastic energy storage in muscle and tendon is important in at least three contexts (i) metabolic energy savings derived from reduced muscle work, (ii) amplification of muscle-tendon power during jumping, and (iii) stabilization of muscle-tendon force transmission for control of movement. Indirect [4,9] and direct [3] measurements show that elastic energy storage in tendons and ligaments is an important means of energy saving during running or trotting and galloping gaits, reducing the amount of work that muscles must perform to move the animal's body and to swing its limbs (Fig. 1b). Although some elastic energy is stored within the cross-bridges and ►parallel elastic elements of the muscle, this is generally considered to be quite small in comparison with that stored and recovered in the muscle's tendon and aponeurosis. In addition to horses and wallabies, tendon energy savings also serve to reduce the metabolic energy expenditure of running in humans and many other animals [2]. Like the distal tendons of cats, dogs, horses and kangaroos, the human Achilles tendon and ligaments in the foot have been estimated to contribute as much as a 30% saving of muscle work [9]. In hopping wallabies, elastic energy savings in leg tendons provide as much as a 100% saving of muscle work, reducing the metabolic cost of locomotion by 50% [3].

Elastic energy storage is also an important mechanism by which the work produced by a muscle in series with a tendon can be used to amplify the power output (work/time) of the muscle-tendon unit as a whole [4]. This allows muscle-tendon units to serve as catapults when an animal jumps or when a person throws a ball. The work done by a muscle to stretch its tendon and store elastic strain energy is limited by the rates of muscle activation and cross-bridge cycling as the muscle shortens. These generally occur much more slowly than the rate of strain energy release from the tendon when it recoils. Consequently, although the work done by the muscle can never exceed the work returned by elastic recoil, power output is amplified relative to power input because the energy return from stored strain energy in the tendon occurs over a much briefer period of time. Amplification of muscle power is an important mechanism in the jumping of many animals, and likely also humans, resulting in muscle-tendon power outputs that can exceed the maximum power output of the muscle alone by threefold or higher [10].

Compliance and elastic energy storage in a muscle's tendons can also play an important role in stabilizing force transmission and improving the control of position for fine scale motor tasks, such as those that involve finger movements, which underlie manipulation and gripping [4]. Although excessive compliance (tendon stretch/force transmitted) can compromise a muscle's ability to control for position, moderate compliance enables elastic energy stored in the tendon during a rise in force to be released as force declines, stabilizing the force output at a more steady level. This is achieved by introducing a time-delay between the induced stretch of the muscle spindles relative to small changes in muscle-tendon force, when the task is to hold force and finger position at a steady level. The time-delay introduced by the tendon's compliance improves the timing of force-feedback achieved via spindle Ia afferents to counter declining muscle force. The result is that a finger muscle can hold force at a steadier level and the finger's position is better controlled.

## Muscle Atonia

### Definition

Muscle paralysis that occurs during rapid eye movement (REM) sleep resulting from active inhibition of motor neurons.

►Sleep – Motor Changes

## Muscle Atrophy

### Definition
Wasting away of formerly normal skeletal muscle (up to 70-80 percent of original muscle bulk), for example as a result of denervation.

## Muscle Compartment

### Definition
The working location of a group of agonistic muscles (with similar function) delimited by the general fascia, intermuscular septum, periost and interosseal membrane.

►Epimuscular Myofascial Force Transmission and Intermuscular Interaction
►Intramuscular Myofascial Force Transmission

## Muscle Endplate

### Definition
The region of the muscle fibers where the motor nerves terminate on each skeletal muscle fiber, is termed the muscle endplate. It is at this endplate that the perisynaptic Schwann cells are found interspaced between the nerve terminal and the muscle fiber. The muscle endplate is where the acetylcholine receptors are concentrated and bind the acetylcholine released from the activated nerve terminals to elicit muscle contraction.

►Acetylcholine
►Axonal Sprouting in Health and Disease
►Neuromuscular Junction (NMJ)

## Muscle Fiber Conduction Velocity

### Definition
Velocity with which the transmembrane action potential propagates along the muscle fiber.

►Action Potential
►Electromyography

## Muscle Fiber End-Effect

### Definition
Non-propagating component of the extracellular action potential waveform due to the extinction of the transmembrane action potential at the fiber termination.

## Muscle Fiber Types

### Definition
A constellation of coordinated biochemical, metabolic, structural, and mechanical characteristics of muscle fibers that differentiate them into a relatively small number of recognizable categories.

►Motor Units

## Muscle Field

### Definition
The set of muscles whose motoneurons have a relatively direct synaptic linkage to a particular corticospinal neuron. Muscles that are part of a neuron's muscle field are referred to as target muscles. The target muscles of corticospinal and other descending system neurons have been identified in alert monkeys using signal averaging methods to detect the synaptic effects of the neuron's excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs) on motor unit firing probability.

►Corticospinal Neurons
►Motor Cortex: Output Properties and Organization

## Muscle Hyperalgesia

### Definition
Muscle hyperalgesia occurs when either noxious or ordinarily innocuous stimulation of muscle evokes a state of increased pain sensation.

►Hyperalgesia and Allodynia

## Synonyms

CT

## Definition

A CT scan is a computer aided imaging technique performed by subjecting the object of interest to a series of X-rays and measuring the attenuation along multiple projections using several detectors. With each projection, detectors measure X-ray absorption, which is used to construct cross-sectional images (tomograms) of the object.

## Purpose

New developments in data-analysis techniques have facilitated the recent use of CT in the quantification of muscle cross-sectional area and volume [2,3]. For example, using a 345 $mm^2$ field of view and a 7 mm slice thickness CT scan, Mitsiopoulos et al. [3] showed that the computed muscle cross-sectional area strongly correlated with the muscle cross-sectional area obtained from actual cadavric measurements on the same muscle ($r < 0.99$; $p < 0.001$).

## Principles

Subsequent tomograms consist of black–gray–white color scale picture elements. Each element of the picture is called a pixel and is characterized by a CT value or density value. These pictures are then combined using computer algorithms to reconstruct two- and three-dimensional images of the object. These algorithms include iterative solutions of simultaneous linear equations, Fourier transform techniques, and approaches that use a combination of back projection and deconvolution. Scan parameters are defined in terms of the size of the field of view and image thickness. For additional material on the mathematical basis of CT, the reader is referred to Shung et al. [1].

## Advantages and Disadvantages

The use of CT in muscle imaging has been limited due to large estimation errors reported in early CT muscle imaging literature [4]. However, advances in post processing and reconstruction techniques, and recent developments in CT technology such as helical CT and multi-detector row helical CT, could further improve resolution in the estimation of muscular volumetric and cross-sectional geometries obtained from CT scans.

## Synonyms

MRI

## Definition

MR imaging technique is based on the detection of the interactions between protons in liquid phase molecules (e.g., water and lipids) and the abilities of certain atomic nuclei, when exposed to a magnetic field, to absorb and release electromagnetic radiations at specific frequencies (Larmor frequency). These radiations are detected via receiving coils which are then used to construct the MR images of the object of interest. Computer integration and transformation of the signals detected by the receiving coils allows a two-dimensional map of proton density to be constructed, which can be visualized as a slice through the object (muscle).

## Purpose

MRI imaging has been successfully used to measure stationary muscle volume and cross-sectional area (Tracy et al., 2003). Although both T2 and T1 weighted images have been used, T1 weighted imaging has been particularly successful for muscle tissues [2].

MRI has also been used to estimate muscle fiber direction. The estimation of fiber direction via MRI is based on the fact that muscle striations seen in MRI images are generated by fat that runs parallel to and between the muscle fascicles [3]. It is assumed that these striations represent the true fascicle orientation within the muscles. When the imaging planes are coplanar to the fascicle orientation, fascicle length and pennation angles can be computed [3]. However, the use of MRI is limited when fascicle orientation is difficult to identify, such as in complexly pennated muscles.

To circumvent this, a diffusion tensor magnetic resonance imaging technique (DT-MRI) has been used to estimate fiber direction. In DT-MRI, measurements are independent of the orientation of the image plane, and three-dimensional fiber directions can be obtained immediately. DT-MRI was introduced in 1988 by LeBihan [4]. It is based on the measurement of the apparent diffusion of water in a (biological) tissue. For muscle tissues, diffusion is not the same (isotropic) in all directions. Hence, applying diffusion sensitization in six independent directions on a series of diffusion-weighted images, a diffusion tensor can be calculated in each voxel [5]. The eigenvalues and eigenvectors of this tensor provide information about local tissue anisotropy. Anisotropic diffusion can be geometrically interpreted as an ellipsoid with its three axes oriented along these eigenvectors and with the three semi-axis lengths proportional to the square root of the eigenvalues of the tensor (mean diffusion distances). The geometric nature of the diffusion tensors can quantitatively characterize the local structure of the muscle. The eigenvector belonging to the largest eigenvalue of the diffusion tensor is assumed to coincide with the local muscle fiber direction in striated muscle [5,6]. DT-MRI based fiber orientation has been successfully verified against histological slices [6].

Van Donkelaar et al. [7] used DT-MRI to measure fiber orientation in the tibialis anterior muscle of the rat. Using a 0.6 mm slice thickness, a field of view of $70 \times 35$ mm$^2$ and a voxel size of 0.09 mm$^3$, they found that computed fiber orientations corresponded to fiber orientations obtained from actual longitudinal sections of the same muscle. More recently Damon et al. [8] provided a more quantitative validation study of fiber orientation estimates using DT-MRI. In the lateral gastrocnemius of Sprague-Dawley rats, Damon et al. [8] showed a strong correlation ($r = 0.89$) between DT-MRI based local fiber orientation estimates and the measured orientations obtained from direct anatomical inspection of the same muscle.

Cine Phase Contrast (Cine-PC) MRI, originally developed to measure blood flow and heart motion, initially showed promise as a non-invasive technique to also measure human muscle fiber velocity in vivo under dynamic conditions. At each time frame, the Cine-PC MRI produces a series of anatomic and velocity images of skeletal muscles synchronized with a periodic motion cycle in three orthogonal planes. The velocity images are then integrated to determine the position of the muscles in vivo. Cine-PC MRI has been shown to accurately measure skeletal muscle fiber velocity in vivo during a dynamic task [9]. Previous studies by the same authors have demonstrated that Cine-PC MRI tracks skeletal muscle motion with a root mean error of 1 mm [9]. However, conventional cine-PC MRI requires multiple cycles of motion; typically 60–120 repetitions are needed to acquire composite images representing one motion cycle. Image quality degrades significantly with small discrepancies among the consecutive motion cycles, resulting in a significant limitation for the use of the conventional Cine-PC MRI in musculoskeletal applications [10].

## Principles

A background magnetic filed is used to align all atomic nuclei within the object of interest along the direction of the background field, producing a nuclei net longitudinal magnetic field. External energy is then applied using radiofrequency (RF) excitation pulses to change the direction of the nuclei net longitudinal magnetic field to point in a perpendicular direction to the background magnetic field and thus create what is known as transverse magnetization. Initially, all nuclei point along the same perpendicular direction representing the transverse magnetization in terms of one vector perpendicular to the direction of the background magnetic field. Because each nucleus has its own Larmor frequency, as time elapses, the transverse magnetization component eventually spans all directions, bringing the net nuclei magnetization component perpendicular to the background magnetic field to zero. T1 relaxation time is defined as the time the atomic nuclei needs to revert to equilibrium (regain their longitudinal mechanism) following the termination of the excitation pulses (RF). T2 (known as the spin echo relaxation time) is the time it takes for the net transverse magnetization to go to zero (decay). T2 (0.05–0.15 s) is always less than or equal to T1 (0.2–1.2 s) and both are intrinsic properties of tissues.

To obtain a successful imaging sequence, the technician defines a set of imaging parameters. These include: (i) repetition time (TR) or the time between two successive radio frequency (RF) excitation pulses measured in milliseconds; (ii) echo delay time (TE), or the time interval between RF pulse and the measurement

of the first echo measured in milliseconds; (iii) field of view (FOV) and slice thickness (interslice distance) both measured in millimeters and; (iv) receiver bandwidth measured in kHz. Tissues with short T1 have greater signal intensity than tissues with longer T1 at a given TR. TE on the other hand determines how much decay of the transverse magnetization is allowed to occur before the signal is read. The application of RF pulses at different TRs and the receiving of signals at different TEs produce variations in contrast of the MR images. For example, by selecting a relatively short TR (on the order of 300–600 ms generally) the image contrast will be primarily influenced by differences in the tissue's T1 relaxation times and hence T1-weigthed images are created. On the other hand, selecting a relatively long TE (on the order of 80–120 ms) will generate a T2-weighted image where the image contrast is primarily influenced by differences in tissue's T2 relaxation times. For further discussion on the underlying physics involved in MRI, the reader is referred to Buxton [1].

## Synonyms

ULT

## Definition

Ultrasound or sonography is based on the application of high frequency sound pulses using an ultrasound transducer (probe; a transmitter and receiver) to a stationary (conventional ultrasound) or a moving (real-time ultrasonography) muscle and recording the echoes (reflections) returning from the muscle-tissue interface. The echoes are processed based on the location of origin and amplitude. From this information, two-dimensional gray scale images are constructed. These images can be analyzed to obtain quantitative structural and functional information from the muscle of interest.

## Purpose

Several studies have used ultrasonography techniques to quantify muscle fiber length and direction under static conditions [3] and dynamic [4]. Under static conditions, measurements obtained by ultrasound were consistent with direct anatomical measurements on cadavers [3]. Under dynamic conditions, several studies have tested the effectiveness of real-time ultrasonography in estimating changes in human muscle architecture in vivo during muscle contractions [4]. However, direct validation studies on the use of ultrasonography under dynamic conditions are warranted.

## Principles

The fundamental principle of ultrasound is based on the idea that sound waves are transmitted though soft tissue relative to the acoustic impedance of each tissue. Sound wave frequencies used in ultrasound technology are in the 2–10 MHz range. The acoustic impedance of a particular tissue is the product of the transmission velocity of sound and the tissue density. For example, the wave velocity in pure fat is approximately 1,450 m/s whereas the velocity through muscle tissue is approximately 1,580 m/s. When two

tissues with different densities/wave velocities are located next to each other, an acoustic impedance mismatch is created and sound waves are reflected by the mismatch. For example, muscle imaging via ultrasound is possible because muscle fascia is a highly echoic structure (provides a significant acoustic mismatch), allowing for muscle differentiation. Scans used to estimate muscle fiber length and directions identify echoes from fascicle interspaces.

Image resolution is divided into spatial and temporal components (important when imaging moving muscles; real-time ultrasonography). The spatial component (the ability to differentiate between two adjacent tissues) consists of axial (the smallest axial distance that must be resolved) and lateral resolution. Axial resolution is dependent on sound wave pulse width and frequency. Two structures will be seen as separate structures only if the pulse length is shorter than the distance between the structures. Also, higher frequency sound waves have shorter pulse lengths and generally greater axial resolution. Lateral resolution is dependent on beam width and sound wave frequency. Narrower beam width and higher frequencies provide greater lateral resolution. Hence, in mapping small structures like muscle fibers, high frequency (>7 MHz) ultrasounds are commonly used. It is important to note, however, that as a wave propagates through a material, the signal amplitude is attenuated. Attenuation within a tissue increases with increasing wave frequency. For example, a 5-MHz transducer will generally image to a depth of 12–15 cm, but a 10-MHz transducer may image to a depth of only 3–4 cm. Thus improving image resolution comes with the loss of distal information when scanning deeper structures.

The temporal resolution of ultrasound is determined by the number of image frames that can be acquired per second. For real-time ultrasonography, images are obtained at a pre-specified rate, usually 65 images per second, during the dynamic task [1]. For more on the underlying physics and the image processing techniques involved in ULT, the reader is referred to Shung et al. [2].

## Advantages and Disadvantages

Improvement in image resolution in an attempt to scan small structures or differentiate between structures with close acoustic impedances limits the field of view hence hindering the ability to scan deep muscles. In addition, muscle architectural properties such as fiber length and angle obtained using ultrasonography are calculated from a two-dimensional image and thus represent the projection of these values on that plane. Recent developments in three-dimensional ultrasonography may prove useful in addressing this limitation of the two-dimensional ultrasonography.

# Muscle Modeling

Eric J. Perreault
Department of Biomedical Engineering, Department of Physical Medicine and Rehabilitation, Northwestern University, Chicago, IL, USA

## Definition

For the purposes of this essay, a muscle model is defined as a set of mathematical equations that can be used to predict the whole muscle forces generated in response to changes in muscle activation and external loading.

## Purpose

The use of muscle models can be categorized broadly into two domains. The first focuses on the properties and function of individual muscles. These applications are often designed to test the limits of our knowledge with respect to how muscle functions. By developing quantitative descriptions of the physiological processes contributing to muscle function, it should be possible to assemble these descriptions into a model describing whole muscle behavior. Comparing the results of such models against experimental data allows the accuracy of the mechanistic descriptions and the assumptions

contained within to be evaluated, a process that can assist in guiding future experimentation.

The second class of applications falls into the category of musculoskeletal modeling. Such applications typically incorporate multiple muscle models to study how muscle properties contribute to the control of movement and posture. The goals of this class again may be to examine the limits of our understanding by comparing experimental data to that predicted by the model, or to predict muscle function in applications where direct measurements are difficult or unfeasible. Examples include investigating how specific muscle activation patterns influence joint contact forces, how different neural control strategies alter movement production or predicting the outcomes of specific surgical interventions.

## Principles

### Contractile Properties

Muscle contracts and realistic models of muscle force generation need to describe this contractile process. There are two different approaches to describing the contractile machinery. Mechanistic models attempt to describe the physiological mechanisms underlying muscle force generation. In contrast, phenomenological models use empirical descriptions to describe how force is generated under a range of conditions.

### Mechanistic Models

Most current mechanistic models stem from the work of Huxley [1]. In his seminal paper, Huxley described the contractile properties of muscle in terms of the number of currently attached cross-bridges. Each cross-bridge was assumed to be elastically linked to the myosin filament and to move randomly about a neutral equilibrium point due to thermal agitation, as depicted in Fig. 1a.

Further, it was assumed that cross-bridges could be in one of two states, either attached or detached to an actin binding site, and that there were no interactions between neighboring cross-bridges. Under these conditions, the rate equation for cross-bridge attachment is given by Equation 1, where $n(x,t)$ is the fraction of attached cross-bridges at time $t$ and displacement $x$ from the equilibrium point, $f(x)$ is the rate at which cross-bridges attach and $g(x)$ is the rate at which they detach.

$$\frac{\partial n(x,t)}{\partial t} = f(x)(1-n(x,t)) - g(x)n(x,t) + v(t)\frac{\partial n(x,t)}{\partial x} \quad (1)$$

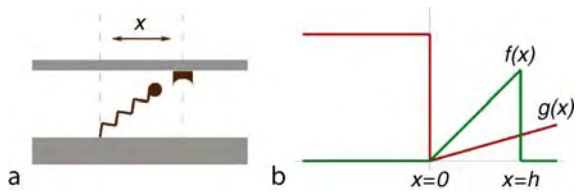
$$F(t) = k\int n(x,t)x\,dx \quad (2)$$

Fig. 1b illustrates the shape of the rate functions originally proposed by Huxley; the asymmetry of these functions leads to muscle shortening. Each cross-bridge is assumed to be elastic. Hence, when attached, a cross-bridge produces a force proportional to its distance from the equilibrium point. The total force generated is given by Equation 2, in which $k$ is defined as the cross-bridge stiffness.

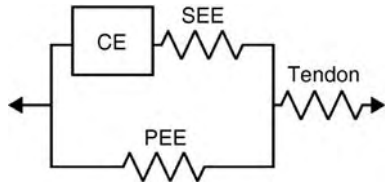
Since Huxley's original work, a variety of extensions have been made to his proposed model including the incorporation of length-tension properties, changes in the attachment and detachment rate functions, the addition of intermediary states between cross-bridge attachment and detachment and the allowance for cooperativity between neighboring cross-bridges.

### Phenomenological Models

A number of linear and nonlinear phenomenological muscle models have been proposed. The most widely used of these stem from the work of A.V. Hill [2], and the modifications outlined by Zajac [3]. These Hill-type models have a structure as shown in Fig. 2. The parallel elastic element (PEE) is often ignored, as it contributes little force within the working range of most muscles and the stiffness of the series elastic element (SEE) is combined with that of the tendon. The contractile element (CE) of a Hill-type model is described in terms of the instantaneous force-length, force-velocity and activation properties of muscle. Many Hill-type models assume that these properties are independent (see Winters [4] for discussion), and that the contractile element force, $F_{CE}$, can be characterized by Equation 3, where $\tilde{A}(t)$ is the normalized muscle activation, $\tilde{F}_{FL}$ is the normalized tetanic force-length relationship, and



**Muscle Modeling. Figure 1** Schematic of original Huxley model. (a) Assumed mechanism. (b) Proposed rate functions.



**Muscle Modeling. Figure 2** Schematic of a typical Hill model.

$\widetilde{F}_{FV}$ is the normalized tetanic force-velocity relationship, measured at the muscle length corresponding to the peak of force-length curve. Alternative formulations assume that the maximum shortening velocity varies with muscle length and activation, requiring that $\widetilde{F}_{FV}$ be dependent upon instantaneous muscle velocity and activation.

$$F_{CE}(t) = F_{\max} \cdot \widetilde{A}(t) \cdot \widetilde{F}_{FL}(L(t)) \cdot \widetilde{F}_{FV}(V(t)) \quad (3)$$

The above descriptions outline the elements common to all Hill-type models. However, a number of extensions to this model have been developed. These include incorporating geometrical parameters to account for changes in muscle architecture, allowing for significant coupling between the $\widetilde{F}_{FV}$ and $\widetilde{F}_{FL}$ properties and acknowledging the fact that these properties do not scale simply with changes in activation level. Each of these modifications has been shown to improve model performance for specific experimental conditions, although head-to-head comparisons of these modified models have not been performed yet, and there is no consensus as to which is most appropriate for a specific application.

### Activation Dynamics

Both mechanistic and phenomenological models need to account for the scaling of muscle force with changes in neural input. This is accomplished through the use of an activation function, which characterizes the processes triggered by the occurrence of a muscle fiber action potential and ending with the binding of calcium to troponin. A number of activation functions have been proposed, ranging from the first-order activation dynamics often incorporated into Hill-type muscle models [3], to detailed descriptions that attempt to account for the physiological processes underlying calcium release and reabsorption [5]. Between these extremes are the many phenomenological descriptions that use the activation function to account for activation-dependent muscle responses such as fatigue, nonlinear summation of neural inputs and movement-related history dependence. A good example of this approach is provided by the work of Brown and Loeb [6].

## Structural Properties

### Intramuscular Structure

There are wide variations in muscle structure and these variations significantly impact muscle function. Hence, whole muscle models must take structural variations into account. Fiber length, cross-sectional area and pennation angle are the factors most often considered. At a minimum, these can be used to scale model parameters such as maximal isometric force and shortening velocity. More involved approaches consider how these factors vary and influence force generation throughout the physiological range. This has been attempted using both 2D and 3D models of muscle architecture. Recent studies have used finite element approaches to investigate and model how these architectural features influence force generation during normal movement conditions [7]. This approach may also prove to be useful for assessing the role of passive mechanical structures such as tendons and aponeuroses. Currently, these are modeled most often as elastic elements in series with the contractile machinery (e.g. SEE in Fig. 2).

### Intermuscular Structure

Significant force can also be transmitted between muscles via myofascial structures. Such transmission poses enormous challenges for the modeling of multiple muscle systems and is ignored in most musculoskeletal models. The essay by Huijing, *Epimuscular Myofascial Force Transmission and Intermuscular Interaction*, covers this topic in detail. It should be noted, however, that most studies demonstrating significant intermuscular force transmission have examined this phenomenon by disrupting the normal transmission pathways. Recent data from out laboratory suggests that intermuscular transmission is less than 5% between muscles with intact tendons and intermuscular linkages. Hence, the problem of intermuscular transmission may be most important when modeling injuries or surgical interventions in which the normal transmission pathways are disrupted.

## Advantages and Disadvantages

There are many choices to be made when choosing or designing a muscle model for a particular application. The advantages and disadvantages of each are driven at least as much by the application as by the model. As always in modeling, there is a tradeoff between physical realism and computational efficiency. A related issue is the ability to estimate appropriate model parameters, for even an accurately modeled system will produce inaccurate results if the parameters cannot be set appropriately. In reviewing the relative merits of the available modeling approaches, we focus on three common applications.

### Mechanisms of Muscle Contraction

Models designed to investigate the mechanisms underlying muscle contraction are typically derived from the Huxley models presented above. Such models are attractive because they have the ability to link macroscopic phenomena, such as force-velocity properties, yielding and short-range stiffness, to the underlying microscopic structure of muscle. As a result, they are the models of choice for muscle biophysicists, and represent an enticing structure upon which to incorporate additional physiological information as it becomes available. A limitation of Huxley-type models is the

difficulty associated with measuring model parameters and choosing appropriate forms for the rate functions. Indeed, many rate functions and parameter estimates have been proposed to match different sets of experimental data. These models are also computationally intensive, which has limited their use in studies of multiple muscle systems as well as those assessing the impact of structure on function, although a reformulation of the Huxley equations by Zahalak and colleagues [8] has a reduced computational cost and helped bridge the gap between mechanistic and phenomenological models.

### Muscle Mechanics

The mechanical properties of muscle describe the dynamic relationship between imposed displacements and the corresponding changes in muscle force. These properties, which are influenced by the contractile properties and passive structures, are critical for understanding the role of muscle in the control of posture and movement. Some mechanical responses, such as yielding and short-range stiffness, appear to be cross-bridge phenomena and are characterized well by Huxley-type mechanistic models. However, a number of phenomena, such as movement history-dependent changes in muscle force, cannot be attributed to cross-bridge dynamics alone.

Hill-type models describe the forces generated during isovelocity movements reasonably well, since they specifically incorporate force-velocity characteristics, but are less capable of describing the forces generated in response to more complex movements, especially at non-tetanic levels of activation [9]. A number of groups have proposed modifications to the Hill model that broaden the range of mechanical responses that can be predicted [6,10]. Often, these modifications rely on coupling the contractile properties of muscle to the activation dynamics. A process that may also be useful for extending the utility of Huxley-type models.

Realistic representations of muscle architecture and the passive structures responsible for transmitting muscle force are essential for modeling muscle mechanics. Currently, finite element models represent the best opportunity for assessing how these structural features impact whole muscle mechanics. The current drawbacks of these methods include the computational demands required for simulation and the lack of reliable parameter estimates for the material properties of muscle.

### Multiple Muscle Systems

In neuroscience, muscle models often are incorporated into multiple muscle systems used to study the neural control of movement. Under these circumstances, computational efficiency becomes a primary concern. As a result, most simulations of multiple muscle systems rely on Hill-type muscle models or even linear visco-elastic models. As discussed above, these models are known to be inaccurate. However, these inaccuracies for predicting the details of muscle force generation may become less important when these forces are filtered by the musculoskeletal system. In contrast, errors may be magnified when such models are used to estimate the activation patterns required to generate an observed set of movements. The difficulties associated with such inverse problems are well described by Hatze [11].

The inability to estimate muscle activation accurately is a major limitation in the use of multiple muscle models for studying the neural control of movement. During physiological conditions, muscle force is graded via changes in motor unit recruitment and firing rate, and it is currently not possible to obtain reliable estimates of these processes during the control of voluntary movement. As an alternative, the whole muscle electromyograms (EMGs) are often used to approximate muscle activation and as inputs to the muscle models in a multiple muscle system. Rectified EMG can be a good predictor of isometric muscle force. However, this relationship is muscle specific. In addition, the EMG-force relationship for a given muscle depends upon recording electrode placements and movement of the electrodes with respect to the muscle. Hence, the use of EMG as an approximation of muscle activation is problematic, and multiple muscle models that rely on EMGs need to assess how these limitations impact model performance.

## Muscle Moment Arm

### Definition
The distance from the line of action of a muscle to the center of rotation of a joint.

►Impedance Control

## Muscle/Muscle Fiber Stiffness

### Definition
Muscle and muscle fiber stiffness are typically evaluated by quick stretch experiments or sinusoidal oscillations of the preparation. Stiffness is then evaluated as the resistance to stretch (for example, as the instantaneous slope of the force elongation curve during stretch). Muscle stiffness has played an important role in muscle physiology and mechanics as it has been viewed as a measure of the proportion of attached cross-bridges.

### Synonyms
Musculoskeletal pain; Myofascial Pain; Deep somatic pain

### Definition
Pain from deep somatic structures.

### Characteristics
Musculoskeletal pain is an important factor in many disorders, including chronic pain conditions, work related disorders, injuries, degenerative diseases, and cancer, but the peripheral and central mechanisms underlying musculoskeletal pain are still poorly understood. The typical characteristics are drilling, aching pain often referred to other somatic structures. Musculoskeletal disorders can be classified as articular (e.g., rheumatoid arthritis, osteoarthritis (see ►Immune system and pain) or non-articular (e.g., myofascial pain syndrome, fibromyalgia (FM). This essay will present manifestations and methods for assessment of human non-articular pain with focus on muscle pain.

### Manifestations of Selected Painful, Musculoskeletal Disorders
Myofascial pain syndromes are regional muscle pain disorders characterised by localized tenderness in muscles (trigger points), leading to persistent, regional pain such as back pain, neck pain, shoulder pain, headaches, and orofacial pain. The affected muscles often display an increased fatigability, stiffness, subjective weakness, pain in movement, and slight restricted range of motion unrelated to joint restrictions. The exact etiology of myofascial pain syndromes is unclear.

Widespread pain is defined as pain lasting for more than three months present as follows: (i) Pain in both

sides of the body, pain above and below the waist, (ii) Axial skeletal pain (cervical spine, anterior chest, thoracic spine, or low back pain) must be present. Widespread pain includes classes of syndromes such as FM, fatigue syndrome, exposure syndromes (e.g., Gulf War illnesses). FM is a chronic, painful musculoskeletal disorder of unknown etiology and defined by chronic widespread pain, involving three or more segments of the body plus the finding of at least 11 out of 18 designated tender points often developing after localised pain problems. However, not all people with chronic, localized or regional muscle pain develop FM. Hereditary factors might be important. Serotonin- and dopamine-related genes have been suggested to be involved in the development of FM. Studies of the endocrine profile of FM patients have indicated elevated activity of corticotropin releasing hormone (CRH) neurones which may not only explain some symptoms of FM, but may also cause alterations observed in the hormonal axes [1]. Hypothalamic CRH neurones may play a role not only in resetting various endocrine loops, but possibly also for nociceptive and psychological mechanisms as well.

FM patients show differentiated ►hyperalgesia to different sensory stimuli indicating that only specific parts of the sensory and nociceptive systems are influenced and that the sensory disturbances are accentuated as the syndrome progresses [2].

Myalgia can be related to a variety of medical conditions, and common terms for the symptom are stiffness, soreness, aching, spasms, or cramps. The associated pain is often described as having a dull, aching quality and can be exacerbated by muscle contractions. The manifestation of pain in some of the myalgias, however, is not the most prominent problem.

For example, in myositis (e.g., polymyositis and dermatomyositis) muscle weakness is often the prominent feature.

Muscle pain of neurogenic origin can be difficult to dissociate from other manifestations of ►neuropathic pain. Examples include cervical radiculopathy with pain radiating into the myotomal distribution of the roots or nerve compressions (e.g., carpal tunnel syndrome), where the pain radiates into muscles in the region. Little is known about muscle sensitization in relation to neuropathic pain as normally only the cutaneous manifestations of neuropathic pain (allodynia, hyperalgesia) are investigated.

Musculoskeletal disorders and pain are more prevalent in females than males, with female predominance in painful musculoskeletal syndromes such as widespread pain, temporomandibular disorders, neck pain, shoulder pain, back pain, joint pain, FM, whiplash, and headache. High rates of comorbidity, particularly in women, have been reported between temporomandibular dysfunctions and other clinical musculoskeletal disorders (e.g., FM). Fluctuations in hormonal levels have been implicated in symptom severity in women with rheumatoid arthritis, temporomandibular disorders, and FM. The many symptoms of FM could be explained by the fact that there are bidirectional connections between the nociceptive system and the immune, sleep regulating and the stress regulating systems. Furthermore, it has recently been described that descending facilitatory pathways may cause widespread hypersensitivity [3]. One mechanism by which hormones may affect ►muscle nociceptor sensitization could be related to nerve growth factor (NGF) and one of its high-affinity receptors (trkA). TrkA receptor expression is influenced by gonadal hormones. Injection of NGF into muscle causes muscle tenderness to pressure which lasts for weeks. There has been some speculation that hormone replacement therapy may increase a woman's risk of developing musculoskeletal pain.

## Fundamentals of Musculoskeletal Pain

The manifestations of musculoskeletal pain include spread of pain and ►referred pain, somatosensory changes in referred pain areas, and interaction with the motor system (e.g., muscle coordination and activation, postural stability, movement initiation, and reflex pathways) [4].

Localization of pain is poor in skeletal muscles, and it is difficult to differentiate pain arising from tendons, ligaments, and bones as well as from joints and their capsules. Referred muscle pain is typically described as a sensation from deep structures in contrast to referred visceral pain, which is described as located both superficially and deeply. The characteristic pattern of referred muscle pain was initially observed by Kellgren in the late 1930s, who injected hypertonic saline into skeletal muscles and ligaments and characterised the referred pain. Similar characterization has been performed clinically when activating trigger points in various muscles [5].

It is obviously important to distinguish the painful tissue, but it may be very difficult due to poor localization and referred pain. Examples can be pain from an arthritic hip, which may refer to the thigh muscles or knee joint, carpal tunnel syndrome, which may refer to forearm muscles, and cervical spondylosis, which may refer to arm muscles. Pain from joints and their capsules tends to be more localised than myalgia, and arthralgia is often worsened by passive joint movements. Capsular pain may be present only in specific joint positions. Bone pain also tends to be poorly localized but, unlike myalgia, usually worse at night and tends to be unaffected by either movement or muscle activity.

Referred muscle pain has been known and described for more than a century and is used extensively as a diagnostic tool. The pattern of referred pain frequently follows the distribution of sclerotomes (muscle, fascia, and bone) rather than the classical dermatomes. A clear distinction between spread of pain and referred pain is not possible, and these phenomena may also share common pathophysiological mechanisms. Firm neurophysiologically-based explanations for referred pain do not exist, but it has been shown that wide dynamic range and nociceptive specific neurons in the spinal cord and brain stem of animals receive convergent afferent input from the mucosa, skin, muscles, joints, and viscera. This may cause a misinterpretation of the afferent information coming from muscle afferents and reaching high levels in the central nervous system, and hence be one reason for the diffuse and referred characteristics of muscle pain. Referred pain is a combination of central processing and peripheral input [6] as it is possible to induce referred pain to limbs with complete sensory loss due to an anesthetic block. However, the involvement of peripheral input from the referred pain area is not clear because anesthetizing this area shows inhibitory or no effects on the intensity of the referred pain. ►Central sensitization may be involved in the mechanism of referred pain. A complex network of extensive collateral synaptic connections for each muscle afferent fiber onto multiple dorsal horn neurons is assumed [7]. Under normal conditions, afferent fibers have fully functional synaptic connections with dorsal horn neurons as well as latent synaptic connections to other neurons within the same region of the spinal cord. Following ongoing strong noxious input, latent synaptic connections become operational, thereby allowing for convergence of input from more than one source. Animal studies show development of new and/or expansion of existing receptive fields after a noxious muscle stimulus. For example, recordings from a dorsal horn neuron with a receptive field located in the biceps femoris muscle show new receptive fields in the tibialis anterior muscle and at the foot after noxious stimulation of the tibialis anterior muscle [7]. In the context of referred pain, the unmasking of new receptive fields due to central sensitization could mediate referred pain [4]. The area of the referred pain is correlated with the intensity and duration of the muscle pain, and the appearance of referred pain is delayed (20–40 s) compared with the local muscle pain, indicating that a time-dependent process, like the unmasking of new synaptic connections (see above), is involved in the neural mediation of referred pain. Recently it has been emphasised that referred pain and central sensitization are closely related [4].

The pattern and size of referral seem to be changed in chronic musculoskeletal pain conditions. For example, FM patients experience greater pain and larger areas of referral after experimental muscle pain compared with matched controls [4]. Interestingly, these manifestations were present in lower limb muscles where the patients typically do not experience ongoing pain. Normally, pain from the tibialis anterior is projected distally to the ankle and only rarely is it projected proximally. In FM patients, substantial proximal spread of experimentally-induced referred pain was found. Enlarged areas of referred pain in pain patients suggest that the efficacy of central processing is increased (central sensitization). Moreover, the expansion in the area of referred pain in FM patients is partly inhibited by ketamine (an *N*-methyl-d-aspartate (NMDA) receptor antagonist) targeting central sensitization. Extended areas of referred pain from the tibialis anterior muscle, indicating central sensitization, have also been shown in patients suffering from other chronic musculoskeletal pain conditions such as whiplash, low back pain, and osteoarthritis.

Somatosensory changes in areas of referred muscle pain have been reported, and it seems that the duration and intensity of pain are important for such manifestations. As well as hypoalgesia, hyperalgesia has been reported in areas of referred muscle pain. Referred muscle hyperalgesia can also be a result of visceral pain due to viscero-somatic convergence. This may occur for example in gastrointestinal, gynaecological/urological, or in chronic visceral painful conditions without known etiology (e.g., irritable bowel syndrome, endometriosis). The degree of referred muscle hyperalgesia is related to the severity of the visceral pathology and hence the degree of visceral pain. Persistent referred muscle hyperalgesia can be manifested not only by chronic conditions, but also after recurrent painful visceral attacks such as in dysmenorrheic women, where lumbar muscles are hyperalgesic to pressure, or after colic attacks following calculosis of the upper urinary tract, where hyperalgesia to pressure is found in muscles in the left lumbar region [8].

## Assessment of Muscle Pain in Experimental and Clinical Studies with Focus on FM

Several methods exist to assess pain sensitivity of musculoskeletal structures. The methods are based on application or induction of standardized pain to musculoskeletal structures to evaluate how sensitive the structure is to that specific stimulus modality. Such procedures can be applied to healthy volunteers in the laboratory for basic experimental studies or to patients for clinical examinations [4].

Pressure algometry is the most commonly used technique to induce muscle pain and hence assess tenderness in myofascial tissues and joints (e.g., tender points, FM, work-related myalgia, myofascial pain, strain injuries, myositis, chronic fatigue syndrome, arthritis/

orthroses, and other musculoskeletal inflammatory conditions). The American College of Rheumatology's classification criteria for FM requires 11 or more tender points to pressure out of 18 specified anatomical sites. Widespread hypersensitivity in chronic musculoskeletal pain conditions means general reduction in pressure pain thresholds assessed from many sites.

Another way to experimentally assess pain sensitivity is to apply repetitive painful pulses and investigate temporal integration/summation and the involvment of central NMDA receptors. ►Temporal summation means that repetitive, identical stimulation at frequencies lower than 5 Hz give rise to gradually increasing pain responses. FM patients show increased and prolonged responses to repetitive stimulation and ketamine (an antagonist of the NMDA receptor) can inhibit this.

Referred pain can be assessed experimentally from muscles by injection of various chemical substances such as hypertonic saline, capsaicin, and glutamate [4].

The balance between descending inhibition and facilitation can be assessed experimentally.

The phenomenon of descending inhibition, in which "muscle pain inhibits pain," has been extensively investigated and the heterotopic character demonstrated in many human studies (for references see [4]). Painful heterotopic conditioning stimuli (thermal, mechanical, electrical, or chemical) decrease pain perception induced by phasic noxious stimulation given elsewhere in the body. Recent data have shown that endogenous pain modulation in FM is impaired [9]. Descending facilitatory pathways originating in frontal cortical areas can contribute to generalized, increased neuronal responses along the neuraxis, suggesting that emotions such as fear may drive the development of wide spread pain and sensitization [3].

Muscle blood flow impairment during and post contractions, resulting in ischemia, has been suggested as contributing to FM pain. Other studies support that decreased relaxation between contractions, which has been found in patients with FM, means that not only static, but also dynamic muscle contractions might cause ischemic pain.

Muscle pain and musculoskeletal pain have implications on many aspects in daily life, and questionnaires for assessment of different dimensions have been developed for general and regional (e.g., back pain and neck pain) pain problems (General Function Score, Roland and Morris Disability Scale, Oswestry Pain Disability Index, West Haven-Yale Multidimensional Pain Inventory, Bournemouth questionnaire, fear avoidance beliefs, life satisfaction) [10].

Verbal assessments of musculoskeletal pain intensity and other subjective characteristics of the pain are obviously needed in clinical and experimental muscle pain studies. Visual analog scales (VAS), verbal descriptor scales (VDS), the McGill Pain Questionnaire (MPQ), and similar scales and questionnaires may be very helpful for the assessment of perceived pain intensity and quality [10]. Musculoskeletal pain is most frequently characterised by descriptors as: "drilling," "aching," "boring," and "taut."

The intensity of musculoskeletal pain is easily measured using VAS. However, this is only a one-dimensional aspect of the pain experienced, and additional VAS should be applied to monitor unpleasantness and soreness for example. Word descriptors on the VAS are important as muscle tenderness and muscle pain may not reflect the same mechanisms. In addition to verbal assessments, psychophysical tests are valuable adjuncts for the examination of musculoskeletal pain [10].

## Summary

A significant part of the manifestations of muscle and myofascial pain (e.g., tenderness and referred pain) in chronic musculoskeletal disorders may be the result of peripheral and central sensitization. Reliable methods for quantitative induction and assessment of muscle sensitization, referred pain and muscle sensitivity are available. Sensory assessment procedures can provide complementary clinical information and give qualified clues to revise and optimize treatment regimes.

## Muscle Spindle

### Definition

A stretch-sensitive muscle receptor. The mammalian muscle spindle is 2–6 mm long and is attached at each end to the (extrafusal) skeletal muscle fibers that envelop it. Two or more sensory endings are located within a capsule near the middle of the spindle. When extrafusal muscle fibers lengthen and shorten, the spindles stretch and shorten too, which modulates the firing rates of their sensory endings. Much of the spindle comprises intrafusal muscle fibers whose sole function is to alter the stretch-sensitivity of the spindle's sensory endings. These muscles fibers are activated by γ-motoneurons (also known as fusimotor neurons). There are typically 100–200 muscle spindles in a medium-sized muscle, each innervated by up to 6 sensory afferents (group Ia and II afferents) and 10 fusimotor neurons.

## Muscle Synergies

Andrea d'Avella
Department of Neuromotor Physiology, Santa Lucia Foundation, Rome, Italy

### Definition

The term "synergy" literally "working together," has been used in the motor control literature with various meanings. Here a muscle synergy is defined as the coordinated recruitment of a group of muscles with specific activation balances or specific activation waveforms. Recent experiments have indicated that many motor behaviors are controlled through the flexible combination of a small number of muscle synergies. This mechanism is believed to simplify the selection of the appropriate muscle commands for a given behavioral goal.

### Characteristics

To control goal-directed movements the central nervous system (CNS) must map sensory input into motor output. For example, ►reaching movements usually require selecting the appropriate muscle activation patterns to move the arm to visually specified targets. This transformation is thought to be performed by an ►internal model implemented in the neural circuits. However, given the complexity of the computations required to select the appropriate activation waveforms of many muscles acting on many articulated body segments, it is not clear what mechanisms allow for an efficient implementation of an internal model. One possibility is that this mapping is simplified by a low-dimensional representation of the motor output. The key idea is that, if all useful muscle patterns can be constructed by the combination of a small number of basic elements, selecting the appropriate muscle pattern for a given goal requires only determining how these elements are combined.

#### Two Types of Synergies

Muscle synergies are suitable basic elements for constructing a low-dimensional representation of the motor output because they capture a set of features

shared by a variety of muscle patterns. Such features can be identified in the spatial domain and in the temporal domain. In the spatial domain, i.e. across muscles, a muscle synergy captures a specific relationship in the muscle activation amplitudes. Considering a set of $D$ muscles, a muscle synergy can be expressed as a $D$-dimensional vector $\boldsymbol{w}$ of weighting coefficients that specify the activation balance among the muscles (Fig. 1a).

Different levels of activation may be generated by a single muscle synergy by scaling in amplitude the entire vector:

$$\mathbf{m} = c\,\mathbf{w} \tag{1}$$

where $\boldsymbol{m}$ is a $D$-dimensional vector that specifies the recruitment level of each muscle and $c$ is a scaling coefficient (Fig. 1b, *columns* 1–3). More generally, a set of $N$ synergies, $\{\boldsymbol{w}_i\}_{i=1\ldots N}$, can generate many distinct muscle patterns by linear combination:

$$\mathbf{m} = c_1\mathbf{w}_1 + c_2\mathbf{w}_2 + \cdots + c_N\mathbf{w}_N = \sum_{i=1}^{N} c_i\ \mathbf{w}_i \tag{2}$$

where $c_i$ is the scaling coefficient for the $i$-th synergy (Fig. 1b, *rows* 4–6).

Since the muscle activation vectors involved in most behaviors are time-dependent, synergistic relationships may also be found in the temporal domain. With respect to time, a synergy may be time-invariant or time-varying. A synergy is time-invariant if the same muscle activation balance, expressed by a vector $\boldsymbol{w}$, holds at all times, i.e. for all the time-varying activation vectors comprising a muscle patterns. If all the synergies are time-invariant, eq. 2 can be written, taking time into account, as:

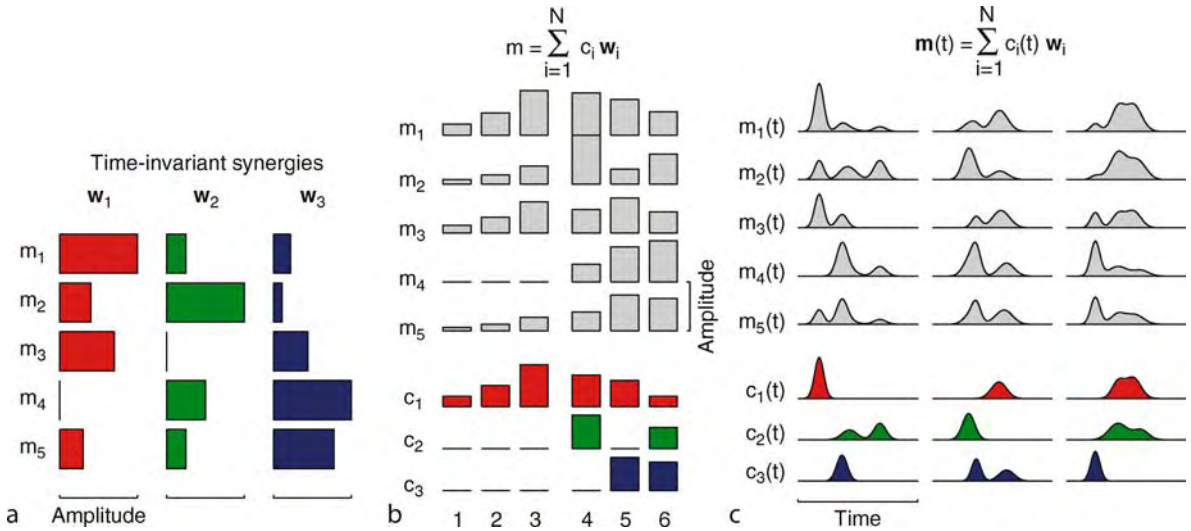
$$\mathbf{m}(t) = \sum_{i=1}^{N} c_i(t)\,\mathbf{w}_i \tag{3}$$

where $\boldsymbol{m}(t)$ is the muscle activation at time $t$ and $c_i(t)$ is the scaling coefficient for the $i$-th synergy at time $t$ (Fig. 1c). Since each time-invariant synergy contributes to the waveform of different muscles with the same $c_i(t)$ waveform, the muscle waveforms associated with each synergy are synchronous. In contrast, a time-varying synergy is comprised by a collection of waveforms, each one specific for a muscle, and thus not necessarily synchronous (Fig. 2a).

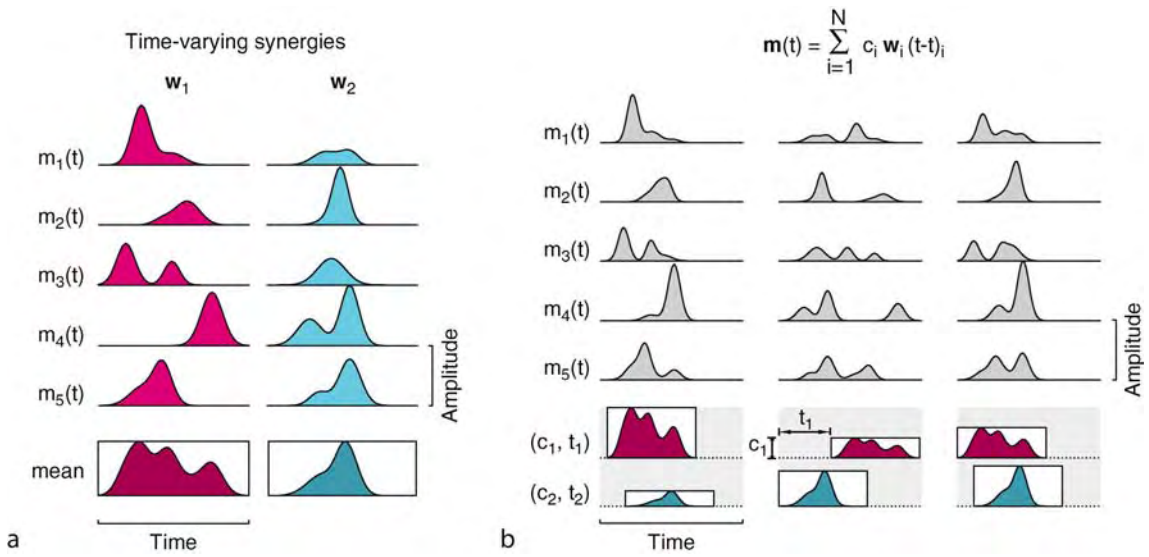
These waveforms can be expressed by a time-varying synergy vector $\boldsymbol{w}(t)$ and eq. 2 can be written as:

$$\mathbf{m}(t) = \sum_{i=1}^{N} c_i\ \mathbf{w}_i(t - t_i) \tag{4}$$

with one scaling coefficient ($c_i$) and one time delay ($t_i$) for each synergy. In this case, the time dependence of the muscle activation waveforms is captured by the temporal structure of the synergies and by their relative delays (Fig. 2b). Time-varying synergies represent parsimoniously the motor output because, once the



**Muscle Synergies. Figure 1** Generation of muscle patterns by combination of time-invariant synergies. (a) Three different activation balances among five muscles are expressed by three vectors ($w_i$), whose components are represented by horizontal bars of different lengths. (b) Different muscle patterns (1–6) are generated by multiplying the three vectors by three scaling coefficients ($c_i$) and summing them together. (c) A time-varying muscle pattern ($m(t)$) is generated by combining the synergies with time-varying scaling coefficients ($c_i(t)$). Different patterns can be obtained by changing the scaling coefficient waveforms.



**Muscle Synergies. Figure 2** Generation of muscle patterns by combination of time-varying synergies. (a) Each one of the two synergies illustrated is composed by a collection of muscle activation waveforms. The profile inside the rectangle below each synergy represents the mean activation waveform for that synergy. (b) A time-varying muscle patterns ($m(t)$) is generated by multiplying all waveforms of each synergy by a single scaling coefficient ($c_i$), shifting them in time by a single delay ($t_i$), and summing them together. In this example, different patterns are obtained by changing two scaling coefficients and two delays.

synergies are given, a few scaling and delay coefficients are sufficient to specify many muscle patterns.

## Muscle Synergy Identification

Muscle synergies provide a useful representation of the motor output if they can generate all muscle patterns observed during the performance of either a task in variety of conditions or multiple tasks. Thus, to test the validity of a synergy model it is necessary to identify a set of synergies from the observed muscle patterns and to show that they capture most of the variability in the data.

The identification of the synergies according to a model that allows for the simultaneous recruitment and combination of multiple synergies (eq. 2) requires a multivariate decomposition algorithm. For time-invariant synergies, the identification of the combination coefficients and synergies of eq. 3 can be obtained with a number of decomposition algorithm such as Principal Component Analysis (PCA), Factor Analysis (FA), Independent Component Analysis (ICA), and Non-negative Matrix Factorization (NMF) [1]. The number of synergies ($N$) is a free parameter for each decomposition algorithm. While the selection of this parameter is performed with different criteria for each algorithm, in general the goal is to determine the minimum number of synergies that explain all the structured variation in the data, interpreting the remaining unstructured variation as noise. Often this minimum number is determined by inspecting a plot of the reconstruction error as a function of the number of synergies. As the number of synergies increases the reconstruction error decreases and the number at which the error curve changes slope, indicating that additional synergies only explain a small additional amount of variation due to noise, is usually taken as correct number of synergies. The identification of time-varying synergies, according to the model of eq. 4, can be accomplished with the same methods used for time-invariant synergies if the simplifying assumption that the synergies are not time-shifted relatively to each other is introduced [2]. More generally, to identify a set of time-varying synergies that can be time-shifted with respect to each other, it is possible to use an iterative optimization algorithm [3].

## Experimental Evidence

Qualitative observations of stereotyped muscle activity patterns in specific tasks, suggestive of a synergistic organization, have long been reported. However, whether muscle synergies are fixed or require task-dependent flexible adjustment has been a controversial issue. Recently, systematic investigations and quantitative analyses of the muscle synergies according to synergy combination models have addressed this issue with a new perspective. Studies conducted on frogs, cats, and humans have provided evidence that the CNS flexibly combines fixed muscle synergies for generating the muscle patterns necessary to perform many motor tasks and behaviors.

Electromyographycal (EMG) activity recorded from many hindlimb muscles of spinalized frogs during withdrawal reflexes [4], decerebrated frogs during spontaneous behavior [5], and intact frogs during defensive kicking [3] and locomotion, has revealed a synergistic organization. These studies have shown that a variety of muscle patterns used in different behaviors are generated by the combination of a small number of time-invariant and time-varying synergies. For example, 90% of the variability in the EMG responses associated with the withdrawal reflexes evoked by skin stimulation at a variety of sites on the frog limb is explained by the combination of four time-invariant synergies.

The study of postural control in cats and humans has also provided evidence for muscle synergies. The activations of cat hindlimb muscles during postural responses to perturbations of the support surface (translations and rotations in multiple directions) are captured by the combination of a five time-invariant synergies [6]. These muscle synergies are associated with specific force vectors applied by the paw against the support, suggesting that they encode task-level biomechanical variables. In humans, the muscle patterns used for shifting the center of pressure during balancing while standing are constructed by combinations of three time-invariant synergies [7].

The muscle patterns in leg and trunk muscles during human locomotion at different speeds and with different fractions of the body weight supported by a harness are accounted by the combination of five time-invariant synergies [8]. The time-varying amplitude scaling coefficients, once the muscle patterns are time-normalized to equal gait cycle duration, have similar waveforms across conditions.

Time-varying muscle synergies have been identified in the patterns of activation of extrinsic and intrinsic hand muscles during fingerspelling [2]. The synergy, identified with PCA, which explains the largest fraction of the data variation has asynchronous waveforms with activity waves unfolding in time across muscles.

Finally, there is evidence that the combinations of time-varying muscle synergies are used for controlling reaching movements in humans [9]. The phasic EMG patterns recorded in arm and shoulder muscles during fast reaching movements to targets arranged in different directions on two vertical planes are generated scaling in amplitude and shifting in time four or five time-varying muscle synergies. The amplitude modulation of the synergy has a simple dependence on the direction of movement, well captured by a cosine function.

In summary, a growing number of studies are unveiling the existence of regularities in the spatiotemporal organization of the muscle patterns observed during the performance of a variety of tasks in many conditions. These regularities are well described by a synergy combination model suggesting that the CNS uses a low-dimensional representation of the motor output and simple combination rules for mastering the complex task of selecting the appropriate muscle pattern for achieving a desired goal.

## Definition

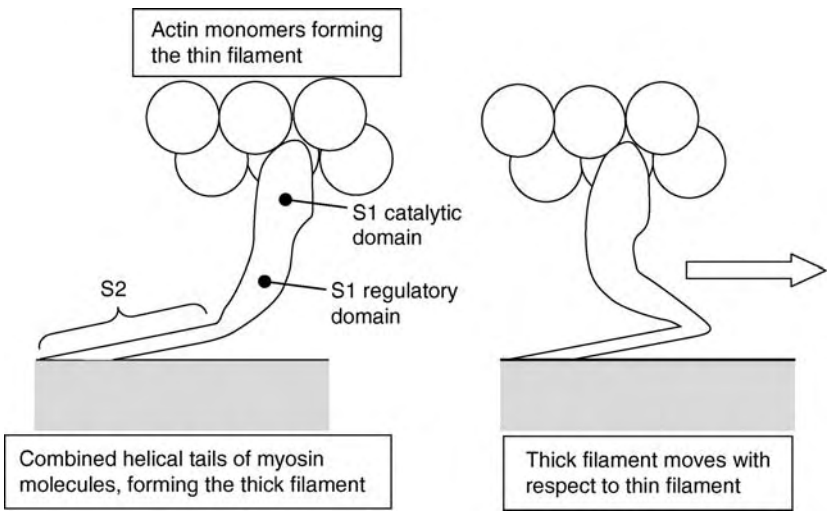
Muscle consists of an exceedingly complex array of molecules. The exertion of force and the production of movements thus rely on the summation of forces and movements of many molecules. The sarcomere provides the basic structural organization of a muscle fiber (see Fig. 1 in ►Muscle). From the perspective of the molecular motor, the sarcomere structure can be divided into three components: the thick filaments (made of up myosin molecules), the thin filaments (made of actin molecules), and the structural proteins that transmit forces to the ends of the sarcomere and among sarcomeres. The primary basis of the molecular motor for movement consists of a configuration change in myosin. This configuration change, however, does not produce movement or force unless the myosin is attached to actin; the forces so produced are transmitted via the structure of the sarcomere to neighboring sarcomeres and so on through to the tendon (see ►Length-Tension) and even to other muscles (see ►Intramuscular myofascial force transmission and Epimuscular Myofascial Force Transmission and Intermuscular Interaction).

## Characteristics

### Quantitative Description

The myosin in muscle is one of a large set of molecular motors consisting of various families of myosins, kinesins and dyneins. Myosins move along actin filaments; kinesins and dyneins along microtubules [1]. These motors provide functions such as moving substrates within the cell. The myosin II family in muscle is unique in being part of the structure of the sarcomere, and produces summed movements that generate the huge forces that muscles are capable of producing. Muscle myosin contains a long helix, which with other myosin molecules, forms the thick filament of the sarcomere. A portion of this helix (called the S2 subfragment) protrudes from the thick filament and connects to a head region (S1 subfragment). For some years, it was assumed that the configuration change in myosin that generated movement involved rotation of the S1 head with respect to actin at the attachment site between these two molecules. However, studies from a number of labs have now demonstrated that the angle between the attached part of the S1 head and actin stays constant during force generation [2,3–5]. Instead, the configuration change occurs within the S1 head. The S1 head comprises of two distinct regions: a regulatory domain that contains the myosin light chains and a catalytic domain for hydrolysis of ATP to ADP + Pi. Force is generated when the angle between the regulatory domain and the catalytic domain changes. The regulatory domain rotates with respect to the catalytic domain, as shown by the cartoon in Fig. 1.

This is known as the "lever arm" hypothesis, with the lever arm being the regulatory domain of S1.



**Muscle: The Molecular Motor. Figure 1**

The hydrolysis of ATP is of course essential for this configuration change. The basic features of how the steps of hydrolysis of ATP are related to the contraction cycle is as follows: (i) binding of ATP to S1 catalytic domain: unbinding of actin and myosin; (ii) hydrolysis of ATP to ADP and Pi: S1 lever arm straightens, moving S1 head to next attachment site; and (iii) release of ADP and Pi from the S1 head: lever arm bends to produce movement of thin versus thick filaments (this is the step illustrated in Fig. 1) [2,5]. Myosin is only tightly bound to actin for about 5% of the total crossbridge cycle; the rest of the cycle involves either weak binding or the unbound state [5]. Speed of the crossbridge cycle is related both to the various subforms of the myosin ATPase, as well as to differences in the myosin light chains. Immunohistochemical techniques to identify these subtypes are the basis of the standard identification of type I (slow), IIa and IIb (both fast) muscle fibers.

### Higher Level Structures
Myofilament, myofibril, muscle fiber, muscle.

### Higher Level Processes
Forces are also transmitted between muscles (see ►Epimuscular Myofascial Force Transmission and Intermuscular Interaction).

### Process Regulation
The interaction of actin and myosin is dependent on calcium; release of calcium is controlled via action potentials from motoneurons (see ►Neuromuscular Junction).

### Function
The function of the molecular motor is clear: generation of movement.

### Pathology
Genetic mutations in the molecular machinery produce severe pathological deficits. Nemaline myopathies can be produced by genetic defects in action, tropomyosin and other sarcomere proteins.

### Definition
An action potential in a skeletal or oculomotor motoneuron axon produces, after neuromuscular synaptic transmission, a propagating action potential in the innervated muscle fibers followed by an increase in intracellular calcium. The calcium activates the actin-myosin cross-bridges and the buildup of force (a process called excitation-contraction coupling). Force peaks at a characteristic "twitch time" that is dependent on the rate of calcium release (fast in most skeletal and extraocular muscles) and the interaction between the muscle's series elastic component (embodied in the connective tissue and muscle proteins) and the force-velocity relationship. In the initial part of the twitch, the muscle contracts rapidly internally as the series elastic component stretches, so less force is produced. Force declines slowly after the peak due to the re-sequestering of calcium. The time course of the contraction depends on the muscle fiber type (type-I, type-II, and subtypes) to the extent that the terms "slow-twitch" and "fast-twitch" fibers are also used as synonyms of type-I and type-II respectively.

## Definition

Muscular stiffness is defined as the change in force divided by the corresponding change in length, when the length change is imposed by an external agent or by a change in the external load on the muscle. In the present context, stiffness is time-varying and therefore has dynamic attributes. Classically, stiffness refers only to the elastic, and therefore static, component of impedance. However, muscular properties are nonlinear, and therefore muscular impedance cannot easily be partitioned into components corresponding to the derivatives of position. Researchers in motor systems have chosen to retain the term "stiffness" to describe the resistance of muscle to length change.

## Characteristics

### Quantitative Description

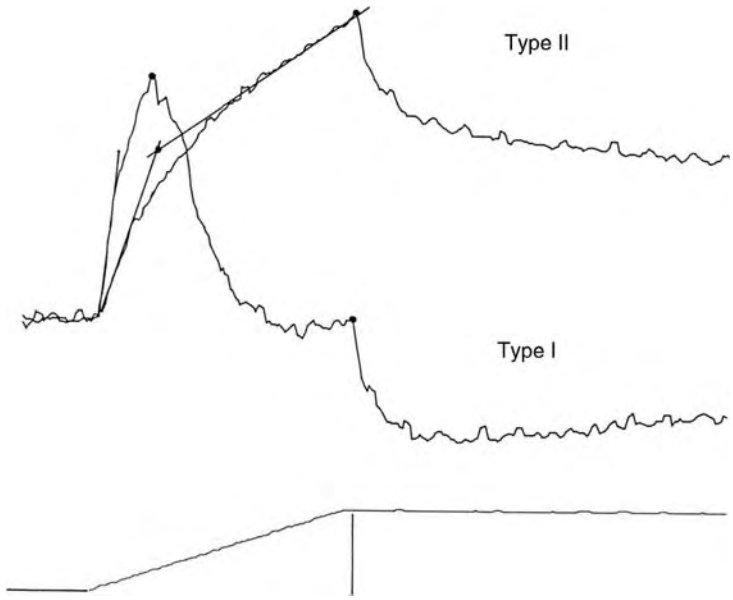
#### *Stiffness of Inactive Muscle*

The stiffness of inactive skeletal muscle is dominated by the elastic properties in-parallel and in-series connective tissue. This stiffness increases at long muscle lengths and can effectively limit extreme joint angles, but is normally low enough through the physiological range of the muscle so as not to offer significant resistance to joint motion. However, inactive muscle can offer some resistance for small disturbances. Evidence does exist that some cross-bridges that cycle either slowly or not at all remain attached at rest. The additional stiffness contributed by these cross-bridges is reduced by stretching the muscle beyond the working range of the cross-bridges or by prior activation of the muscle. These non-cycling cross-bridges can reform over a period of seconds, and re-establish elevated stiffness for small (1% of muscle length) amplitudes of stretch. These "thixotropic" properties of inactive muscle have been observed in experiments on animals and human subjects [1], and may be important during the maintenance of steady postures.

#### *Stiffness of Active Muscle*

When a muscle is activated, the stiffness becomes considerably larger through the physiological range of joint angles. The magnitude of this stiffness, which is intrinsic to the contracting muscle, depends on a number of factors, including the level of motor unit recruitment, length and force, and movement history. The stiffness of actively contracting muscle is thought to arise from the mechanical properties of cycling cross-bridges. Cross-bridges are believed to have spring-like properties, so they contribute to muscular stiffness when attached. In a muscle fiber with a population of cycling cross-bridges, the stiffness of the fiber depends on the average number of attached cross-bridges and the rate of turnover. The contribution of a given cross-bridge to the stiffness of the muscle fiber increases with the length change over which it is attached. For a given rate of stretch, this contribution will decrease with an increase in the rate of turnover. These basic principles can be used to explain how muscular stiffness changes under different contractile conditions and how it depends on the fiber type composition of the muscle.

If, after a period of isometric contraction, a muscle fiber is stretched by a small amount so that the length change remains within the working range of the attached cross-bridges, the muscle fiber exhibits spring-like behavior known as *short-range stiffness*. If the disturbance carries the muscle fiber beyond the working range of cross-bridges, then stiffness abruptly declines as cross-bridges are mechanically disrupted [2] (Fig. 1).



**Muscular Stiffness. Figure 1** Responses of chemically-skinned muscle fibers to constant velocity stretch. The fibers were submaximally activated to the same background force levels in solutions containing calcium and ATP. Stretches lasting 100 ms and 0.05 muscle lengths in amplitude were delivered after periods of isometric contraction in activating solutions. The type II fiber was obtained from the lateral gastrocnemius muscle and the type I fiber from the soleus muscle of the cat. Both fibers show short-range stiffness followed by yielding, but the short range stiffness (indicated by the initial *fitted lines*) and yield were both greater in the type I fibers. This figure was modified from Fig. 2 of [3].

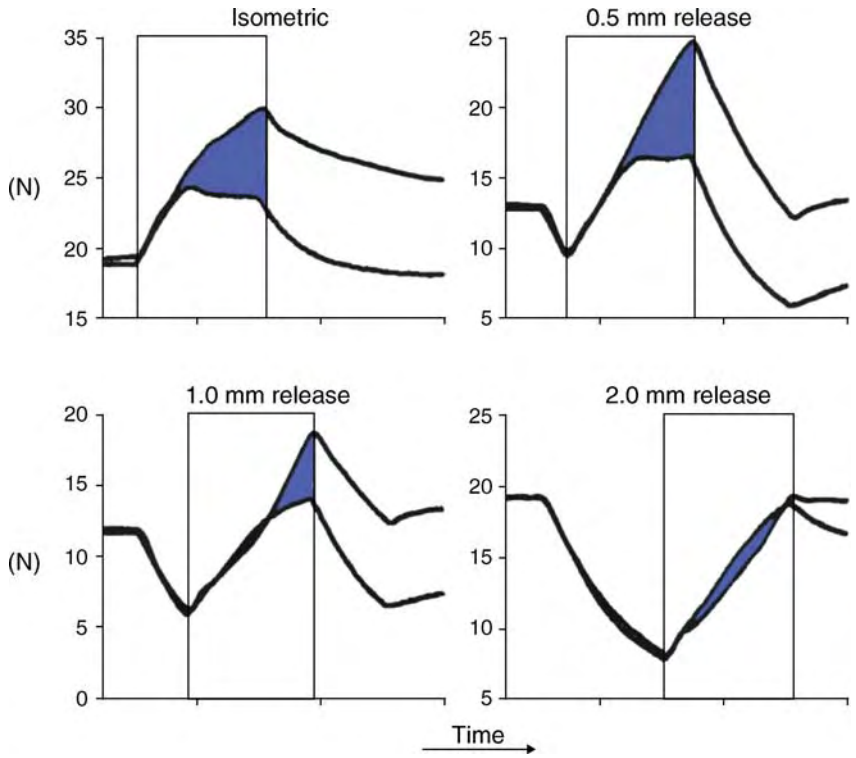
The extent of this decline, or yield, and short-range stiffness depend on the rate of stretch and on the rate of cross-bridge turnover. Increasing the rate of stretch can lead to an increase in short-range stiffness, since the cross-bridges remain attached over a larger change in length [3]. Yield can also increase since there is more synchronous detachment and a decrease in the time for reattachment relative to the rate of stretch. An increase in the rate of turnover would lead to a small decrease in stiffness since cross-bridges remain attached for shorter periods of time and a decrease in yield occurs due to the more rapid reattachment. Therefore, a previously isometric muscle responds to forcible lengthening with short-range stiffness followed by a yield that in some cases can result in a transient reduction in force (Fig. 1). One way to summarize this behavior is that active muscle shows significant damping [4], albeit nonlinear damping, which can have a stabilizing influence on the musculoskeletal system. If the muscle is allowed to shorten instead, force declines throughout the shortening, but the stiffness is also greater over the short range. When the responses to lengthening and shortening are compared, stiffness is greater during shortening [5].

If the muscle fiber is perturbed after a period of motion, its mechanical properties are different from those described above. Constant motion leads to increased turnover and a tendency for cross-bridges to be in positions of lower stress than in the isometric state. As might be expected, the yield decreases and the short range is extended. As a result, the responses of the muscle to length change more closely resemble those of linear springs with some damping [6] than the highly nonlinear behavior described above (Fig. 2).

Under conditions of quiet standing, stability is achieved in part by intrinsic mechanical properties of muscle, including thixotropic properties of inactive muscle, and short-range stiffness and damping of active muscle. During ongoing movements, muscular stiffness is less dependent on amplitude of the perturbation, and thixotropy in inactive muscles is greatly reduced, in keeping with the requirements of a wide dynamic range of joint motion.

### Dependence of Muscular Stiffness on Motor Unit Composition and Recruitment

Muscular stiffness is strongly dependent on the motor unit composition of a muscle and the level of recruitment in the muscle. For muscles that are used for standing or braking and that are rich in slow twitch muscle fibers, the cycling rate of cross-bridges tends to be lower. Consequently, these predominantly slow-twitch muscles exhibit higher short range stiffness and yield to a greater extent than muscles with substantial



**Muscular Stiffness. Figure 2** Dependence of muscular stiffness on movement history. Reflexive and areflexive soleus muscles from a decerebrate cat were subjected to 2 mm ramp stretches following releases of progressively larger amplitude, from 0 to 2 mm. In each panel, the lower trace corresponds to the areflexive muscle. The portions of the responses obtained during the 2 mm stretch are denoted by the rectangles. Note that the yields of the intrinsic responses become progressively small and more delayed as the prior release increases. Reflex action also becomes reduced and delayed, until there is no contribution from the reflex with the largest prior release. This figure is modified from Fig. 1a of [6].

populations of fast-twitch muscle fibers (see Fig. 1). As motor units are recruited into activity, force and stiffness both increase. A dependence of stiffness on force contrasts with the property of a linear spring that stiffness is constant with force. Intrinsic muscular force and stiffness increase together with recruitment, but not in exact proportion (Fig. 3).

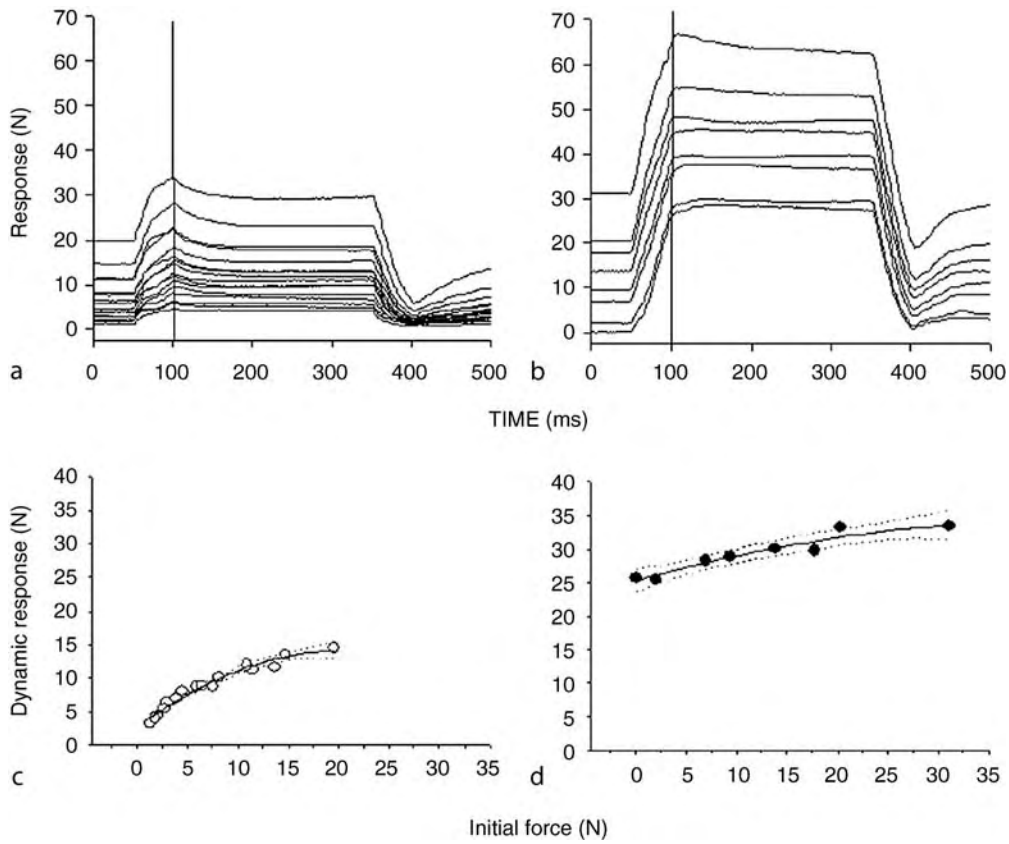
Stiffness increases slightly less rapidly than force due to the presence of series elastic elements [7,8]. The consequence of these nonlinear properties is that high intrinsic stiffness can only be achieved by recruiting many motor units. Co-contraction is one strategy for increasing the stiffness of a joint. Under these conditions, agonist and antagonistic muscles are activated together to provide high joint stiffness with no net joint torque. At low background activity, such as occurs during quiet standing, intrinsic muscular stiffness is low.

## Structural Regulation

Muscular stiffness is influenced by the architecture of the muscle. Stiffness increases with the cross-sectional area of muscle and decreases with length, according to the in-parallel and in-series arrangement of sarcomeres, respectively.

## Process Regulation

The mechanical properties of muscle are subject to local control by reflex circuits in the spinal cord. The initial response of a muscle, and therefore the musculoskeletal system, to a mechanical perturbation depends on the intrinsic mechanical properties described above. After a brief delay, feedback from muscle spindle receptors can increase or decrease the recruitment of motor units as well as influence firing rate modulation in response to muscle lengthening or shortening, respectively, through the monosynaptic (stretch) reflex. Muscle spindle receptors, which contain specialized muscle fibers (intrafusal muscle fibers), signal length changes and the dynamics of length change. Due to the high sensitivity of the primary receptors of the muscle spindle, the monosynaptic reflex can recruit substantial numbers of motor units even at low forces, making the stiffness



**Muscular Stiffness. Figure 3** Dependence of muscular stiffness on initial force. Reflexive and areflexive gastrocnemius muscles of a decerebrate cat were subjected to ramp-and-hold stretches. (a) Responses of muscles in which reflexes were disrupted by prior reinnervation of the muscle obtained at different initial forces. Dynamic responses were computed by subtracting the initial (pre-stretch) force for each trace from the corresponding force measured at the time of ramp completion denoted by the vertical line. These responses are shown plotted against initial force in (c). (b) Responses of untreated contralateral muscles with intact reflexes. Note the greater magnitude and less abrupt yielding of these responses compared to those shown in (a). The dynamic responses are shown plotted against initial force in (d). The amplitude of the ramps was 2 mm, so dynamic stiffness (N/mm) can be computed by dividing the dynamic responses by 2. These plots indicate that intrinsic muscular stiffness increases with force. In the presence of reflexes, stiffness is larger and less dependent on force. This figure is modified from Fig. 3 of [7]. Further experimental details can be found in this paper.

of the muscle-reflex system less dependent on background force than intrinsic muscular stiffness (Fig. 3). As stiffness remains force-dependent to some extent, however, co-contraction still results in an increase in the stiffness of the joint.

Due to the filtering properties of the intrafusal muscle fibers, the length signals are subject to similar history-dependent properties as found in extrafusal muscle fibers as described above [9]. The monosynaptic reflex compensates for muscular yield through recruitment of additional motor units, but compensates less during ongoing motion when the yield is less [6] (Fig. 2). In these ways, the stretch reflex can regulate muscular stiffness over a wide range of forces and movement histories, and therefore reduce the computational burden on the central nervous system.

## Function

The initial response of a muscle to length change is determined by the intrinsic stiffness of the muscle. Reflex pathways then regulate the response after a brief delay. These intrinsic and extrinsic mechanisms regulate the mechanical response properties of joints in a three-dimensional manner according to the attachments of the muscles crossing the joint. For a given axis or rotation, the stiffness of synergistic and antagonistic muscles add together to determine the stiffness of the joint. Muscular stiffness influences interjoint coordination by virtue of the regulation of individual joints, as well as by the mechanical coupling of multi-articular muscles. These intrinsic and extrinsic mechanisms therefore influence the endpoint stiffness of the limb and coordination of the component joints.

### Pathology

Muscular growth and maintenance are strongly influenced by muscular load and length [10]. In disorders that involve prolonged shortening, such as spastic diplegia, muscle fibers may become shortened with the consequent equine posture. In addition, the tendon will account for a greater proportion of total muscle length. The shortened muscle fibers will consequently have reduced shortening velocity, increased active stiffness, and increased overall stiffness.

## Mutagenesis, Structure-Function

### Definition

The process by which selective changes to the amino acid sequence of a protein are made and the functional consequences of such mutations then determined. This process is used to identify functionally important parts of proteins (e.g. ion channels, enzymes), and thus provides insight into the molecular mechanisms by which these proteins function. Such changes are usually made to a cDNA clone of the target protein using recombinant DNA techniques. The choice of which residues to alter is often guided by predictive models of the protein as made by hydropathy or secondary structure analysis of the primary amino acid sequence. Assessment of the functional consequences of such mutations is usually done by expressing the protein in a cell type that is null for this protein.

### Definition

A principle of feature extraction and dimension reduction of multi-dimensional data from multiple information sources. Effective low dimension features are obtained by transforming data to maximize mutual information between them.

## Myasthenia Gravis

Masaharu Takamori
Neurological Center, Kanazawa-Nishi Hospital and Kanazawa University, Kanazawa, Japan

### Definition

Myasthenia gravis (MG) is a disease of neuromuscular transmission, with clinical features of weakness and

fatigue that is mainly caused by an autoimmune response to the nicotinic ►acetylcholine receptor (AChR) in skeletal muscle (Fig. 1).

Anti-AChR antibodies directed against the specific sites of AChR molecular structure, depending on their pathogenic actions, are detected in the sera of 80–90% of generalized MG patients.

The remaining 10–20% of MG patients lack anti-AChR antibodies in sera, termed "seronegative MG (►Seronegative Myasthenia Gravis)", but have a humorally mediated disorder, as evidenced by that their Sera, passively transferred to mice, results in neuromuscular weakness. The seronegative MG could therefore be caused by non-AChR antibodies. The search for non-AChR pathogenic antigens has recently been focused on ►muscle-specific tyrosine kinase (MuSK) (Fig. 1).

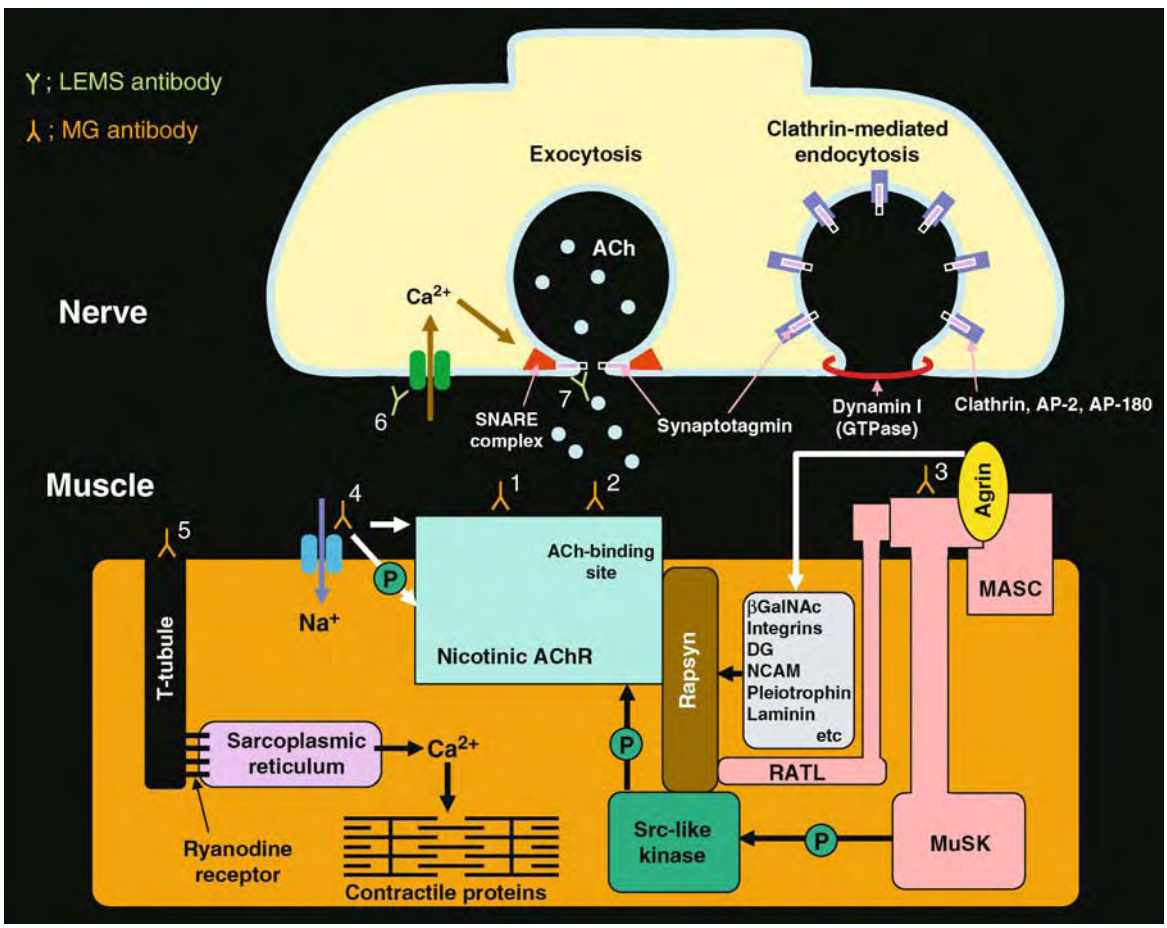
## Characteristics

### Seropositive (Anti-AChR-Positive) Myasthenia Gravis

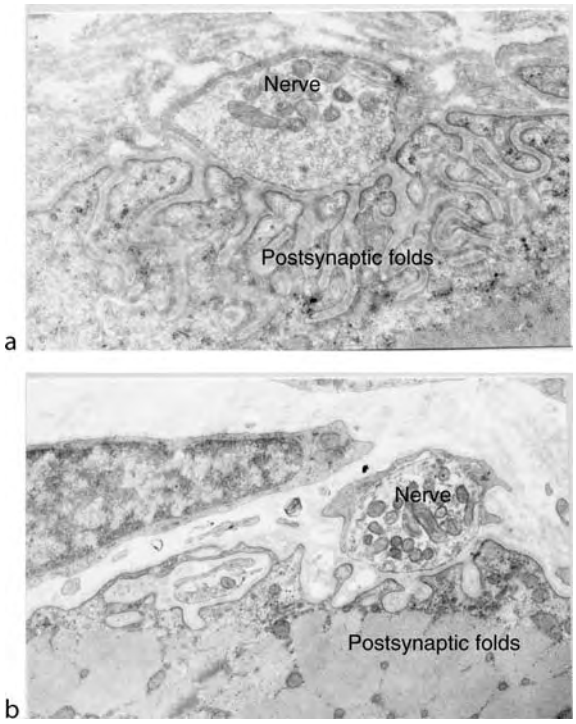
#### *Pathogenesis: Antibodies to AChR*

Anti-AChR antibodies cause the accelerated degradation of AChR, complement-mediated destruction of postsynaptic membrane, and blockade of ACh-binding to AChR resulting in impairment of neuromuscular transmission (Fig. 2).

The search for epitopes bearing on AChR, which are implicated as targets for myasthenic antibodies, has developed through the information about the AChR primary structure comprising of four homologous polypeptide subunits. Based on this, myasthenic domains are localized at the segment alpha 67–76 [1] and alpha 125–147 [2] as the sites recognized by antibodies causing the accelerated AChR degradation and the complement-mediated destruction of postsynaptic



**Myasthenia Gravis. Figure 1** Schematic representation of neuromuscular synapse. Myasthenia gravis (MG) is caused by antibodies to the acetylcholine receptor (AChR) (antibodies-1 and 2), and modified by those to muscle-specific tyrosine kinase (MuSK) (antibody-3), muscle membrane sodium channel (antibody-4) and ryanodine receptor (antibody-5). The antibody-4 (non-IgG) also provides an AChR desensitization through cGMP-mediated protein kinase G or allosteric inhibition. Antibodies numbered 6 and 7 are referred to the section of Lambert-Eaton myasthenic syndrome (LEMS).

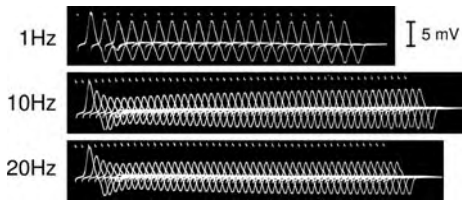


**Myasthenia Gravis. Figure 2** Ultrastructure of neuromuscular junction. Postsynaptic folds are richly developed in normal skeletal muscle (a). In myasthenia gravis, in which anti-AChR antibodies cause the complement-mediated destruction of postsynaptic membrane, the folding becomes less dense than that of the mature configuration in normal muscle, resulting in the AChR loss leading to transmission failure; the synaptic gap becomes widened (b). No abnormality is seen in the nerve terminal.

membrane (Fig. 1, antibody-1), and the segment alpha 183–200 as the site recognized by antibodies preventing the ACh-binding to AChR (Fig. 1, antibody-2) [3]. The factors involved in the initiation or induction of autoimmune MG are unknown. However, MG is associated with other immune system abnormalities, particularly in the ►thymus (thymoma or thymic hyperplasia).

### *Clinical Features, Diagnosis and Treatments*

Only the motor system is impaired with the cardinal features of weakness and fatigability in skeletal muscles. Frequently involved are extraocular muscles, neck extensors, facial and bulbar muscles, and proximal limb muscles. When the muscles concerning swallowing and respiration are involved, the intubation for artificial respirator and feeding is emergently required. There is usually a history of fluctuation of symptoms and fatigability (worse with repeated activity, improved by rest). In women, weakness may worsen in relation to the menstrual cycle. Transient weakness of an infant born to a



**Myasthenia Gravis. Figure 3** Muscle action potentials evoked by repetitive nerve stimulation at rates of 1, 10 and 20 Hz. The initial response is normal in size; during repetitive stimulation, muscle responses show an early rundown (1st–4th responses) even with a slow rate such as 1 Hz, followed by a maintained plateau or partial recovery in amplitude. These phenomena are provided by a narrow safety margin of neuromuscular transmission due to the AChR loss caused by myasthenic antibodies.

myasthenic mother may occur in 15%. Approximately 75% of patients have thymic abnormalities including thymoma (15%). The diagnostic test is (i) muscle responses to repetitive peripheral nerve stimulation (Fig. 3), (ii) ►single-fiber electromyography, (iii) edrophonium (anti-cholinesterase) injection, and (iv) anti-AChR antibody radioimmunoassay [4].

Anti-cholinesterase agents (pyridostigmine bromide etc.) are used as symptomatic management. The long-term immune-directed treatment includes immunosuppressive drugs such as corticosteroids, azathioprine, cyclosporine A, tacrolimus and mycophenorate mofetil. In thymoma-associated MG, thymectomy is indicated universally, occasionally followed by postoperative radiation. In non-thymomatous generalized MG, thymectomy is advocated empirically and possibly reduces the long-term exposure to immunosuppressive drugs, but requires up to 2–5 years for demonstrable efficacy; this estimation is based on data from nonrandomized studies, however. The short-term immune-directed treatment to overcome severe myasthenic states such as respiratory crisis includes ►plasmapheresis and intravenous human immunoglobulin; their effect is short-lasting but tends to be prolonged with the concomitant immunosuppressive drugs [5].

## Seronegative (Anti-AChR-Negative) Myasthenia Gravis

### *Pathogenesis: Antibodies to MuSK*

AChR is clustered to effectively receive the ACh-derived information from the nerve through a pathway in which agrin is a critical nerve-derived signal; MuSK is a key component of the postsynaptic agrin receptor, and rapsyn is a cross-linker of AChR [6] (Fig. 1). The z-site spliced isoform of agrin specifically clusters AChR and is, independently of it, required for neuromuscular junctional differentiation. Jointly with the co-receptor (muscle-associated specificity component, MASC), agrin binds to the first of four Ig-like domains

of MuSK [7]. The fourth Ig-like domain of MuSK is required for interaction with rapsyn through the rapsyn-associated transmembrane linker (RATL) [7]. The MuSK intracellular domain (kinase domain) activates AChR phosphorylation but is not sufficient for AChR clustering; the MuSK ectodomain plays a required role for the clustering process, perhaps by helping to recruit neuromuscular junctional components to a MuSK-based scaffold. Although anti-MuSK antibodies (Fig. 1, antibody-3) inhibit agrin-induced clustering of AChR in cultured muscle cells, the pathogenic role of the anti-MuSK IgG antibody is not clear. The non-IgG fraction, probably including the IgM antibody which blocks the sodium channel, from anti-MuSK-positive and anti-MuSK-negative seronegative (anti-AChR-negative) MG patient sera exerts an inhibitory effect on AChR function [8] (Fig. 1, antibody-4). There is the MuSK-independent agrin-rapsin signal transduction pathway including integrins, beta-linked N-acetylgalactosamine, alpha-dystroglycan, neuronal cell adhesion molecule, heparin-binding growth-associated molecule, beta-2 laminins and heparan sulfate proteoglycan [7] (Fig. 1). Also, antibodies raised against the extrajunctional component, which conducts a signal into the sarcoplasmic reticulum [►ryanodine receptor (RyR)], can be found in some of ►myasthenia gravis patients, often those with thymoma [9] (Fig. 1, antibody-5). These suggest a research direction to search for non-AChR, non-MuSK antibodies pathogenic to the disease.

### *Clinical Features, Diagnosis and Treatments*

Forty to 70% of seronegative MG patients are positive for anti-MuSK antibodies and clinically characterized by a relative prevalence of female patients, the age at onset ranging from 3 to 68 years, prevalent involvement of cranial, bulbar and neck muscles, high incidence of respiratory crisis; wasting of facial and bulbar muscles is evident in some patients [10]. Unlike seropositive MG, the ►repetitive nerve stimulation and edrophonium tests are not necessarily diagnostic; the single-fiber electromyography is only reliable for diagnosis [10]. No satisfactory benefit is provided by ►anti-cholinesterase drugs, conventional immunosuppressive therapy and thymectomy [10]; a short-term response to plasmapheresis can be striking [10]. Thymic histology is reportedly normal. However, the clinical features reported by a recent series do not clearly distinguish MuSK antibody-positive from MuSK antibody-negative serotypes.

# Mydriasis

## Definition

Pupillary dilation, particularly when the pupil approaches maximum dimensions.

►Neural Regulation of the Pupil

# Myelencephalon

## Synonyms

►Medulla oblongata

### Definition
The lowest portion of the brainstem. Here in the transition region to the spinal cord are important nuclear regions (olive, pyramid, gracile nucleus, cuneate nucleus), the cranial nerve nuclei of nerves V-XII as well as the centers of respiratory control. Important pathways are the medial lemniscus (somatosensory), lateral lemniscus (auditory) and vestibulospinal tract.

## Myelin

### Definition
CNS myelin consists of many layers of tightly wound membranes formed from the cytoplasmic extensions of oligodendrocytes. Myelin forms regular patches around axons, called the *internode*. The space between the internodes is the *Node of Ranvier*. The size of the internode and the thickness of the myelin sheath depend on the diameter of the axon it is associated with. The main role of myelin is to insulate the axonal membrane and thus speed the rate of conduction of the action potential, which jumps for one node to the next, a process called *saltatory conduction*. Myelin also contains molecules that can inhibit axon growth and regeneration. Myelin is composed of lipids (about 70%) and proteins (about 30%) such as myelin basic proteins, myelin-associated glycoprotein, proteolipid PLP.

►Inhibitory Molecules in Regeneration
►Node of Ranvier
►Schwann Cell

## Myelin Basic Protein

### Definition
Myelin basic protein (MBP) is the second most abundant protein in central nervous system (CNS) myelin, comprising about 30% of the myelin proteins. It is localized to the cytosolic surface of the cell membranes of oligodendrocytes, which are the cells that produce myelin in the CNS. It mediates adhesion to the cytosolic surface of the adjacent oligodendrocyte membrane that results in compaction of the myelin sheath. MBP can undergo a variety of post-translational modifications, such as phosphorylation, methylation, and deimination. Modifications such as phosphorylation and methylation promote the compaction of myelin, protect MBP from proteolysis, and serves to maintain the integrity of myelin. Deimination of MBP on the other hand makes it more susceptible to proteolysis and induces myelin breakdown. MBP therefore plays a crucial role in the formation and maintenance of the myelin sheath, and imbalance in its normal post-translational modification states may lead to myelin pathology and disease.

►Inhibitory Molecules in Regeneration

## Myelin Stain

### Definition
Myelin stains (such as the Weil or Weigert stains) are those that react with the lipoprotein sheath of myelinated axons making them dark.

## Myelin-associated Glycoprotein (MAG)

### Definition
A glycoprotein found on central nervous system (CNS) myelin which inhibits axon growth.

►Regeneration

## Myelinated Axons

### Definition
Axons surrounded by a compact spiraled sheet of Schwann cell plasma membrane are called myelinated axons.

►Schwann Cell

## Myelination

### Definition
Myelination is the process by which glial cells wrap axons with an insulating sheath. This is done by the

oligodendrocyte in the central nervous system, and by the Schwann cell in the peripheral nervous system.

## Myelitis

### Definition

Myelitis is an inflammation of the spinal cord. One group of diseases is named according to whether primarily white matter or gray matter is affected (see leukomyelitis and poliomyelitis); another group is defined by whether there is coexistent disease of the meninges (►meningomyelitis) or the brain (►encephalomyelitis). In practice, the term is also used to denote non-inflammatory lesions of the ►myelin sheath of the spinal cord.

## Myeloencephalitis

### Definition

Inflammation of the spinal cord and brain (also called ►encephalomyelitis).

## Myelomalacia

### Definition

A process of tissue softening within the spinal cord. It may result from a stroke, trauma or a degenerative process.

►Gliomas
►Stroke

## Myelopathy

### Definition

Disease of the spinal cord or the bone marrow.

## Myeloperoxidase

### Definition

It is a peroxidase enzyme, a lysosomal protein stored in the azurophilic granules, abundantly present in neutrophil granulocytes. It is also detected in the macrophages.

## Myenteric Plexus

### Definition

The myenteric plexus is a plexus of small groups of nerve cells (ganglia) and connecting nerve fiber bundles that lies between the longitudinal and circular muscle layers of the gut wall and forms a continuous network from the upper esophagus to the internal anal sphincter.

►Enteric Nervous System

## Myocardium

### Definition

The heart muscle that makes up the walls surrounding the heart ventricles.

►Cardiovascular Mechanics

## Myoclonus

### Definition

Involuntary, abrupt, brief, rapid jerks of limbs or trunk, which may occur spontaneously at rest, in response to sensory stimuli or with voluntary movements. Myoclonus occurs in a variety of generalized metabolic and neurological disorders.

## Myofascial Force Transmission

### Definition

Transmission of force between muscle fibers and surrounding connective tissue fascia.

►Intramuscular Myofascial Force Transmission

## Myofascial Pain

►Muscle Pain, Including Fibromyalgia

## Myofibril

### Definition

Multiprotein complex in striated muscle cells, in which the contractile proteins actin and myosin are organized into a paracrystalline fashion.

►Actin
►Myosin
►Sarcomere Structural Proteins

## Myofibrillogenesis

### Definition

Process of the assembly of myofibrils during embryonic development.

►Myofibril
►Sarcomere Structural Proteins

## Myogenic Musculature

### Definition

Myogenic musculature refers to the spontaneous generation of electrical and contractile activity by the musculature itself, independent of nerves, hormones or other signaling mechansims.

## Myoglobinuria

### Definition

Appearance of myoglobin ($O_2$ carrier in skeletal muscle) in urine, for example in ►mitochondrial myopathies.

## Myopathies

### Definition

Myopathies can be inherited (►Duchenne muscular dystrophy, ►fascioscapulohumeral dystrophy, ►limb-girdle dystrophy, ►myotonic dystrophy) or acquired (►dermatomyositis, ►polymyositis syndrome, ►endocrine myopathies, ►myoglobinurias).

►Dermatomyositis
►Duchenne Muscular Dystrophy
►Facioscapulohumeral Dystrophy
►Limb-girdle Muscular Dystrophy (LGMD)
►Myoglobinuria
►Myotonic Dystrophy
►Polymyositis Syndrome

## Myosin

### Definition

Myosin (sometimes also referred to as the thick filament) is the second contractile protein in muscle. Myosin contains the cross-bridge heads that interact with actin to produce contraction. The cross-bridges are arranged uniformly on the myosin filament, they contain a binding site for actin and an enzymatic site that catalyzes the hydrolysis of ATP, which is needed for muscle contraction.

►Sliding Filament Theory

## Myosin Motor

### Definition

Myosin motor is a protein that acts as a motor to move along a surface, such as microtubules. The energy for such movement comes from the hydrolysis of ATP. A myosin motor often functions in the active transport of proteins and vesicles in the cytoplasm.

## Myositis

### Definition

Myositis means muscle inflammation.

## Myotendinous Force Transmission

### Definition

Transmission of force between muscle fibers and its microtendon, made up of aligned collagen fibers. The site of such a transmission of each fiber is called the myotendinous junction.

►Intramuscular Myofascial Force Transmission

## Myotendinous Junction

### Definition

The specialized region where fingerlike extensions of the sarcolemma at the ends of muscle fibers interdigitate with similar extensions of the connective tissue of the tendon. This is one region for force transmission.

►Skeletal Muscle Architecture

## Myotonia

### Definition

Muscle stiffness, in which muscle relaxation after voluntary contraction is impaired. Myotonic diseases are hereditary muscle diseases falling into two large groups: ►myotonic dystrophies and ►non-dystrophic myotonias.

## Myotonia Congenita

### Definition

►Non-dystrophic Myotonias

## Myotonic Dystrophy

### Definition

Group of hereditary muscle diseases inherited via a dominant mutant gene on chromosome 19. There are three groups: Myotonic dystrophy type 1 (DM-1), proximal myotonic myopathy/myotonic dystrophy type 2 (PROMM/DM-2), and proximal myotonic dystrophy (variant of DM-2). The disease may be so mild as to be nearly asymptomatic or so severe as to appear in early life. In addition to weakness in limb and cranial muscles, characteristic symptoms are ►myotonia, which is a delayed relaxation of muscle after strong voluntary contraction or electrical stimulation, and often cataracts, baldness and testicular atrophy in men.

## $Na^+$ Channels

### Definition

►Sodium Channels

## $Na^+$-$Ca^{2+}$ Exchanger (NCX)

### Definition

A plasma membrane enzyme that exchanges 3 $Na^+$ for 1 $Ca^{2+}$. It can operate in the forward mode (extrusion of $Ca^{2+}$ from the cytosol) or in the reverse mode (uptake of $Ca^{2+}$ into the cytosol).

►Influence of $Ca^{2+}$ Homeostasis on Neurosecretion

## $Na^+K^+$-ATPase

### Definition

The $Na^+K^+$-ATPase transports three $Na^+$ ions out of and two $K^+$ ions into the cell, using the energy of ATP hydrolysis (electrogenic transport). It maintains the high sodium and potassium gradient across the cell membrane. The $Na^+K^+$-ATPase (also called the "cellular sodium pump") is selectively inhibited by cardiac glycosides.

## Naked DNA Vaccination

►Neuroinflammation – DNA Vaccination Against Autoimmune Neuroinflammation

## Naloxone

### Definition

Drug used to antagonize opioid compounds such as morphine. Chemical name = N-allyldihydrohydroxy-normorphinone. Also known by the trade name Narcan.

►Gender/sex Differences in Pain

## NANC Transmitters

### Definition

NANC transmitters are non-adrenergic, non-cholinergic ransmitters; i.e. other than the classical autonomic ransmitters (noradrenaline and acetylcholine).

►Salivary Secretion Control

## Narcolepsy

Daniel A. Cohen
Harvard Medical School; Department of Neurology, Beth Israel Deaconess Medical Center; Division of Sleep Medicine, Brigham and Women's Hospital, Boston, MA, USA

### Synonyms

Gelineau syndrome

### Definition

Narcolepsy is a neurological disorder that interferes with the normal regulation of sleep and wakefulness. It has been conceptualized as a condition of behavioral state instability in which there is a low threshold to transition between waking, rapid eye movement (REM)

sleep, and ►non-rapid eye movement (NREM) sleep [1]. This view accounts for the associated symptoms, including daytime sleepiness, disrupted sleep, automatic behavior cataplexy, sleep paralysis, and hypnogogic hallucinations.

## Characteristics

### Clinical Features

Excessive daytime sleepiness is a prominent complaint and generally the initial reason for seeking medical attention. The feeling of sleepiness is generally higher than normal throughout the day, and there may also be sleep attacks, with an irresistible urge to sleep that arises with very little warning. Semi-purposeful activities may continue during the transition from sleep to wakefulness, a phenomenon known as automatic behavior. Just as sleep may intrude upon wakefulness, nocturnal sleep is often disrupted by excessive awakenings. Increased daytime sleepiness and fragmented nocturnal sleep are symptoms of a variety of sleep disorders and are not specific to narcolepsy. The more specific aspects of narcolepsy relate to the unusual propensity for elements of ►REM sleep to intrude into wakefulness.

Components of REM sleep include: the rich emotional content and perceptual imagery of ►dreams; paralysis of most skeletal muscles; and phasic bursts of muscle activity, including rapid eye movements. These components of REM sleep may be dissociated from each other in narcolepsy and may intrude into wakefulness. Symptoms of REM intrusions during wakefulness include: hypnogogic hallucinations, sleep paralysis, and cataplexy. Hypnogogic hallucinations are hallucinatory experiences that occur at sleep onset. These are vivid perceptual experiences superimposed on the conscious experience of the background environment. There may be a strong emotional context, often a feeling of fear or dread. These symptoms may reflect inappropriate activation of neuronal networks normally activated during REM sleep, including areas that regulate emotional and visual processing [2]. Sleep paralysis reflects the occurrence of REM related muscle atonia that is present upon awakening. This may last seconds to minutes, and it is often a very frightening experience. Patients may try to scream for help, although in the context of muscle atonia there may be little to no actual sound. Tactile stimulation from an outside observer may terminate the episode. Cataplexy is another example of inappropriate REM atonia. It is the most specific clinical symptom of narcolepsy.

Cataplexy is distinguished from sleep paralysis in that the episodes of muscle atonia arise from a background of wakefulness. Strong emotion, particularly laughter, can trigger episodes of cataplexy. The distribution and degree of muscle weakness varies between individuals and may also vary within individual attacks. Episodes may be subtle, such as a change in facial expression or slurred speech, to gross impairment in the ability to retain postural control. Usually there is enough warning to prevent serious falls. The episodes usually last seconds to a couple of minutes, but in rare cases repeated episodes may not allow the return of normal muscle tone for much longer periods, a condition referred to as status cataplecticus. In addition to inappropriate motor inhibition seen in sleep paralysis and cataplexy, patients with narcolepsy may also have excessive motor activity during sleep, including REM sleep without atonia, increased phasic muscle twitches during REM sleep, and increased ►periodic limb movements of sleep [3].

### Prevalence

Narcolepsy is generally divided into cases of narcolepsy with cataplexy and narcolepsy without cataplexy. It is unclear whether these entities represent distinct diseases, or rather a spectrum of phenotypic differences with common underlying mechanisms [4]. The prevalence of narcolepsy with cataplexy is estimated to be roughly 50 per every 100,000, with a slightly higher prevalence of cases without cataplexy. The onset of symptoms is often during the second and third decade, but this can vary greatly.

### Etiology

Recent insight into the pathophysiology of narcolepsy relates to the discovery of the ►hypocretin (►orexin) neuropeptides, a pair of peptides produced in the lateral hypothalamus that play a role in neurotransmission. Canine narcolepsy has been linked to mutations in the gene encoding the hypocretin (orexin) receptor 2 [5]. A mouse model of narcolepsy was developed by targeted disruption (knock out) of the mouse hypocretin (orexin) gene, confirming the role of this peptide system in the control of sleep-wake behavior [6]. In humans, a low cerebrospinal fluid level of hypocretin 1 is a highly sensitive and specific test for narcolepsy with cataplexy [4]. In addition, hypocretin (orexin) staining in the hypothalamus of human narcoleptic patients is decreased by up to 95%, and recent evidence suggests that this reduction in hypocretin (orexin) staining is the result of targeted cell loss of hypocretin neurons rather than decreased hypocretin production [7].

An autoimmune etiology for human narcolepsy has long been suspected. Focal gliosis, essentially a form of scarring in the brain, has been demonstrated in patients with narcolepsy. Gliosis can occur as the result of an inflammatory process, such as occurs with autoimmune diseases, but this finding is non-specific and can occur with a variety of insults to the brain. Speculation about the autoimmune nature of hypocretin cell loss largely comes from a strong association of narcolepsy with cataplexy and specific alleles of the human leukocyte antigen (HLA) presenting system, particularly the allele DQB1*0602. This allele is present in the majority of narcoleptic patients, but it has a low specificity due

to the relatively high frequency of this allele in the general population. Beyond genetic factors, an association of narcolepsy with ►seasonality, with a peak in March births, suggests that early environmental factors may play a role in the pathogenesis of narcolepsy and is consistent with an autoimmune mechanism. Efforts to find specific auto-antibodies in the sera of narcoleptic patients have been mixed, with both positive and negative results. An autoimmune process targeting the destruction of hypocretin (orexin) neurons has been the prevailing hypothesis, but there is recent evidence that circulating antibodies may play a direct functional role in the altered neurotransmission in narcolepsy [8]. The role of the immune system in the pathogenesis of narcolepsy remains to be clarified, and a neurodegenerative mechanism remains a possibility. There are no clear modifiable risk factors for narcolepsy at this point.

## Pathophysiology

The regulation of sleep and wakefulness is a complex process, incorporating factors such as: the phase of the endogenous circadian cycle, recent sleep and wake history, food intake, posture, environmental stresses or demands, and emotional state. These inputs act on a relatively discrete set of brain structures that form the basic circuitry for switching between the waking and sleeping states. There has been tremendous progress in the recent years in the development of models to understand the basic mechanisms of these circuits. The role of hypocretin (orexin) neurons in the sleep-wake circuitry has been particularly instrumental in understanding the clinical features of narcolepsy.

A prominent model for the regulation of sleep and wakefulness centers on the concept of a "flip-flop" switch [9]. A flip-flop switch is a circuit in which two opposing sides are mutually inhibitory. By inhibiting the competing side, activity on one side reinforces its own advantage in controlling the state of the system. Transitions between states tend to occur relatively rapidly. The major structures involved in the sleep-wake switch reside in the ►brainstem and hypothalamus. Structures that promote wakefulness include: ascending projections from serotonergic neurons of the dorsal ►raphe nucleus, the noradrenergic neurons of the locus coeruleus, histaminergic neurons of the tuberomammillary nucleus, cholinergic neurons of the pedunculopontine and lateral dorsal tegmental nuclei, cholinergic neurons of the basal forebrain, and dopaminergic neurons of the ventral tegmentum. Neurons that promote sleep are predominantly found in the ►ventrolateral preoptic nucleus (VLPO) of the hypothalamus and contain the inhibitory neurotransmitters GABA and galanin. Projections from the hypocretin (orexin) neurons of the lateral hypothalamus activate the wake promoting structures, which tends to stabilize the sleep-wake switch in the wake state. Individual nuclei within the pons contribute to the regulation and generation of components of REM sleep. There are ►REM-off and ►REM-on regions, both of which are mutually inhibitory and also act together as a flip-flop switch so that all components of REM tend to switch on or off with very little transitional states [10]. Hypocretin (orexin) neurons activate the REM-off cell groups. Therefore, the lack of a functional hypocretin (orexin) system in narcolepsy may destabilize both the sleep-wake switch as well as the REM on-off switch, causing relatively frequent transitions between sleep and waking states and inappropriate activation of components of REM sleep.

## Diagnosis

The diagnosis of narcolepsy is generally considered in the evaluation of a patient with excessive sleepiness. Occasionally the diagnosis is considered for symptoms of inappropriate REM fragments during wakefulness, such as isolated episodes of sleep paralysis. However, this can occur in healthy individuals or those who tend to wake during REM sleep such as patients with sleep disordered breathing. Cataplexy is specific to narcolepsy and rarely can be the presenting symptom before the onset of significant daytime sleepiness. Careful clinical history can usually distinguish between the paroxysmal loss of muscle tone in cataplexy and other conditions of transient neurological dysfunction or spells from conditions such as: seizure, syncope, cerebrovascular disease, periodic paralysis, myasthenia, or hyperventilation.

Excessive sleepiness may occur from: processes that disrupt sleep such as ►obstructive sleep apnea, ►periodic limb movement disorder, mood disorders, pain syndromes, and noisy or uncomfortable bed environments; ►chronic insufficient sleep syndrome; medical conditions such as thyroid dysfunction; medication side effects; central nervous system causes such as narcolepsy, ►idiopathic hypersomnia, or ►recurrent hypersomnia. It is not possible to distinguish the etiology based on the degree of sleepiness, since a sudden and irresistible urge to sleep may occur from many causes besides narcolepsy.

A diagnosis of narcolepsy with cataplexy can be made by history and does not necessarily require confirmatory testing. Overnight ►polysomnogram is helpful to search for co-morbid, treatable causes of sleep fragmentation and daytime sleepiness. In order to diagnose narcolepsy without cataplexy, it is necessary to perform the ►multiple sleep latency test (MSLT), which is a daytime napping test. This test is also generally recommended to confirm a diagnosis of narcolepsy even when there is definite cataplexy, but it is less essential when the history of cataplexy is clear. Generally, patients are given five nap opportunities during the daytime, each 20 min in duration and spaced at 2 h intervals. The average time to fall asleep across all naps is roughly 3 min for patients with narcolepsy,

whereas it is greater than 10 min for healthy individuals. To minimize both false positive and false negative tests, a cutoff of 8 min or less has been suggested to document pathological sleepiness. In addition to pathological sleepiness, which is not specific to narcolepsy, the presence of REM sleep during at least two of the naps (►sleep onset REM periods) is required for a diagnosis of narcolepsy. The specificity of this finding for narcolepsy is greater than 90%. The MSLT requires that patients are off REM suppressing medications for at least 15 days for valid interpretation of REM periods during naps, which may be difficult in patients that require stimulant medications to function. Treatment of co-morbid disorders such as sleep disordered breathing is also necessary for accurate interpretation of the MSLT. In patients with questionable cataplexy, particularly those who have the HLA DQB1*0602 allele, CSF testing for hypocretin-1 levels can be done instead of the MSLT. Hypocretin-1 levels that are <110 pg/ml support the diagnosis of narcolepsy. Low CSF hypocretin levels have a specificity of 99% and a sensitivity of 87% in narcolepsy with cataplexy [4]. The sensitivity of this test in narcolepsy without cataplexy is very low.

### Treatment

It is conceivable that therapy targeting the deficient hypocretin system will eventually play a fundamental role in the management of narcolepsy, particularly in patients with cataplexy. However, current treatment options are intended to promote daytime alertness as well as suppress the tendency for inappropriate activation of REM fragments during wakefulness. Stimulant medications such as modafinil, methylphenidate, D-amphetamine, or caffeine are generally used to promote daytime alertness. Medications that increase levels of noreprinephrine or serotonin, such as many antidepressants, tend to activate REM-off cells and minimize REM intrusions into wakefulness such as cataplexy [10]. Sodium oxybate (gamma hydroxybutyrate), taken before sleep and a second dose during the sleep period, has recently been demonstrated to minimize both cataplexy and daytime sleepiness in patients with narcolepsy. Non-pharmacological interventions include: scheduled naps, which narcoleptic patients usually find very refreshing; psychosocial support and counseling to minimize the functional disability from this chronic disorder; and treatment of co-morbid sleep disorders such as sleep disordered breathing.

## Nasal Airflow

### Definition

Nasal airflow is the mechanism by which odorant molecules are delivered to the olfactory receptors although the movement of air through the nose serves important functions beyond odor identification. Nasal airflow allows inspired air to be brought to the temperature and humidity of the lungs and particles ranging from combustion products to airborne bacteria to be trapped in the mucus and removed. In very dry environments nasal airflow also allows water vapor in expired air to be trapped in the mucus and saved.

►Nasal Passageways

## Nasal Passageways

David E. Hornung
Dana Professor of Biology, St. Lawrence University, Canton, NY, USA

### Synonyms

Nasal airflow; Inspiration; Breathing cycle

### Definition

In mammals, the nasal passageways provide the channel through which odorant molecules are delivered to the

airspace above the olfactory receptors thereby allowing the animals to detect and respond to chemical signals in the inspired air [1]. According to some investigators, the structure of the nose itself may even be directly responsible for one of the mechanisms contributing to odor discrimination [2,3,4]. The internal structure of the nose allows air from the outside to be brought to the temperature and humidity of the lungs. It also facilitates a trapping of particles in the inspired air in the nasal mucus thus protecting the lungs from many airborne insults. In very dry environments the structure of the nose allows water vapor in expired air to be trapped in the mucus and saved [5].

## Characteristics

From an evolutionary point of view, the nasal passageways begin as simple blind sacs and at their pinnacle become multi-functional, anatomically complex structures. The earliest stage of evolution of nasal passageways is exemplified in elasmobranches (some sharks for example) where the olfactory organs are paired, blind nasal sacs located well anteriorly on the head. The openings of these blind sacs are the external nares which in some sharks are divided into two sections allowing for the inflow and outflow of sea water. Chemoreception through the first cranial nerve (olfaction) in these animals is accomplished as receptors sample the contents of the water trapped in these blind sacs. In animals slightly higher up on the phylogenic tree, the nasal sacs are connected to the mouth through internal nares. This anatomical development makes olfaction more dynamic by permitting water to flow from the external naris, by the olfactory receptors and into the mouth via the internal naris [2,3].

In air breathing animals the internal naris and accompanying connection to the mouth assumes a major role is respiration. For example, as tadpoles undergo the process of metamorphosis into frogs, the connection between the nasal cavity and the mouth is the pathway by which air enters the lungs from outside the animal. In air breathing animals, it is necessary in the mouth to separate the food destined for the stomach from the air heading toward the lungs. As a result olfaction becomes ancillary both to feeding and respiration.

## Structure

In air breathing vertebrates the structure of the nasal ►nasal airflow passageways can be as simple as the tube located between the external to internal nares as is observed in some salamanders. In these animals, the incoming air follows a straight path through the nasal air passageways (and by the olfactory receptors) on its way to the lungs. In frogs the nasal airflow patterns are slightly more complex as incoming air is deflected by a baffle plate called the eminentia which is located on the floor of the main nasal cavity [2].

In mammals the surface area of the nasal air passageway is greatly expanded through the elaboration of scrolls of bone (turbinals) from the lateral wall of the nasal chamber. In some species, these scrolls produce a very complex nasal labyrinth as is observed in animals like rodents and canines. In general the greater the complexity of the nasal air passageways the better the animal will be at detecting and identifying low concentrations of airborne odorants. The turbinates are also important in reducing water loss from expired air associated with the high ventilation rate that accompanies the maintenance of a constant internal body temperature [5]. The volume of the nasal cavity has been estimated to be 0.4 $cm^3$ in rats, 20 $cm^3$ in beagle dogs and 25 $cm^3$ in humans.

In most mammals the left and right nasal passageways are anatomically distinct structures separated by a bony plate called the nasal septum. As a result, the inspired air flowing through the left and right nostrils does not mix until it gets to the nasopharynx located in the back of the throat. In rodents, however, there is an incomplete nasal septum which allows some of the air flowing through the nostrils to mix just downstream from the olfactory receptor area.

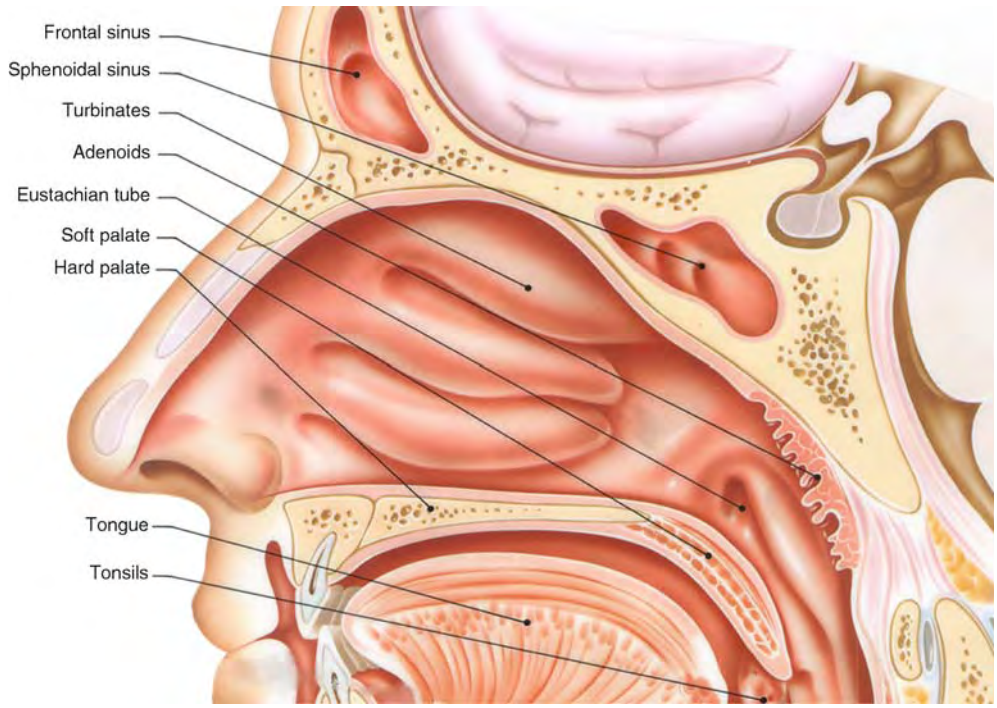
In primates, the nasal air passageways are much less complicated that what is found in rodents or canines. In humans the internal anatomy of the nose is defined on the lateral side by the inferior, middle and superior turbinates (Figs. 1 and 2) [2]. The respiratory and olfactory epithelial cells lining the inner surface of the nasal cavity are bathed in mucus which is secreted by the goblet cells interspersed in the respiratory epithelium and Bowman's Glands found in the olfactory receptor cell area. The mucus located at the air/epithelium border is watery and it is continually flowing into the back of the throat by the beating of the cilia of the respiratory epithelial cells.

## Blood Supply

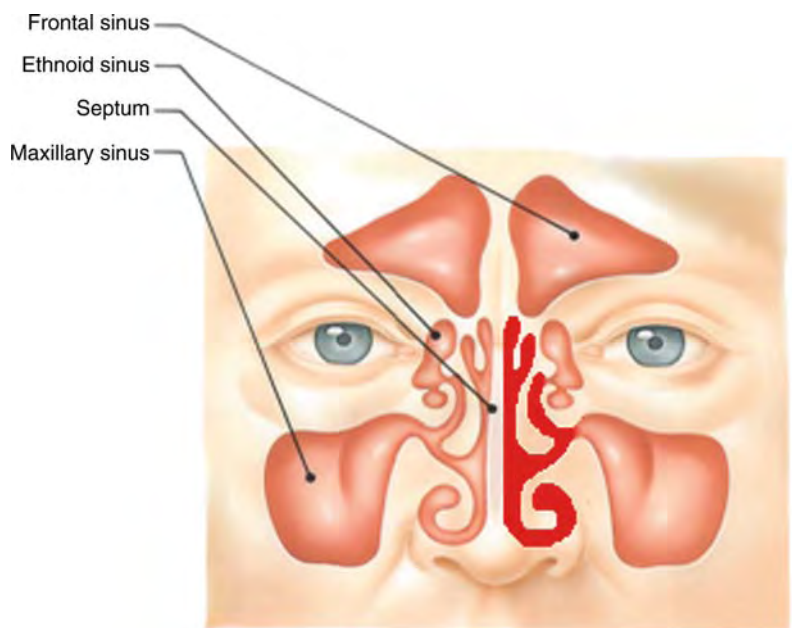
The nasal mucosa has a very rich blood supply. As a result, the size of the airspace defined by the turbinates can be changed quickly and dramatically by changing the amount of blood flow to the dense capillary beds servicing the nasal epithelium. In this regard the lining of the nose is similar to other better know human erectile tissue. The extensive bleeding sometimes seen following nasal trauma reflects this extensive capillary bed. Additionally, the semi-erectile nature of the nose partially accounts for the nosebleeds that are occasionally observed after a sexual organism.

## Nasal Cycle

A pattern has been observed in the nose where congestion on one side of the nose is accompanied by decongestion on the other. This pattern is called the nasal cycle and has been observed in over 50% of the adult human population. The periodicity of the cycle is between



**Nasal Passageways. Figure 1** A cut away view of the human head. The inferior, middle and superior turbinates are in order located above the hard palate. The olfactory area is around the superior turbinate (marked "turbinates"; from Merrell Dow Company).



**Nasal Passageways. Figure 2** A cross-sectional view of the airspaces in the human nose. The lighter area represents bone and other nasal structures. The nasal air passageways have been darkened on the subject's left side.

50 min and 7 h. There has even been a correlation reported between handedness and the nostril that is open for a larger percent of a 24 h period, such that left handed individuals are more likely to have a more open left nostril and visa versa for right handers. Regardless of the more open nostril, the internal structure of the nose produce convoluted (sometimes turbulent) flow paths for the inspired air. The high airflow seen during sniffing may

increase the amount of turbulence and so may improve the sensitivity to smells [1,2].

### Role in Odor Identification

The olfactory receptors in humans are located high in the nose along the septum and on the medial side of the superior turbinate. Because of their location, and because the airspaces defined by the middle and inferior turbinates are relatively much larger that those leading up to the olfactory receptor region, during a ▶sniff only about 10% of the inspired air is directed toward the airspace above the olfactory receptors.

The structure of the nose may play a role in odorant identification as incoming odorant molecules interact with the nasal epithelium as they are directed toward the airspace above the olfactory receptors. The physical and chemical properties of these interactions depend on the natures of the odorants themselves [1,3,4]. For example, for an odorant that is very soluble in the respiratory mucosa, many of the incoming odorant molecules would be expected to be sorbed early in the flow path. As a result, it will take longer for these molecules to get to the receptors as compared to molecules of odorants that were not very mucosa soluble. In addition, there will be a spatial distribution pattern across the receptor sheet itself with most of the mucosal soluble odorant molecules being concentrated early in the flow path as compared to a more even mucosal distribution pattern that would be seen for less mucosa soluble odorants. It has been hypothesized these different arrival times and olfactory mucosal distribution patterns may play some role in odorant identification. These distribution patterns have been called "imposed" patterns. Although imposed patterns may play a role in olfactory function, the fine tuning and spatial distribution of receptors within the olfactory receptor area (inherent patterns) are thought by most investigators to be the primary peripheral mechanism for odorant detection and identification.

### Non-Olfactory Functions – Nasal Air Conditioning

The non-olfactory nasal functions of the nasal cavity are together referred to as nasal air conditioning [5]. Some evolutionary biologists suggest the primary selective pressure on nasal structures comes from these non-olfactory functions. During the process of nasal air conditioning, the inspired air is brought to the temperature and humidity of the lungs. In addition, a filtration process occurs in which particles ranging from combustion products to airborne bacteria that are found in the inspired air are trapped in the mucus and removed as the mucus is carried to the back of the throat.

### Swell Space

Because of the speed and magnitude of the diameter change that can occur in the area around the inferior turbinate, this area of the nose is sometimes referred to as the "swell space." As cold air enters the nose during inspiration the blood flow to the swell spaces increases dramatically. This increased blood flow causes a swelling of the nasal erectile tissue and so reduces the size of the airspace the incoming air must traverse on its way through the nose. Because the air passageways are now narrower, heat can be more efficiently transferred from the respiratory and olfactory mucosas to the incoming air. As a result, the cold air is effectively warmed before it gets to the back of the throat and the lungs [5].

### Humidification

When warmer air (especially if it is also humidified) enters the body the reverse happens and the swell spaces shrink, resulting in a more open nasal air passageways. This temperature and humidity related widening of the nasal cavity explains why, when the nose is blocked because of an upper respiratory infection, breathing warmed, humidified air can sometimes reduce the felling of stuffiness.

Because the nasal mucus has such a high water content, it is able to humidify the incoming air such that when the inspired air has a low humidity, water evaporates from the mucus into the air. As a result of the evaporation from the mucus to the inspired air, the surface of the mucosa is cooled, so that when it is time to discharge the air from the lungs the expired air passes over the cooled surface of the mucosa. Because of the lower surface temperature along the mucosa, some of the water in the expired air condenses and so it is not lost. This process is not very efficient in humans since the air passageways are not very convoluted [5]. However, this process can be very efficient in animals with narrower and more convoluted air passageways. For example, this process is so efficient that animals like the Kangaroo Rats of Australia loose no water during breathing even with ambient temperatures in excess of 50°C.

### Particle Trapping

In addition to supplying water for humidification purposes, the nasal mucus serves as a trap for particulate matter including smoke, dust particles and airborne bacteria. The respiratory epithelium lining the nasal passageways contain cilia, hair-like protrusions extending into the overlying mucus layer. As these cilia beat, they create a slow wave-like action in the mucus that is responsible for moving the mucus through the nose and to the nasopharynx, where the mucus is then swallowed. The trapped particles flowing with the mucus are more easily dealt with by the alimentary canal than they would be by the blind sacs in the alveoli of the lungs. The mucus likely even contains some white blood cells to deal with trapped airborne bacteria. Cigarette smoke, with contains high levels of carbon dioxide, can temporarily anesthetize the beating of respiratory cilia, thereby slowing the flow of mucus. This would be expected to make it more difficult for the nose to clear trapped particles and may even contribute to the "smoker's cough."

# Naturalism

## Definition

In the philosophy of mind naturalism is usually thought of as the view that, at a minimum, philosophical theories should be consistent with our scientific picture of the world. A stronger view, which is also sometimes called naturalism, is the view that philosophical investigation really has no place in our understanding of the world, that philosophers, rather than devising theories of their own, should defer to the scientists.

Finally, naturalism is sometimes thought of the view that philosophical investigation should itself be a sort of scientific investigation.

## Nausea Syndrome

### Definition

Syndrome characterized by epigastric awareness and discomfort, nausea and vomiting.

## Nauta Technique

### Definition

The Nauta technique is a reduced silver impregnation method for the staining of degenerating axons. It was used to trace the connections of a particular part of the brain by damaging that part and then describing the position and course of degenerating axons. Modifications of the basic Nauta technique have been developed to localize degenerating axons near axon terminals to characterize where the axons of neurons in the damaged area terminate.

## Navigation

### Definition

Navigation is the process of calculating and executing routes. Animals use navigation to optimize the collection of spatially dispersed resources, to find safety or to interact with individuals. In simple forms of navigation the animal moves towards or away from the goal location which is also to source of beacon signals.

For example, it an animal wants to interact with another, the simplest mechanism to approach the second animal using sensory cues emanating from the second animal.

In many cases navigation is inferential. The animal uses stationary environmental cues – landmarks – to estimate the location of the goal. Landmarks can serve as beacons, where the animal moves in the direction of the landmark to approach the goal, or part of a group, where the animal uses the configuration of landmarks to estimate the location of the goal. When animals compute navigation routes using the relationship among landmarks, the process is considered "mapbased".

Path integration or dead reckoning may be used to return from the current position to the starting position. Path integration requires knowledge of the starting position and direction and the estimation of the current position and direction from the path traveled. It may rely on optic flow and/or internally available information without the use of external landmarks (e.g., in darkness or in visually unstructured environments), which capacity is shown by animals as simple as ants and bees. This in turn requires the continuous monitoring of the intermittent self-generated movements. Location and direction in space are represented by distinct neuronal populations, place cells and head-direction cells.

## NCF

### Definition

Nucleus cuneiformis.

## Near Response

### Definition

Convergence, accommodation of the lens and constriction of the pupil (also called triple response or near reaction).

►Eye Movements Field

## Near Response Neurons

Lawrence Mays
University of North Carolina at Charlotte, Charlotte, NC, USA

### Synonyms

Vergence neurons; Convergence neurons

### Definitions

Ocular convergence (►Convergent eye movement) refers to the nasalward movement (►Ocular adduction) of the eyes required to binocularly view a nearer visual

target. Divergence (►Divergent eye movement) is the opposite movement (►Ocular abduction) of the eyes as gaze is shifted from a near to a far object. These ►vergence (►disparity dependent vergence, ►radial flow dependent vergence) movements are accomplished by the coordinated actions of the medial and ►lateral rectus extraocular muscles. Convergence requires contraction of the ►medial rectus and relaxation of the lateral rectus muscles, while the opposite occurs for divergence. Vergence eye movement may be initiated by the need to reduce binocular disparity, which is the difference between locations of an image of a single target on the two retinas. Convergence of the eyes is accompanied by lens accommodation (►Accommodation of the lens), which is an increase in the refractive power of the crystalline lens needed to focus on the near object.

## Characteristics

### Higher Order Structures

Single binocular vision requires very precise (≈0.25°) alignment of the two eyes on the object of regard if ►diplopia, or double vision, is to be avoided. Processing of this error signal, which is termed binocular disparity, takes place initially in the primary visual cortex [1]. The mechanism by which binocular disparity is transformed into a motor command signal to converge or diverge the eyes is not known, but such a motor command is seen on midbrain neurons termed near response cells.

### Parts of this Structure

The location of midbrain near response cells (including convergence cells) has been identified in macaques, but not yet in humans. They are located in two areas within the midbrain; a peri-oculomotor area, just dorsal and lateral to the oculomotor nucleus and a second area in the ►pretectum [2]. The properties of the neurons in these two zones appear to be similar.

### Functions of this Structure

The function of near response cells is to provide the downstream motor elements with appropriate signals to generate vergence eye movements and associated changes in lens accommodation. Considering vergence movements first, the ►extraocular motoneurons encode signals to move the eye by means of a position-rate code and an eye velocity code [3]. The commands for all eye movements include these two elements. Extraocular motoneurons fire at a remarkably (≈5% variation) constant rate for a given eye position, and this rate increases linearly as the eye moves in the motoneuron's on-position. This activity is needed to overcome the elastic restoring forces operating on the oculomotor plant (the mechanical properties of the eye and associated muscles, tendons, and ligaments). In addition, a phasic burst of neural activity by the motoneurons, proportional to eye velocity, overcomes the viscous drag of the oculomotor plant. Medial rectus motoneurons receive inputs related to conjugate eye movements (e.g. ►saccades, smooth pursuit) via the ►medial longitudinal fasciculus (MLF), but this is not the source for vergence commands [4]. Instead, vergence signals are likely due to projections from near response cells in the peri-oculomotor region. Many of these near response cells have tonic firing rates directly proportional to vergence angle and so were termed "convergence cells". A subset has been shown to project to the medial rectus subdivisions of the oculomotor nucleus [5]. Some convergence cells have a position signal and no velocity signal, some show both, and others appear to have a signal related to vergence velocity but not position. Near response cells do not have conjugate eye movement signals. The firing pattern of a convergence cell for convergence is shown in Fig. 1. This activity pattern corresponds to that needed by the medial rectus motoneurons to execute vergence eye movements. In addition to near response cells which increase their activity for convergence, about 25% of near response cells show a linear decrease in activity for convergence, and an increase for divergence. These are termed "divergence cells" [2]. Some of these cells have a divergence velocity signal (divergence burst) alone, or in addition to the divergence position signal. Although no direct projection to the abducens nucleus has been shown, divergence cells have a firing pattern which is appropriate for abducens neurons.

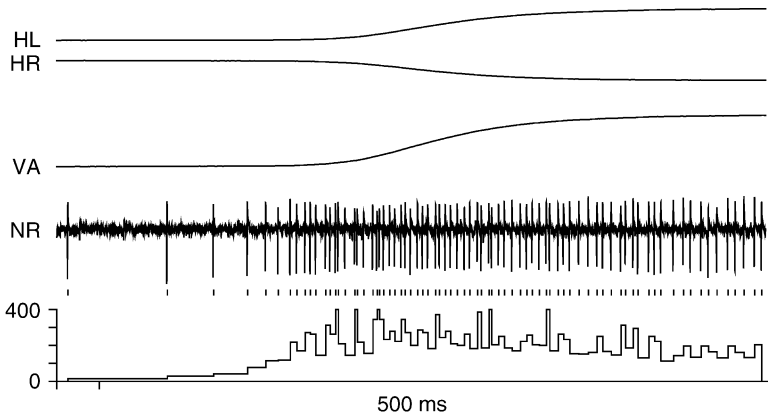
In addition to the signal related to vergence, most ►near response neurons also carry a signal related to lens accommodation. Although it has not been conclusively demonstrated, it is likely that some near response cells provide an input to the Edinger-Westphal nucleus, which in turn provides an input to the ciliary ganglion to effect lens accommodation.

### Higher Order Function

Ocular convergence is associated with lens accommodation (see ►Accommodation-vergence interaction) and it is very likely that near response cells are critical elements in this interaction. The model for this interaction is described in the Accommodation-vergence interaction entry, and the role of near response cells in this interaction is described in the following section.

### Quantitative Measure for this Structure

With disparity open loop (e.g. one eye occluded), lens accommodation drives convergence, and convergence cells increase their firing rate. Similarly, with accommodation open loop, convergence drives lens accommodation, and convergence cells also increase their firing rate. In order to quantitatively assess the roles of near response cells in the accommodation-vergence interaction, it is necessary to dissociate accommodation



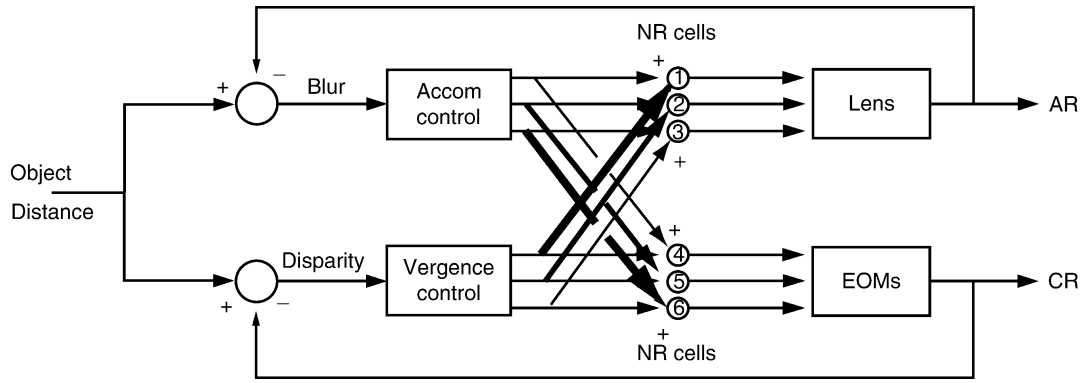
**Near Response Neurons. Figure 1** Firing pattern of midbrain near response cell for convergence. Traces are *HL*, horizontal left eye position; *HR*, horizontal right eye position; *VA*, vergence angle (HL-HR); *NR*, extracellular recording of action potentials of near response cell. The histogram at bottom is the firing rate in spikes/s (scale = 400 spikes/s). The time base is 500 ms. This cell shows a linear increase in activity for convergence as well as a small vergence velocity signal.

and vergence in the closed loop condition. This can be accomplished, at least partially, by requiring the subject to maintain clear focus on a target while forcing the eyes to converge, or alternatively, by requiring a constant vergence angle while changing the accommodative response by means of lenses. To the extent to which the accommodative and vergence responses can be dissociated, it is possible to characterize near response cells by the following equation:

$$\Delta FR = R_0 + k_y \times \Delta CR + k_a \times \Delta AR$$

where FR is the firing rate of the cell, $R_0$ is the firing rate for zero accommodation and convergence, CR is the convergence response, AR is the accommodative response, and $k_v$ and $k_a$ are the coefficients describing the influence of vergence and accommodation, respectively. If a near response cell has a zero $k_a$ value and a non-zero $k_v$ value, then its activity is related exclusively to vergence; if the $k_v$ value is zero and the $k_a$ value is non-zero, then it is related exclusively to accommodation. An analysis of a relatively large number of convergence cells showed that most were not related to accommodation or vergence exclusively, but were related to both (i.e. had a non-zero $k_a$ value and a non-zero $k_v$ value) [5]. Indeed, some near response cells which increased their activity for convergence and accommodation (convergence cells) decreased their activity for convergence when accommodation was held constant (i.e. had a negative $k_v$ value) and *vice versa*. The mechanism for this pattern of results is shown in Fig. 2.

Figure 2 is a representation of the dual-interaction model of accommodation and vergence. Both the accommodative and vergence systems are controlled by negative feedback, and they are cross-linked by the diagonal connections. The near response cells (labeled 1–6) are presumed to be in both systems. Consider the situation in which a subject is required to keep the accommodative response constant while increasing the convergence response. This action will increase the output of the vergence controller (required for more convergence), but it will also increase the cross-link drive to the accommodative system, which is not needed. The accommodation controller will then produce a negative output to counteract this unwanted drive, if accommodation is to remain constant. However, this negative accommodation drive will be sent to the vergence system through the accommodative vergence link, and so will require an increased output from the vergence system to counter it. As long as the cross-link gains are not too high, the system will stabilize at a point at which the increased output of the vergence controller will be great enough to produce the required convergence response and counteract the accommodative vergence cross-link input. In addition, the negative output of the accommodative controller will cancel the input from the convergence accommodation cross-link. Consider near response cell 5, which receives a cross-link input that is equivalent to the average for the accommodative vergence cross-link. For this cell, the negative cross-link input exactly cancels the extra output that the vergence system supplies to deal with the conflicting viewing cues. In this case, the activity of this cell is always associated with the convergence response and is independent of the accommodative response. This cell will have a positive vergence gain ($k_v$) and a zero accommodative gain ($k_a$). Consider near response cell 4, which receives a relatively weak cross-link input from the accommodative controller. In the conflict viewing situation described above, this cell's activity will be



**Near Response Neurons. Figure 2** Putative role of near response cells in dual-interaction model of accommodation-vergence interaction. Abbreviations are: *AR*, accommodative response; *CR*, convergence response; *EOMs*, extraocular muscles. The accommodation (top half of figure) and vergence systems (lower half) are controlled by negative feedback mechanisms responding to the distance of the object of regard (object distance). In addition, the accommodative controller provides an input to the vergence system (downward angled cross-link arrows), and the vergence controller also drives the accommodative system (upward angled cross-link arrows). Near response cells (1–6) are thought to be elements in this linkage.

driven primarily by the output of the vergence controller, and thus will fire at a higher rate for a given convergence response when the accommodative response is restrained. Since reinstating the accommodative response would cause this cell to fire at a lower rate, the accommodative gain ($k_a$) must be characterized as negative, even though the cell's vergence gain ($k_v$) is positive. Similarly, near response cell 3 would have a positive $k_a$ and a negative $k_v$, while near response cells 1 and 6 would have positive (non-zero) $k_a$ and $k_v$ values. In this way, small differences in the relative gains of the cross-link and direct inputs to near response cells allow the activity of these cells to be related to both accommodation and vergence. The overall pattern of accommodation and vergence gains of near response cells strongly implies that they are involved in the linkage between accommodation and vergence, but this has not yet been confirmed by more direct physiological or anatomical evidence.

# Nearfield

## Definition

The area surrounding an acoustic or hydrodynamic source wherein source energy is dominated by inertial rather than viscous forces. In the nearfield, bulk movements of the medium, (hydrodynamic flow) is of much greater energy than the elastic motions of the medium that make up the propagating pressure wave (i.e., sound in common parlance). The spatial extent of the nearfield depends upon the density of the medium and the frequency of the sound source. The majority of biological relevant sound sources in water have extensive (several meters or more) nearfields, and most fish hearing occurs within the nearfield.

►Evolution of Mechanosensory and Electrosensory Lateral Line Systems

# Necessity

## Definition

Some statements are not only true but necessarily true (see truth). The fact that they state cannot possibly be otherwise. Consider the necessary "My mother is a woman" versus the non-necessary (i.e. accidental or contingent) "I have a brother." There are, however, different kinds of necessity: a logical necessity, like

"It is raining or it is not raining," has its source in the rules of logic; a conceptual necessity, like "Bachelors are unmarried men," is true in virtue of the meanings of the words of the statement; a metaphysical necessity, like "Water is H2O," is said to be necessarily true because it is the essence of water to be H2O. Nomological necessity, finally, is grounded in the laws of nature:

"Increased heat at constant volume necessitates (or causes) higher pressure" (see also reasoning – a priori).

►Meaning

## Necessity, Conceptual

### Definition

A statement that cannot turn out to be false, no matter what in fact is said to be necessarily true (opposite: contingently true; see truth). If this necessity has its source in the meaning of the words used in the statement one speaks of conceptual necessity (or analyticity). Examples: "All bachelors are unmarried" or "If an object is red then it has a color." Denials of conceptually necessary truths are baffling if not meaningless: "My car is red but it does not have a color".

►Analyticity
►Meaning
►Necessity, Nomological

## Necessity, Nomological

### Definition

Scientists and philosophers who do not think that laws of nature are mere summaries or descriptions of the regular events happening in our world claim that the laws bring about or necessitate those events. If it is a law that every C event (or property instantiation) is followed by an E event (or property instantiation), then C nomologically necessitates E. In other words, if C then, according to the law, it must be the case that E. The relation of nomological necessity between events or properties is often thought to be identical to the causation relation (or, at least, a derivative thereof).

Compare nomological to conceptual necessity, which is supposed to be a property of sentences or statements rather than a relation between events or properties.

►Meaning

## Nef

### Definition

This protein is released by HIV and found to be associated with HIV pathogenesis. It is known to perform an important role in HIV associated neurological disorders and viral replication.

►Central Nervous System Disease – Natural Neuroprotective Agents as Therapeutics

## Negative Feedback Control

### Definition

A mechanism used to regulate the value or time course of an output variable or signal when the output variable is determined by the value of an input signal or the time course of an input signal. The control mechanism is said to be closed loop when the value of the output variable is sensed or measured, is fed back and compared to some desired reference value and is then used to determine the value of the input signal. The closed loop control mechanism is referred to as negative feedback control when a given change in the output variable is compensated for by changing the input signal to produce an opposite change in the output. Negative feedback control is associated with homeostasis and regulatory processes, but a system regulated by negative feedback control can become unstable.

## Definition

Connections between neurons within and between cerebro-cortical areas.

## Characteristics

### Cortical Architecture and Processing

Every thought, every idea, every memory, every decision, and every action we have to make, arise from the activity of neurons in our brains. The results of some of this activity surround us: household objects, books, technology and art. Of all brain structures, the ►neocortex, which forms over 80% of the volume of the human brain is, arguably, the most critical to what makes us human. This is a paradox, because the basic local architecture of the neocortex in all mammals, from mouse to man, appears to be very similar and is determined by the laminar distribution of relatively few types of excitatory and inhibitory neurons organized according to common principles of connectivity. These local circuits are organized in a framework of a six-layered columnar architecture, in which neurons with functional properties in common lie in discrete layers and in vertical slabs or columns [1] (►Striate cortex functions).

The uniformity of its construction suggests that the neocortex provides circuits that are optimized for a class of cortical "algorithm" that can be implemented for the full range of demands of behavior, including perception, cognition, and action. A number of models indicate the forms of general computation that could be carried out in a uniform cortical architecture. Typically these models address a single principle of operation in a small group of neurons; in others a more detailed model is imposed on the columnar architecture of cortex. Experimental results in alert behaving primates and together with theoretical studies, suggest that cognitive operations proceed very rapidly across different cortical areas (►Cerebro-cortical areas; ►Extrastriate visual cortex) by feedforward categorization and feedback modulation, with slower refinement by lateral local interactions. Specification of local and long-distance connections in the cortex will go some way to explaining the implementation of these processes.

### Structural Specification of Cortical Connectivity: Integration of Intra- and Inter-Areal Connectivity

What is so special about the circuits of the neocortex? What makes them so efficient and so adaptable to different tasks? A major contribution to our understanding of the structure of the cortical circuit came with the model of a "canonical cortical microcircuit" [1]. This circuit expresses the functional relationships between the excitatory and inhibitory neurons in the different cortical layers and shows how the inputs to a local region of cortex from the sensory periphery via the ►thalamus, or from other cortical areas, are integrated by the cortical circuits. The most critical feature of the canonical circuit is that the neurons are connected in a series of nested positive and negative feedback loops called "recurrent circuits." Because the

excitatory and inhibitory neurons are interconnected, excitation and inhibition remain in balance and so the positive feedback does not overexcite the circuit. This organization explains how it is that the relatively tiny numbers of neurons that provide the external inputs to this circuit are nevertheless effective, as they are amplified selectively by recurrent excitatory circuits [1]. Explorations of this model in the visual cortex (►Visual cortex – neurons and local circuits), e.g. [2] have shown how this key notion of recurrent amplification explains the emergence of cortical properties, such as direction sensitivity and velocity sensitivity, orientation selectivity (►Striate cortex functions), masking, and ►contrast adaptation.

The canonical model provides for a richer array of behaviors than the simple feedforward models that preceded it, and is readily applied across the cortex. For example, it is clear that the interlaminar connections have characteristic patterns across cortical areas and across species and thus may perform a generic computation [3]. What has been lacking until very recently is a quantitative model of the vertical (interlaminar) circuits. However, the studies by Binzegger et al. now clearly indicate that, in general, the contribution of the spiny neurons to interlaminar connections exceeds that of their intralaminar connections [4]. Hence, in the infragranular layers (layers 5 and 6), the majority of ►pyramidal cells connect outside their layer of origin. Layer 4 spiny neurons do connect within layer 4 (the "granular" layer), but their major projection is to layer 3. It is only in the supragranular layers (layer 1, 2 and 3) that the pyramidal cells make the majority of their synaptic connections to the same layer. The consequence of this is that the monosynaptic recurrent connectivity of layer 2 and 3 pyramidal cells predominates more than recurrent connectivity in any other layer. The recurrent connectivity of layers 2/3 is intriguing in that the local axons of the pyramidal cells are not uniformly distributed, but form patches or clusters. This pattern of patchy connections, referred to as "lattice connections" by Rockland are embedded within inter-areal feedforward and feedback connections [5]. Because of its appearance when viewed from the surface of the cortex we refer to the local horizontal network formed by a small cluster of pyramidal neurons as a "Daisy" In the neocortex many pyramidal neurons serve a dual function: all of them form the major excitatory neurons in the local cortical circuit, but many of them also project outside their own cortical area to other cortical areas or subcortical structures. Thus many of the same neurons that form a Daisy could also project to other cortical areas.

## Inter-Areal Projections

The inter-areal connections come in three flavors: feedforward, feedback, and lateral connections [5,6] (►Visual cortex – neurons and local circuits). Feedforward connections originate principally from the supragranular layers, target layer 4 and connect lower to higher visual areas (►Extrastriate visual cortex) in a sequence tending to show increases in ►receptive field (Visual cortical and subcortical receptive fields) size and response latency. Feedback connections originate from principally infragranular layers, and connect higher to lower visual areas in a sequence suggesting decreases in receptive field size and response latency. It has been suggested that feedforward neurons have a "driving" and feedback neurons a "modulatory" influence. This is why the feedforward and feedback pyramidal cells located in the supragranular layers could also participate in the local Daisy circuits. The feedback neurons located in the infragranular layers likewise may participate in the local Daisy circuit via the local vertical connections with the supragranular layer pyramidal cells [3]. The infragranular feedback neurons probably provide an input to the Daisy, because one of the principal targets of the feedback projections are the supragranular layers (particularly layer 1).

Thus far, most of our knowledge concerning the local horizontal network is derived from studies of the ►primary visual cortex (Visual cortex – neurons and local circuits) of cats and monkeys, where it has been claimed that the horizontal clusters link columns of cortex with representations of like-orientation (►Striate cortex functions). In other cortical areas, including areas of ►prefrontal cortex in the monkey, such as area 46, horizontal clusters are equally apparent, but the representations they link have yet to be defined. At a structural level there are important regularities, whose functionality has yet to be divined. Across all areas and species examined (which include the major divisions of neocortex), there is a linear relationship between the size of the clusters and their spacing [3]. The size of the patches also correlates with the diameter of the lateral spread of the dendrites of pyramidal cells, which increases from ►occipital cortex to prefrontal cortex. It is not known what determines the constancy in the relations of these dimensions.

## Inter-Areal Hierarchies

Van Essen and colleagues have gone a long way in exploring the particular hierarchy to be found in the visual system and beyond. They showed that pair-wise comparison of the laminar organization and connections linking cortical areas made it possible to define all inter-areal pathways as either feedforward, feedback or lateral (linking areas on the same hierarchical level) (►Extrastriate visual cortex). While the Felleman and Van Essen model has continued to exert a powerful influence on concepts of neorcortical function and brain organization, it has been questioned by the group of Malcolm Young that showed that there are 150,000

equally plausible solutions to the Felleman and Van Essen model [7].

In order to obtain a determinate model, it is necessary to define the hierarchical distance between stations. Precise quantification of the laminar organization of inter-areal connectivity provides a useful measure of hierarchical distance [5,6]. Injections of retrograde tracers in a mid-level target area show that afferent areas contain both labeled supra- and infragranular layer neurons. Feedforward projections originate predominantly from supragranular layers, and the exact proportion of supragranular neurons labeled relative to all labeled neurons in the same area depends on the hierarchical distance from the target area. Feedforward projections to far-distant areas originate almost exclusively from supragranular layer neurons, and as one approaches the target area, there is a smooth increase in the contribution from the infragranular layers. Likewise in the case of feedback projections, as the hierarchical distance increases there is a steady increase in the proportion of infragranular layers so that far-distant feedback projections are almost uniquely from infragranular layers. This regularity has been encapsulated in a "distance rule" that has the power to define the hierarchical organization of a cortical network from the analysis of the projections to only a small number of key areas [6].

Tracing experiments reveal that around 90% of the projections are local (within 1–2 mm), that is, most of the projections onto a cell are from neurons within the same area. Of the remaining 10%, about two thirds come from neighboring areas and are lateral, so that information flow across the hierarchy is assured by a truly minute proportion of feedforward and feedback neurons. The observation of dense local connections coupled with sparse long-range connections conforms to the idea of a "Small-World" network and goes along with a model of areas as functionally specialized modules, with the long-distance connections serving to communicate the information processed locally within areas rapidly across the cortex.

## Physiological Integration of the Daisy Architecture with the Connections between Cortical Areas

How long-range connections influence local circuit functions is an important step in understanding the computational function of the neocortex. One approach is to temporarily inactivate the area by cooling and study what effect the inactivation as on a target area the projecting regions. Cortical areas ►V2 (Cerebro-cortical area V2) and MT (►Cerebro-cortical area MT) have feedback connections to the primary visual cortex (area V1 (►Cerebro-cortical area V1)), and cooling area V2 or area MT reduces the receptive-field center response of area V1 neurons. This suggests that there may be a summing of feedback activity with feedforward input from the thalamic ►lateral geniculate nucleus (LGN), which relays ►retinal activity to area V1. Integration is further suggested by the evidence that feedback projections from extra-striate cortex overlap with clusters of area V1 cortical output neurons [8].

One way to investigate the dynamics of the interaction of inter- and intra-connectivity is to examine the visuo-topic scales of both systems and compare them to the receptive field response of neuronal aggregates in area V1 [8]. In these studies the representation of the ►visual field (►Vision) is determined for the extent of the local Daisy connection as well as for the inter-areal connections. These studies suggest that Daisy connections have the appropriate spatial extent to mediate a restricted portion of the visual response of area V1 neurons, which corresponds to the spatial summation zone within the receptive field. The extent of the Daisy connections was however insufficient in extent to account for the full surround response from beyond the classical receptive field (►Vision). This makes sense because the relatively long delays of the suppressive orientation-selective effects of surround stimulation are similar to those reported for the slow propagation of excitatory activation mediated by horizontal connections.

The visuotopic representation of feedback projections from extra-striate cortex to area VI are commensurate with the full center-surround response of the area V1 neurons (►Visual cortical and subcortical receptive fields). The influence of extra-striate cortex on Daisy connectivity is coherent with the temporal constraints: the timing of the visual responses of higher visual areas largely overlap with area V1 responses, the conduction velocities of the large-caliber fibers projecting from extra-striate cortex to area V1 are considerably faster than those of the horizontal intrinsic fibers, and the inactivation of extra-striate cortex influences the early part of the area V1 neuron visual response. Hence, it would seem that the physiology and the visuospatial correspondence between the intra- and inter-areal connection systems provides the basis for the integration of local and global signals in the primary visual cortex [8].

## Conclusions

One fundamental question about feedback and feedforward pathways is whether they constitute distinct functional systems, as implied by the terminology used. Taking the geniculo-cortical pathway (►geniculo-striate pathway) as a model, cortical feedforward pathways supposedly mediate driving influences and feedback mediate modulatory influences. Physiological studies support this general view, e.g. cooling area V1 in the monkey leads to silencing of area V2 neurons, whereas cooling area V2 has only marginal effects on the activity of area V1 neurons. However, if a small driving projection was contained in the feedback pathway that

remains dominated by a modulatory function, the driving function might not show up in the cooling experiments. The distance rule suggests that the physiology of feedforward and feedback pathways linking cortical areas is determined by the composition of the parent neurons in terms of supra- and infra-granular layers [6]. The differences in the physiology of feedforward and feedback pathways could be the consequence of (i) differences in the cellular targets and/or (ii) differences in the intrinsic properties of the parent neurons.

The idea that a cortical area is homogenous both in function and structure has been floating for over a century. In a seminal paper, Daniel and Whitteridge [9] showed that while the amount of cortex devoted to a degree of the visual field (the "magnification factor") (►Striate cortex functions) does change across the cortex, there appears to be a constant ratio between the numbers of peripheral receptors and the number of visual degrees represented in the cortex. In the 1970s, Hubel and Wiesel took this a step forward in suggesting that the entire apparatus for representing a point of the retinal image is contained in a small region of cortex a few millimeter in area, which they called a "►hypercolumn." The primary visual cortex thus consists of many such hypercolumns. However, the dynamic properties of neuron response have been shown to change dramatically within a visual cortical area at different eccentricities, and a recent paper shows marked differences in the inputs to the central and peripheral representation of area V1 [10]. The dominance of inter-areal projections by nearby areas could lead to such a specialization because the layout of the visual areas results in different sets of areas being closer to central than peripheral visual field representations. This in turn leads to the prediction that the central representation of early visual areas will be preferentially connected to the ventral processing stream and peripheral to the dorsal processing stream (►Extrastriate visual cortex). Thus while a given cortical area may be formed by multiple copies of a canonical circuit, each region of the area could be modulated independently by its nearest neighbors. Eccentricity-dependent differences in organization would be consistent with the anatomical specializations in the retina (fovea vs. periphery) as well as the behavioral evidence of eccentricity dependence of different tasks (for example, object recognition in central vision vs. global spatial localization in the periphery). Such observations raise questions about how a cortical area should be defined, since it cannot be done by assuming that one area behaves as a single functional entity.

Our approach to investigating cortical hierarchy is based on Graph Theory, in which the distribution of connections between areas is analyzed over the whole network to infer the connectional distances between areas [7]. Such an analysis shows that the distribution of areas bears a close resemblance to their spatial layout in the cortex suggesting organizational principles linking connectivity, adjacency and cortical folding. This study, however, is based only on the presence or absence of a connection between two areas and does not take into account the strength of connections. Because strong connections are very short-range, integrating the strength of neural connections in these models will strongly emphasize the importance of adjacency. Given that the strength of connectivity is eccentricity-dependent, comparing graphs across the cortex will allow us to explore structural features of contextual processing. The challenge will then be to extract the rules allowing integration of Daisy architecture in the contextual process. Significant efforts are now being made to understand how graphical processing can be instantiated in networks of uniform processing elements, how this can be done using asynchronous event-based methods, which are the essence of neuronal computations, and whether graphical processing can be promoted from simple uniform propagation between nodes (whether defined as neurons, clusters of neurons, or cortical areas) to a dynamic "intelligent" selective propagation. The solution to such problems will be an important step to understanding the principles by which biological brains achieve their intelligence.

# Nervous, Immune and Hemopoietic Systems: Functional Asymmetry

Valery V. Abramov, Irina A. Gontova, Tatjana Ya. Abramova, Vladimir A. Kozlov
Laboratory of Neuroimmunology, State Research Institute of Clinical Immunology of SB RAMS, Novosibirsk, Russia

## Synonyms

Asymmetry – absence of symmetry; Contralateral lobes – left and right lobes; Thymocytes – cells of thymus; Splenocytes – cells of spleen; Syngeneic mice – compatible on H-2 antigens mice; Immunization – injection of antigens; Paw preference – preference of paw in taking food; Maturation of cells – differentiation of cells

## Definition

The ►asymmetry of the brain hemispheres has been studied for a long time. While studying this phenomenon, numerous facts on structural, functional, and molecular-biological differences of the hemispheres have been accumulated. Based on these data, some studies have been conducted showing that there is asymmetry of not only the brain hemispheres but also of the neuroendocrine system as a whole, including the gonads, adrenal glands, and lobes of the thyroid gland. For example, our experiments discover the existence of functional asymmetry of adrenal glands in ►(CBAxC57Bl/6)F1 hybrid mice.

At the same time, it is known that the hemopoietic and lymphoid organs (bone marrow, thymus, lymph nodes, etc.) as well as the brain hemispheres are presented by two morphologically-divided lobes (contralateral lobes). This enabled us to suppose and prove that not only the neuroendocrine system but also the hemopoietic and immune systems demonstrate the functional asymmetry of bilateral organs.

## Characteristics

### The role of Functional Asymmetry of a Bone Marrow and of Brain's Hemispheres in Hemopoiesis

#### *Design for Experiment*

The recipient mice were prepared by exposure to a whole-body-radiation dose (950 R). Marrow cells were obtained from the femora of mice-donors, suspended in saline and the nucleated cells were counted with a hemacytometer. These suspensions were kept at ice-water temperature until they were injected. The recipient animals then received an intravenous injection with $10^5$ of marrow cells (0.5 ml). The effect of functional asymmetry of the bone marrow on hemopoiesis was evaluated by injections of cells from the left or right femoral bone of left- or right-pawed donors to irradiated recipient animals (left- or right-pawed). Eight days after injection of the transplanted cells, the mice were killed and the number of colonies (i.e. in the number of 8-day colony-forming units in spleen – ►CFUs-8) in their spleens was determined by Till and McCulloch method.

#### *Results*

Our experiments discovered the existence of functional asymmetry of the bone marrow cells [1–6]. For example, the evaluation of functional asymmetry of the bone marrow showed significant differences in the hemopoiesis (CFUs-8) only in irradiated left-pawed recipients receiving an intravenous injection of marrow cells from the right or left femoral bones of left-pawed donors. No appreciable differences in the formation of CFUs-8 were observed in cases when left and right femur marrow cells were transplanted from right-pawed donors to left-pawed recipients (►left-pawed and right-pawed mice), or marrow cells from either femur of left- and right-pawed donors were injected to right-pawed recipients. These results indicate that the: (i) hemopoietic potential of the bone marrow from the right and left femoral bones is different; and (ii) manifestation of asymmetry of bone marrow hemopoietic functions depends on motor asymmetry of donors and recipients [4–6].

### The role of Different Lobes of the Thymus and Different Hemispheres of the Brain in the Development of Humoral Immune Response

#### *Design for Experiment*

The mice recipients were thymectomized to evaluate the role of the cells from either left or right thymus lobes in the ►humoral immune response. Five weeks after thymectomy, left and right-pawed recipients animals were intravenously injected with thymocytes from the right or left thymus lobes of left-pawed syngeneic donors ($10^7$ cells/mouse). These recipient mice were subsequently immunized with sheep red blood cells (►SRBC) 10 days after thymocyte administration. The humoral immune response (antibody-producing cells) in the spleen was counted by the method of Cunningham 4 days after the immunization.

#### *Results*

Our experiments showed the existence of functional asymmetry of the thymus and demonstrated that the asymmetry in the nervous and immune systems (hemispheres of the brain and the thymus) plays an important role in the development of humoral immune response to SRBCs. So, the *in vivo* experiments showed that the properties of cells from contralateral lobes of the thymus proved to be a deciding factor that defines the differences at the level of humoral immune response in recipient

mice with left-dominant hemispheres. This effect was less pronounced in mice with right-dominant hemispheres. Further analysis showed that left and right-dominant hemisphere mice differ according to the immune response only if mice from both groups received cells from the left but not from the right lobes of the thymus. That is, in the formation of the humoral immune response to SRBCs the functional asymmetry of both the brain and thymus is of great importance [7–9].

## The role of Motor Asymmetry of Brain Hemispheres and Functional Asymmetry of Regional Lymph Nodes in the Development of Cellular Immune Response

### *Design of Experiment*

While studying the ►cellular immune responses in the paws, mice were intraperitoneally immunized with 0.5 ml of 5% SRBCs. On the fourth day, the delayed-type hypersensitivity (DTH) reaction was used as an *in vivo* measure of antigen specific T-lymphocyte reactivity. In order to study the cellular immune response, 50% suspension of SRBCs in 0.05 ml of physiologic saline was injected under aponeurosis of the left paw. In addition, 0.05 ml of physiologic saline was injected under aponeurosis of the right paw as a control. The cross-section of a paw at the site of injection was measured 24h later. In order to study the cellular immune response in the right paw, mice were injected with 50% suspension of SRBCs in 0.05 ml of physiologic saline under aponeurosis of the right paw. Further, 0.05 ml of physiologic saline was injected under aponeurosis of the left paw as a control. The index of reaction (DTH) was calculated for each mouse by the formula: $IR = (P_o - P_c)/P_c$, where $P_c$ – paw cross-section in control; $P_o$ – paw cross-section in experiment.

### *Results*

The results obtained showed that the degree of cellular immune response in (CBAxC57Bl/6) $F_1$ mice depends on the functional asymmetry of regional lymph nodes and paw preference. The thymus functional asymmetry is of insignificant importance in DTH reaction. For example, we found that the intensity of the DTH reaction to SRBCs in the front paws of (CBAxC57Bl/6) F1 mice depends not only on whether the antigen is injected into the left or right paw but also on the motor asymmetry of the hemispheres. While comparing the DTH reaction in the hind left and right paw of mice, we showed that in both right- and left-handed mice it was much more pronounced in the left paw than in the right one [6,10].

## Discussion

It is known that autonomic nerves are well presented in the bone marrows, thymus lobes and lymph nodes of mice where, together with specialized cells, they form the neuroendocrine microenvironment that influences the maturation of cells. These data together with our results on differences in the functional properties of cells from contralateral (left or right) bone marrow and lymph nodes, and thymocytes from the thymus lobes allow us to suggest the following: (i) there are differences in the sympathetic and parasympathetic innervation of the contralateral lobes of the organs; and (ii) differences in the functional properties of cells from the contralateral lobes of the organs are caused by differences in the neuroendocrine environment of the lobes mentioned; i.e. preferential influence of catecholamines, acetylcholine and peptides on the cells.

It has been established that sympathetic and parasympathetic activity is preferably regulated by different brain hemispheres. So, sympathetic activity is preferentially regulated by the right hemisphere, whereas parasympathetic activity is regulated by the left hemisphere. In this connection, one can speak about the lateralizing effect of the brain hemispheres on the organs by creating differences in the neuroendocrine environment of the right and left lobes.

At the same time, our data, for example, on the different roles of cells from the contralateral lobes of the thymus in the formation of a humoral immune response confirm the supposition that thymocytes from the lobes mentioned have different functional properties. Moreover, we speculate that the number of T-helper precursors of type 2 might be different in the thymus lobes and/or the precursors mentioned are at different stages of their differentiation. Since the injection of thymocytes from the left thymus to thymectomized recipients is accompanied by the greatest effect on the formation of a humoral immune response, there might be more T-helper precursors in the left lobe and/or they are more mature in comparison with cells from the right lobe. That sympathetic and parasympathetic activity is mainly regulated from different brain hemispheres can help explain their role in the formation of a humoral immune response in thymocyte recipients. If functional differences in cells from the contralateral lobes of the thymus of donors define the preferential influence of catecholamines and acetylcholine, the influence mentioned can also explain the role of the hemispheres in the formation of antibody-forming cells in the recipients who received thymocytes from a given lobe. For example, specific receptors to definite neuromediators might be expressed on the surface of the thymocytes mentioned.

We speculate that the more pronounced DTH reaction on the left than on the right may be connected too with asymmetry of peripheral innervation of contralateral lymph nodes that, in its turn, is controlled by brain hemispheres. That is, peripheral vegetative innervation of regional lymph nodes, regulated by brain hemispheres, might be very important in asymmetrical development of reactions of cellular immunity in front and hind paws of mice. The data testify to an important role of sympathetic innervation in DTH reaction. For

instance, they showed that stroke lateralized T-cell-mediated cutaneous inflammation. This effect may be mediated by alteration of the cutaneous sympathetic nerve traffic. The authors also demonstrated that there is lateralization of cutaneous inflammatory responses in patients with paresis after poliomyelitis. This lateralization of DTH responses is related to deficiencies in motor and sympathetic innervation of the paretic extremity.

It is possible that sympathetic and parasympathetic activity that is mainly regulated from different brain hemispheres can help to explain their role in the formation of CFUs-8 in mice-recipients.

### Conclusion

Thus, our data allow us to speak about the asymmetry of the integrated Hemopoietic, Immune, Endocrine and Nervous systems, i.e. the HIMEN system (Fig. 1) [1,6,9].

## Network Oscillations

### Definition

Oscillatory activity generated in distinct brain regions by networks of often electrically coupled neurons are fundamental to information processing in the mammalian brain. Many of these rhythms correlate with distinct behavioral states. Electrical synapses appear to play a role in the generation and synchronization of these network oscillations.

►Electrical Synapses

## Network Oscillations in Olfactory Bulb

### Definition

Oscillatory variations of the field potential can be revealed by extracellular recordings. It presumably results from the synchronized activity of a group of neurons. Several types of oscillations have been described in diverse brain areas. They are classified with respect to their oscillatory frequency. For example, in the main olfactory bulb, there are three types of oscillations. Slow "Θ" oscillations (1–8 Hz) are generated by respiratory cycle. Fast "β" (15–30 Hz) and "γ" (40–80 Hz) oscillations are induced by inhalation of odorant molecules and reflect information processing by the olfactory bulb neuronal network.

►Olfactory Bulb

## Network Oscillator

### Definition

A neuronal network that produces a rhythmic activity pattern in response to a general excitation as a result of the synaptic connections between the individual neurons. Each neuronal type may discharge during a different phase of the rhythm. In a network oscillator none of the component neurons possess endogenous bursting properties (i.e. the individual neurons on their own would not produce any rhythmic activity). Instead, generation of the rhythmic activity is due to synaptic interactions. The simplest network oscillator configuration is the half-center oscillator that consists of two neurons or groups of neurons, which are connected

by mutual inhibitory connections. This configuration can lead to rhythmic switching of activity between the two half-centers producing a biphasic activity pattern.

►Central Pattern Generator
►Half-center
►Respiratory Network
►Rhythmic Movements

## Network Reconfiguration

### Definition

A process that alters the interactions and output pattern of a neuronal network by changing the number of active neurons, their intrinsic membrane and/or synaptic properties. Network reconfiguration is typically mediated by endogenously released neuromodulators.

The reconfiguration of neuronal networks imbues the nervous system with a high degree of plasticity. It enables, for example, a behaving animal to alter the output of a neuronal network in response to changes in the behavioral, environmental and metabolic conditions.

## Neural and Behavioral Responses to Immunologic Stimuli

Alexander Kusnecov
Rutgers University, Department of Psychology, Piscataway, NJ, USA

### Introduction: What the Brain Cannot See But Needs to Know

From a behavioral perspective, the nervous system evolved for organisms to approach and avoid stimulus components of their environment. This is predicated on the existence of sensory systems that transduce physical information into the electrochemical events of neural transmission, and which forms the basis for information processing. Each stimulus, no matter how discrete, is an informational package, and can be arranged along a continuum varying in the intensity and magnitude of some specific criterion. For the nervous system, differentiation and identification of objects includes such characteristics as size, texture, and weight, information which is processed and acted on to orchestrate an appropriate response. Thus, pot plants falling off balconies, oncoming motor vehicles, a baseball speeding through the air, all signify to an individual appropriate steps to take in avoiding or engaging a potentially dangerous stimulus. However, this form of signal detection fails in the realm of stimulus encounters with the microbial world of bacteria, viruses and other parasitic entities that represent biological threats against the organism. It is against biological agents at this end of the continuum of environmental stimuli that the nervous system is at a loss to avoid and/or engage with an appropriate response. To address this problem, vertebrate animals evolved a cell-mediated molecular recognition system that recognizes and eliminates microbial organisms. This is the immune system, a heterogeneous collection of cells (collectively referred to as leukocytes) that consists of macrophages and monocytes, which represent the first line of immunologic defense by ingesting and degrading particulate cellular invaders, while T and B lymphocytes (or T and B cells) serve to regulate immune responses, produce antibodies (by B cells) and exert cytotoxic effects by killing virally infected cells. A general review of the immune system is not possible here, although for a general introduction the reader is referred to other sources [1].

### The Immune System Communicates with the Brain

For many years it was thought that the immune system functioned independently in exercising this defensive function, and to a large extent in the ►initial phase of encountering and responding to pathogens, it is the main system involved. However, the past several decades have emphasized that the immune system can be influenced by the central nervous system (CNS), and in reciprocal fashion, the activity of the immune system can affect the CNS. A number of publications have compiled reviews of empirical research attesting to this mutually interactive functional relationship [2]. In retrospect, this interaction makes considerable sense, given that the behavior of an organism can serve to control levels of exposure to environments that may contain infectious microorganisms. However, in the absence of foresight, exposure to bacteria or viruses renders too late any evasive and/or protective measures. Therefore, some form of learning and/or knowledge about each infectious episode must be relayed to the CNS to ensure control over future potential encounters. For this reason pathways of communication exist from the immune system to the brain, activating brain mechanisms that essentially perceive the presence of infection in the body. One of the most instructive examples of this is the behavioral phenomenon of conditioned taste aversion (CTA; also referred to as food aversion) a form of avoidant learning in which tastes and foods are rejected if their ingestion had

previously been associated with illness. This behavior can be elicited by immune responses and molecular products of the immune system, illustrating the notion that the immune system, as it engages microbial pathogens, simultaneously alerts the brain to initiate adaptive behavioral responses.

The immune system engages microbial antigens by generating *inter alia* a cascade of chemical mediators called cytokines which regulate the cells of the immune system, but in addition, are capable of binding to receptors on afferent nerves (e.g., the vagus) as well as the endothelial cells of the vasculature. The production of cytokines during the immune response signals to the CNS the presence of potential pathogens, leading to the elaboration of various efferent mechanisms (viz., endocrine and autonomic nervous system activity) that result in physiological changes that contribute to the removal of the pathogen. In addition, and perhaps the most important from an adaptational perspective, the CNS response to cytokines initiates behavioral adjustments that result in cognitive processing of all relevant information pertaining to the potential source of the illness and how it can be managed. Returning to the CTA example introduced above, infectious illness following ingestion of a novel food should result in a memory for the contextual circumstances surrounding food intake. Indeed, it is known that memory is enhanced shortly after ingestion of food, and perhaps this phenomenon ensures that in the face of food poisoning there is more effective retrieval of information pertaining to the "eating event." As discussed below, these behaviors are part of a constellation of changes called "sickness behaviors."

## The Immune System as a Stressor

Stress is a much used and abused term. The intended (and commonplace) connotation of the term is either as a threat to the organism or a state of the organism that is potentially harmful to health. In order to allow for effective communication of the conditions leading to "stress," investigators use the term "stressor" to denote any stimulus or condition that produces a biological state significantly different from that observed prior to stressor exposure. In recent years, a distinction has been made between two classes of stressors: (i) those that operate through cognitive and exteroceptive sensory stimulation (e.g., pain), and (ii) those occurring within the internal milieu – the molecular signals arising from the cells and tissues of the organism. The former are referred to as *processive* stressors, and involve psychogenic components, while *systemic* stressors involve endogenous changes in the internal milieu which signal the CNS through alternative interoceptive pathways (blood, afferent nerves) [3]. Examples of systemic stressors can include metabolic changes such as insulin elevations and reductions in blood glucose, as well as changes in the chemical composition of the blood as a result of exposure to a pathogen. Therefore, the immune system and the cytokines produced following its stimulation are now viewed as systemic stressors, generating a similar profile of changes in the brain that are produced by processive stressors. These changes include an elevation of the production and release of classical neurotransmitters, including the monoamines (serotonin, dopamine and norepinephrine), in regions of the brain that are known to be involved in the generation of fear, anxiety, reward evaluation, decision-making, and memory. Such regions include the septum, amygdala and associated areas (which process fear and anxiety), hippocampus (involved in memory), prefrontal cortex (decision-making), nucleus-accumbens and other components of the mesolimbic dopaminergic pathway (reward evaluation). All these areas are part of the brain circuitry involved in emotion regulation. Activation of these areas has been determined by measuring the appearance of immediate-early genes (e.g., *c-fos*) that reflect excitation of neurons, as well as through electrophysiological recording of the firing rates of neurons generating action potentials. Many of the changes in these brain regions are observed following exposure of laboratory animals to painful and/or fearful stimuli (i.e. processive stressors). And while the study of these brain regions and their role in cognition and emotion continues to evolve, it is apparent that they are essential to the ability of organisms to adapt in the face of challenges to survival and/or well-being. Consequently, it must be the case that similar engagement of such areas by immunologic factors serves to mediate similarly adaptive behavioral and physiological changes.

## The Role of Cytokines

In the early 1970's and 1980's CNS activation by the immune system was demonstrated using sheep red blood cells (SRBC) as the antigen [4], and showed that during the peak of the antibody response there were increases in plasma corticosterone, brain electrophysiological activity, and release of monoamine neurotransmitters in regions of the brain involved in stress and adaptation. This work has been extended to include protein antigens, bacterial toxins, and viruses. Collectively, it is now well established that the CNS is a recipient of "sensory" signals from the activated immune system. Indeed, this was recognized early and led to the concept of the immune system as a "floating brain" or "sensory organ" [4,5].

The search for molecules that might be responsible for the CNS activation observed during the immune response to specific antigens led to important discoveries that opened wide the field of neural-immune research. As stated above, cytokines are the chemical mediators of the immune system, responsible for

suppressing, enhancing, and fine-tuning the various cellular mechanisms of the immune system. Cytokines play an important role in the final stage of an immune response which involves an effector component that constitutes the ultimate death blow to an invading pathogen. This effector stage includes T lymphocytes being cytotoxic for bacteria or virally infected cells and B lymphocytes producing antibody that binds and neutralizes antigen. Antibodies also serve as tags that allow macrophages to bind the antibody-bound antigen (e.g., bacterial cell) and summarily eliminate the antigen through cytotoxic means and phagocytosis. The role of cytokines in these processes is to either augment, suppress or maintain control of the effector arm of the immune response. Failure to regulate this process can result in immunopathology, including autoimmune disease and prolonged infection. Numerous cytokines have now been identified, and many more await characterization. However, a number of cytokines have already been designated with neuromodulatory functions. A substantial body of evidence exists on the neural effects of the cytokines interleukin-1 (IL-1), IL-6 and tumor necrosis factor (TNF α). Many other cytokines, including IL-2, interferon α (IFNα) and IFNγ, and transforming growth factor (TGF), have been linked to brain function either through demonstrations of behavioral and neurophysiological changes, or through their involvement in neuropathology. Many more cytokines will continue to be implicated in neuromodulation through research on degenerative and regenerative events in the brain, as for example, in animal models of stroke, dementia and neurological impairment. However, in terms of influences affecting ongoing neural and behavioral functions due to systemic immune responses, there is general acceptance that IL-1, IL-6 and TNFα are involved, given that their administration replicates many of the effects seen in response to many of the experimental antigens shown to activate the brain. Indeed, these cytokines are also produced within the brain by glial cells (viz., astrocytes and microglial cells) which can support neuronal function through regulation of nutrient and neurotransmitter biosynthetic pathways. The production of cytokines by glial cells is an area of intense interest, and clarity of conceptual understanding in terms of precisely how intra-CNS cytokines promote brain function is yet to be realized.

The direct effects of cytokines on CNS function reinforced the principle of immune-derived activation of neural processes. However, demonstrations of the contribution provided by endogenous cytokines, focused largely on the use of lipopolysaccharide (LPS), which has been studied as a model of gram negative bacteremic infection. Exposure of animals to LPS produces significant in vivo production of IL-1, IL-6 and TNFα; and many of the neural and behavioral effects of administered cytokines can be easily induced by LPS. However, LPS activates the cells of the myeloid lineage, such as monocytes and polymorphonuclear phagocytic cells (i.e. macrophages). The study of other antigens that engage T cells, is also needed. These cells are a significant source of cytokines, some of which are exclusive to T cells (e.g., IL-2 and IL-4), while others are produced by both T cells and macrophages (e.g., IL-1, TNF, IL-6, IL-10 and IL-12). A more complete image of the immunological influence on brain function requires the use of antigens that also stimulate T cells.

## Bacterial T Cell Superantigens and the CNS

The term "superantigen" (SAg) was coined by Marrack and colleagues [6] to describe the unusually exaggerated proliferative and cytokine response of T cells to staphylococcal enterotoxins derived from gram positive bacteria. The appellation "super" served to contrast these enterotoxins with regularly tested protein antigens (e.g., egg albumin or keyhole limpet hemocyanin), which are highly selective and do not engage as large a T cell population as SAgs, and fail to induce readily observable *in vivo* T cell proliferation and ►measurable concentrations of cytokines in the blood. A fuller discussion of SAgs and their unique neuroimmunological uses can be found in [7].

The best characterized SAgs are the staphylococcal enterotoxins, which are identified by letter codes, such as A, B, C, and so on (e.g., staphylococcal enterotoxin A, SEA; staphylococcal enterotoxin B, SEB). The impact of SAgs on CNS function has been demonstrated with SEA and SEB, which produce activation of the hypothalamic-pituitary-adrenal (HPA) axis. The HPA axis is exquisitely sensitive to the effects of stress, and its activation is detected by blood plasma or serum measures of glucocorticoids (e.g., corticosterone) released by the adrenal gland, ACTH released by the pituitary gland, and corticotropin releasing hormone (CRH) released by neurons of the hypothalamus in the brain. Collectively, CRH, ACTH and corticosterone represent different hormonal components of the HPA axis, a neuroendocrine pathway essential to the survival of the organism under conditions of stress. Indeed, it is well known that optimal activation of the HPA axis is necessary using models of infection, such as exposure to LPS. Moreover, while SAgs have been shown to activate the HPA axis at all levels, similar activation had also been demonstrated using cytokines, such as IL-1, TNF and IL-6.

Bacterial SAgs also activate stress-related brain pathways that are known to influence the HPA axis. For example, regions previously mentioned, such as the amygdala, hippocampus and septum were activated after injection of SEA and SEB. Activation of these areas likely produces anxiety and/or stress-like states in the animal, supporting much of the research on the

effects of LPS and cytokines like IL-1 and TNFα on sickness behavior [8]. Sickness behavior is characterized by lethargy, anorexia and reduced exploration, and is also associated with anhedonia, somnolence, and deficits in learning and memory [9]. The wide range of behavioral changes observed speaks to a general behavioral adjustment in keeping with the protective goals of the immune system. Interestingly, the sickness behavior profile is similar to the symptomatology of depressive illness, which has led many to consider that dysregulation of the immune system may contribute to clinical depression [10,11]. Whether this compelling hypothesis is true remains to be determined.

Evidence exists that the neurobiological effects of bacterial SAgs noted above involve behavioral changes that approximate sickness behavior, but appear to lack signs of malaise that might account for anorexia and lethargy. Administration of SEA and SEB reduces food intake, but only if the food is novel (i.e. unfamiliar). Moreover, there is no evidence of weight loss, although increased body temperature has been noted. Why animals would show reduction of a novel, as opposed to familiar food, has been suggested to reflect an increase in anxiety. It is well known that exposure to novel food causes a neophobic (i.e. fear of novelty) reaction in animals. Therefore, if SAgs activate stress pathways in the brain, this may be altering the threshold level of processing and responding to mildly arousing stimuli. Indeed, the augmented reactivity to a novel food after SAg treatment was also seen in regard to exploration of a novel object, which similarly produces a neophobic reaction (i.e. reduced or more wary exploration). Further discussion of the behavioral effects of SAg treatment is provided elsewhere [7].

## Concluding Comments

This brief overview focused primarily on the idea and fundamental findings relating to immunological activation of brain and behavioral functions. The emphasis was in illustrating that defense against challenges to biological integrity are the province of both the nervous system and immune system, and with this common purpose, evolution has ensured that some form of cooperative signaling exists between the two. Ultimately, the organism learns and refines its behavioral repertoire of protection, and in doing so, relies on information relayed by the activities of the immune system. The sensation of illness communicated by elevated cytokines creates a state of arousal that generates a memory for the illness state in and of itself, and through the host of different cognitive mechanisms at the host's disposal, lays down a neural memory that can be used to plan and avoid future exposures to illness. More recent evidence, not covered here, has also demonstrated that cytokines (such as those mentioned in this article) are synthesized and released by glial cells in the brain. The distinction between the immune system and nervous system has become blurred, and it is clear that where defense against infection is concerned, both systems must eventually play a critical role [12].

# Neural Bases of Spatial Learning and Memory

Karim Benchenane, Michaël Zugaro, Sidney Wiener
LPPA, Collège de France, CNRS, Paris, France

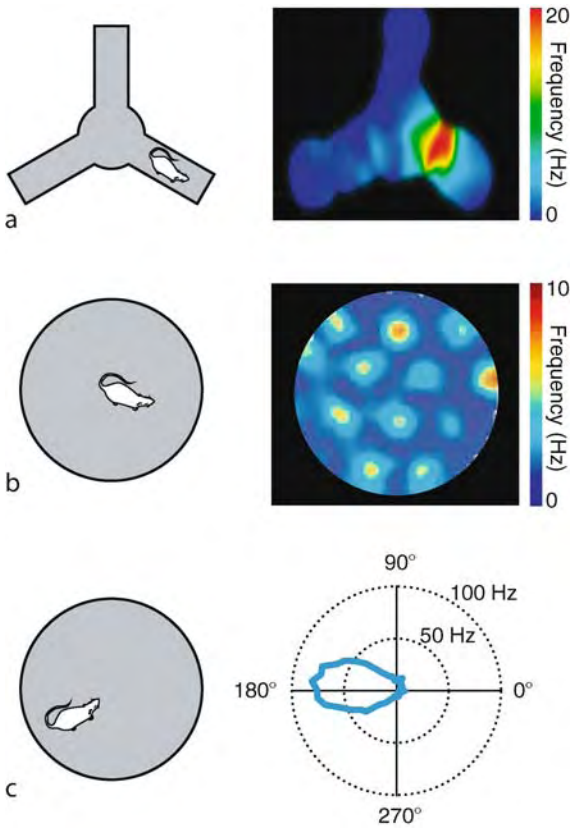
## Definition

For survival many animals have evolved neural mechanisms permitting to localize resources, protection and conspecifics in changing environments. During

exploration, information is acquired about cues, cue gradients, landmarks, and appropriate movements for dead reckoning, wayfinding, piloting and other types of spatial navigation. The goal of studying the neural bases of spatial learning and memory is to understand how specific patterns of brain activity underlie these complex spatial capabilities, and in particular how they emerge in novel environments, and how they are dynamically reorganized in changing environments.

*Lesion and comparative anatomy studies* have pinpointed the ►hippocampal formation as integral for the formation of spatial memory, as well as various types of contextual memories. However, long-term storage of these memories is attributed to other structures, in particular the parahippocampal cortex in humans. *Immediate early gene* imaging and *inactivation* studies by the group of Bontempi have shown that the hippocampus and posterior cingulate cortex are involved in the early phase of spatial memory, but later phases depend on anterior cingulate and prefrontal cortex (it was also found that different layers of the parietal cortex are sequentially involved in spatial memory formation). While the hippocampus is involved in more elaborate navigation capabilities, the striatum is associated with learning spatial habits triggered by simple or more complex cues. For example, in the *Morris water maze*, efficient swimming to a visible platform requires an intact dorsal striatum, while navigating to an immersed, non-visible platform requires an intact hippocampus. Whereas learning spatial layouts is primarily attributed to the hippocampal formation, exploitation of this information for spatial and other contextual based decision-making engages other closely associated structures such as the amygdala, prefrontal cortex and nucleus accumbens. *Brain imagery studies* in humans and studies of brain damaged patients indicate that the right medial temporal lobe, in particular the hippocampal and parahippocampal regions, is important for spatial cognition (see chapter 8 in [1] and chapter 12 in [2]).

*Neurophysiological studies* in the hippocampal formation and associated structures have demonstrated ►single unit and ►local field potential activity that *computational studies* show to be sufficient to support spatial learning and memory (see chapter 14 in [2]). The primary single unit responses are ►place cells, head direction cells and ►grid cells (Fig. 1) – although spatial responses have also been recorded in other areas (e.g., place selective responses in the subiculum, presubiculum and parasubiculum [8]).



**Neural Bases of Spatial Learning and Memory.**
**Figure 1** (a) Place cells selectively discharge when the animal is in a specific location ("place field") in the environment. *Left*. The rat explores a Y-shaped maze (*top view*). *Right*. Color-coded rate map (*blue*, zero firing; *red*, maximal firing rate; *black*, area not visited by the animal). This place cells fires when the animal enters the South-East arm (Benchenane, Larrieu, Wiener and Zugaro, unpublished data). (b) Grid cells fire when the animal is located at one of the nodes of a regular hexagonal lattice. *Left*. The rat explores a circular arena (*top view*). *Right*. Color-coded rate map (adapted from 4). (c) Head direction cells discharge when the head of the animal is oriented in a specific ("preferred") direction of the horizontal plane. *Right*. Tuning curve in polar coordinates. This cell fires maximally when the rat faces 180° (Zugaro, Berthoz and Wiener (2001), J Neurosci 21:RC154).

## Characteristics

### Place Cells

►Place cells (discovered by O'Keefe and Dostrovsky, in 1971; see Chapter 11 of [2]) are hippocampal pyramidal cells that discharge selectively when the recorded subject occupies a delimited region of its environment referred to as a "firing field" or "place field" [3,10]. Within a given environment, only a fraction of neurons recorded have firing fields. Of these, at any given moment while the animal explores its environment, a different ensemble of place cells are active. Taken together, place cells potentially code for the entire environment: this activity is a supporting pillar of the theory [3] that the hippocampal formation is the neural basis of a ►cognitive map, an internal representation of space which Tolman (1948) postulated in his riposte to

►behaviorism. There is no anatomically topographic arrangement of firing fields (as opposed to, for example, ►somatotopic or ►visuotopic organization in corresponding sensory areas). Place cell activity has been found in the hippocampal formation of various species: rats, mice, birds, bats, and primates (by Ono and colleagues, although Rolls' group observed "view cells" selective for where the monkey looks, rather than its position) including humans.

Place responses in hippocampal neurons demonstrate several properties suggesting that they are key elements for circuits enabling high level cognitive processing [5]. In particular, place cells exhibit *supramodal responses:* although visual cues can dominate the polarization of place responses (e.g., in a cue-controlled environment, if the constellation of background cues is rotated, the positions of the firing fields will rotate in a similar manner), place responses are maintained in darkness and in blind rats, presumably on the basis of idiothetic (vestibular, proprioceptive, and perhaps efferent collaterals of motor commands) and ►somatosensory processing. Thus the same responses can be arrived at independently of sensory modality. Another remarkable property of place cells is their *abstract, stimulus-invariant responses:* during unrestricted movement in an open field, place responses are not directionally modulated - that is, the cell fires when the rat is in the firing field regardless of what direction it is facing and what is in its field of vision. Hippocampal pyramidal cells also have c*ontext-sensitive responses*: they have place responses as well as non-place responses, for example in delayed ►eye-blink conditioning which depend on the current situation. An example in the spatial domain is *remapping*, which refers to the observation that when a rat is transferred from one environment to another, firing fields can shift in relative position, or disappear, while other initially silent neurons may now manifest firing fields. Interestingly, although in markedly different environements the respective layouts of firing fields are uncorrelated, when the rat is exposed to two novel environements with more subtle differences, place cell firing fields are initially similar in both environments, and only gradually shift to more dissimilar positions with repeated exposure.

Recent findings indicate that hippocampal activity reflects more dynamic information than initially envisioned. Many place cells fire maximally or remain virtually silent in the very same location depending on the past or future trajectory. At the population level, hippocampal activity includes information not only about current position, but also about ongoing trajectories. Indeed, it was shown that as the animal walks through the firing field of a place cell, the cell fires at earlier and earlier phases relative to the ongoing theta (7~12Hz) oscillation of the hippocampal local field potential. This property is known as *theta phase precession*. As a consequence, during each theta cycle, cells coding for recently visited locations fire first, then cells coding for current location, and then cells coding for locations further down the trajectory: that is, at each theta cycle, hippocampal discharges encompass information about past, present and future positions.

Strikingly, these patterns of sequential activation observed while the animal explores its environment are later "replayed" during subsequent sleep, in particular during short lasting fast (200 Hz) oscillatory field events called ►ripples, that occur repeatedly during slow wave sleep [7]. This is believed to be a critical mechanism underlying memory consolidation, possibly via ►long term potentiation of ►synapses targeted by the reactivated neurons, consistent with the observation that such *replay* occurs at accelerated rates relative to the original experience.

How are hippocampal place responses generated? Virtually all neocortical inputs to the hippocampus synapse first in the entorhinal cortex (EC). Two principal loops have been highlighted, the *indirect pathway* EC → dentate gyrus → CA3 → CA1 → subiculum + EC, and the *direct pathway* where EC projects directly to CA1. Numerous computational modelling studies have suggested that the recurrent connectivity of area CA3 could endow the hippocampus with ►continuous network attractor properties: this would ensure that at any given moment only a small subset of coactive cells could fire, while the rest remain silent; activity could then be propagated within the network by velocity modulated signals as the animal moves, or be directly imposed onto the network by external signals of sensory origin, the influence of which would be acquired through learning. Surprisingly however, it was shown experimentally that surgical isolation of CA1 from CA3 inputs neither disrupts the ability of CA1 pyramidal cells to acquire place fields nor the capability of the animal to learn a spatial task. This indicates that direct inputs from the EC are sufficient to support the emergence of place cell firing in CA1.

## Grid Cells

Grid cells of the dorsolateral part of the medial EC [4] discharge selectively at multiple locations distributed in a regularly spaced (30–70 cm) hexagonal grid - i.e., each node is surrounded by a hexagon of adjacent nodes). The internode spacing and node diameter increase gradually in more ventral zones. At a given depth, nearby neurons have grids laterally displaced relative to one another and can also have different angular polarizations of the grids.

The EC is the principal high-level input to the hippocampal formation. Thus, place cell activity is likely to emerge from a combination of intra-hippocampal dynamics with grid cell and other entorhinal signals.

This can be observed using a protocol known to induce hippocampal remapping (see *Place Cells, above*). There are actually two ways in which hippocampal place cells can remap: either the relative firing rates of the recorded cells change in an unrelated manner, while the spatial position of their firing fields are maintained ("rate remapping"), or the firing fields are relocated in an unpredictable manner ("global remapping"). Interestingly, entorhinal grid cells also demonstrate this dichotomy: in conditions where place cells undergo rate remapping, grid cells maintain stable fields; but when place cells undergo global remapping, grids are shifted and rotated consistently with modifications observed in the hippocampus. Thus, the relative locations of hippocampal firing fields depend on the relative grid layouts of their input grid cells.

In addition, precise spike timing of entorhinal ouputs might also influence spike timing in the hippocampus. Similar to place cells, layer II entorhinal grid cell firings also show phase precession relative to the ongoing theta oscillation. Note that the EC is a principal source of the theta rhythm in hippocampus. It is possible that hippocampal phase precession is not generated purely endogenously, but is at least partly inherited from EC, consistent with previous work where transient perturbation of hippocampal theta rhythm and cell firings did not disrupt phase precession.

## Head Direction Cells

Complementary to place cells, head direction (HD) cells (discovered by Ranck, in 1984) discharge selectively when the head is oriented in a particular direction in the horizontal plane, independent of position in space [6]. These responses are not controlled by the geomagnetic field; instead, they are thought to emerge from the interaction between intrinsic neural dynamics and multisensory and possibly motor signals (see chapter 18 of 6). HD cell responses are anchored to background visual cues (likely identified from ►optic field flow cues), but responses are maintained in darkness, presumably engaging ►vestibular and other self-movement cues (see Chapters 6 and 7 of [6]. Different cells are selective for different "*preferred*" *directions*, and all directions are equally represented. No anatomically topographic organization of directional responses has been reported. HD cells have been found in rats, mice, chinchillas and monkeys.

Unlike remapping in place cells, after environmental changes the preferred directions of simultaneously recorded HD cells rotate coherently, maintaining their angular differences. Thus the HD cell system may provide a more stable spatial reference.

HD cells have been found in over ten different brain areas including parts of Papez' circuit: dorsal tegmental nucleus of Gudden (DTN; which also has cells selective for head velocity) → lateral mammillary nucleus (LMN) → anterior-dorsal thalamic nucleus → post-subiculum + retrosplenial cortex → dorsal part of medial EC → hippocampus (which also has a low incidence of HD cells). Other areas with HD cells include lateral-dorsal thalamic nucleus, dorsomedial striatum and medial precentral cortex (FR2 or AGm).

HD and place responses are both suppressed by inactivation of the vestibular nuclei (sensitive to linear and angular accelerations of the head) which send axonal projections to the DTN. Neurocomputational and neuroanatomical data point to the DTN-LMN circuit as the generator of head direction responses by means of attractor network dynamics. From a computational point of view, this system would effectively compute a mathematical integration of the head angular velocity signal to yield head angular orientation. Progressive drift of this representation due to imperfect integration could be corrected for by sensory inputs (e.g., triggered by familiar visual landmarks).

## Space-Related Neuronal Responses and Navigation

A key issue is whether the spatial responses of place cells, grid cells and HD cells do subserve complex navigation capabilities, consistent with theoretical considerations, correlative experimental results and computational models and simulations.

To date, finding a clear link between HD cell responses and behavioral performance in spatial navigation tasks has remained elusive. Given that grid cells have only been discovered in 2005, it should not come as a surprise that no experimental results support their role in spatial navigation yet.

There is however an increasing amount of evidence for a critical role of place cells in spatial learning and memory. Initial support was brought by studies using either ►long term potentiation (LTP) induction protocols, or pharmacological or transgenic approaches. For instance, protein synthesis inhibitors and NMDA antagonists, the two major blockers of LTP, alter both place cell stability and spatial behavior. Similar results have been obtained in mice where the major proteins involved in the molecular cascade of LTP were knocked-out, such as CA1 NMDA knock-out mice, R(AB) mice (with reduced forebrain PKA), GluR2 mutant mice (knock-out for the GluR2 sub-unit of AMPA receptors), αCaMKII-T286A mice (with altered calcium sensitivity of CaMKII) and CREBαΔ- mice (deficient for the α and Δ isoforms of CREB). Remarkably, these studies show relatively good correlations between the level of LTP, place field stability and performance in spatial memory tasks [9].

In addition to these studies, perhaps some of the most convincing evidence to date that place cells do underlie spatial navigation capabilities is that in rats trained to find an unmarked goal in order to receive food rewards, experimental shifts of environmental cues

that provoke displacements of place fields relative to the goal location are associated with impaired spatial performance, provided that goal localization requires map-based navigation (see chapter 10 in [1]).

## Neural Cell Adhesion Molecules (NCAM)

### Definition

Belongs to the immunoglobulin superfamily. It mediates cell-cell interactions by homophilic binding, especially during axon fasciculation and nerve sprouting and cell migration.

## Neural Coding

### Definition

Neurons create, store and convey information. There are two basic codes they may use: rates of action potentials (unitary signals) or timing of action potentials. From a different perspective, neural coding also refers to the question whether specific information is stored in one neurons or in networks of neurons (see Ensemble Coding, Grandmother Neuron).

## Neural Coding of Taste

Martin Witt
Smell and Taste Clinic, Department of Otorhinolaryngology; Department of Anatomy, University of Technology Dresden, Medical School, Dresden, Germany

### Synonyms

Gustatory neural coding; Taste coding

### Definition

Basic gustatory stimuli are conveyed to the brain via activation of neurons connected in series or in parallel. The gustatory information needs several "simple" codes for representation at various neuronal levels. However, "taste" encompasses more than just the activation of the gustatory system by chemical stimuli, but include also touch, vision, olfaction, which all contribute to the perception of foods or drinks. Components of the gustatory pathway are taste receptors, gustatory nerve fibers, as well as relay stations within the brainstem (nucleus of the solitary tract), diencephalon (thalamus, parts of the ventral striatum), and telencephalon (insula/frontal operculum, orbitofrontal cortex, amygdala).

### Characteristics

The sense of taste is regarded as the main mechanism protecting the individual from intake of hazardous food. Usually, "taste" comprises at least five relatively distinct sensations such as "salty", "►bitter," "sweet," "acid," and "umami." Other sensations include trigeminally mediated, painful sensations, or the sensations of fattiness or astringency. Identical stimuli may elicit distinct reactions under various behavioral or environmental conditions, implying that various modulatory systems in the central nervous system interact with taste-selective pathways. Most flavors (e.g., cherry or chocolate) are the result from the complex interaction between trigeminal, olfactory and gustatory activations.

These multimodal properties contribute to an understanding how variable taste stimuli may be related to the activity of one or more neurons. In its stricter sense, "taste coding" comprises taste characteristics, which are translated into a specific neuronal firing pattern.

## What can be Coded?

- The relative number of stimulus molecules per volume of solution is coded by the rate of impulses in taste-responsive neurons: spike rate.
- Quality of taste stimuli, represented as "breadth of tuning" of ►gustatory neurons. The entropy measure (H) compares how selectively a cell responds to a standard array of chemical stimuli, usually NaCl, quinine hydrochloride, sucrose, and HCl. This method is a mathematical expression with H values ranging from 0.0 representing one of the five basic stimuli, to 1.0 representing equal responses to all five stimuli [1].

## Coding of Taste Qualities

There are two competing hypotheses how basic taste qualities may be relayed to the brain:

1. The labeled-line hypothesis: One taste quality is conveyed by one specific neuron type.
2. The across-fiber pattern theory: Taste qualities are coded by the relative activities across the population of responsive neurons.

### *The Labeled-Line Hypothesis*

The old observation that certain regions of the tongue are relatively specialized to convey various taste qualities led to the idea that neurons innervating taste buds in different regions were specialized for these taste sensations. Specifically, certain gustatory neuron types were specific coding channels for taste quality [2]. For example, the strict application of this theory would imply that the perception of the quality "sour" would arise from the activation of only one "sour" neuron type. As an example, Hellekant et al. [3] observed sweet-cluster fibers in the ►Chorda tympani nerve of chimpanzees, which could be specifically blocked by gymnemic acids. However, individual ►gustatory neurons were activated also by different taste stimuli. Consequently, as a variant of the labeled-line theory, taste cells were associated with neuron populations which evoke the greatest number of action potentials after a given gustatory stimulus. This number of neurons reacts as, for example, "sucrose-best" or "NaCl-best" [4]. On the other hand, some animals may behaviorally discriminate between related stimuli, for example, sucrose and maltose, which requires more subtle discrimination abilities than expected for specifically tuned cells. Also, neurophysiological recordings demonstrated that more than one basic taste stimulus was able to activate peripheral gustatory neurons. This strengthens the hypotheses related to an across-fiber pattern taste quality code (see below).

## The Across-Fiber Pattern Theory

The across-fiber pattern (ensemble) theory assumes that large ensembles of neurons contribute to the quality of a taste stimulus, because there is no absolute stimulus specificity in the responsiveness of afferent gustatory fibers [2]. On the other hand, reception of complex taste qualities may be understood as a parallel activation of several labeled lines, making the labeled-line theory a special case of the across-fiber pattern theory. The validity of various models of the neural coding of taste quality suffers from a nearly complete reliance on correlative statistical procedures and a lack of available techniques that allow selective manipulation of putative classes of gustatory neurons [5].

## Taste Coding in the Gustatory Periphery: Convergence within the Taste Bud vs. Labeled Lines of Gustatory Nerves

Taste stimuli can be mediated either by receptor proteins or apical ion channels. Do taste sensor cells (TSC, Type II cells) respond to a single quality or are they broadly tuned to multiple qualities? TSC are rather neuroepithelial cells than neurons; only a few exhibit synaptic contacts to nerve fibers. Recent studies show that about 80% of TSC (Phospholipase C β2-positive, SNAP-25-negative, i.e., lacking synapses) are narrowly tuned and respond to only one taste quality. In contrast, most presynaptic cells (SNAP-25-positive) are broadly tuned and respond to two or more taste qualities [6]. What is more, TSC may communicate with presynaptic cells by secreting ATP via pannexin-1 hemichannels. Only these broadly-tuned cells form synapses to afferent gustatory nerve fibers [7]. Presumptive transmitters are ATP, serotonin and possibly neuropeptides. Moreover, one afferent nerve fiber branches and synapses to more than one presynaptic taste bud cell, which leads to convergence and breadth of tuning. Chorda tympani fibers of rodent and monkeys have been subdivided into narrowly-tuned S-, N-, and Q-fibers (for sweet, sodium, and bitter), as well as more broadly tuned A- and H-fibers (for acids and electrolytes). Though some authors argue most taste stimuli seem to be transferred in selective populations of neurons in a labeled-line manner [5], others are hesitant to such a conclusion because of difficulties in interpretation of salty stimuli and the fact that neurons are more broadly tuned at higher concentrations [1].

## Taste Coding in the Central Nervous System

### *Central Taste Pathways*

Generally, central taste neurons are relatively broadly tuned. Gustatory information is conveyed by afferent fibers of three cranial nerves: [1] Fungiform papillae of the anterior portion of the tongue are innervated by the chorda tympani (CT), a branch of the intermediofacial nerve complex (CN.VII), which runs with the lingual nerve [2]. Vallate and foliate papillae are innervated by gustatory fibers of the glossopharyngeal nerve (CN.IX), and taste buds on the laryngeal surface of the epiglottis, larynx, and proximal part of the

oesophagus are supplied by the superior laryngeal branch of the vagal nerve (CN.X). Their nuclei lie in various peripheral ganglia, but the first central relay stations in the gustatory pathway are in the nucleus of the solitary tract (NST) of the brainstem. In humans, ipsilateral monosynaptic neurons run immediately to the ventral posteromedial nucleus of the thalamus, whereas in rodents an additional relay, the parabrachial nucleus, is interconnected. Dorsal neurons terminate in the "gustatory cortex," the anterior insula/frontal operculum and caudolateral orbitofrontal cortex. In rodents, a ventral affective pathway turns to the lateral hypothalamus, central nucleus of the amygdala, substantia innominata, and bed nucleus of the stria terminalis of the ventral striatum, but the exact pathways are somewhat less clear in primates/humans [8].

### *There is a Remarkable Intra-Individual Coding Stability, but no Clear Topographical Projection for Basic Taste Qualities in Structures of the CNS*

A clear chemo-topographical organization of particular taste qualities is a matter of debate. Recent functional magnetic resonance tomography investigations in humans show inter-individual differences for taste stimuli; taste fields of individual subjects do barely overlap, but there is stable intra-individual activity over a prolonged period of time [9]. In mice, coding stability is maintained over time, even after taste nerve crush and regeneration. Moreover, activity in taste neurons encodes also information about the hedonic value of a gustatory stimulus, regardless if there is a segregation or convergence of taste stimuli in central pathways.

Different neurons of the rodent NST respond best to NaCl, glucose, HCl, and quinine-HCl, but they have relatively broad tuning to different stimuli, as compared to the peripheral gustatory fibers [1]. This is mostly due to convergence of peripheral fibers. Also, many central taste neurons also carry thermal and mechanosensory information. In primates, a similar distribution has been found in neurons of the insular and opercular primary taste cortices [10] showing statistically independent neuron types for the basic taste qualities. Neurons devoted to bitter (quinine) quality comprise approximately 22% of measured insular/opercular cells, and those responding to sweet and salty account for 73%. Only 5% of all measured neurons were activated for the detection of acids [10].

## Conclusion

Taste information processing is based on complex interconnections. It has been hypothesized that it exhibits specific cerebral representation fields for the basic gustatory qualities which are nevertheless difficult to identify. Based on molecular, electro-physiological, and behavioral findings, the breadth of tuning at all anatomical levels and multimodal sensitivities of mostly central neurons render it difficult to clearly decide which coding algorithm is "used" for taste processing. Most likely various neuron types define specific across-neuron patterns. New insights have yet to come before clearly understanding syndromes related with taste deregulations such as the ►gourmand syndrome.

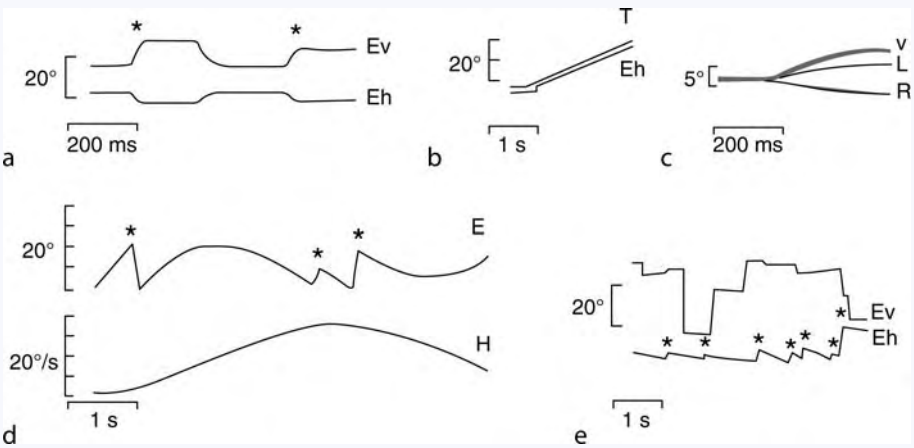
# Neural Control of Eye Movements

Adonis Moschovakis
Institute of Applied and Computational Mathematics, FO.R.T.H., Department of Basic Sciences, University of Crete, Heraklion, Greece

Understanding the neural control of actions is a central goal of the Neurosciences. It is for ►eye movements that we are closest to attaining this goal, at least in the

case of fairly complex brains such as those of mammals. Accordingly, ►oculomotor control has become a test bed of theories encapsulating general principles of motor control potentially applicable to additional effectors such as the head or the arm. In part this is due to the simplicity of ►oculomotor dynamics and kinematics. It is also due to the simplicity of the muscular apparatus that controls the eyes (just six ►extraocular muscles per eye). Finally, ►eye orbital mechanics are straightforward and because the eye is a spherical joint, its movements have a small number of degrees of freedom (just three). As with other motor systems, this number is often further reduced in behaving subjects. For example, ocular ►torsion is determined from the horizontal and vertical rotation of the eyes, measured in a coordinate system that moves with it. This fact has been known for more than a century, ever since ►Donders enunciated it in the form of the law that bears his name. It results from a more fundamental one, ►Listing's law [1], according to which for all eye positions, defined as single rotations from primary position, rotation axes lie on a plane perpendicular to the line of sight at primary position (i.e., the position of the eyes when looking approximately straight ahead and the head is upright).

In terms of metrics and kinematics, eye movements can be classified into several distinct types (Fig. 1). Figure 1a provides typical examples of ►saccades (marked with an asterisk). These are the eye movements that rapidly redirect the line of sight in a variety of circumstances, i.e., when exploring the visual world (scanning saccades), toward targets (►pro-saccades) which may appear suddenly in the extrafoveal visual field (►foveating or ►reflexive-saccades) or away from visible targets (►anti-saccades). On the average, the time that elapses between the presentation of a visual target and the onset of a saccade to it (saccadic latency) is equal to about 200 ms. In some human subjects, latency histograms demonstrate a second early peak, made of ►express saccades. Human saccades often undershoot their targets by about 10% and are followed by secondary shorter latency movements, called ►corrective saccades. The goal of other eye movements is to stabilize the projection of visual images on the retina. For example, movements of the head engage the ►vestibulooculomotor system, which evokes compensatory eye movements (slow phases of the ►vestibuloocular reflex – VOR) whose velocity is usually less than or equal, and opposite in sign, to that of the head (Fig. 1d). This ►rotatory VOR is engaged when the head rotates on the neck, and is driven by modulation of afferent signals arising in the semicircular canals. Linear acceleration of the head (e.g., during its forward propulsion on a walking body) evokes the ►translational VOR while keeping the head bent toward the shoulder evokes a static ►ocular counter-rolling response; both of these responses are driven by the otolith organs. Dynamic rotations about off-vertical axes activate both canal and otolith responses. Slow phases can be cancelled when the line of sight fixates a target moving with the head (►VOR suppression) and are interrupted by quick phases (Fig. 1b asterisks) which correspond to saccades. Sequences of slow and quick phases, collectively called ►nystagmus, are also produced after the end of constant velocity rotation (►postrotatory nystagmus), and when the vestibular sensorium is activated by stimuli other than the natural ones, such as after ►caloric stimulation of labyrinths. They are also produced by visual stimuli evoking ►optokinetic eye movements (►optokinetic response – OKR; Fig. 1e), e.g., during rotation of a drum



**Neural Control of Eye Movements. Figure 1** Distinct types of eye movements readily observed in monkeys. (a) Saccades. (b) Smooth pursuit. (c) Vergence. (d) VOR. (e) OKR. Note the difference in the time scales employed. Upward trace deflection indicates rightward movement. Asterisks in (a), (d) and (e) mark saccades. Abbreviations: dH/dt, head velocity; E, eye position; Eh, horizontal eye position; Ev, vertical eye position; L, eye position – left eye; R, eye position – right eye; T, target position; v, vergence angle.

N

around the subject at a constant velocity (►optokinetic nystagmus – OKN). Finally, ►ocular following responses (OFR) are the relatively low velocity eye movements that subjects use to follow slowly moving visual scenes. They are further developed in primates which are able to generate ►smooth pursuit eye movements (Fig. 1b) to accurately track small objects moving across a stationary background. Smooth pursuit eye movements can be preceded by saccades (►catch-up saccades; Fig. 1b) and they can be interrupted by saccades. Saccades, smooth pursuit, vestibular and optokinetic eye movements are ►conjugate in the sense that during such movements both eyes move simultaneously in the same direction and by roughly the same amount. Other eye movements (►disjunctive) are not (Fig. 1c). This is the case when the line of sight shifts from near objects to far ones (►divergent eye movements) and vise versa from a far to a near object (►convergent eye movements). The ►near response reflects the intimate relationship of the system that controls the angle between the lines of sight of the two eyes (►vergence angle) and the system that controls the focal point of the lens (►accommodation-vergence interactions).

The ability to accurately record the instantaneous position of the eyes with the ►electrooculogram (EOG) and ►electronystagmographic methods provided the impetus for a large number of studies of the relation between the instantaneous discharge of oculomotor related cells and the parameters of ocular movements. To date, two large families of theories have been proposed to account for the control of movements of body parts. On the one hand, position control theories suggest that neural signals guide effectors to a particular position in space. Alternatively, neural signals could dictate the metrics of the movements that the effectors should execute, as suggested by movement control theories. Recording from the neurons which innervate extraocular muscles, the ►extraocular motor neurons (MNs), allows one to test which of these two families of theories is correct. If a position control theory were implemented in the brain, extraocular motoneurons should be activated in proportion to the position of the eyes in the orbit. Their remarkable conceptual simplicity notwithstanding, the discharge pattern of extraocular motoneurons does not fulfill expectations based on position control theories. During saccades, for example, extraocular MN discharge is characterized by transient bursts accompanying movements and sustained tonic discharges whose intensity is proportional to the position of the eyes in the orbit. This pattern of discharge underscores the use of the term ►burst-tonic (BT) ►neurons to refer to extraocular MNs. In a more quantitative vein, their firing rate ($F_R$) approximately obeys the expression $F_R = \alpha + \beta.E + \gamma.dE/dt$, where E the instantaneous position of the eyes (vertical or horizontal depending on the cell), dE/dt is the instantaneous velocity of the eyes and α, β, γ. constants of proportionality which differ for different neurons. To obtain an intuitive feeling for these parameters, consider that some neurons discharge at a low rate (small α) and others at high rate (large α) when the eyes point straight ahead, some are deeply (large β) and others little (small β) modulated with eye position while some emit modest (small γ) and others emit considerable (large γ) bursts for saccades in their on direction.

Saccades, smooth pursuit, vestibular, optokinetic and vergence/divergence ocular movements are separately controlled by five, largely distinct neural circuits all of which feed into the final common path embodied by the extraocular MNs. Some of these circuits are anatomically simple. For example, the anatomical substrate of the VOR is a three neuron arc, composed of: (i) primary afferent vestibular fibers, (ii) ►vestibulo-oculomotor connections primarily arising from ►position-vestibular-pause (PVPs) neurons, (iii) extraocular motor neurons. The system that controls disjunctive eye movements is more complex. It comprises ►near response neurons and ►divergence neurons in the brainstem which are in turn driven by ►disparity dependent vergence and ►radial flow dependent vergence cortical signals. At the other extreme of the simplicity-complexity spectrum, saccades rely on more than 30 distinct cell classes found in more than ten widely distributed brain areas [2]. To cope with its structural complexity it is meaningful to divide the saccadic system into smaller sub-circuits, each one of which can be thought of as a central pattern generator responsible for a conceptually distinct operation: the ►brain stem burst generators (BG) in the reticular formation, the horizontal (►Neural integrator - horizontal) and vertical (►Neural integrator - vertical) ►neural integrators (NI) in the brain stem, and the metric computer in the ►superior colliculus. Although largely independent from the point of view of anatomy and physiology, to efficiently control the line of sight, systems responsible for different kinds of eye movements need to interact with each other. For example, the saccadic system needs to interact with the vestibular one (during nystagmus), as well as with the systems controlling smooth pursuit (►pursuit-saccade coordination) and vergence (►saccade-vergence interactions). It also needs to interact with systems controlling the movements of other effectors such as the ►head (►eye-head tracking), the hand (►eye-hand coordination), the eye-lids, etc.

The burst generators (BG) in the brain stem supply MNs with the high frequency signals they need to cause the contraction of the muscles they innervate during a saccade in their pulling direction. They contain cells that exhibit a brief burst of activity before saccades of particular directions (►burst neurons). Depending upon

the latency of the burst in relation to the onset of the movement, they are called ►medium lead burst (MLB) neurons or ►long lead burst (LLB) neurons [3], the term ►short lead burst neurons being reserved for the neurons with the shortest burst latencies, i.e., the MNs. The amplitude and direction of saccades are specified in terms of the amplitude of their horizontal and vertical components which are determined relatively independently by distinct groups of premotoneuronal MLB neurons. ►Horizontal (left and right) ►MLB (HMLB) neurons are located in the ►paramedian pontine reticular formation while ►vertical (up and down) ►MLB (VMLB) neurons are located in the ►rostral interstitial nucleus of the medial longitudinal fasciculus (►riMLF). Axons of MLB neurons convey the output of the burst generators directly to extraocular MNs, thus directly providing them with the excitatory drive they need for ipsiversive saccades. One of the most prominent projections of the horizontal ►excitatory burst neurons (►EBNs) is to the ipsilateral abducens nucleus [4] (which contains MNs innervating the ipsilateral lateral rectus muscle, a muscle engaged for ►lateral gaze deviations). Similarly, VMLB neurons ramify extensively within regions of the oculomotor complex housing MNs with vertical pulling directions. For the eyes to move conjugately, which is the case for saccades, synergistic muscles of the two eyes should be activated simultaneously and by roughly the same amount (an expectation known as ►Hering's law of equal innervation [5]). To implement Hering's law, axonal terminations of single VMLB neurons contact motoneurons innervating yoked muscles of both eyes [6]. In the horizontal system, Hering's law is implemented through an additional class of neurons, the abducens ►internuclear ones [7]. The axons of these neurons travel with the ►medial longitudinal fasciculus (MLF) and their interruption causes the syndrome of ►internuclear ophthalmoplegia. In addition to the coactivation of MNs innervating synergist muscles of both eyes, extraocular MNs supplying antagonist muscles are inactivated during saccades (Descartes' principle). For example, activation of abducens MNs in one side of the brain is accompanied by inhibition of the contralateral abducens MNs as well as disfacilitation of ipsilateral medial rectus (MR) MNs (these innervate the MR muscle of the ipsilateral eye). Both are mediated by projections of ►inhibitory burst neurons (IBNs) to the contralateral abducens nucleus [8].

Not all MLB neurons deploy axonal terminations appropriate for influencing extraocular motoneurons. For example, the interstitial nucleus of Cajal (NIC) contains cells whose bursts of discharge are identical to those of downward premotoneuronal MLBs [9]. However, instead of supplying the oculomotor nucleus, their terminal fields overly the riMLF, i.e., a nucleus housing VMLBs and other burst neurons. Such neurons are better suited for conveying corollary discharges through the feedback paths of a BG configured as a ►local feedback loop controller. LLB neurons also vary a lot in terms of projections, discharge pattern and function. Some, such as the ►pontopontine long-lead burst ►(PPLLB) neurons, are likely to embody the front stage of the BG thus receiving presaccadic commands from the superior colliculus (SC) as well as feedback from the MLBs. Other LLB neurons, such as the ►burster-driving neurons (BDNs), are probably involved in the generation of vestibular quick phases. ►"Trigger" neurons, i.e., interneurons mediating higher order commands to initiate saccades, and ►"latch" neurons, i.e., interneurons inverting the sign of MLB discharges to prevent ►omnipause neurons (OPNs) from firing during saccades, may also belong to the LLB class. Not all neurons of the BG burst for saccades. Instead, some pause for saccades in all directions and are for this reason called omnipause neurons (OPNs). Coupling orthogonal (vertical and horizontal) burst generators through OPNs can help coordinate them so that the vertical and horizontal components of oblique saccades have roughly similar duration despite their dissimilar size thus giving rise to oblique saccades with fairly straight trajectories [10].

In addition to the phasic eye displacement signals produced by the BG, extraocular MNs are supplied with tonic signals proportional to eye position. The latter are generated from the former through a process akin to mathematical integration; because it is less than perfect it is referred to as ►leaky integration. The medial vestibular nucleus and the nucleus prepositus hypoglossi are thought to house the ►horizontal neural integrators (HNI) while the interstitial nucleus of Cajal is thought to house the ►vertical neural integrators (VNI). Other oculomotor subsystems, such as those responsible for the VOR, the OKN and the smooth pursuit eye movements, also rely on the neural integrators to function properly [11]. Again contrary to expectations based on position control theories, the discharge of most of the neurons that comprise the vertical and horizontal neural integrators does not reflect the position of the eyes alone. Instead, their discharge resembles that of the extraocular motoneurons they contact and justifies the use of the term burst-tonic (BT) neurons when referring to such cells as well. Intrinsic cellular membrane properties, synaptic mechanisms and network properties could in principle account for the fact that the time constant of the neural integrator (30 s; estimated from the time course of ►ocular drifts in the dark) is more than three orders of magnitude higher than that of single neurons (about 5 ms). A second device with roughly similar impulse responses, known as the "►velocity storage integrator," is also employed by the rotatory VOR to extend the dynamics of its afferent input into the low frequency range.

The ►superior colliculus (SC) is a layered midbrain structure that computes the amplitude and direction of desired saccades and relays appropriate commands to the burst generators. It also plays a crucial role in ►sensorimotor integration in the sense that sensory signals about target location must also be taken into consideration before the requisite motor commands can be issued [12]. The superficial layers of the SC contain a map of visual space while its deeper layers contain additional ►sensory maps as well as a ►motor map of oculomotor space. These are embodied by partially overlapping classes of cells, several of which can be distinguished in the primate SC. The best studied are the ►saccade related burst neurons (in short ►SRBNs), which are characterized by low levels of spontaneous activity and high frequency bursts which they emit shortly before (about 20 ms on the average) saccades of the appropriate amplitude and direction [13]. The SC also contains ►buildup neurons (in short ►BUNs) whose activity increases about 80–100 ms before saccade onset, reaches a peak value preceding saccades by 10–20 ms, and then wanes (discovered by Sparks and his colleagues [14]). Other deeper layer neurons, called ►Visually Triggered Movement cells (VTMs), emit discrete bursts in response to visual stimuli and before saccades to the same stimuli, but not before spontaneous saccades of the same metrics [15]. Each of these neurons discharge only before saccades having a relatively narrow range of sizes and directions, which defines an area known as the cell's ►movement field. Optimal saccades are measured from initial eye position, and not in a frame of reference centered in the head, so the SC works in an ►oculocentric frame of reference. Movement fields are arranged in an orderly topographic map of the SC. Cells discharging for upward saccades are located medially and cells discharging for downward saccades are located laterally while cells preferring small saccades are located more rostrally than cells preferring bigger saccades. It is for this reason that the SC can be thought to use a ►place code to implement the motor map it contains. A particular class of SC presaccadic neurons, the ►tectal long lead burst neurons (►TLLBs), have been characterized both functionally and morphologically [16]. Their axons are responsible, at least in part, for conveying command signals from the SC to the burst generators. To determine saccade size, the strength of these projections to the horizontal and vertical BG increases linearly with the size of the saccades coded by the region they originate from [17]. TLLBs also deploy a rich plexus of recurrent connections which may be instrumental in determining the intensity of discharge and the spread of TLLBs engaged for particular saccades [18]. Another crucial aspect of TLLB physiology is the strong and tonic inhibitory input they receive from the ►basal ganglia, in particular the pars reticulata of the ►substantia nigra. This is relaxed for saccades due to the inhibitory input nigral neurons receive from the ►caudate nucleus.

The input to the saccadic system is retinal error (i.e., the distance of visual targets from the fovea). This is represented in the superficial layers of the SC, retinotopically, in terms of the location of active cells in a neural map of visual space. To account for the subsequent activation of the appropriate presaccadic cells in the deeper SC layers, an early hypothesis of tectal function, the "►foveation hypothesis" [19], invoked the spread of excitation from superficially located visual neurons to underlying presaccadic cells. Because the visual receptive fields of superficial SC cells are aligned with the movement fields of deeper SC cells, flow of information from the superficial to the deeper SC layers would enable the eyes to move accurately and foveate the target. Consistent with the "foveation hypothesis," axons originating from a particular class of superficial SC cells, the L neurons (►interlayer neurons), deploy dense terminal fields in the deeper layers of the primate SC [20]. The ability to make accurate saccades toward targets briefly flashed before the onset of a saccade to a previous target (►double-step saccade paradigm) or elicited in response to the electrical stimulation of the SC demonstrates that the "foveation" hypothesis was too simplistic. An alternative, the "vector subtraction" hypothesis [16], assumes that a neural replica of the eye displacement due to the first saccade is fed back to the SC where it is subtracted from the retinal error vector that signals the location of the second target. The vector that results from this subtraction (represented by a new focus of excitation in the deeper tectal layers) drives the burst generators in a way that produces the correct saccade [18]. Additionally, the "vector subtraction" hypothesis provides an explanation for the response properties of two more classes of neurons. Firstly, it explains the discharge of ►Quasi-visual (Qv) neurons [21] for targets initially presented outside their receptive field and extinguished before saccades such that their location is encompassed by the cell's receptive field. The corollary discharges needed to account for the discharge of Qv neurons are carried by the ►Reticulo-Tectal Long Lead Burst (RTLLB) neurons of the ►central mesencephalic reticular formation [16].

Besides determining saccade metrics, the deeper layers of the SC are also involved in ►eye-head coordination in part due to the ►tectoreticulospinal neurons (TRSNs) they contain [22]. The response properties of TRSNs are more complex than those of primate SRBNs in that they display multisensory

convergence, and their bursts are non-obligatorily coupled to saccades. Their projections also target widespread midbrain and rhombencephalic areas. Together with ►reticulospinal long-lead burst (RSLLB) neurons [23] and eye-neck reticulospinal neurons [24] they could cause the fairly widespread facilitation of premotor extracollicular circuits needed to reorient the body, the head and the eyes toward a crudely defined region of space (►orienting reflex). In this manner, body and ►head movements are coordinated with saccades and the VOR to generate shifts of the line of sight (►gaze shifts).

►Precerebellar long-lead burst (PCbLLBs) ►neurons convey to the ►cerebellum saccade related signals originating in the SC and other higher structures [23]. Similarly, mossy fibers arising from several brainstem nuclei (including the dorsolateral pontine, the reticular pontine tegmental and the vestibular ones) supply it with smooth pursuit related signals. Electrical stimulation of the ►cerebellum, in particular lobules VI and VII of the vermis, has been long known to elicit saccades [25]. The saccade related discharges of neurons located in the ►oculomotor vermis influence the contralateral BG in the brain stem through the caudal part of the fastigial nucleus (the ►fastigial oculomotor region) as well as parts of the interpositus and dentate nuclei [26,27]. Both the oculomotor vermis and the fastigial oculomotor region participate in the control of smooth pursuit eye movements, as well [28,29]. At least two more cerebellar regions are also involved in the control of smooth pursuit eye movements: the ►flocculus, which also participates in the modulation of the gain of the VOR (►VOR adaptation) possibly through its projection to ►flocculus target neurons, and the ventral paraflocculus. Both areas contain Purkinje cells discharging for horizontal eye velocity during smooth pursuit and for horizontal head velocity during VOR cancellation (i.e., when the subjects' eyes follow a target moving with the head). Because eye and head velocity signals are roughly equal, and almost cancel each other during VOR in the dark, these neurons are thought to encode the horizontal angular velocity of gaze in space (►horizontal-gaze-velocity Purkinje cells). Purkinje cells with preferred directions other than horizontal can also be found in these regions. Given the variety of oculomotor related signals encoded by cerebellar neurons and the variety of ocular movements evoked in response to the electrical stimulation of several distinct cerebellar regions, it is reasonable to expect that cerebellectomy would cause a variety of oculomotor deficits. These include partial neural integrator failure and impairment of smooth pursuit eye movements [30] as well as ►saccadic dysmetria [31] and disruption of ►saccadic adaptation and VOR adaptation [32].

The neocortex contains several areas participating in the control of ocular movements. One of the best studied is the ►frontal eye field (FEF; [33]), in and near the arcuate sulcus (AS). It contains cells discharging briskly before saccades [34] and its electrical stimulation evokes contraversive saccades [35]. Neighboring subregions of the arcuate sulcus are devoted to the control of eye movements other than saccades. For example, the ►frontal pursuit area is a small region in the depths of the arcuate fissure, sandwiched between the small saccade area of the FEF and the somatic premotor cortex; its electrical stimulation evokes smooth pursuit eye movements and it contains cells discharging for smooth pursuit eye movements. Another subregion, located more rostrally in the prearcuate convexity, contains cells active during the vergent, divergent and accommodative movements accompanying near or far viewing and its electrical stimulation induces convergence and ocular accommodation [36]. Also, a small part of the fundus of the AS near its genu corresponds to a ►fixation zone. The notion that the primate FEF participates in the ►fixation system is supported by the fact that its removal interferes with ►visual fixation and the fact that it contains neurons which discharge tonically while gaze is held stable toward a ►fixation point and pause for saccades (►fixation neurons). Other frontal lobe saccade related areas include the ►supplementary eye field in the dorsal premotor cortex, the principal and periprincipal cortex and the ►anterior cingulate. Finally, regions of the parietal and temporal cortex are also important for the higher order control of ocular movements. The ►parietal eye fields, including the ►lateral intraparietal area (►LIP) in the lateral bank of the intraparietal sulcus, contain saccade related neurons and their lesion causes ►ocular apraxia. Areas in and around the superior temporal sulcus (STS), such as the middle temporal (MT), the medial superior temporal (MST), are also activated for saccades and their lesion impairs smooth pursuit eye movements [37].

## Definition

The term imprinting, derived from Oskar Heinroth and Konrad Lorenz, defines rapid learning events with remarkably stable and long-lasting behavioral outcomes, which occur during specific time windows or sensitive periods in newborn and juvenile vertebrates. The term imprinting is used not only by ►ethologists, but also in more recent literature by psychologists and clinicians in a broader sense, implying a particular ►aetiology of adult behaviors in both animals and human beings. Darwin, who showed great interest in child development, including infancy learning, was one of the first scientists who tried to link child psychology and animal behavior. He thereby prepared the ground for the study of the interplay of instinct and early learning, soon to be taken up by Spalding, and later, in different ways, by both Freud and the ethologists. D. A. Spalding published in 1873 a paper entitled "Instinct, with Original Observations on Young Animals," in which he described the behavior of young domestic chicks. He observed that these animals' ability to recognize the parents is not instinctive, but is in fact learned. Spalding also reported that this learning was confined to a short period soon after hatching, and we now say that during such a critical or sensitive period a chick becomes imprinted to the mother-figure when it learns her characteristics, and forms an emotional bond to her. Heinroth described this type of ►attachment-behavior by the verb "einprägen," corresponding to the English "to stamp in" or "to imprint"; and the word "stamped in" had earlier been used by, among others, Spalding and Thorndike in relation to firmly acquired modes of behavior. Lorenz used the noun Prägung, or imprinting, in his seminal paper in 1935, to refer to the process of rapid bound-formation early in the life of the so-called ►nidifugous birds (e.g., fowl). Accordingly, imprinting occurs when an animal learns to recognize a stimulus that will later release instinctive behavior. For example, a gosling follows the first moving object it sees after hatching. The young goose "recognizes" the moving object as its parent and it later "recognizes" similar objects as members of its own species. Lorenz went further than Spalding in that he claimed that imprinting differed fundamentally from, what he called, ordinary learning, because of its restriction to a brief critical period in the individual's life, its rapid occurrence, and its irreversibility. It was later questioned whether these features would separate imprinting sharply from other forms of learning, and the modern view of imprinting is that it might be continuous with, or be a form of, ►conditioning.

Imprinting can be considered to be an evolutionary old concept of juvenile learning, which is critical for the survival and fitness of the offspring and which occurs in many species including man. Imprinting entails much more plastic mechanisms than were claimed by Lorenz, thus, imprinting is a phenomenon that is of great interest to ontogenetic studies of animal behavior and it has important implications for human developmental psychology and psychopathology. Imprinting is an important aspect of early learning not only in birds but also in ►precocial mammals (e.g., guinea pigs, ►degus, sheep, horses, etc.), and it also plays an important part in the socialization of ►altricial species (e.g., dogs or monkeys) including human and non-human primates. Newborn zebra foals follow any object near to them during the first few days of life, and because of this their mothers show aggressive behavior towards any other zebras that come too close. Many animals, e.g., giraffes, give birth to their young in isolation away from other family members to prevent the newborn from confusing them with its mother, and they only return to the family unit when imprinting has taken place, which usually occurs after three days. Animals can also imprint on humans, and this could be one of the reasons why many captive animals in zoos fail to breed, and similarly, cross fostering in the wild can also lead to fostered animals failing to breed. It appears likely that this failure is due to "faulty" sexual imprinting, i.e., another form of juvenile learning during which the preference of a mate later in life is determined. The sensitive period for sexual imprinting is dependent on the species and lifespan of the animal. Lions, for example, live in prides and form their sexual preference through community bonding over an extended period of time, whereas an animal with a shorter life span, such as insects, need to find a mate quickly and therefore have a shorter sensitive period for sexual imprinting. A third example of imprinting is vocal learning in songbirds (see essay by M. Gahr), and, at least in part, speech learning in humans. The critical period hypothesis of language acquisition claims that a sensitive period exists from birth to puberty, and that during this time window the brain is receptive to language, and is learning rules of grammar quickly. After puberty, language learning becomes more difficult, which is attributed to a drastic change in the way the brain processes language after puberty. The common feature of all forms of imprinting is that "templates" or "concepts" about the species, vocal repertoire/language or behavioral strategies are shaped during early life periods, which are incorporated into adult behaviors.

## Characteristics

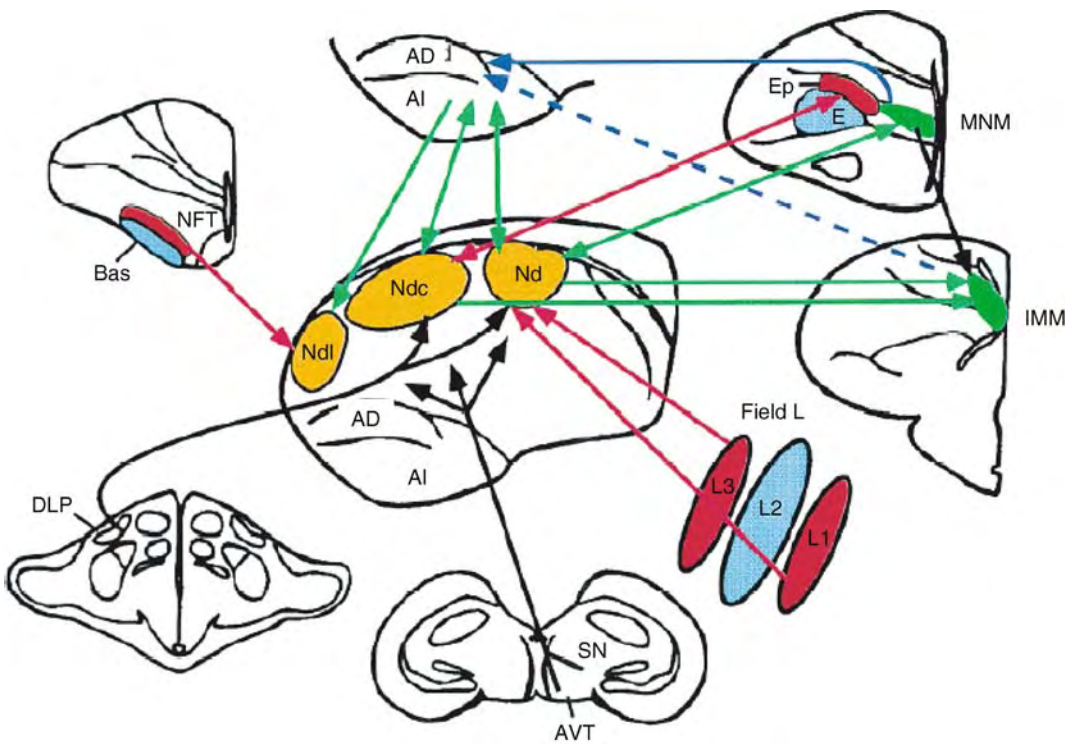
### Higher Level Structure

The brain circuits that are involved in filial imprinting (compare Fig. 1) include the forebrain structures medio-rostral nidopallium/mesopallium MNM (according to the old nomenclature this area was formerly termed medio-rostral neostriatum/hyperstriatum ventrale, MNH), i.e., the homologue of the vocal motor nucleus medialis magnocellularis nidopallii anterioris, MMAN (formerly termed medial nucleus of the anterior neostriatum) and the presumed avian analogue of the mammalian prefrontal cortex/cingulate cortex [1] as well as the intermediate medial mesopallium IMM (which in the old avian nomenclature was termed intermediate hyperstriatum ventrale IMHV), and the nidopallium dorsocaudale Ndc (which in the old nomenclature was the dorsocaudal neostriatum Ndc), i.e., the presumed avian analogue of the mammalian polysensory association cortex [1].

This brain pathway can be considered to represent the avian analogue of the mammalian ►limbic system, which not only plays a critical role in filial imprinting in the young, but which is also the essential pathway for the regulation of emotional behavior, and in learning and memory formation in the adult.

### Lower Level Structure

Whereas the basic wiring diagram of the brain is genetically pre-programmed, its fine tuning throughout different phases of infancy, childhood, and adulthood is highly experience dependent. Normal brain development requires the precise interactions of environmental signals with genes and molecules that drive cellular differentiation and circuit formation. Imprinting, i.e., juvenile learning is "used" to fine tune functional pathways, e.g., sensory, motor as well as limbic circuits, in the brain. This view is supported by experimental studies that have demonstrated that filial imprinting, and most likely also song imprinting, results in the "pre-formatting" of functional brain circuits and thereby determines the behavioral outcome in later life. Whereas during song imprinting a relatively precise



**Neural Correlates of Imprinting. Figure 1** Schematic diagram of the brain circuits for filial imprinting in birds including the regions for sensory processing. Modified after Metzger et al 1989 J. Comp. Neurol. 395: 380–404. The belt regions (red) of primary sensory areas (light blue) send projections (red arrows) to distinct areas (light brown) of the dorsocaudal nidopallial complex (dNC) complex. From there, information is conveyed (green arrows) either to the arcopallium intermedium (AI) or to the medio-rostral nidopallium/mesopallium MNM; (green) and the intermediate medial mesopallium IMM; (green). The MNM and IMM project to the AId (blue arrows). Black arrows indicate other major pathways defined in the present study. Note that minor reciprocal connections between the MNM and nidopallium dorsocaudale Ndc are not included here. The dashed blue arrow from the IMM to the archistriatum intermedium, pars dorsale (Aid) indicates a projection defined by Csillag et al. (1994) J Comp Neurol 348:394.

acoustic template is stored, the long-term consequence of filial imprinting, for example, is not so much to form memories for specific details of the imprinting object, the mother, but to establish the "grammar" of social, emotional and cognitive behavioral strategies. On the "hardware" side, imprinting could be viewed as formatting the harddrive, if we compare the brain with a computer, and this will determine its capacity to operate the "software" i.e., behavioral strategies, cognitive and emotional concepts etc. later in life. In fact, there is considerable experimental evidence from a variety of studies on filial imprinting and song learning (cp also essay by M. Gahr) in support of this view, which have shown that such juvenile learning events are accompanied by massive molecular-genetic, neurochemical, physiological and structural changes of neurons and their synaptic circuits.

## Structural Regulation

Imprinting is a rapid, efficient and rather stable form of learning that occurs in a more or less immature brain, i.e., in a brain that is still growing. The characteristic features of imprinting (speed and stability) might be explained by the fact that it occurs during developmentally "critical" or sensitive time windows of elevated cellular plasticity. Thus, imprinting takes advantage of the entire spectrum of the molecular, genetic and metabolic cellular cascades, which are highly activated during early postnatal brain development. For visual imprinting, a "time course" of a variety of changes have been described in the chick forebrain region intermediate medial mesopallium, IMM, the earliest changes involve the induction of the ►immediate early gene c-fos, followed by changes in ►phosphorylation of the ►protein kinase C substrate MARCKS, morphological changes in ►axospinous synapses, an increase in ►NMDA receptor number and increases in neural ►cell adhesion molecules [2]. The initial phase of acoustic imprinting is characterized by the activation of the immediate early genes and ►transcription factors zenk and arg3.1 in the chick forebrain regions MNM and the IMM [3]. Quite comparably, during the initial phase of sexual imprinting in male zebra finches, i.e., the first exposure to a female after an isolation period, enhanced zenk expression was measured in a variety of brain areas including lateral nidopallium/mesopallium (formerly termed lateral neostriatum/hyperstriatum LNH), MNM, and the optic tectum. At later stages of acoustic imprinting, an enhanced release of ►glutamate in response to the learned acoustic imprinting stimulus has been observed in the MNM of domestic chicks, which is paralleled by an increased neuronal activation during the presentation of the acoustic imprinting stimulus [4]. Similarly enhanced neuronal responses have been reported in the IMM after visual imprinting [2]. Results from in vivo ►microdialysis experiments in domestic chicks suggest that the emotional bond that develops through auditory imprinting entails an addictive process, which is mediated by the release of ►endorphins and altered ►dopamine and ►serotonin release [5]. Functional imaging revealed elevated metabolic activation in the MNM and Ndc areas of successfully imprinted domestic and guinea chicks in response to the acoustic imprinting stimulus [6]. Quite similarly, young rodents display activations in the anterior cingulate cortex in response to the presentation of the learned acoustic stimulus (maternal vocalizations). Such stimulus-evoked neuronal responses, which occur during filial imprinting, in particular those mediated via the glutamatergic NMDA receptor, appear to trigger the long-term structural changes. There is convincing evidence from several series of experimental studies that acoustic imprinting is linked to a synaptic selection process [7] that serves the fine-tuning of limbic circuits. Successfully imprinted chicks, but not chicks that have been passively, i.e., without the chance to form an association, exposed to the identical acoustic stimulus, display reduced densities of excitatory ►spine synapses in higher associative brain regions (MNM, Ndc) compared to naïve, "Kaspar-Hauser" control animals. Interestingly, during sexual imprinting in zebra finches similar metabolic changes, activations of immediate early genes and reductions of dendritic spines were reported in the MNM and Ndc, and the vocal motor nucleus MMAN of zebra finches undergoes successive pruning of spine synapses during song imprinting [8]. Thus, in contrast to the adult brain, where primarily increased numbers of synaptic connections have been reported after learning [7], imprinting appears to leave its "footprints" within the juvenile brain mainly by using the opposite plasticity mechanism, namely the pruning of synapses. These imprinting-induced synaptic changes may be compared to a sculptor, who creates a statue by removing material from an unshaped marble block, and it may reflect the formatting of the "harddrive." In particular, the long-term structural changes may explain the speed and stability of the memory for a learned imprinting object, stimulus or behavioral strategy.

## Function

All animals perform both instinctive actions and learned actions. Instinct almost completely determines the behavior of most insects, spiders, and crustaceans. These animals can learn comparably little, and therefore their survival depends mainly on innate behavioral patterns. Higher animals, including fish, amphibians, reptiles, birds, and mammals can learn more, and they can also modify their instinctive behavior by learning. The primary function of imprinting is to enable the young animal to shape and adapt its behavior, and to optimize the underlying brain circuits (in particular

the limbic system) for the behavioral output within its environment.

### Pathology

The most fascinating aspect of imprinting is the timely establishment of a particular preference over the course of the animal's development, which is particularly evident in primates, including humans, where "critical periods" develop from neonatal to early childhood, through juvenile to adulthood. For instance, monkeys who are reared separately from all other monkeys will not develop normal social or sexual behavior if, after reaching adulthood, they are placed with other monkeys. As pointed out earlier, brain development requires adequate sensory and also emotional stimulation, provided during filial imprinting, to develop and maintain synaptic connections and to fine tune synaptic circuits. Functional imaging in young rodents revealed that acute separation from the parents induces a massive downregulation of brain metabolism in most limbic regions as well as in sensory and polysensory cortices, whereas the presentation of a learned acoustic imprinting stimulus (the mother's voice) induces metabolic activation in the limbic cortex [9] (Braun and Scheich 1997). Long-term consequences of repeated separation from the parents (causing the disruption of the imprinting process?), chronic social isolation and early weaning are changes of excitatory as well as monoaminergic modulatory synaptic inputs in cortical and subcortical limbic areas. In the rodent anterior cingulate cortex, orbitofrontal cortex, hippocampus, and amygdala region-, cell-, and dendrite-specific changes of synaptic densities [10] have been found in parentally deprived animals. These observations confirm that the prevention or disruption of filial imprinting can affect synaptic development in the prefrontal cortex and other limbic areas. Since the limbic system is critical for a variety of emotional behaviors and associative aspects of learning, such experience-induced morphological changes may lead to altered behavioral and cognitive capacities in later life.

### Therapy

Animal studies unveiled the remarkable influence of the parent-infant contact (and most likely also other imprinting-like juvenile learning events) on brain development, in particular on the functional maturation of the limbic pathway. Therefore, learning early in life has always been of great interest on the one hand to all involved in child care and education, but also with indoctrination, and on the other hand to clinical research in child and adult psychiatry, where imprinting also fits into Freud's and other's conception of the aetiology of neurotic symptoms and other mental disorders. The detailed knowledge of the neurobiology of such self-organizing plastic systems may begin to change our conceptual approaches to psychopathology, and open new avenues of therapeutics for the major psychiatric illnesses that are critically dependent on such learning and memory mechanisms. Furthermore, the knowledge of the basic principles of learning- and memory-related neuronal plasticity may in the future be applied to innovative educational concepts for the preschool/elementary school levels.

# Neural Crest

### Definition

The neural crest is derived from embryonic ectoderm. It is located in the small space between the dorsolateral part of the neural tube and the overlying ectoderm,

extending from the diencephalon to the tail. Cells of the neural crest give rise to glial cells, neurons of sensory, sympathetic, and parasympathetic ganglia, chromaffin cells, and melanocytes.

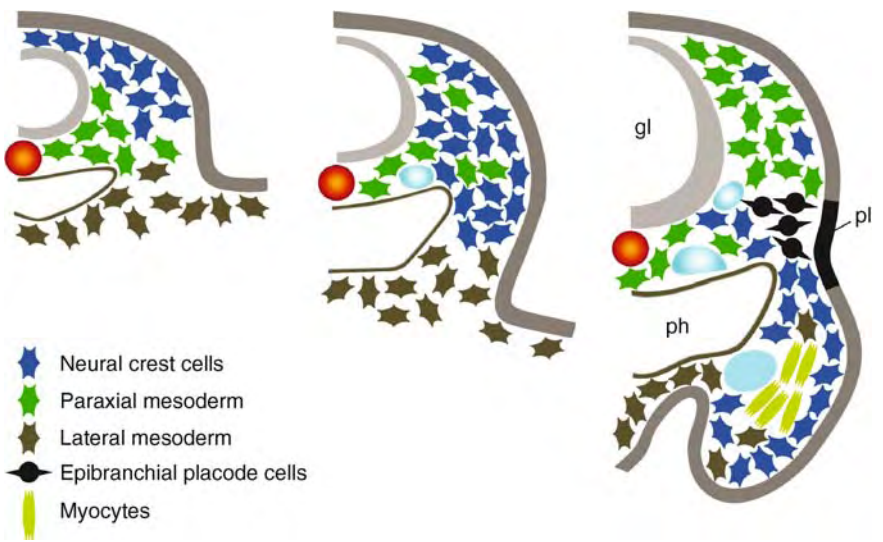
## Definition

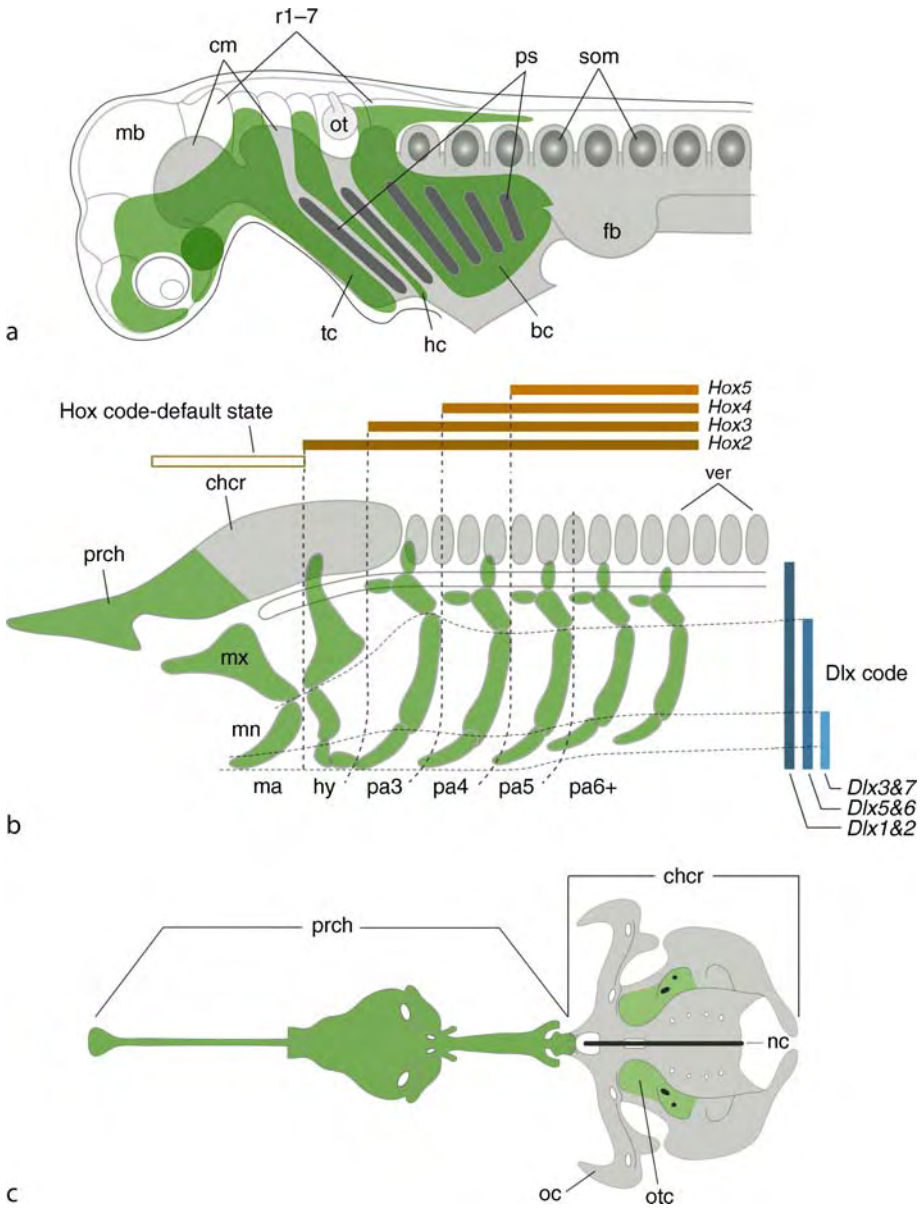
An epithelial neural ridge developing on either side of the neural plate of the early vertebrate embryo. The crest is secondarily de-epithelialized becoming migratory mesenchymal cells called "neural crest cells" (Fig. 1). These move in a stereotypical manner within the embryo following certain specific migratory pathways to be distributed in various locations within the embryo and differentiate into various cell and tissue types, including peripheral neurons, supporting tissues of the peripheral nervous system and some skeletal muscles, endocrinal cells (or many of the cell types belonging to the category of "paraneurons"), pigment cells, smooth muscle cells associated with arteries, cartilage and bones.

## Characteristics

Embryonic environments are crucial for the differentiation of the crest cells. Skeletogenic differentiation especially, is specific to the neural crest cells in the region ranging from the head to the neck [2]. Here the cells form an extensive mesenchyme, often called "ectomesenchyme" (meaning the "mesenchyme" derived from the ectoderm; Fig. 1). Thus the neural crest is generally divided into "cephalic" and "trunk" neural crest, depending on the differences in migration pathway, distribution pattern and repertoire of differentiating cell types. The boundary between these two categories, is not clear. Between these two regions, a third population of crest cells, called "vagal crest," has been inferred, corresponding to the region of the neural crest that gives rise to enteric neurons [2]. This part also includes the crest that contributes to the septation of the outflow tract of the amniote heart primordia and is thus alternatively called the "cardiac crest" [3].



**Neural Crest and the Craniofacial Development. Figure 1** Schematic representation of three successive stages of neural crest migration in the head of chicken embryo. The neural crest cells (*blue*) migrate laterally and ventrally from the dorsal aspect of the neural tube to the pharyngeal arch to form an extensive ectomesenchyme. The pharyngeal arch ectomesenchyme will later differentiate into branchial arch skeletons. Note that during crest cell migration, cephalic paraxial mesoderm (*green*) barely changes its position. Also note that there is another group of cells derived from the ectoderm (epibranchial placodes). The placode-derived cells and neural crest cells together form a cranial sensory ganglion. Based on [1].



**Neural Crest and the Craniofacial Development. Figure 2** Ectomesenchyme in the gnathostome pharyngula, and craniofacial development in the vertebrate head. (a) Schematized model based on a shark embryo. Cephalic crest cells (green) form three distinct cell populations called, from anterior to posterior, the trigeminal crest- (*tc*), hyoid crest- (*hc*) and branchial crest- (*bc*) cells. These cells are located laterally to the cephalic mesoderm (*cm*), proximally attached onto even-numbered rhombomeres (r1–7), separated distally by pharyngeal slits (*ps*) to be distributed in each pharyngeal arch. (b) Generalized vertebrate chondrocranium based on the morphology of a sturgeon larva. Putative mesodermal derivatives are colored *gray*, and crest-derivatives *green*. The chondrocranium consists of dual anatomical components, the dorsal neurocranium and the ventral viscerocranium (pharyngeal arch skeletons). The neurocranium is further divided anteroposteriorly into the crest-derived prechordal (*prch*) and mesodermal chordal (*chcr*) parts. Position-dependent specification of the arch skeleton is based on the Cartesian grid of homeobox gene expression domains, consisting of Hox code along the anteroposterior axis and Dlx code along the dorsoventral axis. Note that the mandibular arch is patterned by the absence of Hox transcripts. (c) Mesenchymal origin of chicken chondrocranium. The scheme *B* is largely based on this mapping performed by Couly et al [6]. Abbreviations: *fb*, fin bud; *mb*, midbrain; *nc*, notochord; *oc*, orbital cartilage; *ot*, otocyst; *otc*, otic capsule; *som*, somites; *ver*, primordial vertebrae.

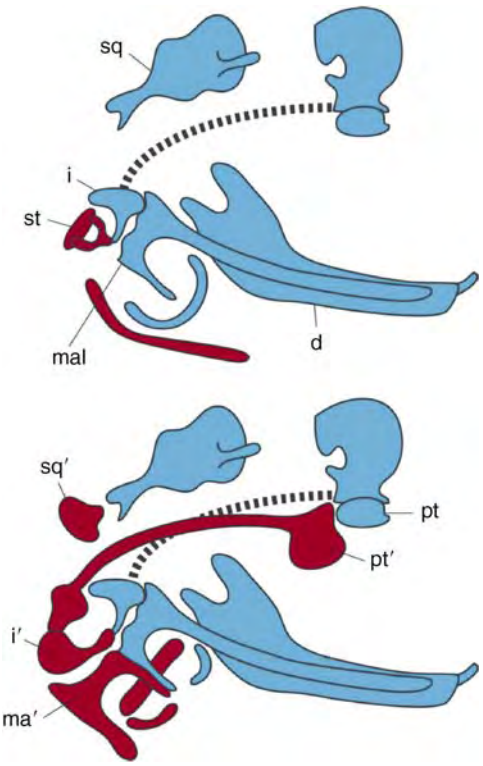
The pluripotency of the crest cells as well as their highly sophisticated morphogenetic capability are defining features of the neural crest. Although non-vertebrate chordates, including amphioxus and tunicates, share the same basic body plan as vertebrates, for example the notochord and the dorsal neural tube, they do not appear to possess the neural crest or crest-derivatives. In this context, the origin of the neural crest has recently drawn the interest of biologists investigating the evolutionary origin of vertebrates. Vertebrates are characterized by the possession of an overt head with well-developed sensory organs, brain and cranium, associated with vertebrate-specific cell lineages derived from neural crest and ►placodes (both sensory and ganglionic, Fig. 1). The theory of "New Head" by Gans and Northcutt [4] regards the acquisition of placodes and the neural crest as a key innovation that has permitted the development of the vertebrate head. The most recent study, however, has implied the presence of crest-like cells in tunicate larva, although this animal does not develop an extensive ectomesenchyme that characterizes the true vertebrates [5]. Consequently the evolutionary relationship may not be so simple.

Crest-derived cephalic ectomesenchyme is predominantly found in the ventral portion of the head, subdivided into ►pharyngeal arches [1] (Fig. 2a).

This mesenchyme will differentiate into skeletal and connective tissues, that is, the craniofacial and branchial arch skeletal elements, whether they are bones or cartilages, are all of neural crest origin (Fig. 2b). The rostral part of the ►neurocranium is also of crest origin, unlike the more caudal part that is derived from the cephalic mesoderm and somites [6] (Fig. 2c). There still remain controversies as to the origin of the dermal calvarium and there is a possibility that these dermal bones may have different origins of cell lineages regardless of their morphological homology. Nevertheless, the rostral elements such as the amniote frontal and nasal bones are unanimously thought to have a crest origin.

The crest-derived vertebrate cranial skeleton offers a model for the understanding of the morphological specification of the skeletal system, both in development and evolution. Of particular interest is the developmental mechanism that provides positional values to each part of the ectomesenchyme through the spatially organized expression of homeobox genes. One well-known example is the Hox code, the nested pattern of *Hox* gene expression along the anterior–posterior axis of the head. In the pharyngula embryo, no *Hox* genes are expressed in the rostral part of the head including the mandibular arch, *Hox2* genes are expressed in the second (hyoid) and more posterior arches, *Hox3* genes in arch 3 and posteriorly (Fig. 2b). *Hox* genes are tandemly assembled on the DNA as a cluster, with *Hox1* toward the 3′ end and *Hox13* toward the 5′ ends of the cluster. Thus the order of the *Hox* genes roughly coincides with the axial levels of the embryo at which the genes are expressed (colinearity), giving an impression that the genome plays a role as a blueprint for embryonic development [7] (Fig. 2b).

Each *Hox* gene contains a domain called a "homeobox" encoding a DNA-binding protein that recognizes a specific DNA sequence. Thus the Hox proteins can act as a "switch" to regulate specific target genes and the Hox code provides positional values or "identity of pharyngeal arches" to the ectomesenchyme [7]. Consistent with this idea, disruption of *Hoxa-2*, the gene expressed in the hyoid arch, leads to the homeotic transformation of this arch into the identity of the



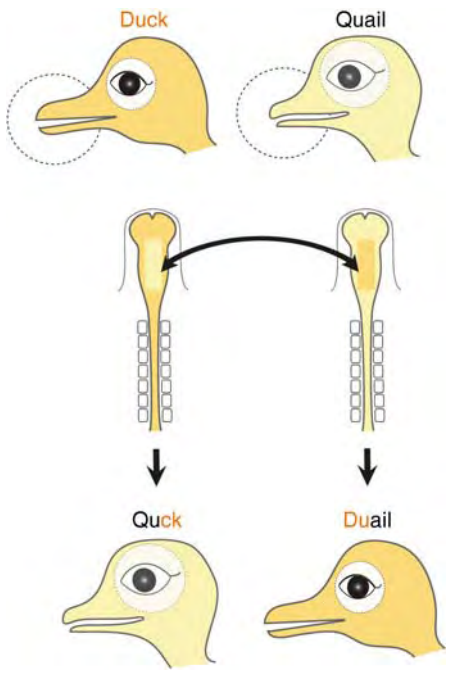
**Neural Crest and the Craniofacial Development.**
**Figure 3** Disruption of *Hoxa-2* in the mouse. *Top*. Wild type morphology. Mandibular arch-derivatives are colored *blue* and the hyoid arch-derivatives *red*. In the *Hoxa-2*-mutant mouse, the morphological identities of the hyoid arch derivatives are transformed into those of the mandibular, resulting in a mirror-image duplication of mandibular arch skeletons. Based on [8]. Abbreviations: *d*, dentary; *i*, incus; *mal*, malleus; *pt*, pterygoid; *sq*, squamosal; *st*, stapes.

N

mandibular, presumed to be a "Hox-code-default state" (Figs. 2b and 3) [8].

The Hox code appears to be conserved in all vertebrates. Even the invention of the jaw seems to have taken place in the mandibular arch based on the same basic code, since the lamprey also seems to have *Hox*-negative mandibular arch [9].

Nested expression of another set of homeobox containing genes, the Dlx code, has been recognized in the head ectomesenchyme of the mouse [10] (Fig. 2b). This code is thought to direct the dorsoventral pattern of each arch by the dorsoventrally nested expression of the *Dlx* genes. Specifically, *Dlx1* and *Dlx2* are expressed in the entire arch ectomesenchyme, *Dlx5* and *Dlx6* in the ventral half and *Dlx3* and *Dlx7* in the ventral tip. Thus the Cartesian grid pattern of homeobox gene expression as a whole is the basis of the skeletal patterning of the vertebrate head (Fig. 2b). To establish such a pattern, epithelial–mesenchymal interaction may play fundamental roles, since information on which skeletal identities the ectomesenchyme is to acquire is not necessarily predetermined in the premigratory crest, but appears to be instructed secondarily by the rostral endoderm of the embryo. The actual shape of the skeletal elements however may rather be obtained through downstream developmental pathways mainly exerted cell-autonomously in the crest cells themselves, since interspecific grafting of cephalic crest results in the host gaining the craniofacial morphology of the donor animal [1] (Fig. 4). The neural crest and its derivatives thus characterize most conspicuously the body plan of vertebrates and its evolution.



**Neural Crest and the Craniofacial Development. Figure 4** Species-specific shape of face? The cephalic neural crest was transplanted between embryos of quail and duck, birds with distinct faces. The cranial shape of the chimera resembles the donor of the crest more than that of the host. Based on [1].

# Neural Crest Cells

## Definition

Unique to vertebrates, these cells are derived from the edges of the folds of the neural plate. They migrate to different regions of the body and give rise to a wide variety of tissues, including autonomic and sensory nerves, pigment cells and some cartilage in the head.

## Neural Induction

The formation of the nervous system follows ►the body plan, which is composed of the definition of body axes and the allocation of each organ into the body. A portion of dorsal ectoderm is induced to become ►neural ectoderm. This region is called the ►neural plate, which gives rise to the ►neural tube. The tube is formed as the cells surrounding the neural plate. The neural plate cells proliferate, invaginate and pinch off from the surface to form a hollow tube.

The induction of the neural plate occurs owing to signals emanating from the mesoderm of the ►organizer region. In amphibians, the cells that develop in the region of the gray crescent, a light-colored band that appears opposite the point where the sperm enters, migrate into the embryo during gastrulation and form the ►notochord. By utilizing transplantation experiments, Spemann and Mangold demonstrated that this region is capable of inducing a nervous system and called this region as "organizer" [1].

Several molecules that act as antagonists against bone morphogenic protein (BMP) are involved in ►neural induction. These include ►noggin, ►chordin and ►follistatin. These molecules bind to BMP4 suppressing its activity as an inhibitor of neural fate. Fibroblast ►growth factor (Ffg)s also seems to be involved in neural development.

## Neural Tube Formation

### Regionalization

#### *Regionalization along the Rostrocaudal Axis*

►Regionalization of the neural tube is associated with changes in the shape of the neural tube. Early in development, the neural tube differentiates into three distinct regions along the rostocaudal axis: ►prosencephalon, ►mesencephalon and ►rhombencephalon. Caudal to the rhombencephalon, the ►spinal cord differentiates. As development proceeds, the prosencephalon is divided into the ►telencephalon and ►diencephalon, and the rhombencephalon into the ►metencephalon and ►myelencephalon. The telencephalon eventually differentiates into the ►cerebral cortex, ►hippocampus and ►basal ganglia, the diencephalon into the ►thalamus and ►hypothalamus, the metencephalon into the ►cerebellum and the ►pons, and the myelencephalon differentiates into the ►medulla oblongata.

The anteroposterior patterning of the neural tissue is dominated by the head organizer and tail organizer. The former includes FGFs, Wnts and retinoic acids, and the latter includes Cerberus, which inhibits the activity of BMPs, Wnts and nodal-related molecules by strongly binding to these molecules.

#### *Regionalization along the Dorsoventral Axis*

The ►differentiation of the neural tube along the dorsoventral axis also takes place concurrent with differentiation along the rostrocaudal axis. In the spinal cord, distinct types of neurons differentiate depending on the position along the dorsoventral axis: Motor neurons, for example, differentiate in the ventral spinal cord and commissural neurons that receive sensory inputs differentiate in the dorsal spinal cord. The differentiation of distinct cell types in the ventral neural tube is dependent on inductive signals derived from axial midline of the notochord and the ►floor plate. The signal is mediated by the secreted protein ►Sonic Hedgehog (Shh) [2]. Neurons generated in progressively more ventral positions are exposed to higher concentration of Shh, which is required for their development.

The differentiation of the dorsal neural tube is also dependent on inductive signals but derived from ectodermal cells; one of the responsible molecules is BMP. Another secreted molecule, Wnt, also appears to function as a dorsalizing signal. These signals and Shh antagonize one another, creating opposing gradients along the dorsoventral axis, which induces expression of different ►transcription factors, ►PAX6 and PAX7 dorsally, and Nkx2.2 ventrally, for example. Expression of a transcription factor or a combination of different transcription factors gives rise to distinct types of neurons along the dorsoventral axis [3].

#### *Secondary Induction from the Midbrain/hindbrain Boundary*

The boundary region between the midbrain and hindbrain, the isthmus, has an inducing activity and contributes to the differentiation of the cerebellum and the ►tectum [32,33]. Some brainstem nuclei such as the ►substantia nigra and ►locus coeruleus are also under the influence of molecules released from the ►isthmic organizer. This region expresses several transcription factors such as Pax2, Pax5, Engrailed1 and Engrailed 2, and secreted factors such as FGF8 and Wnt1, which are thought to contribute to the differentiation of the structures adjacent to the isthmus [3]. These molecules are distributed in a graded manner. This, in turn, contributes to the graded expression of guidance molecules in the tectum.

### Segmentation

#### *Segmentation in the Hindbrain*

The neural tube becomes segmented at some stage of the development. This is an important step for

the development of the central nervous system (CNS). The segmentation has been most extensively studied in the hindbrain. Developing hindbrain show 7–8 bulged structures called ►rhombomeres. Rhombomere boundaries are characterized by the expression of a paralogous set of ►Hox genes. Experiments such as the deletion and mis-expression of Hox genes indicate that these genes are involved in specification of rhombomeres. In each rhombomere, a unique set of motor neurons is generated, and these neurons project axons towards unique targets defined by their levels along the rostrocaudal axis. Similarly, sensory axons at different axial levels project to corresponding rhombomeres.

### *Forebrain*

Segmentation of the neural tube can also be seen in the forebrain region. For example, a transcription factor *emx1* is expressed in the anterior half of the forebrain and *emx2* in the posterior half. The expression pattern of additional genes allows to define six rostrocaudally aligned compartments, called ►prosomeres, in the forebrain region (Fig. 1).

### *Patterning of the Neocortex*

The cerebral cortex can be divided into functionally distinct areas such as the ►motor, sensory and visual cortex, which are differentially connected to subcortical structures. Cortical areas appear to be under the control of two transcriptional factors, *pax6* and *emx2*, which are distributed along the anteroposterior axis in a graded manner. The gradient of these genes appears to be regulated, in part, by *fgf8* [4].

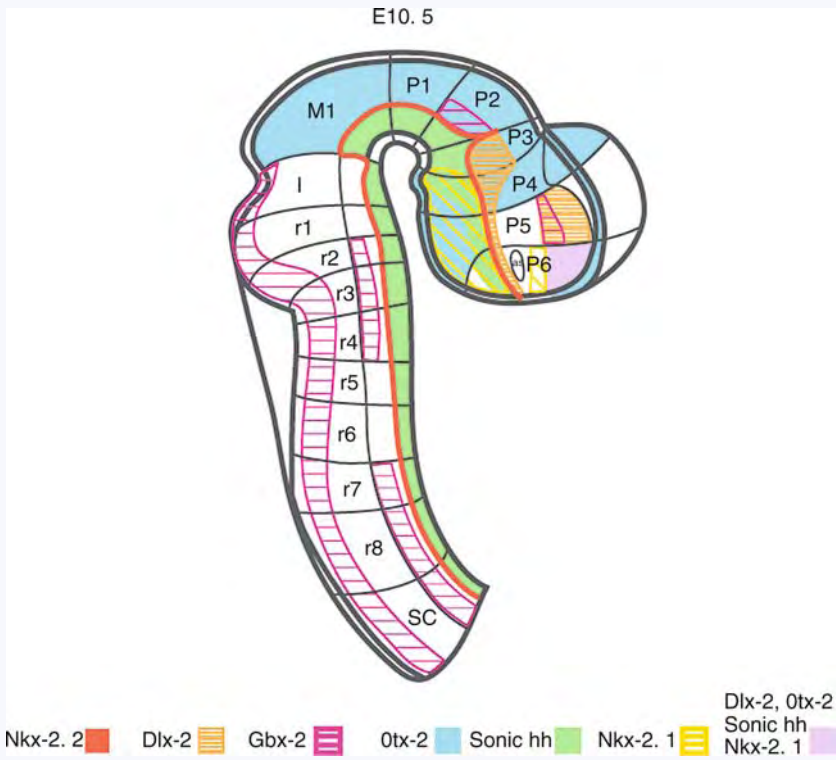
## Migration and Differentiaion of Neural Crest Cells

A specialized type of cells, called ►neural crest cells emerge from the dorsal-most region of the neural tube at the level of the hindbrain and the spinal cord. These cells migrate ventrally away from this region and differentiate into several types of neuronal and non-neuronal cells. This includes cells of the ►dorsal root ganglia, sensory ganglia of cranial nerves, ►sympathetic chain ganglia, pre-aortic ganglia, ►enteric ganglia, chromaffin cells of the adrenal medulla and melanocytes.

## Differentiation and Proliferation of Neurons

### Neurogenesis

►Neurogenesis takes place mostly during embryonic stages. Most neurons are generated from progenitors situated in the ventricular zone of the neural tube by symmetric and asymmetric divisions from progenitors, or multipotent neuroepithelial cells or neural stem cells. During the early stage of development, the cells in the



**Neural Development. Figure 1** Expression patterns of five transcription factors (Dlx-2, Gbx-2, Nkx-2.1, Nkx-2.2, Otx-2) and one morphogen (sonic hedgehog) in E10.5 mouse neural tube. I, isthmus; M, mesencephalon-midbrain; os, optic stalk; p, prosomere; r, rhombomere; sc, spinal cord (modified from [34]).

ventricular zone extend their process to the pial surface and the nuclei of these cell undergo specialized interkinetic movement, in which the position of the nuclei depends on the phase of ►cell cycle: the nuclei accumulate the ventricular surface during M phase, but in the superficial margin of the neuroepithelium during S phase. Studies of neurogenesis in the neocortex revealed that the subventricular zone is not only the site of ►gliogenesis but also a site of neurogenesis for late-born neurons.

## Neuronal Fate

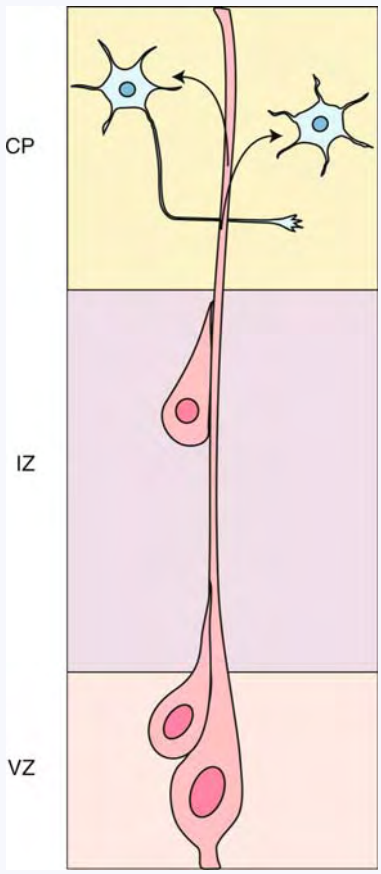
Neural stem cells can produce neural progenitors, neurons and glial cells, but the nervous system is composed of balanced numbers of neuronal and glial cells. There is evidence that secreted factors such as FGF2 and ►Neurotrophin3 promote neural fate, while ►ciliary neurotrophic factor (CNTF) and ►epidermal growth factor (EGF) promote the differentiation into astrocytes. For the generation of neural progenitors and their commitment to the neuronal fate, ►basic helix loop helix (bHLH)-type proneural genes play a pivotal role. These include factors that inhibit the neural differentiation, such as Hes, and neural differentiation promoting factors such as ►Mash1, ►Math1 and ►Neurogenin1. The expression of the latter is regulated by several factors such as ►Notch, which negatively regulates the neurogenesis, and BMP.

## Migration of Neurons

### *Mode of Migration*

When neurons become post-mitotic, the neurons must emigrate from the ependymal layer to their future (mature) place/layer/lamina/nucleus. The same is true for the cells from the neural crest, which must find their final (mature) destinations. Such changes in the location of neurons are called ►neuronal migration. Neuronal migration in the neural tube is categorized into two modes; one is radial migration and another is tangential migration: The former occurs in directions of radial glia and perpendicular to the ventricular and pial surfaces and the latter occurs tangential to the pial surface. In the CNS, neurons generated from neuroepithelial cells typically migrate radially (Fig. 2), although some neurons show ventricle-directed radial migration after tangentially traveling over a long distance. Radially migrating neurons are thought to use the process of radial glial cells as substrate and tangentially migrating neurons use axons of other neurons. However, neuronal migration occasionally occurs obliquely to either of these processes, indicating that migration of neurons does not necessarily require physically defined structures.

It is noteworthy that tangential migration of neurons often occurs underneath the pial surface. This would be quite advantageous for migrating neurons, because this region is not crowded by other cells and facilitates migration.



**Neural Development. Figure 2** Radial migration of neurons along radial glia and differentiation into postmitotic neuron. CP, cortical plate, IZ, intermediate zone, VZ, ventricular zone.

### *Significance of Migration*

Migration of neurons is required for the establishment of proper laminated structures such as the cerebral cortex, hippocampus and the cerebellum. In the ►pallium of the cerebral cortex, late-generated neurons migrate radially past early-generated neurons, giving rise to inside-out laminated structures of excitatory neurons. Inhibitory cortical neurons also form birthdate-dependent laminated structures, although the route of their migration to their final destinations appears to be more complicated than those of excitatory neurons. These neurons, which originate from ganglionic eminences in the basal forebrain, initially migrate tangentially towards the cortex mainly along the intermediate and subventricular zones, translocate towards the marginal zone, and then descend into the cortical plate to settle in their final destinations. In the marginal zone, these neurons execute multidirectional migration, possibly contributing to dispersion of these neurons [5,6]. A part of these neurons may directly penetrate into the cortical plate without passing through the marginal zone.

The migration of neurons also contributes to the establishment of non-laminated neuronal aggregates, nuclei. A subset of nuclei is formed as a result of a combination of radial and tangential migration. A typical example is a group of ►precerebellar nuclei in the hindbrain, a set of neurons that relay information to the cerebellum. Neurons that are destined to form precerebellar nuclei originate from a germinal zone in the dorsal recess of the hindbrain, called rhombic lip, and migrate circumferentially beneath the pial surface and then they change the direction of migration from tangential to radial. They eventually terminate radial migration at a distance from the pial surface forming aggregates of neurons, namely, nuclei [7]. During the tangential migration, subsets of these neurons cross the ventral midline. Thus, ►nucleogenesis is a consequence of successive events with distinct modes of migration.

Neuronal migration is also important to achieve a balance of excitation and inhibition in mature brain. In the cerebral cortex, for example, excitatory and inhibitory neurons have different origins but are intermingled as a result of neuronal migration [8], creating an opportunity for inhibitory neurons to terminate nearby excitatory neurons.

### *Molecular Mechanisms*

Several molecules are known to be involved in neuronal migration. *In vitro*, migrating neurons respond to diffusible molecules that are known as ►axon guidance molecules. These include Slits, Netrin-1 and ►Semaphorins. Netrin-1, whose role as chemo-attractant for spinal cord and hindbrain commissural axons has been well established, attracts a subset of precerebellar neurons [9], while Slit repels cortical interneurons and inferior olivary neurons. A chemokine, SDF-1, whose expression is prominent in the meningeal tissue, also regulates migration of several types of neuronal cells. SDF-1, for example, attracts GABAergic interneurons *in vitro* and their distribution is disrupted in SDF-1 knock out mice [10]. For radial migration of cortical neurons, a secreted molecule derived from Cajal-Retzius cells, ►Reelin, has been shown to play a pivotal role.

Defects in neuronal migration lead to various ►developmental disorders. This includes human classical ►lissencephaly (smooth brain) and ►double cortex. Genes responsible for these defects are *lissencephaly-1*, encoding Lis1 and *NUDEL*. These molecules form a complex together with ►dynein, which is essential for nucleokinesis, movement of the cell nucleus towards neurites. Doublecortin, loss of which causes human ►subcortical heterotopia, is a microtubule-associated protein and may probably stabilize microtubles. Manipulation of this gene both *in vitro* and *in vivo* affects migration of neurons.

Migrating neurons *in vitro* typically exhibit bipolar morphology headed by a leading process and a trailing process. In many instances, extension of the leading process from migrating neurons *in vitro* is followed by its shrinkage that is associated with forward movement of the cell body. Real-time imaging of cortical neurons revealed that there are at least two modes of migration. One is locomotion and another is translocation [11]. Translocating cortical neurons retain their leading process attached to the pial surface, and their somata move as their leading process shrinks, while locomoting neurons are guided by glial fibers with their processes unrestrained.

Recent progress of imaging technology demonstrated that migrating neurons exhibit a more intricate morphology than has been thought. They have multiple leading processes showing extension and retraction, and the direction of their migration depends on the direction of the longest leading process [5].

## Survival of Neurons

The number of neurons is regulated not only by the regulation of its proliferation but also by their naturally occurring death, namely, apoptosis of neurons. The reason for occurrence of the death is not known, but there is evidence suggesting that survival of neurons depends on their synaptic target. The number of neurons of the dorsal root ganglion and motor neurons of the chick, for example, is reduced when the limb bud is removed, whereas more neurons can survive, compared to intact animals, when an extra limb bud is transplanted [12].

The survival of neurons is supported by various growth factors, called ►neurotrophins. The most well known and the first discovered neurotrophin is the ►nerve growth factor (NGF). NGF is secreted from target tissues and supports survival of a subset of neurons.

There is a family of neurotrophins. This includes ►neurotrophin (NT)-3, ►brain-derived neurotrophic factor (BDNF) and ►NT-4/5. Different members of neurotrophins show differential distribution in the nervous system and affect different sets of neurons but by a similar mechanism. These molecules bind to neurons via a family of high affinity receptors, ►TrkA, B or C, with distinct affinities as well as a low-affinity receptor, ►p75. Although these molecules generally support survival (prevent suicide) of neurons, recent studies revealed proNGF, a precursor of NGF can also bind to p75 and negatively regulates cell survival.

## Axon Pathfinding

### *Growth Cone*

Postmitotic neurons extend axons, after or during migration. Growing axons are headed by a swelling called ►growth cones, which is a highly motile structure and known to express receptors for various guidance molecules. Growth cones are characterized by

thin protrusions called filopodia, which are bounded by sheet-like structures called lamellipodia. Microtubules extending from the axon reach the base of the lamellipodia. The structure of filopodia is supported by a bundle of actin filaments and polymelization of actin molecules causes extension of filopodia. In addition to having motility, growth cones have the capability of detecting environmental cues. They find their growth directions and pathways by responding to such cues (see below).

### *Long-range Diffusible Cues*

A number of guidance molecules are involved in their guidance and are categorized into repulsive and attractive molecules. They can also be categorized into long- and short-range cues.

The most well characterized guidance of axons by a long-rage cue is chemo-attraction of commissural axons by the ventral midline floor plate. *In vitro*, a floor plate explant can attract commissural axons derived from the dorsal spinal cord or the cerebellar primordium in the hindbrain. This is in harmony with in vivo behavior of these axons which course circumferentially through the floor plate. This attraction in vitro can be mimicked by ►laminin-related molecules, Netrin-1 and Netrin-2 [13,14], mRNAs of which are expressed in the floor plate. In mice deficient in Netrin-1 or its receptor, DCC, spinal commissural axons fail to reach the midline [15].

Growth cones that are attracted by a source of chemo-attractant might stall when they arrive at the source. This, however, is not the case. Commissural axons in the hindbrain, for example, continue growing after arriving at the midline. This is because the growth cones lose responsiveness to the midline attractant on their arrival at the midline [16]. In the spinal cord, commissural axons seem to use a similar but somewhat different mechanism: they acquire responsiveness to midline repellent on their arrival at the midline [17].

Floor plate explants also exhibit a repulsive activity to subsets of axons *in vitro*. Candidate molecules for this repulsion are Slits, which typically exert repulsive influence on growth cones via their receptors, Robos.

Long-range attractants expressed by an intermediate target thus contribute to the regulation of crossing and uncrossing axons, but they also serve to guide axons to their final target. Long-range repellents restrict the pathway along which growing axons can advance.

A different kind of diffusible cues contributes to the growth polarity of axons along the rostrocaucal axis. There is evidence that a family of secreted proteins, Wnts, guide post-crossing spinal commissural axons rostrally and corticospinal axons caudally [18,19].

### *Short-range Cues*

Short-range cues can be extracellular matrix molecules such as laminin or membrane-associated proteins such as ►Cadherins and NCAM. It is well established that a number of ►immunoglobulin superfamily cell adhesion molecules are involved in axon guidance. These molecules exert their effect by way of elevating or reducing adhesiveness between growth cones and their environment. In some occasions, these molecules are expressed by pre-existing axonal tracts and later growing axons follow these tracts by utilizing adhesion molecules expressed by them.

Some guidance molecules such as transmembrane ►Semaphorins are associated with cell membranes, and growth cones respond to these molecules by a direct contact with cells expressing such molecules. A member of ►Eph receptors and their ligands, ephrins also play important roles in axon guidance. A notable example of their roles is the establishment of retinotopic organization in the optic tectum [20]. In the tectum, Ephrin A2 and A5 are expressed in a graded manner along the rostrocaudal axis, while one of their ligands, EphA3, is expressed in a graded manner in the retina along the temporal-nasal axis. *In vitro* experiments along with analyses of knockout mice of these molecules indicate that these molecules play pivotal roles in the targeting of retinal axons. Ephrin A/EphA signaling also plays an important role in the regulation of axonal growth polarity along the rostrocaudal axis [21].

## Axon Targeting

Targeting of axons is thought to be initially diffuse, but is followed by a sculpturing process, which leads to sharper targeting. For example, corticorubral projections in the cat are initially bilateral but become unilateral as development proceeds [22,23]; rat retinotectal projections, which are initially diffuse become to be topographically organized. These sculpturing processes are associated with elimination of incorrectly projecting axonal branches and proliferation of axon branches in correct targets. Previously, the importance of regressive events such as retraction of axonal branches and death of inappropriately projecting neurons was stressed. However, with development, the proliferation of axonal branches, axon terminals as well as ►dendritic growth takes place, all of which are progressive. Indeed, recent studies have revealed the importance of a progressive process such as the proliferation of axons terminals. In any case, these processes are believed to be regulated by synchronized activities of presynaptic and postsynaptic neurons: synchronized activities of pre- and post-synaptic elements might lead to reinforcement and non-synchronized activity leads to weakening of connections.

## Plasticity of Neuronal Connections in the Developing Brain

Developing animals show marked plasticity of neuronal connections compared to adults. Diffuse axonal

projections in young animals appear to be related to prominent plasticity of neuronal connections that takes place after early brain damage. Projections of the deep cerebellar nuclei, for example, are bilateral in early postnatal developmental stages in the cat, but become unilateral (crossed projections) as the animal matures [24,25]. On the other hand, removal of the nucleus on one side during the time when bilateral projections are present, causes permanent bilateral projections from the cerebellum. The period during which the lesion of the nucleus is effective in inducing the bilateral connection coincides with the period when bilateral projections are present in normal animals. A similar coincidence of the period of plasticity and the period of the exuberant projection existence can be found in the cortico-rubral system [22,26,27]. Thus, an interesting possibility is that a denervation causes proliferation of pre-existing axonal branches [27].

## Synaptogenesis

### *Structure*

The synapse is a key structure for synaptic transmission and the site of transmitter release. The synapse is morphologically defined by electron microscopy: the synaptic differentiation includes the presynaptic density, postsynaptic density, accumulation of synaptic vesicles in the presynaptic membrane and the synaptic cleft, although immature synapses exhibit less pronounced synaptic specialization with few numbers of synaptic vesicles. Typically, synapses are formed on somata and dendrites in mammalian neurons and can be excitatory or inhibitory.

On arrival at their final destinations, growth cones cease growing and form many branches. These branches are associated with swellings both along their length and terminals; such swellings or varicosities contain synaptic vesicles and often form synapses. Synaptogenesis takes place during late developmental stages and is pronounced postnatally.

### *Process of Synaptogenesis*

Synaptogenesis requires the accumulation of synaptic vesicles in the presynaptic site and receptors on the postsynaptic site and adhesion of pre- and postsynaptic membranes. Studies using the ►neuromuscular junction, where acetylcholine serves as a neurotransmitter, indicate that the presynaptic terminal is capable of inducing aggregation of neurotransmitter receptors. Actually, a molecule that has a receptor aggregating activity, ►Agrin, has been identified [28]. Agrin is a proteoglycan synthesized in the motor neuron and released from its terminal. Although Agrin mRNA can be found in the brain, it does not appear to play a role in receptor aggregation in CNS synapses.

Postsynaptic neurons show remarkable dendritic growth during the period of synaptogenesis. In particular, numerous thin filopodial protrusions emerge from dendrites. Although the significance of the presence of these structures remains unknown, these filopodial structures may possibly search for growing axons from presynaptic neurons, and once they encounter growing axons, these structures may retract and form mature synapse [29,30].

### *Molecules*

Several molecules are implicated in synaptogenesis between central synapses. These include Neurexin and its receptor, neuroligin, which are expressed on the pre- and postsynaptic sites, respectively. These molecules can induce synaptic contacts by bidirectional signaling [31].

There is evidence that neuronal activity plays a role in the aggregation of receptor molecules. In this case, the neurotransmitter itself should be involved in maturation of synapses.

During the period of synaptogenesis, other morphological maturation processes proceed. This includes myelination and thickening of axons, both of which contribute to upregulation of conduction velocities.

## Neural Filters

### Definition

Filters are instruments that let pass only selected information or particles. Tea leaves are filtered out by a tea filter, because they are too large. Likewise, neurons also may filter the incoming information a let pass only a selected part. The mechanisms may be multiple. Thresholding, by which potentials with small amplitudes do not generate an action potential at the output of a neurons, is a powerful means. Other possibilities are coincidence detection or more complex processes.

## Neural-Immune Interactions: Implications for Pain Management in Patient with Low-Back Pain and Sciatica

Angela Starkweather
Intercollegiate College of Nursing, Washington State University, Spokane, WA, USA

### Synonyms

Neural-immune interactions: Neuroimmunology; Low-back pain: Lumbago; Sciatica: Radiculopathy; Sciatic neuritis

## Definition

This essay reviews neuroimmune pathways involved in the initiation and maintenance of low-back pain and sciatica.

## Characteristics

Quantitative description: Bidirectional communication between the immune system and the brain and the implications of this communication are emerging concepts in pain research. Although representing a small portion of the disc degeneration syndromes, lumbar herniated discs can cause significant symptoms that may persist even after surgical interventions. Evolving evidence demonstrates that proinflammatory cytokines are key mediators in the process of disc degeneration as well as in the pain experienced by those afflicted with lumbar herniated discs. Activated immune cells release proinflammatory cytokines, which signal the brain through humoral and neural routes. The brain responds by altering neural activity and promoting further production of proinflammatory cytokines within the brain and spinal cord. Increased local cytokine production by disc tissue irritates spinal nerve roots resulting in pain and functional changes in neural activity. This essay explores the importance of cytokine and other related ►neuroimmunology pathways within the context of lumbar disc degeneration and lumbar spine ►pain.

Description of the structure/process/conditions: Disc degeneration is the initial process leading to nontraumatic disc herniation (Fig. 1). This theoretical pathway explains the biomechanical and biochemical events implicated in the process of disc aging, or degeneration, which ultimately leads to the experience of pain phenomena (low-back pain and ►sciatica). Traditionally, it has been believed that the displaced disc tissue was a by-product of the disease and not an interactive element in the disease process itself. However, the discovery of elevated levels of proinflammatory cytokines within injured disc tissue led researchers to conceptualize it as a biologically active tissue. Since that time, connections between the immune system, nervous system, and pain behavior in disc injury have continued to evolve. The current understanding of the mechanisms of disc degeneration and nontraumatic herniation will be reviewed in relationship to the aforementioned Fig. 1.

## Regulation of the Structure/Process/Conditions

### *Mechanical Shear Stress*

The function of the intervertebral disc is to provide the spine with mobility while retaining axial stability. While physiological loading helps to maintain metabolism and function in intervertebral discs, excessive mechanical loading appears to be detrimental. Lifestyle, occupational, genetic and biochemical factors influence the effects of mechanical loading on disc degeneration [1].

### *Neovascularization*

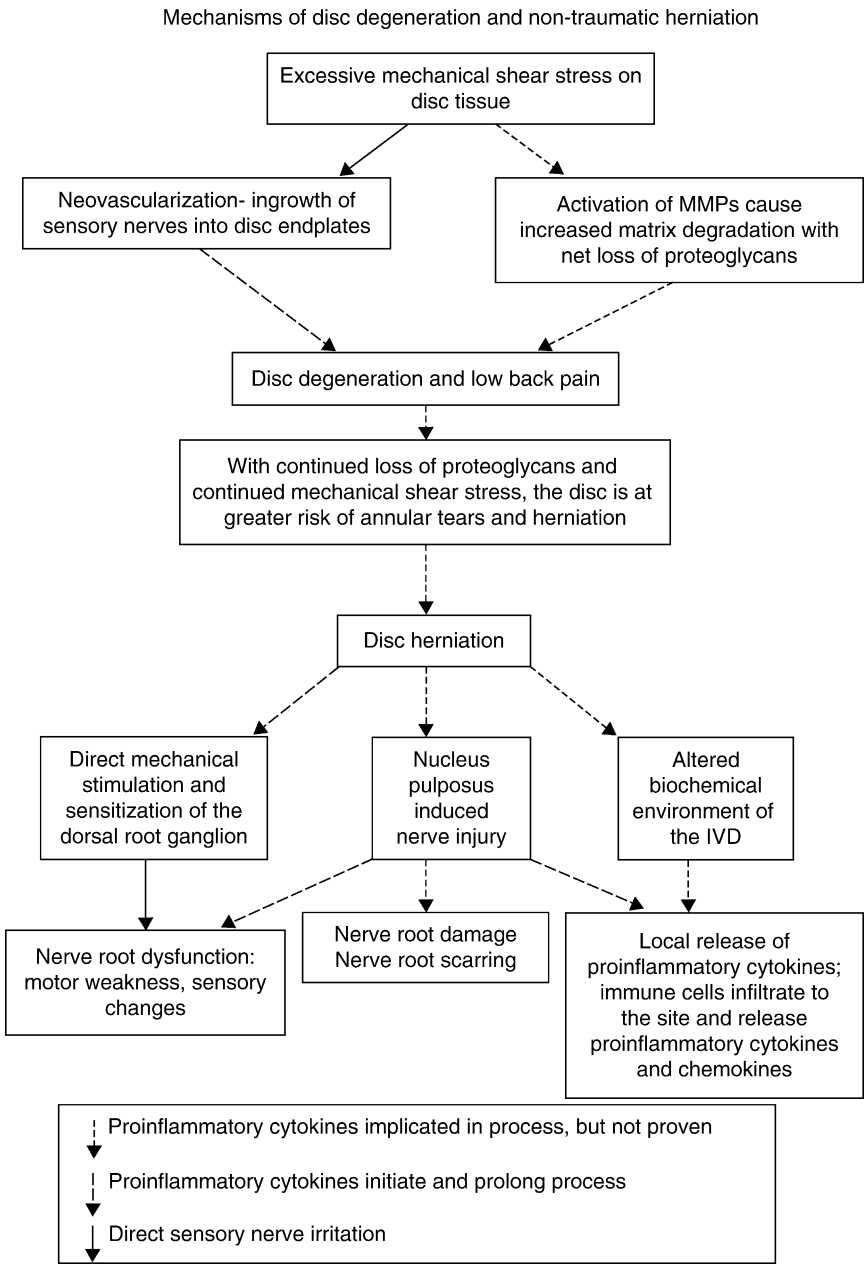
Small nonmyelinated nerve fibers grow into the intervertebral disc in areas where there is local production of nerve growth factor (NGF) ("►The role of the NGF family in the regulation of neuroinflammation"). NGF is produced by microvessels, which populate the normally avascular (and aneural) intervertebral disc by extension from adjacent bone. This pattern of nerve growth and receptor expression is implicated in the innervation of painful tissues through NGF-driven axonal growth and maturation. The stimulus that promotes microvessels to release NGF, triggering the process of nerve and vessel ingrowth, remains uncertain. However, IL-1 has the ability to switch chondroctyes from anabolism to catabolism, inducing cartilage breakdown at molecular and morphological levels through stimulating ►matrix metalloproteinases (MMPs). Thus, there is growing evidence of the role of proinflammatory cytokines in matrix degradation (disc degeneration), nerve and vessel ingrowth, and pain. In fact, there is mounting evidence that immune factors are involved not only in the initiation of disc degeneration but also in the progression of disc disease. As the injured disc tissue continues to produce elevated levels of MMPs, thereby losing proteoglycans, the diseased tissue begins to wear down. Annular tears form along the outer wall of the disc, making it more susceptible to splitting, and thus herniating, in the face of exertional forces that raise the intervertebral pressure [2]. Disc-related biomarkers of degeneration are currently being investigated [3].

### *Direct Mechanical Stimulation and Sensitization of the Dorsal Root Ganglion*

Dislocation of intervertebral disc tissue (IVD) by nucleus pulposus (NP) protrusion or extrusion (i.e., herniated disc) is a common source of severe pain. Herniated NP can potentially contact and compress the dorsal root ganglion (DRG) and spinal root that enters the spine at the vertebral level. Acute mechanical compression is sufficient to produce spontaneous activity in the sensory afferents, supporting the classic assumption that mechanical compression is the cause of pain and other neurological symptoms. Mechanical compression has been thought to account for the ischemia, edema, and demyelination that occur in the DRG and the pain that may arise from nerve endings in the outer annulus fibrosus.

### *Nucleus Pulposus-Induced Nerve Injury*

Pathological pain can arise as a consequence of the protrusion of the NP into contact with the DRG and dorsal root. Although pressure per se has classically been considered as a major cause of pain, there is growing evidence that immune-derived substances may be involved as well. Diverse immune cells and equally



**Neural-Immune Interactions: Implications for Pain Management in Patient with Low-Back Pain and Sciatica.**
**Figure 1** Mechanisms of disc degeneration and non-traumatic herniation. MMP = matrix metalloproteinases; IVD = intervertebral disc.

diverse immune cell products are potential mediators. Of these, proinflammatory cytokines have received by far the most attention. Data to date suggest a strong case in support of proinflammatory cytokine involvement in the pain of herniated discs through astrocyte and microglia activation ("►Functions of microglia in immune mechanism in the central nervous system (CNS)") [4]. The cytokines may do this by inducing expression of receptors within DRGs. Also, axonal interactions with proinflammatory cytokines could increase electrical conductivity. Each of these processes could then lead to pain processing.

### *Biochemical Mediators in Herniated Disc Tissue*

Neuropathic pain can occur as a consequence of nerve trauma, with physical damage to nerves altering pain perception and the function of pain transmission pathways ("►Spinal immunology and neuropathic

pain"). However, neuropathic pain can also occur in the absence of any detectable physical injury. In these situations, pathological pain appears to be a consequence of immune activation and inflammation, which can also amplify pain as a consequence of physical trauma. The role of immune activation in neuropathic conditions has been firmly established, and a consistent picture has emerged from these models of traumatic and/or inflammatory neuropathic pain. The key cellular mediators are most likely inflammatory cells recruited into the affected area from the general circulation along with locally stimulated cell populations. These cells produce proinflammatory cytokines (tumor necrosis factor [TNF], IL-1, IL-6) within the affected area and create and maintain pathological pain [5].

### *Alterations in the Biochemical Environment of the Intervertebral Disc (IVD)*

Nucleus pulposus-induced effects on adjacent nerve root(s), include alterations in nerve conduction velocity, mechanosensitization, pain behavior, histological degeneration, reduced blood flow, and increased endoneurial fluid pressure. The biochemical changes initiated by exposed NP and the increased production of proinflammatory cytokines create an environment of degradation. This process has been hypothesized to be part of disc resorption, influenced by migrating macrophages. The synergistic effects of nerve compression and the altered chemical environment of the IVD appear to produce the pathophysiologic network leading to the pain experienced by those with herniated discs.

## Function

Lifestyle, body weight, aging, and genetics all influence the load environment of the normal IVD. Lifestyle (including occupation) and body weight are capable of accelerating the rate of degeneration and thus further complicates the starting point from which to assess IVD degeneration. The studies to date provide evidence of connective tissue degradation, nerve and vessel ingrowth, and increased production of proinflammatory cytokines that characterize IVD degeneration and herniation. There is considerable need for more investigation into the precise role of cytokines for each of these biological processes. Concurrently, the study of immune involvement in neuropathic pain is in its infancy. Many more immune cells and immune-derived substances may be implicated in the etiology of pathological pain syndromes. Much remains to be learned about the dynamics of immune system modulation of pain and neural function.

The recognition that the immune system may be involved in neuropathic pain has important potential implications. If proinflammatory cytokines contribute to pain and to neuropathological changes in the sensory neurons, it may be possible to devise much-needed alternative approaches for treatment of patients with low-back pain. Surgery for herniated discs is not without cost, and surgical treatment of disc herniation is advised only if nonsurgical treatment fails. Furthermore, resolution of pain is not guaranteed with surgery, as complications and failure rates remain relatively high. Understanding the role of the immune system in disc-related pain may lead to a better appreciation of not only the nature of organic pain but also alternative therapeutic approaches or drug strategies to treat pain and its antecedents. Moreover, the evaluation of immune markers as indices of pain and of immune responsiveness consequent to pain may provide insight into the means by which to fine-tune the therapy provided to individual patients.

A remaining conundrum in clinical practice is how to define disc degeneration. It has been proposed that Modic changes may be an objective marker of discogenic low-back pain. Modic changes are signal intensity changes on plain radiograph X-rays and magnetic resonance imaging that reflect a spectrum of vertebral body marrow changes associated with degenerative disc disease. A correlation between Modic changes on spinal magnetic resonance images and the production of proinflammatory cytokines has been made: Modic 1 changes were more common in patients with discogenic low-back pain, whereas Modic 2 changes occur in patients suffering from sciatica (with increased production of proinflammatory cytokines). Advances in imaging techniques are being applied to disc degeneration which will hopefully lead to a standard method of quantifying disc degeneration in humans [6].

Traditional treatment for low-back pain includes nonsteroidal anti-inflammatory medication, which inhibits prostaglandin synthesis, as first-line therapy. Patients exhibiting ▶sciatic symptoms are often prescribed steroids (by mouth or epidurally) to decrease swelling in the affected nerve root. The use of these substances in long-term therapy, however, must be weighed against their side effects. Gabapentin has been added to the armamentarium for treating sciatic pain. Although its mechanism of action is unknown, it is structurally related to the neurotransmitter γ-aminobutyric acid. All of these medications have limited success in relieving symptoms of low-back pain and sciatica, and none prevent progression of degenerative disease.

The recognition of peripheral and central immune cell involvement in neuropathic pain of diverse etiologies may offer a new avenue or approach to pain control. There are multiple situations in which immune-derived proteins (TNF, IL-1, IL-6) have been correlated with and are the likely cause of neuropathic pain conditions. The pervasive and potentially key involvement of the proinflammatory cytokines within an affected body region or within the spinal cord are likely and desirable targets for drug development. The role

of gene therapy in disc degeneration is currently being investigated [7–9]. Using genes introduced into target cells, proteins are produced within the degenerate disc, which provide a chemical environment conducive to restoring cell function toward normality. Although some pathologic conditions require immediate decompressive surgery, as in cauda equina syndrome, the role of surgery in disc degeneration syndromes is becoming less clear. As new therapies continue to evolve that are able to target the biochemical factors involved in pain transmission, perhaps the ultimate test will be whether a pathway can be found that reverses the degenerative condition.

# Neural Integrator

## Definition

A neural network that integrates, in a mathematical sense, its input signals. For example, if a pulse of neural activity was the input to a neural integrating circuit, the circuit's output would be a sustained step of neural activity.

►Neural Integrator – Horizontal
►Neural Integrator – Vertical

# Neural Integrator – Vertical

## Definition

An ensemble of neurons of the vertical oculomotor system that engage in integration in the sense of Newtonian calculus. They receive signals roughly indicative of vertical eye velocity (such as those produced by the vertical burst generators in the rostral interstitial nucleus of the MLF) and generate signals proportional to vertical eye position that they convey to the appropriate ►extraocular motoneurons (those with vertical pulling directions).

## Description of the Theory

Although originally thought as a unitary brain device responsible for all eye velocity to position transformations, it is now clear that several cell assemblies are needed to implement neural integration in different planes and for different kinds of eye movements. The nucleus prepositus hypoglossi is crucial for integration in the horizontal plane (►see Neural Integrator – Horizontal) and the same is true for the ►interstitial nucleus of Cajal (NIC) for integration in the vertical plane. For example, unilateral chemical inactivation of the NIC prevents monkeys from holding eccentric vertical eye positions but does not affect their ability to hold eccentric horizontal eye positions. The same is true of human patients suffering from midbrain lesions that encroach on the NIC; they display vertical (but not horizontal) gaze holding failure [1].

The oculomotor subsystem subserving the ►vestibuloocular reflex (VOR) also relies on velocity to position integration. Its input, carried by primary vestibular afferents, encodes (and is in phase with) the angular velocity of the head whereas its output (motoneuron discharge) encodes (and is in phase with) eye position. There is evidence from several species to indicate that the NIC participates in this process, at least in the vertical plane. Its lesions impair the pitch VOR (as documented by gain reduction and phase advancement) while the horizontal VOR remains normal. Because vertical VOR impairments are not as profound as would be expected from the concurrent impairment of vertical gaze holding, it is unlikely that a single neural integrator underlies the generation of both saccadic and VOR signals [2].

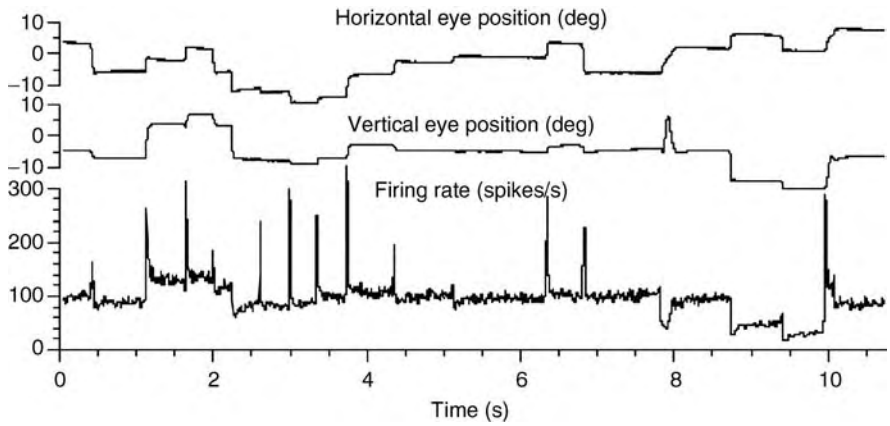
To understand how integration is achieved neurally it is important to know the discharge pattern and

connections of relevant neurons. Of the several classes of cells contained in the NIC (for reviews see [3,4]), it is the burst-tonic neurons that are of particular interest for the purposes of this essay. The discharge of a typical such unit is illustrated in Figs. 1 and 2.

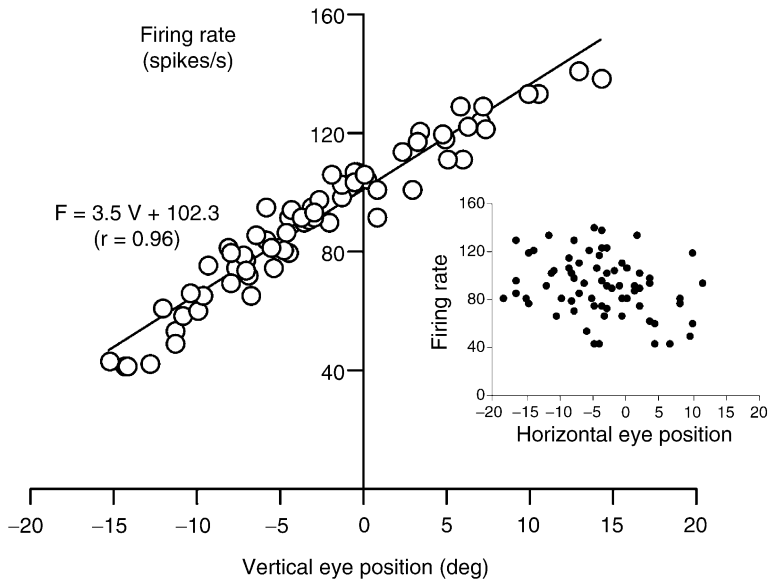
As shown here, it remains roughly constant in between saccades at a value specified by the vertical position (usually both up and down) of the eyes and its bursts precede saccades with an upward component, whether rightward or leftward. The firing rate ($F_R$) of such units is described by the expression

$$F_R = F_0 + kE + rdE/dt \quad (1)$$

Where E is the instantaneous vertical position of the eyes. $F_0$ (the neural discharge at primary position), k (the slope of the rate-position curve) and r (the slope of the rate-velocity curve) are constants that differ for different cells. The average values they obtain have been determined in several species (for a review see [4]). For example, $F_0 = 88$ spikes/s, $k = 3.1$ spikes/s/deg and $r = 0.8$ spikes/s/deg/s (when r was evaluated from smooth pursuit eye movements), in a sample of units of



**Neural Integrator – Vertical. Figure 1** Oculomotor related discharge pattern of a regular upward efferent fiber of the NIC. (modified from [5], used with permission). Traces from top to bottom illustrate the instantaneous horizontal and vertical eye position and the instantaneous firing rate.



**Neural Integrator – Vertical. Figure 2** Quantitative analysis of the relationship (modified from [5], used with permission) between the mean intersaccadic firing rate (ordinate) of the unit shown in Fig. 1 and the mean intersaccadic vertical eye position (abscissa). The solid line is the linear regression line through the data (open circles). The inset is a plot of horizontal eye position (abscissa) versus firing rate (ordinate).

the squirrel monkey, while the same units also emitted about 0.6 spikes per degree of vertical displacement of the eyes during saccades [5]. Differences between NIC burst-tonic units can be appreciable as shown by the fact that 25% of these units modulated their discharge in relation to upward or downward eye position, but not both, while about 25% of them did not emit any bursts for saccades (tonic neurons).

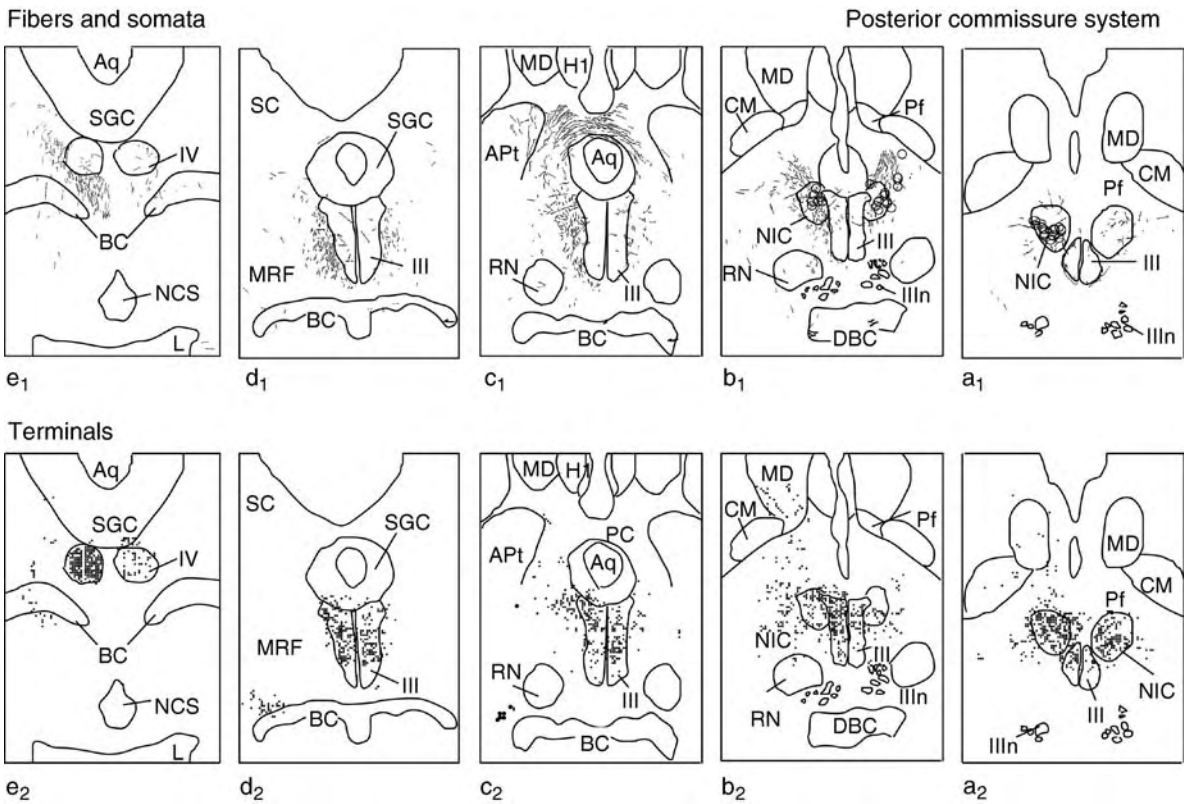
Axons arising from burst tonic units of the NIC have been shown to travel with the posterior commissure (PC; [6]). The trajectory of such PC fibers and the terminal fields they deploy in the contralateral NIC, the oculomotor nucleus and the trochlear nucleus are illustrated in Fig. 3.

Their virtual disappearance, after PC lesions that preceded the injection of tracer in the NIC, indicates that PC fibers are likely to be the conduit of most of the NIC output to these nuclei [7]. Their integrity is necessary for normal velocity to position integration in the vertical plane since inactivation or lesion of the PC disable vertical gaze holding and advance the phase of the vertical VOR in the dark [8].

To gain insight into the operation of this network and understand how the properties of its neurons endow it with the ability to transform velocity signals into position signals it is instructive to consider a model of the vertical neural integrator that captures the crucial biological facts that are known about it such as those described above. To recapitulate, such a model should account for the qualitative (e.g., whether they emit saccade related bursts or not) and quantitative (e.g., the range of values of the parameters $F_0$, k and r) properties of discharge of its units, the cross-connections between neural integrators located in opposites sides of the brain (via the PC) and the properties of the eye movement deficits which result from lesions of its units (e.g., drifts of appropriately short time constants).

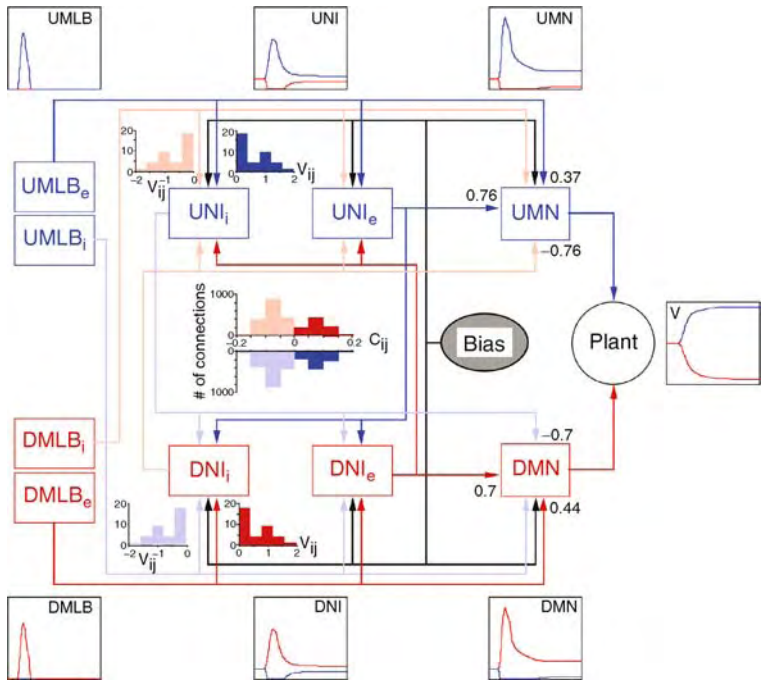
Figure 4 is a block diagrammatic illustration of a lumped version of this model together with typical signals encountered at several of its stages for saccades of two different directions (up, blue; down, red).

The same color code is used to distinguish upward (UNI) from downward (DNI) units while solid lines indicate connections arising from excitatory ($UNI_e$,



**Neural Integrator – Vertical. Figure 3** Location of retrogradely labeled somata ($a_1$–$e_1$, open circles), trajectory of PC fibers ($a_1$–$e_1$) and terminal fields in and around the oculomotor and trochlear nuclei ($a_2$–$e_2$) following biocytin injection in the NIC (reproduced from [7] and used with permission). Sections are shown in the frontal plane and are arranged from rostral (a) to caudal (e).

N



**Neural Integrator – Vertical. Figure 4** Schematic illustration of a lumped version of a model of the vertical neural integrator (reproduced from [9], with permission). Units with upward on-direction and the signals carried by all units during upward saccades (waveforms placed inside boxes) are shown in blue. Units with downward on-direction and the signals carried by all units during downward saccades are shown in red. Boxes illustrating discharge patterns measure 200 ms (abscissa) and 800 spikes/s (ordinate). The size of the box containing examples of the eye position output of the system is 200 ms (abscissa) and 20 deg (ordinate). Solid arrows indicate excitatory connections. All other connections are inhibitory. Insets are histograms of connection strengths. Abbreviations: *DMLB*, downward medium-lead burst neuron; *DMN*, downward motoneuron; *DNI*, downward neural integrator; *UMLB*, upward medium-lead burst neuron; *UMN*, upward motoneuron; *UNI*, upward neural integrator. Subscripts indicate the excitatory (e) or inhibitory (i) influence units exert on their targets.

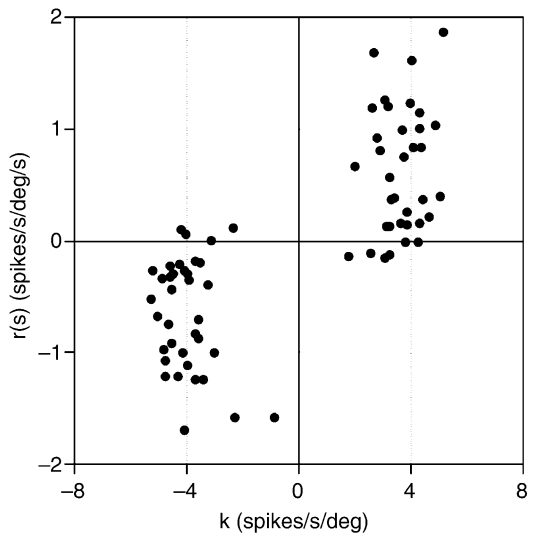
$DNI_e$) units and stippled lines those arising from inhibitory ($UNI_i$, $DNI_i$) units. Each model unit is assumed to establish excitatory ($NI_e$ units) or inhibitory ($NI_i$ units) connections onto NI units with opposite on-direction. They all project to motoneurons as well. The strength of these connections ($c_{ij}$) and the precise number of excitatory and inhibitory units is less critical. Provided that the number of excitatory neurons is not greater than or equal to the number of inhibitory ones it is always possible to find an average value (of $c_{ij}$) such that T = 20 s. When inhibitory neurons are sufficiently more numerous than excitatory ones (e.g., when $n_i = 2n_e$) T is about equal to 20 s (dashed line), if c is equal to 0.0835. However, there is no need to assume that the weights of all interconnections ($c_{ij}$) between the NI units of the distributed model obtain this absolute value. Instead, they can vary quite freely around it forming a normal distribution with a coefficient of variation equal to 0.5. This relatively large number implies that the model is quite impervious to the precise values obtained by any of these connection strengths. The histograms near the center of Fig. 4 (solid, excitatory; stippled, inhibitory) illustrate distributions that were obtained with the help of a random number generator after specifying the mean and the standard deviation of the populations and are compatible with a normally operating neural integrator.

The signals carried by the units of such a model (e.g., insets of Fig. 4) are remarkably similar to the discharge pattern of primate NIC neurons. Just like primate neurons, model units generally burst for vertical saccades (up or down) and their tonic discharge in between saccades is proportional to vertical eye position. The similarity is not just a broad, qualitative one. For example, the position sensitivity (k) velocity sensitivity (r) and primary position rate ($F_0$) of upward model units are statistically indistinguishable from the the position and the velocity sensitivity and the primary position rate of the burst-tonic upward efferent neurons of the NIC [5]. Although most model units (N = 62 of 72) modulated their discharge for saccades and eye position in the same direction (in-phase units) a few behaved quite differently in that they display opposite on-directions for saccades and eye position (anti-phase units). The same is true of NIC neurons found in both cats [3] and monkeys [5]. Finally, as with primate

NIC neurons, a few model units did not emit bursts for saccade which again agrees well with the discharge patterns of neurons encountered in the NIC [5]. Although few in number, such tonic neurons are of particular importance as it has been argued that they carry the output of the neural integrators in contrast to burst-tonic cells that are limited to computational stages closer to its input (see the chapter on ►Neural Integrator – Horizontal). Efforts to test this argument experimentally have had mixed results. Tonic neurons have been shown to project to the abducens nucleus more frequently than burst-tonic cells of the horizontal neural integrator (in the NPH; [10]). In contrast, burst-tonic cells have been shown to comprise the majority of efferent fibers conveying the output of the vertical neural integrators to extraocular motoneurons [5]. All in all, work in the vertical system demonstrates that the neural integrator need not be more than one layer deep and that both its tonic and burst-tonic units send their output to motoneurons.

Given the large variety of their response properties, it is meaningful to ask if the units of the model integrator of Fig. 4 comprise a functional continuum, or alternatively, whether they can be broken up into distinct functional classes and, if so, which. To this end we plotted their position sensitivity ($k_V$) against their velocity sensitivity ($r_{(s)}$) in Fig. 5.

In this scatter-plot, the units occupy two distinct clouds, to the right and to the left of zero $k_V$, corresponding to upward and downward units, respectively. No other demarcation point can be found to further subdivide units according to their position sensitivity (high or low).



**Neural Integrator – Vertical. Figure 5** 2-D scatterplot of the slope of the rate position curves ($k_V$, abscissa) against the slope of the rate-velocity curves ($r_{(s)}$, ordinate: evaluated from saccades) of all 72 units of the model (reproduced from [9], with permission).

Similarly, no demarcation can be found on the orthogonal axis to subdivide units according to their velocity sensitivity. Both up and down units form elongated clouds straddling zero $r_{(s)}$. Most of the points are confined to the upper right (up units) or lower left (down units) quadrants. These correspond to units that are generally sensitive to up or down ocular deviation and emit more or less strong bursts for saccades in the same direction. Both clouds encompass points on or close to the horizontal abscissa of the scatterplot; these correspond to tonic units. Finally, both clouds encompass a few points belonging to the lower right (up units) or the upper left quadrant (down units); these correspond to anti-phase units.

Selective lesions of subpopulations of integrator units could help elucidate how each of these distinct subtypes contributes to neural integration. Such experiments cannot be carried out *in vivo* with presently available techniques. Instead they exemplify one of the strong points of computational approaches. As expected, elimination of the inhibitory units of the model shown in Fig. 4 abolishes integrator function. On the other hand, elimination of excitatory units does not lead to integrator failure provided that the weights of commissural connections are readjusted "postlesionally". Instead, it abolishes anti-phase activity and more importantly, it raises the slope of the rate position curve dramatically, to between ± 23.5 and ± 33.5 spikes/s/deg. With rate position slopes such as these, and since the eyes reach eccentricities as high as ± 45°, NI neurons would have to sustain very high firing rates (often exceeding 1,000 Hz). In other words, the vertical neural integrator could function normally even if all connections between its neurons were inhibitory ones but not if the dynamic range of the neurons involved must be kept within physiological bounds.

# Neural Network in Olfactory Bulb

## Definition

Group of interconnected neurons, which are together responsible for a particular neural function, either at the periphery or at the central brain level. The network typically comprises different types of neurons, having different electrical and/or physiological properties. A typical example is the olfactory bulb, primary olfactory center of vertebrates that comprises different neuron types within a number of anatomical and functional units, the glomeruli. Olfactory sensory neurons at the periphery (olfactory mucosa) detect odorants and convey this information to the glomeruli. There, sensory neurons connect onto output neurons (mitral cells/tufted cells), which will further convey olfactory information to higher brain centers (cortex, etc.). Most importantly, two types of local bulb neurons (periglomerular and granule cells) carry out lateral inhibition to neighboring glomeruli. All these neurons constitute the neural network of the olfactory bulb, whose function is to format odor representation, increase signal to noise, and improve odor discrimination ability. Because of the very high number of connections between neurons within neural networks, and the fact that the action of one neuron on the other can be excitatory or inhibitory, neural networks usually induce highly non-linear results at their output. Consequently, their activity should not be studied at the "single-neuron" level but techniques taking into account the connectivity and complexity of the network, like multi-unit electrophysiological recordings or optical imaging techniques should be applied. Furthermore, computational neural networks have proved useful to reproduce the architecture of biological neural networks, in order to understand their processes and outcomes. Such mathematical models have become a whole field in computational neuroscience, and they are now used for developing artificial intelligence applications, for instance for voice or face recognition, automated image analysis, etc.

## Definition

### Neural Networks and Architectures

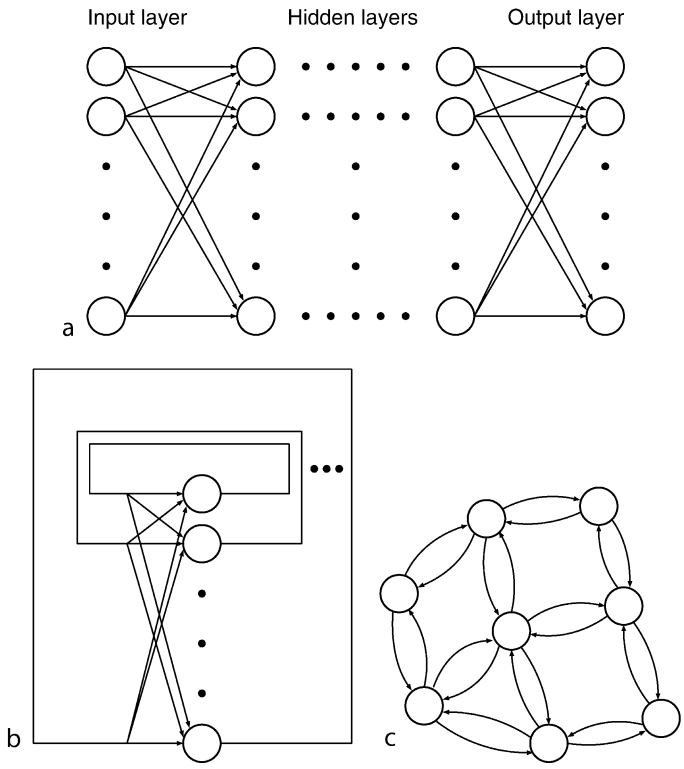
Neural networks, here, mean mathematical models of biological neural networks composed of neurons. There have been many works on neural networks since the seminal paper by McCulloch and Pitts in 1943 [1]. Although neurons are connected through synapses in complicated ways in the living brain, typical architectures of neural network models are classified into ►feedforward networks and ►feedback networks as shown in Fig. 1.

While the former is ►multilayer networks with the input layer, the output layer, and hidden layers between them, the latter is recurrent networks with feedback connections. Typical examples of the feedforward networks are ►perceptron [2] and ►back-propagation learning networks [3]; recently, forward-propagation learning is also proposed [4]. The feedback networks, on the other hand, have been used in many models such as ►associative memory and combinatorial optimization where nonlinear dynamics plays important roles like deterministic ►chaos in ►chaotic neural networks and stochastic synchronization.

## Characteristics

### Learning Theory in Neural Networks

Learning in models of neural networks is incorporated as rules to update and establish synaptic weights between neurons. The learning rules are classified



**Neural Networks. Figure 1** Network architectures: (a) feedforward networks and (b) feedback networks which are equivalent to (c) networks composed of mutually connected neurons. Each circle represents a neuron.

into supervised and unsupervised learning, respectively, with and without teaching signals. Examples of the former are perceptron [2] and back-propagation learning [3] in feedforward networks, while a typical example of the latter is the Hebbian learning. The beauty of learning in neural networks is its generalization property; acquisition of desired responses to a training data set in feedforward networks can result in correct responses to a new data set. Therefore, unlike conventional software programming, we do not need to figure out the rules and logics behind a given problem, but simply provide examples of correct responses to the networks with respect to input signals.

The learning algorithm in feedforward networks can be roughly categorized into two. One is that the network receives a target vector signal, that is, desired output values of the output layer like the perceptron and the back-propagation learning. Another is reinforcement-learning-based algorithm that assumes only a scalar "reward" signal that tells how much good or bad the present output is, like forward-propagation learning [4].

## Perceptron

The perceptron is a multilayer feedforward neural network where changes in synaptic weight take place only at the final output layer [2]. It is a type of supervised learning where a target vector is provided to the final layer as teaching signals.

Let us consider the following two-layer network only with input and output layers for the sake of simplicity:

$$z_i = 1\left(\sum_j w_{ij} a_j\right),$$

where $z_i$ denotes the output of neuron $i$ in the output layer, $a_j$ input $j$ in the input layer with $a_j = 0$ (nonfiring) or 1 (firing), $w_{ij}$ the synaptic weight from input $j$ to neuron $i$, and function $1(\bullet)$ is the Heaviside output function with $1(u) = 1$ for $u \geq 0$ and $1(u) = 0$ for $u < 0$. We omitted the neuronal threshold, since the threshold can be represented as the synaptic weight from a constantly firing input unit.

The update rule of synaptic weights is given as

$$\Delta w_{ij} = \eta(\delta_i - z_i)a_j,$$

where $\delta_i$ denotes the desired output of neuron $i$ and $\eta$ the learning coefficient. The synaptic weight is changed in the direction to decrease the difference between $z_i$ and $\delta_i$, whenever the outputs do not match the target vector. The perceptron learning has been mathematically proven to realize appropriate values of synaptic weights under a condition that a set of input patterns are linearly separable.

## Back-propagation Learning

Back propagation is a learning rule that updates synaptic weights in hidden layers together with the output layer, provided a target vector [3]. Learning ability is much higher than the perceptron, and many practical problems that are nonlinearly separable can be solved with a moderate number of hidden layer neurons.

For simplicity, we assume a three-layer network with a single hidden layer as follows:

$$z_i = f\left(\sum_j s_{ij} x_j\right),$$

$$x_j = f\left(\sum_k w_{jk} a_k\right),$$

whereas $x_j$ denotes the output of neuron $j$ in the hidden layer, $f$ is a continuously differentiable output function like the sigmoid function $f(u) = 1/\{1 + \exp(-u/\varepsilon)\}$ with the steepness parameter $\varepsilon$, $s_{ij}$ the synaptic weight to output neuron $i$ from hidden layer neuron $j$, and $w_{jk}$ that to hidden neuron $j$ from input $k$.

To derive the update rules of synaptic weights in each layer [3], we define an error function $E$ as follows:

$$E = 1/2 \sum_i (\delta_i - z_i)^2,$$

which is the sum of squared errors at the output layer.

Here, the synaptic changes in the final layer are implemented as the gradient descent of the error function

$$\Delta s_{ij} = -\eta \frac{\partial E}{\partial s_{ij}}.$$

Defining the learning signal $r_i$ as

$$r_i = (\delta_i - z_i) f'\left(\sum_j s_{ij} x_j\right),$$

the learning rule becomes as follows:

$$\Delta s_{ij} = \eta r_i x_j.$$

Likewise, necessary synaptic change in the hidden layer to decrease the error at the output layer is derived as follows:

$$\Delta w_{jk} = -\eta \frac{\partial E}{\partial w_{jk}}$$

$$= \eta \tilde{r}_j a_k,$$

where

$$\tilde{r}_j = \left(\sum_i r_i s_{ij}\right) f'\left(\sum_m w_{jm} a_m\right).$$

The term "back propagation" originates from the interesting behavior that learning signals in the output layer seem to propagate backward through synaptic weights $S_{kj}$'$S$ and become learning signals in the hidden layer. Moreover, although the back-propagation learning rule may get stuck in local minima, it has been shown that the learning rules work well in a wide variety of learning tasks.

While the back-propagation learning provides a powerful method to train multilayer neural networks, it suffers from the lack of biological plausibility. Therefore, attempts have been made to train multilayer networks using scalar reinforcement signals like dopaminergic activity [5], which only tell the networks whether the current output is good or bad. The difficulty in this approach is that the reinforcement signal is assumed to be broadcasted to the local neural circuit and hence leads to nonconvergence of learning when directly applied to feedforward network models. Recently, a method to overcome this problem, or forward-propagation learning [4] was introduced, where learning propagates from the input to the output layer under certain neuronal activity conditions that could be observed in the monkey prefrontal cortex. In short, each layer does its best to provide additional dimensions to solve the problem, eventually transforming it linearly separable with a moderate number of hidden neurons.

## Associative Memory and Nonlinear Dynamics

Next let us consider a simple feedback neural network model consisting of $N$ mutually connected neurons where output $x_i(t)$ of neuron $i$ at the time step $t$ takes 1 (firing) or 0 (resting) as follows:

$$x_i(t+1) = 1\left(\sum_{j \neq i}^{N} w_{ij} x_j(t)\right),$$

$$w_{ij} = \frac{1}{N} \sum_{\mu=1}^{p} \left(2\xi_i^\mu - 1\right)\left(2\xi_j^\mu - 1\right),$$

where $w_{ij}$ is the synaptic weight from neuron $j$ to neuron $i$. The neuron $i$ receives inputs from all the other neurons through $w_{ij}$. Stored patterns $\xi^\mu = \left(\xi_1^\mu, \ldots, \xi_N^\mu\right)$ $(\mu = 1, \ldots, p)$ are embedded as fixed-point attractors of convergent nonlinear dynamics in the recurrent neural network through the Hebbian learning. This model is called the associative memory model. The number of patterns that can be stored as stable fixed points has a certain limit [6]. This limitation is termed storage capacity, which can be theoretically derived by the statistical mechanical methods. The basin of attraction of stored patterns in the convergent dynamics of the feedback networks means error-correcting ability of the associative memory model. It is known that there exist stable fixed points, the number of which increases

exponentially with $N$, besides the stored memory patterns. These are called spurious memory patterns. We can not distinguish the stored patterns and the spurious ones without the information of the memory patterns themselves, since both of them are fixed point attractors of convergent dynamics in the feedback networks of the associative memory.

## Chaotic Neural Networks

Neuron models with chaotic dynamics are called chaotic neurons [7]. A discrete-time chaotic neuron model consists of the following terms: the internal states of the external inputs, the feedback inputs, and the relative refractoriness, where the refractoriness means the property of a biological neuron that the firing threshold increases for a certain period after firing. Essential features of the model to exhibit chaotic responses are that all the internal states show exponential decay and the output function of the neuron is continuous like a sigmoid function [7]. Neural network models that are composed of chaotic neurons are called chaotic neural networks. The dynamics of constituent neuron $i$ in the chaotic neural network is represented by the following equations [8]:

$$\xi_i(t+1) = \sum_{j=1}^{M} v_{ij} \sum_{d=0}^{t} k_e^d A_j(t-d),$$

$$\eta_i(t+1) = \sum_{j=1}^{M} w_{ij} \sum_{d=0}^{t} k_f^d x_j(t-d),$$

$$\zeta_i(t+1) = -\alpha \sum_{d=0}^{t} k_r^d x_i(t-d) - \theta_i,$$

$$x_i(t+1) = f(\xi_i(t+1) + \eta_i(t+1) + \varsigma_i(t+1))$$

$\xi_i$, $\eta_i$, and $\zeta_i$ are internal state terms, $k_e$, $k_f$, and $k_r$ are the decay parameters for external inputs, feedback inputs from the neurons in the network, and refractoriness of neuron $i$, respectively. $x_i$ and f denote the output of neuron $i$ and the output function that is usually a sigmoid function, respectively. $A_j$ and $\theta_i$ are external input $j$ and the threshold of neuron $i$, respectively. $v_{ij}$ and $w_{ij}$ denote synaptic weight to neuron $i$ from external input $j$ and synaptic weight to neuron $i$ from neuron $j$, respectively. $M$ and $N$ are the number of the external inputs to neuron $i$ and that of the neurons in the network, respectively.

The model of the chaotic neural networks is applied to associative memory networks and combinatorial optimization networks with chaotic dynamics beyond convergent dynamics of conventional models. An example of recalling behavior of dynamically associative memory in a chaotic neural network [8] is shown in Fig. 2.

In this example, 100 chaotic neurons are interconnected with synaptic weights to store four patterns in Fig. 2a. The filled and open squares in each pattern represent 1 (firing) and 0 (resting) in the neuronal output $x_i$, respectively. As shown in Fig. 2b, the process of recalling the stored patterns is neither convergent to a fixed point of a stored pattern nor periodic even if the synaptic connection weights among constituent neurons in the network are determined by the Hebbian learning with the stored patterns like the conventional associative memory. Such aperiodic recalling of the stored patterns is caused by the characteristics of the constituent neurons that can exhibit chaotic dynamics as a single neuron.

## Synchronization of Neurons and its Modeling with Coupled Phase Oscillators

A visual object is processed in parallel at different visual areas of the brain. Each visual area extracts such specific visual features as orientation, brightness, color, and motion. To recognize the visual object as a whole, these features should be bounded. This is called the binding problem. One hypothesis of the feature binding mechanism is synchronization of neurons in the different visual areas. Some physiological experiments support the synchronization hypothesis. The coupled phase oscillator system is one of the simplest models, which captures essential properties of a general class of nonlinear oscillator systems [9]. Let us consider the following system of two phase oscillators,

$$\frac{d\phi_1}{dt} = \omega_1 + \Gamma(\phi_2 - \phi_1) + \xi_1,$$

$$\frac{d\phi_2}{dt} = \omega_2 + \Gamma(\phi_1 - \phi_2) + \xi_2,$$

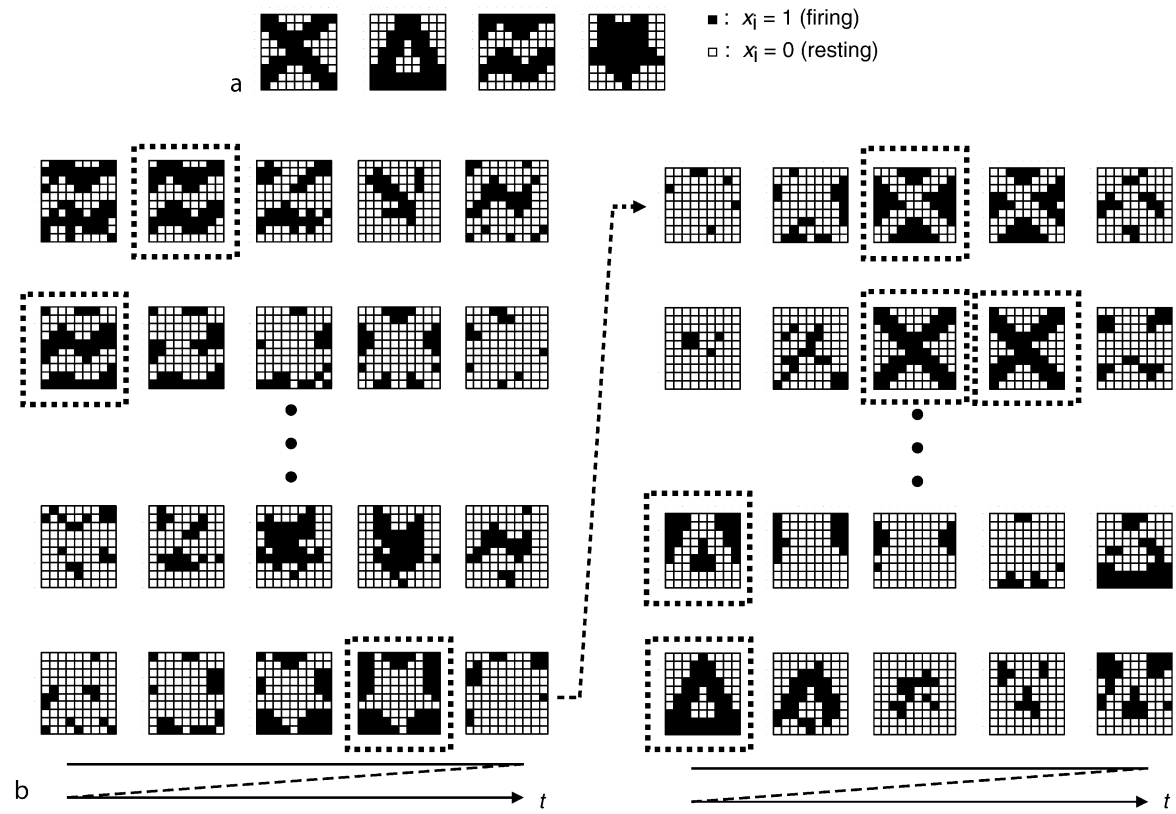
where $\phi_i \in [0,2\pi)$ and $\omega_i$ denote the phase of a periodic oscillation and its natural frequency for oscillator $i$, and $\xi_i$ is additive noise. The function of the phase response curve (RPC) $\Gamma(\cdot)$, which is periodic with the period $2\pi$ represents the interaction between the two oscillators. Here, $\Gamma(\cdot)$ is assumed to be an odd function. In the case without the additive noise, the dynamics of the phase difference $\Delta\phi$ with $\Delta\phi = \phi_2 - \phi_1$ is described by the following equation,

$$\frac{d\Delta\phi}{dt} = \Delta\omega - 2\Gamma(\Delta\phi),$$

$$\Delta\omega = \omega_2 - \omega_1.$$

The synchronization of the two oscillators occurs under the equilibrium condition that $\Delta\omega = 2\Gamma(\Delta\phi)$, while they desynchronize otherwise [9,10]. The stochastic synchronization emerges even in the case that the frequency mismatch $\Delta\omega$ is large enough to be

N



**Neural Networks. Figure 2** Associative memory in a chaotic neural network. (a) Stored patterns of the dynamically associative memory [8]. (b) Example of the recalling pattern sequence of the dynamically associative memory in a chaotic neural network.

$\Delta\omega \neq 2\Gamma(\Delta\varnothing)$ for any $\Delta\varnothing$ if the noise has appropriate characteristics. Thus, interaction between nonlinear dynamics and noise is an important problem.

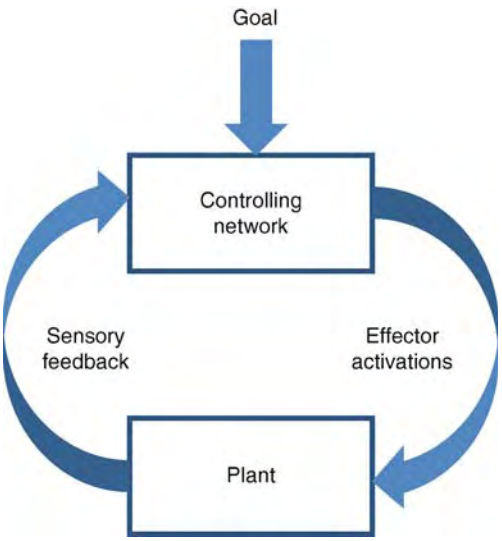
# Neural Networks for Control

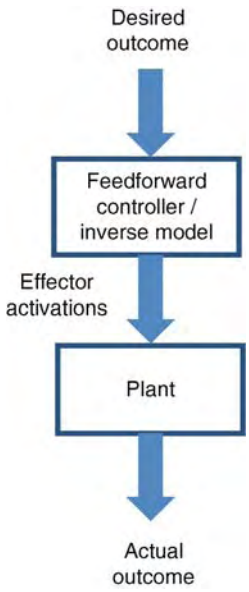
Uri Rokni
Center for Brain Science and Swartz Center for Compentational Neuroscience, Harvard, Cambridge, MA, USA

## Definition

In this essay we deal with ►neural networks which interact with the external environment, referred as a ►plant, in order to achieve a specified goal (Fig. 1). The network receives goal related inputs and sensory inputs from the plant, and in response influences the plant by activating ►effectors. At any given time, the state of the plant is fully specified by a set of variables termed the ►state variables. The dynamics of the plant is described



**Neural Networks for Control. Figure 1** A controlling network. The network interacts with the external environment, referred as the plant, to achieve a desired goal.



**Neural Networks for Control. Figure 2** A feedforward controller. The feedforward controller does not use sensory feedback. It maps the desired outcome to effector activations, inversely to the mapping from effector activations to actual outcome performed by the plant.

by equations of motion which dictate how the state changes as a function of the current state and the current activation of the effectors. The goal may be to reach a desired state, or more generally to minimize a specified ►cost function. Generally, a device which solves such problems is referred as a ►controller. In this essay we are concerned specifically with the implementation of controllers by neural networks in the ►central nervous system (CNS).

## Description of the Theory

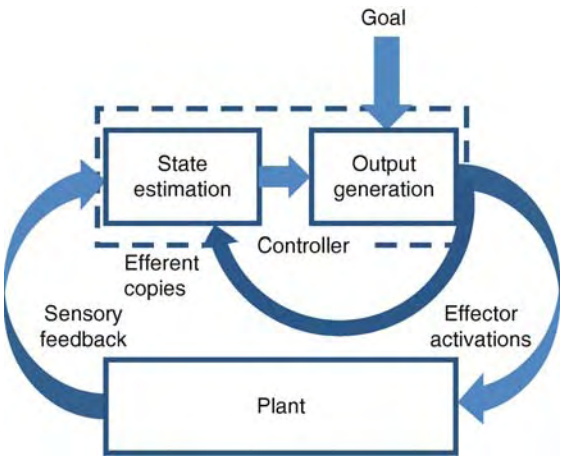
►**The reaching example**. Consider the problem of arm reaching to a specified target. The plant is the arm and the effectors are the arm muscles. The arm state variables are the joint angles and joint velocities. The equations of motion of the arm specify the joint angle accelerations as a function of the arm state and muscle activations. To reach the target, the controller needs to convert goal related inputs, which represent the target position, and sensory information on the arm state into the appropriate muscle activations.

## The Operation of Controllers

Controllers which do not use online sensory feedback from the plant are referred as ►feedforward (open-loop) controllers (Fig. 2). Feedforward controllers are often termed ►inverse models of the plant, because they map the desired outcome of the plant to effector activations, inversely to how the plant maps the effector activations to the actual outcome. For example, the arm plant maps muscle activations into hand acceleration. To properly control the arm, a feedforward controller needs to invert this relation and map the desired hand acceleration to the appropriate muscle activations. Feedforward controllers may be inaccurate because of noise in the plant, or because they do not invert the plant dynamics accurately. In these cases, online sensory feedback to the controller may improve its performance. Controllers which use online sensory feedback are referred as ►feedback (closed-loop) controllers.

Usually, in order to control the plant effectively at any given time, the controller needs to know the plant state, at least implicitly. Therefore, the operation of a controller can be divided into: (i) estimating the plant state, and (ii) mapping the estimated plant state and goal related inputs to effector activations (Fig. 3).

To estimate the plant state at a given time the system may rely on: a previous estimate of the plant state, current sensory feedback, knowledge about the plant dynamics and copies of the current effector activations (referred as ►efferent copies). A module which estimates the plant state from the efferent copies is known as a ►forward model, because it models the plant dynamics in the normal flow from effector activations to plant state. Typically, the different sources of information on the plant state are noisy. For accurate ►state estimation, the system needs to combine these different sources optimally, giving more weight to the more reliable sources of information. An optimal state estimator is known as a ►Bayesian filter. Commonly, engineers approximate the plant dynamics by linear dynamics, and the noise by Gaussian noise. In these



**Neural Networks for Control. Figure 3** The control problem is decomposed into two problems. First, estimate the plant state from the sensory feedback and efferent copies of the effector activations. Second, map the estimated plant state and the goal to effector activations.

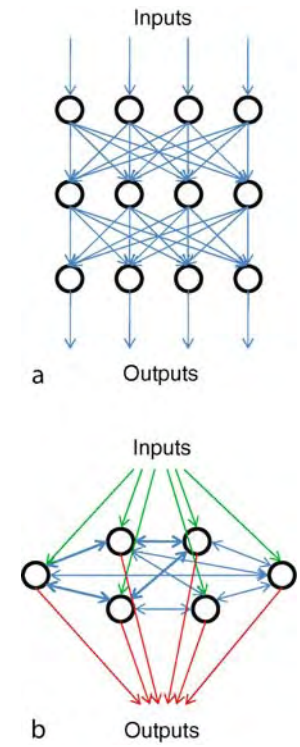
cases, there is a closed form solution of the Bayesian filter, known as a ►Kalman filter.

The problem of generating the appropriate effector activations given the current plant state may be straightforward when the effector activations can set the plant in its desired state, immediately. But typically, the plant responds gradually and the controller needs to generate the current effector activations that are best *in the long term*. For example, at the beginning of reaching, activating the arm muscles strongly may bring the arm closer to its target at first, but later cause the arm to overshoot. To reach optimally, the controller needs to take into account the future effects of the current effector activations. This problem has been extensively studied in the field of ►optimal control theory.

## Computing and Learning with Neural Networks

Neurons are believed to be the basic computational elements in the CNS. A neuron integrates action potentials from different cells, performs temporal filtering and transmits the result to other neurons in the form of action potentials. By combining neurons into networks much more complicated computations can be carried out. Networks that are arranged in layers of neurons, each layer projecting to the next, are known as ►feedforward networks (Fig. 4a). Inputs traveling through several layers of neurons may undergo complicated nonlinear transformations. Networks with connections that allow activity to travel in loops are known as ►recurrent networks (Fig. 4b). Inputs traveling through multiple loops in the network may undergo complicated temporal filtering.

To learn a desired input-output relation the strengths of the synaptic connections between neurons need to be

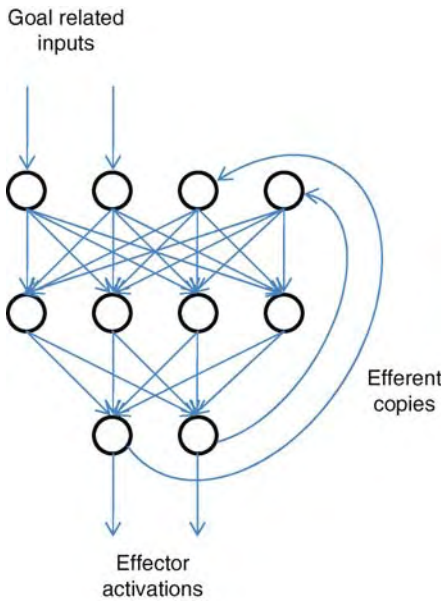


**Neural Networks for Control. Figure 4** Feedforward versus recurrent networks. (a) Feedforward networks are arranged in layers without loops in their connections. (b) Recurrent networks contain loops in their connections.

tuned. Training data may consist of pairs of inputs and desired outputs. A rule that specifies how synaptic strengths are changed, given the training data, is generally referred as a ►learning rule. A successful learning rule should decrease the output errors of the network (at least on average), so that after repeated applications of the rule the network performance improves. The ►back-propagation learning rule achieves this for feedforward networks by propagating measured output errors back through the network layers to obtain errors of the synaptic strengths. The back-propagation learning rule has been generalized for tuning the synaptic strengths of recurrent networks as well (for a review of neural network theory see [1]).

## Control with Neural Networks

The CNS is believed to implement controllers by networks of neurons. In particular, it has been suggested that controllers are implemented by networks that are feedforward, except for recurrent projections from the output layer back to the input layer [2,3, fig. 5]. Static goal related inputs to the network travel through the layers to produce the effector activations. Efferent copies of these muscle activations are fed back to the input layer, thus affecting the effector activations at the



**Neural Networks for Control. Figure 5** A sequence generating network. By sending efferent copies back to the input layer the network generates a sequence of effector activations. The network may be used as a feed forword controller.

next time step. In this fashion, the network implements a feedforward controller that maps static goal related inputs to a sequence of effector activations. This approach was generalized to feedback control by adding delayed sensory feedback to the network, and assuming the network is fully recurrent [4].

An alternative model asserts that prior to movement the entire trajectory of the effector activations is represented by static neural activity, where different neuron populations represent the planned effector activations at different times [5]. Recurrent network dynamics are used to find a trajectory that obeys task constraints, e.g. reaching the target, and minimizes a smoothness cost function. To execute the movement, the static representation of the planned trajectory is converted to effector activations that unfold in time.

Another study proposes how the CNS may estimate the plant state [6]. This study implements a Kalman filter for estimating the state of a linear arm model with Gaussian noise, by a recurrent neural network. The activity of the population of neurons in the network represents the current estimate of the arm state. This state estimate is modified by external inputs which convey sensory information on the plant state. The state estimate is also affected by the previous state estimate via the recurrent network connections. Thus, the recurrent connections encode knowledge of the arm dynamics. When simulating the network dynamics its activity estimated the plant state nearly optimally.

## Learning Neural Networks for Control

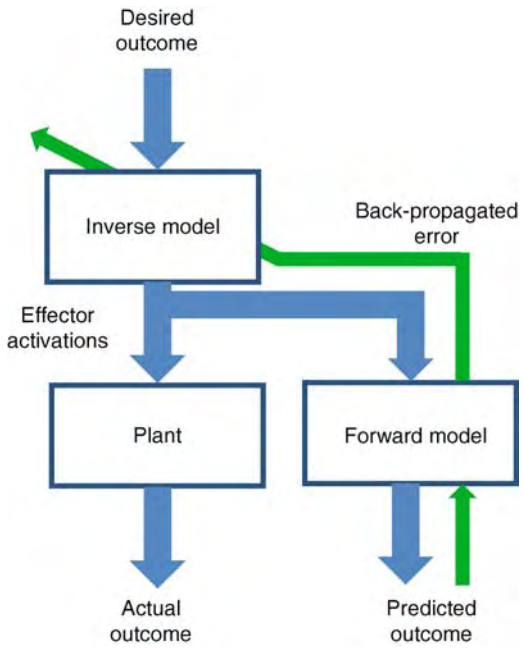
When the CNS encounters an unknown environment (e.g. new loads applied to the arm) it needs to adjust the controlling network. This adjustment is believed to occur by changing synaptic connections between neurons. To implement conventional network learning algorithms, such as back-propagation, the CNS needs to provide the output errors of the network. However, in control problems rather than being provided with the output errors of the network it is provided with the output errors of the plant. Not knowing the plant, which is the problem to begin with, how can the network translate the plant errors into network errors?

The ►direct inverse learning approach solves this problem by obtaining training data from the plant when it is randomly activated [7]. Each input-output pair of the plant is provided to the network *inversely*, as desired output-input, respectively. By training the network with this data it learns the inverse model of the plant. This method suffers from several problems. First, it learns offline. Second, the plant may be non-invertible, meaning that different plant inputs generate the same output. Thus, for a given input (plant output) the network may learn the mean of multiple desired outputs (plant inputs). Generally, this mean will not be either of the correct network outputs (plant inputs). Finally, direct inverse learning minimizes the error in the plant *inputs*, which may not be optimal for minimizing the error in the plant *outputs*.

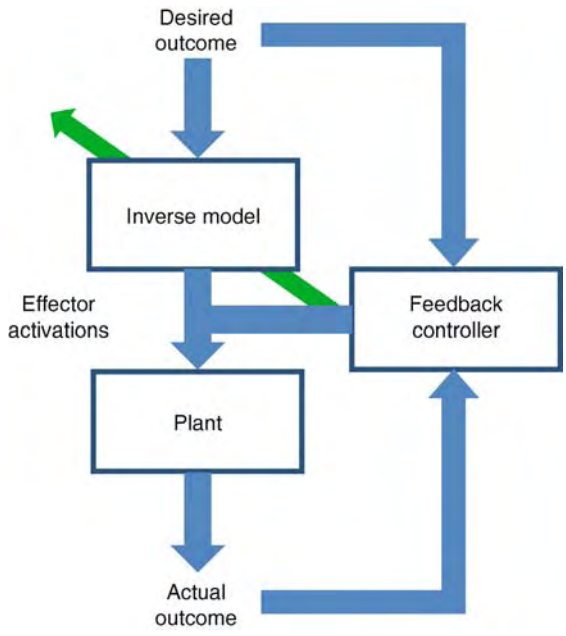
These problems are solved by an alternative method, known as ►distal supervised learning, which learns the inverse model in tandem with a forward model [8, fig. 6]. During operation of the system, the forward model is trained to imitate the plant by providing the plant input-output pairs as training data. At the same time, the plant errors are back-propagated through the forward model to obtain the output errors of the inverse model. These error signals are used to train the inverse model.

Another approach for learning an inverse model, known as ►feedback error learning, assumes a sensory feedback loop in parallel with the inverse model [9, fig. 7]. The same feedback loop that is used for control, is also used as an error signal for training the inverse model. This approach requires a stable sensory feedback loop to begin with, and leaves open the question of how the feedback loop is learned.

Finally, a different approach, known as ►reinforcement learning, uses noise in the controlling network and a ►scalar performance measure known as the ►reward signal [10]. By correlating the noise with the reward signal, the reinforcement learning rule changes synaptic weights such that outputs that yield greater reward become more likely. Over time the average reward increases to its maximum. Reinforcement learning does



**Neural Networks for Control. Figure 6** Distal learning. A network which unitates the plant, referred as a forward model, is learned. At the same time, the errors in the plant output are backpropageted through the forward model network to obtain the errors of the inverse model (green arrow). These errors are used to train the network of the inverse model.



**Neural Networks for Control. Figure 7** Error feedback learning. The same sensory feedback that is used for controlling the plant is also used for training the inverse model (green arrow).

not rely on back-propagation of errors. But, it is slower than other methods because it requires averaging over noise and because it uses a scalar performance measure, which is less informative than a ►vector of output errors.

# Neural Regulation of the Pupil

Peter G. Smith
Department of Molecular and Integrative Physiology and Kansas Intellectual and Developmental Disabilities Research Center, University of Kansas Medical Center, Kansas City, KS, USA

## Definition

The pupil is an aperture formed by the margins of the iris. Pupillary diameter determines the amount of light traversing the lens to focus on the retina, producing a visual image. The primary factor determining pupil diameter is the concentration of autonomic transmitters at contractile cells of the iris. This is regulated by the ►sympathoadrenal and parasympathetic nervous systems.

## Characteristics

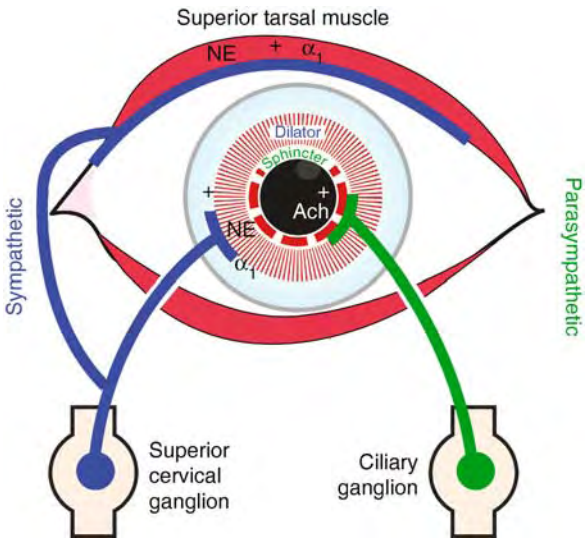
### Quantitative Description

Pupillary diameter is determined by the relative tone of two opposing contractile elements within the iris. The pupillary sphincter (constrictor) muscle abuts the margin of the pupil. It consists of smooth muscle fibers with their long axes oriented circumferentially with respect to the pupil (Fig. 1).

When these cells contract, the pupil margins are drawn closer together, causing a decrease in pupil diameter (constriction, or ►miosis).

The iris contains a second contractile component, the pupil dilator (radial) muscle. This structure is composed of myoepithelial cells oriented radially, with their long axes directed outward from the pupil center as if spokes in a wheel (Fig. 1). When they contract, the pupil margins are drawn away from the center, increasing pupil diameter (dilation, or ►mydriasis).

Pupil diameter of is thus determined by the relative activity, or tone, of these two opposing muscles.



**Neural Regulation of the Pupil. Figure 1** Schematic diagram of the innervation of the iris and related structures. The iris sphincter (constrictor) muscle contains smooth muscle cells oriented circumferentially. It is innervated by parasympathetic excitatory (+) nerves from the ciliary ganglion, which release acetylcholine (Ach). The dilator (radial) muscle consists of myoepithelial cells oriented radially. This muscle, as well as the superior and inferior tarsal muscles of the eyelids, is innervated by excitatory (+) sympathetic nerves which release norepinephrine (NE) that act on alpha-1 adrenergic receptors.

N

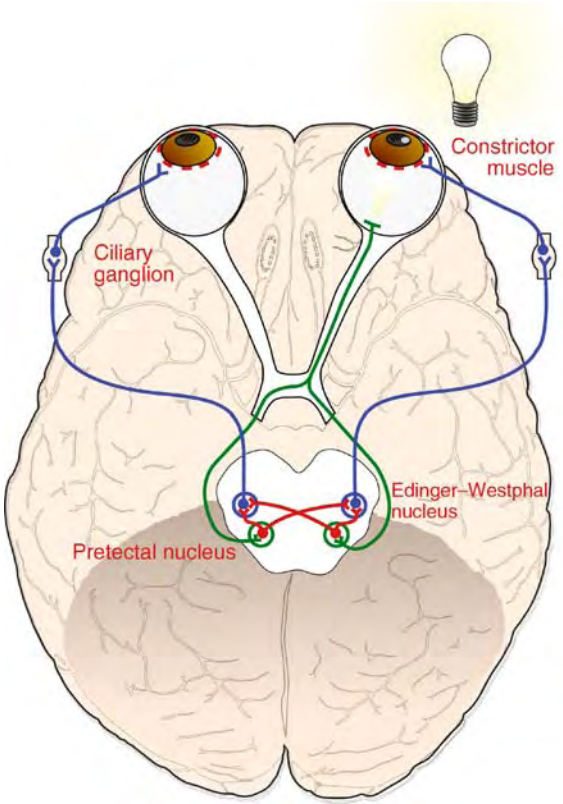
## Higher Level Structures

Regulation of pupil diameter involves integration of afferent information transmitted by the optic nerve to diencephalic processing structures, as well as emotive pathways incorporating fear, anxiety, pleasure and pain.

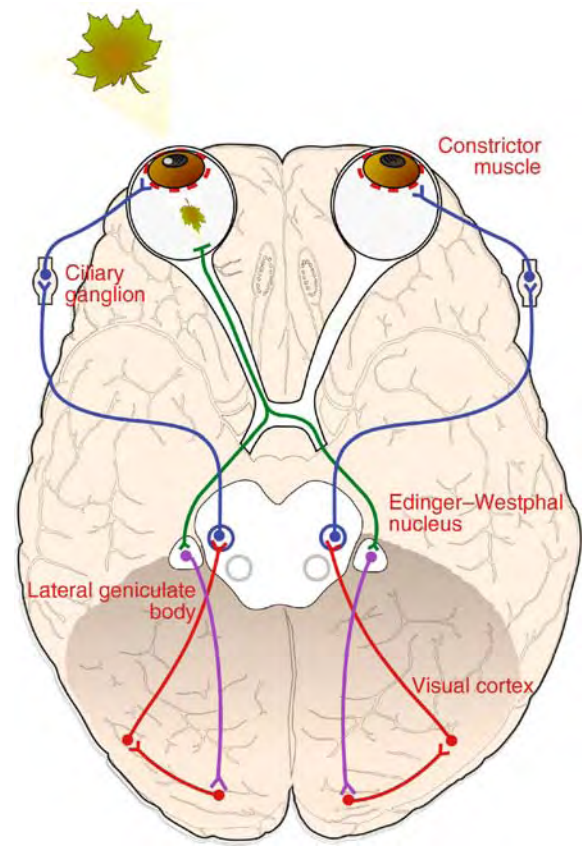
Constrictor pathways. Light elicits pupil constriction by way of a subcortical reflex initiated by light passing through the anterior eye and impinging upon photoreceptor cells of the retina. Photoreceptive impulses travel along retinal ganglion cell axons in the optic nerve, which hemi-decussate at the optic chiasm, and travel to the superior colliculus to enter the pretectal nucleus where they synapse on pretectal neurons (Fig. 2).

These neurons send projections to the ipsilateral and contralateral Edinger–Westphal nucleus [1]. This nucleus contains preganglionic parasympathetic neurons, which send axons in cranial nerve III (oculomotor) to postganglionic neurons of the ciliary ganglion, whose axons travel in the short ciliary nerves to innervate the sphincter muscle of the iris (Fig. 2).

Pupillary constriction is also elicited in association with accommodation, which occurs when viewing near objects. Photoreceptive impulses conducted to the visual cortex activate efferent projections to the



**Neural Regulation of the Pupil. Figure 2** Parasympathetic light reflex pathway. When the eye is illuminated, retinal ganglion neurons projecting axons (*green*) to midbrain excite pretectal neurons (red). Pretectal neurons project excitatory synapses to the ipsilateral and contralateral Edinger–Westphal nucleus, which contains parasympathetic preganglionic neurons (*blue*). These neurons provide excitatory innervation to postganglionic neurons in the ciliary ganglion, which innervate the pupillary constrictor (sphincter) muscles in each eye, where they elicit pupil constriction.



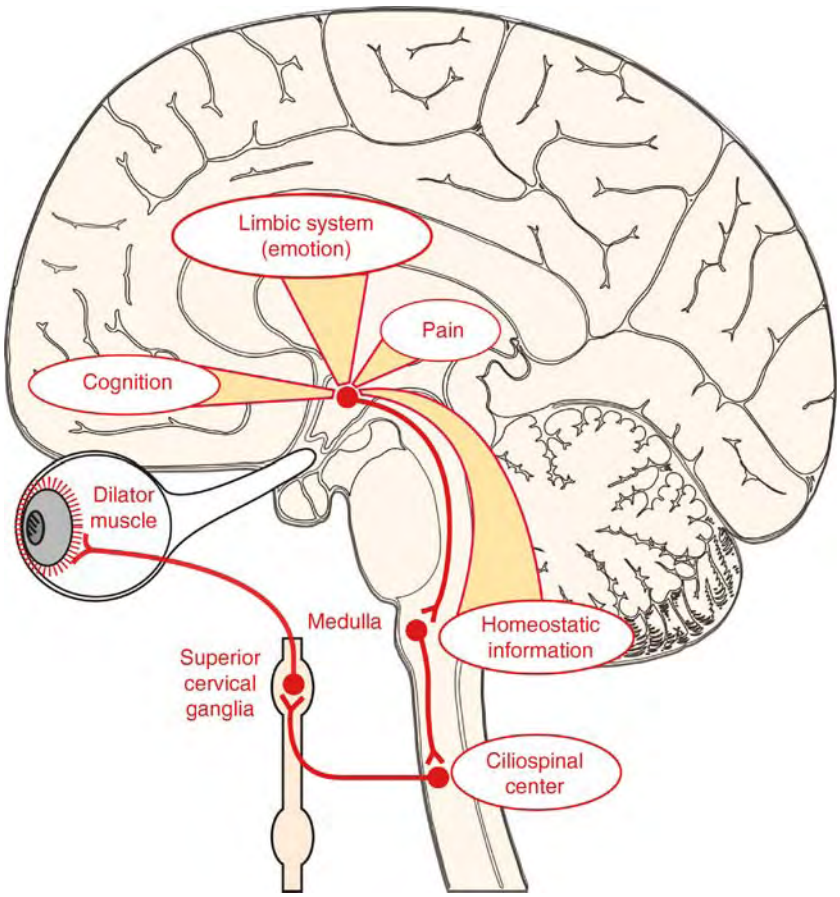
**Neural Regulation of the Pupil. Figure 3** Pupillary constriction associated with accommodation. When an object is placed close to the eye for near vision, retinal ganglion axons (green) excite neurons bilaterally in the lateral geniculate body (purple), which project to the visual cortex and associated structures. Descending pathways provide excitatory innervation ipsilaterally to neurons in the Edinger–Westphal nucleus (blue), which excite postganglionic neurons in the ciliary ganglion to elicit constrictor muscle contraction and pupil constriction.

Edinger–Westphal nucleus, which activate oculomotor nerve pathways to the iris constrictor muscle (Fig. 3).

Dilator pathways. Central nervous system pathways mediating pupil dilation are complex and less well defined. Generally, factors leading to sympathoadrenal activation cause pupil dilation. The hypothalamus serves as a central integrative center for pupil dilation [1]. Structures that influence hypothalamic output include inputs from cognitive centers (prefrontal cortex), limbic system including the amygdala, sensory pathways involved in pain perception, and sensory pathways involved in homeostatic regulation such as blood chemical composition (glucose, oxygen, carbon dioxide, pH) and blood pressure. Hypothalamic neurons project to neurons in the lateral medulla, which innervate ipsilateral spinal cord intermediolateral neurons (ciliospinal center of Budge). Axons from these preganglionic neurons exit at C8–T2 and ascend proximate to the carotid artery to the superior cervical ganglion. Postganglionic axons travel in the internal carotid nerve and enter the orbit with the ophthalmic division of the trigeminal nerve. Sympathetic fibers travel in the nasociliary branch of the trigeminal nerve ophthalmic division and long ciliary nerves to innervate the iris dilator muscle (Fig. 4).

## Higher Level Processes

Constrictor pathway. The primary stimulus activating parasympathetic pathways is photoreceptive input. The pupillary light reflex is responsive to the intensity of ambient light impinging on retinal rods and cones, as well as melanopsin-expressing retinal ganglion cells that are directly photosensitive [2]. Increasing photointensity produces graded activation of axons projecting to the



**Neural Regulation of the Pupil. Figure 4** Sympathetic pathways mediating pupil dilation. Neurons in the paraventrictular region of the hypothalamus receive input from multiple pathways encoding cognitive information from the cortex, emotion from the limbic system, pain from somatosensory pathways, and homeostatic information concerning blood pressure and composition from ascending pathways. Hypothalamic neurons project to neurons in the medulla, which send axons to the ciliospinal center of the intermediolateral column of the spinal cord. Preganglionic ciliospinal neurons project axons through the ventral roots, which ascend with the paravertebral chain to synapse upon postganglionic sympathetic neurons of the superior cervical ganglion. Postganglionic axons traverse intracranially to enter the orbit and innervate the dilator (radial) muscle of the eye.

pretectal and Edinger–Westphal nuclei, which elicits graded firing of oculomotor neurons bilaterally. The net result is pupillary constriction corresponding roughly to light intensity.

Pupil constriction also occurs when the eye focuses on a near object. A coordinated triad of responses is initiated, involving bilateral ocular convergence, ciliary muscle contraction leading to a more spherical lens with greater refractive index, and pupil constriction. In contrast to the light reflex, accommodation involves higher visual cortical structures associated with near object focality, activating efferent preganglionic motor neurons of the Edinger–Westphal nucleus.

While light intensity and accommodation are major factors eliciting pupil constriction, it is noteworthy that somatic input can also influence this pathway. For example, lingual nerve stimulation can actually inhibit preganglionic activity, thus attenuating pupillary constriction [3].

Dilator pathways. Activation of the pupillary dilator pathway is closely linked to sympathoadrenal tone. The sympathetic nervous system in conjunction with the adrenal medulla is activated when the organism enters into a “fight or flight” response. This occurs when a challenge is perceived – as innocuous as mental arithmetic or as threatening as being confronted by a bear. Visual information recognized as threatening is conveyed via the thalamus to the amygdala and on to the hypothalamus, where descending pathways lead to sympathetic activation and adrenomedullary catecholamine release, leading to a number of responses including pupillary dilator muscle contraction. This response can be further modified by visual information from the sensory and prefrontal cortex, which can alter

amygdala output by reinforcement or inhibition. Conditions producing mild or intense anxiety, mental concentration, or sexual arousal can also lead to pupil dilation through similar pathways.

Other types of sensory stimuli promote pupil dilation. Loud noises can lead to startle and result in dilation. In particular, mild to intense pain activates the sympathoadrenal system and promotes pupil dilation, and olfactory inputs leading to emotive activation can influence pupil diameter. Pupillary diameter can also be influenced by baroreceptor pathways, which monitor blood pressure and elicit sympathetic nerve activation when blood pressure falls [4].

## Lower Level Processes

The iris dilator and sphincter muscles receive innervation from three ipsilateral sources: parasympathetic axons from the ciliary ganglion, sympathetic axons from the superior cervical ganglion, and sensory axons from the trigeminal ganglion.

Sensory innervation to the iris derives primarily from small diameter trigeminal ganglion neurons giving rise to C fibers, which innervate the dilator and sphincter muscles. These presumptive nociceptor axons display a peptidergic phenotype that includes immunoreactivity for substance P, calcitonin gene-related peptide, galanin and somatostatin. These sensory neurons also express a splice variant of choline acetyltransferase that is largely restricted to peripheral neurons [5]. The function of iridial sensory fibers remains unclear, but they likely provide the CNS with information on noxious stimuli and intraocular pressure, and may subserve efferent functions via postjunctional effects of peptides and possibly acetylcholine on iris smooth muscle, and prejunctional actions on co-projecting autonomic axons.

Postganglionic neurons from the ipsilateral cilliary ganglion provide parasympathetic excitatory innervation to the iris sphincter muscle. Acetylcholine from parasympathetic varicosities elicits contraction via $M_3$ muscarinic receptors [5].

The primary neural mechanism for pupil dilation is noradrenergic sympathetic innervation of the dilator muscle. Sympathetic axons release norepinephrine within the radial muscle, which acts on excitatory alpha 1A adrenergic receptors [6].

While cholinergic effects dominate in the sphincter muscle and noradrenergic effects dominate in the dilator muscle, it should be noted that sympathetic and parasympathetic nerves co-project to both muscles [5], implying cross-talk between spatially proximate axons. Indeed, acetylcholine from parasympathetic nerves acts on sympathetic prejunctional $M_2$ muscarinic receptors to inhibit norepinephrine release [7], indicating parasympathetic presynaptic inhibition of sympathetic neurotransmission. Sympathetic neurotransmission can be inhibited prejunctionally by other mechanisms, including $\alpha_2$ autoreceptors and histaminergic receptors. Noradrenaline released by sympathetic nerves may elicit additional effects, including β-mediated sphincter muscle relaxation and inhibition of sensory neuropeptide release [8].

## Process Regulation

The contractile states of iris dilator and constrictor muscles are determined primarily by 3 factors: ambient light, near vision, and emotional state. With moderate ambient light intensity, the primary variable determining differences in pupil diameter is sympathoadrenal activation. If an individual is normotensive and not emotionally aroused, an intermediate pupil diameter is expected (somewhere in the midrange between about 2 mm minimum and 8 mm maximum). In total darkness, pupil diameter increases toward its maximum.

With increasing light, pupil constriction occurs as parasympathetic nerves release acetylcholine to contract the sphincter muscle and to inhibit release of norepinephrine from sympathetic axons innervating the dilator muscle. If only one eye is exposed to light, both ipsilateral and contralateral pupils constrict (►consensual light reflex). This occurs because midbrain pretectal fibers project to the contralateral as well as the ipsilateral Edinger–Westphal nucleus (Fig. 2). A similar mechanism occurs with near-vision in which pupil diameter is constricted directly and consensually, although this does not involve pretectal neurons (Fig. 3).

## Function

By constricting the pupil in bright light, light entering the posterior chamber is reduced, preventing excessive bleaching of rods and cones and protecting the eye from possible damage. A reduction in pupil diameter in near vision increases depth of field. As in photography where a smaller aperture provides a greater range of distances in which objects appear in focus, reduced pupil size works similarly, which is important in near vision where greater refractive index of the lens limits the depth of field.

Sympathoadrenal activation dilates the pupil, which has converse effects. In fight or flight, mydriasis serves two functions. First, under threatening conditions, it may be useful to have an enlarged pupil to gather more light and to have a larger peripheral field, making the individual more perceptive to environmental cues. Second, mydriasis occurs in conjunction with alpha adrenoceptor-mediated contraction of the superior and inferior tarsal smooth muscles of the eyelid, which increase palpebral fissure width. Together, these provide important body language cues. The individual may appear "wide-eyed" with rage, signaling a state of emotional activation. On a more subtle note, pupil diameter increases when an individual perceives another to be romantically attractive, thus providing another important cue.

## Pathology

Neurological disturbances can occur at several sites, leading to differences in diameters of the two pupils (►anisocoria). Loss of afferent transmission along one optic nerve results in a normal consensual pupillary light reflex when the eye with intact innervation (contralateral to the lesion) is illuminated, but diminished response (apparent dilation) when the light is alternated to the affected eye. This is referred to as the Marcus Gunn pupil.

Degenerative conditions in the central nervous system can affect the light reflex. A fairly common one in advanced syphilis is the ►Argyll–Robertson pupil. The affected eye fails to respond to light but the pupil constricts normally during near vision accommodation. The reason appears to be that pretectal neurons mediating the light reflex degenerate selectively in this disease. Since pretectal neurons are not involved in accommodation, that reflex is preserved.

Damage to efferent postganglionic parasympathetic axons can lead to loss of constriction in response to light and accommodation. This is referred to as Adie's pupil. It is frequently accompanied by an elevated response to cholinomimetic drugs due to parasympathetic denervation supersensitivity.

Interruption of the sympathetic pathway to the pupil results in Horner's syndrome. This consists of unilateral miosis (constrictor predominance in the absence of dilator tone), ptosis (drooping of the upper eyelid and diminished palpebral fissure width due to loss of alpha adrenergic activation of the tarsal smooth muscle), anhydrosis (loss of sympathetically mediated facial sweating), and facial flushing (loss of sympathetic vasoconstrictor tone). These symptoms are all due to interruption of sympathetic innervation to the head. Damage can occur anywhere along the pathway, including higher level first order neurons of the hypothalamus or medulla (frequently due to a stroke or tumor), second order preganglionic neurons leaving the spinal cord and traveling with the carotid artery (tumor, aneurism, trauma) or to the third order postganglionic axons (internal carotid artery dissection, viral infection). Third order lesions can be distinguished from higher order deficits by placing a drop of the hydroxyamphetamine onto the eye. This drug releases norepinephrine from intact sympathetic varicosities. If the lesion involves postganglionic axons, then hydroxamphetamine will not cause mydriasis normally seen in the normal eye because the nerve terminals have degenerated.

## Therapy

Adie's pupil often occurs in young females and frequently resolves spontaneously. Because it often accompanies migraines or cluster headaches, it may improve with effective headache management. In Marcus Gunn pupil or Horner's syndrome where a tumor may compress neural pathways, surgical resection or chemotherapy may reverse the deficit. In Horner's syndrome, nerve regeneration and functional restoration usually is more complete if the lesion involves only postganglionic axons. In Argyll–Robertson pupil where a diagnosis of syphilis is confirmed, patients often respond beneficially to antibiotics.

# Neural Respiratory Control During Acute Hypoxia

Diethelm W. Richter, Michael Müller
DFG Research Center Molecular Physiology of the Brain, Department of Neurophysiology, Georg-August-Universität Göttingen, Göttingen, Germany

## Definition

In mammals, breathing movements are driven by an oscillatory activity generated by a neuronal network located in the lower ►brainstem. Being exposed to

severe ►hypoxia this network shows a typical sequence of responses. This essay focuses on the molecular physiology underlying the acute hypoxic responses of this respiratory rhythm generating network (►respiratory network) without considering hypoxia-induced changes in gene regulation.

## Characteristics

### Structural and Functional Organization of the Respiratory Network

Breathing originates from respiratory movements of the chest and abdomen that are driven by rhythmic discharges of motoneurons innervating inspiratory muscles (diaphragm, external intercostal muscles) and expiratory muscles (internal intercostal muscles and abdominal muscles). The normal (eupneic) pattern of this central respiratory activity is separated into three discrete phases – inspiration, post-inspiration and expiration (Fig. 1).

The phasic activity pattern is generated by a neuronal network composed of distinct sub-populations of pre-motoneurons located within the lower brainstem (medulla oblongata). The kernel of the network is localized bilaterally in the ►pre-Bötzinger complex (►pre-Böztinger neurons and rhythm generation) – a distinct region in the "ventral respiratory group", in the neighboring Bötzinger complex, and – within the "dorsal respiratory group" – in the ventrolateral nucleus of the solitary tract. Another rhythmically active region is localized around the retrotrapezoid nucleus/parafacial respiratory group containing expiratory neurons (►parafacial neurons and respiratory control). In summary, several brainstem regions cooperate to generate a neural respiratory activity that controls effortless quiet breathing movements (►eupnea) (►medullary raphe nuclei and respiratory control; ►pontine control of respiration). The medullary respiratory network communicates synaptically with several other vital neuronal control systems by which it essentially influences amongst others the control of vocalization, swallowing and cardiovascular regulation.

The respiratory neurons receive tonic synaptic excitation from arterial chemoreceptors (►carotid body chemoreceptors and respiratory drive) and the reticular formation that provides a basic activity level on top of which rhythmic activity is generated. An alternating volley of excitatory and inhibitory synaptic inputs then ensures a powerful membrane voltage management and vigorously controls activation or inactivation of ►voltage-gated ion channels ("synaptic voltage clamp"), thereby effectively determining a characteristic rhythmic discharge pattern [1].

Inhibitory synaptic interconnections between the respiratory neurons are vital. ►GABA and ►glycine largely control chloride ion ($Cl^-$) currents that do not only terminate neuronal discharges, but also precisely define the onset of activity, the activity pattern and the duration of discharge for the different types of respiratory neurons. Furthermore, these currents shape a smooth transition between the individual respiratory phases.

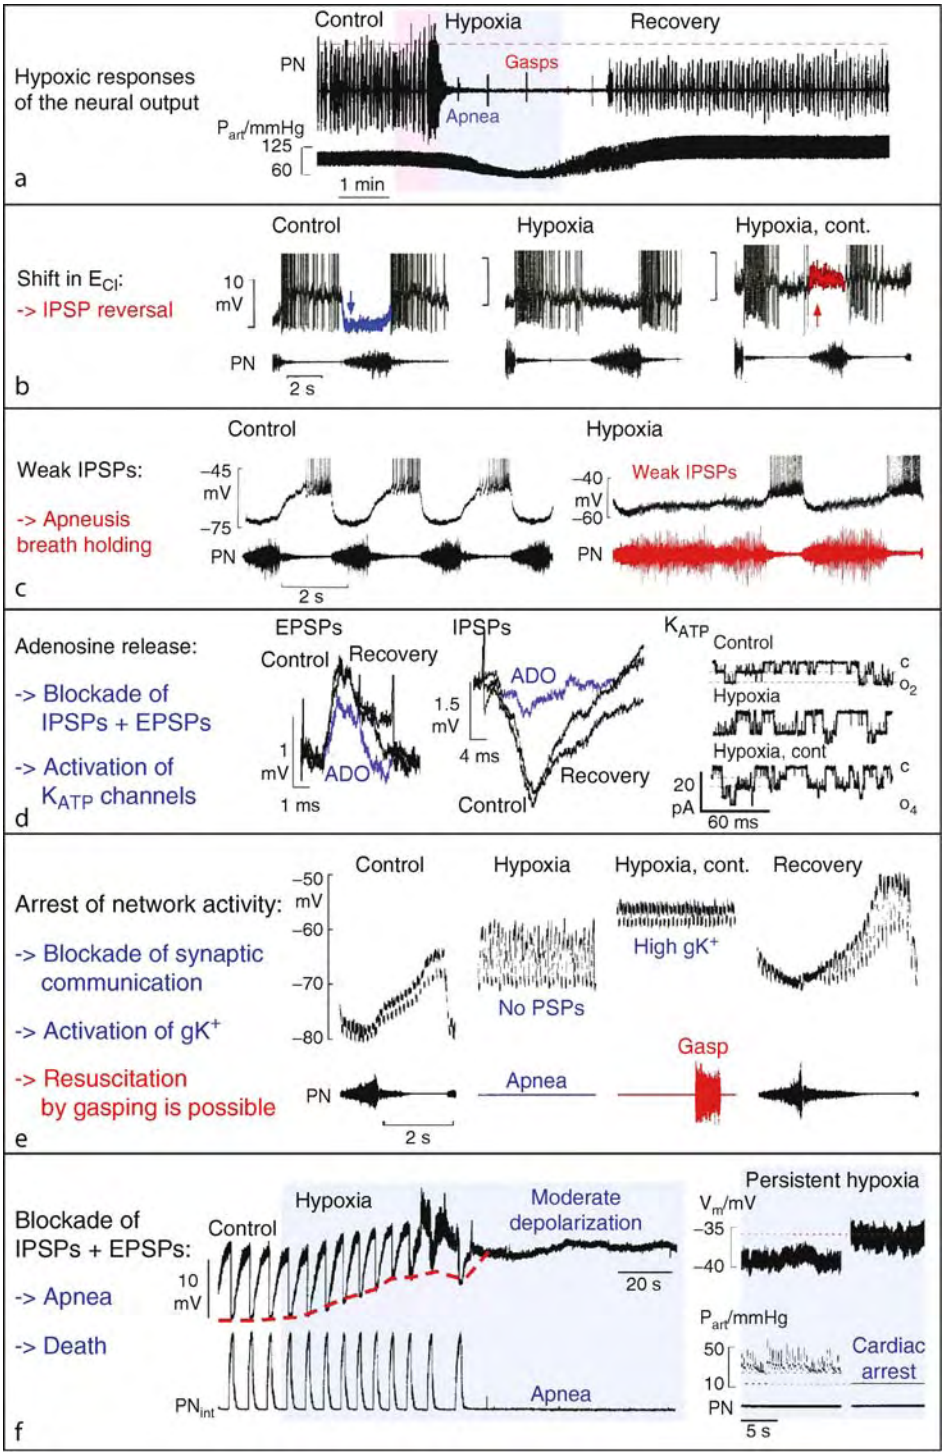
### Energy Supply of the Network

Just as other parts of our brain, the respiratory network requires a constant $O_2$ supply to maintain normal oxidative phosphorylation. "►Cellular respiration" occurs at complex IV of the mitochondrial electron transport chain where $O_2$ accepts 2 electrons – donated from either NADH or $FADH_2$ – and is reduced to water. In the presence of $O_2$, the electron transport chain generates and maintains an inwardly directed proton gradient across the inner mitochondrial membrane, thereby supplying the driving force fueling ►ATP synthesis by the mitochondrial ATP synthase (complex V or $F_0F_1$ ATPase). Yet, when tissue $pO_2$ drops below 5 mm Hg the proton gradient collapses and ATP synthesis by oxidative phosphorylation ceases. Under such conditions of severe ►hypoxia, only anaerobic glycolysis remains intact, which contributes no more than 1–5% of the normal ATP production. This is, however, not sufficient to ensure undisturbed neuronal function over a longer period of time.

The duration of acute hypoxia that can be tolerated varies among the different brain regions. Neurons are more vulnerable than glial cells, and among the most ►anoxia/►ischemia vulnerable neurons are hippocampal CA1 and cortical pyramidal neurons, cerebellar Purkinje neurons and medium spiny neurons of the striatum. In contrast, most of the brainstem including the respiratory network is far less vulnerable to anoxic/ischemic insults.

In neurons cultured from mouse respiratory center, mitochondria form functionally coupled, dynamically organized aggregates such as "chains" and "clusters." Mitochondrial chains predominate in dendrites and reveal a directed movement that is arrested upon mitochondrial depolarization or blockade of mitochondrial ATP synthesis as it occurs under severe hypoxia [2]. Depolymerization of the cytoskeleton also disrupts mitochondrial chain movements and the mitochondria accumulate in the soma. The consequence of such immobilized mitochondria is that the local energy supply at energetically hot spots like dendritic synapses is no longer assured.

Impaired mitochondrial metabolism is also associated with a change in reactive oxygen species output inducing a strong modulation of the cytosolic redox status. To what degree such redox changes are involved in the hypoxic modulation of the respiratory network is as yet unclear. From the "rhythmic brainstem slice preparation" (►respiratory network analysis: rhythmic slice



**Neural Respiratory Control During Acute Hypoxia. Figure 1** The sequence of hypoxic responses consists of 5 discrete phases. Exposed to severe hypoxia the neural output in the phrenic nerve innervating the diaphragm shows an initial, transient phase of augmentation. This turns into apneustic (►Apneusis) breathing with prolonged inspiratory bursts (the neural equivalent of breath holding), proceeding into respiratory depression and protective ►apnea if hypoxia persists. ►Gasping constitutes the final attempt of auto-resuscitation. If it fails, terminal apnea and irreversible cellular damage will occur.

N

preparation) of neonatal rats we know, however, that redox changes modulate rhythmic activity. A reducing shift causes an augmentation, while an oxidative shift leads to a depression of inspiratory activity.

## Hypoxic Changes in Ionic Homeostasis

Most energy is consumed by ATP–driven pumps that maintain ionic homeostasis. Among these the ubiquitous $Na^+/K^+$ ATPase is most demanding. Due to the extraordinary number of neurons and glial cells in the brain, the $Na^+/K^+$ ATPases account for approximately 60% of total ATP consumption. Accordingly, depletion of cellular ATP results in a failure of the $Na^+/K^+$ ATPase and thus a severe disturbance of ionic homeostasis in and around neurons and glial cells. $Na^+$ continues to leak into cells and $K^+$ which is released by the neurons accumulates in the narrow interstitial space, causing a progressive depolarization of neurons and glial cells. Accordingly, irreversible decline of membrane potential and destruction of neural tissue will occur, if $O_2$ supply is not restored in time. However, such high sensitivity and rapid voltage decline is only seen in hippocampal and cortical brain regions, where hypoxia induces a quick rise in extracellular $K^+$ to a ceiling level of approximately 9 mM, before it finally continues to rise to levels beyond 40 mM, when the anoxic/terminal depolarization (►ischemic stroke) occurs [3]. In the lower brainstem, however, such massive changes in the extracellular ion levels do not occur as quickly. It is surprising that in the fully intact *in vivo* preparation extracellular $K^+$ rises only by maximally 1–1.5 mM, even though tissue $pO_2$ had dropped to zero levels for a duration of several minutes. The robust protection of the respiratory network against hypoxia might in part be referred to a slower decline of ATP, possibly due to an efficient utilization of alternate metabolites and the "loose" tissue architecture of the reticular formation. Together with a "distributed organization" of the respiratory network along the rostrocaudal axis of the medulla this might efficiently protect the network against disturbances in extracellular ion concentrations.

## Hypoxic Disturbances of Respiratory Network Functions

A fall of the arterial and tissue $pO_2$ provokes a sequence of responses that is composed of at least five discrete phases (Fig. 1). As long as the network has not entered the state of terminal apnea, all these changes are reversible and normal network function can be restored by reoxygenation.

### *Augmentation*

In the intact *in vivo* preparation, the respiratory network activity increases very sensitively from the very beginning of hypoxia, because the slightest fall in arterial $pO_2$ causes an arterial chemoreceptive activation of the entire respiratory network (►carotid body chemoreceptors and respiratory drive). If this reflex activation of breathing movements does not quickly reset normal $pO_2$ levels and hypoxia persists, a sequence of cellular and systemic trials is initiated, aiming to protect the network.

### *Apneusis or Breath Holding*

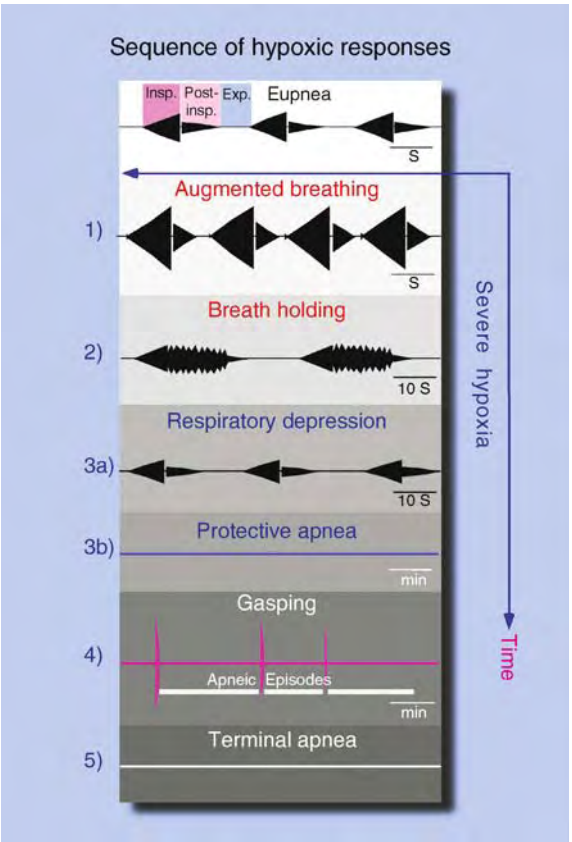
During the initial phase of hypoxia, glutamate mediated synaptic excitation is progressively enhanced, but remains stable. Release of increased amounts of glutamate can even activate ►metabotropic receptors of the mGluR1/5 type and ryanodine receptors gating intracellular $Ca^{2+}$ stores. A concomitant activation of Ca(L) channels seems to contribute to a cytosolic $Ca^{2+}$-rise. This is, however, followed by the activation of hyperpolarizing $Ca^{2+}$-activated $K^+$ conductances (►calcium-activated K± channels).

Fairly soon, however, synaptic inhibition starts to be diminished until $Cl^-$ mediated (GABA and glycine induced) IPSPs (inhibitory postsynaptic potentials) finally disappear completely [4] (Fig. 2b, d).

This correlates with the finding that increased release and extracellular accumulation of GABA occurs only initially, is transient and comparably weak and then declines below control levels [5]. Diminished synaptic inhibition disturbs the discharge patterns of the different neuronal subtypes that are no longer phase-locked. As a consequence, inspiration inhibitory processes are fading, resulting in a loss of inspiratory patterning and off-switching and thus pathologic prolongation of inspiratory bursts, which is equivalent to the frequently observed ►breath holding (Fig. 2c). This is a severe disturbance of highest clinical relevance because the dramatic fall in respiratory frequency potentiates hypoxia.

A declining release of GABA indicates an early failure of synaptic inhibition in mature preparations due to a higher anoxia vulnerability of inhibitory interneurons. There is common agreement that the key reason is a disruption of the $K^+$ and $Cl^-$ gradients. An important player regulating this gradient is the $K^+$- $Cl^-$ cotransporter KCC2 that is found at inhibitory synapses. It seems that hypoxia induces a rapid loss of tyrosine phosphorylation of KCC2 resulting in a functional disturbance of transport activity and thus intracellular $Cl^-$ accumulation. Consequently the $Cl^-$ gradient across the membrane declines and with a shift of the $Cl^-$ ►equilibrium potential above −70 mV IPSPs that normally hyperpolarize become depolarizing (Fig. 2b). Accordingly, KCC2 knockout mice die immediately after birth due to abolished breathing.

In the rat preparation, IPSPs of respiratory neurons are depolarizing at birth and obviously not yet essential for rhythmogenesis. But interestingly, shortly before delivery, maternal oxytocin release induces a transient reduction in the intracellular $Cl^-$ concentration and an excitatory-to-inhibitory switch of GABA actions in the



**Neural Respiratory Control During Acute Hypoxia.**
**Figure 2** Molecular mechanisms of the hypoxic response. The molecular and cellular mechanisms contributing to the failure of the respiratory network during severe hypoxia originate from a functional loss of synaptic interactions, not the loss of membrane potential or severely disturbed ionic homeostasis. The key processes are firstly reversal of IPSPs, but then attenuation and finally block of synaptic transmission that originates from a strong activation of ATP sensitive pre- and postsynaptic $K^+$ conductances. Prominent depolarization of the single neurons does not occur even after the network has passed the point of no return and has entered the state of terminal apnea.

fetus. Thus, maternal oxytocin generates hyperpolarizing IPSPs in fetal neurons and protects the fetus against excitotoxic insults during delivery.

### *Protective Apnea*

During progressive periods of hypoxia depression of respiration becomes the principal strategy that is typified by only moderate membrane depolarization of respiratory neurons (Fig. 2f). The release of ►adenosine [5] blocks synaptic transmission by inhibition of $Ca^{2+}$ conductances in axon terminals. Postsynaptically it inhibits the formation of ►cyclic adenosine monophosphate (cAMP and activates ►ATP-sensitive $K^{\pm}$ channels ($K_{ATP}$ channels) (Fig. 2d) [6]. This ATP/ADP/adenosine regulated $K_{ATP}$ conductance keeps the membrane potential of neurons at a relatively negative level of approximately −40 mV to −50 mV and thus protects neurons against massive intracellular $Ca^{2+}$ accumulation that would destroy neurons in such a hypoxic situation. The unfavorable consequence of such a negative membrane potential firmly "clamped" by $K^+$ currents is that synaptic drive potentials are further reduced and respiratory neurons are completely silenced. Most respiratory neuronal spike discharges cease, although the neurons in fact remain excitable by antidromic stimulation [4].

This "cell-endogenous" protection is getting competent assistance by "cell-external" support through a variety of neurotransmitters and -hormones, such as ►serotonin [5] and endorphins or leucine enkephalin to mention just a few. Together they reinforce protective $K^+$ effluxes through their action on G protein coupled signaling pathways, inhibiting intracellular cAMP production [7]. Such concerted action of neuromodulatory substances is capable to protect the respiratory neurons for a astonishingly long time that might last up to 20 min as measured in the anesthetized cat [8].

In this respect, it should be mentioned that the time course of hypoxic responses clearly differs between perinatal and adult respiratory networks. In embryonic day E21 rats and in the isolated brainstem of neonatal (1–3 days old) rats, breathing movements even continue relatively unchanged for 25–50 min of hypoxia.

### *Auto-Recuscitation Through Gasping*

After prolonged hypoxia, gasping is the ultimate time point at which re-oxygenation of the blood is still able to completely re-establish brain stem function [9]. Basically, gasping resembles the last operative mechanism and the final attempt to mechanically defeat airway obstruction and anoxia and thus to ensure auto-resuscitation (Fig. 2e). Voltage sensitive dye imaging (►respiratory network analysis: calcium/voltage sensitive dyes imaging) revealed that gasping involves extensive medullary regions covering a much larger region of the rostral ventrolateral medulla and probably the recruitment of additional regions that are normally not active during eupnea [10]. Mechanistically, gasping involves activation of a persistent sodium current ($I_{Nap}$) that is also discussed to contribute to the endogenous bursting properties of *in vitro* isolated respiratory neurons.

### *Terminal Apnea*

The gasping effort declines steadily in strength and frequency as the respiratory network approaches the "point of no return"and irreversible damage starts to occur. This is the period when the respiratory network proceeds into the terminal and irreversible apnea. Cell swelling occurs, which affects the cytoskeleton and in

turn activates the persistent $Na^+$ current, L-type $Ca^{2+}$ channels (►voltage-gated calcium channels), and $Ca^{2+}$-sensitive non-selective cationic channels (►calcium-activated non-specific cation current). The resulting accumulation of cytosolic $Ca^{2+}$ is massive and causes irreversible damage of neurons and the collapse of network functions. The cardio-respiratory part of the network also fails and the blood circulatory control is lost as well (Fig. 2f).

**In conclusion**, the five phases of the hypoxic response, the underlying molecular mechanisms and their time courses impressively demonstrate that the medullary respiratory center is astonishingly resistant to hypoxia. It remains vital even after prolonged periods of severe hypoxia which is due to an efficient protection through metabolic and neuromodulatory adjustment of $K^+$ conductances. Lack of spontaneous breathing movements, therefore, is not at all a reliable sign for cell destruction (see Fig. 2f) and brainstem death, although most of the structures rostrally of the brainstem including the cerebellum, the striatum and the cortex are definitively irreversibly damaged at that time.

# Neural Stem Cells

## Definition

Neural stem cells (NSC) are an heterogeneous population of mitotically active, self-renewing, multipotent cells of both the developing and the adult central nervous system (CNS). A single NSC is capable of generating various kinds of cells within the CNS, including neurons, astrocytes, and oligodendrocytes.

In vivo and in vitro lineage analyses have shown that the multilineage potential of NSCs is at least partly mediated by the generation of cell-lineage-restricted intermediate progenitor cells, which produce only neurons (neuronal progenitor cells), and glial progenitor cells that produce only astroglial or oligodendroglial cells. Thus, the cellular diversity of the CNS is likely to be generated in a stepwise fashion. NSCs have been successfully isolated from the entire embryonic as well as adult CNS.

The ganglionic eminence(s), in the embryo, and both the subventricular zone (SVZ) of the lateral ventricles and the sub-granular zone (SGZ) of the hippocampus dentate gyrus (DG), in the adult, have been shown to consistently contain stem-like cells capable of driving neuro- and glio-genesis. These regions are then defined as highly specialized CNS germinal niches. Protocols to obtain in vitro large-scale numbers of NSCs are available, thus supporting the concept that these cells might represent a renewable source of uncommitted ready-to-use cells for transplantation purposes.

### Definition

Brain infection, hemorrhage and aging are associated with activation of the innate immune system as expressed by resident glial cells and neurons. The innate immune

response (►innate immunity) relies on the detection of "self" and "non-self" (►self, non-self and altered-self) structures in mounting a protective response to promote the clearance of pathogens, toxic cell debris and apoptotic cells accumulating within the brain parenchyma and the cerebrospinal fluid (CSF). Innate immune molecules can also stimulate neurogenesis and contribute to brain tissue repair. However, in some diseases, these protective mechanisms lead to neurodegeneration on the ground that several innate immune molecules can promote neuronal loss. The response is a "double-edged sword," representing a fine balance between protective and detrimental effects. Several key regulatory mechanisms have now been evidenced in the control of the innate immune response and which could be harnessed to explore novel therapeutic avenues.

## Characteristics

### Quantitative Description: Cellular and Molecular Innate Immune Responses

Classically, innate immune cells are known as neutrophils, natural killer (NK) cells, dendritic cells and macrophages involved in the selective recognition and the clearance of pathogens and toxic cell debris during infection or tissue injury [1]. However, there is little evidence of an immunosurveillance of the brain by these peripheral cells and it is now evident that resident cells, glial cells and neurons, are capable of mounting a robust innate immune response. The local innate immune response is based on the recognition of "non-self" and "altered-self" (self, non-self and altered-self) patterns, also called ►danger signals, by molecules and receptors expressed by microglia, astrocytes, oligodendrocytes and neurons [2]. These molecules and receptors are called pattern-associated recognition receptors (PARRs) and are displayed on the cell membrane or released in soluble forms. The decoding and sampling of the microenvironment for danger signals will contribute to the removal of the harmful intruders. In addition, there is mounting evidence that innate immune molecules (e.g., C3a) can contribute to tissue repair notably by stimulating the mobilization of neural stem cells and with the production of growth factors [3,4]. Critically, several innate immune molecules have also cytotoxic and cytolytic activities and must be controlled to avoid neuronal loss (neurodegeneration) and robust inflammation. Cellular and regulatory mechanisms have recently been described and thought to be at the route of neuroprotective mechanisms.

### Description of the Process

#### *Innate Immune Response in Health: The Key Role of Physical Barriers*

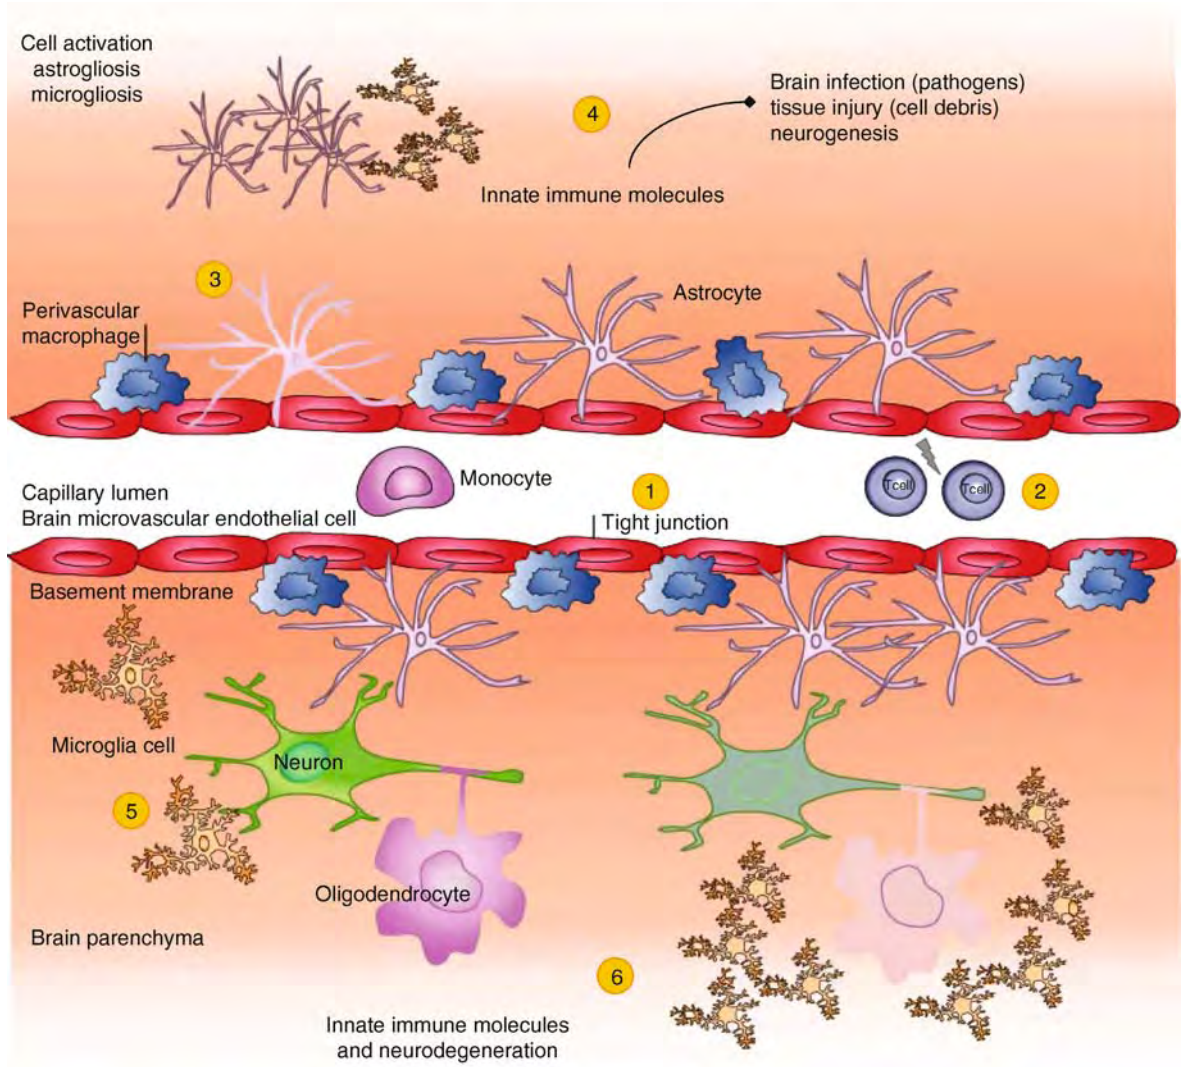
The brain is isolated from the systemic circulation by a protective blood brain barrier (BBB) composed of endothelial cells linked by tight junctions and surrounded by the end feet of astrocytes (Fig. 1). A further protective barrier composed of specialized ciliated glia, the ependyma, lines the ventricles preventing entry of pathogens from the cerebro spinal fluid (CSF) into the brain. Within the ventricles is the choroid plexus containing Kolmer phagocyte cells. Cells within the choroid plexus and the ependymal layer express receptors that are capable of detecting pathogens in the CSF and regulating the inflammatory response. These innate immune receptors are highly conserved and include Toll-like receptors (TLR), CD14 and ►complement receptors CR3 and CR4. The details regarding the recognition and interaction between glia and pathogens will be discussed below.

#### *Immunoprivileged Status of the Brain by Preventing the Infiltration of Potentially Harmful Systemic Immune Cells*

The active destruction of infiltrating T lymphocytes through induction of apoptosis provides the brain with a degree of low immuno-surveillance, preventing the entry of lymphocytes and down regulating inflammation (Fig. 1). Active apoptosis of infiltrating T lymphocytes is induced by neurons and glia utilising the "death signaling pathways" based upon CD95FasL/CD95 (Fas) and the TNF lymphotoxin receptor-TNF receptor 1 (TNFR1) pathway. The initiator of apoptosis, CD95L, is expressed by both astrocytes and oligodendroglia and transmits an apoptotic signal to target T cells. This interaction at the cell surface induces the activation of caspases and subsequent apoptosis of the target cell, with engulfment by microglia and down regulation of their activation. For instance, recovery from experimental EAE is increased through induction of apoptosis in inflammatory T cells by the TNFR signaling pathway and in TNFR knock out mice T cell apoptosis is reduced by 50% in the periphery of demyelinating plaques. In multiple sclerosis, it is possible that this death signaling pathway is functional in reducing the severity of demyelination.

The induction of apoptosis in infiltrating T lymphocytes and virally infected cells will reduce host tissue destruction, but only if they are rapidly cleared by resident cells. Apoptotic cells contain large amounts of toxic enzymes that are able to activate proinflammatory cytokine release. Phagocytosis of apoptotic cells is termed non-phlogistic and is accompanied by a down regulation of proinflammatory cytokines contributing to the limitation of tissue damage and "self" defense [5].

Apoptotic cells are "altered self" and express apoptotic cell associated molecular patterns, ACAMPs. The identity of ACAMPS has not been fully elucidated but includes nucleic acids, sugars, oxidized low density lipoproteins and alteration of membrane electrical charge. The best characterized ACAMP to date is phosphotidylserine (PS). Glia and macrophages express a range of PARRs that recognize ACAMPS including the



**Neurodegeneration and Neuroprotection – Innate Immune Response. Figure 1** Innate (natural) defense mechanisms in health and diseases of the CNS: (i): The physical blood brain barrier composed of endothelial cells linked by tight junctions and surrounded by the end feet of astrocytes prevents the infiltration by pathogens. (ii): Brain cells such as microglia and astrocytes can also induce apoptosis of autoimmune T lymphocytes through the Fas/FasL pathway. (iii): In response to infection or tissue injury, resident cells will be activated, i.e., reactive gliosis with the activation and proliferation of astrocytes and microglia. (iv): Remarkably, innate immune molecules will contribute to the selective recognition and removal of pathogens and toxic cell debris (apoptotic corpses, amyloid fibrils) while preserving self cells. Furthermore, several innate immune molecules will initiate tissue repair (neurogenesis). (v): This response will have to be kept under safe guard through the expression of inhibitory/regulatory molecules for example by neurons to control phagocytosis by microglia. (vi): In sharp contrast, several innate immune molecules have been involved in neuronal loss and oligodendrocyte damage in diseases such as Alzheimer's disease and multiple sclerosis, respectively. For example, host defense complement proteins are known to induce adverse cytotoxic activities against myelin-forming cells and neurons. Hence, a fine balance must exist and which is at the route of future therapeutic strategies.

phosphotidylserine receptor (PSR), CD14, CD36 and milk fat globulin (MFG-EGF 8).

Activation of the classical innate immune complement pathway by virtue of C1q recognition of nucleic acids initiates the generation of ▶opsonins C3b and iC3b that bind to apoptotic cells and act as targets for the phagocytic CR3 and CR4 receptors expressed by macrophages and microglia.

### Protective Innate Immune Response During Brain Infection and Inflammation: To Promote the Clearance of Pathogens, Apoptotic Cells and Other Cell Debris

After penetrating a damaged BBB, an infiltrating pathogen will encounter the innate immune response delivered by professional (microglia) and non-professional phagocytes (astrocyte, ependyma neurons and oligodendroglia) (Fig. 1). These cells provide the second line of the brain's innate defense against infection, but must also be regulated to prevent destruction of host "self" cells. Astrocytes and microglia express a large array of membrane and soluble PARRs. These include lectins (e.g., phagocytic macrophage mannose receptor (MMR)), scavenger receptors (e.g., SRA), TLRs and associated molecules (TLR2 and 4, CD14) and complement molecules (e.g., C1q, C3, CR1, CR3, CR4). These innate immune receptors are capable of detecting unique arrangements of lipopolysacharides (LPS) and peptidoglycan (PG) molecules termed pathogen associated molecular patterns (PAMPS) within the cell walls of microorganisms. PAMPS are uniquely expressed by pathogens and therefore distinguish "self" (host) from "non-self" (pathogen). Removal of pathogens therefore reduces the severity of an inflammatory response before its destructive effects outweigh the benefits of pathogen clearance. The recognition of pathogens or "not self" also relies upon the defense collagens, a group of PRRs composed of a globular carboxy sequence that recognizes PAMPS together with an amino terminal sequence that binds to specific phagocytic receptors on the surface of phagocytic cells. These include C1q, the first component of the complement classical pathway, mannan-binding lectin (MBL) and surfactant protein A (SPA). C1q and MBL have been shown to be expressed by astrocytes whereas the expression of SPA in the CNS is yet to be defined. The complement receptors (CR), CR3 and CR4 are important for identifying pathogens and apoptotic cells opsonised with complement components C3 fragments (C3b and iC3b).

### Innate Immune Responses in Neurodegeneration and Demyelination

Any disruption of the BBB invariably permits entry into the brain of neurotoxic systemic proteins, including thrombin a serine protease vital for blood coagulation and complement proteins. Thrombin, at low concentrations (50–100 pM) is neuroprotective, regulating NGF synthesis and synaptic outgrowth; it is protective against oxygen and glucose deprivation due to its modulation of intracellular calcium. At high levels (500 nM), as found following intra cerebral hemorrhage, thrombin is neurotoxic as it activates NMDA excitotoxic receptors and PAR-1 inhibiting neurite extension and neuronal repair [6].

The complement system is a vital component of the CNS innate immune defense system as it recognizes and clears pathogens and apoptotic cells, but its activation must be closely regulated to prevent excessive tissues destruction. High levels of complement proteins from plasma could infiltrate the brain from a damaged BBB. Moreover, the expression of complement components of both the classical and alternative pathways has been well described in astrocytes, microglia and neurons in vitro and in vivo. The classical complement pathway is activated by C1q interacting with neurons, myelin basic protein (MBP) myelin oligodendrocytic protein (MOG). The alternative pathway is activated independently of C1q and immune complex formation, but through a binding of C3 to activating surfaces that cleaves C5 to initiate the terminal pathway. One component, C3b is abundantly deposited on target cells and functions as an opsonin for microglia and Kolmer cells expressing the PARRs CR1 (CD35), CR3 and CR4 receptors to promote robust phagocytosis. Uncontrolled C3b opsonisation of oligodendrocytes and neurons will lead to demyelination and neuronal loss by phagocytes expressing CR3 and CR4. The terminal pathway provides the membrane attack complex (MAC) composed of C5b-9. This complex is capable of producing cell lysis unless inhibited by complement regulator proteins (regulators of complement activation, RCA), see below. Complement is activated in Alzheimer's Disease as the result of C1q binding to fibrillary beta amyloid, activating complement and increasing C1q, C3 and C5 as part of the protective response promoting clearance of the amyloid plaque. Amyloid plaque formation in complement deficient mice was significantly increased supporting the interpretation that amyloid clearance was related to microglia phagocytosing complement opsonised amyloid. However, in the context of acute inflammation associated with robust expression of complement proteins by microglia and astrocytes, it is plausible that complement activation by myelin/neuronal debris contributes to secondary brain injury. The formation of the MAC and non-specific binding to surrounding cells would cause bystander damage. Complement activation is also present in the tauopathies (including Pick's disease) resulting in localization of complement products on ballooned neurons; the details regarding the identity of the C1q binding molecule in these diseases is not yet known. Interestingly, administration of a C1 inhibitor C1-INH, resulted in neuroprotection after experimental ischaemia, but it protective effect was interpreted as independent of C1q activating the complement pathway. Experimental models of demyelination and multiple sclerosis have demonstrated C9 and MAC deposition in at least half of the MS cases with active myelin destruction. Knock-out mice for CD59, a natural MAC inhibitor, increased the severity of EAE whereas the failure to produce MAC in C6 deficient animals reduced the severity of axon damage in diseased animal compared with the control group.

## Regulation of the Process

### *Innate Immune Regulatory Molecules*

To counter the neurotoxic effects of innate immune molecules, both glia and neurons express a range of "self" defense proteins. These include the serine protease inhibitors (serpines) that prevent the synthesis of thrombin. The serpins include the anti thrombin colligin (Hsp47) expressed by microglia and astrocytes, plasminogen activator inhibitor (PAI-1) and protease glial derived nexin-1 (PN-1) both of which are expressed by astrocytes and neurons. Neuroserpin, an inhibitor of plasminogen (tPA) expression is restricted to neurons and astrocytes.

In the systemic organs and brain, the activation of the classical and alternative complement pathways is tightly regulated in order to prevent unrestrained activity resulting in cytolytic destruction of host cells, brain cells being particularly vulnerable to complement attack. The complement regulators can be divided into two groups, the membrane bound and those located within the extracellular fluid, the so called fluid phase regulators. Together they inhibit the activation of the complement pathways (for detailed review see [7]). In brief, the membrane bound regulators, CR1 (CD35) and membrane cofactor protein (MCP, CD46) expressed on nucleated cell membranes bind to C4b or serve as cofactors to increases its cleavage inhibiting this step in the C pathway. Decay accelerating factor (DAF, CD55) inhibits the C3/C5convertase step and CD59 blocks MAC formation in the terminal pathway. The fluid phase regulators are composed of C1 inhibitor (C1-INH) an effective inhibitor of the C1 component of the classical pathway; Factor H and FI (alternative pathway) accelerates C3b/C4b degeneration, whereas S protein and clusterin prevents C5b-7 assisting formation of MAC pathway, inhibiting the final the terminal pathway.

In primary culture, fetal neurons spontaneously activate C classical pathway with formation of MAC resulting in significant lysis because in vitro they express low levels of the membrane regulators (CD59, CD46, C1 INH and FH) and no CD55. By comparison with neurons, astrocytes and microglia express a wider range of inhibitors such as, CD46, CD59 and CD55 together with the fluid phase regulators. Initial observations demonstrated rat oligodendrocytes in culture were susceptible to C attack and did not express CD59. However in human, CD59, CD46 and CD55, together with C1 INH, FH, S protein and clusterin are all expressed and do not spontaneously activate complement. In Alzheimer's disease, AD, and Picks diseases neurons did not express CD35, CD59, CD46 and CD55, whereas in Huntington's disease (HD) neurons expressed high levels of CD46. Overall, the combined data from in vitro and in vivo experiments indicates that astrocytes, microglia and oligodendrocytes are well protected from the effects of direct or bystander complement lysis because they express high levels of CD59, CD46 and CD55. Neurons, particularly lacking CD55, are vulnerable to the detrimental effects of complement attack.

Interestingly, there is a growing body of evidence that neurons may be capable of evading detection by activated microglia and macrophages by expressing the so-called "don't eat me" signals or SAMPs (self associated molecular patterns). SAMPs are markers of "self" preventing recognition of host cells and reducing the severity of any inflammatory response through inhibition of innate immune cells such as microglia and infiltrating macrophages [8].

A number of SAMPS have been identified including CD200 (and its receptor CD200R), the integrin CD47 with its receptor SIRPα, both regulating myeloid cell and lymphocyte activity and, hence, protecting from autoimmunity [9]. On the basis of their regulatory activity in vitro and in vivo CD46, CD55 and FH could also be important don't eat me signals. A further group of SAMPs is sialic acids ubiquitously expressed and interacting with the newly described immunoglobulin (Ig)-like lectins, the siglecs expressed on lymphocytes and microglia.

CD200 is a 41–47 kDa surface molecule and a member of the immunoglobulin Ig supergene (Igsf) family characterized by two IgSF domains [10]. It is a highly conserved molecule found in the invertebrates and vertebrates and many of the glycoproteins containing this arrangement are involved with regulation of the immune system. In the brain OX2 now CD200 is expressed by cerebellar and retinal neurons, together with vascular endothelium. Astrocytes do not express CD200 in contrast to microglia.

The counter receptor to CD200, CD200R, also contains two IgSF domains and is expressed by myeloid cells and brain microglia. In CD200 deficient mice the number of activated microglia and macrophages were more numerous after a lesion, than the wild type animal providing evidence that the CD200/CD200R interaction is related to regulation of microglial activation and local inflammation. This interpretation is supported by experiments in mice inoculated with MOG peptide to induce EAE. Animals that received a blocking monoclonal antibody against CD200R had an increased disease severity as compared with animals without the monoclonal antibody treatment. Furthermore, after EAE in CD200−/− mice, microglia became rapidly activated as compared with type animals. Interestingly in CD200 deficient animals the increased number of phagocytic cells in the retina could also represent the failure to inhibit macrophage entry across the BBB into the eye.

CD47 is constitutively expressed by endothelium, neurons, macrophages and dendritic cells. CD47 has five transmembrane regions with alternatively spliced

isoforms of CD47 having a tissue specific expression, form 2 is present in bone marrow, whereas form 4 is highly expressed in brain. The counter receptor for CD47 is signal regulatory protein SIRP alpha (CD172a) a plasma membrane protein with three Ig domains in its extracellular component. CD172 is expressed by myeloid cells and neurons. The interaction between CD47 on a host cell and CD172a recruits tyrosine phosphotases SHP-1and SHP-2 with down regulation of macrophage phagocytosis, complement activation and cytokine synthesis including TGF β all contributing to the reduction of any inflammatory response.

The interaction between CD47 and CD172a has been shown to reduce neutrophil migration across endothelium and blocking CD47 reduced bacterial induced expression of inflammatory cytokines by dendritic cells. Furthermore CD47 is capable of inducing apoptosis in T cells and cells deficient in CD47 are rapidly cleared from the systemic circulation by the spleen. Hence, CD47 represents an important "don't eat me signal" preventing inappropriate phagocytosis of host cells. Whether or not the CD47-CD172a pathway is capable of regulating microglial activity in disease remains to be determined.

Siglecs represent a group of at least 11 recently identified Ig lectins expressed by a wide range of myeloid cells, lymphocytes, macrophages and microglia [11]. Two siglecs, myelin-associated glycoprotein (MAG) and Schwann cell myelinated protein (SMP) are restricted to the CNS and expressed by oligodendrocytes; they are considered important for myelin–axon interaction and control of neuron growth after injury. The non-neural siglecs are characterized by their specific binding to the sialic acids groups, (a group of nine carbon sugars) derivatives of either neuraminic acid or keto deoxynonulosonic acid). Typically these molecules are expressed by "non-self" pathogens and (potentially) apoptotic cells. The interaction between a pathogen expressing the appropriate sialic acid residue and a siglec on microglia will activate phagocytosis and clearance, whereas the absence of the sialic acid residue, for example on a neuron, provides a signal defining "self" and "don't eat me." CD33 (siglec 3) is expressed by myeloid stem cells, monocytes and dendritic cells. CD22 (siglec 2) is expressed by B cells and siglecs 5–7 on macrophages, neutrophils and eosinophils. Microglia express siglec 11 and the tyrosine phosphtases SHP-1 and SHP2, both known to participate in down regulation of phagocytosis.

Moreover, the expression of sialic acids also inhibits the activation of the alternative complement pathway through binding to the complement regulator fH.

Activation of the complement pathway produces C3a and C5a chemoattractant to myeloid cells expressing the anaphylatoxin receptors C3aR and C5aR and contributing to proinflammatory activities. However, C3a also has regulatory properties based on its capacity to block LPS stimulation of macrophage TNF alpha cytokine expression as well as IL 6 and IL1 beta expression by lymphocytes increasing synthesis of IL-10 and NGF. This new "self defense" role for C3a is supported by the presence of C3aR on adrenal and pituitary gland cells, both glands having important roles in the synthesis of corticosteroids to control systemic and central inflammation and infection. More recently, it has been shown that complement anaphylatoxins may be involved in the control of neurogenesis and with anti-apoptotic activities by its capacity to reduce NMDA induced neuronal death.

### *Innate Immune Regulatory Cells*

The presence of large numbers of T lymphocytes inside the brain would normally be expected to have a detrimental effect upon neuronal survival because of increasing the inflammatory response and uncontrolled tissue damage. However, data has accumulated to show that a regulated innate inflammatory response can be beneficial to neuronal survival and enhance axonal repair. Recovery from retinal cell death induced by glutamate was increased in animals with an intact T cell response whereas in those without T cells, recovery was poor. Similarly passive transfer of T cells from injured animals into recovering animals increased the likelihood of recovery, as did immunization against the same antigen/with glutamate. The vital observation was the protective T cells had to be activated specifically against antigens at the site of axon and neuron injury, this was termed protective autoimmunity. The mechanism responsible for T cell neuroprotection is not clear, although lymphocytes can express neurotrophic growth factors including brain derived neurtrophic factor (BDNF) and ciliary trophic growth factor as do macrophages. These finding have therapeutic implications and studies have shown human T cells in vivo stimulated with glatiramer acetate express BDNF as well as the anti inflammatory cytokine IL 10. Currently a clinical trial involving this compound in MS patients has found some benefit especially reducing the number of new lesions on MRI scanning.

## Function

The balance between the protective and harmful effects of the innate immune response mounted against pathogen invasion and brain injury has been termed a "double edged sword." This balance must be critically regulated in order to promote conditions supportive of brain repair but without excessive destruction of "self" or host cells. The CNS innate immune response is regulated by a number of "self defense" pathways. "Self" is distinguished from "non-self" by the detection of surface PAMP and ACAMP molecules and by the expression of SAMPs by host cells. The CNS has a range of defense strategies at its disposal, each capable of regulating the protective

components of the innate immune response while at the same time limiting the extent of accompanying brain injury. The therapeutic manipulation of the immunoregulatory and defense strategies designed to reduce brain injury and promote repair, as described in this review, is now becoming a clinical reality.

## Synonyms

Mitogen-activated protein kinases

## Definition

►Neurodegenerative diseases refer to degenerative changes of the nervous system dependent on multiple mechanisms resulting in neurological disease. Acute and chronic immune and inflammatory mechanisms mediated by resident cells such as ►microglia and ►astrocytes contribute to their pathogenesis through the secretion of potent regulatory mediators, including an expanding array of ►cytokines, chemokines, proteases, complement proteins and reactive oxygen species (ROS). Whether inflammatory changes within the brain tissue are a consequence or a primary cause of brain damage still is a matter of debate. However, inflammatory mediators and cellular processes are known to be central to the pathogenesis of many neurodegenerative diseases, such as multiple sclerosis (MS), Alzheimer's disease (AD), stroke, HIV-dementia and others. On the other hand, there is compelling evidence indicating that inflammatory cells and mediators also have beneficial functions in the CNS, assisting in repair and recovery processes. The dual role for glial-mediated ►neuroinflammation suggests that glial cells dysregulation may be involved in the genesis of neurodegenerative diseases. As crucial components of the regulatory machinery underlying inflammation

and other phosphorylation/dephosphorylation-dependent mechanisms, ►Mitogen-Activated Protein Kinases (►MAPKs) are good candidates to be involved in the regulation of glial cells and on the progression of neurodegenerative diseases such as AD [2].

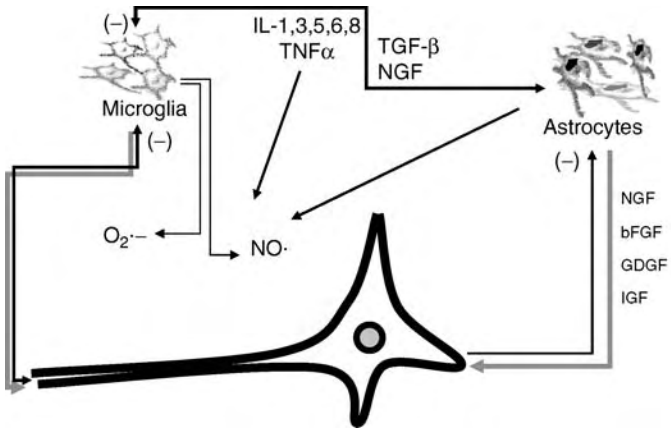
## Characteristics

### Quantitative Description of the Process

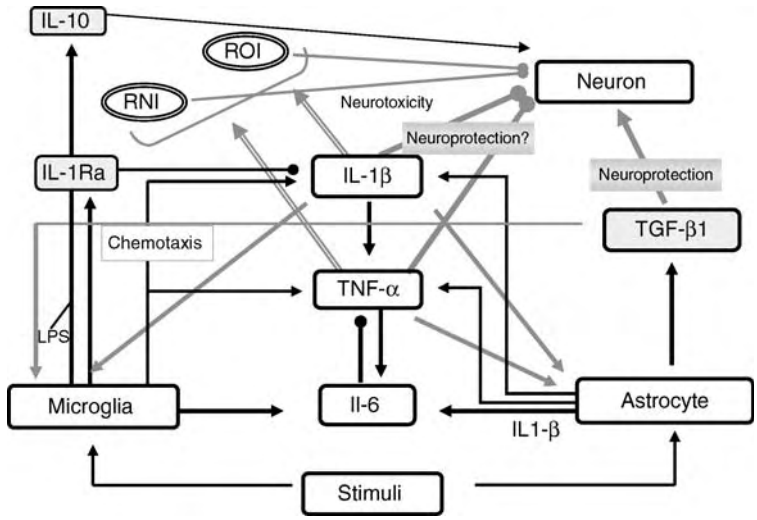
Dementia associated with neurodegenerative diseases is accompanied by morphological changes in the brain, including the development of characteristic lesions, but underlying mechanisms ensue before the clinical disease is established. Evidence suggests that the activation of glial cells in response to injury, illness, ageing, or other causes begins a cascade of events leading to a chronic inflammatory process. Through various pathways, inflammatory mediators cause neuronal death, which further activates glial cells that in turn release more inflammatory mediators in a self-amplifying process. Factors secreted by ►microglial cells in response to injury induce activation of astrocytes. Activated astrocytes secrete growth factors promoting microglial growth and activation, but also modulate their cytotoxicity. It has been proposed that microglia-derived factors are responsible for neurotoxicity whereas astrocytes secrete neuroprotective factors. However, astrocytes may also cooperate with microglia enhancing oxidative stress. The association of several pro-inflammatory molecules with neurodegenerative lesions suggests a state of persistent inflammatory activation that could escape endogenous control and become cytotoxic. Genetic research identified susceptibility genes influencing the inflammatory process of neurodegenerative diseases. Polymorphisms in the interleukin genes, IL-1α and IL-1β, are associated with increased risk of early onset AD and the C allele of IL-6, associated to reduced IL-6 activity decreases the risk and delays the onset of sporadic AD. Thus, inherited variations in inflammation mechanisms may influence AD as well as other neurodegenerative diseases pathogenesis.

Astrocytes and microglia are highly reactive to environmental changes and work cooperatively, exerting mutual regulatory activity (Fig. 1). There is constitutive expression of interleukin-1 (IL-1) by astroytes, microglia, neurons and endothelium. Activation of glial cells induces the release of cytokines, such as tumor necrosis factor-α (TNF-α) and IL-1β, which participates at early stages of neuroinflammation [10] and IL-6 at latter stages. IL-1β has been described as a potent activator of host inflammatory responses within and outside the CNS. Microglia appear to be its early source following experimental CNS injury, infection or inflammation. Production by astrocytes usually follows slightly later [10] (Fig. 2).

Besides the central role of cytokines in neuroinflammation, they also influence neuronal and synaptic function via diverse mechanisms contributing to cognitive impairment, including regulation of neurotransmission, neurotransmitters receptors and synaptic efficacy [6]. A cohort study of healthy ageing individuals showed that high levels of IL-6 correlates with lower cognitive functioning in cross-sectional analysis, also predicting subsequent cognitive impairment. Cytokines are also involved in the pathophysiology of neurodegenerative diseases of vascular origin, by



**Neurodegenerative Diseases – MAPK Signalling Pathways in Neuroinflammation. Figure 1** Modulation of the CNS: neuron-glia interaction. Homeostasis in the nervous tissue depends on a finely tuned cross talk among glial cells and neurons. There is a reciprocal structural and functional regulation of glial cells and neurons by growth factors and cytokines. Pro-inflammatory cytokines induce the production of NO and ROS, which are deemed as responsible for cell damage. Factors, such as TGF-β, modulate the activation of glial cells. Neurons have an inhibitory regulatory role on glial activation. Neuroinflammation could depend on the inability of microglial cells to respond to modulatory effect or on the failure to establish the modulatory mechanism.



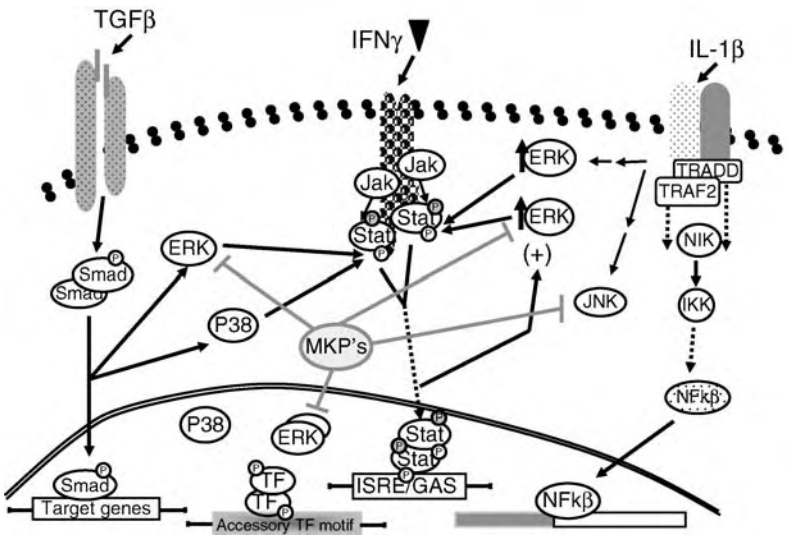
**Neurodegenerative Diseases – MAPK Signalling Pathways in Neuroinflammation. Figure 2** Major inflammatory cytokines involved in glial activation. Schematic overview of the principal cytokines produced by glial cells in response to pro-inflammatory stimuli. Stimuli lead to the activation of microglial cells and later of astrocytes. Glia secrete pro-inflammatory cytokines. This, in turn, induces second line cytokines with pro- and anti-inflammatory cytokines, such as IL-6 and TGF-β, IL-10 and IL-1Ra, which also modulate production of pro-inflammatory cytokines, and reactive short life molecules such as oxygen radicals and NO. Pro-inflammatory cytokines and reactive species can promote neurotoxicity. However, pro-inflammatory cytokines also have neuroprotective functions.

influencing the response to ischemia, influencing the coagulation cascade favoring thrombosis and promoting the atherogenic process.

Activated astrocytes and microglia release mediators like ►nitric oxide (►NO) and activated microglia also secrete important amounts of ►reactive oxygen species (►ROS) like superoxide ($O_2^{\bullet -}$), deleterious oxidative molecules capable of inducing hippocampal cell damage [11]. Several neurodegenerative conditions show enhanced oxidative damage. Increased amounts of $O_2^{\bullet -}$ and NO are among the proposed mechanisms for neuronal death and demyelization. Cerebrospinal fluid have increased levels of nitrite and demyelinating lesions show increased levels of nitrotyrosine in multiple sclerosis patients. Increased NO production depends on transcriptional up-regulation of inducible nitric oxide synthase (iNOS) and release of $O_2^{\bullet -}$ by the multicomponent phagocyte NADPH oxidase. Activated microglia also express myeloperoxidase, which generates the potent oxidizing agent hypochlorous acid.

Pro-inflammatory cytokines activate a number of signaling mechanisms (Fig. 3). Activation of IL-1 receptor leads to translocation of NF*k*B to the nucleus and activation of mitogen-activated protein kinases (MAPKs) ERK1/2, P38 and JNK1 [10]. Inhibition of each of the MAPK pathways inhibits inflammation-induced IL-1β production in a concentration-dependent manner. In astrocytes, IL-1β plus TNF-α induce the expression of pro-inflammatory cytokines and iNOS and the production of NO through the activation of ERK1/2 and NF*k*B [7]. Although IL-1β or TNF-α alone is capable of activating NF*k*B, the expression of iNOS appears to require activation of additional transcription factors modulated by MAPKs. IL-1β and IFN-γ induce the activation of the transcription factor AP-1, but the combination of both cytokines markedly inhibits its activation. It has been defined that the activation of AP-1 and expression of iNOS depends on the activation of JNK, an effect observed only during low level of iNOS induction but not during high level of induction by IL-1β and IFN-γ. IL-1 also increases expression and processing of amyloid precursor protein (APP), which could favor production of amyloid β (Aβ) in humans and animal models of AD. Activity of ERK and JNK kinases appear to be required for the induction of APP processing by IL-1.

The main signal pathways induced by IFN-γ are the signal-transducer and activator of transcription-1 (STAT1) and MAPKs (Fig. 3). STAT-1 is the main transcription factor involved in the induction of iNOS by IFN-γ. NF*k*B does not play a key role in the regulation of iNOS expression in response to IFN-γ. However, extracellular signal-regulated kinase (ERK)1/2 MAPK plays an important modulatory role. STAT-1 is activated by a JAK-dependent phosphorylation of a tyrosine residue ($pSTAT1^{tyr}$), whereas its full activation depends on a second phosphorylation at a serine residue



**Neurodegenerative Diseases – MAPK Signalling Pathways in Neuroinflammation. Figure 3** Effect of ERK and P38 on IFN-γ signaling. Binding of IFN-γ induces receptor dimerization and their phosphorylation by Jaks. The phosphorylated receptor serves as a docking site for STATs, and adaptors linking to MAPK and PI-3-kinase/Akt. Phosphorylated STATs dimers translocate into the nucleus, regulating the transcription of target genes. TGF-β signaling depends on phosphorylation of Smad proteins and their translocation to the nucleus. Activated Smads regulate diverse effects resulting in cell-state specific modulation of transcription. TGF-β signaling also has Smad-independent pathways, including ERK, JNK and P38 MAPKs. IL-1β binds to IL-1R associated to Nuclear factor-κB (NF-κB) proteins. IL-1β triggers phosphorylation of IκB leading to its degradation, freeing NF-κB. Active NF-κB translocate to the nucleus where, either alone or with other transcription factors including AP-1, Ets and STAT, induce target gene expression. The MAPK/ERK signaling cascade is activated by many receptors. The pathway usually involves small GTP binding proteins (Ras, Rap1), which in turn activate the kinase cascade composed of a MAPKKK (Raf), a MAPKK (MEK1/2) and MAPK (ERK). Activated ERK regulates targets in the cytosol and translocate to the nucleus phosphorylating several transcription factors. Stress-activated protein kinases (SAPK)/Jun N-terminal kinases (JNK) are activated by a variety of signals that are delivered by small GTPases (Rac, Rho, cdc42). SAPK/JNK kinases and P38 MAPKs activation is similar to that of ERKs. P38 is involved in regulation of several transcription factors including ATF-2, Stat1, Max/Myc complex, MEF-2, Elk-1 and indirectly CREB via activation of MSK1. Specific phosphatases for ►MAPK (MKP) end ►MAPK signaling.

(pSTAT1$^{ser}$). ERK and P38 signaling are implicated in the expression of iNOS and the generation of NO [5,7]. IFN-γ induce ERK1/2 and P38 phosphorylation while their inhibitors attenuate IFN-γ-induced NO, suggesting that those MAPK signaling pathways are important on the modulation of NO production by glial cells. In contrast, $O_2^{\bullet -}$ production induced by IFN-γ is associated to increased levels of pERK1/2, but not pP38. Inhibition of P38 pathway potentiates LPS-induced ROS production. There is evidence that NADPH oxidase component $p67^{PHOX}$ is phosphorylated by ERK2, suggesting that NADPH oxidase activity is ERK1/2 dependent. Besides regulation of NADPH oxidase, there is a complex cross-talk between ROS and MAPK through multiple mechanisms. MAPKs are implicated in the regulation of pro-inflammatory cytokines, including TNF-α and several ILs, which in turn induce ROS production. On the other hand, ROS signaling modulates not only cytokines transduction pathways but also appears to regulate the MAPK-induced transcription of some pro-inflammatory cytokines [1]. Further more, ROS inactivation of MAPK phosphatases leads to prolonged activation of MAPK pathways.

There is a differential temporal contribution of ERK1/2 and P38 in the full-activation of the STAT-1 pathway in glial cells. pERK1/2 and pP38 levels are increased in glial cultures exposed to IFN-γ. However, whereas phosphorylation of ERK1/2 persisted after 24 h, phosphorylation of P38 rapidly decreased to control levels. Their differential timing suggests that both ERK and P38 modulate STAT-1 at short times, but only ERK1/2 participates after long time stimulation [3]. There are also differences depending on the glial cell type. IFN-γ-induced phosphorylation of P38 only increases in microglial cells but not in mixed glial cell cultures. Similarly, soluble factors secreted by astrocytes decreases IFN-γ-induced phosphorylation of STAT-1 and ERK1/2 in microglial cell cultures [11]. There is evidence that microglial cells are more reactive than mixed glial culture, which is supported by the fact that astrocytes modulate microglial cell reactivity [9].

## Lower Level Processes

MAPKs include ERK1/2, ERK3 and ERK5, P38 Hog and JNK/SAPK. Genetic or epi-genetic alterations of MAPKs or of the signaling cascades that regulate them have been implicated in a variety of human diseases including inflammation. Activated MAPKs act in the cytoplasm or translocate into the nucleus phosphorylating other proteins, like transcriptional factors. MAPK signaling is ended by a specific family of phosphatases for MAPK (MKP). ERK1/2 and P38 appear to be key actors in the production of free radicals by glia [7].

## Higher Level Processes

Neuroinflammation requires the coordinated activity of a network of intracellular pathways. MAPKs are signaling molecules capable of mediating crosstalk among pathways allowing the generation of complex responses to different combinations of pro-inflammatory stimuli or the presence of other modulatory conditions. It can be achieved through several mechanisms, ranging from direct communication between intracellular pathways to feedback processes depending on autocrine signaling.

The presence of various pro-inflammatory signals, depending on their underlying molecular mechanisms, could be additive (their combined effect is the sum of the effect expected for each of the stimuli), could show a synergy or inhibition as manifestation of a regulatory crosstalk, or saturation if a common upstream signaling component is involved [8]. Factors as age, cell damage, metabolism or oxidative stress are just some of the many input that will influence an inflammatory response involving activation of MAPK, making the response dependent on the context of the environment. MAPK could be involved in the both the magnitude and the temporal pattern of the response. Different outcomes, such as cell proliferation, expression of cytokines or production of ►ROS among others can be expected to be differentially regulated by a certain combination of stimuli.

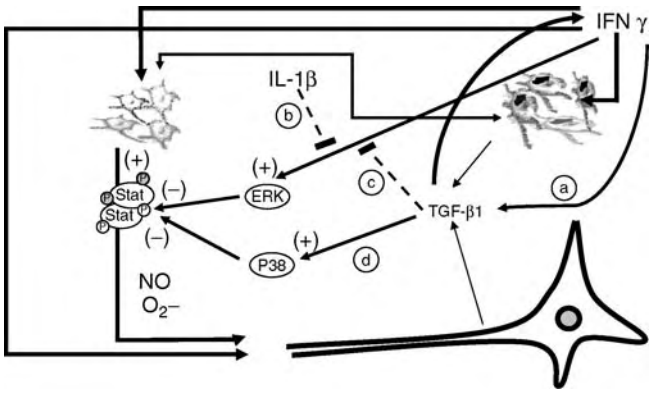
## Regulation of the Process

Feedback mechanisms mediated by crosstalk among brain cells restrain the amplitude and duration of ►glial activation, and restore glial cells to their resting state. Neurons have an inhibitory role on glial activation, regulating the production of many proteins associated with reactive gliosis. Astrocytes attenuate activation of microglial cells and confer protection to hippocampal cells [9]. Hippocampal cells and activated astrocytes secrete transforming growth factor β1 (TGF-$\beta_1$). TGF-$\beta_1$ modulates ►microglial activation inhibiting production of IL-1 and TNF-α, expression of Class II-MHC and Fas glycoprotein, NOS induction, release of NO [11] and $O_2^{\bullet -}$ production.

There is controversy regarding the negative or beneficial effects of IL-1β, although IL-1β is considered a pro-inflammatory ►cytokine, it can both contribute to and limit neuronal damage serving neuroprotective functions [10]. Beneficial effects are particularly observed when low concentrations are released. IL-1β appears to be capable of inhibiting further activation IL-1β at early stages of inflammation, reducing production of NO by microglial cells [11]. In contrast, anti-inflammatory cytokines, like TGF-β1, exerts a delayed effect on the modulation of microglial cell activity. The fact that pro-inflammatory cytokine have inhibitory effects suggests that the timing for the activation of the different pathways is important for the cell response outcome.

TGF-β1 plays a prominent role in homeostasis and tissue repair. Functions exerted mainly through its receptor-activated Smad signaling. It also has neuroprotective effects through the activation of PI3 kinase/Akt and ERK1/2 pathways [12]. The effect of TGF-β1 on glial cell activation is mediated by regulation of ERK1/2 and P38 MAPKs (Fig. 3). Activation of MAPKs in response to TGF-β1 is transient and renders microglial cells refractory to further activation by pro-inflammatory cytokines. TGF-β1 induces a strong expression of MAPK phosphatase type 1 (MKP-1) persistently up-regulated under pro-inflammatory conditions. An increased MKP-1 activity could be the mechanism responsible for the decrease of IFN-γ-induced pERK1/2 in cells exposed to TGF-β1 [3].

It has been proposed the existence of complex regulatory interactions between TGF-β1 and IFN-γ involved in tissue repair. IFN-γ null mice have an increased amount of TGF-β1 and activation of Smad signaling pathway [4]. On the other hand, TGF-β1 null mice have high levels of IFN-γ and over-expression of STAT-1, iNOS and NO production. The over-activation of STAT-1 in TGF-β1 null mice supports the notion that TGF-β1 is an essential immune-regulator for the control of inflammatory events. In glial cells, TGF-β1 treatment results in a reduction of IFN-γ–induced pERK1/2, STAT-1 phosphorylated at serine$^{727}$ (pSTAT-1$^{ser}$) and tyrosine$^{701}$ (pSTAT-1$^{tyr}$), and total STAT-1. After long lasting stimulation, IFN-γ decreases TGF-β1-induced pP38 signal transduction. IFN-γ-TGF-β1 crosstalk regulates the production of oxidative molecules through the reduction of STAT-1, ERK1/2 and P38 activation [3]. ERK is involved in the modulation of microglial response by both anti-inflammatory cytokines (TGF-β1) and pro-inflammatory cytokines (IL-1β). TGF-β1 and IL-1β decrease phosphorylation of ERK and the NO production induced by IFN-γ. IL-1β inhibits ERK1/2 phosphorylation after 30 min of activation with IFN-γ and the inhibition is short-lived. In contrast, TGF-β1 inhibits ERK1/2 phosphorylation only after several hours of activation (24 h) and inhibition persists for a long time (Fig. 4). Only certain pro-inflammatory cytokines, like IL-1β has an orchestrating role, TNF-α is unable to inhibit neither production of radical species nor ERK1/2 phosphorylation.



**Neurodegenerative Diseases – MAPK Signalling Pathways in Neuroinflammation. Figure 4** Modulation of microglial activation by TGF-β and IL-1β. IFN-γ activates glial cells and neurons. Microglia secrete radical species mediated by the activation of JAK/STAT and MAPK. ERK-dependent phosphorylation of STAT1 in the serine position potentiates its activation. (a) IFN-γ also induce production of cytokines, IL-1β at early times and later TGF-β. IFN-γ and TGF-β show several reciprocal modulatory effects. The increased secretion of TGF-β modulates the production of radical species. (b) IL-1β inhibited IFN-γ-induced activation of ERK. The effect could be part of an early mechanism to limit inflammation when stimuli are mild ending glial cell activation. (c) If the inflammatory stimulus persists, the increased secretion of TGF-β could further inhibit ERK and P38 activation. (d) At later times, activation of P38 will be inhibited by IFN-γ, further reducing the positive modulation on STAT1.

## Function

MAPK-regulation in neuroinflammation allows for the integration of specific signaling pathways to yield unique output responses. MAPK can be involved in both convergence and divergence of signaling cascades (see Fig. 3). The combinatorial complexity of signaling may account for the fact that depending on specific background determined by both genetic and environmental factors, pro-inflammatory stimuli can result in limited inflammation and repair or cell damage resulting in a neurodegenerative disease.

## Pathology

In a large number of neurodegenerative diseases, including ►multiple sclerosis (MS), Alzheimer's disease, Parkinson's disease, cerebro-vascular diseases and CNS trauma among others, inflammatory response is evident, including complement activation, elevated pro-inflammatory cytokines, chemokines and glial activation. There is increasing evidence that neurotoxicity is mediated by CNS inflammatory processes.

## Therapy

The participation of neuroinflammatory mechanisms in the genesis or progression of neurodegenerative diseases has led to extensive investigation of the therapeutic effect of anti-inflammatory and anti-oxidant treatments. There are mixed results depending on the type of neurodegenerative disease and among basic research and clinical trials. Whereas treatment of MS with IFN-β and treatment of CNS trauma or inflammation secondary to radionecrosis with corticosteroids are generally approved, most trials of anti-inflammatory agents report no significant beneficial effect on Alzheimer's patients. Nevertheless, epidemiological studies suggest that the risk of the disease is reduced in patients treated with non-steroidal anti-inflammatory drugs (NSAIDs). Observational studies also suggested that intake of antioxidants, such as vitamin E, could reduce the risk of disease. However randomized controlled clinical trials show at the best only marginal benefits.

Candidate protein kinase inhibitors have been tested in vitro assays and in mouse models for their ability to suppress putative mechanisms of neuroinflammation including iNOS induction and production of IL-1β. The use of MAPKs inhibitors for the treatment of inflammatory disorders has been suggested for infectious diseases, but MAPK cascades have been not proposed as possible therapeutic targets for neurodegenerative diseases. However, due to the variation in responses due to cell type and dose-dependence, the therapeutic use of these inhibitors will demand extensive evaluation. Therapeutic approaches including combination of drugs, each aimed at a different inflammatory target, probably will be more effective than single agents.

# Neurodegenerative Diseases: Tryptophan Metabolism

Gilles J. Guillemin
Centre for Immunology and Department of Pharmacology, Faculty of Medicine, University of New South Wales, NSW, Australia

## Synonyms

Kynurenines

## Definition

►Tryptophan is an essential amino acid required by all forms of life, for metabolic functions and synthesis of essential proteins including serotonin and melatonin. More than 95% of dietary tryptophan is catabolized through the kynurenine pathway (Fig. 1). The kynurenine pathway leads to the biosynthesis of nicotinamide adenine dinucleotide (NAD), which is an essential cellular cofactor for many cellular reactions, ranging from adenosine tri-phosphate (ATP) synthesis to DNA repair. This metabolic step appears to be highly conserved. In the process, several neuroactive intermediates are produced including kynurenine, kynurenic acid, 3-hydroxykynurenine, 3-hydroxyanthranilic acid, picolinic acid and quinolinic acid [1,2].

## Characteristics

### Quantitative Description

In physiological conditions, concentrations of most of the kynurenine pathway metabolites are very low. Significant quantitative changes happen in pathological conditions (see below).

### Higher-Level Structures

- The cellular location of the kynurenine pathway is only partly understood. It is known to be complete in monocytic lineage cells, including macrophages, microglia and dendritic cells. Whereas in astrocytes, neurons, brain microvascular endothelial cells and oligodendrocytes, the kynurenine pathway is only partly present [3].
- Expression of the enzymes and production of the compounds of the kynurenine pathway vary significantly between species and between cell lines and the respective primary cell type [4].

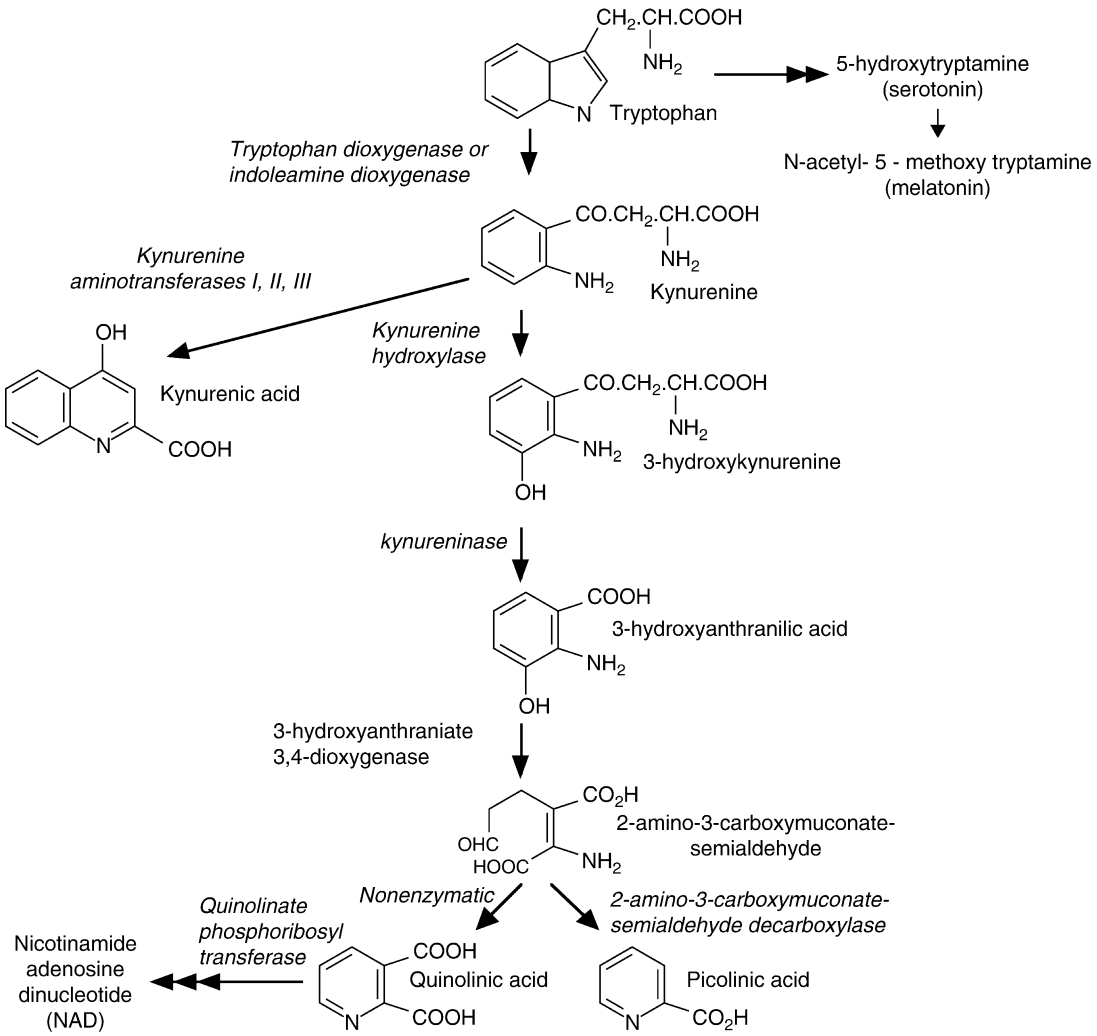
### Process Regulation

The kynurenine pathway is regulated by its first and rate limiting enzyme indoleamine 2,3 dioxygenase (IDO) [5]. IDO is activated during neuroinflammation. Inflammatory molecules such as platelet activating factor, lipopolysaccharides, lentiviral proteins Nef and Tat, amyloid aggregates, and cytokines can induce IDO expression. Among the cytokines, interferon gamma (IFNγ) is the most potent IDO inducer. Interferons beta and alpha, interleukin 1 and tumor necrosis factor α induce IDO to a lesser extent. IDO can also be down regulated by interleukin 4 and nitric oxide.

### Functions

The kynurenine pathway has a role in physiological functions.

- The involvement of the kynurenine pathway in psychological functions is mainly due to its ability to divert tryptophan catabolism from the serotonergic



**Neurodegenerative Diseases: Tryptophan Metabolism. Figure 1** Simplified diagram of the kynurenine pathway.

pathway (Fig. 1). Modulation of serotonin (5 hydroxytryptophan; ►5HT) levels is associated with changes in behavior, mood, sleep regulation, and thermoregulation.

- Recent findings have shown that the kynurenine pathway is one of the major regulatory mechanisms of the immune response [6]. Two theories have been proposed: (i) that tryptophan degradation suppresses T cell proliferation by dramatically depleting the supply of this critical amino acid; (ii) that some downstream kynurenine pathway metabolites act to suppress certain immune cells. Induction of the kynurenine pathway in dendritic cells completely blocks clonal expansion of T cells.
- Tryptophan depletion is associated with IDO and kynurenine pathway activation are implicated in the development of immuno-tolerance associated with pregnancy. IDO activation plays a key role in the protection of the fetus by suppressing T cell-driven local inflammatory responses against the fetal alloantigens [7].

## Pathophysiological Conditions

The kynurenine pathway is involved in the anti-bacterial, anti-parasites and anti-viral immune defenses.

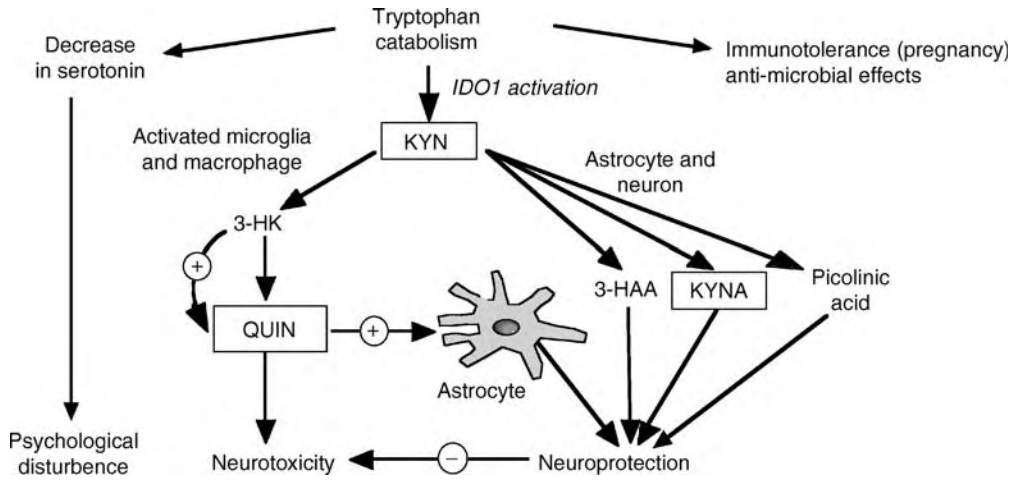
- Since tryptophan is an amino acid essential for many metabolic processes, depletion of available tryptophan is an important mechanism for the control of rapid-dividing microbial pathogens including bacteria, parasites and viruses.

## Pathology

Two sides have to be considered here: decrease of tryptophan levels and production of kynurenine pathway metabolites (Fig. 2).

- Tryptophan depletion has been associated with mood and psychiatric disorders such as schizophrenia,

N



**Neurodegenerative Diseases: Tryptophan Metabolism. Figure 2** Summary of the effects of tryptophan depletion through the kynurenine pathway.

depression, panic disorder, seasonal affective disorder and obsessive–compulsive disorder.

- Activation of the kynurenine pathway and production of neuroactive metabolites have been shown to be involved in a number of neurodegenerative disorders, such as Huntington's disease, Parkinson's disease, Alzheimer's disease, amyotrophic lateral sclerosis, multiple sclerosis, AIDS dementia complex, stroke and epilepsy [1,8].

Products derived from the kynurenine pathway can have either neurotoxic and neuroprotective effects. At least four of them are known to have marked effects on neuronal survival: quinolinic acid, 3-hydroxykynurenine, kynurenic acid and picolinic acid.

## Quinolinic Acid (QUIN)

Among the kynurenine pathway intermediates, QUIN is the main toxic compound produced (see Fig. 1). In 1981, Stone and Perkins showed for the first time the ability of QUIN to selectively activate neurons expressing NMDA receptors. QUIN neurotoxicity was demonstrated by Schwarcz et al. who showed that intra striatal and intra hippocampal injection of QUIN in the rat brain led to neurodegeneration around the injection site. QUIN leads acutely to human neuronal death and chronically to dysfunction by at least five mechanisms. (i) Activation of the NMDA receptor in pathophysiological concentrations. Neurons within the hippocampus, striatum and neocortex are more sensitive to QUIN, than cerebellar and spinal cord neurons; (ii) QUIN increases glutamate release by neurons and inhibits glutamate uptake by astrocytes leading to excessive microenvironment glutamate concentrations and neurotoxicity; (iii) More recently, it has become clear that a major mechanism of QUIN neurotoxicity is through lipid peroxidation; (iv) QUIN can potentiate its own toxicity and that of other excitotoxins (for example NMDA and glutamate) in the context of energy depletion and (v) Lastly, QUIN leads to astrocyte apoptosis with consequent loss of detoxifying and neurotrophic support of neurons. It is also likely that QUIN toxicity is additive or synergistic with other immune system-derived toxins, which act also via or modulate the NMDA receptor (Fig. 3).

## 3-Hydroxykynurenine

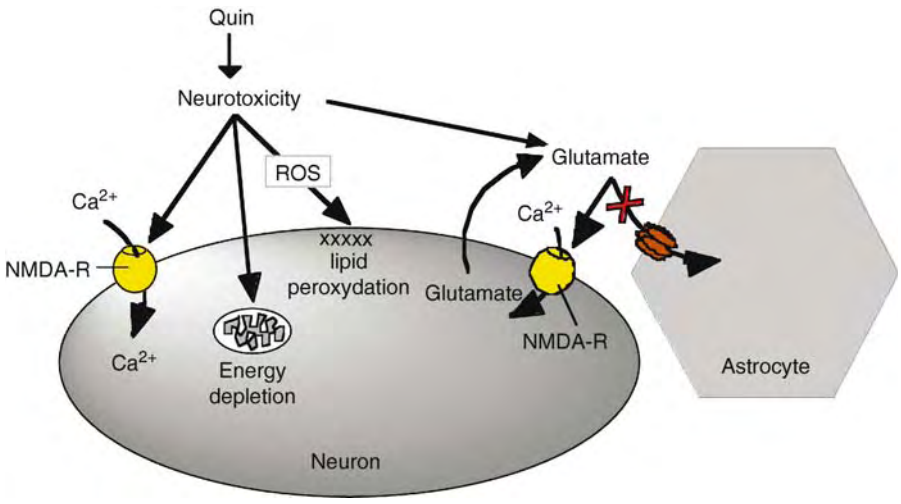
3-Hydroxykynurenine can produce neuronal damage by the induction of oxidative stress rather than an action on glutamate receptors. 3-Hydroxykynurenine also acts synergistically with QUIN and potentiates its toxicity.

## Kynurenic Acid

Kynurenic acid is an antagonist of all ionotropic glutamate receptors including N-methyl-D-aspartate (NMDAR), kainic acid and α-amino-3-hydroxy-5-methyl-4-isoxazole (AMPAR) receptors. Furthermore, kynurenic acid non-competitively inhibits α 7-nicotinic acetylcholine presynaptic receptors (nAChRs). Kynurenic acid is the only known endogenous NMDA receptor inhibitor, which act at the glycine site of the NMDAR and can antagonize some of the effects of quinolinic acid and other excitotoxins. It is noteworthy that in disease states where a large excess quinolinic acid is produced there is insufficient kynurenic acid to block quinolinic acid.

## Picolinic Acid

Picolinic acid has been shown to be neuroprotective. Picolinic acid protects against quinolinic acid ands kainic acid-induced neurotoxicity in the brain. However, picolinic acid blocks the neurotoxic but not the excitatory effects of QUIN. The mechanism of its



**Neurodegenerative Diseases: Tryptophan Metabolism. Figure 3** Mechanisms of quinolinic acid neurotoxicity.

anti-neurotoxic action is unclear but might involved zinc chelation and/or inhibition of nitric oxide synthase. Picolinic acid can influence the immune response and has antifungal, antitumoral and antibacterial activities.

### Therapy

Over the last two decades, manipulation of the kynurenine pathway has led to the development of a large number of neuroprotectant and anticonvulsant drugs [9,10].

- Some of these drugs target specific enzymes of the pathway. For example, tryptophan analogs such as 1-methyl tryptophan or 6-chlorotryptophan inhibit IDO activity; another family of compounds such as Ro 61–8,048 and m-nitrobenzoyl-alanine inhibit kynurenine hydroxylase activity.
- Other drugs are developed for their ability to block glutamate receptors and stop excitotoxic mechanisms. Kynurenine and kynurenic acid have been used as the original molecules for several groups of this kind of compounds. For example, 4-chlorokynurenine crosses the blood brain barrier and blocks quinolinic acid toxicity at the glycine site on NMDA receptors. Some kynurenic acid analogues are in or about to enter clinical trials for treatment of epilepsy, stroke and possibly Parkinson's disease.
- More recently, small interfering RNA (siRNA) targeting IDO, a new generation of inhibitors, has shown a great capacity to block the kynurenine pathway.

## Neuroeffector Junction

### Definition

A neuroeffector junction is the gap, typically 20–100 nm wide, between a varicosity of an autonomic axon and an effector cell in the target organ. These junctions

are wider and not as specialized in structure as synapses in autonomic ganglia or the central nervous system, or motor end plates in skeletal muscle.

►Postganglionic Neurotransmitter

## Neuroendocrine Axis

### Definition

It provides the structural and functional basis for interactions between brain, hormones, and glands that allow an organism to respond to external stimuli with complex, sometimes long-lasting physiological changes, such as during stress or reproduction.

Typically, it refers to any of these three pathways and their respective feedback mechanisms: the "Hypothalamus-Pituitary-Adrenal (HPA) axis," which extends from the hypothalamus in the brain via the anterior part of the pituitary gland to the adrenal cortex, the "Hypothalamo-Pituitary-Thyroid (HPT) axis," which leads to the thyroid gland, or the "Hypothalamo-Pituitary-Gonadal (HPG) axis," involving the male and/ or female gonads.

►Hypothalamo-Pituitary-Adrenal (HPA) Axis, Stress and Depression
►Hypothalamo-Pituitary-Thyroid (HPT) Axis

## Neuroendocrine Regulation

### Definition

In the central nervous system several specialized neurons produce peptides and/or proteins that are released as hormones in the circulation. One class of these hormones is the 'releasing factors' secreted in the portal system of the median eminence in order to target especially the adenohypophysis, where they liberate or inhibit the secretion of pituitary hormones. The other class of hormones is directly released into the main circulation either via the neural lobe part of the pituitary or via the pineal. The autonomic nervous system has important influences on the release and the efficiency of all these hormones.

### Definition

#### Neuroendocrine Regulation

In the central nervous system several specialized neurons produce peptides and/or proteins that are released as hormones in the circulation. One class of these hormones is the "releasing factors" secreted in the portal system of the median eminence in order to target especially the adenohypophysis, where they liberate or inhibit the secretion of pituitary hormones. The other class of hormones is directly released into the main circulation either via the neural lobe part of the pituitary or via the pineal. The ►autonomic nervous system has important influences on the release and the efficiency of all these hormones.

#### Autonomic Nervous System

The autonomic nervous system is that part of the central nervous system that operates outside voluntary control. The executing part of the autonomic nervous system is divided into a parasympathetic and a sympathetic branch. These two branches have, in general, antagonistic functions with an anabolic role for the parasympathetic and a catabolic function for the sympathetic branch. In addition information about the functional condition of our organs is transmitted back to the brain via these two branches.

### Characteristics

#### Quantitative Description

Very soon after the discovery of the principle of neurotransmission, Ernst and Bertha Scharrer proposed that certain specialized neurons in the hypothalamus would be able to produce hormones and release them into the blood stream. However, it took the scientific community more than 20 years to get used to this idea and only after Wolfgang Bargmann confirmed and elaborated on these findings was their "Neurosecretion" theory accepted. At about the same time, Frederick Banting and Charles Best made their groundbreaking discovery of insulin as a hormone of the pancreas that could save the life of many diabetic patients. These two findings should have made scientists aware that the areas of endocrinology and neuroscience are intimately integrated. Instead the complexity of the brain and the

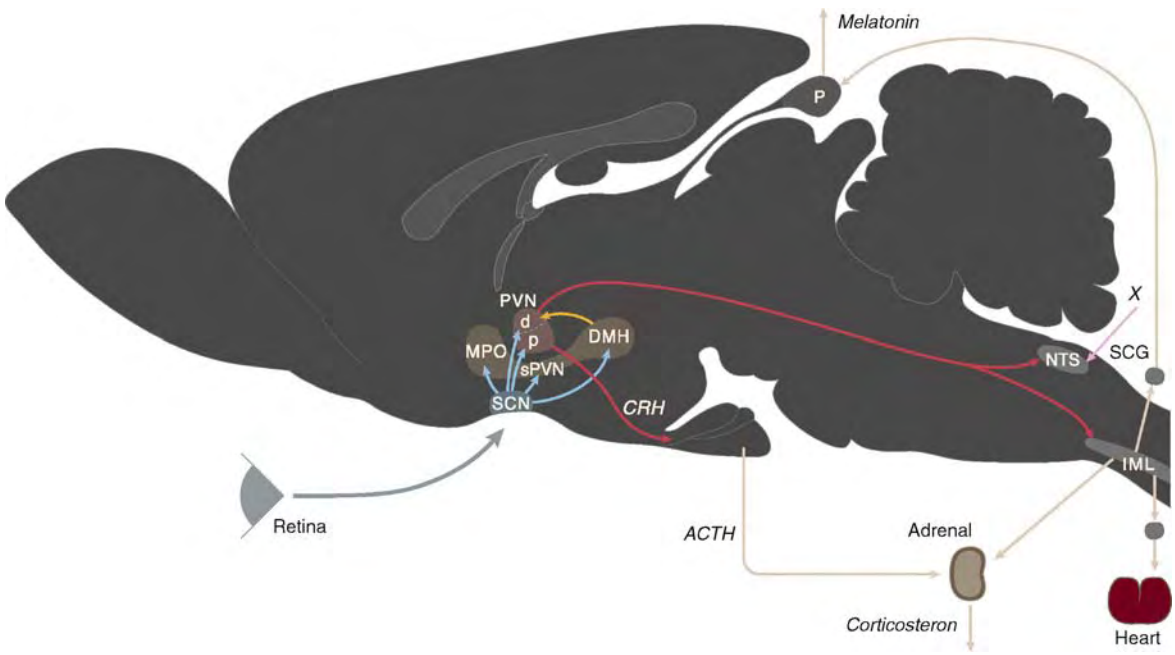
enormous life saving potential of hormones drove these fields further apart. Now the restoring movement is in progress and more and more it becomes clear that body and mind cannot be separated. Via the autonomic nervous system (ANS), the brain not only affects the production and efficacy of its own hormones but also of the hormones produced by the other organs of the body. Here special attention will be paid to the organization within the central nervous system (CNS) of structures that affect autonomic output and integrate autonomic information in relation with ►neuroendocrine regulation.

## Hypothalamus and the Organization of Autonomic Output and Input

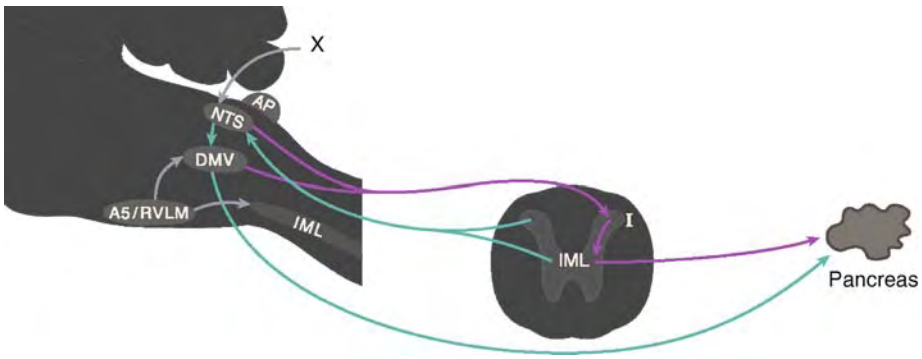
ANS outflow to the periphery is organized in sympathetic and parasympathetic pathways that have, by and large, opposing functions. Autonomic motor neurons responsible for driving this outflow are located in the brain stem and spinal cord respectively. Tracing and stimulation studies demonstrated that mainly the prefrontal cortex, amygdala and hypothalamic nuclei have direct access to autonomic motor centers. Within the ►hypothalamus, the paraventricular nucleus (PVN) is the single most important structure for neuroendocrine and autonomic integration. The PVN consists of neuroendocrine neurons projecting to the neurohypophysis and median eminence and of pre-autonomic neurons projecting to sympathetic and parasympathetic motor neurons in the intermediolateral column (IML) of the spinal cord and the dorsal motor nucleus of the vagus (DMV) in the (Fig. 1) brain stem respectively.

SCN projections seem to reach the neuroendocrine neurons in the PVN (i.e. CRH, TRH) via an indirect pathway. Interneurons are mainly located in the MPO, subPVN and DMH. As described in the text, this indirect pathway is involved in the control of the daily rhythm of corticosterone release. The neuroendocrine CRH neurons in the PVN project to the median eminence. CRH released in the median eminence will stimulate ACTH secretion from the anterior pituitary, which will finally reach the adrenal cortex via the general circulation and stimulate corticosterone secretion.

The PVN output to non-autonomic sites in the brain in contrast is limited and mainly organized to support its hormonal and autonomic output. For instance, the PVN projects to sites where visceral (sensory) information is transmitted from autonomic sensory fibers to neurons of the CNS (Fig. 2). Via these projections, the PVN is able to modulate incoming information as well. Recent studies have shown that PVN axons projecting to sympathetic and parasympathetic motor neurons have collaterals to the NTS, suggesting that "a copy" of the outgoing signal is sent to the neurons receiving incoming information, as if to inform them what the



**Neuroendocrine Regulation and the Autonomic Nervous System. Figure 1** Pathways via which light affects hormonal and autonomic output by the hypothalamus. Via the retina, light information is transmitted to the SCN and passed on to the pre-autonomic neurons in the PVN via direct SCN–PVN connections. The autonomic neurons of the PVN pass the light information to the sympathetic motor neurons in the IML, with collaterals to the NTS (see Fig. 2) and directly inhibit melatonin secretion from the pineal. Along the same pathway, light will also change the sensitivity of the adrenal cortex to ACTH and thereby affect corticosterone secretion and reduce the heart rate in rats.



**Neuroendocrine Regulation and the Autonomic Nervous System. Figure 2** The autonomic circuit. The parasympathetic-sympathetic interaction illustrates the relationship between the cell groups that may influence the vagal output in *green* or the sympathetic output in *pink*. It is clear that both vagal and sympathetic output influence each other.

action of the brain is. To make this picture of the organization of the autonomic output of the brain complete, it is essential to keep in mind that within the parasympathetic DMV and sympathetic IML, not only motor neurons are present but also interneurons that project to respectively the IML and DMV. In this way the autonomic output and input forms a feedback circuit that can function on its own and forms the basis for the autonomic control that can operate in decerebrate animals. Via the PVN this "autonomic" circuit is open to central (hypothalamic, amygdalar and cortical) modulation (Fig. 2).

Consequently, the PVN can be seen as the major center, controlling the neuroendocrine and autonomic output of the brain.

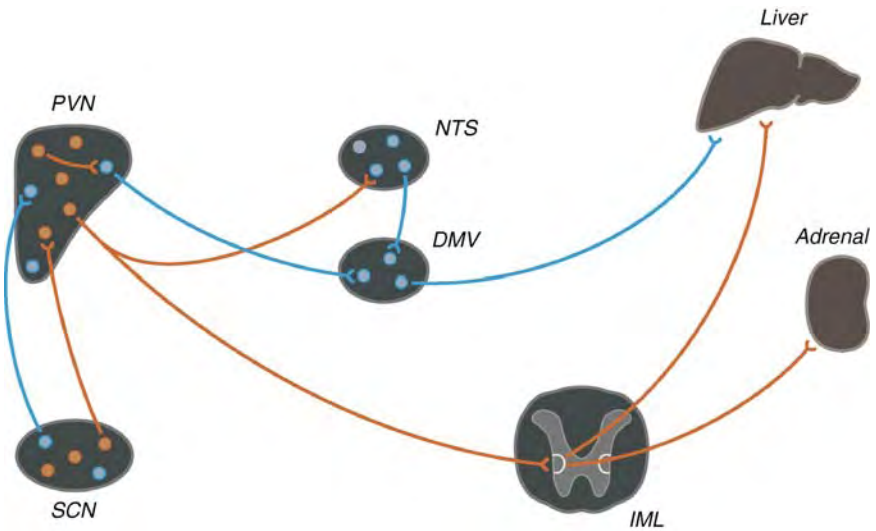
## Balancing Autonomic Output

Our evolutionarily shaped homeostatic systems have "learned" to adapt to the ever-changing light/dark cycle so that the body anticipates coming periods of sleep or activity. In all organisms, mechanisms have developed that can predict when the day ends or starts. These mechanisms are known as the "circadian system." In all cells of the body, clock mechanisms have evolved that in one way or another can keep track of time. However, the brain is the only location where an autonomous biological clock is located, i.e. in the suprachiasmatic nuclei (SCN) of the ventral hypothalamus. By enforcing its message to the PVN, the SCN is able to transmit its daily signal via hormones and the autonomic nervous system to all tissues of the body. Via these signals body tissues are prepared for activity or sleep. The SCN needs to activate body organs and tissues depending on their function at different times of the day, for example muscles work in the active phase when the digestive tract slows down. Thus, during the active phase, an opposite autonomic tone on vasculature will redirect blood away from the abdominal compartment towards the movement compartment. At the same time cerebral blood flow is kept constant. The major advantage of an endogenous oscillator is that it allows the body to anticipate these changes. One of the questions that puzzled investigators for a long time is how SCN neurons, that are mainly active during the daytime, are connected to these two different autonomic systems. Thus in a series of tracing experiments a strict separation between sympathetic and parasympathetic projecting neurons at the level of the PVN was shown to persist up to the SCN (Fig. 3).

The complete segregation of parasympathetic and sympathetic pre-autonomic neurons provides the anatomical basis for a differential control of these two autonomic branches by the hypothalamus. Functionally this separation between parasympathetic and sympathetic pre-autonomic neurons makes perfect sense. For instance, at night the SCN slows down heart function, resulting in a dip in blood pressure. The sympathetic and parasympathetic autonomic nervous systems are proposed to have opposing functions, with alternating activities over the sleep-wake cycle. Moreover, even when we consider sympathetic input alone, it cannot be activated over the whole body at the same moment. At the time when melatonin secretion from the pineal is stimulated by sympathetic terminals, the sympathetic input to the heart needs to be inhibited, at least in humans.

## The Autonomic Nervous System Differentiates Between Functionally Different Body Compartments

Recent studies indicate that the body can be divided into different functional autonomic compartments and that at least a thoracic, a movement and a visceral compartment should exist. In this setting, a balanced and flexible autonomic nervous system can oscillate the activities of the organs within the different compartments according to the actual needs of the body. Using



**Neuroendocrine Regulation and the Autonomic Nervous System. Figure 3** Sympathetic and parasympathetic differentiation. Scheme of interaction between the hypothalamic suprachiasmatic nucleus (*SCN*) and paraventricular nucleus (*PVN*). Separate sympathetic (*red*) or parasympathetic (*blue*) neurons of the SCN project to pre-autonomic neurons of the PVN, where a similar sympathetic-parasympathetic separation can be observed. Pre-autonomic neurons of the PVN project either to the preganglionic sympathetic neurons in the intermediolateral (*IML*) column of the spinal cord or to the preganglionic neurons of the dorsal motor nucleus of the vagus (*DMV*). The pre-sympathetic PVN neurons have axon collaterals to pre-parasympathetic neurons, either in the PVN itself or via the nucleus tractus solitarius (*NTS*).

viral retrograde tracers to label the motor neurons that innervate specific organs, abdominal organs such as liver, pancreas and intra-abdominal fat were shown to share the same vagal motor neurons. In contrast, distinct sets of vagal motor neurons project to fat tissue that is located in the intra-abdominal or subcutaneous compartments. Again this somatotopic organization was shown to exist up to the hypothalamic biological clock and the amygdalar limbic system. Most probably this astonishing capacity of hypothalamic neurons to specialize also coordinates the "dawn phenomenon," where enhanced glucose production by the liver coincides with enhanced glucose uptake by the target organs at the beginning of the daily activity phase. These two processes will need different actions of the sympathetic neurons that project to the liver (i.e. activity) and to the muscular vasculature (i.e. inactivity). On the other hand, when unbalanced, the shared command of intra-abdominal organs may also result in the simultaneous occurrence of diabetes type 2, dyslipidemia and visceral obesity.

## The Hypothalamus Targets the Organs of the Body both by Hormones and by Autonomic Output

The PVN is a hypothalamic center that is able to adapt and coordinate hormonal and autonomic responses, not only by virtue of a highly differentiated hormonal output but also by an equally well-differentiated autonomic output. The enormous variety of different neuroendocrine and autonomic neurons offers the PVN a great potential for integration and harmonization of function. In fact, several studies have demonstrated the presence of an anatomical network for intra-PVN integration and coordination. As an example, the daily rhythm in the activity of the hypothalamo-pituitary-adrenal axis will be discussed in somewhat more detail. The SCN has both direct and indirect connections with the CRH producing neurons in the PVN to control CRH and thus ACTH secretion. The indirect connections run via SCN projections to the interneurons in the DMH that project to the PVN. Next to these neuroendocrine connections the SCN also has direct connections with the pre-autonomic neurons in the PVN projecting to sympathetic motor neurons in the IML that are in direct contact with the adrenal. Probably the SCN also has indirect connections (via the DMH) with the pre-autonomic neurons in the PVN. Using this myriad of connections, the SCN synchronizes its actions so that it affects the autonomic output of the PVN and thus sensitizes the adrenal cortex for ACTH at the same moment that ACTH secretion from the pituitary is stimulated. As a result, the response of the adrenal cortex to ACTH is greatly facilitated.

It is proposed that by the combination of hormones and autonomic output not only the biological clock, but also other brain structures will be able to optimally affect the functioning of organs. Naturally it is also possible that the functionality of organs is affected only

by changing their sensitivity and that the hormones are regulated by another mechanism.

## Synonyms

Steroid hormones; Neurosteroids; Neuroactive steroids

## Definition

Neuroendocrinological drugs may be naturally occurring steroid hormones, or synthetic hormones that mimic the activity of the naturally occurring steroid hormones. These steroid hormones, referred to as neurosteroids are synthesized in the CNS and in the peripheral nervous system. Neuroactive steroids are steroid hormones that act on neurosteroid receptors, regardless of the origin of the steroid. Examples of neuroactive steroids include ►estrogens, ►progestagens, and progestagen metabolites including allopregnanolone, testosterone and metabolites including 3α-androstanediol. In this entry, "estrogen" is used as a generic term to refer to any neuroactive steroid with estrogenic activity while "progestagen" refers to the naturally occurring ►progesterone or a progestagen, synthetic progesterone. "►Androgens" refers to neuroactive steroids with masculinizing effects. Corticosteroids may also be neuroactive steroids.

## Characteristics

### Overview

Neuroactive steroids, or their synthetic analogs, exert their actions in the CNS by binding to specific neurosteroid receptors or by binding to neurosteroid binding sites on other types of receptors in the CNS, e.g. the $GABA_A$ receptor.

Neuroactive steroids, like all steroid hormones, are synthesized from cholesterol via discreet enzymatic pathways. Neuroactive steroids are secreted largely under the control of the hypothalamic-pituitary-adrenal (HPA) axis. Specific neurosteroids are secreted within the CNS by several types of cells including oligodendrocytes. The factors controlling neurosteroid secretion are less well understood. In addition, in pregnant females, the neuroactive steroids estrogen and progesterone, are secreted by the placenta and the corpus luteum, respectively.

Neurosteroid receptors are members of the large family of "ligan-dependent nuclear transcription factors" (steroid receptors), with cytosolic or nuclear binding complexes that, in the case of the cytosolic receptors, are translocated to the nucleus, and bind to a promotor region on DNA. The binding of the receptor complex to the promotor region initiates the release of mRNA from the nucleus into the cytoplasm and ultimately, to the production of new protein by the endoplasmic reticulum. However, not all neuroactive steroid activities are modulated by intracellular receptors. It is evident from a number of experimental results that membrane-bound neurosteroid receptors are also active in the CNS. In addition, an allosteric binding site for a ►progesterone metabolite has been identified on the $GABA_A$ receptor and sigma receptors, nicotinic acetylcholine receptors and the NMDA, kainate and AMPA subtypes of the glutamate receptors have been demonstrated to be

modulated by neuroactive steroids [1]. As these neurotransmitter receptors are the targets of many non-steroidal neuroactive drugs, the importance of neuroactive steroids as potential therapeutic agents is clear.

One ramification of the discovery and identification of neuroactive steroids has been to identify a mechanism for sex differences in brain function, specifically in brain activity not related to reproductive status. Estrogen, progestagen and androgen receptors are distributed throughout the brains of both females and males. The levels of the hormones, as measured in blood plasma, differ markedly between females and males, depending upon the timing of the measurement. In males, testosterone is released in a pulsatile manner throughout the 24 h cycle, while the low levels of estrogen and progesterone in males remains fairly stable. In females, estrogen and progesterone levels fluctuate on an approximately 28 day cycle, with an estrogen peak on day 14 and a lower estrogen peak again around cycle day 20. Finally, it tapers off by day 28. Progesterone, on the other hand is extremely low until cycle day 17, when it increases rapidly and peaks around day 21, dropping rapidly again by day 28. Changes in mood and behaviour have been associated with these hormonal changes. It is only recently that the implications of the hormonal changes for neurotransmitter function have been recognized.

## Historical Perspective on Neurosteroids and Neuroactive Steroids

McEwen and colleagues [2] were responsible for landmark experiments in the 1960s demonstrating the presence of steroid hormones in the brain tissue of rats. Over the next 10 years, extensive research demonstrated the presence of steroid hormone receptors throughout the mammalian brain, and many of these receptors were found outside areas of the CNS associated with reproductive behaviour. This latter result led to the suggestion that steroid hormones might modulate brain activity associated with non-reproductive behaviour. Baulieu [3] coined the term "neurosteroids" in 1981 and in the following years identified many of the neuroactive steroids.

Elucidation of the binding characteristics of neurosteroid receptors has been a major focus of research since the 1980s. While it has been clearly established that neurosteroid receptors have response characteristics in common with most members of the steroid receptor family, some experimental results have not been consistent with intracellular receptor binding. It has been demonstrated that some neuroactive steroids activate membrane bound receptors associated with ion channels and G-proteins, some transporter systems are sensitive to neuroactive steroids, a number of neurotransmitter systems are modulated by neuroactive steroid activity (see above) and both estrogen and progestagen have been reported to modulate the expression of different subunits of the $GABA_A$ receptor [4,5]. It is the interactions with the GABAergic and serotonergic system that have been of particular interest to the development and administration of psychoactive drugs such as benzodiazepines and selective serotonin reuptake inhibitors for the treatment of anxiety and depression [6].

Numerous studies have demonstrated that neuroactive steroids modulate memory and cognition [6]. Estrogen is generally considered an "activator" in the brain, administration of estrogen lowers seizure threshold, prolongs the duration of seizures. The relationship of estrogen to seizure activity is recognized is the term "catamenial epilepsy," a form of epilepsy that is linked to the menstrual cycles in females. Progestagen is known to have sedative effects, administration lowers the seizure threshold, shortens seizure duration, and it has been used as an anesthetic.

## Current Therapeutic Strategies

The use of neuroactive steroids as therapeutic agents is relatively recent. Corticosteroids, such as methylprednisolone, have been and continue to be used to prevent and treat edema following head injury. This antiinflammatory effect is, however, independent of the actions of neuroactive steroids that are the focus of this discussion.

Estrogen has been used in conjunction with conventional treatments in females suffering from Parkinson's disease or Alzheimer's disease with limited success [7]. Dementia occurs in some patients with Parkinson's disease and it has been reported that hormone replacement therapy (HRT) decreases the incidence of dementia in older patients. It has also been reported that taking HRT decreases the risk of developing Alzheimer's disease. There are numerous studies showing that estrogen, when taken alone, has a positive effect on mood and cognitive function, but that with the addition of progesterone, the positive effects disappears [6]. This observation on progesterone administration raises one of the potential problems for the use of estrogen as a therapeutic agent. Estrogen has a proliferative effect, enriching the endometrium, causing tissue thickening in preparation for implantation of a fertilized ovum. When fertilization does not occur, the release of progesterone causes the retraction and ultimate sloughing of the excess tissue. If estrogen is given without progestagen administration, either concomitantly or sequentially, the endometrial thickening continues unchecked, increasing the risk for the development of endometrial cancer. In HRT and the contraceptive pill, progestagen is an essential component. An area where the actions of progestagen could be an advantage is in the treatment of catamenial epilepsy. Given the antiepileptic properties of progestagens, the

choice of a progestagen only contraceptive might provide antiseizure activity to enhance the action of antiepileptic drugs, while providing the desired contraceptive effect.

A current impediment to the use of neuroactive steroids as therapeutic agents is the side effect profile and adverse events associated with their administration. Deep vein thrombosis, for example, is associated with both progestagen and estrogen administration. Estrogen is contraindicated for administration to individuals with a history of cardiovascular disease, stroke, blood clotting disorders, focal migraine, hypertension and some kinds of cancers. Progestagen, when administered alone as an injectable contraceptive, is associated with a disruption of calcium metabolism and is currently only recommended for an administration period of 2 years.

**Neuroendocrinological Drugs. Table 1** Examples of neuroactive steroids

| Class | Neuroactive steroid |
|---|---|
| Estrogen | 17β-estradiol |
| | Estrone |
| | Estradiol |
| Progestagen | Progesterone |
| | Allopregnanolone, |
| | 17α-hydroxyprogesterone |
| | 20α-hydroxyprogesterone |
| Androgen | Testosterone |
| | 3α-androstanediol |
| Corticosteroid | 3α, 5α-tetrahydrodeoxycortocosterone (THDOC) |

## Future for Drug Development

The therapeutic uses of neuroactive steroids will depend upon the specificity of the action that can be achieved. There are two known types of estrogen receptors (ER), α and β, with different actions and distribution for each. ERα are found predominantly in the amygdala, septum and hypothalamus, and in smaller numbers in brainstem nuclei including the periaqueductal grey, locus coeruleus and area postrema. ERβ are found in lower concentration than ERα with the highest numbers being found ιν the amygdala, septum, hypothalamus and olfactory cortex. There are two types of progestagen receptors with functions that are yet to be clarified. Androgen receptors are also found in the bran. Undoubtedly, there are additional types and subtypes of these receptors yet to be discovered. There are also neurosteroid binding sites associated with classical neurotransmitter receptors as allosteric binding sites. There are different estrogens (17β-estradiol, estrone and estradiol), progestagens (e.g. progesterone, allopregnanolone, 17α-hydroxyprogesterone, 20α-hydroxyprogesterone) and ►androgens, with slightly differing chemical structures (Table 1). Targeting specific populations of neurosteroid receptors is one obvious direction for drug development. Another direction is the targeting of allosteric binding sites on particular populations of neurons with classical neurotransmitter receptors or transporter proteins such as the dopamine transporter.

The $GABA_A$ receptor is a particularly good candidate for this approach. The $GABA_A$ receptor, in addition to the GABA binding site, has allosteric binding sites for benzodiazepines, barbiturates, progestagens and alcohol. It is the primary inhibitory neurotransmitter receptor found in the brain. The $GABA_A$ receptor is composed of assemblies of subunits arranged around a central chloride channel (see Chapter on Anxiolytics and Hypnotics). The subunits are found in different combinations of subunit type (α, β, γ, δ, ε, π, ρ). The subunit combination of any given receptor determines the pharmacological actions associated with activation of the receptor. Receptors with certain subunit combinations are distributed differently throughout the brain. Binding of ligands to the allosteric binding sites enhances the effect of GABA. It is conceivable that a neurosteroid could be synthesized to target the progestagen binding site, and by modifying the action of benzodiazepines, barbiturates or alcohol overcome some of their adverse side effects.

Epidemiological studies show that females have a higher incidence of anxiety and depressive disorders. Serotonin levels are significantly lower in the female brain than in the male brain. Females are also receive more prescriptions of anxiolytic and antidepressant drugs than males [7]. It may, in the future, be possible to capitalize on the changing levels of neuroactive steroids associated with the menstrual cycle to target and refine drug effects.

The progesterone metabolite allopregnanolone (which may act only on the $GABA_A$ receptor and not progestagen receptors) has been reported to have detrimental effects on mood, memory, cognitive function and has been reported to be associated with premenstrual mood changes. One possibility would be to develop antagonists to allopregnanolone that act specifically to reduce the adverse events associated with its administration. 3β-hydroxypregnane has recently been reported to reduce the learning deficits produced by allopregnanolone administration [6] suggesting that this may be a useful direction for drug development.

## Definitions

►Neuroendocrinology is the field that studies hormone production by neurons, the sensitivity of neurons for hormones, as well as the dynamic, bidirectional interactions between them. These processes function in concert to allow maintenance of homeostasis for the organism. The central region of interest in this field is the ►hypothalamus, as many endocrine cascades are initiated there and ►feedback regulation of these very same cascades also takes place in this area. In addition to the hypothalamus, most other brain areas are sensitive to hormonal action as well.

The human hypothalamus is a small (4 $cm^3$) but very complex heterogeneous brain structure. Together with its adjacent areas it is composed of some 20 well-defined (sub)nuclei between 0.25 and 3 $mm^3$ in size, with very different chemical components and functions (Fig. 1). Their neurons contain one or more of all four types of neuroactive substances; acetylcholine, amines, amino acids, and a multitude of ►neuropeptides.

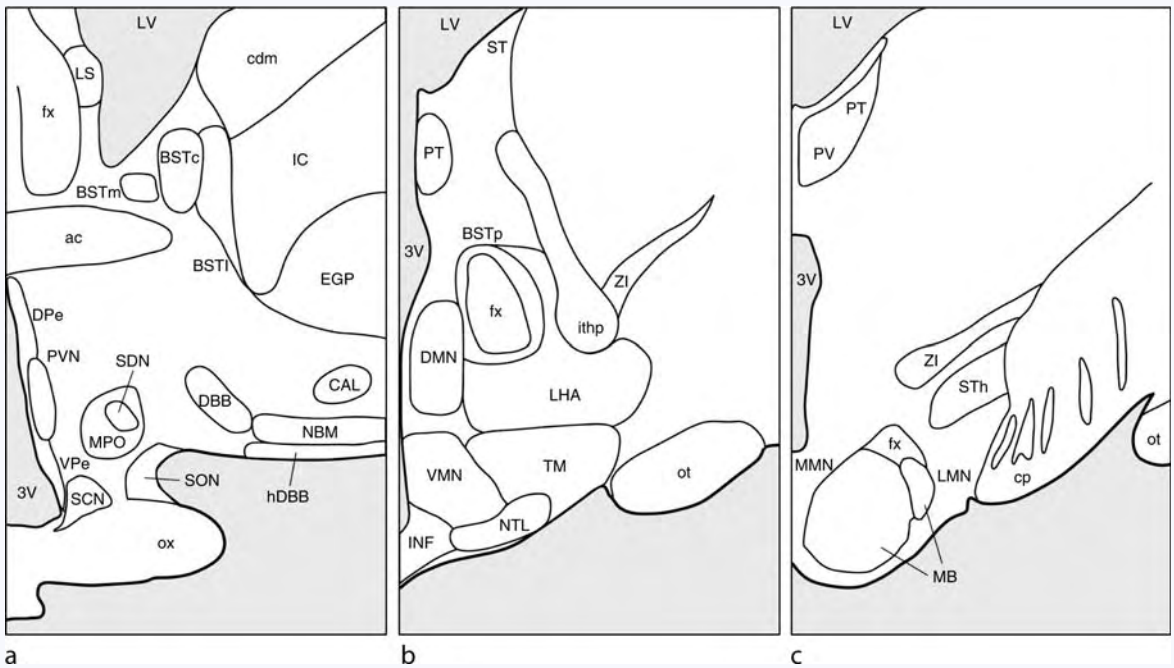
A special characteristic of the hypothalamus is that some neurons projecting to the ►neurohypophysis or to the portal vessels of the pituitary in the ►median eminence, release their peptide into the blood and act as ►neurohormones. Other neurons project to neurons within and outside the hypothalamus, where they function as ►neurotransmitters or ►neuromodulators, and regulate central functions, including the ►autonomic innervation of all our body organs [1]. In this way, the hypothalamus acts as a center that integrates endocrine, autonomic, and higher brain functions. The fact that neuropeptides are generally very stable after death makes them very suitable as markers of hypothalamic nuclei that enables the identification of structural and functional changes in key hypothalamic nuclei and transmitter systems in postmortem material obtained from patients with e.g. different ►neuroendocrine disorders.

The hypothalamus regulates essential processes throughout all stages of life, and is also the primary structure involved in a number of disorders. A few examples of such hypothalamic disorders will be presented in this synopsis in relation to the different hypothalamic areas.

## The Classical Neuroendocrine Neurons in the Supraoptic (SON) and Paraventricular Nucleus (PVN)

The ►supraoptic and paraventricular nucleus (SON and PVN) and their axons running to the neurohypophysis form together the ►hypothalamo-neurohypophysial system (HNS), which represents the classic example of a neuroendocrine system. ►Vasopressin (= ►antidiuretic hormone, ADH) and ►oxytocin are key hormones produced in the large, magnocellular neurons of the SON and PVN, and are e.g. involved in ►antidiuresis, ►labor and ►lactation. A second type of smaller neuroendocrine cells, the parvicellular neurons, is found in the PVN. They release their peptides into the ►portal capillaries that transport them to the ►anterior lobe of the pituitary. Examples are ►corticotrophin releasing hormone (CRH) and ►thyrotropin releasing hormone (TRH). A third type of PVN cells projects to other neurons, where the peptides act as neurotransmitters/neuromodulators. These involve e.g. vaspressin, oxytocin, CRH and TRH neurons that thereby regulate the autonomic nervous system [1]. The entire SON contains some 78,000 neurons on one side from which 88% contains vasopressin and 12% contains oxytocin. The PVN has been estimated to contain about 56,000 neurons of which some 25,000 express oxytocin and 21,000 produce vasopressin. A large number of other, often co-expressing peptides are found in both nuclei [2].

The SON is the main source of circulating vasopressin. Disorders of this vasopressin system involve familial central ►diabetes insipidus with mutations in the vasopressin precursor, autoimmune diabetes insipidus with antibodies against the vasopressin neurons, pregnancy-induced diabetes insipidus due to increased breakdown of plasma vasopressin, ►nephrogenic



**Neuroendocrinology. Figure 1** Schematic representation of the nuclei of the human hypothalamus. diabetes due to mutations in the gene of the vasopressin receptor-2 or in the gene of the water channel protein aquaporin-2, nocturnal diuresis, ►inappropriate secretion of vasopressin (Schwartz–Bartter syndrome), ►Wolfram's syndrome, and glucocorticoid administration, in which we found a processing disorder of vasopressin, and ►septo-optic dysplasia (De Morsier's syndrome), in which we observed that the SON and PVN were virtually absent [2].

The PVN contains a large number of different neuropeptides [2]. CRH is produced by parvicellular neurons and is a crucial neuropeptide in the regulation of the ►hypothalamo-pituitary-adrenal (HPA)-axis, the final common pathway in the ►stress response. Once a stressor is perceived, rapid rises in CRH in the PVN subsequently stimulate the release of ►adrenocorticotropic hormone (ACTH) from the anterior pituitary into the circulation. The ACTH-releasing activity of CRH is strongly potentiated by vasopressin when co-produced by the same CRH containing parvicellular neurons. ACTH is released into the blood and frees ►cortisol from the adrenal, the main steroid hormone in humans that coordinates various aspects of the stress response throughout the body and CNS. These include changes in behaviour, such as rises in alertness and anxiety, an activation of the autonomic nervous system, causing increases in heart rate and respiration, redistibution of the bloodstream and mobilization of energy sources. At the same time, various processes and bodily systems are temporarily inhibited that are of lesser importance during an acutely threatening situation, including suppression of gastrointestinal function, sleep, sexual activity and growth. In addition, cortisol is one of the most powerful endogenous feedback compounds on the ►pro-inflammatory signal transduction machinery. Hyperactivity of the HPA axis is furthermore a key phenomenon in ►depression and is held responsible for symptoms like decreased ►food intake, decreased sexual activity, disturbed sleep and motor behavior and increased anxiety. The HPA-axis is also activated in ►multiple sclerosis (MS).

After being released from the adrenal, cortisol inhibits its own release through feedback inhibition on the very same brain areas where its release was initially coordinated, through binding to glucocorticoid receptors (GR) in the pituitary and PVN. ►Corticosteroids, at least in rodent, also target the hippocampus that is richly endowed with corticosteroid receptors and is involved in modulation of the stress response. In addition to corticol, also exogenously applied

corticosteroids inhibit CRH production in the PVN [3]. In addition to a crucial role in initiation of the stress response, CRH also has central effects, including cardiovascular regulation, respiration, appetite control, stress-related behavior and mood, cerebral blood flow regulation and stress-induced analgesia.

TRH is released in the median eminence as the major hypothalamic hormone stimulating thyroid function, acting on thyroid ►stimulating hormone (TSH) cells of the pituitary, whereas ►somatostatin and dopamine inhibit TSH secretion. The large number of dense TRH fiber terminations in the hypothalamus suggests an important role of this neuropeptide as a neuromodulator [4]. The human PVN is furthermore densely innervated by fibers from the ►infundibular nucleus. In juxtaposition to the TRH neurons in the PVN, NPY, agouti-related peptide (AGRP) and ά-MSH-containing fibers are found, which are involved e.g. in eating behavior. The TRH neurons of the PVN are less active, not only in depression, where decreased amounts of TRH mRNA were found in the PVN [5], but also in ►sick euthyroid syndrome (or ►nonthyroidal illness), a condition often seen in serious illness conditions [6].

## The Suprachiasmatic Nucleus (SCN)

The SCN is the biological clock of the brain that regulates the ►circadian and seasonal variations occurring in many endocrine and other functions. The ►circadian pacemaker is localized in the SCN, on top of the optic chiasm, and the clock is entrained to fluctuations in light intensity during the day–night cycle by direct innervation from the ►retinohypothalamic tract. Vasopressin and ►vasoactive intestinal polypeptide (VIP) expressing neurons of the SCN project to the ►dorsomedial nucleus, the subparaventricular zone, and the PVN. Transmeridian flights and shiftwork might lead to disturbances in the functional organization of the biological clock. Moreover, disorders of the circadian timing system are held responsible for advanced and delayed sleepsyndrome, a number of other ►sleep disorders, and nightly restlessness in patients with ►Alzheimer's disease. In addition, day–night fluctuations in the SCN may be the basis of the clear day–night differences found in the course of various diseases and conditions. For example, the moment when death occurs from myocardial infarction, intracerebral hemorrhage, or ischemic stroke, or the moment when complaints about migraine, depressive symptoms, tremor in Parkinson's disease, and sleep disorders in depression are at their most serious, do not occur at random over the day but all have a strong preference for a particular moment of the day [2]. We have shown a decreased amount of vasopressin mRNA in the SCN of depressed patients [7], indicating a diminished activity of the biological clock that might be the neurobiological basis of sleep disturbances and circadian disorders in these patients.

## Hypothalamic Nuclei with Structural Sex Differences

►Sex differences in the size of the ►sexually dimorphic nucleus of the preoptic area (SDN-POA) were first described in the rat by [8]. We have found a similar nucleus in the human hypothalamus. Morphometric analysis of the human SDN-POA revealed that its volume is more than twice as large in young adult men as it is in women, and contains about twice as many cells in men [9]. It seems to be homologous to the SDN-POA in the rat in view of its sex difference in size and cell number, localization, cytoarchitecture, and neurotransmitter/neuromodulator content. [10] gave this nucleus another name: ►Interstitial nucleus of the anterior hypothalamus-1 (INAH-1) and also described two other cell groups (►INAH-2 and -3) in the preoptic-anterior hypothalamic area of humans that were larger in the male brain than in the female brain. [11] found a sex difference in INAH-3. Another sex difference was described by [18], in what they called the "►darkly staining posteromedial component of the bed nucleus of the stria terminalis" ►(BNST-dspm). The volume of the BNSTdspm was 2.5 times larger in males than in females. We found a similar sex difference in the ►central nucleus of the bed nucleus of the stria terminalis (BSTc). The BSTc is defined by its dense VIP innervation and by its somatostatin fiber plexus and somatostatin neuron population. The BSTc in men is 40% larger than in women, and men have almost twice as many somatostatin neurons as women [12,13]. We have furthermore found a female-sized central nucleus of the bed nucleus of the BST in male-to-female ►transsexuals [13]. These data were confirmed by neuronal counts of somatostatin cells, the major neuron population in the BSTc [12].

## Infundibular (Arcuate) Nucleus

The horseshoe-shaped infundibular (or ►arcuate) nucleus surrounds the lateral and posterior entrance of the ►infundibulum and is situated outside the blood–brain barrier. The infundibular nucleus contains some 520,000 neurons [14] and is involved in reproduction, pain, eating behavior and metabolism, thyroid hormone feedback, growth, and dopamine regulation.

In addition, the infundibular nucleus is continuous with the ►stalk/median eminence region that contains the ►portal capillaries of the adenohypophysis. The ►neuropeptide-Y (NPY) fibers in the median eminence are mainly restricted to the internal zone and only scarcely innervate the neurovascular zone, whereas CRH, LHRH, ►opiomelanocortins, somatostatin, ►GHRH, ►galanin, TRH, and ►substance-P fibers do innervate the stalk/median eminence region. The NPY neurons project to the PVN and NPY together with ghrelin e.g., is one of the most active food intake stimulating peptides.

The infundibular nucleus is chemically characterized by the presence of (pre)proopiomelanocortin neurons, containing e.g. ►ά-melanocyte-stimulating hormone (ά-MSH). The sites of fiber termination of the opiomelanocortin neurons are consistent with the brain sites where pain relief was obtained by deep brain stimulation. Moreover, this nucleus contains peptides that inhibit feeding like ά-MSH that acts by the ►MC-4 receptor and ►cocaine- and amphetamine-regulated transcript (CART). AGRP and NPY stimulate feeding and co-localize in the infundibular nucleus. GHRH neurons are involved in metabolism and are activated during prolonged illness [2,15]. Severe ►obesitas has been reported due to mutations in the genes for preproopiomelanocortin-, MC-4 receptor-, ►leptin, the ►leptin receptor and ►prohormone convertase-1.

The infundibular nucleus also contains ►luteinizing hormone-releasing hormone (LHRH; gonadotropin releasing hormone)-containing cell bodies that, like opioid peptides, play a role in reproduction and sexual behavior, the latter in erections. ►Estrogen and ►androgen receptors and all four thyroid hormone receptors (TR) isoforms are present in the infundibular nucleus.

A subdivision of the infundibular nucleus in ►postmenopausal women and in hypopituitarism was named the ►subventricular nucleus after its location beneath the floor of the third ventricle. The production of neurokinin-B (NKB), substance-P, and estrogen receptor transcripts is strongly increased in postmenopausal women due to the diminished inhibitory action of estrogens. The NKB neurons are presumed to be involved in the initiation of menopausal flushes [16].

## Lateral Hypothalamic Area (LHA), Including the Perifornical Area

The LHA is involved in the regulation of food intake and body weight. The classic syndrome following lesions of the lateral hypothalamus involves ►aphagia and ►adipsia. ►Melanin concentrating hormone (MCH) is a neuropeptide produced in the LHA, perifornical and periventricular areas, and in the tuberomammillary and posterior nuclei. MCH increases food intake and lowers plasma glucocorticoid levels in the rat. Quite recently two novel neuropeptides were discovered, designated ►hypocretin 1 and 2 (from hypothalamus and secretin), or ►orexin A and B, that stimulate food consumption in rat. These peptides are localized in the lateral and posterior hypothalamus and accumulate in the perifornical area. The hypocretins are involved not only in food intake, but also in sleep and neuroendocrine control. In ►narcolepsy patients that are ►cataplectic a 85–95% loss of hypocretin neurons was found without gliosis or signs of inflammation, possibly as the result of an autoimmune process [17].

## Other Hypothalamic Nuclei

Following destruction of the ►ventromedial hypothalamic nuclei (VMN) e.g. by a tumor or neurochirurgical intervention, a classic tetrad of symptoms has been described, i.e. (i) episodic rage, (ii) emotional lability, (iii) hyperphagia with obesity and (iv) intellectual deterioration, mainly based upon memory loss.

The ►tuberomamillary nucleus (TMN) contains the only ►histaminergic system of the brain and participates in the modulation of the state of arousal, the control of vigilance, sleep and wakefulness, cerebral circulation and brain metabolism, locomotor activity, neuroendocrine and vestibular functions, drinking, sexual behavior, stress, food intake, analgesia, and the regulation of blood pressure and temperature.

The ►nucleus tuberalis lateralis (NTL) can only be recognized as a distinct nucleus in man and higher primates, and contains somatostatin as its main transmitter. The NTL is hypothesized to play a role in feeding behavior and metabolism.

The ►corpora mamillaria, its input from the ►fornix and the efferent ►mamillo-thalamic tract of Vicq d'Azyr are involved in memory processes.In neurodegenerative diseases such as ►Huntington's disease, Alzheimer's disease, and ►Down syndrome, the nucleus tuberalis lateralis, tuberomammillary nucleus, and corpora mamillaria are seriously affected. The latter structure is also destroyed in ►boxer's dementia (punch drunk syndrome).

# Neuroendocrinology of Eating Disorders

Dick F. Swaab[1], Paul J. Lucassen[2]
[1]Netherlands Institute for Neuroscience, Meibergdreef, Amsterdam, The Netherlands
[2]SILS Centre for Neuroscience, University of Amsterdam, Amsterdam, The Netherlands

## Definition

The crucial role of the human hypothalamus in eating and metabolic disorders may, in the case of a disorder, lead to either increased or decreased body weight. An increasing number of such disorders and mechanisms are distinguished. In disorders of eating and metabolism, frequent hypothalamic co-morbidity occurs in terms of mood, sleep and rhythm disorders that are due to the intense hypothalamic interconnectivity and integrative mechanisms. Moreover, these symptoms often occur in an episodic way and generally have a differential prevalence between the sexes.

## Characteristics

Obesity is one of the most pressing health problems in the Western world; anorexia nervosa is a serious psychiatric disorder leading to death in some 10% of the cases. Although for anorexia nervosa the cause is as yet unknown, for many other eating and metabolic disorders, clinical studies have for a long time established a central role for the hypothalamus. In diencephalic syndrome or hypothalamo-optic pathway glioma, emaciation of the entire body is found in infancy and childhood. Lesions in the ventromedial hypothalamus cause increased appetite and obesity, whereas tumors in the lateral hypothalamic area (LHA) can cause anorexia. Seasonal fluctuations in the hypothalamus are the basis for the increases in eating behavior and body weight in fall/winter that reflects the expression of a basic evolutionary process, i.e. ensuring a maximum conservation of energy when food supplies become scarce. Although adaptive in evolution, the same process has become maladaptive in humans when highly palatable, high caloric foods are readily available in present Western society, which may lead for example to the seasonal weight gain in seasonal affective disorder. Narcolepsy is characterized by a tetrad of symptoms, excessive daytime sleepiness, cataplexy, hypnagogic hallucinations and sleep paralysis. There is a substantially (85–95%) reduced number of neurons producing hypocretins/ orexins in the lateral hypothalamus of narcoleptics with cataplexy. An autoimmune cause is considered but not proven.

### Genetic Factors

Human obesity certainly has an important inherited component. Yet the genetic factors responsible for obesity in the general population have remained elusive. As far as single gene mutations are concerned, mutations in the gene encoding for leptin or for the leptin receptor have been described in obese subjects. Another genetic defect leads to extreme childhood obesity, abnormal glucose homeostasis, hypogonadotropic hypogonadism, hypocortisolism and elevated plasma proinsulin and (pro-opiomelanocortin) POMC concentrations, but a very low insulin level. This disorder is based upon a mutation in the prohormone processing endopeptidase, prohormone convertase 1 (PC1). Severe early onset obesity, adrenal insufficiency and red hair pigmentation were found to be caused by POMC mutations. Mutations in the MC-4 receptor gene seem

to be the cause of monogenic human obesity in up to 4–6% of severely obese humans. A glucocorticoid receptor polymorphism is further associated with obesity and dysregulation of the HPA axis. The brain derived neurotrophic factor (BDNF) Met66 variant is strongly associated with all eating disorders, including bulimia [1]. Even though the inheritability of anorexia nervosa is estimated to be around 70%, it remains difficult to distinguish "psychogenic" and "organic" causes. Psychological disturbances without neurological manifestations may in some cases be due to occult intracranial tumors that can result among other things in anorexia nervosa.

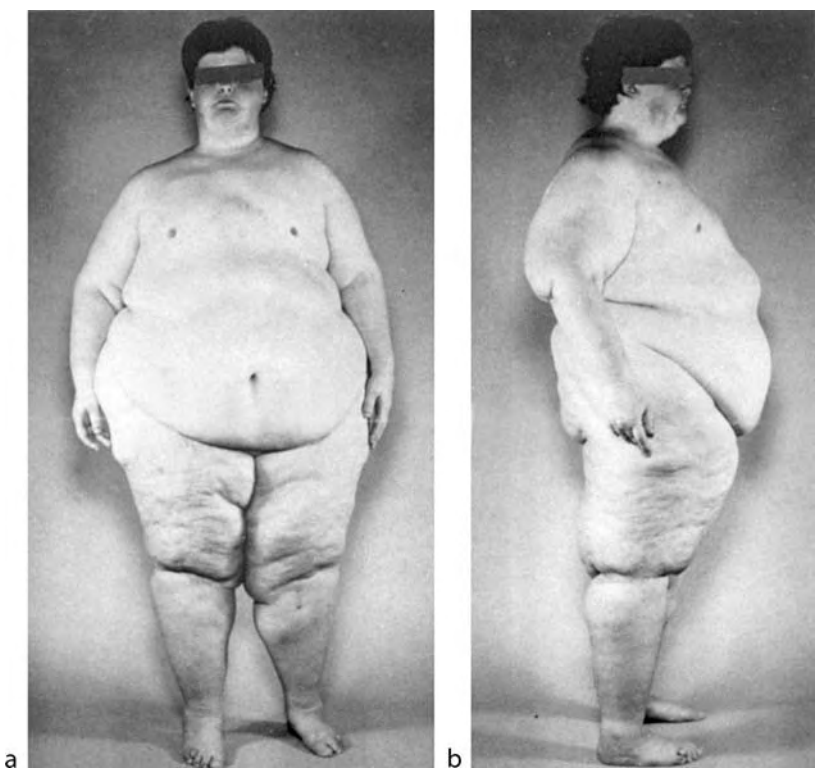
Prader-Willi syndrome (PWS), the most common syndromal form of human obesity, is characterized by grossly diminished fetal activity and hypotonia in infancy, mental retardation (mean IQ of 65) or learning disability and a number of hypothalamic symptoms, i.e. feeding problems in infancy that later develop into insatiable hunger and gross obesity (Fig. 1). The patients usually have a *de novo*, paternally derived, deletion of the chromosome region 15q11–13. Severe fetal hypotonia is often already noticed by the mother during pregnancy; the baby does not seem to move much. Apart from the baby's low level of activity, its position in the uterus at the onset of labor is often abnormal. Timing of the moment of birth is often also abnormal; many children with PWS are born either prematurely or too late. So far, research into the hypothalamus has revealed an intact Neuropeptide-Y (NPY)/Agouti-Related Protein (AGRP) and Growth Hormone Releasing Hormone (GHRH) system in PWS, which is inhibited in a normal way by obesity, but the number of oxytocin expressing neurons in the PVN is clearly diminished. Oxytocin is a satiety peptide and may thus be related to the eating disorder in this syndrome.

## Hormones

Cushing syndrome may result from exogenous administration of glucocorticoids or from ectopic ACTH production by a tumor often in the lungs or in the pituitary gland, a supra- or extra-sellar microadenoma. High levels of corticosteroids may lead to central or visceral obesity, hypertension and atypical depression. Metabolic syndrome includes the symptoms insulin resistance, abdominal or visceral obesity, elevated lipids and high blood pressure.

## Episodic Disorders

Many eating syndromes are closely related, include a number of hypothalamic symptoms and often have a recurrent nature. Bulimia nervosa for example is characterized by recurrent, often seasonal episodes



**Neuroendocrinology of Eating Disorders. Figure 1** Characteristic pattern of obesity in a patient with Prader–Willi syndrome. (From [2] Fig. 1 with permission.)

of binge eating and a depressed mood. There is also inappropriate compensatory behavior to prevent weight gain such as vomiting or excessive exercise. Light therapy not only improved mood but also the eating disorder in these patients, suggesting an involvement of the hypothalamic circadian timing system. Binge eating disorder differs from bulimia nervosa in that there is little or no behavior related to weight control, such as self-induced vomiting and laxative misuse. A characteristic of this disorder is a mutation in the MC4 receptor. The night eating syndrome is characterized by morning anorexia, evening hyperphagia and insomnia and occurs during periods of stress. In "nighttime eating syndrome" a disconnection is present between the circadian control of eating relative to sleep.

### Major Depressive Disorder

Major depressive disorder is not only characterized by a depressed mood but also by a significant weight loss or decrease or increase in appetite. Classically, the melancholic type of depression features anorexia or weight loss. Patients with bipolar disorder may have elevated rates of overweight, obesity and abdominal obesity. The typical patient with seasonal affective disorder (SAD) is a premenopausal woman with marked craving for high carbohydrate/high fat foods and significant weight gain during winter depression. These patients have a high prevalence of the seven repeat allele of the dopamine-4 receptor gene (DRD4). A strong argument for a close relationship between the pathogenetic mechanism of depression and the circadian timing system is the effectiveness of light therapy in patients suffering from SAD.

### Fetal programming

Fetal undernutrition has been well documented in a selected group of subjects in follow up studies on the effects of the Dutch Hunger Winter in Amsterdam, 1944–1945 during the German occupation. This condition, which may also occur in the case of placental insufficiency, leads to an adaptive reaction based upon the "fetal expectation" of the presence of a scarcity of food in the environment. This has long-term clinical consequences that are induced by programming effects on fetal hypothalamic function. It leads to an increased risk of obesity, hypertension, hyperphagia, hyperinsulinemia and hyperleptinemia in the offspring. In addition, the offspring have a reduced locomotor behavior and such children are at risk of depression and schizophrenia.

The physiological mechanisms involving the same hypothalamic systems that regulate eating and metabolism in the adult are also proposed to be involved in the fetus for the initiation of parturition. The decreased levels of fetal glucose, increased levels of cortisol and changes in leptin are presumed to activate NPY neurons in the fetal infundibular nucleus, activating the fetal hypothalamo-pituitary- adrenal (HPA) axis and thereby inducing a cascade that will lead to birth. Cortisol not only triggers an increased fetal hypothalamic CRH production, but also a rise in placental CRH. The observation that in anorexia nervosa patients an increased prevalence of obstetric problems is present around the period when they were born indicates that the glucose sensitivity of the hypothalamus of these children was possibly already abnormal at the moment of birth.

# Neuroendocrinology of Multiple Sclerosis

Inge Huitinga
Netherlands Institute for Neurosciences, Amsterdam, The Netherlands

## Definition

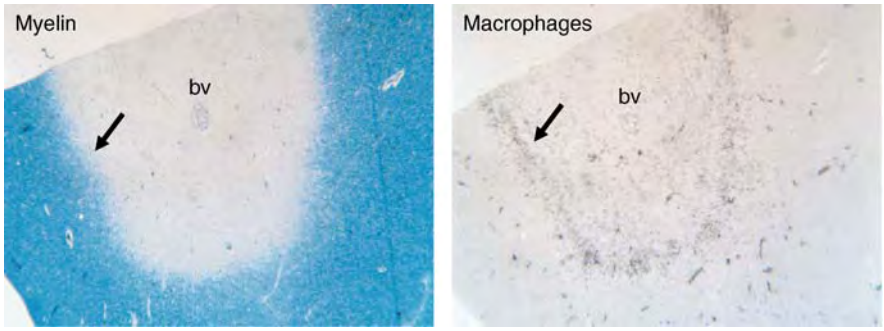
Multiple sclerosis (MS) is an inflammatory demyelinating disease of the central nervous system that causes severe motor impairment, sensory disturbances and cognitive and memory deficits [1].

## Characteristics

MS is the major paralyzing disease amongst young people in the Western World. The disease mostly starts at 25–35 years of age and two thirds of MS patients are female. World wide there are 2.5 million MS patients [1].

## Process

In MS, activated macrophages and microglial cells phagocytose myelin, resulting in demyelinated lesions (Fig. 1).



**Neuroendocrinology of Multiple Sclerosis. Figure 1** Macrophage mediated demyelination in a chronic active MS lesion.The *left* photograph is a Kluver staining in which myelin is *blue* and demyelination is *white*. The *right* picture is of the same chronic active MS lesion stained for human leukocyte antigen (HLA) DR-DP-DQ. This stains activated demyelinating macrophages *grey-brown* (magnification x 2.5). Note that MS lesions are in many cases surrounding a blood vessel (*bv*). The shelving edge of demyelinating macrophages (*arrow*) moves towards the myelinated area, leaving a gliotic hypocellular plaque behind. Magnification x 2.5. Tissue was obtained from the Netherlands Brain Bank.

Demyelination is confined to the central nervous system (CNS). In the absence of myelin, conduction in the axons is impaired, resulting in neurological deficits. Active demyelinating lesions turn into inactive hypocellular and sclerotic plaques. MS owes its name to the presence of multiple sclerotic plaques. In addition to demyelination, axonal damage also occurs frequently. Axonal damage is caused by the direct effects of inflammatory cells but the harsh environment of the demyelinated sclerotic areas is also thought to induce loss of naked axons. The cause of MS is unknown but involves both genetic and environmental factors. As the cause is unknown, therapeutic approaches are tentative. Most used therapies include anti-inflammatory drugs like synthetic glucocorticoids and immune modulating therapies like beta-interferon and glatimer. MS runs either a relapsing remitting course (RR-MS) or can be primary progressive (PP-MS). In the end stage of relapsing remitting MS, the clinical course often becomes secondary progressive (SP-MS) [1].

## Neuroendocrinology of MS

The neuroendocrinology of MS includes the functioning and effects of the hypothalamus-pituitary adrenal (HPA) axis, the hypothalamus-pituitary-gonadal (HPG) axis and the hypothalamus-pituitary-thyroid (HPT) axis in MS.

## Quantitative Description

There are several indications that the endocrine status contributes to the start and severity of MS. Sex hormones and glucocorticoids especially have been implicated in both susceptibility to and severity of MS. MS presents itself after adolescence when sex hormone levels rise. Also, pregnancy, especially the third trimester, protects from exacerbations of MS. The period shortly after delivery is highly prone to exacerbations and the first exacerbation of MS often occurs shortly after delivery. The premenstrual period also triggers relapses. In fact, 45% of all exacerbations seem to start in this period. Interestingly, estrogen levels are low just before menstruation, whereas levels comparable to those in the third trimester of pregnancy reduce the number and size of MS lesions as observed by MRI, suggesting a protective role for estrogens [2].

Psychological stress has been considered a contributing factor in MS exacerbation and accumulating evidence is summarized in a recent meta-analysis [3]. How exactly stress influences MS is not known but the stress response systems, the hypothalamus-pituitary-adrenal (HPA) axis and the autonomic nervous system are powerful modulators of immune responses. Indeed the synthetic glucocorticoid methylprednisolone is the major drug used to treat relapses of MS. Interestingly, the activity of the HPA system increases with age as the susceptibility and severity MS decreases [4].

## Regulation of the Process

### *The Hypothalamus-Pituitary-Adrenal (HPA) Axis in MS*

Pioneer experiments in the animal model for MS, ►experimental allergic encephalomyelitis (EAE), suggested that decreased activity of the HPA axis may play a role in increased susceptibility and severity of the disease [5]. Glucocorticoids are anti-inflammatory and at physiological concentrations shift antigen specific immune responses from a ►T helper 1 phenotype as is seen in MS, towards a ►T helper 2 phenotype. In turn, inflammatory mediators that are produced in MS lesions such as interleukin-1 (IL-1) activate the HPA axis at the level of the corticotrophin-releasing hormone (CRH) in the hypothalamus and induce a rise in plasma corticosterone levels, the main glucocorticoid in the rat [6]. Indeed, during a clinical episode of EAE, plasma

levels of glucocorticoids rise and this rise in corticosterone levels is crucial for recovery from the clinical episode. Rat strains that have a genetically determined low responsive HPA axis are prone to develop EAE. Recently it has been shown that during a chronic model of EAE a first episode of disease was accompanied by high plasma levels of corticosterone. However, during subsequent relapses, plasma glucocorticoid levels were significantly lower. Subsequent experiments showed reduced sensitivity of the HPA system to IL-1 during the course of chronic EAE. Importantly, compensation of plasma corticosterone levels as seen during the first relapse of EAE ameliorated the clinical signs of CR-EAE, indicating that inadequate HPA responses contribute to a more severe course of this chronic model of EAE.

Inspired by the neuroendocrine findings in the animal model for MS, several clinical studies aimed at revealing inadequate cortisol responses related to MS [5]. However, in contrast to the findings in EAE, the HPA system in MS is highly activated. There are indications that this chronic activation of the HPA system relates to both active inflammation in the CNS and neurodegeneration.

Postmortem studies show enlarged adrenals and increased cortisol in the cerebrospinal fluid (CSF) and increased numbers of corticotrophin releasing hormone (CRH) neurons in the hypothalamus, that drive the HPA axis. The increased numbers of CRH neurons concerned solely those CRH neurons that co-localized vasopressin, a sign of chronic activation of the system. Clinical studies showed normal or increased basal cortisol levels. The dexamethasone suppression test showed diminished or normal suppression of cortisol in MS. Activity and responsivity of the HPA system appeared to depend on the type of MS (i.e. PP-MS, RR-MS or SP-MS) and the lesion activity in the CNS. In RR-patients in relapse, it was found by using the ►combined dexamethasone-CRH (Dex-CRH) suppression test that cortisol was elevated. This hyper-responsiveness correlated with inflammatory activity in the brain, as assessed by white cell counts in the CSF and ►gadolinium enhancing ($GD^{\pm}$) lesions on MRI. Interestingly, in a group of both RR-MS and SP-MS patients who were not in relapse, hyper-responsivity in the Dex-CRH test showed no correlation with inflammatory markers in blood and CSF. A negative correlation between hyper-responsivity in the Dex-CRH test with numbers and volume of $GD^{+}$ lesions in this study may furthermore indicate that adequate cortisol responses in MS are needed to control MS lesions.

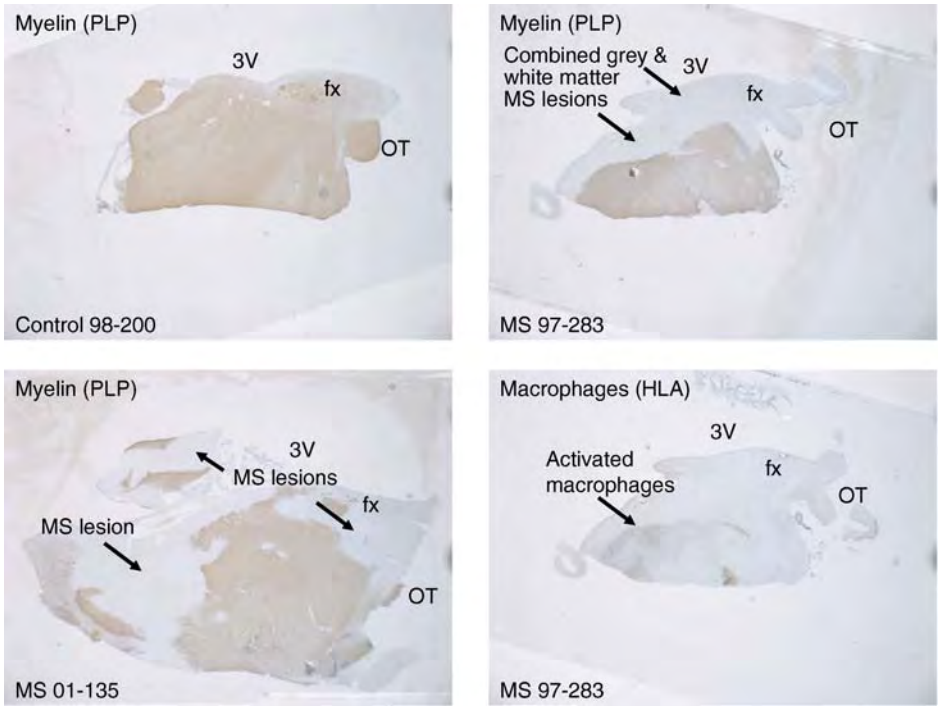
There are several indications that with progression of the disease and increased axonal damage and disability, the activity of the HPA axis also increases. There is a positive correlation between HPA activity in the Dex-CRH test and atrophy as assessed by MRI. Also, hyperactivity of the HPA system in the progressive stage of the disease (PP-MS and SP-MS) correlates with disability. Recently, in a first longitudinal study, Dex-CRH reactivity significantly predicted disease progression, which implies that the Dex-CRH test might be a prognostic tool.

MS pathology implies the possibility of the occurrence of inflammatory MS lesions within structures controlling the HPA system, i.e. the hippocampus and hypothalamus. Although memory deficits in MS are frequently reported, not much is known about the incidence of lesions in the hippocampus. However, the hypothalamus is prone to the development of MS lesions. Several cases of autonomic disturbances, i.e. temperature and sleep control have been reported in relation to hypothalamic lesions. Systematic post mortem pathological analysis of the hypothalamus in MS showed the occurrence of many MS lesions (Fig. 2).

Although the mean duration of the disease was 20 years in this study, the majority of the lesions in the hypothalamus contained actively demyelinating macrophages. Hypothalamic grey matter was also frequently demyelinated. Apparently the hypothalamus is prone to MS lesion formation. Interestingly, the more active the hypothalamic MS lesions, the less active the CRH neurons were found to be. Whether active MS lesions suppress CRH neurons or MS patients with a genetic predisposition for low CRH develop many MS lesions is currently not clear. The fact is that MS patients that have many MS lesions in the hypothalamus also have a low HPA activity and very severe MS. This favors the idea that low cortisol relates to uncontrolled inflammation and consequently to a severe course of MS.

In the presence of a hyperactive HPA system, the glucocorticoid sensitivity of the immune system is decreased in MS. IL-6 and TNF production by leukocytes is reduced in relapsing remitting MS patients, whereas in progressive MS this reduced sensitivity to glucocorticoids is less pronounced [5]. Mechanisms of glucocorticoid resistance of leukocytes in MS have not yet been elucidated.

In summary, in MS the HPA system is hyperactivated. There is a correlation between activation of the HPA system and inflammation only during a relapse, indicating that inflammatory mediators may activate the HPA system in MS. Hyperactivity of the HPA systems correlates with progressive stages of MS and atrophy and correlates with disease progression. There seems to be a subgroup of MS patients with severe MS and active MS lesions in the hypothalamus that have impaired activation of the HPA system. In particular, younger patients with RR-MS suffer from impaired restraint of inflammation by cortisol due to reduced glucocorticoid sensitivity.



**Neuroendocrinology of Multiple Sclerosis. Figure 2** Hypothalamic MS lesions. Immunohistochemical staining of proteolipid protein (PLP) shows myelin (*brown*) on one side of the hypothalamus of control subject NBB # 98–200 (*upper left*) and MS patients NBB #01–135 (*lower left*) and # 97–283 (*upper right*) and HLA DR-DP-DQ to identify activated macrophages in MS patient #97–283 (*lower right panel*). Note the presence of both grey and white matter lesions in the hypothalamus in MS (*arrows*). The lesion in MS #97–283 is active as indicated by the presence of many activated macrophages (*arrows*). *3V* = third ventricle, *fx* = fornix, *OT* = optic tract. Magnification x 1.8. Tissue was obtained from the Netherlands Brain Bank.

### The Hypothalamus-Pituitary-Gonadal System in MS

The functioning of the HPG axis is only sporadically investigated in MS. Sex hormones have major effects on immune cells and pregnancy related high levels of estrogens have been related to suppression of relapses during pregnancy, whereas prolactin has been proposed to be responsible for the strongly increased risk of developing relapses of MS after delivery. Increased levels of prolactin, follicle stimulating hormone (FSH) and luteinizing hormone (LH) have been reported in MS, as have decreased levels of estrogens [8]. In several studies, a relationship between altered hormone plasma levels and hypothalamic lesions was observed. Sexual dysfunctions commonly occur in both men and women with MS; some of these cases have been related to decreased sex hormone levels [2,9].

### The Hypothalamus-Pituitary-Thyroid System in MS

Like the HPG axis, there have been only a few studies addressing the functioning of the HPT axis in MS. Decreased levels of T3 have been reported in the presence of normal levels of T4 and TSH. Interferon-beta, one of the major drugs for treating MS has been demonstrated to increase the risk of hyperthyroidism slightly. The immune system is known to modulate the activity of the HPT axis at several levels, but much less is known about the effect of TSH, T3 and T4 on the immune system. Interestingly, thyroid hormones are crucial in brain development including myelination and therapeutic possibilities for thyroid-potentiated remyelination in MS have been suggested [10].

# Neuroendocrinology of Psychiatric Disorders

Ai-Min Bao[1], Paul J. Lucassen[2], Dick F. Swaab[1]
[1]Netherlands Institute for Neurosciences, Meibergdreef, Amsterdam, The Netherlands
[2]Swammerdam Institute of Life Sciences, Centre for Neuroscience, University of Amsterdam, Amsterdam, The Netherlands

## Definition

Hypothalamic and neuroendocrine alterations in some important psychiatric disorders diagnosed according to DSM-IV will be discussed.

## Characteristics

The hypothalamus plays an important role in emotional expression. Tumors, e.g. in the third ventricle region or in the area of the ventromedial hypothalamic nuclei (VMN) may cause overt psychiatric symptoms such as visual hallucinations, violent psychomotor agitation, personality changes and aggression. In addition, changes in hypothalamic nuclei and transmitter/receptor systems are present in different psychiatric disorders and may lead to endocrine alterations that can contribute to the signs and symptoms of these disorders [1].

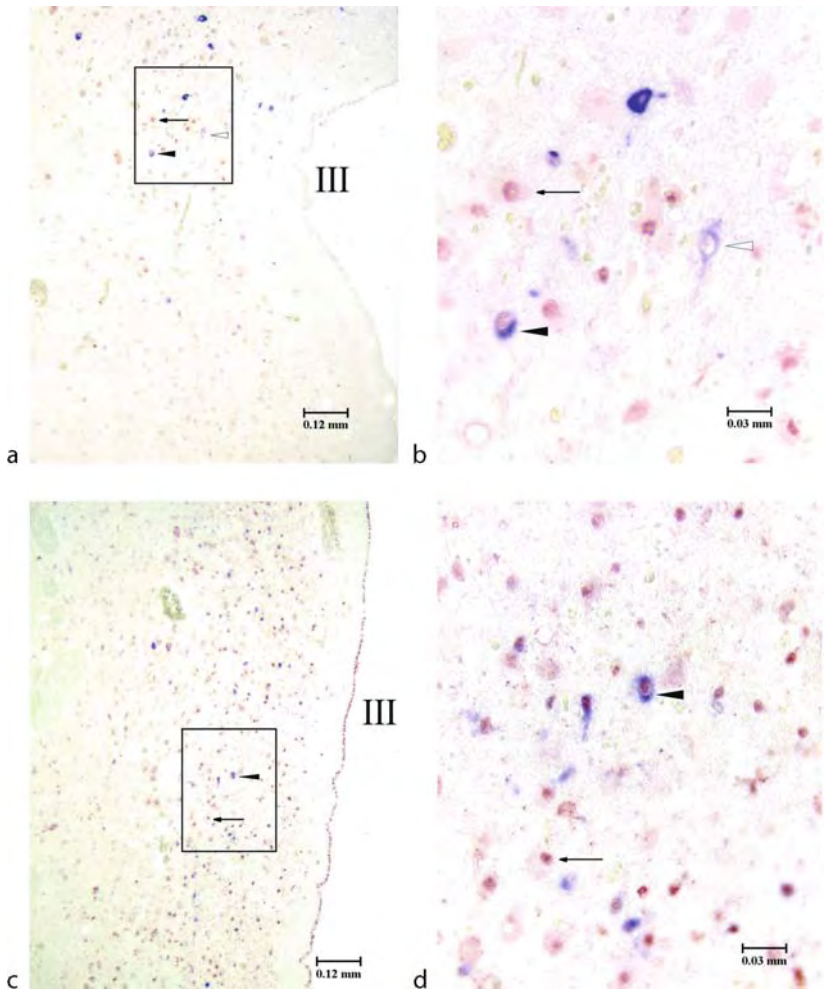
### Depression and Mania

Depression is thought to result from an interaction between environmental stressors and genetic/developmental predispositions that cause a permanent activation of the CRH neurons of the ►HPA axis [2]. The CRH neurons project to the median eminence and co-express vasopressin (AVP) that potentiates the effects of CRH. In addition, the CRH neurons project into the brain. Both centrally released CRH as well as the elevated cortisol levels contribute to the signs and symptoms of depression (see Lucassen and Swaab, HPA-axis). The AVP neurons in the hypothalamic paraventricular nucleus (PVN) and supraoptic nucleus (SON) that project to the neurohypophysis are also activated in depression, which may contribute to the increased release of ACTH from the pituitary. Increased levels of circulating AVP are associated with an increased risk of suicide. The increased activity of oxytocin (OXT) neurons has been implicated in the eating disorder in depression, since OXT acts as a satiety peptide. Moreover, opioid peptides inhibit the HPA-axis, while fewer $\beta$-endorphin containing neurons are found in the infundibular nucleus and lower numbers of $\beta$-endorphin innervated neurons are present in the PVN of depressed patients. Despite a normal ►body mass index (BMI), lower levels of leptin are found, which may also relate to the changes in appetite, food intake and weight in depressed patients.

In depression nitric oxide synthase containing neurons are found to be reduced in the PVN, but not the SON, which may be related to the increased neuropeptide production of CRH, OXT and AVP in the PVN. ►The hypothalamo-pituitary-thyroid axis also shows a decrease in thyrotropin releasing hormone mRNA in the PVN [3] parallel to alterations in basal thyrotropin (TSH) and thyroxin levels. Consistently with this, thyroid hormone supplements increase the efficacy of antidepressant drugs. Depressed patients showed decreased cerebral spinal fluid (CSF) levels of ►somatostatin in a state related way, while in suicide attempters somatostatin levels are significantly increased.

There is a clear sex difference in depression; the prevalence, incidence and morbidity risk is higher in females than in males, which may be due to both organizing and activating effects of sex hormones on the HPA axis besides social factors. Fluctuations in sex hormone levels, e.g. in the premenstrual period, ante- and post-partum, during the transition phase to the menopause and from the use of oral contraceptives are also involved in the etiology of depression. In mood disorders, the activation of neurons expressing CRH in the PVN is accompanied by increased estrogen receptor (ER$\alpha$) colocalization in the nucleus of these neurons (Figs. 1 and 2) [4].

Estrogen responsive elements are found in the CRH ►gene promoter region and can stimulate CRH expression. Activation of androgen responsive elements in this region, however, initiates a CRH suppressing effect.

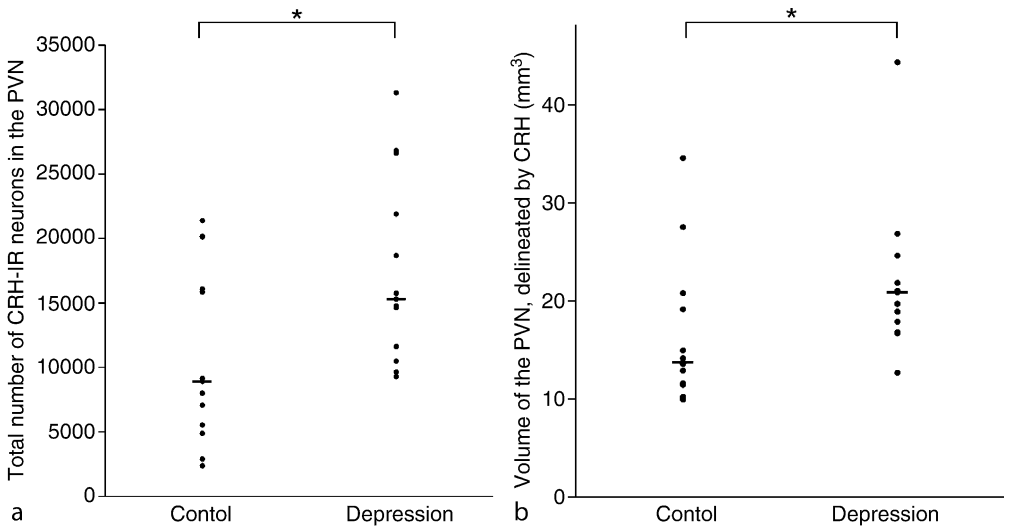


**Neuroendocrinology of Psychiatric Disorders. Figure 1** Frontal section of the PVN in a control subject (a, b) and a patient with mood disorder (c, d) stained for CRH (*blue*) and ERα (*red*). b and d represent a 4 x higher magnification of a and c The *arrows, solid and hollow arrowheads* in (a, b) and (c, d) indicate the same place in the preparation to facilitate comparison. Both sections show the central part (mid-level) of the PVN and contain the largest number of stained neurons. It is clear by comparing (a) with (c) and (b) with (d) that the number of stained neurons is markedly increased in the patient with mood disorder. *III:* the third ventricle. The *arrow* points to an ERα nuclear single staining cell; the *solid arrowhead* points to a cytoplasmic CRH-ERα nuclear double staining cell and the *hollow arrowhead* points to a CRH single staining cell.

A decreased activity of the suprachiasmatic nucleus (SCN), the ►hypothalamic clock, is the basis for disturbances of circadian and circannual fluctuations in mood, sleep and other rhythms found in depression [5]. Light therapy for depression activates the SCN, while melatonin improves both sleep and mood.

It should be noted that the interactions between the peptidergic and aminergic networks such as serotonin (5-hydroxytryptamine or 5-HT), noradrenalin, histamine and dopamine contribute to the endocrine changes in depression.

Mixed manic patients, i.e. patients who have both manic and depressive symptoms, have higher HPA axis activity than pure manics. Afternoon plasma cortisol and CSF cortisol levels correlate significantly with a depressed mood, while urinary free cortisol correlates with anxiety indices. Patients with a first episode mania demonstrate significantly larger third ventricular volumes, indicating large hypothalamic changes. In addition, manic patients show hypersecretion of AVP and its ►neurophysin both in CSF and in plasma. Seasonal fluctuations in admissions to psychiatric wards are obvious in mania. Manic-depressive patients generally showed lower levels of melatonin, which again implies the involvement of the circadian and seasonal timing systems.



**Neuroendocrinology of Psychiatric Disorders. Figure 2** Graph depicting total numbers of CRH-IR neurons in the PVN (a) and the volume of the PVN as delineated by the presence of CRH neurons (b) of control subjects (n = 13) and patients with mood disorders (n = 13). Note that the total number of CRH neurons and the PVN volume in the patients with mood disorders were significantly larger than in controls (a: z = −2.128, p = 0.034; b: z = −2.282, p = 0.022). *Horizontal line* indicates the median value.

## Anxiety Disorders

Females show a two-fold increased risk for panic disorder as compared to males. Moreover, higher rates have been found in thyroid disease patients. Panic disorder is characterized by hypercortisolemia and increased nocturnal melatonin levels. A hyporesponsive hypothalamic growth hormone system is indicated by blunted growth hormone responses to specific chemical challenges. Patients with a generalized social phobia show significantly higher cortisol response to psychological stressors, although no peripheral HPA axis pathological change has been found, suggesting no basal alterations are present.

Higher rates of ►obsessive compulsive disorder have been found in thyroid disease patients. CSF CRH and somatostatin levels are significantly elevated and the increased secretions of AVP and CRH presumably contribute to persistent behavior. However, it should be noticed that there is no clear relationship between CSF CRH levels and symptom severity.

## Posttraumatic Stress Disorder

The clinical symptomatology of post-traumatic stress disorder (PTSD) involves flashbacks, nightmares, sleep problems, emotional numbness or emotional outbursts, anhedonia, inappropriate startle reflexes and problems with memory and concentration. Deficits in short-term verbal memory have been associated with a smaller right side hippocampal volume in these patients. Victims of childhood abuse also have a smaller left side hippocampus. Smaller ►hippocampi may be a risk factor for PTSD rather than the result of this disorder. It is unlikely that hypercortisolism is responsible for the hippocampal atrophy, since PTSD is associated with decreased HPA axis activity and glucocorticoid supersensitivity rather than feedback resistance [6]. Victims of rape or motor vehicle accidents who later developed PTSD appeared to have – by a few hours after the traumatic event – lower cortisol levels than victims who do not subsequently develop a psychiatric disorder or major depression. Pituitary and adrenal hyperactivity to exogenous CRH and ACTH has been demonstrated in these patients. An increased sensitivity or up-regulation of glucocorticoid receptors in PTSD, lowered basal cortisol levels accompanied by an increased sympathetic drive and a pre-existing smaller hippocampal volume thus seems at present the best explanation for all the data.

## Aggressive Behavior

Aggression is determined by genetic factors such as ►polymorphisms of enzymes involved in the production and degradation of neurotransmitters, hormones in development and adulthood and specific lesions in the hypothalamus and other brain areas.

Neoplastic or surgical destruction of the VMN may cause the ventromedial hypothalamus syndrome that is characterized by a tetrad of symptoms including episodic rage, emotional liability, hyperphagia with obesity and intellectual deterioration. High rates of aggression are also found in children with ►gelastic seizures due to hypothalamic ►hamartomas or following exposure to androgen based synthetic progestins during gestation. Children and adolescents with

conduct disorder are found to have low HPA axis activity correlated with severe and persistent aggression. Adrenal androgen functioning as measured by dehydroepiandrosterone (DHEAS) levels is elevated in patients with conduct disorder. Men are much more aggressive than women, mainly due to the difference in testosterone levels *in utero* and in adulthood. Individuals whose life histories involve numerous antisocial behaviors and personality disorder criminals with multiple offences tend to have higher testosterone levels. Women with bulimia nervosa have increased plasma testosterone levels that correlate with aggression. The use of anabolic androgenic steroids may also lead to aggressive reactions and accompany antisocial personality traits.

The SCN may be involved in rhythmic occurrence of aggressive behavior. Excessive ►cholinergic stimulation can promote serious aggression in man. Central AVP also plays a facilitative role in aggressive behavior.

## Schizophrenia

The hypothalamus is atrophied in schizophrenia. Third ventricle enlargement is significantly associated with the persistence of auditory hallucinations and poor response to treatment. The symptoms of schizophrenia can be induced by a tumor in the hypothalamic region [1], which also suggests possible involvement of the hypothalamus in this disease.

Water intoxication, ►polydipsia and ►hyponatremia are serious symptoms of chronic schizophrenia. However, no indication of a corresponding hyperactivity of AVP neurons could be found in schizophrenic patients [7]. ►Hypothalamo-pituitary-gonadal axis abnormalities may also be involved, as evidenced by an irregular menstrual cycle, loss of hair, mid-cycle bleeding and hirsutism. The typical onset of schizophrenia is found during late adolescence and early adulthood when increased levels of sex hormones reach the brain. In women, there is an additional small peak in incidence around the age of 45 when estrogen levels drop. Estrogens may protect against schizophrenia although this is not consistent with the increased incidence of schizophrenia around puberty. Alternatively, androgens may be considered as a risk factor. Abnormal growth hormone responses to TSH and ►luteinizing hormone releasing hormone are present in adolescents but not in adults. There is a high prevalence of thyroid function abnormalities in chronic schizophrenia. In spite of the fact that 36% of schizophrenic patients fulfilled the criteria for major depression, the ►dexamethasone suppression rates were very low, suggesting that depression in schizophrenia may have a different neuroendocrine profile from that in major depressive disorder. A decreased response of the HPA axis to psychological stress or to the stress of lumbar puncture has been found in schizophrenic patients. Reduced numbers of nitric oxide synthase containing neurons in the PVN have also been reported, while plasma leptin levels are decreased in patients with normal BMI.

SCN disorder seems to be present in a subgroup of schizophrenic patients, since circadian rhythm disturbances occur in chronic cases. In addition, in drug free paranoid schizophrenic patients, plasma melatonin circadian rhythm is completely absent, whereas the 24 h profile of plasma cortisol is preserved. A smaller pineal gland has been observed, while high dose melatonin treatment may exacerbate psychosis, both implying a possible relationship between the pineal gland and schizophrenia. The CSF hypocretin levels correlate significantly and positively with sleep latency, which is obviously increased in schizophrenia. ►Hypocretin is produced in the perifornical area of the lateral hypothalamus and involved in ►narcolepsy. The concentrations of α- and γ-►endorphins are elevated, whereas the number of β-endorphin containing neurons in the PVN and the innervation of PVN neurons by β-endorphin containing fibers are reduced in schizophrenic patients. Intravenous injection of β-endorphin resulted in statistically significant but not clinically apparent reduction of symptoms. Increased levels of norepinephrine were found in ►the bed nucleus of the stria terminalis, ventral septum and ►mammillary body in postmortem tissues of patients. The hypothalamic tuberomammillary nucleus (TMN) is proposed to be involved in the pathogenesis of schizophrenia, although both favorable effects of histamine injections, indicating decreased activity of the histaminergic system and elevated CSF histamine metabolite levels, indicating increased activity of the TMN, have been observed in schizophrenia.

## Autism

Autism is a developmental disorder characterized by stereotypical repetitive behaviors and disturbed social interactions and communications. The prevalence is four times higher in boys than in girls. AVP and OXT are involved in socialization skills. Male autistic children have lower plasma OXT levels and there is some evidence that OXT infusions significantly reduce repetitive behaviors. A deficiency in AVP was also reported in this disorder. An association of the OXT receptor gene and the AVP receptor-1$\alpha$ gene with autism has recently been described. Some data indicate further HPA axis dysfunction, e.g. abnormal diurnal cortisol rhythm and changes in the ►dexamethasone suppression test. In addition, lower basal levels of TSH, a diminished response of TSH to TRH and abnormalities in dopaminergic and noradrenergic neurotransmission have been found. Increased cell packing density, reduced neuron size and swollen axon terminals (spheroids) are present in different hypothalamic nuclei,

suggesting a defect in axonal transport or synaptic transmission.

### Chronic Fatigue Syndrome

Noradrenaline, 5-HT and CRH are presumed to be involved in the mechanism of central fatigue. The hypothalamus shows a significant perfusion reduction. HPA axis function is unaffected or reduced, although depression is ubiquitous in this syndrome. Some patients have excessive thirst with a low plasma level of baseline AVP. Lower morning and higher evening cortisol levels further suggest a deficient SCN function.

### Fibromyalgic Syndrome

Abnormal function of the HPA-axis has been reported in this disorder. Both the histaminergic TMN system and the SCN have been hypothesized to participate in the daytime somnolence characteristic of fibromyaliga. Some patients show impaired hypothalamic somatotropic reactivity. The nociceptive neurotransmitter substance P is elevated in the CSF. Both growth hormone replacement and DHEAS replacement show beneficial effects.

### Postviral Fatigue Syndrome

Most patients with this syndrome have a hypothalamic dysfunction, including changes in body weight and appetite, minor fluctuations in body temperature, excessive sweating, a reversed pattern of sleep or rather excessive sleep, an impaired libido, menstrual irregularities, depression and sometimes fluid retention. Secretion of AVP may be erratic. In addition, an increased sensitivity of hypothalamic 5-HT receptors has been reported (for more detailed references see [1]).

# Neuroendocrinology of Tumors

Dick F. Swaab[1], Paul J. Lucassen[2]
[1]Netherlands Institute for Neuroscience, Meibergdreef, Amsterdam, The Netherlands
[2]SILS Centre for Neuroscience, University of Amsterdam, Amsterdam, The Netherlands

## Definition

Primary tumors and metastases when located in, or in the vicinity of the hypothalamus can, depending on their size, location and age induce a wide range of nonspecific symptoms including brain edema, nausea, headaches, vomiting, aphasia, papilledema and even seizures. They can further induce specific autonomic and/or endocrine disturbances that are characteristic for this brain structure.

## Characteristics

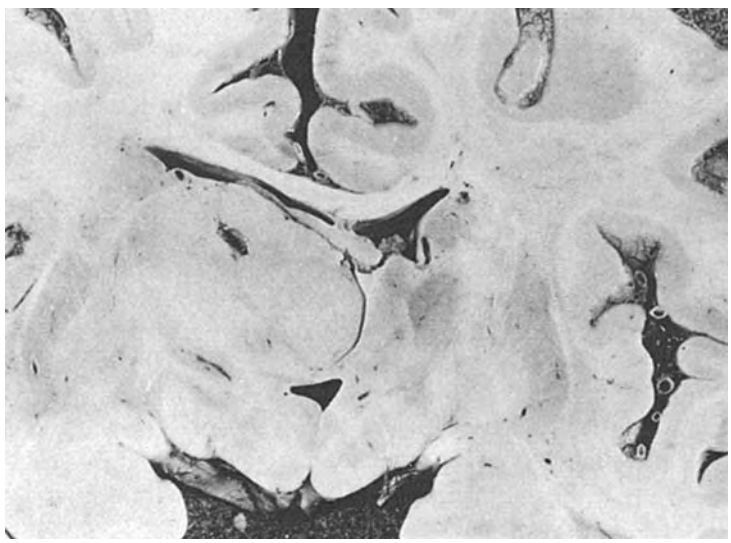
Tumor related symptoms characteristic for the hypothalamus are hyperphagia, obesity, amnesia, diabetes insipidus, dysthermia, circadian rhythm alterations, cachexia, hypogonadism, changes in sexual behavior and precocious puberty. Some of the typical hypothalamic symptoms are in fact nonspecific symptoms of tumors elsewhere. For instance, plasma and cerebrospinal fluid (CSF) levels of vasopressin are increased in those types of brain tumors that are accompanied by brain edema.

Tumors themselves, but also damage inflicted by brain tumor surgery, may affect overall hypothalamic function or induce specific hypothalamic symptoms such as diabetes insipidus (due to destruction of the supraoptic and paraventricular nucleus, SON, PVN), absence of thirst (characteristic of a lesion of the anterior hypothalamus destroying osmoreceptors), hyperphagia (based upon lesion of the PVN or ventromedial nucleus, VMH), diabetes mellitus resulting from hyperphagia, an impairment of temperature regulation (following damage to for example, the preoptic area), or an abnormality of sleep pattern and a reversal of the diurnal-nocturnal sleep rhythms, probably due to a lesion of the suprachiasmatic nucleus. Other

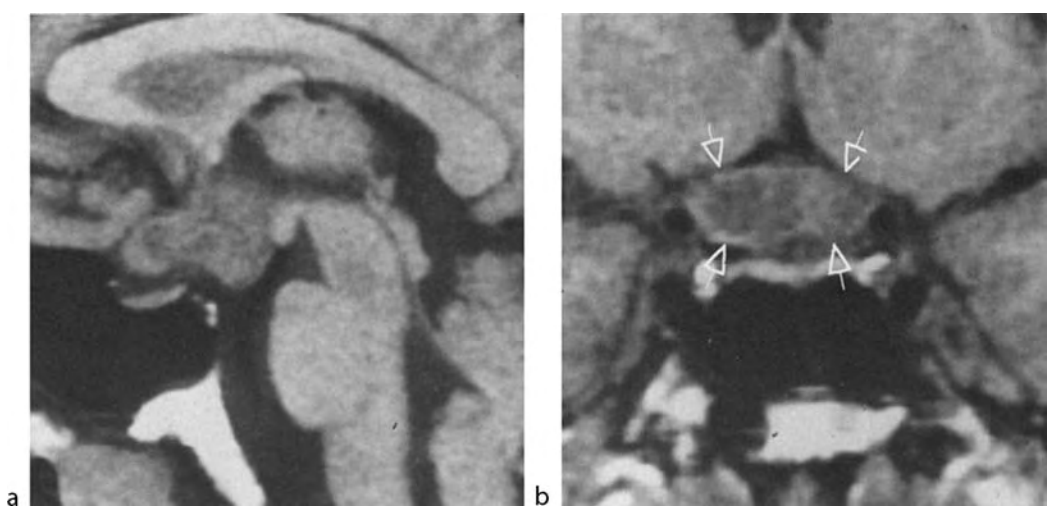
symptoms may be present depending on the size of the tumor and its location.

Tumors that affect the posterior region of the hypothalamus, in particular the corpora mammillaria or the pineal region may cause precocious puberty. Tumors of the tuberal and preoptic region of the hypothalamus are often found in hypogonadism. Following a hypothalamic glioma, a patient's sexual orientation has been reported to change from heterosexual to pedophile with impotence (Fig. 1).

Other symptoms of hypothalamic tumors are hyperphagia and obesity, subcutaneous fat depletion, cachexia, autonomic seizures, paroxysm of hypertension, tachycardia and sweating (in diencephalic syndrome) and fits of rage (ventromedial hypothalamus syndrome), amnesia and attacks of laughter or crying (in the case of hamartomas). When tumors cause ventricular obstruction with a rise in intracranial pressure and/or hydrocephalus, a loss of circadian temperature fluctuations and changes in posture and walking pattern or incontinence may occur. Hypothalamic lesions due to craniopharyngioma (Fig. 2) or pilocytic astrocytoma may be accompanied by decreased nocturnal melatonin levels and increased daytime sleepiness.



**Neuroendocrinology of Tumors. Figure 1** An infiltrating hypothalamic glioma in a patient with a change in sexual orientation from heterosexuality to pedophilia. (From [1] Fig. 3 with permission.)



**Neuroendocrinology of Tumors. Figure 2** Intrachiasmal craniopharyngioma. Sagittal (a) and coronal (b) T1-weighted MR scans. The tumor has a slightly heterogeneous appearance and has caused marked expansion of the chiasm (*arrows*). (From [2] fig. 20 with permission.)

Other hypothalamic symptoms frequently found in cases with tumors are retarded growth, amenorrhea, panhypopituitarism, dysthermia, bulimia, hydrocephalus, prolonged fever and hyponatremia. Tumors in the region of the optic pathway or infundibulum may cause optic atrophy, visual deficits, visual field defects or visual hallucinations.

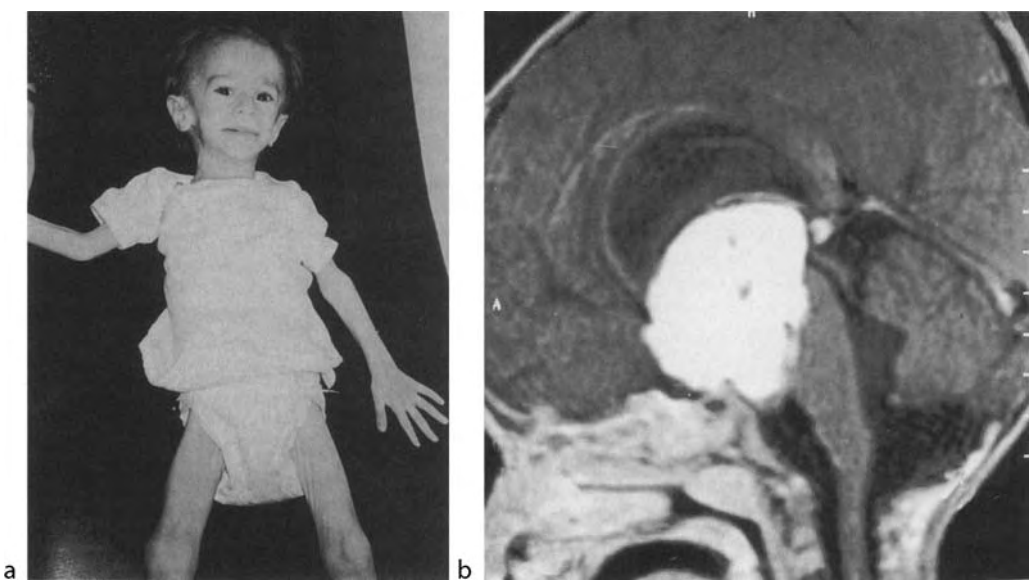
Cognitive and psychiatric symptoms are also observed in the case of hypothalamic disorders. Examples are a psychosis and misdiagnosis of schizophrenia, hypersexual behavior, manic excitement, confusional syndromes and hallucinations. Patients with tumors of the region of the third ventricle may exhibit the symptoms of Korsakoff's syndrome i.e. some impoverishment of intellect, changes of personality (usually euphoria or apathy), disorientation, confabulations and memory impairment (for example in the case of tumors that cause bilateral destruction of the fornix). The memory defects caused by hypothalamic tumors may concern both imprinting and retrieval. Akinetic mutism was observed following surgical removal of an epidermoid cyst from the anterior hypothalamus, by a procedure that had probably destroyed the median forebrain bundles that contain the dopaminergic projections. Selective destruction of the hypocretin/orexin system by a tumor in the lateral hypothalamus may cause symptomatic cataplexy.

Hormone production by the tumor itself has also been described. In men, germinomas of the pineal region may cause precocious puberty because these tumors may secrete chorionic gonadotropins (HCG) that stimulate the secretion of testosterone. Hypothalamic neuronal hamartomas are rare malformations that may arise from the mammillary bodies or the tuber cinereum and that occur at the ventral aspect of the posterior hypothalamus. Some of them contain corticotropin releasing hormone (CRH), LHRH, metenkephalin or growth hormone releasing hormone containing neurons. Gelastic seizures, characterized by attacks of laughter, have been noted in 48% of the hamartomas. In addition, visual disturbances, precocious puberty, a great number of psychiatric disorders and cognitive deficits, acromegaly, diabetes insipidus or other endocrinopathies have been reported. Precocious puberty is found in over 74% of the cases and usually small, autonomous LHRH-producing pedunculated hamartomas are present.

Diencephalic syndrome is caused by a hypothalamo-optic glioma or optic pathway glioma (Fig. 3).

This low grade astrocytoma accounts for 5% of all brain tumors. The main clinical features of the diencephalic syndrome include a failure to thrive, extreme cachexia with normal height, hyperkinesis, alert appearance, vomiting, surprisingly happy affect or euphoria, pallor without anemia, hypothermia, excessive sweating, nystagmus and decreased visual acuity. The age of onset ranges from the newborn period to four years.

A low-grade developmental neoplasm, craniopharyngioma, is thought to be derived from Rathke's



**Neuroendocrinology of Tumors. Figure 3** (a) Diencephalic syndrome. Note the severe emaciation of the whole body and the characteristic "pseudohydrocephalic" appearance. (b) MRI of the brain. T1-weighted sagittal images (repetition time/echo time: 570/15) after gadolinium enhancement demonstrate the presence of a large tumor involving the hypothalamic region, distorting the chiasm and brainstem and extending into the third ventricle. Neuropathologically, the tumor proved to be a hypothalamic astrocytoma with pilomyxoid features. (From [3] figs. A, B, with permission.)

pouch, the pituitary anlage and can arise anywhere along the craniopharyngeal canal. This canal is usually obliterated during the 12th week of gestation. In the majority of cases, the craniopharyngioma does not remain confined to the sella and hypopituitarism often ensues. This frequently extends into the third ventricle and stretches the optic chiasm (Fig. 2). The signs and symptoms of a craniopharyngioma are characteristic and the most prominent ones include headache, nausea and vomiting, a failure to grow, increased intracranial pressure and visual loss, depending on the size of the tumor and its location, as well as the age of the patient. Endocrine complaints are infrequently presented, but some typical hypothalamic symptoms may include diabetes insipidus, inappropriate antidiuretic hormone secretion, hyperprolactinemia, deficiencies of LH, FSH, ACTH, TSH or cortisol, panhypopituitarism and hypogonadism.

Brain metastases are common in patients whose systemic cancer is quiescent. Diabetes insipidus due to a tumor in the infundibulum or neurohypophysis is the usual clinical manifestation, especially seen in the terminal stages. Since the posterior lobe and not the anterior lobe of the pituitary is directly supplied by arterial blood from the systemic circulation, the predilection for metastasis in this structure is understandable. The most common sources of metastatic tumors in the pituitary-hypothalamic region are carcinomas of the lungs or breasts and leukemia/lymphoma. Metastatic carcinomas originating from the gastrointestinal tract have also been described.

In the chiasmal and sellar region, approximately 10% of the neoplasms are meningiomas. They may originate from the superior leaf of the diaphragma sellae anterior or posterior of the pituitary stalk or from the inferior leaf of the diaphragma sellae.

A large adenoma of the pituitary may exert upward pressure on the front of the chiasm or between the optic nerves. The first symptom is usually bitemporal hemianoptia and there is optic atrophy. Less often the tumor may impinge on the back of the chiasma. Physical pressure exerted on or in the hypothalamus may lead to fatigue and sleepiness, excessive eating or anorexia, hypothermia, diabetes insipidus, hydrocephalus and hypopituitarism. The patient may also "feel cold" due to subsequent hypothyroidism, may perform less well in daily life activities and suffer from headaches.

Freje Universität, Berlin, Germany

## Definition

Neuroethics is a field of research concerned with normative and *metaethical* (►Metaethics) problems posed by increasing knowledge of the central nervous system and especially the brain. As the term is not yet established in moral philosophy and neuroscience, other definitions highlight only specific aspects of the field, the *ethical* (►Ethics) implications of treatments for neurological diseases, *moral* principles and rules guiding neuroscience itself or the consequences of neuroscience for the understanding of moral reasoning and moral behavior. Most contributions however, cover a broader range of topics [1–3] for which a more comprehensive definition is appropriate.

## Description of the Theory

Research on the brain is research concerning the mind. It is closely connected to the way mankind sees itself as sentient and sapient beings. It also seems to offer new

possibilities of reading and controlling mental states and manipulating character traits. Most prominent among the scientific advances in the field are functional neuroimaging, insights into the neurochemistry of thought and a better understanding of the molecular mechanisms of neurotransmitting [4]. For an ethical evaluation it is crucial to weight chances and risks, gains and losses in a principled and nonarbitrary way, aiming at ►norms that are rationally justified for everyone concerned. Normative and metaethical problems associated with new knowledge of the brain can be differentiated as follows:

1. Consequences for ►individual *well-being* and ►*personal autonomy*
2. Consequences for ►*justice*
3. Consequences for the ►*common good* and for objective ►values
4. Consequences for the idea of ►moral agency

### Individual Well-being and Personal Autonomy

A central purpose of ►morality is the protection and promotion of fundamental interests that can be subsumed under the terms "individual well-being" and "personal autonomy." Both individual well-being and personal autonomy may be seriously impaired by diseases connected with the central nervous system. Neuroscience can help to identify, cure and prevent shortfalls from normal functioning that cause suffering and reduce the range of individual opportunities. As in bioethics more generally, moral restrictions are justified for the sake of sentient beings – human beings as well as animals – potentially or actually used in research and medical testing. Morality does also matter in the evaluation of serious side effects. It seems reasonable that a significant chance to cure a disease justifies a higher level of risks than a prospect of enhancements beyond the level of normal functioning [4]. This is especially important with respect to young children and other individuals who cannot take responsible decisions by themselves.

Specific problems concerning neuroscience arise whenever interventions in the brain cause personality disorders (e.g. temporarily occurring "religious" experiences induced by magnetic stimulation). Generally speaking, interventions in the brain may affect character traits that are central for an individual's qualitative identity. Forcing a mature person to use pharmacology in order to change her thoughts, feelings or behavior is a clear violation of her autonomy. Taken to the extreme, the subject of the decisions and actions would become blurred and therefore the attribution of autonomy would lose its target.

Autonomy is also diminished if someone voluntarily decides to use mind-enhancing drugs or implants but lacks appropriate information in the light of which he or she would have decided otherwise. Neuroscience might encourage a climate of hope that in turn might make unenlightened decisions more likely. There is some evidence supported by evolution theory that a normally healthy human brain is almost perfect, optimized for purposes of human problem solving. As a consequence, a mentally healthy person might buy a gain in one dimension, e.g. memory, at the price of losses in another dimension, e.g. generalizing [5].

Apart from this assumption, we can ask whether enhancements of brain functions, as distinguished from mere remediation of diseases, would really contribute to individual well-being [6]. Enhancements might consist in the avoidance of challenges that would confront a person with important insights and/or would offer him or her worthwhile opportunities for agency. It is implausible to reduce well-being to pleasant feelings and success without effort. Maybe a lot of problems and even painful feelings are a price that has to be paid for leading full lives as responsible agents.

The more there can be reasonable disagreement on these matters the more important autonomy proves to be. This does also affect duties towards non-autonomous individuals. Persons taking decisions in the name of others should refrain from enhancements, at least from irreversible ones, for which a hypothetical agreement of the persons affected is disputable. Parents projecting and technically imposing their own particular values onto their children neglect the fact that everyone has to lead his or her own life and therefore has a right to an open future [7]. On the other hand, respecting personal autonomy includes respecting decisions made by mature individuals to use mind-enhancing drugs or technologies as long as the enhancement does not result in harming others, violating valid principles of justice or the like. Enhancements as such are a normal objective of human strivings, as the widespread use of caffeine, viagra, and cosmetic surgery shows. It is far from clear whether continuing to do so on a molecular or genetic level would confront mankind with totally new problems.

Functional neuroimaging is another source of threats to autonomy. Although literally reading another person's thoughts is now and for the foreseeable future sheer science fiction, neuroscientists are successful in correlating some psychological states and traits like neuroticism, racial prejudices and intentional deception with distinct patterns of brain activity [8]. This might encourage the use of neuroimaging for the purpose of lie detection, especially in societies obsessed by security issues. Even if neuroimaging cannot really decipher propositional states, its use against the will or without the informed consent of the patient would violate the right to privacy in an especially intimate domain, the privacy of what goes on in the mind.

### Justice

The availability of mind-enhancing drugs and techniques as well as neuroimaging can also become a source of discrimination. In order to reduce their risks, insurance companies and employers might expect persons to undergo examinations and pharmacological treatment of the brain. This could lead to different classes of people with the willing on the one hand and the unwilling on the other. Results of those tests could also be used to stigmatize still healthy persons and to look at them as if they were already ill or handicapped. Discrimination of this sort is incompatible with a fundamental principle of justice in modern societies, to treat everybody with equal respect and concern [9]. As far as enhancements are possible, e.g. improving the working memory of older people, they might be expensive and therefore not accessible to all. Without equal access to the new advantages however, equality of opportunity would decline. Preventing some (categories of) people from taking unfair advantage is a well known requirement of justice that is already in tension with respecting the autonomy of parents e.g. in choosing schools for their children. Again, not all that looks new at first sight is new in principle.

### The Common Good and Objective Values

Harmful testings, bad side effects, forced interventions, violations of privacy, discrimination and unfairness do not sufficiently explain why many people are disturbed about the new developments in genetics as well as in neuroscience. A fear in the background might be that a society in which those techniques and opportunities would be available and used on a large scale would in important respects be a dehumanizing society. For example, such a society might leave less room for human excellence. There might no longer be reasons to admire other people, e.g. professionals in sports or brilliant thinkers, for what they perform using their natural endowments. Another worry might be that the social relations in such a world would be dominated by reciprocal blaming in domains that are at present up to nature: "Why didn't you enhanced my affiliative behavior and my higher cognitive functions when I was in school?" Taken to the extreme, it might no longer be possible to identify what really belongs to a person and the sense of personal responsibility might become pointless. An even more familiar, yet more dubious ►reason might be that many people take "the natural" to be objectively valuable, independent of its contributions to well-being or goal-attainment. Nature, it seems to them, is a necessary counterpart to human hubris; it is the epitome of what man still cannot and never shall master [10].

Images of a good society and objective values have in common that they do not directly relate to goods that can be possessed by individuals as such. Some goods are essentially shared, e.g. a climate of tolerance and creativity in the public sphere. Other goods might even be totally independent of any interests. They might be good as such, as for many nature seems to be. Such evaluations, however widespread they may be, are much more controversial and even unclear in status, than those concerning fundamental interests and justice. The more disputable they are, the less should they serve as grounds for preventing other people from taking free decisions. Nevertheless, an unrestricted and ongoing public debate about strong evaluations concerning the common good and probably also non-subjective values is an essential part of any reasonable will formation in a political community confronted with developments that might modify the way in which mankind and the world are seen.

### The Idea of Moral Agency

Probably the most fundamental change concerns understanding of moral agency and responsibility. Neuroscience and genetics seem to support naturalist positions in the philosophy of mind that in turn seem to undermine the ideas of free will and justified blame. This is not the right place to discuss such positions. If they were true, all that has been said so far about the agenda of neuroethics would prove to be senseless. When engaged in moral deliberations it is necessary to presuppose that it is possible to act out of insights. Every "ought" refers to ►rationality. It is far from self-evident that sense could no longer be made of these presuppositions if the progress in neuroscience were taken seriously. For example, it is in no way metaphysically convincing to see the author of free decisions and actions as a causally independent agent (an *homunculus*) within the person. It is much more convincing to ascribe responsibility to the entire person; given that he or she is able to do what he or she is reasonably convinced he or she has to do. Neuroscience can inform us about the neurological states and processes that enable people to act with reasons – or that prevent people from doing so. It can sharpen the sense of the individual limits of moral responsibility. But that is totally different from undermining the very idea of responsibility.

# Neuroethological Aspects of Learning

Frank W. Ohl
BioFuture Research Group, Leibniz Institute for Neurobiology, Magdeburg, Germany

## Definition

From an ethological viewpoint, ►learning is the process by which animals and humans can adapt their behaviors and internal states to an ever-changing environment. Simultaneously, from the viewpoint of evolutionary biology, equipping animals with the ability to learn frees natural selection processes from having to genetically fixate a vast variety of different behaviors and signal processing mechanisms to differentially recruit these behaviors in appropriate situations. From the viewpoint of neurophysiology, learning is made possible by a capacity of the nervous system to respond to certain classes of experiences encountered by an animal with changes in some of its functional features, a capacity called ►neuronal learning-induced plasticity.[1]

As the phenomenon of learning will be treated in more generality elsewhere in this volume [1], this essay will focus on some neuroethological aspects of learning. Learning can be defined as the process by which relatively permanent changes occur in behavioral potential as a result of experience [1]. In this definition, the attribute "*relatively permanent*" aims to exclude short-lasting changes in behavior, like fatigue. Experience-induced changes are referred to the "*behavioral potential*", rather than to behavior, because it is known that learning can be "behaviorally silent," i.e., need not express itself in immediate behavior. Finally, the definition clarifies that these changes should be due to *experience*, because other reasons exist for changes in behavioral potential, like the state of arousal, the state of (ontogenetic) development, age, injury, etc.

Central to neuroethological accounts of learning is the question of the relationship between learning and ►neuronal plasticity. This relationship is non-trivial, as the former is an ethological or psychological concept and the latter a physiological concept. Establishing the exact role of neuronal plasticity for learning is therefore predictably difficult, similar to other fields of science where conceptually different levels have to be linked, like for example in the relation between Newtonian mechanics and thermodynamics[2], or in the case of the mind-body problem. Historically, attempts to conceptualize the role of neuronal plasticity for learning have moved from the appreciation of the capacity of the nervous system for rerouting the flow of excitation through a neuronal network in simple learning situations [2], to neural processes that reflect the subjective creation of meaning in cognitively demanding learning situations like category learning and concept formation [3].

This essay will address the following neuroethological aspects of learning: (i) Structure of stimulus relationships that lead to learning, (ii) Motivational aspects of learning, and (iii) Neural aspects of information processing and meaning generation during learning.

## Characteristics

### Higher Level Processes

#### *Structure of Stimulus Relationships that Lead to Learning*

It is now realized that many generalities in learning behavior across species reflect the fact that they are evolutionary designed solutions to similar demands, rather than reflecting similar neuronal mechanisms. Therefore, generalities on the level of learning behavior cannot in general be expected to be supported by generalities on a physiological level [1]. Much research has been conducted to reveal those generalities in environmental or laboratory situations that lead to learning. Studies of the early twentieth century, e.g., by Ivan P. Pavlov, Edward L. Thorndike, Clark L. Hull, Edward C. Tolman, B. F. Skinner, and others, focused on classical conditioning and instrumental conditioning paradigms, and identified the temporal relationship

[1]The addition "learningnduced" distinguishes this form of neuronal plasticity from those observed during ontogeny (►developmental plasticity) or after injury (►compensatory plasticity).

[2]In this example, a conceptual link between both levels has been possible to provide, at least for the equilibrium state of matter, by the framework of .

N

(►contiguity) between stimuli or events as facilitating behavioral changes that could be interpreted as being the result of formed associations between these stimuli or events. Later studies, e.g., by Rescorla and Wagner [4], revealed that the contiguity is neither sufficient nor necessary for the formation of associations. For example, by carefully varying the probabilities of occurrences of events conditional on the occurrence of other events, it was shown that animals can show different levels of association even under constant contiguities. Learning mechanisms rather seem to exploit the probability structure of stimulus relationships, estimated from previous experience, to form associations. Animals can therefore use the information that one stimulus or event carries about the occurrence of another stimulus or event (►contingency).

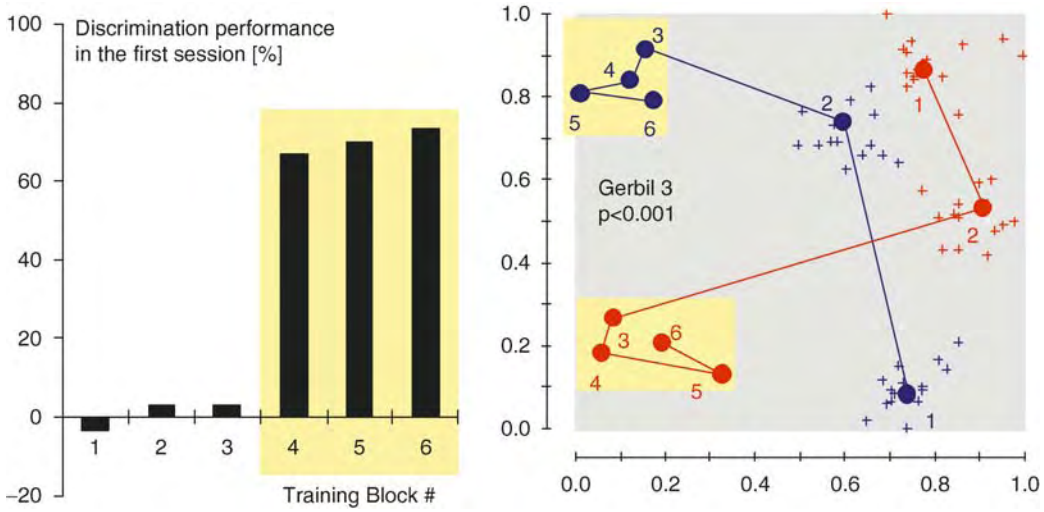
### Motivational Aspects of Learning

For methodological reasons, one of the events referred to above was typically a stimulus that elicits a defined, easily observable, behavioral response. Such stimuli are most often reward stimuli or aversive stimuli that will elicit approach or escape responses, respectively, and are called ►reinforcers. In experiments where reinforcers are applied in dependence of behaviors produced by a subject, reinforcers change the probability with which such behaviors will be emitted in the future. Reinforcers act by at least two discernable mechanisms [5]. The first mechanism, the ►enhancing function [5], works by enhancing the "storage" of information about situations in which they are encountered. This does not require that the animal learns anything about the reinforcer itself. The second mechanism, ►conditioned motivation [5], works by conditioning motivating effects of reinforcers to other brain activity present at a temporal relationship to the experience of the reinforcer. The dopamine system and the striatum have been associated with both types of action [5].

On theoretical grounds, the task of neural coding for reinforcers can be distributed to a number of hypothetical functions [6]. Among those are the *detection* of a reinforcer, i.e., a neural representation of whether a reinforcer is present or not, the *prediction* of a reinforcer, i.e., a neural response to a stimulus which the subject associates with a reinforcer to be followed, and the *expectation* of the reinforcer, i.e., a neural activity which develops temporally between reinforcement prediction and reinforcement detection, for example to support processes of maintaining attention. For all such functions neurons have been found whose firing properties could be associated with all of these functions and their combinations in such structures as the striatum, the prefrontal cortex and orbitofrontal cortex. As learning can be viewed as a process of reducing the discrepancy between a predicted and actually experienced outcome of a learning situation (a magnitude called the ►prediction error), such neurons are likely to have an important function for the neuronal mechanisms underlying learning. For example, in the striatum of monkeys tonically active interneurons have been reported that respond more frequently to unpredicted rewards than to predicted ones [7]. Analogously, microdialysis studies in the rodent medial prefrontal cortex have revealed an increased dopamine efflux in the *very early phase* of the establishment of a behavioral avoidance strategy, but not in later acquisition phases when performance was still increasing or during retrieval sessions. The hypothesis that the dopamine efflux in medial prefrontal cortex correlates with the establishment of *new behavioral strategies* for solving problems in learning situations could be further supported by relearning paradigms [8].

### Neural Aspects of Information Processing and Meaning Generation during Learning

For the neuroethological perspective on learning, those learning paradigms of particular importance are those that contain aspects beyond mere associations between stimuli or between stimuli and responses. This is because such paradigms preclude explanation of learning phenomena by a broad class of simple neurophysiological models that are otherwise discussed as elemental for physiological theories of learning. For example, while classical conditioning can in principle be explained by very simple neuronal networks [2], this is not possible for cognitively more demanding learning phenomena like *category learning* (*concept formation*). A few animal models of category learning have been designed to allow the study of the neural basis of such aspects of learning. For example, the Mongolian gerbil (*Meriones unguiculatus*), a rodent with exquisite auditory learning abilities amenable to physiological investigation [e.g., 9], can be trained using frequency-modulated tones to form the categories "rising" and "falling" and sort even novel, previously unheard, frequency-modulated tones into these categories depending on how the pitch of these sounds develops over time [10]. The formation of categories involves development of a new cognitive structure that represents qualities beyond the information given. It allows that a particular meaning (defined by the category) is assigned to even novel stimuli that are processed by a sensory system. The neurophysiological analysis of this learning behavior [3] revealed that during category formation particular spatio-temporal activity states emerge in the auditory cortex. These states have a *metrical structure*, i.e., similarity relations between spatio-temporal patterns correspond to similarities in the perceived category belongingness. This metrical structure is unlike the topographic maps known from various brain structures in which physical stimulus attributes are represented, because it represents the only subjectively valid perceptual scaling experienced by a given individual. These neuronal observables represent



**Neuroethological Aspects of Learning. Figure 1** Neurodynamics in auditory cortex during learning of acoustic categories exemplifying the physiological correlate of a learned cognitive structure. Example of behavioral and electrophysiological data from a Mongolian gerbil, which was trained to discriminate rising from falling frequency-modulated tones in a sequence of training blocks. In each training block, a novel pair of a rising and a falling frequency-modulated tone was trained. The left panel displays discrimination performance (quantified by the difference between hit rate and false alarm rate) at the beginning of a training block when the stimuli were novel to the subject. In training blocks 1–3, (*discrimination phase*) initial performance was insignificant but would improve in later sessions of the block (not shown). Starting with training block 4 and for subsequent blocks the subject showed transfer of the learned behaviors to the novel stimuli (*categorization phase*), indicating that a new cognitive structure had been formed in the subject. The transition from discrimination phase to categorization phase occurs abruptly, and for different individuals at different points in time. This behavioral *state transition* is accompanied by a transition in the neurodynamical states of auditory cortex. The right panel is a graphic representation of the similarity and dissimilarity relations between cortical activity patterns during different phases of the learning. Points represent activity states, numbers correspond to the training block, and colors red and blue to the categories "rising" and "falling," respectively. The spatial distance between any two points in the graph is a measure of the dissimilarity between the corresponding cortical activity states. For blocks 1 and 2 patterns for all trials (+) are shown together with their center of gravity values (•), for subsequent blocks only the center of gravity values are shown to avoid cluttering of the graph. It can be seen that as long as the subject remained in its discrimination phase (blocks 1–3), dissimilarities of cortical activity patterns *within* a category were of the same order of magnitude than *between* categories. After the transition to the categorization phase (blocks 4–6), dissimilarities within a category were abruptly reduced compared to dissimilarities between categories[3]. This indicates the establishment of a new metric in cortical representation of stimuli. This metric does not reflect physical stimulus attributes (as topographic feature maps do), but reflects the subjective perceptual scaling experienced by a given individual. Modified after [3].

an objectively accessible physiological representation of a subjectively existing cognitive structure [3] (Fig. 1).

# Neuroethology of Biosonar Systems in Bats

Hans-Ulrich Schnitzler, Annette Denzinger
Tierphysiologie, Zoologisches Institut, Universität Tübingen, Tubingen, Germany

## Definition

Evolution has equipped microchiropteran bats for nocturnal life by morphologically, physiologically, and behaviorally adapting their sensory and motor systems. Bats' abilities to echolocate and to fly play a particularly important role in allowing them to exploit resources which are not accessible to other animals. Around 800 species of echolocating bats (suborder Microchiroptera) emit tonal signals and analyze the returning echoes to detect, localize and classify the reflecting targets. All bats use their biosonar systems for spatial orientation and many of them also for food acquisition. Like technical systems bats have a transmitter which produces and radiates the echolocation signals and a receiver which analyzes and evaluates the returning echoes. Comparative neuroethological studies reveal how sound production and hearing in bats have been adapted during evolution to perform habitat-specific echolocation tasks.

## Characteristics

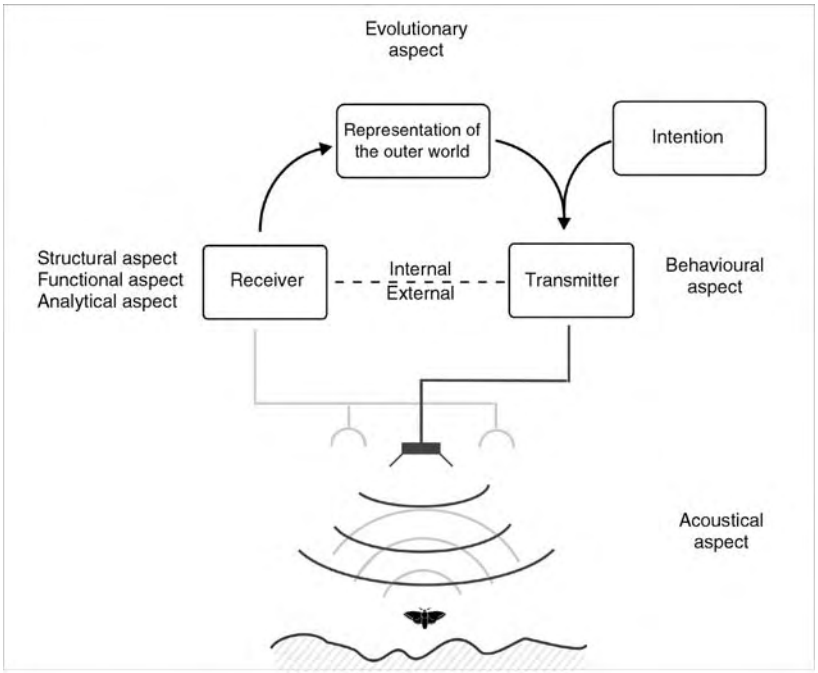
### The Action-Perception-Loop of Echolocation

Bats' echolocation systems are comparable to other active orientation systems such as radar and sonar systems, and are therefore referred to as biosonar systems. In active systems, the transmitter is connected to the receiver in an action-perception loop (Fig. 1).

Various neuroethological approaches to the study of bats' biosonar systems have been, as demonstrated in Fig. 1, describing the action-perception-loop of echolocation. The ►evolutionary aspect of these systems is examined in studies that develop plausible scenarios for the evolution of echolocation. The ►acoustical aspect is addressed by research that describes the various types of echolocation signals, measures the directionality of signal emission and echo reception, and characterizes the information content of echoes from various targets. The ►behavioral aspect is investigated in studies that define the constraints acting on signal structure, and explain the adaptive value of signal design according to the echolocation tasks and the bats' performance in natural echolocation situations. This aspect is also addressed by psychophysical experiments in the laboratory. The ►structural and functional aspects of echolocation are addressed by studies on the morphology, neuroanatomy, physiology, and pharmacology of the sensory and motor parts of echolocation systems. The ►analytical aspect is explored by those who develop computational theories of echolocation by defining problems related to echolocation tasks, searching for algorithms to solve these problems, and testing these algorithms by implementing them in biomimetic sonar systems. Here, we summarize these different approaches to investigating biosonar systems in bats, by presenting a survey of the reviews that we believe are relevant to understanding the neuroethological basis of echolocation in bats.

### The Evolutionary Aspect of Echolocation

The key characteristics that distinguish bats from other mammals are their ability to fly and their use of an active orientation system. Due to the paucity of fossil records, scenarios explaining the evolution of flight and echolocation are speculative and have been developed on the basis of plausibility (Denzinger et al. 2004). The evolution of echolocation presumably took place in several steps (Schnitzler et al. 2004). Echolocation signals may have evolved from high-pitched communication signals, and may have been used by pre-bats to estimate distances before jumping from one branch to the next. With the evolution of gliding and finally of flapping flight, echolocation may have become useful for obstacle avoidance during flight and improved landing control. With increasing maneuverability, the demand for spatial information increased and bats may have used echolocation to identify landmarks and habitat elements, i.e. for spatial orientation within



**Neuroethology of Biosonar Systems in Bats. Figure 1** The action-perception-loop consists of a transmitter, which generates signals transmitted via a sender antenna, and a receiver, which picks up the returning echoes with receiving antennae and decodes the information contained in the echoes to create a spatial representation of the area covered by the sonar footprint of the emitted signals (Denzinger and Schnitzler 2004). Bats produce their signals in the larynx (phonation), filter them in the vocal tract (articulation), and transmit them either through the open mouth or the nose (transmitter antenna, depicted in black)). The returning echoes are picked up with both ears (receiving antennae, depicted in grey) and echo information is evaluated in the auditory system (receiver). The resulting representation of the outer world and the behavioral intentions determine which signal type of the repertoire will be the next to be generated and transmitted (adapted from Denzinger and Schnitzler 2004).

their home range. Thus, echolocation is likely to have evolved primarily for spatial orientation, and its use for the detection of prey was a later step in evolution. Bats may have encountered situations in which the acoustical cues of an insect colliding with vegetation were preceded by the flight tone of the insect. By reacting with foraging flights towards the flight tones, bats evolved the ability to approach the moving sound source guided by echolocation. Finally, they made the transition to detecting flying insects on the basis of echolocation alone and to hunting for airborne prey on the wing.

## Acoustical and Behavioral Aspects of Echolocation

When performing echolocation tasks, microchiropteran bats continuously emit signals that are mostly in the ultrasonic range. These signals differ between species in terms of their duration, pulse interval, frequency, harmonic content, and sound pressure level (SPL). Each species has a specific signal repertoire containing a variety of signal types evolved to perform species-specific echolocation tasks. The tasks performed by bats depend on their behavioral intentions and also on where bats fly and forage, what they eat, and how they acquire their food. Echolocation tasks can be attributed either to spatial orientation or to food acquisition.

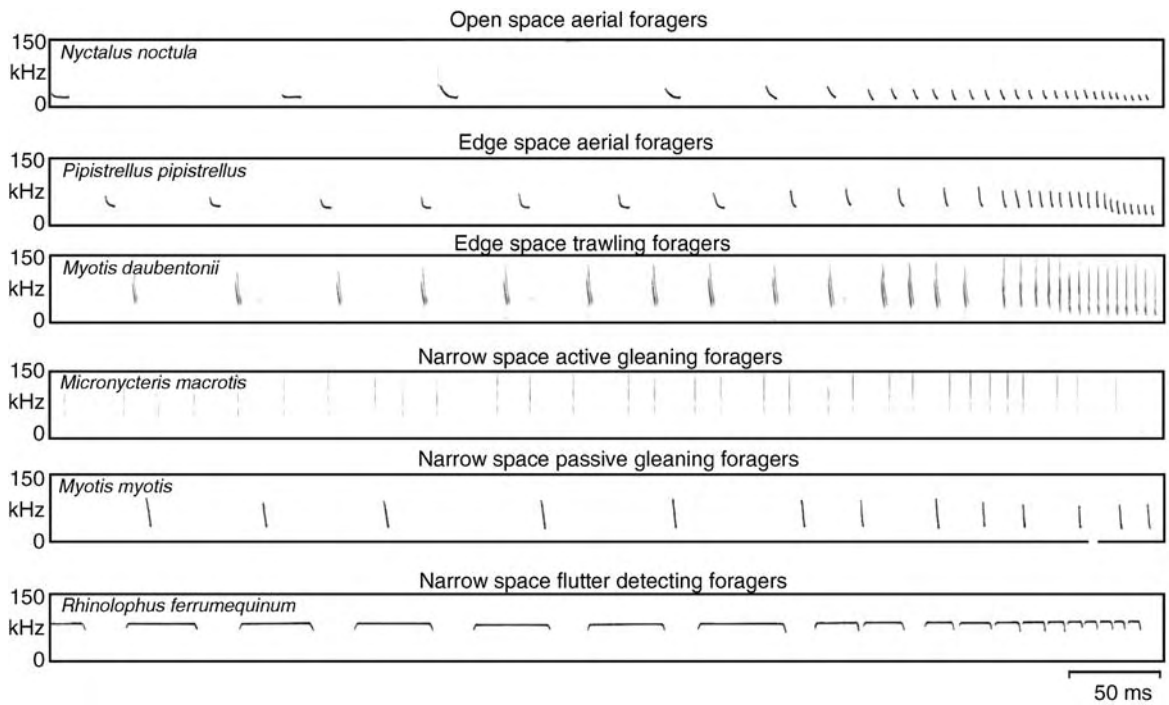
All bats use echolocation for spatial orientation. Information derived from returning echoes is used to move in relation to stationary targets along routes and to build up a spatial representation of the environment. Little is known about which part of the information contained in echoes is used to orient in space. Extended targets such as landmarks contain many reflecting facets that generate stochastic echo sequences. Random process parameters distinguish between different vegetation types (Müller and Kuc 2000) and could be used by bats for landmark classification. There is behavioral evidence that bats are able to distinguish between echo trains differing in roughness (Grunwald et al. 2004). In addition, bats emit short, broadband, highly frequency-modulated (FM) signals in classification tasks. Due to the wide range of wavelengths and the strong directionality of high frequencies in such signals, they are well-suited for target classification (Siemers and Schnitzler 2004). Important information might also be encoded in changes within echoes over time.

Theoretical studies show that changing echo parameters create time-variant echo features, such as acoustic flow, that might contain information about the position of targets in relation to the bat's motion. Long, constant-frequency (CF) signals are especially well-suited for evaluating acoustic flow information (Müller and Schnitzler 1999, 2000).

Many bats also use echolocation to find their food. Comparative studies reveal that the proximity of prey to background targets is the most relevant ecological constraint on the design of bats' echolocation signals, and can therefore be used to define foraging habitats. Three main habitat types have been described: in the open, or "open space," between and along vegetation, or "edge space," and within vegetation and close to it and the ground, or "narrow space" (Aldridge and Rautenbach 1987; Neuweiler 1990; Fenton 1995; Schnitzler and Kalko 2001; Schnitzler et al. 2003). In open space, bats forage so far off from the background that they do not react to it in their echolocation behavior. In edge space, bats react to the background but the prey echo does not overlap with background echoes. In narrow space, the echoes of prey positioned on substrate or flying very close to the background overlap with background echoes, which may result in masking.

Ecological conditions exert strong selective pressure on signal design, thus favoring species-specific signal types closely connected to habitat type, foraging mode, and prey. This connection can be used to define functional groups based on the preferred habitat type and foraging modes of various bat species. Members of each functional group are confronted by a common set of constraints and must solve similar echolocation tasks. This results in many similarities in signal design within functional groups (Schnitzler et al. 2003). "Open space aerial foragers" catch flying insects and use rather long, narrowband, shallow FM signals of low frequency that are adapted for long-range detection (Fig. 2).

"Edge space aerial/trawling foragers" search for insects flying near vegetation edges, in gaps, near the ground, or drifting on flat water surfaces. They often emit mixed search signals of medium duration. These signals consist of a narrowband, shallow FM component adapted for medium-range detection and a broadband, steep FM component adapted for orienting with respect to background targets. Narrow space bats that either glean their food from the substrate or capture prey close to it face the problem that overlapping clutter echoes may mask the prey echo. Three different strategies have been evolved to cope with this problem. "Narrow space active aerial/gleaning foragers" find their food by echolocation. They either use target-specific echo cues or specific echolocation strategies to separate prey from the background (Denzinger and Schnitzler 2004). "Narrow space passive gleaning foragers" cannot solve the masking problem and use



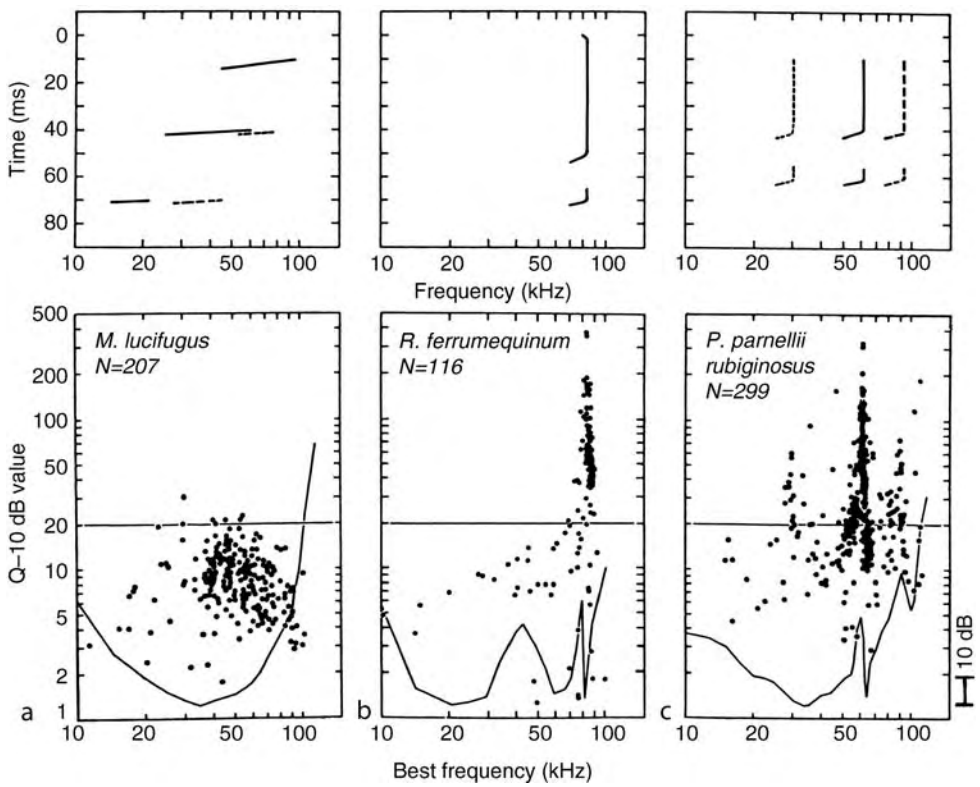
**Neuroethology of Biosonar Systems in Bats. Figure 2** Search and approach signals of different functional groups.

prey-generated acoustic or olfactory cues to find their food. Bats in both functional groups emit broadband uni- or multi-harmonic signals of short duration and low sound pressure level. Active gleaners use these signals both for spatial orientation and for food acquisition, whereas passive gleaners use them for spatial orientation only. "Narrow space flutter detecting foragers" have a very specialized echolocation system with signals consisting of a long component of constant frequency followed by a terminal FM component. With Doppler shift compensation and a specialized hearing system, these bats are able to recognize echoes from fluttering prey insects modulated by the rhythm of beating wings in unmodulated background echoes (Schnitzler and Ostwald 1983; Neuweiler 1990; Moss and Schnitzler 1995). Bats have highly variable foraging and echolocation behavior and often forage in more than one habitat (Fenton 1990). According to their behavioral goals and to incoming information, bats choose the most suitable signal types from their repertoire to perform specific echolocation tasks.

A multitude of psychophysical experiments have been conducted to investigate auditory information processing in bats and to clarify which receiver type is implemented in the bat's auditory system. These studies include behavioral audiograms, performance in target echo detection, range estimation and resolution, horizontal and vertical localization, movement discrimination (Moss and Schnitzler 1995; Masters and Harley 2004) and, recently, the bats' performance in stochastic echo parameter evaluation tasks (Grunwald et al. 2004).

Bats hear over a wide range of mainly ultrasonic frequencies, often spanning several octaves. The frequency range of bats' echolocation signals corresponds closely to the range in which they have high auditory sensitivity (Fig. 3). Sensitivity to frequencies below the range of the echolocation signal is crucial for social communication and the detection of prey and predators through passive listening.

For detection, a bat has to decide whether it perceives an echo of its own signal or not. Detection thresholds depend on the bat's signal structure, environmental conditions, and the bat's sonar receiver. Thresholds between 0 and 60 dB SPL have been obtained in various experimental procedures. This variability may have been caused by different masking situations.



**Neuroethology of Biosonar Systems in Bats. Figure 3** Comparison of sonagrams (*upper row*) with audiograms (*solid line*), and $Q_{10dB}$ values of single auditory fibers (*dots*) (*lower row*) of a bat using broadband steep FM signals (*Myotis lucifugus*, A) and of two flutter-detecting foragers (*Rhinolophus ferrumequinum*, B and *Pteronotus parnellii*, C) (adapted from Grinnell 2004). The sonagrams are tilted so that the frequency is displayed in the x-axis as in the audiograms below.

For localization, a bat determines the range and the angle of a target of interest. The range is encoded in the time delay between the emitted signal and the returning echo. The ranging performance of bats has been tested using three different tasks: range difference discrimination, range jitter discrimination, and range resolution. Range difference experiments revealed an accuracy of about 1 cm, which is close to the accuracy estimated from successful prey interception experiments. In range jitter experiments, in which one target jitters while the other is stable, discrimination thresholds down to 10 ns (corresponding to 1.7 μm) have been reported (Simmons et al. 1990). These results have often been questioned because it is hard to imagine how such minimal differences in echo arrival time could be processed in the nervous system. Studies on range resolution tested bats' perception of target depth structure. In range resolution experiments, bats using FM signals were able to discriminate one-wavefront echoes from interfering two-wavefront echoes when the delay offset within the two-wavefront echo was about 12 μs. Range perception is most likely not a single process, but rather a set of perceptual processes in the bat's receiver; the described experimental approaches may be tapping into different processes in the set.

Binaural and monaural echo cues encode the horizontal and vertical angles of targets. Accuracy in determining these angles has only been measured in the FM bat Eptesicus fuscus. Threshold estimates were 1.5° in the horizontal plane and about 3° in the vertical plane.

To classify targets, bats use target-specific spectral and modulation patterns in the echoes or stochastic parameter distributions. Flutter information is used by bats to identify insect echoes and to discriminate them from the stationary background. CF-bats also use flutter information for the classification of insect prey. In behavioral experiments, horseshoe bats were able to sense 8–9% differences in wing beat rate. They also discriminated between different insect species even if they had the same wing beat rate and were presented at novel aspect angles. It has only recently been proven that bats are able to classify echoes according their roughness (Grunwald et al. 2004).

## Structural and Functional Aspects of Echolocation

A multitude of publications deal with the question of how echo information is processed in the auditory systems of bats (recently summarized in the books "Hearing by Bats," Popper and Fay (eds.) (1995) and "Echolocation in Bats and Dolphins," Thomas, Moss and Vater (Eds.) (2004)). Most studies were conducted with either vespertilionid bats that use broadband, steep FM signals, or rhinolophids, and the mormoopid bat *Pteronotus parnellii* that uses long, CF-FM signals. The auditory systems of the two groups differ in many ways, reflecting structural and functional differences that are critical to echolocation. Nevertheless, the auditory systems of bats consist of the same basic elements as those of other mammals.

In all bats, the cochlea is specialized for the analysis of high frequencies. Bats that rely on broadband, steep FM signals possess a non-specialized mammal-like frequency representation on the basilar membrane. In flutter-detecting bats, a so-called acoustic fovea is used for the analysis of a narrow band of frequencies around the second harmonic of the CF component of the Doppler-compensated echoes (Grinnell 1995; Kössl and Vater 1995; Vater and Kössl 2004; Vater 2004). Both this difference in frequency representation in the cochlea and in increased sharpness of frequency tuning of neurons connected to the auditory fovea are found throughout the entire ascending auditory pathway (Fig. 3).

In no other mammal is the auditory system proportionally larger and more differentiated than in echolocating bats. Studies on the processing of echo information in the central auditory system of bats focus on the question of how and where the information bearing spectro-temporal attributes of pulse-echo trains are decoded (Covey and Casseday 1995, 1999; Pollak and Park 1995; Wenstrup 1995; O'Neill 1995; Fuzessery et al. 2004).

Between the cochlea and the midbrain, parallel pathways provide multiple transformations of the cochlear signal through the interplay of excitatory or inhibitory outputs, which differ in their temporal discharge patterns and latencies. This results in auditory midbrain neurons that are tuned to parameters relevant for echolocation, such as signal duration, delay between two signals, FM sweep direction, and the rate of periodic frequency and amplitude modulation (Covey and Casseday 1995, 1999). Binaural processing of interaural intensity (and perhaps time differences) in the superior olivary complex provides angular information. However, there is some controversy surrounding the question of whether or not the large and specialized medial superior olive is equivalent to this structure in non-echolocating mammals (Covey and Casseday 1995).

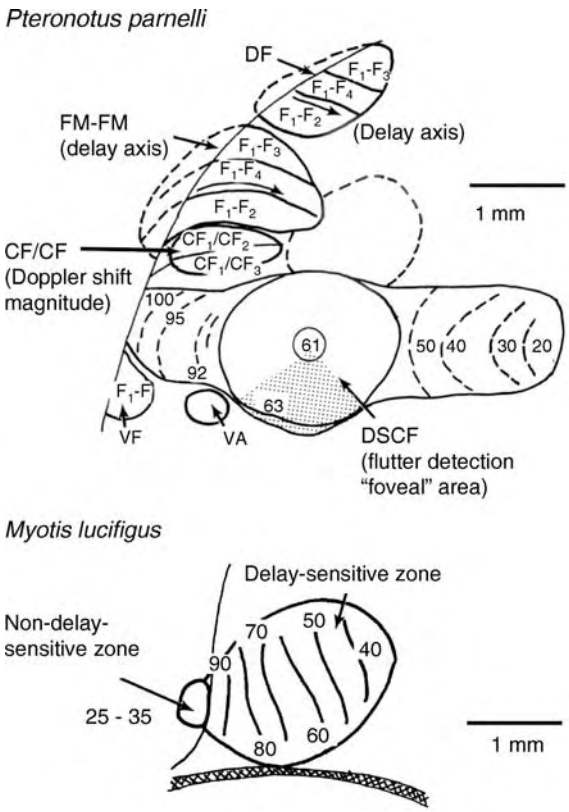
The processing of echolocation information in the colliculo-thalamo-cortical pathway leads to a further decoding of the features that describe echolocation scenes (Suga 1990; Pollak and Park 1995; Wenstrup 1995). Feature extraction is species-specific and reflects the adaptations of the corresponding echolocation systems to species-specific echolocation tasks. Such differences become evident when one compares the analysis and representation of relevant echolocation features in flutter-detecting bats such as *Rhinolophus ferrumequinum* and *Pteronotus parnellii* and bats that use broadband, steep FM signals such as *Myotis lucifugus* (O'Neill 1995; Suga 2004; O'Neill 2004;

Wong 2004). For instance, the functional organization of the auditory cortex of the flutter-detecting forager *Pteronotus parnellii* is characterized by three distinct areas representing different task-relevant features. One region contains neurons that respond solely to certain signal frequencies and amplitudes. There, the area around the second harmonic of the echolocation signals corresponds to the auditory fovea and is greatly enlarged, as it is in all lower nuclei and in the cochlea. A second region contains combinatorial neurons that respond solely to frequency differences between signals. The combinatorial neurons of a third region represent echo delays measured as the time interval between two signals. Within these regions, information-bearing parameters such as echo delay and relative velocity are arranged in maps (Suga 1990, 2004; Pollak et al. 1995; O'Neill 1995, 2004) (Fig. 4).

In rhinolophids, which are also specialized for flutter detection, the functional organization of the cortex is in part similar to that of *Pteronotus parnellii*, but there are also notable differences in the arrangement of feature-encoding cells (Schuller et al. 1991). The cortices of other bats also contain combinatorial neurons that express echolocation features by combining information from two signals that simulate signal echo pairs. The functional organization of the cortex in bats that use broadband, steep FM signals, such as *Myotis lucifugus* and *Eptesicus fuscus*, is very different from that of flutter-detecting foragers. In *Myotis lucifugus*, the cortex consists of two tonotopic regions. One region covers the frequency range of the echolocation signals. It can dynamically change to provide multidimensional feature extraction, which meets the behavioral needs of echolocation in this species (Wong 2004).

Recent studies indicate that cortifugal systems are essential in shaping the response properties of subcortical neurons, thus adjusting and improving signal processing according to auditory experience (Jen et al. 2004; Suga et al. 2004).

Successful echolocation depends on the coordination between auditory and motor systems. Therefore, the control of signal production is tightly coupled to auditory processing of pulse-echo trains (Moss and Shina 2003; Schuller and Moss 2004). Several nuclei at different levels of the brain have anatomical connections and functional responses that indicate their importance for audio-vocal control. The emission of sonar signals is also linked to breathing and other motor activities such as wing beat, pinna movements, and middle ear contraction.



**Neuroethology of Biosonar Systems in Bats.**
**Figure 4** Functional organization of the auditory cortex in *Pteronotus parnellii* and *Myotis lucifugus*. In Pteronotus, a tonotopically-organized field with an overrepresentation of foveal neurons (DSCF area) is surrounded by areas containing maps that represent either relative velocity (CF/CF area), as indicated by Doppler shift magnitude, or echo delay (FM-FM and DF area). Neurons in the foveal area are sensitive to flutter information. Myotis has two tonotopically-organized fields. The larger delay-sensitive zone covers the frequency range of sonar pulses and contains delay-sensitive neurons. The tonotopic gradient of the smaller non-delay sensitive zone is reversed and only covers frequencies from 25–35 kHz (adapted from O'Neill 1995).

## The Analytical Aspect of Echolocation

A model of echolocation based on spectrogram correlation and transformation (the SCAT receiver model) describes the auditory computations necessary to estimate target range (Saillant et al. 1993; Simmons et al. 1996). This model is used to explain the extraordinary range accuracy found by Simmons in his range jitter experiments, results that other authors have cast in doubt (Schnitzler et al. 1985; Pollak 1988, 1993). Another model delivers a biologically-plausible framework for auditory perception in FM bats, by using functional units inspired by what is presently known about the neurobiological elements of the bat's auditory system (Palakal and Wong 2004). In other approaches, properties of bat echolocation systems have been implemented in biomimetic sonar systems. Such systems were able to recognize objects directly from

their echo waveform (Kuc 2004) or from stochastic echo properties (Müller and Kuc 2000), or they were able to determine echo direction using pinna morphology and motion (Walker et al. 2004). A computational theory for the classification of natural biosonar targets was developed on the basis of echoes from real targets recorded with a biomimetic sonar system (Müller 2003).

## Outlook

There is still a long way to go before we have attained a complete understanding of echolocation in bats and its neural underpinnings. Most behavioral studies have focused on the detection and localization of single targets, and neurobiological studies have simulated auditory scenes by simply mimicking pulse echo pairs using two succeeding signals. In nature, however, bats are confronted with echolocation scenes that generate complex echo trains from which the relevant information has to be extracted. Further research should therefore focus on the echolocation behavior in natural situations, with a strong emphasis on the adaptive value of signal design and on the adaptive strategies that bats apply to perform complex echolocation tasks. For a better understanding of the neuronal mechanisms underlying echolocation, it will be necessary to study echo processing in vocalizing animals, thereby producing pulse echo trains that are comparable to those occurring in natural scenes. Studies that evaluate the bat's ability to use stochastic echo properties are a promising new approach that may shed new light onto the complex information processing involved in echolocation.

# Neuroethology of Sound Localization in Barn Owls

Terry Takahashi
Institute of Neuroscience, University of Oregon, Eugene, OR, USA

N

## Synonyms

Spatial hearing

## Definition

Sound localization is the ability to determine the spatial relationships of sound sources in the environment.

## Characteristics

### Higher Level Structures

The barn owl can hunt in pitch darkness guided by auditory neurons with discrete ►spatial receptive fields (SRFs) [1,2]. These neurons form a topographic map of frontal auditory space in the external nucleus of the inferior colliculus (ICx). The SRFs of these space-specific neurons are based on neuronal sensitivity to interaural differences in the timing and level of sounds (►ITD (interaural time difference) and ►ILD (interaural level difference)), which are also the major cues (►spectral-shape cues) for sound-localization in humans and other mammals [3–5]. Lesions of the space map lead to scotoma-like defects in sound localization, and microstimulation of the optic tectum (OT), which receives a direct, topographic projection from the ICx, and evokes a rapid head turn to that area of space

represented at the point of stimulation [6,7]. Finally, the smallest angular separation of sources that the owl can resolve has recently been traced to the granularity of the focal activity evoked on the map [8].

Neurons that are sensitive to the location of sources or the binaural cues associated with source location are found not only in the ICx, but also in Field L, the analog of the mammalian primary auditory cortex, and in the archistriatum, the analog of the mammalian basal ganglia [9–11], although maps of space have not been found [12]. Lesions of the OT lead to inaccurate and long-latency head turns, but do not obliterate these movements, suggesting that forebrain regions may serve as parallel pathways for sound localization [13].

## Lower Level Components

Acoustical Cues Barn owls rely primarily on two cues, ITD and ILD, to localize sounds. For the owl, ITD varies with the sound source's azimuth due to the ears' separation along the horizontal axis. For a given azimuth, ITD remains largely constant across the entire range of frequencies (►best frequency) [14] that owls use for sound localization (3–9 kHz) [15]. ILD also varies with the source's azimuth at low frequencies (2–4 kHz), but as frequency increases, the axis along which ILD changes becomes increasingly vertical, allowing for the representation of elevation [14]. This, in turn, is due to the asymmetry in the morphology of the two ears, which causes the right and left ears to be more sensitive to sounds coming from above and below eye-level, respectively.

The manner in which the ears and head alter the magnitude and phase of sounds in a location-specific manner is called the ►head-related transfer function (HRTF). By filtering sounds with the HRTFs for a location in space, we can re-create, over headphones, the sound wave that would have arrived at the eardrums from a sound source at that location. The stimulus is said to have been presented in virtual auditory space (VAS), and the application of VAS techniques allows not only the rapid assessment of neural spatial tuning, but also the analysis of the contribution of the two binaural cues to the neural responses.

Computation of ITD The computation of ITD begins with the encoding of the phase angles of each spectral component by ►phase locking neurons of the nucleus magnocellularis (NM), one of the cochlear nuclei [16]. In the barn owl, phase-locking extends to neurons with best frequencies as high as 9 kHz where strong ILDs are generated. It is for this reason that ITD and ILD can operate over the same frequency range, allowing the owl to localize sounds in two dimensions. NM projects bilaterally to the nucleus laminaris (NL), the avian analog of the mammalian medial superior olive (MSO). In the NL, the ITD of each spectral component is computed by a ►binaural cross-correlation operating over short segments of time [17–22], thus resulting in neurons selective for the ITD.

The NL projects directly to the core of the contralateral ICc that, in turn, projects to the lateral shell of the opposite ICc [23]. As a result of this doubly-crossed pathway, the lateral shell gains a representation of contralateral space. Neurons of the core and lateral shell of the ICc are selective for ITD and frequency and are organized into tonotopic columns. Cells in a column of the ICc-lateral shell project convergently onto a cluster of space-specific neurons, thus endowing them with selectivity for the ITD preserved by the column [24].

Computation of ILD We understand less about the processing of ILD. The sound level in the ipsilateral ear is encoded by cells in the nucleus angularis (NA) [16], which project contralaterally to the nucleus ventralis lemnisci lateral pars posterior (VLVp) [25]. The VLVp of the two sides are interconnected by an inhibitory commissure. The neurons of the VLVp are excited by stimulation of the contralateral ear, via the direct input from NA, and are inhibited by stimulation of the ipsilateral ear, via the commissural input [26,27]. The VLVp projects bilaterally to the lateral-shell of the ICc [28], where ILD and ITD cues are merged. A clear topographical representation of ILD, however, has never been found [29].

The application of VAS techniques has recently shown that if space specific neurons were sensitive to ILD alone, their SRFs would be horizontal swaths of space at the elevation of the cell's normal spatial ►spatial receptive field (SRF). If neurons were sensitive to ITD alone, their SRFs would be a vertical swath at the azimuth of the cell's normal SRF [30,31]. The normal RF thus lies at the intersection of the ITD and ILD-alone RFs where the cell's optimal ITD and ILD-spectra are present and are combined by a multiplication-like process [32].

## Higher Level Processes

Multiple sound sources. When there are multiple sources, as is typical in nature, the sound waves from each source will add in the ears, and if the sounds have broad, overlapping spectra, the binaural cues will fluctuate over time in a complex manner [33,34], making it difficult for the space map to image the sources accurately. One key to the space-specific neurons' ability to resolve two simultaneous sources is the difference in spectra [34]. When two sources of identical broadband noises were passed through a neuron's SRF, the neuron discharged maximally when the two speakers flanked the SRF, generating a response function with a single peak. This is to be expected, because the frequency-specific superposition generates binaural cues that are the vector average of those of the two individual sources. When the two sources emitted comb-filtered noises with the energy from each source

in alternate frequency bands, the neurons responded when each speaker was in their SRFs, generating bimodal response functions. This too is expected, because superposition of the waves happens within frequency-specific channels and the two sources' energy is contained in alternate bands, resulting in less spectral overlap. Interestingly, neurons were also able to resolve two speakers that emitted ►uncorrelated broadband noises as well as identical broadband noises that were temporally reversed versions of one another. In both cases, the moment-by-moment spectrum differed enough for the neuron to resolve. Thus, the neurons are capable of resolving sounds from two sources as long as their ►short-term spectra differ.

Echoes Early psychophysical studies demonstrated that directional information conveyed by the sound coming directly from the active source (leading source) dominates perception, and that listeners are relatively insensitive to directional information conveyed by reflections (lagging sources). The perceptual dominance of the leading sound and a host of related perceptions are collectively referred to as the "precedence effect." (For reviews, see [33,35,36]).

When two identical sounds are presented within 100 μs of one another from two separate sources, owls and their space-specific neurons respond as though there was a single target located between them [37,38]. This phenomenon, termed "summing localization" can be explained largely by binaural cross-correlation [37]. If the delay between leading and lagging sources is increased to the 1–5 ms range in humans, the single fused phantom target is localized close to the leading source. This is termed "localization dominance" [36,39,40]. At the same time, spatial information regarding the lagging source is degraded, a phenomenon, termed "lag discrimination suppression" [41–46].

Localization dominance has also been reported in studies with non-human subjects, including owls [38,47,48]. At delays between 1 and 10 ms, the owls turned their heads to the side of the leading source. At delays above 10 ms, owls aimed their heads at the lagging source or made double-head turns, first localizing one speaker then turning to the other [38]. The latter observation indicates that the lagging source had become localizable at the longer delays. To our knowledge, the only study of lag discrimination suppression in non-human species is the recent study in the owl [8], which measured the minimal audible angle (MAA), the smallest perceptible change in sound-source location, in the presence of echoes. For a sequence of two noise bursts from locations separated horizontally by 30° and in time by 3 ms, the MAA for lag sources was considerably larger than for lead sources, suggesting that the owl experiences lag discrimination suppression. The MAA for the lead sources was also found to be larger than that for single sources. This ordering of effects, $MAA_{single} < MAA_{lead} < MAA_{lag}$, replicates findings with humans for similar stimuli [49].

There are a growing number of neurophysiological studies of the precedence effect, which generally show that a cell's response to the lag source is weaker than its response to the lead source or to a single source [37,38,50–56]. A recent study in owls has shown that neuronal MAAs, estimated using signal detection theory, have the same ordering found behaviorally; specifically, $MAA_{single} < MAA_{lead} < MAA_{lag}$ [57].

Motion The best evidence for the owl's sensitivity for the direction of object motion is an early observation that whenever an owl struck a mouse in darkness, it arranged its talons so that it grasped the long axis of the mouse's body [1]. When the mouse's trajectory was co-linear with the owl's flight-path, the owl put one set of talons in front of the other to strike, but when the mouse's trajectory was perpendicular to the owl's, the owl arranged its talons side-by-side. Since visual cues were not available in this experiment, the mouse's path was likely determined by acoustical cues.

A number of neurophysiological studies have documented neuronal sensitivity to motion direction using either an array of sequentially-activated speakers simulating saltatory motion [58–62] or continuously varying binaural cues [63,64]. A recent survey demonstrated that neurons in the left and right colliculi prefer, respectively, motion in the clockwise and counter-clockwise directions [62]. The authors suggest that the cells may be involved in orienting movements to the contralateral auditory hemisphere.

Neuronal directional sensitivity has been modeled as a circuit in which the motion-direction sensitive neuron receives an excitatory input from a spatially-selective neuron and a delayed inhibitory input from a second spatially-selective neuron with an SRF some distance away. If a sound source travels from the excitatory neuron to the inhibitory neuron, the excitatory input to the motion sensing neuron arrives first, causing a discharge. If the source travels in the opposite direction, the delay causes the inhibitory input to coincide with the excitatory input (which is stimulated later), nullifying it. This mechanism depends on the delay imposed on the inhibitory input and the distance separating the two spatially tuned inputs, thus allowing for some selectivity for speed. Kautz and Wagner [61] demonstrated that biccuculine reduces sensitivity to motion direction, suggesting GABA-mediated inhibition.

Takahashi and Keller [63] reported auditory motion-unmasking. Using ►binaural beats, which simulates a moving pure-tone source, they showed that space-specific neurons detected the moving tone in noise more easily than static ones. This finding could not be replicated, however, with saltatory-motion [60]. Two psychophysical studies in humans have yielded conflicting results [65,66].

N

Attention and Working Memory Studies of audiospatial cognition are rare. Knudsen and Knudsen [67] showed that an owl's ability to remember the locations to which it recently oriented is affected by lesions of the archistriatum, suggesting its role in spatial working memory [67].

In a study of attention, the reaction time of owls trained to turn their heads toward a sound source when visual stimuli provided a truthful or a misleading cue to the side from which the sound would appear [68]. As in humans [69], the owl's reaction times were significantly faster when the cues were valid than when they were invalid, suggesting that attention is capable of modulating the owl's orienting behavior. Interestingly, however, even the validly cued trials had reaction times that were considerably longer than when an owl was trained simply to turn its head toward a sound source, without a cue. This may indicate that the cued reaction-time task is difficult for owls.

## Process Regulation

Once the binaural cues are computed, these cues must be translated into space. In a baby bird, which has a small head, the maximal ITD, generated by a source to the extreme right or left, may be some 90 μs. A neuron tuned to an ITD of, say, 30 μs represents a location about 30% of the distance to the extreme periphery. The adult, by contrast, has a maximal ITD of about 200 μs [14], so the same neuron represents a more central location.

This process of translation occurs during a critical period, of up to ca. 200 days, during which visual input is crucial [70]. Birds that are blind may form inverted and otherwise distorted maps of auditory space [71,72]. Moreover, if a baby bird matures with a pair of prisms that laterally shifts the visual scene, the now mature bird mis-localizes a sound by the amount that the prisms shifted the visual world [73]. Correspondingly, a space-specific neuron will shift its ►auditory SRF by an amount equal to the prism shift. The plasticity is thought to occur in the ICx, and involves the inputs from the OT, which contributes a visual input, and the ICc, which contributes the spatially selective auditory input [74]. The mechanism of audiovisual calibration in the owl is an example of supervised learning and has been thoroughly investigated and reviewed [75].

## Function

Audiospatial Discrimination and Localization Audiospatial discrimination is the ability to detect changes in the position of a sound source. This is to be distinguished from "localization," the ability to point to a sound source in space. In the owl, whose eyes and ears are nearly immobile, sound localization is measured by its head turns. Owls can point their heads to within 2.5° to 5° of a target in azimuth and 3.5° to 8° in elevation [3,76,77]. For both dimensions, accuracy and precision decline slightly with target eccentricity.

Spatial discrimination was recently investigated in the barn owl using a newly developed method based on pupillary dilation response (PDR) [78,79]. In the barn owl, the pupil dilates upon presentation of a sound, and habituates when the same sound is repeated. When the stimulus is changed, for example, by presenting the identical waveform from a different location, the PDR recovers. The degree of recovery is proportional to the magnitude of the difference between the habituating and testing loci, making the PDR similar to a psychophysical ►rating task. The magnitude of the PDR evoked by test stimuli can be expressed in terms of the variance of the PDR evoked by habituating stimuli to derive a ►z-score-like statistic called the "standard separation," $D$ [80]. The MAA, defined as the spatial separation between habituating and test loci at which $D = 0.8$, was found to be about 3° in azimuth and 7° in elevation [81]. This value is considerably finer than that of animals with heads of comparable sizes.

How does owl's MAA compare with the acuity of its space-specific neurons? Such comparisons are often confounded by the lack of a common metric. Signal detection theory, which is based on the premise that the variance in neuronal responses limits behavioral discrimination, provides such a metric [82]. By scaling a neuron's responses to its variance, we can estimate how well an animal might be able to discriminate between two stimuli, if its higher centers were relying strictly upon that neuron's firing. Recent application of this approach by Bala and colleagues [79] to the owl's space-specific neurons predicted its horizontal MAA. It is particularly interesting to note that the SRFs of the space specific neurons are about 2–3 times taller than they are wide. This corresponds roughly to the ratio of the vertical and horizontal MAAs [81].

# Neuroethology of Visual Orientation in Flies

Anne-Kathrin Warzecha[1,2], Roland Kern[1]
[1]Lehrstuhl Neurobiologie, Fakultät Biologie, Universität Bielefeld, Bielefeld, Germany
[2]Institut für Psychologie II, Münster, Germany

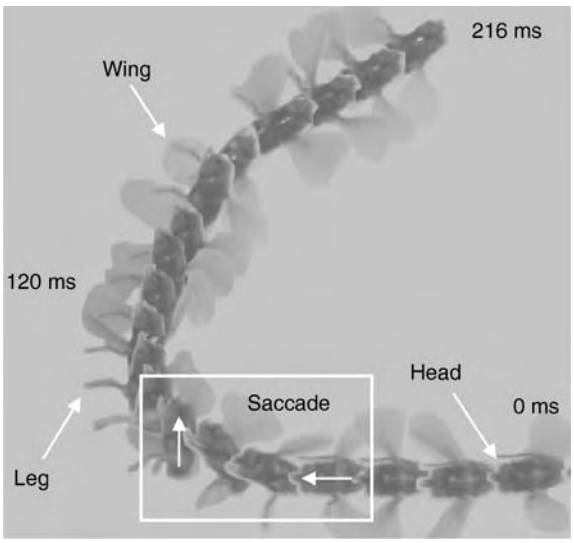
## Definition

The central goal of neuroethological research is to account for the behaviour of an animal in terms of

the underlying neuronal mechanisms. The blowfly (Calliphoridae) has proven to be a very fruitful model system for the analysis of how the nervous system controls visually guided orientation behaviour (reviews: [1,2]).

When the blowfly, or any other agent equipped with eyes, moves around, the retinal images of the surroundings are continually displaced. This ►optic flow is characteristic of the animal's path of locomotion and the spatial layout of the environment. Flies exploit optic flow information for controlling various behaviours such as course stabilisation, compensatory head movements, landing, the detection and fixation of objects, and the pursuit of conspecifics in the context of mating behaviour (review: [2,3]). Due to technical advances, it has recently become possible to record the flight behaviour of freely moving flies with great precision. When cruising around, flies usually fly straight and then very quickly change their flight direction by abrupt, saccadic turns of the head and trunk (Fig. 1 review: [1,2]), reminiscent of eye movements in primates. This behaviour constrains the optic flow patterns experienced during cruising flight and may thus facilitate an evaluation of the retinal information.

The computations underlying optic flow processing can partly be understood in terms of the biophysical properties of individual nerve cells and their synaptic interactions.



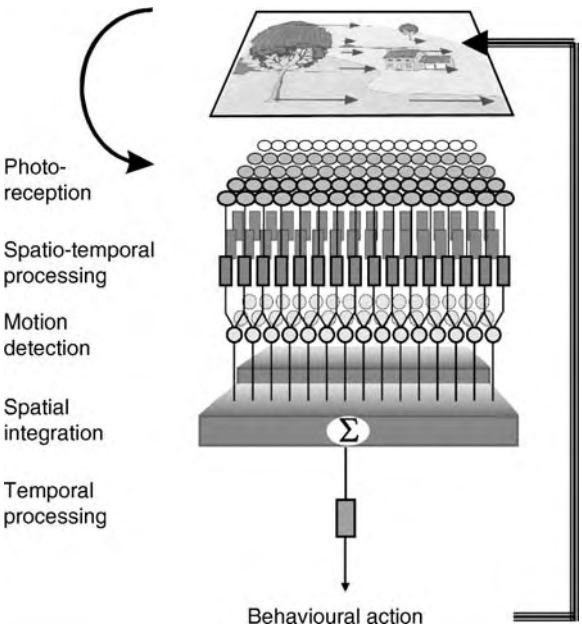
**Neuroethology of Visual Orientation in Flies.**
**Figure 1** Flight sequence of blowfly that was videotaped from above with a high-speed camera. Here video images of the fly taken every 12 ms are superimposed. The fly performs a short saccadic turn (indicated by the arrows on the fly's body long axis). Within only 36 ms, it has turned by almost 90°. During such turns the animal can reach turning velocities of more than 3,000° $s^{-1}$ (R. Kern unpublished data).

## Characteristics

Motion information is not explicitly represented at the level of the retina. Instead, several processing steps are necessary in order to obtain a neuronal representation of optic flow information (Fig. 2).

### Local Information Processing

Optic flow is initially processed by successive layers of retinotopically arranged columnar neurons. The retinal luminance changes are sensed by photoreceptors and are spatio-temporally filtered by them, as well as by their postsynaptic elements, in the lamina. This filtering is thought to remove spatial and temporal redundancies and to play a role in adapting the system to the ambient light level (reviews: [4,5]).



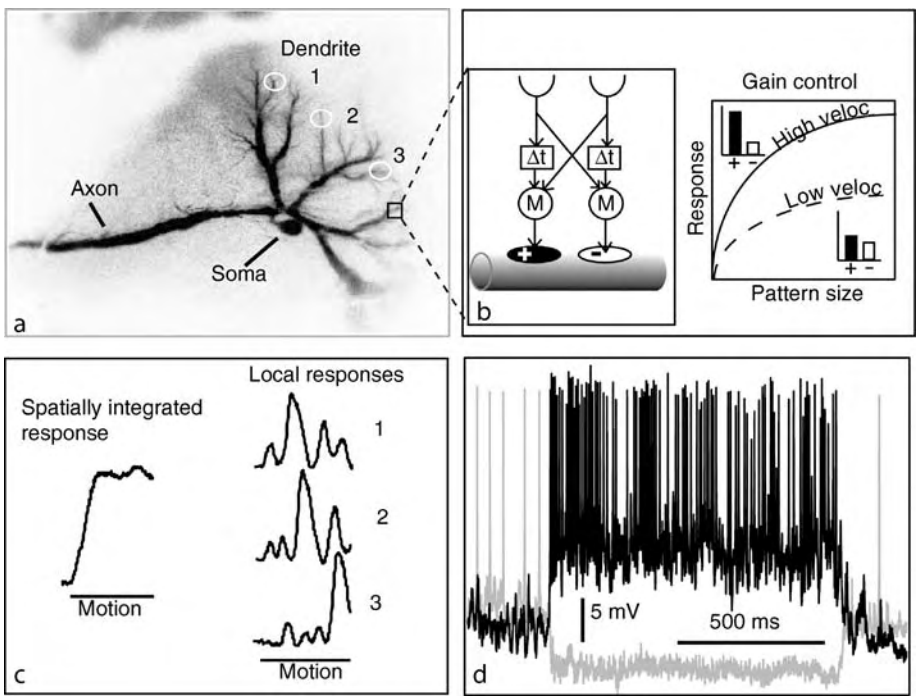
**Neuroethology of Visual Orientation in Flies.**
**Figure 2** Scheme of the principle processing steps in visual course control. When moving through a landscape, the images of the surroundings move across the retina of the observer. This optic flow is indicated by the arrows in the uppermost box. The local luminance values of the scene are sensed by a two-dimensional array of photoreceptors. The next layer indicates that this information is spatially and temporally processed in parallel for the entire array of retinotopically organised, local elements. Consecutively, motion is computed on a local basis. Motion information is then spatially pooled over extended parts of the visual field. Again, this process takes place in parallel for different parts of the visual field. In the simplest case, this global motion information is then temporally filtered, and used directly to control behaviour that in turn changes the retinal input. The connections between consecutive elements are only indicated for the foremost row.

## Computation of Local Motion Information

Directionally selective responses to motion are computed on a local retinotopic basis in the second visual neuropile, the medulla. The cellular mechanism underlying ►motion detection is still largely unknown because of the difficulties in recording the activity of the extremely small neurons in this brain area (review: [6]). However, the computational properties of this processing step have been revealed in detail. They can be described by a computational model, the so-called correlation-type movement detector (Fig. 3b, reviews: [1,2]). This movement detector is composed of two mirror-symmetrical subunits. In each subunit, the input arising from two neighbouring points in visual space are compared by a multiplication after one of them has been delayed. Subtracting the outputs of the two subunits yields the final detector response.

## Dendritic Integration of Local Motion Information

In order to evaluate the global structure of optic flow fields, local motion information needs to be combined from large parts of the visual field. This is accomplished by the large motion-sensitive neurons in the third visual



**Neuroethology of Visual Orientation in Flies. Figure 3** ►Dendritic integration and response properties of fly tangential cells (TCs). (a) Image of a TC after it has been injected with a fluorescent dye (Warzecha A-K, unpublished fluorescent photography). (b) TCs acquire their direction selectivity by dendritic integration of the signals of two types of input elements with small receptive fields and opposite preferred directions (*left*). One type of input element is excitatory whilst the other is inhibitory. Many properties of the local input elements can be modelled successfully by correlation-type movement detectors. This type of detector consists of two mirror symmetrical subunits that share their input signals. The delayed (Δt) signal of each movement detector input line is multiplied (M) with the un-delayed signal of the other input line. The outputs of the two subunits are subtracted from each other. Due to the fly's panoramic vision, nearly every point in visual space is subserved by such an input pair. Both subunits of the movement detector are activated even during preferred direction motion. Several hundreds of such local movement detectors impinge onto the TC dendrite. With increasing pattern size, i.e. with an increasing number of activated input elements, the postsynaptic potential saturates at a level between the excitatory and the inhibitory reversal potentials (*right diagram*). The exact value of saturation is set by the activation ratio of excitatory and inhibitory input elements, which in turn is a function of stimulus parameters such as velocity or contrast (*right diagram*). (c) Dendritic integration smoothes out pattern dependent fluctuations in the time course of the local inputs. The local responses elicited in three different areas of the dendrite (schematically indicated by *white circles* in a) are plotted underneath each other. In the axon, these time-varying signals are integrated and the fluctuations are largely smoothed out. (d) Single responses of a TC to preferred (*black*) and null (*grey*) direction motion. This TC responds even close to its output terminal with graded changes of the membrane potential that are superimposed by spikes. Electrophysiological data courtesy of Jan Grewe.

neuropile, known as tangential cells (TCs). With their large dendritic trees, they pool motion information from up to about 3,000 retinotopically arranged directionally selective input elements (reviews: [1,2,7,8]). Two types of input elements with opposite preferred direction of motion converge onto the dendrite of TCs, one excitatory and the other inhibitory. Consequently, TCs respond directionally selective to motion in a large part of the visual field (Fig. 3).

The preferred directions of the local retinotopic elements that synapse onto a given TC have been concluded to coincide with the directions of velocity vectors characterising the optic flow induced during particular types of self-motion [8]. Hence, the spatial input organisation of TCs forms a basis for their sensitivity to optic flow.

Approximately 60 different TCs can be individually identified on the basis of their physiological and anatomical characteristics. Some TCs have been suggested to respond specifically to the optic flow resulting from certain types of self-motion (but see below), whereas others detect movements of small objects. Depending on the cell type, TCs respond to visual motion by graded shifts of their membrane potential, by spike-like events superimposed on graded membrane potential shifts (Fig. 3d) or by large amplitude action potentials (reviews: [1,2,7]).

►Dendritic integration of the local motion signals influences the representation of optic flow in several ways (Fig. 3, [1,3]): (i) Representation of velocity: The responses of the retinotopic input elements of the TCs modulate in time even during constant-velocity motion depending on the local luminance changes of the moving pattern (►dendritic integration/dendritic processing). By pooling over many input elements that all experience phase-shifted luminance changes, these response modulations are smoothed out and the integrated signal becomes to some extent proportional to the velocity of the stimulus (Fig. 3c). (ii) Gain control: Saturation nonlinearities of the pooling TCs render their responses largely independent of pattern size while they still depend on other stimulus parameters such as velocity or contrast.

## Integration of Global Motion Information from Populations of Motion-Sensitive TCs

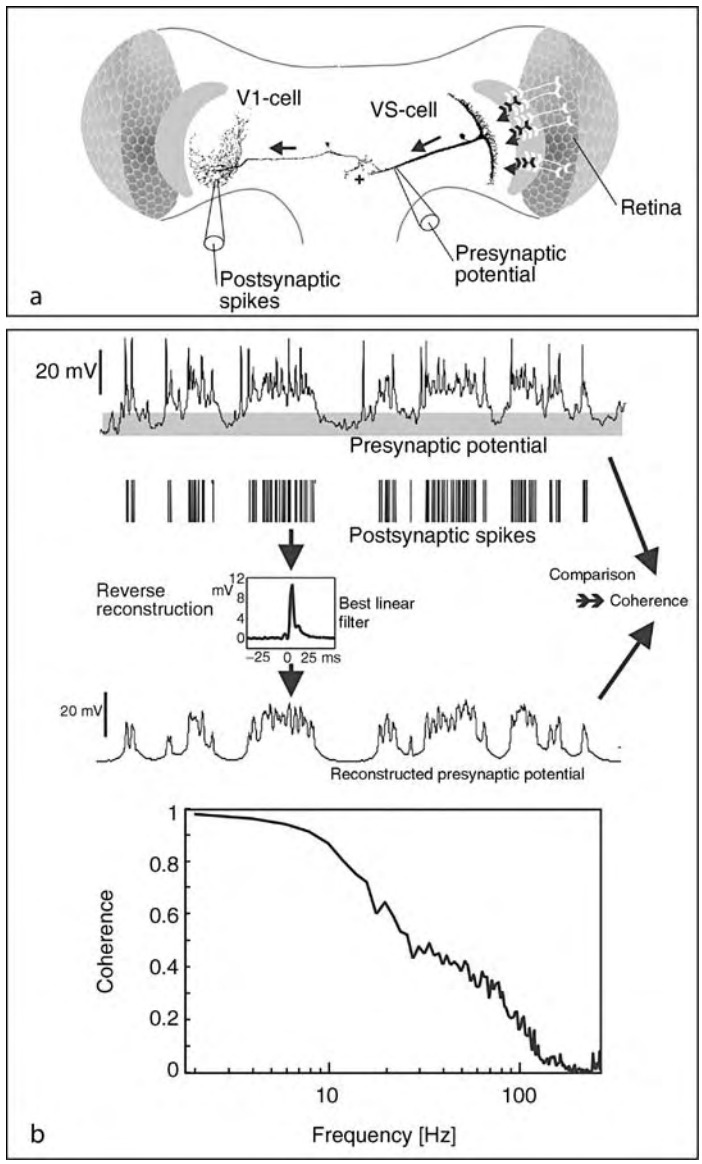
Dendritic pooling of local motion information is not the only computation that takes place in the blowfly visual motion pathway to obtain a representation of global optic flow. Instead, motion information from various TCs is pooled at the level of the lobula plate (reviews: [1,10]). This processing step is assumed to render TCs more specific to particular types of self-motion, such as rotation or translation, or to tune them to the detection of a nearby object moving in front of a more distant background.

Pooling motion information from several TCs requires synaptic transfer. Unless the intervening synapses are carefully adjusted to the presynaptic activity levels that occur during sensory stimulation, synaptic transmission may distort the information being transmitted. The properties of the transmission of pre- to postsynaptic signals has been investigated in detail by electrophysiological and optical imaging studies for various pairs of TCs that differed with respect to the response modes of the pre- and postsynaptic neuron (reviews: [2,9]). For one synaptic connection, it could show, for instance, that signal transfer is linear for frequencies up to about 10 Hz (Fig. 4). This synaptic tuning appears to be adaptive, because in this frequency range TCs transmit most information about changes in the velocity of motion stimuli.

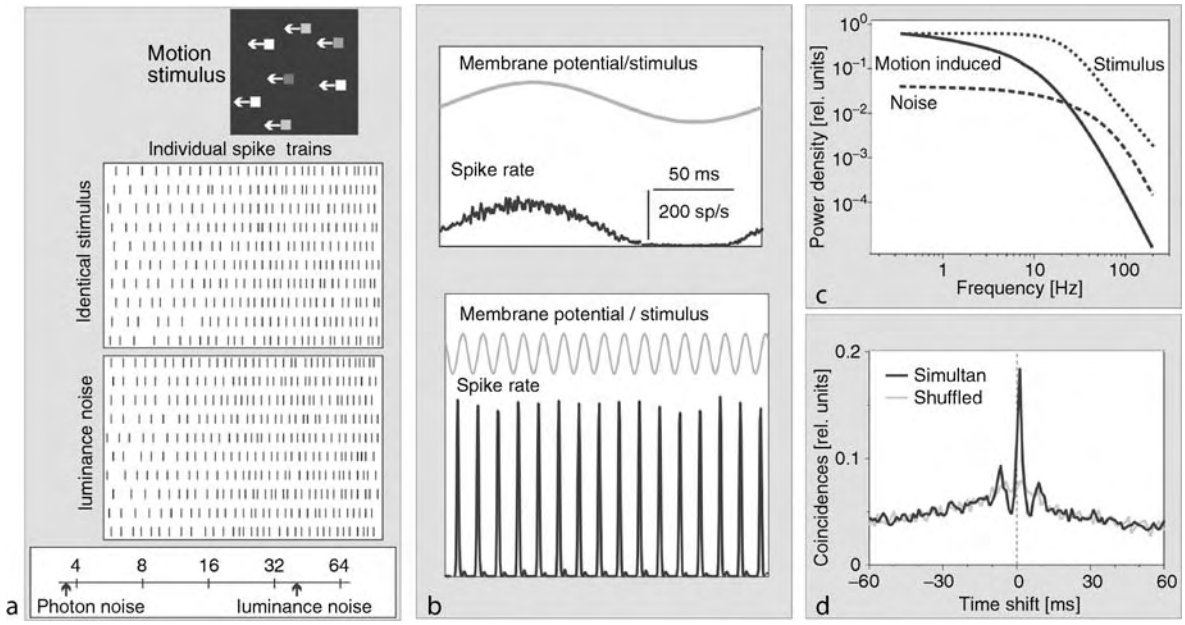
## Reliability of Encoding Visual Motion Information

In order to understand the performance of motion-sensitive neurons in real time, the analysis of the mechanisms of motion computations need to be complemented by investigating how reliably these neurons represent visual motion information. Due to noise from several sources, neuronal responses to repeated presentation of the same stimulus are variable. Although the spike count variance across trials is relatively small in blowfly TCs (review: [10]), significant neuronal response variability still constrains the timescale on which time varying optic flow characteristic of behavioural situations can be conveyed. The noise sources limiting the performance are still under investigation. However, photon noise could be shown not to limit the reliability of a TC in representing a motion stimulus, at least under photopic conditions (Fig. 5a, review: [2]).

The process of generating spikes from the postsynaptic potential is generally thought not to limit the timescale of motion information processing. Accordingly, spikes in TCs time-lock with a millisecond precision to a motion stimulus, if the stimulus induces fast membrane potential fluctuations that are larger than the membrane potential noise (Fig. 5b, c). If, however, the motion stimulus induces only slow membrane potential fluctuations, the exact timing of spikes is determined by the high frequency components of the membrane potential noise. Then spikes are not precisely time-locked to the stimulus and the spike rate rather than spike timing reflects the stimulus induced changes. Since the computations underlying motion detection require time constants of some tens of milliseconds, motion computation inevitably attenuates the neural representations of high frequency velocity fluctuations. Hence only when the velocity changes in the motion stimulus are very rapid and large, the resulting depolarisations of the TCs are sufficiently pronounced to elicit spikes at a millisecond precision. It is still under debate to what extent rapid and slow velocity



**Neuroethology of Visual Orientation in Flies. Figure 4** Synaptic transmission between two motion sensitive tangential cells (TCs). (a) Schematic of the visual motion pathway of the fly illustrating the compound eyes, the local retinotopically organised local elements involved in the local computation of motion, and a particular TC, a so-called VS-cell, that spatially pools the output of the small-field motion sensitive elements with its large dendrite. The VS-cell is synaptically coupled to the V1-cell that transmits optic flow information to the contralateral half of the brain via its extended output arborisation (anatomical reconstructions taken from Hausen K, Egelhaaf M (1989) Neural mechanisms of visual course control in insects. In: Stavenga DG, Hardie RC (eds) Facets of vision. Springer, pp 391–424; and Krapp et al (1998) J Neurophysiol 79:1902–1917, with permissions). (b) Presynaptic membrane potential of a VS-cell and postsynaptic spike train of the V1-cell (occurrence of a spike indicated by a *vertical line*) during presentation of white noise velocity fluctuations. In order to quantitatively relate the time-dependent postsynaptic signal to the presynaptic input, the reverse reconstruction approach was applied as schematically outlined in the figure. For this approach, the linear filter was determined that when convolved with the presynaptic spike train leads to the best estimate of the presynaptic potential. Since hyperpolarisations do not have much effect on the activity of the postsynaptic neuron, the presynaptic potential was rectified at the resting potential (shaded bar underneath the presynaptic potential trace). The coherence function serves as a measure of the similarity of the recorded and the estimated presynaptic membrane potential traces. Coherence values close to 1 for frequencies up to 10 Hz indicate that the system can be regarded as very reliably and approximately linear in this frequency range (modified from Warzecha A-K et al (2003) Neuroscience 119:1103–1112, with permission from Elsevier).



**Neuroethology of Visual Orientation in Flies. Figure 5** Reliability of motion sensitive neurons in the fly. (a) Origin of ►neuronal variability. The equivalent noise paradigm was adapted to investigate whether photon noise limits the reliability of the motion detection system. In order to mimic photon noise, the luminance of individual dots was chosen randomly. The motion stimulus consists of a group of coherently moving dots with variable luminance. The two raster plots illustrate a 300 ms section of the responses of a spiking TC. Each vertical bar denotes the occurrence of a spike. Consecutive responses are plotted underneath each other. Either exactly the same luminance values were presented (*upper raster*) or new luminance values were drawn randomly for each trial (*lower raster*). Even if exactly the same stimulus was presented from trial to trial, there is considerable neuronal variability. Analyses derived from signal-detection theory revealed that the response statistics are affected only when luminance noise is much larger than photon noise (*bottom*). Hence, photon noise does not limit the reliability of a motion sensitive neuron under photopic conditions (details in Grewe et al (2003) J Neurosci 23:10776–10783. (b) Time-locking of spikes to sinusoidal stimulus-induced membrane-potential fluctuations (5 and 80 Hz) in a model cell. The model is adjusted to fit the responses of a fly TC to motion stimuli. The stimulus-induced membrane potential fluctuations fed into the model cell were superimposed by stochastic fluctuations mimicking ►neuronal noise. PSTHs illustrate that fast stimulus-induced membrane potential fluctuations are necessary to trigger spikes with a high temporal precision. Slow stimulus-induced fluctuations lead to spike activity with a rate about proportional to the membrane potential (details in Kretzberg et al (2001) J Comput Neurosci 10:79–97, with permission). (c) Dynamic properties of membrane potential fluctuations of a fly TC (HS-cell) elicited by band-limited white-noise velocity fluctuations. Power spectra of the motion stimulus (*dotted*), the motion induced response component (*solid*) and the stochastic membrane potential fluctuations (*dashed*). The motion induced response component was obtained by averaging many individual response components thereby smoothing out stochastic response fluctuations. The stochastic response component results from the difference of each individual response trace to the motion-induced component. The motion-induced component contains most power below 20 Hz, although the stimulus contained higher frequencies. In the low frequency range, the motion-induced response component is larger than the stochastic response component. At higher frequencies, the relationship reverses (details in Warzecha et al (1998) Curr Biol). (d) Cross-correlogram of responses of two TCs (H1 and H2) to band-limited white-noise velocity fluctuations. Either synchronously recorded responses were cross-correlated (*black*) or responses were not recorded synchronously but obtained from the same cell pair in repetitive presentations of the same stimulus (*grey*). AlthoughTCs can generate spikes very precisely (*black*), most spikes time-lock even to dynamical motion stimulation on a much coarser time scale (reprinted from Warzecha et al (1998) Curr Biol 8:359–368, with permission from Elsevier).

changes and thus the exact timing of spikes are functionally significant (review: [10]). This issue can only be resolved if the dynamics of the retinal image displacements as experienced by the blowfly in different behavioural contexts are taken into account.

## Encoding of Visual Stimuli Under Naturalistic Conditions

The functional significance of the information that is processed in the visual motion pathway of the blowfly can be assessed only by analysing the neuronal

performance under conditions the blowfly experiences in a normal behavioural situation. These conditions comprise of the properties of the visual stimuli with respect to e.g. their dynamics, brightness and textural properties, as well as the context in which they appear with respect to the stimulus history and the internal state of the animal. The stimulus history has been shown to affect the properties of several processing stages along the visual motion pathway including TCs (review: [9]).

Due to technical advances, it has recently become possible to confront the blowfly with visual stimuli that come close to those the blowfly is confronted with in natural situations. Natural stimuli differ largely from those usually employed for an analysis of the mechanisms underlying visual motion processing. This difference in particular pertains to the dynamics of natural optic flow, which is largely determined by the animal's self-motion. Since it is not yet possible to record from neurons in freely moving flies in order to assess the functional role of TCs, an alternative approach has been chosen (review: [3]). The trajectories of freely moving flies were recorded in known surroundings; the optic flow experienced by the flies was reconstructed and then replayed to the animal while recording the activity of a TC in electrophysiological experiments. Using a naturalistic behaviourally generated optic flow led to conclusions that partly contradict those obtained with simple experimenter-designed motion stimuli. The neuronal responses of a TC previously thought to encode rotations of the animal about its vertical body axis astonishingly provide information about the spatial relation of the animal to its surroundings. Thus, one of the great issues of future research is to understand how the neuronal hardware that underlies a given behaviour processes information under natural operating conditions.

### Outlook

With their relatively simple and accessible nervous system, blowflies are excellent organisms in which to investigate how visual information is acquired and processed to guide locomotion. Many important aspects of the neuronal computations that underlie visually guided behaviour in blowflies have been elucidated in recent years, ranging from the biophysical properties of individual neurons and their synaptic interactions, to the performance under conditions that come close to what the animal might encounter in normal behaviour. In almost all parts of the above mentioned aspects, models have proved to be an essential element for unravelling the mechanisms underlying visual orientation behaviour in flies (reviews: [1,2]). Also in future research, models will serve as touchstones to challenge our hypotheses about how the blowfly manages to control its virtuosic flight behaviour. It thus appears possible, by studying the blowfly visual system, to understand visually guided behaviour under naturalistic conditions at the level of individual neurons and small neuronal networks.

## Neurofibroma

### Definition

Neurofibroma is a benign neoplasm composed of the fibrous elements of a nerve.

## Neurofibromatosis Types I (NF-I) and Type II (NF-II)

### Definition

Autosomal-dominantly inherited neuro-cutaneous disorders presenting with a plethora of manifestations involving the central and peripheral nervous systems, the circulatory system, the skin, and the skeleton.

Lifespan is reduced, frequently due to malignant tumors and hypertension. The common *neurofibromatosis type I (NF-I)* results from an alteration in the long arm of chromosome 17. The diagnosis is clinically based on the presence of two of seven criteria. One criterion is the presence of neurofibroma (a benign peripheral nerve sheath tumor), which is one of the most frequent tumors of neural origin. Others include are central nervous system tumors, skin lesions (café au lait spots), bone malformations and vascular abnormalities. *Neurofibromatosis 2 (NF2)* is clinically and genetically distinct from NF-I by being rarer, exhibiting less skin manifestations and malignant tumors, with the cardinal sign being bilateral vestibular ►schwannomas and ocular abnormalities (cataract).

## Neurofilament

### Definition

Neurofilaments are intermediate type cytoskeletal proteins which lend structural support to especially axons. They are thought to play a major role in determining the axonal caliber (diameter of the axon). These proteins are intermediate filaments being composed of three different proteins: NF-L (low weight), NF-M (medium weight) and NF-H (high weight).

Developing neurons produce few neurofilaments, however once the growth phase is complete neurofilaments are seen extending from the soma into both axons and dendrites providing structural support to these processes. Neurofilaments can be used to identify and visualize mature neurons using histochemical techniques.

## Neurogenesis

Koji Oishi, Kazunori Nakajima
Department of Anatomy, Keio University School of Medicine, Tokyo, Japan

### Definition

In the narrow sense, "neurogenesis" is the process by which neurons are generated by their progenitor cells. However, the term "neurogenesis" is occasionally used in the broad sense to refer to the entire process of generating functionally mature neurons, including the process of proliferation and neuronal fate specification of progenitor cells and regulation of the cell death of neurons/progenitor cells.

Neurogenesis in the mammalian central nervous system (CNS) used to be thought to occur only during early embryonic development and only recently has it come to be generally accepted that new functional neurons are generated in at least two regions of the adult brain, the ►subventricular zone (SVZ) along the lateral ventricle and the subgranular zone (SGZ) of the dentate gyrus in the hippocampus [1].

### Characteristics

#### Quantitative Description

Approximately 100 billion neurons are thought to be present in the human CNS, and even in mice the number is estimated to be about 40 million. Since each neuronal progenitor cell produces one or two neurons for each

neurogenic cell division, a comparable number of progenitor cells is necessary. Moreover, 50–80% (depending on the region) of the neurons generated undergo apoptosis during formation of the neural network in the neonatal CNS, suggesting that much more neurogenesis has to occur to establish the mammalian CNS [2].

It is estimated that about 80,000 and 9,000 new neurons a day are produced in the SVZ and SGZ respectively of the adult rat brain. However, more than 50% of them are eliminated by apoptosis within a week.

## Higher Level Structures

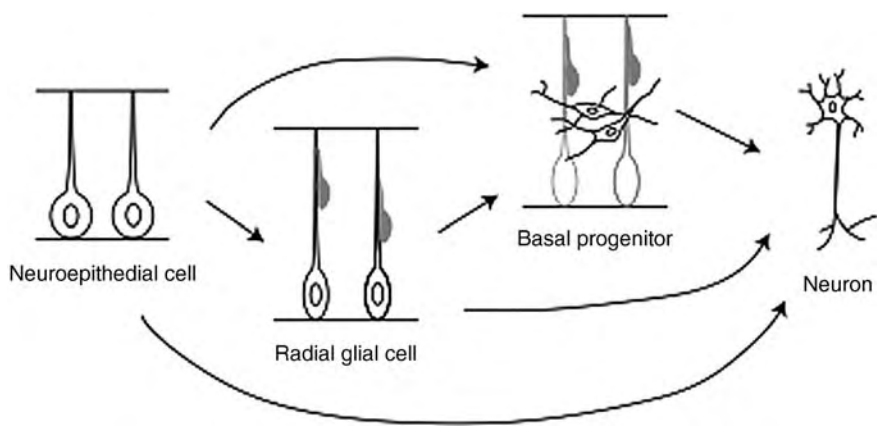
Before neurogenesis, the neural plate and neural tube are composed of neuroepithelial cells that form a pseudostratified epithelium. Neuroepithelial cells are bipolar and each of them extends from the apical (ventricular) surface to the basal lamina (radial orientation). Neuroepithelial cells translocate their nucleus from the top to the bottom of the ►neuroepithelium during the cell cycle (referred to as interkinetic nuclear migration or elevator movement) [3]. As the neuroepithelial walls thicken at around E12.5 in the mouse telencephalon, the primitive neuroepithelial cells elongate, while maintaining their orientation and become ►radial glial cells, which are defined as cells with a radial morphology and some glial characteristics (e.g. glycogen granules). The cell bodies of the radial glial cells are in the ►ventricular zone (VZ) and the cells undergo cell divisions at the ventricular surface. One of the most exciting recent discoveries is that radial glial cells, which used to be thought of primarily as migratory scaffolds for young neurons and as glial progenitors, are neurogenic progenitors. A distinct type of progenitor cells, referred to as basal progenitors (also called SVZ, intermediate, or non-surface-dividing progenitors), has been identified as cells that lose contact with the ventricular surface and undergo cell division away from the surface. At later stages basal progenitors are mainly present in the SVZ, a histologically distinct structure adjacent to the VZ. These three cell types, neuroepithelial cells, radial glial cells and basal progenitors, all contribute to the generation of neurons (Fig. 1; see also higher level processes) [4,5].

A primate-specific layer of progenitor cells called the outer SVZ has recently been described and shown to be one of the major sites of cortical neuron production in primates. In contrast to the basal progenitors in rodents, these cells in primates possess radial morphology, strongly suggesting that they are polarized cells [6].

What is the site of neurogenesis? In the embryonic stages, CNS neurons are produced from almost all regions of the neuroepithelium in the neural tube with the exception of a few specialized areas, such as the optic stalk and the floor plate and roof plate of the spinal cord. The onset and period of neurogenesis vary greatly depending on the location along the neuraxis. During the development of the dorsal pallium, for example, neurogenesis, including developmental changes in cell cycle dynamics, maturation of the cortical plate and later events (such as the development of callosal projections or synaptogenesis), progresses along a latero-rostral to medio-caudal gradient.

Neurons in the peripheral nervous system (PNS) are generated from neural crest cells that originate at the border between the neural plate and the prospective epidermis. Around the time of neural tube closure, neural crest cells emigrate from the neural tube, migrate along defined paths in the embryo and differentiate into a wealth of derivatives, including PNS neurons [7].

In most mammals, active neurogenesis occurs throughout life in discrete regions of the intact adult CNS. From rodents to primates, neurons are generated continuously in the SVZ along the lateral ventricle and migrate anteriorly through the rostral migratory stream



**Neurogenesis. Figure 1** Various lineage relationships have been shown to exist or are thought to exist between neuroepithelial cells, radial glial cells, basal progenitor cells and neurons. Three types of progenitor cells contribute to the generation of neurons in the mammalian central nervous system.

into the olfactory bulb to become interneurons. In the SGZ of the dentate gyrus of the hippocampus, new granule neurons have been found to be continuously produced locally in all mammals examined, including humans. Neurogenesis in the intact adult mammalian CNS outside these two regions appears to be extremely limited or nonexistent. After pathological stimulation, such as by a brain insult, adult neurogenesis appears to occur in regions otherwise considered non-neurogenic [1].

## Higher Level Processes

Neuroepithelial cells, radial glial cells and basal progenitors have been shown to generate CNS neurons. All three types of these progenitor cells are known to undergo symmetric or ►asymmetric cell divisions during neurogenesis. ►Symmetric cell divisions generate two daughter cells having the same fate while asymmetric cell divisions generate one daughter cell that is identical to the mother cell and a second cell of a different type. Progenitor cells are thought to produce neurons by a variety of processes (Fig. 1) [4,5].

Early in development both neuroepithelial cells and radial glial cells increase in number by undergoing symmetric divisions that lead to the expansion of the progenitor pool and the neural tube wall. There is another type of ►symmetric cell division that produces two neurons. Some neuroepithelial cells and radial glial cells and almost all basal progenitors are thought to divide by this type of cell division. However, the symmetric neurogenic divisions may very well be asymmetric in terms of neuronal subtype, consistent with the observation that some pairs of neurons arising from single progenitors have been found to differ in the expression of certain transcription factors.

Most radial glial cells divide asymmetrically, with some divisions generating another radial glial cell and a neuron, while others generate a radial glial cell and a basal progenitor. This type of cell division enables progenitor cells to generate neurons without losing the characteristics of the original cell.

Neuroepithelial cells and radial glial cells undergo cell division at the ventricular surface, whereas basal progenitors divide away from the surface. Investigation of the relationship between the location of the dividing cell and cell fate has shown that basal divisions only generate neurons, consistent with the expression of neuronal markers in basal progenitors. This finding suggests that basal progenitors are committed to the neuronal lineage. The length of the cell cycle of the basal progenitors is also different. They have a longer G2 phase than progenitors that divide at the ventricular surface [4].

## Lower Level Processes

How do the immature neurons generated behave after neuronal differentiation? Various classes of CNS neurons migrate from their birthplace to their final positions [8]. In the developing neocortex, neurons are generated in the VZ and/or SVZ and then move to the developing cortical plate via radial migration. Recent studies by time-lapse imaging in slice cultures have revealed three modes of radial movement by cortical neurons. They are described briefly as ►somal translocation, in which the cell body moves toward the pial surface by shortening its radial process, ►locomotion, i.e. guided migration in which neurons move to a position beneath the pial surface along the basal process of radial glia and ►multipolar migration, migration of neurons residing in the SVZ and intermediate zone in which neurons with multiple processes extending and retracting dynamically move slowly toward the pial surface. In addition, most cortical interneurons in mice are known to derive from the subpallial telencephalon, including the medial and caudal ganglionic eminences and to migrate tangentially into the pallium. While medial ganglionic eminence-derived cells migrate laterally and spread widely throughout the cerebral cortex, caudal ganglionic eminence-derived cells migrate caudally toward the caudal-most end of the telencephalon (named the caudal migratory stream) and spread into the hippocampus and posterior cerebral cortex. There may be additional modes of neuronal migration in distinct areas that lead to the construction of elaborate structures.

## Process Regulation

A number of pathways regulating neurogenesis in the CNS have recently been identified [9]. Extrinsic cues, including cell-cell interactions and secreted molecules, are key determinants of progenitor cell fate regulation. Exposure to growth factors, such as fibroblast growth factor (FGF)-2 and epidermal growth factor (EGF), as well as activation of the transmembrane receptor Notch, inhibits neuronal differentiation from progenitor cells, while several extrinsic factors (such as platelet-derived growth factor [PDGF], vascular endothelial growth factor [VEGF], neurotrophic factors, etc.) promote neuronal differentiation.

The molecular machinery governing whether progenitor cells divide symmetrically or asymmetrically has recently begun to be unraveled and centrosomal proteins and heterotrimeric G-proteins have been reported to control these divisions. Nde1, a central component of the centrosome, is expressed in the VZ and Nde1-deficient mice have smaller brains as a result of an increase in asymmetric cell divisions that leads to premature neurogenesis and depletion of the progenitor pool. Other centrosomal proteins, such as ASPM (abnormal spindle-like microcephaly associated), CDK5RAP2 and CENPJ, have been shown to be crucial determinants of cerebral cortex size, suggesting that these proteins also participate in the regulation of symmetric and asymmetric cell divisions. In addition, the Gβγ subunits of heterotrimeric G-proteins have recently been reported to play a key role

in regulating spindle orientation and the asymmetric cell fate of progenitor cells [5].

Two transcription factors have been reported to have a role in determining whether progenitor cells undergo symmetric or asymmetric progenitor cell division. Emx2, a homeodomain transcription factor, promotes symmetric cell divisions by progenitor cells, whereas the paired-type homeodomain transcription factor Pax6 promotes asymmetric, neurogenic cell divisions. These transcription factors may therefore regulate cell fate and the appropriate mode of cell division in a coordinated manner.

## Pathology

One of the neurodevelopmental disorders, autosomal recessive primary microcephaly (MCPH), has been suggested to be the result of deficient neurogenesis within the neuroepithelium [10]. MCPH is characterized by two principal features, microcephaly (small brain) present at birth and nonprogressive mental retardation. There are at least seven MCPH loci, and four of the genes have been identified, MCPH1, Microcephalin; MCPH3, CDK5RAP2; MCPH5, ASPM and MCPH6, CENPJ. Present evidence suggests that these genes are involved in mitosis by neural progenitor cells and are presumably related to DNA repair and control of mitotic spindles. Autosomal recessive periventricular heterotopia with microcephaly (ARPHM) is another disorder related to deficient neurogenesis and it has recently been reported that mutations in the ARFGEF2 gene cause ARPHM. This finding suggests that vesicle trafficking in neural progenitors is an important regulator of their proliferation and migration during cerebral cortical development.

Genetic studies of human malformations have proved a surprising source for discovery of molecules that regulate neuronal migration [8], including doublecortin and Lis1, mutations of which cause a profound migratory disturbance known as classical lissencephaly (smooth brain). There are other lissencephaly syndromes and mutations in the RELN (reelin) gene have been found in lissencephaly with cerebellar hypoplasia. X-linked lissencephaly with abnormal genitalia is associated with agenesis of the corpus callosum and ambiguous or underdeveloped genitalia. Mutations in the Aristaless-related homeobox transcription factor gene, ARX, have recently been found in these patients.

# Neurogenesis and Inflammation

Liliana Bernardino, Fabienne Agasse, João O. Malva
Center for Neuroscience and Cell Biology, Institute of Biochemistry, Faculty of Medicine, University of Coimbra, Coimbra, Portugal

## Definition

Inflammation and ►neurogenesis is a research area devoted to dissect the functional interplay between brain immune response and inflammation and production of new neurons and self-repair capacity of the brain.

## Characteristics

### Introduction

Until recently, the brain was considered as an immune privileged organ, unable to respond with an immune reaction in response to neurodegeneration or to infection, a property mainly attributed to the special protection conferred by the endothelial barrier. However, in the last decade the immune privileged status of the brain has been questioned mostly because in pathological conditions, molecules and cells of the immune system enter the brain and target the brain parenchyma [1]. In healthy conditions, the Central Nervous System (CNS) is routinely surveyed by few immune cells (e.g., T lymphocytes) in search of pathogens. Nevertheless, under pathological

conditions, T cells accumulate and can reach relatively high density in inflammatory sites in brain parenchyma. Moreover, it is now well known that the inflammatory response in the CNS (►neuroinflammation) comprises a complex and integrated interplay between different cellular types of the immune system (macrophages, T and B lymphocytes, dendritic cells) and resident cells of the CNS (►microglia, astrocytes, oligodendrocytes, neurons).

Recently, neurogenesis in the CNS has emerged as an important physiological process, especially for plastic structures like the hippocampus and the olfactory bulb. The identification of stem cell niches in the adult brain opens new and fascinating perspectives for future development of strategies for ►brain repair. With this major challenge in mind we must better understand how local cell microenvironment and inflammation (usually accompanying neurodegeneration) affects the final outcome of stem cell proliferation and differentiation.

## Inflammation in the Brain

### *Microglia: The Brain Immune Survey*

Microglial cells are the major resident immunocompetent population of cells in the CNS parenchyma. Under physiological conditions, microglia cells display a resting-like phenotype with a ramified morphology and a low or absent expression of immunological molecules and their receptors. Although, in response to an injury, microglial cells became rapidly activated, changing to a round-shaped morphology with thickened and short or retracted processes, proliferate, are recruited to the site of injury and strongly up-regulate the expression and the release of inflammatory mediators such as pro-inflammatory ►cytokines, ►chemokines, reactive oxygen species and nitric oxide [2]. Equipped with receptors and ion channels, microglia can sense their microenvironment and detect the appearance of unusual concentrations of several soluble factors such as neurotransmitters, abnormal endogenous proteins such as beta-amyloid peptide, cell debris and exogenous compounds such as the endotoxin lipopolysaccharide (LPS) and some viruses. LPS, a component of the outer membrane of Gram-negative bacteria, is a well known inducer of cytokines, chemokines and other inflammatory mediators in brain experimental models of neuroinflammation. The most well accepted assumption is that the primary role of activated microglia is to support neuronal function; however, the sustained or excessive activity of these cells may have detrimental consequences and can be associated with the onset and/or exacerbation of neuronal death associated with neurodegenerative disorders [2].

### *Cytokines*

An essential feature of the early immune response to pathogens and cell debris is secretion of pro-inflammatory cytokines by immune cells. Cytokines are low molecular weight proteins responsible for the communication between glial, neuronal and immune cells. Upon binding to their receptors, either soluble or located on the cell membrane, several intracellular pathways are usually triggered, which in turn regulate the activity of transcription factors such as NF-κB, and AP-1. The expression of these molecules and their respective receptors in the CNS are barely detectable under normal conditions, but become stimulated in response to pathological conditions, like ischemia, excitotoxicity and epilepsy. In the brain, cytokines can be originated from two different sources: (i) from infiltrating peripheral immune cells (lymphocytes and macrophages); (ii) from CNS resident cells (neurons, microglia, astrocytes, oligodendrocytes, endothelial cells and perivascular microglia). Functionally, cytokines have been described as being either pro-inflammatory (e.g., Tumor Necrosis Factor (TNF)-α, Interleukin (IL)-1β) or anti-inflammatory (e.g., IL-10, Transforming Growth Factor (TGF)-β, IL-1ra) depending on the final balance of their effects. Although, contributing to the complexity of this classification, the functional role of individual cytokines in CNS inflammation can shift from beneficial to detrimental [3]. Moreover, many cytokine actions are indirect, acting by stimulating the synthesis and function of other cytokines, resulting in a complex "cytokine cascade" triggered by immune and inflammatory responses. Cytokine activity can also be modulated by neurotransmitters, neuropeptides, growth factors and hormones. Therefore, cytokines can act in the CNS as both immunoregulators and neuromodulators in health and disease.

### *Chemokines*

Chemokines are a family of chemo-attractant proteins, structurally related to cytokines with a major role in chemotaxis. In the CNS, chemokines and their receptors are constitutively expressed, at low levels, in astrocytes, microglia, oligodendrocytes, neurons and endothelial cells both in the developing and healthy adult brain, and their expression is induced by inflammatory mediators [4]. They have been reported to be involved in the developmental organization of the brain and in the maintenance of normal brain homeostasis by regulating the migration, proliferation and differentiation of glial and neuronal precursor cells. Moreover, other physiological functions of chemokines have been reported in CNS, such as regulation of synaptic transmission and plasticity, regulation of neurotransmitter release, modulation of ion channel activity, and cell death and survival. Up-regulation or dysregulation of chemokines expression plays a crucial role in neurodegeneration and excitotoxicity, being involved in the communication between damaged neurons and surrounding glial cells and in the regulation of neuronal signaling by a diversity of

processes. Moreover, the expression of chemokines can be regulated by cytokines, and this has been associated with several acute and chronic inflammatory conditions in the CNS.

### Inflammation in Brain Diseases

The efficient regulation of the inflammatory cascade results from a fine-tune equilibrium of events regulating both immune privilege, in health, and effective responses to injury or disease. In general, acute inflammation is beneficial to the organism in limiting the survival and proliferation of invading pathogens and promoting regeneration of the tissue. However, prolonged, excessive inflammation is highly detrimental, leading to the onset and/or to the exacerbation of cell damage in neurodegenerative diseases. Increasing evidence has shown that neurotransmitters released from nerve terminals are involved not only in the communication between neurons, but also between nerve terminals and glial cells, including microglia. Most forms of neuronal injury have been associated with excitotoxicity, i.e., excessive release of excitatory amino acids such as glutamate, and subsequent activation of NMDA and AMPA/Kainate receptors. Besides glutamate, ATP is a co-transmitter released by injured or dying neurons. Thus, glutamate and ATP, play important roles in modulating microglia activation and in determining the fate and extent of neuronal injury. In particular, both IL-1β and TNF-α, released mainly by microglia, can be neuroprotective and/or neurotoxic, contributing directly or indirectly to the initiation, maintenance and outcome of neuronal cell death, including acute insults such as ischemia, trauma and seizures and chronic neurodegenerative disorders such as Parkinson's and Alzheimer's disease.

## Neurogenesis in the Brain

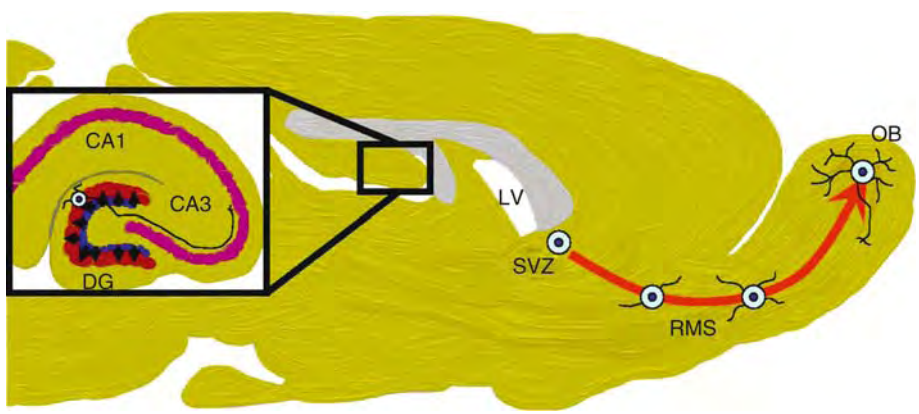
### Stem/Progenitor Cells and Neurogenesis

New neurons are constantly generated in the adult mammalian brain. This process called neurogenesis occurs mainly in two restricted regions: the subventricular zone (SVZ) and the dentate gyrus of the hippocampus (DG) (Fig. 1). The new neurons generated in the SVZ migrate long distances towards the olfactory bulb where they differentiate into functional interneurons, and contribute to improve odor memory and discrimination [5]. In the hippocampus, new neurons migrate out of the subgranular zone (SGZ) of the dentate gyrus (DG) and differentiate into the granule cell layer (GCL) where they mature and participate in hippocampal functions associated with learning and memory.

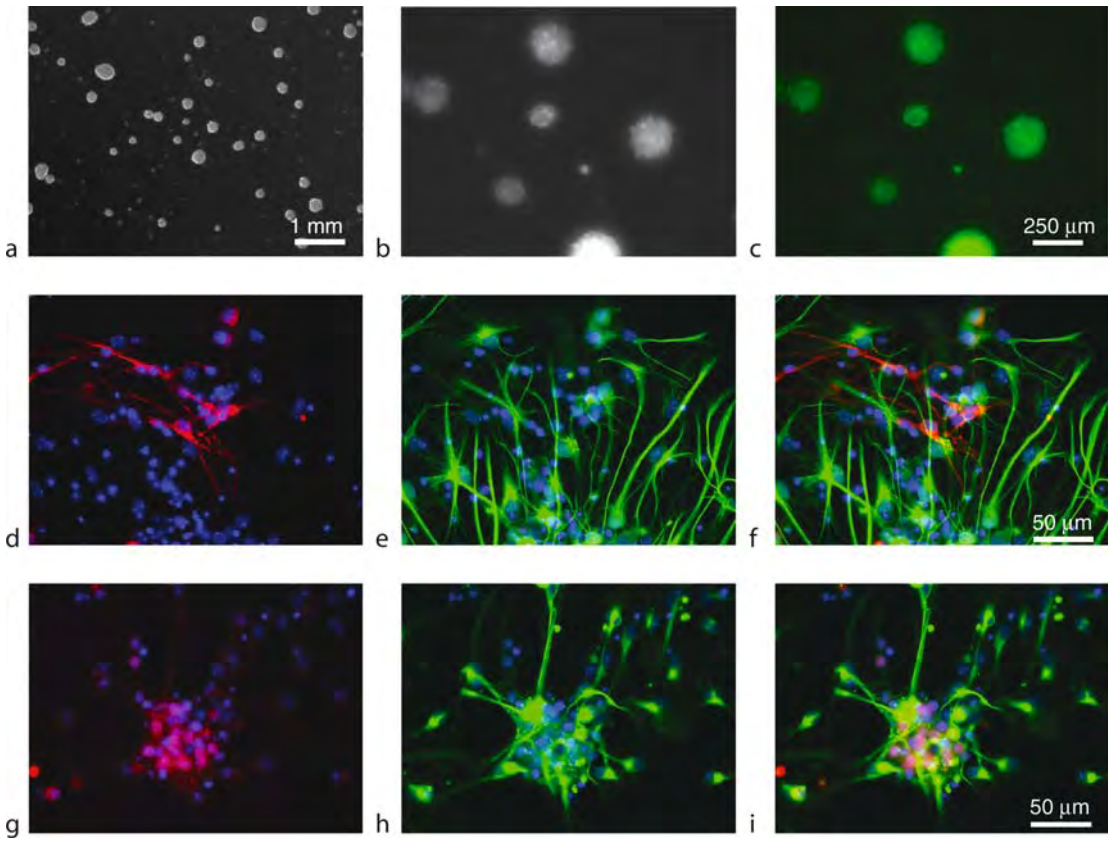
In both regions, new neurons arise from a particular population of cells: the ►stem cells/►progenitor cells. In vitro, the stem/progenitor cells constantly proliferate in the presence of growth factors (EGF, FGF-2). Proliferation of a single stem cell leads to the formation of a floating spherical neurosphere formed by a clone of immature cells. Plated on an adherent support, cells differentiate and migrate out of the sphere, where it is possible to identify the presence of neurons, astrocytes (Fig. 2) and oligodendrocytes.

### Neurogenesis/Gliogenesis and Self-Repair

Upon brain injury, neurogenesis is modulated in both the SVZ and the DG. Neurogenesis increases in the SVZ following injury, including neurodegenerative diseases, and newly born neurons can migrate towards lesion areas where they can differentiate and replace damaged neurons or oligodendrocytes [6,7]. Neurogenesis also increases in the DG after ischemia or epilepsy. However, in epilepsy, aberrant migration and synaptic



**Neurogenesis and Inflammation. Figure 1** Sagittal view of a rodent brain showing the localization of the neurogenic areas: subventricular zone (SVZ) and the dentate gyrus (DG) of the hippocampus. The new neurons generated in the SVZ, adjacent to the lateral ventricles (LV), migrate long distances through the rostral migratory stream (RMS) and integrate in the olfactory bulb (OB) where they differentiate into interneurons. The new neurons generated in the subgranular layer of the hippocampus migrate locally into the granular layer, of the DG, where they differentiate into new granular cells (adapted from Taupin and Gage, 2002, J. Neurosci. Res. 69:745–749).



**Neurogenesis and Inflammation. Figure 2** Representative photos of SVZ cell cultures from newborn mice in proliferation (a–c) and differentiation conditions (d–i).(a)–(c): in serum free medium with the growth factors EGF and FGF-2, SVZ cells generate clonal aggregates of cells called neurospheres (a–c). SVZ neurospheres obtained from GFP mice represent a useful tool for grafting studies (c).d–i: after plating on poly-D-lysine and withdrawal of the growth factors, cells arise from the edge of the neurosphere and develop into neurons expressing MAP-2 (d) and NeuN (g), and glial cells such as astrocytes expressing GFAP (e, h). (f) and (i) photos are merged of (d), (e) and (g), (h), respectively.

connections of newborn neurons may exacerbate recurrent seizures.

In spite of our growing knowledge about stem/progenitor cell physiology, efficient replacement of the damaged neuronal circuits is far away from full accomplishment using cell-based strategies of brain repair.

### *Neurogenesis and Inflammation in the Brain*

Inflammation, activation of glial cells and release of inflammatory mediators play ambiguous effects on neurogenesis with stimulatory or inhibitory roles, depending on the specific players and brain disorder.

### *Inflammation Promotes Neurogenesis/Gliogenesis*

Following injury, a great diversity of factors is secreted around the damaged area and these factors can diffuse, act on progenitor cells inducing neurogenesis/gliogenesis. For instance, injury-activated astrocytes and microglial cells produce the growth factors VEGF and FGF-2 and the pro-inflammatory cytokine (TNF-α) able to promote SVZ neurogenesis and proliferation. These processes involve the activation of transcription factors, including NF-κB.

In experimental demyelination, microglial cells secrete IL-1β that induces the secretion of IGF-1 by astrocytes, promoting proliferation of oligodendrocyte progenitor cells and remyelination [8].

### *Inflammation Inhibits Neurogenesis*

On the other edge of the sword, inflammation can inhibit neurogenesis and regeneration. Indeed, activated astrocytes that accumulate in the lesion core forming a glial scar can limit the propagation of the injury. However, the glial scar is also rich in repulsive axon guidance molecules such as proteoglycans, ephrins, semaphorins and Nogo. So, on the one hand the glial scar limits the propagation of the injury, but also constitutes a barrier for efficient regeneration.

In the hippocampus, seizure activity promotes neurogenesis, but subsequent neuronal death and

microglial activation inhibits neurogenesis hampering brain repair. In these conditions, systemic administration of minocycline, which inhibits microglia activation, restores neurogenesis in the dentate gyrus. Part of these effects may involve TNF-α, IL-6 and TGF-β since these cytokines are secreted by activated microglial cells and impair neurogenesis in the dentate gyrus [9].

In conclusion, the glial scar and "the dark side" of the inflammatory response appear to hold in check brain repair endeavors.

### *SVZ Cells as a Tool for Brain Repair*

The results of several studies show that SVZ cells are good candidates for cell-based therapy. For instance, in animal models of Parkinson's and Huntington's diseases, SVZ cells grafted in the striatum are able to differentiate respectively into dopaminergic neurons and spiny neurons with a concomitant improvement of motor performance. SVZ cells have also been used in models of multiple sclerosis where chronic inflammation is a major cause of demyelination of the axons. Grafts of SVZ cells into the subcortical white matter of myelin-deficient mice results in the migration of PSA-NCAM progenitors cells, differentiation of oligodendrocytes and successful remyelination [10].

# Neurogenetic Diseases

Thomas D. Bird
Department of Neurology, UW Medical Center, Seattle, WA, USA

## Synonyms

Hereditary neurological disorders

## Definition

Neurogenetic Diseases are disorders of the central and peripheral nervous systems caused by molecular defects in heritable material (usually DNA).

## Characteristics

Neurogenetic diseases can be classified on the basis of the clinical syndromes or on the basis of the genetic etiology and inheritance pattern [1–3]. The genetic classification is used here with each category containing examples of clinical syndromes.

### Chromosomal

Major aberrations of chromosomal material usually produce defects in multiple organ systems and are frequently recognized at birth. They may be caused by a variety of chromosomal aberrations including deletions, duplications, translocations, and ring chromosomes. They are often associated with mental retardation, epilepsy, and dismorphic features. Examples include Down syndrome (trisomy 21), Cri du chat (5p-) and Miller-Dieker Lissencephaly syndrome (17p-).

### Mendelian

Diseases in this category are caused by mutations in nuclear DNA, including missense, nonsense, deletions, and duplications of one or more nucleotides. The disease is inherited as an autosomal dominant if the clinical syndrome is present in heterozygous carriers of a single mutation. Examples include Huntington's disease, Myotonic muscular dystrophy, Fascioscapulohumoral muscular dystrophy, tuberous sclerosis, Charcot-Marie-Tooth hereditary neuropathy, ►familial spastic paraplegia, and hereditary ataxias [4]. If clinical manifestations occur only in carriers of two mutations, one on each of the homologous chromosomes (homozygotes or compound heterozygotes), the disease is

autosomal recessive. Examples include Friedreich's ataxia, Tay-Sach's disease, Neimann Pick diseases, and phenylketonuria. Mutations on the X chromosome produce x-linked inheritance in which the mutations are usually confined to, or more severe in males and absent or much milder in carrier females. Examples include Duchenne's muscular dystrophy, Pelizaeus-Merzbacher leukodystrophy, and x-linked Charcot-Marie-Tooth hereditary neuropathy.

Many of these neurogenetic syndromes show remarkable genetic heterogeneity. For example, there are more than 20 genetic subtypes of hereditary neuropathy and more than 30 subtypes of familial spastic paraplegia and dominant hereditary ataxias.

Nucleotide repeat expansions: A special category of neurogenetic diseases is caused by abnormally large expansions of normally occurring nucleotide repeats. Many are trinucleotide repeats, often CAG. They are inherited in a mendelian fashion and age of onset is correlated with the size of the repeat expansion (larger expansions having earlier age of onset). Huntington's disease and several autosomal dominant spinocerebellar ataxias (SCA) are caused by CAG repeat expansions. Type 1 myotonic muscular dystrophy is caused by a CTG repeat expansion in the non-coding region of a gene and this expansion interferes with RNA transcription of multiple other genes. This explains the systematic nature of the clinical syndrome affecting many organ systems. X-linked Spinobulbar muscular atrophy is caused by a CTG repeat expansion in the androgen receptor gene on the X chromosome. One form of autosomal recessive myoclonic epilepsy is caused by expansion of a 12 nucleotide repeat (dodeca repeat).

### Mitochondrial

►Mitochondrial diseases are the result of primary abnormalities in the respiratory chain electron transport system of mitochondria. Mutations of mitochondrial DNA are inherited from the cytoplasm of the mother's egg. All children of a mother with the mutation will also inherit the mutation. However, males with the mutation do not pass the mutation on to any children. Whether or not the individual expresses clinical signs of the mutation depends on the numbers of mitochondria with the relevant mutation in any given tissue (heteroplasmy). Mitochondrial diseases often have a combination of signs and symptoms frequently including cognitive deficits, seizures, visual loss, hearing loss, peripheral neuropathy, or myopathy. Examples include MELAS (mitochondrial encephalomyopathy with lactic acidosis and stroke), MERRF (myoclonic epilepsy with ragged red fibers), and NARP (neuropathy, ataxia and retinitus pigmentosa). Some mitochondrial disorders are caused by mutations in nuclear genes that control mitochondrial enzymes and these are inherited in a mendelian fashion.

### Polygenic/Multifactorial

Individual autosomal, x-linked and mitochondrial neurogenetic diseases are each relatively rare. However, many common neurological disorders also have important genetic contributions to their pathogenesis. It is assumed that they represent the additive affect of several genes (polygenic) interacting with multiple environmental factors (multifactorial) [5]. Examples would be Alzheimer's disease, Parkinson's disease, Epilepsy, Stroke and Multiple Sclerosis. In some instances (e.g. Alzheimer's, Parkinson's and epilepsy) rare forms of the disease are caused by identified mutations in single genes, but the more common form of the disease in the general population is thought to be polygenic/multifactorial. In most instances the multiple genes and environmental factors are unknown. However, genome wide association studies are beginning to identify many candidate genes for these common complex diseases.

# Neurogenic Inflammation

### Definition

Precapillary arteriolar vasodilation generated by activity in peptidergic afferent C-fibers and Aδ-fibers and postcapillary plasma extravasation generated by activity in peptidergic afferent C-fibers. The vasodilation is generated by release of calcitonin-gene-related peptide (CGRP) and (to a lesser degree Substance P) and the plasma extravasation by release of Substance P.

## Synonyms

Neuronal regeneration in the nervous system

## Definition

A neurogenic niche is a region where neurogenesis takes place. Neurogenesis refers to the entire set of events leading to the production of new neurons from ►precursor cell in the brain. The degree of neurogenesis depends on the interaction of the microenvironment (niche) with precursor cells that have neurogenic potential.

## Characteristics

The adult mammalian central nervous system (CNS) has traditionally been divided into four major cell types: the neurons, the myeling-forming oligodendrocytes, the astrocytes, and the ependymal lining of the central lumen. All of those cell types are generated during development from a common source, the neuroepithelial cells that arise in early embryos in the form of the neural tube. There are three different cell types that contribute to neurogenesis, early neuroepithelial cells for the first neurons, radial glial cells for most neurons in most brain regions, and subventricular zone (SVZ) precursors predominantly at later stages of neurogenesis.

Moreover, it has become clear over the past decades that new neurons are continually generated in the adult brain. This postnatal neuronal production is a conserved biological phenomenon throughout evolution – it has been reported in fishes, amphibians, reptiles, birds, rodents and primates, including humans [1] – but its adaptive functions deserve yet to be explored.

Places were neurogenesis take place are called ►neurogenic niches. In this neurogenic niche, specialized cells are neural stem cells, capable of self-renewing and generating neurons and glia. In general, stem cells niches are composed of microenvironmental cells that nurture stem cells and enable them to maintain tissue homeostasis. An appropriate spatiotemporal dialog occurs between stem and niche cells in order to fulfill lifelong demands for differentiated cells. The niche concept was introduced in 1978 by Schofield [2]. In ecological terms, an organism's niche refers to where it lives, what it does, and how it interacts with its close environment. Altering an ecosystem (or neurogenic environment) can produce disastrous consequences for an organism (or stem cell). Niche cells provide a sheltering environment that sequesters stem cells from differentiation stimuli, and other stimuli that would challenge stem cell reserves. The niche also safeguards against excessive stem cell production that could lead to cancer. Stem cells must periodically activate to produce ►progenitor or transit amplifying cells that are committed to produce mature cell lineage. Thus, maintaining a balance of stem cell quiescence and activity is a hallmark of a functional niche. Importantly, stem cells themselves extensively interact with and participate in the niche. Furthermore, niches may in fact be dynamic structures that alter their characteristics over time concomitant with tissue remodeling.

## Regulation of the Neurogenic Niches

It is clear now that complex bidirectional interactions between intrinsic programmes and extrinsic cues take place in the neurogenic niches to control its behavior. We can define intrinsic programmes here as the ensembles of factors expressed by stem cells and progenitors that control different neurogenic phases. By contrast, external factors are produced by surrounding tissues to act on stem cells and progenitors. Consequently, whether a cell undergoes self-renewal or differentiation is the result of the spatial and temporal convergence of niche cues and intrinsic state of the cell.

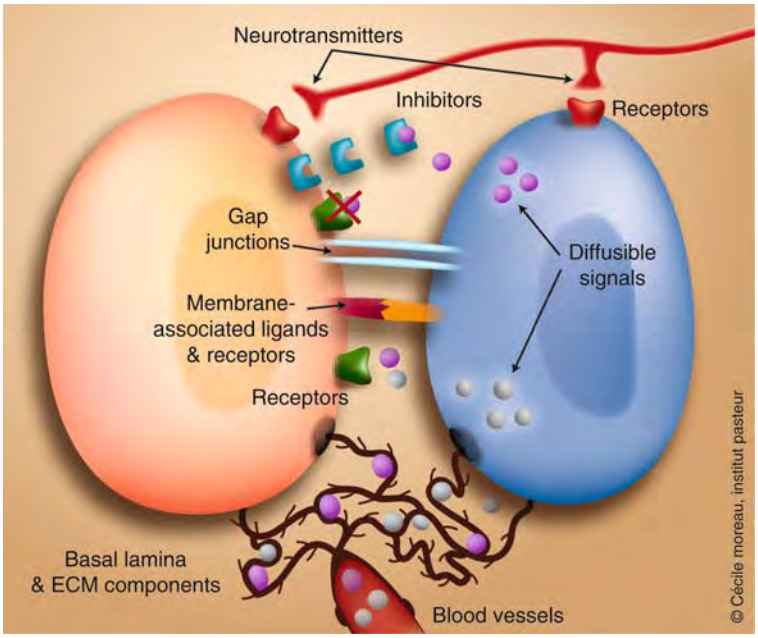
For instance, cell-cell interactions and diffusible signals are key elements allowing feedback control of stem cell activation and differentiation from progeny or the niche support cells (see Fig. 1).

Moreover, an emerging feature of several stem cells niches is the close association with endothelial cells forming blood vessels, which regulate stem cell self-renewal and differentiation. Within a niche, stem cells are frequently anchored to a basal lamina or stromal cells that can provide a substrate for oriented cell division. The basal lamina is also an important regulator of the accessibility of growth factors and other signals, as associated extracellular matrix molecules and glycoproteins can both concentrate and sequester factors in inactive or active forms. In addition, cell anchoring may orient cell division resulting in the segregation of key determinants into one or both daughter cells depending on the plane of division [3]. In this line, given that multipotent progenitor cells can give rise to neuronal and glial cell types in a characteristic order of birth, it is clear that progenitor cell proliferation must be precisely regulated.

Finally, the processes of newborn neuron production, migration, maturation and survival are all subject to modulation by external factors. Neurotransmitters, hormonal status, growth factors and injuries are known to influence proliferation [4] (Fig.1).

## Neurogenic Niches in the Adult Mammalian Brain

Two regions, the olfactory bulb (OB) and the dentate gyrus (DG) of the hippocampus, have been shown beyond doubt to receive and integrate constitutively



**Neurogenic Niche. Figure 1** Membrane-associated receptors and ligands mediate cell-cell contacts, defining cell self-renewal and differentiation. In addition, gap junctions coordinate behavior between couple cells. Diffusible signals can direct stem cells to either self-renew or generated differentiated progeny. The availability of diffusible factors that bind to receptors in turn can be regulated by ligand inhibitors which can sequester these factors and prevent signaling. An extracellular matrix-rich basal lamina, which can be associated with blood vessels, has several functions in stem cell niches, including anchoring cells to the niche, sequestering and presenting diffusible signals, and linking cells and the extracellular matrix. Endothelial cells and the vasculature can regulate stem cells fate decisions. Stem cells can also be regulated by the release of neurotransmitters and other factors from axons.

newborn neurons throughout adult life in the mammalian brain [5] (see Fig. 2a and 2b).

In adult mammals, neurogenic zones where neural stem cells are harbored, exists at least, in two discrete areas of the brain: the subgranular zone (SGZ) of the DG (Fig. 2a) and the SVZ located near the lateral wall of the lateral ventricles (Fig. 2b). The neuroblasts that originate from SVZ precursor cells migrate long distances through the rostral migratory stream (RMS) to populate the OB where they differentiate into granular and periglomerular interneurons and establish contacts with their neuronal targets.

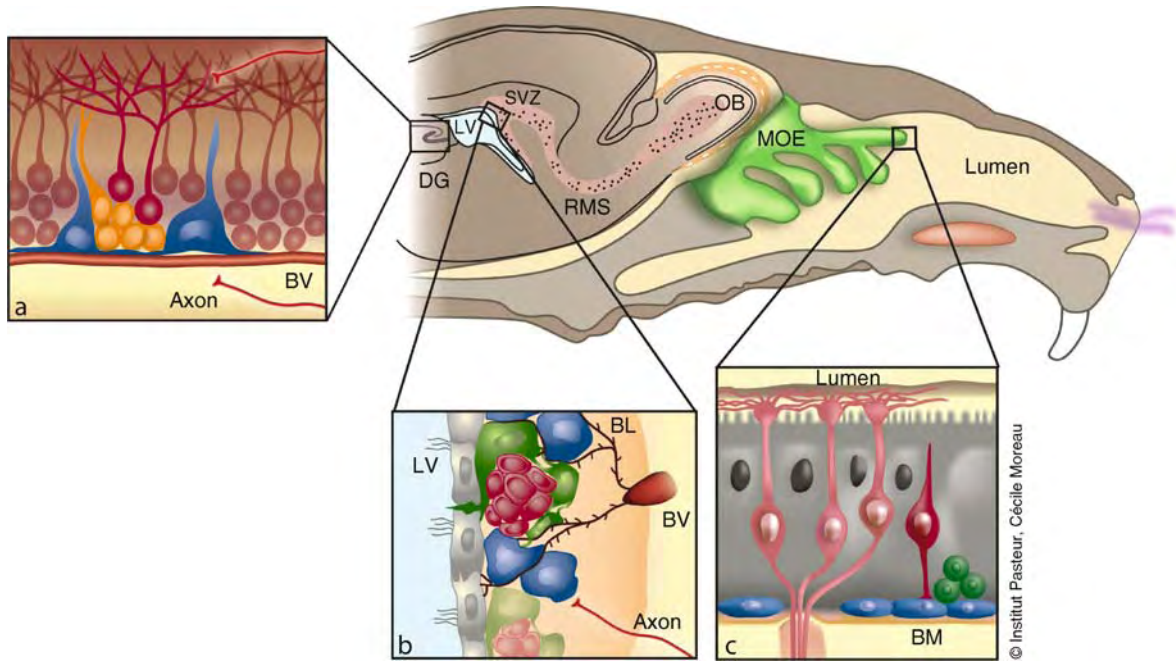
Thousand of young neurons migrate into the OB every day but only a fraction of them survive to complete their differentiation. The newborn cells recruited into the OB and the DG became truly neurons, throughout a unique sequence of events that leads to their functional maturation followed by complete integration.

In the two neurogenic areas of the adult brain, a subset of astrocytes, are the in vivo precursors for adult neurogenesis. In the SVZ, some of these cells contact the ventricle lumen and have a single cilium. Rapidly dividing, transit-amplifying cells derived from stem cells give rise to neuroblast.

As we mentioned before, the neurogenic behavior in both regions appears determined by signals restricted to their niches. Stem cells are in intimate contact with all other cell types, including the rapidly dividing transit amplifying and the neuroblasts (Fig. 2a and 2b).

Therefore, neural stem cells occupy niches formed by both astrocytes and endothelial cells. In general, endothelial cells encourage stem cells to renew themselves, and astrocytes instruct them to become neurons. More surprisingly, mammalian neural stem cells are not passive elements of their microenvironment: they can, under certain conditions, give rise to endothelial cells. This suggests that, if the need arises, stem cells can populate their niche with the features that they need to thrive.

Transplantation studies in mammals support the principle of defining neurogenic and non-neurogenic regions and provide evidence for the role of microenvironment in influencing the potential of neural precursors. If precursor cells are transplanted into neurogenic regions, they can differentiate into neurons in a region-specific manner. SVZ precursor cells generate hippocampal neurons when transplanted into the hippocampus, and SGZ precursor cells generate olfactory interneurons after transplantation into the RMS. When implanted outside the neurogenic regions, both types of precursor cells generate only glia. An inhibitory environment that is refractory to neurogenesis is therefore present throughout



**Neurogenic Niche. Figure 2** Neurogenic niches in the adult mammalian brain. Simplified sagital view of rat head showing neurogenic niches. (a) Dentate gyrus (DG) neurogenic niche. Astrocytes (blue) give rise to progenitors (orange), which mature into new granule cells (red). (b) Subventricular zone (SVZ) neurogenic niche. Astrocytes (blue) are the SVZ stem cells and also serve as niche cells. Transit-amplifying cells (green) derived from stem cells give rise to neuroblast (red) that migrate to the olfactory bulb. The basal lamina (BL, brown) extends from the blood vessel (BV) and interdigitates extensively with the SVZ cells. Ciliated ependymal cells (gray) line the lateral ventricule (LV) are shown. (c) Main olfactory epithelium (MOE) neurogenic niche. Horizontal (blue) and globose basal cells (green) are the stem cells. Some globose basal cells are transit-amplifying cells that give rise to olfactory sensory neurons (red). Basement membrane (BM) and supporting cells (gray) are shown. RMS, rostral migratory stream.

most of the adult brain. Thus, adult neurogenic niches have an instructive role in directing neuronal production and stem cell maintenance and shield ongoing neurogenesis from possible external inhibitory influences. Although the components of adult neurogenic niches that mediate these processes are still being elucidated, it is clear that both neural and non-neural cell types are key players. Finally, if it were a static, merely restorative process, adult neurogenesis could not be regarded as a mechanism for adult brain plasticity. However, we know that every aspect of adult-born cell production is tightly regulated and modulated. This strongly suggests that the adult brain can tailor its production of new neurons to match the demands of its environment.

## Neurogenesis in the Olfactory Epithelium

In the olfactory system, the main olfactory epithelium (MOE) is also submitted to continual neurogenesis in adults (Fig. 2c). The olfactory sensory neurons (OSNs), which detect odors in the air we breathe, are located within this epithelium and continue to be generated throughout life. This lifelong neurogenesis occurs as a result of continual proliferation and differentiation of progenitors cells located near the base of the epithelium. The olfactory neuroepithelium is in direct contact with the external environment and, as a consequence, has evolved a remarkable ability to replenish sensory neurons lost during natural turnover and in the event of extensive lesions or traumatic injuries. This ongoing adult neurogenesis is essential for maintaining olfactory sensory function.

In the postnatal brain of rodents, and continuing into adulthood, three cell types comprise the OSNs lineage within the olfactory epithelium: the horizontal basal cells (HBCs) which lie directly against the basal lamina, the globose basal cells (GBCs) which are primarily situated immediately apical to the HBCs, and the OSNs (Fig. 2c).

HBCs function as adult olfactory neuroepithelium stem cells and are competent to regenerate both neuronal and non-neuronal lineage in this region (Fig. 2c). HBCs serve as a reservoir of long-lived progenitors that remain largely quiescent during normal neuronal turnover or even after acute, selective loss of mature neurons. Under these conditions, GBCs are largely responsible for tissue maintenance. This characteristic is unique showing a

model of adult neurogenesis in which distinct cell population within the same niche mediate normal neuronal turnover and neuronal replacement upon traumatic injury [6]. As was describe previous, different factors that are both made by and found within the microenvironment of the MOE stem and progenitor cells exert crucial growth regulatory effects on these cells. Thus, as with other regenerating tissues, the basis of regeneration in the MOE appears to be a population of stem cells, which resides within a microenvironment (neurogenic niche) consisting of factors crucial for maintenance of its capacity for proliferation and differentiation.

### Relevance to Humans

Elucidating the nature of microenvironmental factors released by host tissue in the neurogenic niches that might affect these processes became particularly interesting given that it was demonstrated that adult neurogenesis occurs also in adult human brain. Adult neurogenesis was demonstrated in human hippocampus [7]. As well, a ribbon of SVZ astrocytes lining the lateral ventricles of the human adult brain that proliferate *in vivo* and behave as multipotent progenitor cells *in vitro* was recently describe [8]. In addition, a recent study demonstrates the presence of a human RMS containing migratory progenitor cells some of which become mature neurons in the OB [9]. Moreover, adult neurogenesis was also found in the human MOE [10].

In this context, adult neurogenesis is attracting a lot of attention because of the hope raised by the use of adult neuronal stem cells in regenerating and reconstructing the damaged brain, for instance, in the therapies of neurodegenerative diseases. However, before elaborating strategies aimed at using endogenous progenitors and their relevance to human clinics, it is urgent to precise theirs normal function(s) in a non-pathological brain.

## Neurogenic Pain

►Neuropathic Pain

## Neurogenic Vasodilatation

### Definition

Vasodilatation induced by depolarization of nociceptive nerve terminals in the body periphery. These terminals release calcitonin-gene–related peptide (CGRP), a vasoactive substance. Synonyms: neurogenic inflammation, axon reflex flare.

►Calcitonin Gene Related Peptide (CGRP)
►Nociceptors and Characteristics

## Neurogliaform Cells

### Definition

Neurogliaform refers to the neuroglial ectodermal cell type. Neurogilaform cells, neuroglial cells, and glial cells are synonymous terms.

## Neurogram

### Definition
Multi-unit recording from a nerve.

►Extracellular Recording

## Neurohormone

### Definition
A compound released by a neuron into the circulation, with other neurons as its major target.

## Neurohumoral Agent

### Definition
Synonym for neurotransmitter. A chemical substance released at a synapse from a presynaptic neuron that binds on a receptor of a postsynaptic neuron and stimulates or inhibits it.

►Neurotransmitter
►Synapse

## Neurohypophysis

### Definition
Neurohypophysis or the posterior lobe of the pituitary, is the site where the terminals of the Supraoptic and Paraventricular nuclei release neurosecretory granules containing vasopressin or oxytocin.

►Drinking Disorders and Osmoregulation
►Posterior Lobe of the Hypophysis
►Diencephalon

## Neuroimaging

### Definition
The use of radiographic studies and magnetic resonance imaging to detect structural abnormalities in the central nervous system; visual display of structural or functional patterns of the nervous system as a whole or any of its parts for diagnostic evaluation or visualization of anatomical structures; includes measuring physiologic and metabolic responses to physical and chemical stimuli.

►Magnetic Resonance Imaging (MRI)

## Neuroimaging

Modern techniques applied in order to assess alterations of the central nervous system.

►Forensic Neuropsychiatry

## Neuroimmune Interactions – Serotonin

David Dubayle, D. Menetrey
CNRS UMR 8119, Neurophysique et Physiologie, Université René Descartes, UFR Biomédicale, Paris, France

### Synonyms
5-Hydroxytriptamine (5-HT) Neuroimmunomodulation

### Definition
The role of ►serotonin (5-hydroxytriptamine or 5-HT) in the bidirectional influences that the nervous and immune systems exert over each other by biochemical and cellular routes.

### Characteristics
#### Characteristics of Serotonin
##### *Dual Location*
Serotonin (5-HT) is common to both the nervous and immune systems and, in consequence of its dual

location, is involved in the bidirectional interactions these systems generate with each other. By extension, serotonin must be regarded as a fundamental element of the defence system that living organisms have developed against stressors.

### Metabolism

Serotonin is formed by tryptophan (5)-hydroxylase from L-tryptophan. L-tryptophan is common to the immune-related ►kynurenine synthesizing pathway (Fig. 1). An increase of kynurenine biosynthesis will lead to a decrease in the availability of L-tryptophan, and reduce 5-HT levels.

### Receptors

Serotonin acts through a variety of receptor subtypes. Fourteen subtypes have been recognized to date, with specific location within the central nervous system, and at least four (5-$HT_{1A}$, 5-$HT_{1B/1D}$, 5-$HT_2$ and 5-$HT_3$) are present on immunocompetent cells [2]. 5-$HT_{1B/1D}$ receptor activity is down-regulated by an endogenous tetrapeptide named 5-HT-moduline, likely originating from the adrenal medulla and released by stress.

### Functions in Immune Regulation

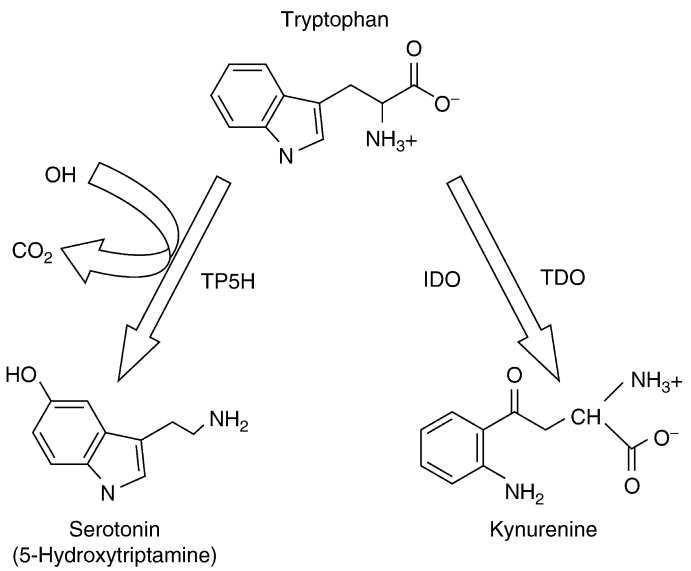
Four major serotonin actions have been recognized in immune regulation: (i) the activation of T-cells and natural killer-cells, (ii) the production of chemotactic factors, (iii) the modulation of delayed-type hypersensitivity responses, and (iv) the regulation of the natural immunity delivered by macrophages [3].

### Responses to Immune Activity

Immune activity affects 5-HT brain levels. Effects depend on circumstances. Acute peripheral immunization raises brain 5-HT turn-over through the local release of specific inflammatory cytokines, mostly interleukin-1, and via sympathetic nervous system activity. On the other hand, chronic immune activation, which is common in normal ageing and accompanies ►neurodegenerative disorders such as Alzheimer's, Huntington's and Parkinson's diseases, leads to 5-HT depletion [1] by promoting L-tryptophan degradation via the kynurenine synthesizing pathway. 5-HT lowering could account for the mood alteration and impaired cognition that accompany ageing and chronic pathological conditions. Light exposure raises 5-HT levels [4] and fights moodiness.

### Anatomical Substrate

The anatomical substrate for 5-HT-based neuroimmune interactions is triple including: (i) the central serotonergic system of the brain stem raphé nuclei (►raphé nuclei system), (ii) the "serotonergic/noradrenergic" nerve terminals of the peripheral ►autonomic nervous system (NS) and, (iii) the 5-HT-positive immunocytes that penetrate the nervous system. 5-HT cellular-mediated actions are essential for neuroimmune cross-talk since access of blood-borne 5-HT and



**Neuroimmune Interactions – Serotonin. Figure 1** The dual catabolic pathway of tryptophan. On the left, tryptophan (5)-hydroxylase (TP5H) initiates the production of serotonin (5-hydroxytriptamine); on the right, tryptophan (2,3)-dioxygenase (TDO) and indoleamine (2,3)-dioxygenase (IDO) catalyze the formation of kynurenine. Adapted from [1].

L-tryptophan to the brain is highly restricted by the endothelial ►blood-brain barrier (BBB) except for the circumventricular organs where this later is disrupted. The metabolism of L-tryptophan by microvascular endothelial cells is primordial in restricting microbial expansion in the nervous system [5].

## Characteristics of the Raphé Serotonergic System

### Anatomy

This system, which is the only source of central nervous serotonergic innervation, widely distributes to the brain via arborescent efferents bearing thousands of 5-HT containing varicosities enabling it to interfere with widespread target cells. Both synaptic and non-synaptic contacts have been described suggesting that neuronal communication is relevant of both synaptic – a point-to-point contact – and volume – a passive at distance tissular diffusion – transmission mechanisms. The raphé serotonergic system influences the immune system through two pathways: (i) via the caudal raphé nuclei (nucleus pallidus, obscurus and magnus) brain stem and spinal cord projections that contact the preganglionic motoneurons of both the sympathetic and parasympathetic columns, thus interfering with the autonomic nervous system outflow, (ii) via the rostral raphé nuclei (nucleus median and dorsalis) ►hypothalamic-pituitary gland axis projections, thus interfering with the pituitary neuroendocrine outflow.

### Serotonin and Pituitary Hormones

Pituitary hormones and related substances modulate immune functions. Corticosteroids have immunosuppressive effects while prolactin and growth hormone favor immune functions and counter the immunosuppressive effects of the former. 5-HT modulation of pituitary activity would be 5-$HT_{1B/1D}$ receptor dependent [6]. Sumatriptan, a specific agonist for 5-$HT_{1B/1D}$ receptors, lowers levels of plasma prolactin, increases those of growth hormone, but does not affect cortisol concentration. Since 5-$HT_{1B/1D}$ receptors concentrate in the median eminence on non-serotonergic fibers, possibly of hypothalamic origin secreting neuropeptides acting as releasing factors for pituitary neurohormones, 5-HT could interact with the release of these products, finally altering the internal status of the organism [6].

## The Peripheral Autonomic Nervous System

The nerve terminals of the peripheral autonomic nervous system are possibly fundamental in neuroimmune interactions as they anatomically ensure the interface between the nervous and immune systems at local peripheral levels. Nerve fibers of the autonomic innervation developing close contacts with lymphocytes, hemopoietic elements, thymocytes, macrophages, ►mast cells and T cells, have been described for a long time. Autonomic fibers comprise noradrenergic terminals that take up and accumulate non-neuronal peripherally released 5-HT in a process that can alter their functions when both transmitters, noradrenaline and 5-HT, are simultaneously released. 5-HT positive immunocytes mast cells are potential providers for this peripheral 5-HT. The 5-HT content of peripheral tissue will evidently increase in inflammatory pathological circumstances. Central nervous autonomic outflow regulation through raphé 5-HT innervation of preganglionic motoneurons also exists, suggesting a central-mediated modulation of local autonomic-immune interactions. Finally, 5-HT could also modulate peripheral nervous inflow since 5-$HT_{1B/1D}$ receptors are present on primary afferent fibers [7]. Primary afferent fibers are one of the ways through which immune changes induced during the course of an infection can generate the central release of cytokines (interleukin 1 and tumor necrosis factor), which in turn acts on 5-HT levels.

## The Brain Immunocytes

The CNS of healthy animals is classically viewed as an immune-privileged organ because of the blood-brain barriers ( blood-brain, blood-nerve and blood-cerebrospinal fluid barrier) that limit the access of systemic immune cells. This immune privilege is not, however, as strict as it has long been claimed. Both activated T-lymphocytes and mast cells are known to penetrate the brain. Activated T-lymphocytes patrol the brain for immune surveillance; nervous resident mast cells (nsMCs) are present at both ends (primary afferent fibers, diencephalon) of the sensory network and in sympathetic ganglia where they provide a direct cell-to-cell contact opportunity for 5-HT-based neuroimmune cross-talk. NsMCs activities result in significative nervous changes depending on their location.

### Primary Afferent Fibers-Associated Mast Cells

These cells lie in close apposition with unmyelinated fibers, contacting both peripheral terminals and ganglionic cells of origin (spinal and nodose ganglia). They promote peripheral fiber elongation and excitability in inflammatory conditions.

### Sympathetic Ganglia-Associated Mast Cells

These cells increase ganglionic synaptic transmission when sensitised by immune challenge.

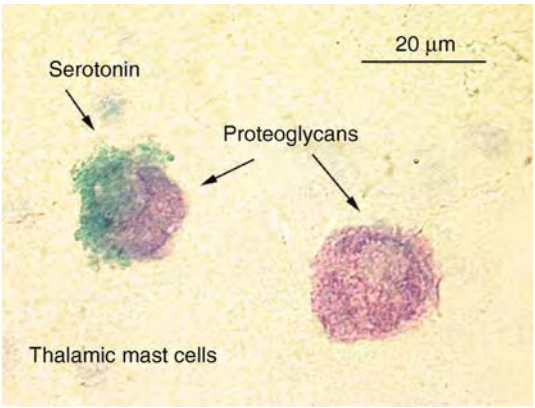
### Diencephalon-Associated Mast Cells

These cells comprise several subpopulations that are present in (i) the parenchyma of both the ►thalamus (thalamic mast cells) and main olfactory bulb, as the

final central relays for sensory and olfactory inputs before cortex, (ii) the leptomeninges including those surrounding the median eminence, as the key structure for the hypothalamic-pituitary neuroendocrine process, and (iii) the choroid plexus where the cerebrospinal fluid is secreted.

### *Thalamic Mast Cells*

These cells have recently received much attention. Evidence has been given that they (i) have a predominant perivascular location, lying at the vascular interface in the adventia of the arterioles and venules, excluding capillaries, (ii) show some phenotypic specificities, (iii) release substances, including 5-HT, over piecemeal rather than overt degranulation and (iv) constitute a dynamic population that is triggered behaviorally, hormonally, pharmacologically and respond to sensory challenges. Interestingly, they do not express c-kit receptor and cyclooxygenase-2 as their peritoneal and leptomeningeal homogeneic counterparts do, thus precluding classical proliferating and pro-inflammatory properties. Considering properties related to 5-HT dependent mechanisms, evidence have been given that they store 5-HT in proteoglycan-free granules [8] and do not express 5-$HT_{1B/1D}$ receptors although they respond to a systemic injection of sumatriptan [6] (Fig. 2). Recent evidence has been given that thalamic mast cell activation results in neuronal activity variations [9]. Their prevalent location within the thalamic nuclei having cortical projections has been argued for a role in integrative and cognitive sensory processes. It has also been proposed that thalamic mast cells could act on the permeability of the endothelial blood-brain barrier [10], thus making local parenchymal cell populations accessible to humoral signals. Effects at neuronal level could affect the thalamic nuclear receptivity to incoming sensory events; effects at glial level could influence either neuronal or immune surveillance activities.



**Neuroimmune Interactions – Serotonin.**
**Figure 2** A micrograph (brightfield illumination) of two thalamic mast cells in double-stained material in which purplish-red granules identify proteoglycans (toluidine blue histochemistry) and therefore mast cells, while brilliant green granules identify serotonergic contents (5-HT immunohistochemistry). The fact that granules kept their specific colors, either red or green, suggests that they are mediator-specific. The nuclei remain visible for both cells. Modified from [6]. The staining technique is from [8].

## Overview

Given its widespread distribution and the variety of its receptors, 5-HT and its precursor L-tryptophan appear to be involved in the regulation of a number of physiologic functions linked to the afferent and efferent pathways of communication between the nervous and immune systems. 5-HT-based cross-talk between these two systems could be essential for an adapted immune regulation and preventing immune mediated disorders.

## Introduction

The nervous system is the body's master controller. It monitors changes inside and outside the body, integrates sensory input and activates an appropriate response. In conjunction with the ►endocrine system, which is the body's second important regulating system, the nervous system is able to constantly regulate ►homeostasis. The nervous system, along with the endocrine and immune systems, thus forming the nexus of neuroimmune-endocrine interactions, help keep controlled conditions within limits that maintain homeostasis [1]. The nervous system is practically responsible for all of our behaviors, memories and movements. The branch of medical science that deals with the normal functioning and disorders of the nervous system is collectively called neurology and that of neuroimmune interactions neuroimmunology.

## Neuroimmunology: Neuroimmune Interactions, Pathways and Mechanisms

Burgeoning research over the past few decades and continuing apace has shown that the immune, nervous and endocrine systems, or the "*trio*," are tightly linked via specialized communication pathways and mechanisms [1]. Interactions between the nervous and immune systems, specifically, provide a physiological (homeostatic) basis for understanding neuroimmune-associated disorders and medical conditions emanating from them. In approximately 200 AD, the Greek author Galen wrote that "melancholic women were more susceptible to breast ►cancer than sanguine women." Since then, a wealth of anecdotal evidence has convinced physicians and researchers of the importance of psychological factors in the prognosis of disease. This belief is now bolstered by substantial evidence that the nervous system output can indeed modulate immune functions and mechanisms of action [2].

Neuroimmune interactions are not by any chance unidirectional. The bidirectional influence emanates from the fact that the immune system can have substantial influence on the nervous system [1]. Anomalies of immune system function or malfunction can certainly cause diseases of, or relating to, the nervous system. It is clear that effective defense mechanisms against infections or immune disorders requires a complex coordination of the activities of the nervous and immune systems, and that abnormalities in the relationships between the two of them can cause disease or pathophysiologic aberrations [3].

Classically, the brain has long been regarded as an "*immunologically*" privileged site [1]. The relative non-immune responsiveness of the brain has been attributed to a lack of lymphatic drainage, the presence of the ►blood-brain barrier (BBB) (as emphasized above), the lack of constitutive expression of the ►major histocompatibility complex (MHC) cluster and the presence of chemical mediators or cofactors purported as capable of inhibiting ►lymphocyte traffic during inflammation [1] (►neuronal cell death and inflammation). This evasion of systemic immunological recognition confers a *privilege* property that is so unique and, in many ways, plays a major role in shaping the grounds for neuroimmune interactions. However, accumulating evidence indicates that immune responses propagate in the nervous system in a manner similar to that in other tissues (non-immune).

The nervous system, in fact, has a number of attributes that influence local immune responses, hence the "*bidirectional*" effect concept [1]. The experimental evidence for neuroimmune interactions can be summarized as follows: (i) alterations or changes in immune responses can be conditioned and regulated; (ii) electrical stimulation or lesions of specific brain sites can alter and modulate immune functions; (iii) ►stress (and the ►hypothalamo-pituitary-adrenal (HPA) axis; see below) alters immune responses and infections in experimental and physiological models; and (iv) activation of the immune system is correlated with altered neurophysiological, neurochemical and neuroendocrine activities of brain tissue [4].

This evidence is elaborated on below, but it is pertinent for now to consider first what the potential links between the nervous and immune systems might be. There is little scope for understanding neuroimmune interactions, but with the benefit of hindsight I can postulate a number of specific neuroimmune mechanisms by which the nervous system might affect immune function. (*This is also evident by the various entitled contributions authors have made to the Neuroimmunology field.*) These interactions include ►glucocorticoids (discussed later) secreted from the ►adrenal cortex, ►catecholamines secreted from ►sympathetic nerve terminals and the ►adrenal medulla, other hormones secreted by the ►pituitary (►hypophysis) and other endocrine organs, and peptides (including endorphins) secreted by the adrenal medulla and autonomic nerve terminals [1]. This network includes not only the ►autonomic nervous system (ANS) and classical neuroendocrine mechanisms, but involves an endocrine function of the immune system. A variety of immune system products (e.g., ►cytokines,

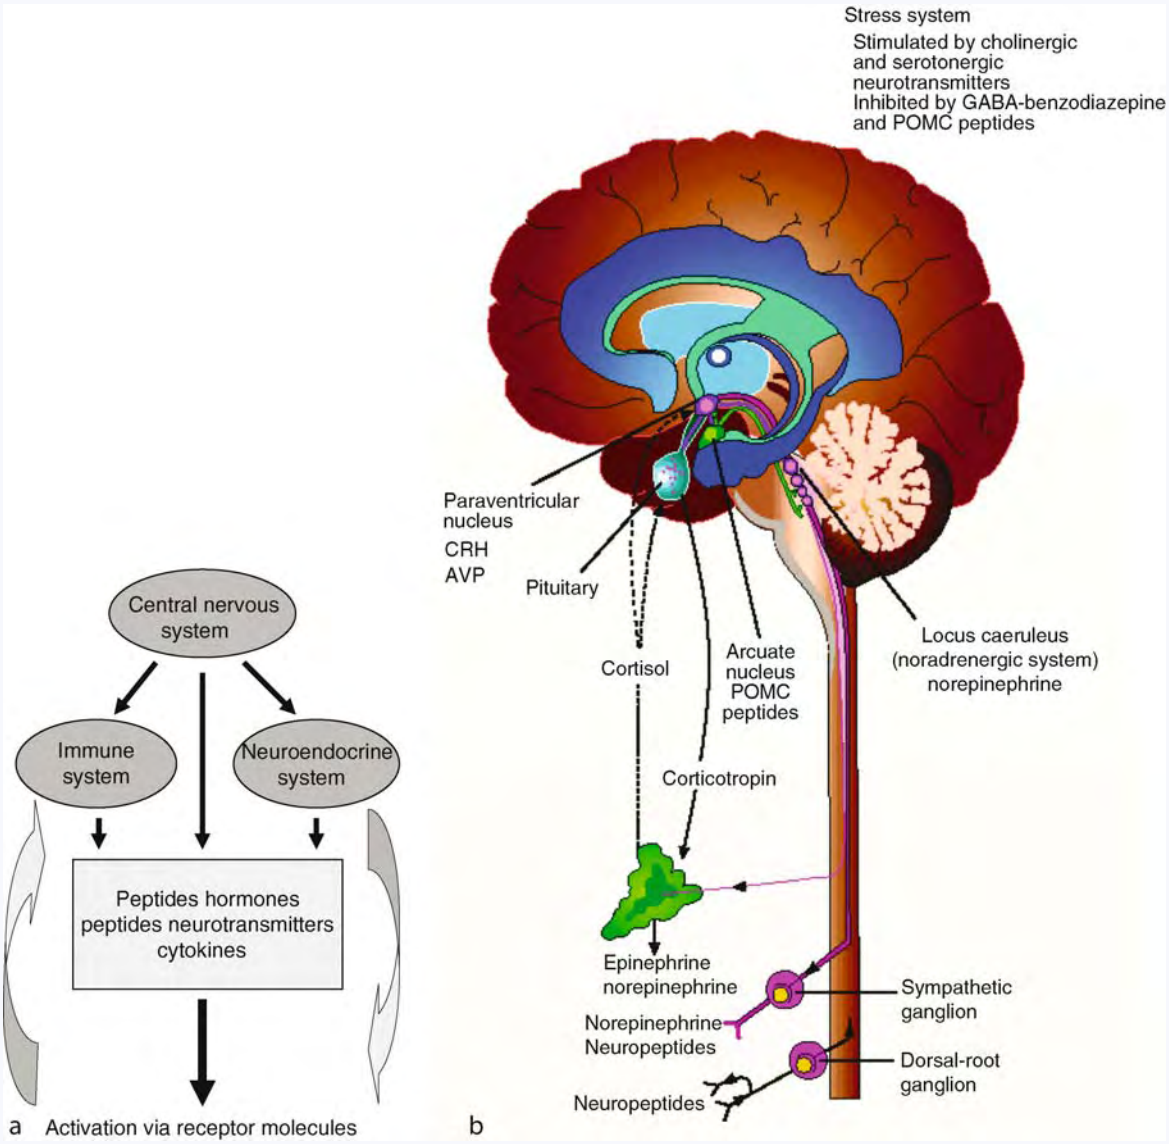
peptides and other factors) that function to coordinate the immune response may also provide important signals for the nervous system [2]. Thus, chemical messengers can account for a variety of interactions between both systems. The illustrations in Fig. 1a and b provide a hypothetical schematic model of the most well-known interactions between the nervous system and components of the endocrine and immune systems.

## Immunity and the Immune System – An Overview

The immune system is critical to our survival. Examples of what happens when it fails (►acquired immunodeficiency syndrome; AIDS) or when it fails to develop properly (►severe combined immunodeficiency; SCID), just to cite few examples, are abounding [5]. The body is a rich place for microorganism growth. Without our immune system, we, conspicuously, are an excellent propagating growth medium.

## What is the Immune System?

Liken it to a colony of ants within us; the immune system is, nonetheless, a restless microenvironment [5]. Instead of separate organisms, however, there are many different cellular components distributed in our organs and tissues and blood stream. These cells are not static but rather move throughout the body, "looking" for



**Neuroimmunology. Figure 1** (a) A hypothetical schematic for substantial molecular communication circuits existing between the immune and neuroendocrine systems and involving shared ligands and receptors. (b) Classic components of the CNS systems and the connections with stress and immune system [1].

N

situations that demand a response. Generally, communication between two or more cells is required before an attack is launched – a system of checks and balances. When we talk about immunity, we must be careful to say just what kind of immunity is meant. For example, there is *innate immunity*. This is a response that is not specific for a particular microorganism or strain of microorganism. It is rather set off by a property that is shared by a whole class of microorganisms (►neurodegeneration and neuroprotection – innate immune response).

## Types of Immunity

Innate immunity involves cell surface polymers characteristic of classes of microorganisms. These are referred to as ►pathogen-associated molecular patterns (PAMPs) [6]. They involve major molecular signatures of classes of microorganisms, such as: (i) ►Lipopolysaccharide (►LPS; ►endotoxin) for Gram-negative bacteria (►endotoxic fever); (ii) Lipoteichoic acid for Gram-positive bacteria; and (iii) Lipoproteins for *Mycobacteria, Mycoplasma and Spirochetes*. PAMPs are recognized by ►pattern recognition receptors (PRRs) on the surface of macrophages – phagocytic cells – and also on lymphocytes. The PRRs in mammals resemble Toll, one of a family of receptors in the invertebrate fruit fly, *Drosophila melanogaster* [6]. On binding of infectious organisms to Toll and similar receptors in *Drosophila*, anti-fungal or anti-microbial peptides are released that are appropriate to the infectious organism [7].

►Toll-like receptors (TLRs) share the following molecular properties: (i) an extracellular ►leucine-rich domain (LRD); (ii) a small cysteine-rich domain that differs among different toll-like receptors; and (iii) a cytoplasmic domain that is homologous to the ►interleukin (IL)-1 receptor (IL-1R), a receptor that binds the vertebrate cytokine, IL-1; it is referred to as a ►Toll/IL-1R homology domain (TIR). In mammals, cells interacting with PAMPs through their PRRs appear to release cytokines – small glycoproteins that recruit cells involved in a form of immunity not present in invertebrates like *Drosophila* – *specific acquired immunity* [7].

In specific acquired immunity or *specific adaptive immunity*, the response is against a particular organism and, in fact, usually against multiple aspects of that organism. For example, you may mount a response against a single strain of influenza virus and even against many proteins of that strain. But that particular response will not protect you against a different strain of influenza virus. This is why ►vaccination against one strain does not protect the human body against a different strain [7].

We will learn how the colony of cells that mediate specific acquired immunity is set up and how it operates. In brief, during embryonic development and throughout life, a very large number of cells called lymphocytes are generated. There are several different classes of lymphocytes and millions to billions of cells in each class. Each lymphocyte has a receptor on its cell surface (in fact, many copies of a receptor, but all identical). But each lymphocyte has a different receptor. The job of the receptor on each lymphocyte is to bind to or recognize a potential foreign invader – what is commonly referred to as ►antigen. Antigens, the invading organism or part of organisms against which our immune system must fight, may take many forms [7].

The immune system does not "know" what invaders exist out there in the world. The system has evolved to express such an enormous number of different receptors – each on a different lymphocyte – that at any one time, it contains lymphocytes that could recognize any invader that we encounter. Of course, the particular cell must be able to find and interact with that invader in order to make its protective response. That is the function of the specialized immune tissues (spleen, thymus, lymph nodes) and the circulation of lymphocytes in the blood stream – to bring the protective lymphocytes into contact with the invaders that they must fight [7].

When an invader is encountered by protective lymphocytes and the validity of that encounter is verified, a process is set in motion whereby the lymphocyte is caused to divide multiple times to generate a clone of identical cells expressing the same receptor. These cells set about destroying the invader in one of two major ways: (i) they manufacture and secrete ►antibodies, proteins that bind to the invader and contribute to its demise by one of several means that we will discuss later on. This is called *humoral immunity*; and (ii) the cells destroy the invader directly by direct action of the cells. This is called *cellular immunity* [1] (►stress effects during intense training on cellular immunity, hormones and respiratory infections).

After the invader is effectively beaten down, there now remain an increased number of antibodies, antibody-producing cells, and memory cells than there were before the invader appeared on the scene. These persist in the body and are, in fact, scattered throughout via the blood. If the same invader strikes again, the protective response occurs more quickly and is stronger than it was at first due to the presence of more cells at the outset that recognize the invader. This is called ►immunological memory, and it is why vaccination works (►neuroinflammation – DNA vaccination against autoimmune neuroinflammation).

## Developmental Immunity

Immunologists, furthermore, have learned about how this remarkable system is set up during development. In fact, the immune system is perhaps the best-understood developmental system, largely because many of the

key cell types are "free floating" (lymphocytes, macrophages), which are much more easily manipulated than solid tissues [1]. This attribute, combined with the ability to study the genetics of immune responses and of the molecules that mediate these responses, has allowed a wealth of information to accumulate – mostly for mice and humans.

## Self/Non-self Recognition

How does our immune system distinguish between an invader and our own tissues – our "self?" After all, if we can produce lymphocytes that have receptors that can recognize any invader, surely we produce lymphocytes that recognize molecules in and on our own cells. Why does our own immune system not destroy us? In fact, we do produce lymphocytes that recognize ourselves all the time, but only rarely do they cause ►autoimmune disease (►central nervous system degeneration caused by autoimmune cytotoxic CD8+ T cell clones and hybridomas). We will learn a lot about self-recognition and why it is generally not a serious problem. In the course of addressing this question, we will deal with a subject that I will refer to as the *genetics of the self*. It underlies both our ability to set up a safe and functional immune system, and also the whole area of tissue and organ transplantation.

It revolves around a set of closely linked genes that are lumped together and referred to as the major histocompatibility complex (MHC) of genes. The MHC is the focus for how the immune system avoids attacking our own bodies. The cellular and molecular biology that is involved in MHC-related recognition is one of the most fascinating aspects of how the immune system works. Finally, one should always be considering how we might apply our knowledge of how the immune system works to improve human health. This may involve using vaccines or mediators produced by the immune system itself to enhance immunity when the body's own system is not mounting a strong enough response. In other instances, we may wish to squelch immune activity when it has been misdirected against our own tissues. Also of great interest is the possible use of ►gene therapy to enable the body to manufacture a needed substance that it was unable to make due to an inherited mutation or deletion in an important gene [8–10].

## What is the Functionality of the Relationship Between the Nervous and Immune Systems?

There is considerable evidence suggesting that immune system signaling and activation are communicated to the nervous system via specific pathways [1]. This communication essentially occurs through the release of peripheral soluble factors (particularly cytokines, commonly known as "*biologic response modifiers*") by cells of the immune system (lymphoid vs. myeloid) and cells of non-immune origin [11] (►central nervous system inflammation – cytokines and JAK/STAT/SOCS signal transduction). These factors or cofactors function as hormones or modifiers to affect and modulate the responses of the central nervous system (CNS) and peripheral nervous system (PNS). They can affect the CNS directly by crossing (bypassing) the blood-brain barrier (see above) or indirectly by stimulating the ►vagus nerve (see Fig. 1a and b). As a consequence of the diversity of specialized cells and subcellular components in the nervous system, there is a wide range of potential target antigens and clinical syndromes associated with that [1].

## Bidirectional Influence: Immune System Effects on the Nervous System – Types of Signaling Molecules and Cofactors

Amongst biological modifiers, cytokines, particularly, can directly influence the electrophysiological function of neurons in the CNS or PNS; this is especially evident during the ensuing inflammation of the brain or PNS, despite the immunologically privileged status [8]. ►Chemokines, on the other hand, resemble a family of proteins associated with the trafficking (emigration) of ►leukocytes in physiological immune surveillance and inflammatory cell recruitment in normal host defense mechanisms [1]. Beside their well-established role in the immune system, evidence indicates that chemokines also play an integral role in the CNS. In fact, they are constitutively expressed by ►microglial cells (or macrophages of the brain) (►microglia – functions in immune mechanisms in the central nervous system), ►astrocytes and neurons, and their expression can be induced with inflammatory mediators, such as cytokines. Chemokines can also modulate neuronal signaling via the regulation of the flow of $Ca^{2+}$ currents [12].

Immunologically active molecules, not necessarily involved with inflammatory reactions, similar to cytokines or chemokines (secreted from cells invading the tissue from the blood stream or secreted centrally by local microglia or astrocytes (►central nervous system inflammation – astroglia and ethanol) as well as bacterial-derived (like lipopolysaccharide (LPS)) or virus-derived molecules can affect voltage-dependent ion currents and ►transmitter receptor-operated ion currents of peripheral or central neurons [1]. Cytokines released by the immune system can influence cognitive processes, for example, and thus modify central neurotransmission and the function of PNS. In addition, cytokines and neuropeptides secreted by peripheral immune cells have dramatic effects on behavior or behavioral aspects of the CNS. Pro-inflammatory cytokines, furthermore, can activate the HPA (discussed below) and thus induce, for example, ►sickness behavior (weakness, malaise, listlessness, inability to concentrate, decreased food and water intake) during the inflammatory ►acute phase response (APR) [1].

The acute phase response has been reported to have specific components (physiological and inflammatory): (i) fever: cytokines such as IL-1, IL-6 and ►tumor-necrosis-factor-α (TNF-α) act at the level of the ►hypothalamus to install and activate thermocenters [1] (►brain inflammation – tumor necrosis factor receptors in mouse brain inflammatory responses); (ii) sickness behavior can be induced by systemic circulating IL-1β and TNF-α; this phenomenon is likely mediated by the vagus nerve since ►vagotomy (severance of the vagus nerve) has been shown to attenuate the behavioral actions of peripheral cytokines; IL-1β, moreover, binds to vagal fibers and thus can increase vagal discharge; (iii) blood-brain barrier: IL-1β can slowly diffuse across the parenchymal blood-brain barrier and activate the basolateral ►amygdala (involved with depressive effects on social behavior) and ►area postrema (this brainstem region activates the HPA axis and gives rise to feelings of nausea) (►bickerstaff's brainstem encephalitis).

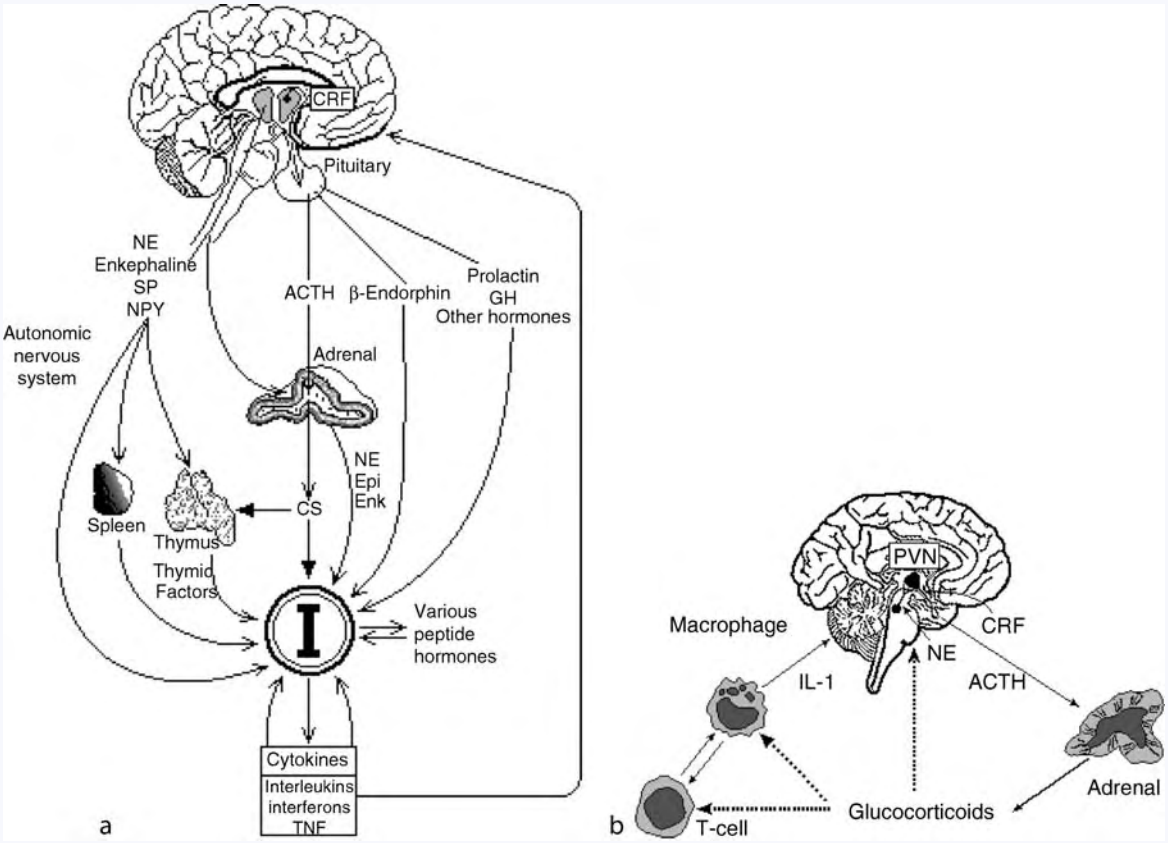
## Nervous System Components Associated with and/or Affected by Immune Responses

Neurons carry information coded in the form of electrical signals (►Membrane potential, ►Action potential). Evidence indicates that neurons can counter-regulate brain immunity in intact CNS areas. For example, microglia are kept in a quiescent state in the CNS by interactions between the microglia receptor ►cluster of designation *(CD)200* and its ligand, which is inducibly expressed on neurons [13]. Furthermore, neurons can downregulate MHC expression in surrounding glial cells, in particular microglia and astrocytes (►glial and neuronal reactivity to unconjugated bilirubin). Certain chemokines are also associated with the surface of many neurons (e.g., ►fractalkine is bound to the outside of neurons in the dorsal horn of the spinal cord). Microglia, moreover, have been shown to express fractalkine receptors (CX3CR1). When ►spinal cord dorsal horn neurons are activated by nociceptive stimuli, for example, they release fractalkine, which binds to the microglial receptors and stimulates the microglia, causing the release of cytokines [1]. This seems to be a vital mechanism in the generation of ►chronic pain condition [9] (►neural-immune interactions – implications for pain management in low-back pain and sciatica).

Glia (neuroglia) can also form an innate immune system offshoot, within the "immune privileged" CNS, which has the potential to initiate immune responses to exogenous antigens or endogenous degenerative processes [13]. ►Oligodendrocytes (components of the CNS) and ►Schwann cells (components of the PNS), which produce a ►myelin sheath around axons, are sensitive to injurious and/or pharmacologically active agents including antibodies, complements and cytokines (►autoimmune demyelinating disorders – stem cell therapy). Astrocytes, on the other hand, affect neuronal function by the release of ►neurotrophic factors (►neurotrophins), guide neuronal development physiologically, contribute to the metabolism of neurotransmitters and regulate extracellular pH and $K^+$ concentrations and currents. The astrocyte, specifically, is an immuno-competent cell in the CNS. The reason is that these cells can express MHC class II and co-stimulatory molecules (B7-1 and B7-2 [CD80/CD86] and CD40) that are critical for antigen presentation and subsequent T-cell (lymphocyte) activation [1]. Microglia essentially resemble brain macrophages, the phenotype of which is thought to represent an adaptation to the specialized neural microenvironment. These features include, but are not restricted to, the following: (i) Microglia exhibit a downregulated (less differentiated) phenotype; (ii) serve major homeostatic and reparative functions (can secrete cytokines and neurotrophic factors); (iii) play a role in host defense (can become activated to perform several innate immune functions, such as induction of inflammation; cytotoxicity and regulation of T-cell responses through presentation of antigen); and (iv) are involved in CNS immune surveillance and response [1] (►neuroinflammation – modulating pesticide-induced neurodegeneration).

## Nervous System Influence on the Immune System – Unidirectional or Bidirectional?

Converging evidence has demonstrated that the immune system is not regulated in an autonomous fashion, but is influenced by external factors particularly mediated by the nervous system (Fig. 2a and b). What are the major connecting mechanisms mediating neuroimmune interactions? There are at least three putative pathways by which the nervous system can communicate or crosstalk with the immune system: (i) Autonomic nervous system (ANS) route via direct nerve fiber connections; (ii) sensory portion of the nervous system via primary afferent nerve fibers; and (iii) neuroendocrine output via the HPA axis. In particular, accumulating evidence indicates that neural control in immunological phases ranges from induction and activation to effector functions and inactivation zones [1]. Autonomic nervous system influence on the immune system involves the following mechanisms: (i) Sympathetic fibers innervate lymphoid organs; (ii) noradrenergic fibers make synapse-like contacts with systemic lymphocytes (spleen) and release ►noradrenaline (NA; also norephinephrine, NE), ►vasoactive intestinal peptide (VIP) and ►neuropeptide Y (NPY); lymphocytes and macrophages can express $\alpha_2$ and $\beta_2$ adrenoceptors, and lymphocytes also express the $Y_1$-NPY receptor; (iii) Noradrenaline suppresses immune responses by tonically inhibiting pro-inflammatory cytokine biosynthesis; (iv) sympathetically released NPY inhibits ►natural killer (NK) cell cytotoxic responses and



**Neuroimmunology. Figure 2** (a) A schematic diagram of the interactions between the brain and components of the endocrine and immune systems. The ability of the brain to alter immune system function by a variety of endocrine pathways and the autonomic nervous system is emphasized, and the effects of peptides and cytokines produced by the immune system on immune cells and the brain is indicated. *CRF*, corticotropin-releasing factor; *CS*, corticosteroids; *Enk*, encephalin; *Epi*, epinephrine; *GH*, growth hormone; *I*, immunocytes; *NE*, norepinephrine; *NPY*, neuropeptide Y; *SP*, substance P; *TNF*, tumor necrosis factor. (b) A schematic diagram of the relationship between the brain, the HPA axis, and immune cells and the role of glucocorticoids. Interleukin-1 (IL-1) produced by lymphocytes during the immune response activates noradrenergic (NE) projections for the brainstem to the hypothalamic paraventricular nucleus (PVN). This input activates the hypothalamic-pituitary-adrenocortical (HPA) axis, stimulating the release of corticotropin-releasing factor (CRF) in the median eminence region of the hypothalamus, which in turn stimulates the secretion of ACTH from the anterior lobe of the pituitary, which then activates the adrenal cortex to synthesize and secrete glucocorticoid hormones. The glucocorticoids in turn provide a negative feedback on cytokine production by lymphocytes [1].

humoral antibody production; and (v) vasoactive intestinal peptide inhibits IL-12 and ►nitric oxide (NO) production by resident macrophages [1].

The major influence of the ►sympathetic nervous system (SNS) on the immune system is to inhibit immune responses. However, there appear to be regional (localized) differences in the effects of NA on immune function. In the thymus, for example, it modulates T-cell proliferation and differentiation; in the spleen and lymph nodes it enhances the primary antibody response. Primary afferents and peptidergic innervations, in particular, exert great influence on the immune system. A number of neuropeptides released from primary afferent nerve fibers have been shown to affect the immune system. For example, ►substance P (SP), a pro-inflammatory undecapeptide, has been localized in the CNS, peripheral sensory neurons, in nerve plexuses of the gut and in the spleen, lymph nodes and thymus (primary and secondary lymphoid organs) [1]. This peptide is found particularly at sites of inflammation and appears to be a regulator of cell-mediated and humoral immune responses. Substance P is involved in (to cite a few examples): (i) early induction of local and systemic host defense responses to inflammation/injury (►traumatic brain injury – rat model of neuroinflammation and expression of matrix metalloproteinases); (ii) causing vasodilatation and increased vascular permeability; (iii) enhancing phagocytosis by neutrophils and/or

N

macrophages; (iv) induction of the release of ►histamine (secondary allergic mediators) and other substances from ►mast cells; and (v) controlling bacterial infections of the gut (►gut-associated lymphoid tissue; GALT); SP blockade has been shown to increase the susceptibility to *Salmonella* infections. Another example is ►calcitonin gene related peptide (CGRP), localized in the bone marrow, lymph node, spleen and thymus where it is released by primary afferent fibers [1]. It has the following properties: (i) it has binding sites on T-cells; (ii) it is a potent vasodilator; and (iii) it inhibits mitogen-stimulated proliferation of T-cells and inhibits T-cell stimulation of ►epidermal Langerhans cells (antigen-presenting cells of dendritic cell origin).

## Influence of Hypothalamic/Pituitary Neuroendocrine Hormones on the Immune System

Early studies identified the pituitary gland as an essential component in the regulation of immune system development and activity. Following surgical removal of the pituitary, Gisler and Schenkel-Hulliger [14], for example, observed reduced antibody responses (sera-localized immunoglobulins were diminished); growth-hormone treatment restored antibody production. Since these early observations, numerous studies have implicated neuroendocrine hormones in immune regulation (Fig. 2a). A list of a few major hormones that influence immune function is succinctly provided below (elaborations are expressed in the section entitled "neuroimmune interactions").

### *Adrenocorticotrophic Hormone (ACTH)*

►Adrenocorticotrophic hormone (ACTH) is extracted from the pituitary glands of animals or made synthetically. ACTH stimulates the adrenal glands to release glucocorticoid hormones. These hormones are anti-inflammatory in nature, reducing edema and other aspects of inflammation. Data from the early 1970s indicate that ACTH may reduce the duration of ►multiple sclerosis (MS) exacerbations (►multiple sclerosis – macrophages and axonal loss). In recent years it has been determined that synthetically produced glucocorticoid hormones (e.g., cortisone, prednisone, prednisolone, methylprednisolone, betamethasone, dexamethasone), which can be directly administered without the use of ACTH, are more potent, cause less $Na^+$ retention and less $K^+$ loss, and are longer-acting than ACTH. ACTH, in brief, has the following properties: (i) it is derived from ►pro-opiomelanocortin (POMC), an unusual hormone complex manufactured by the anterior lobe of the pituitary (hypophysis). This complex is metabolized into four separate hormones: ACTH, ►melanocyte stimulating hormone (MSH), ►enkephalin and ►β-endorphin; (ii) it is secreted by the anterior pituitary into blood stream; (iii) its release is regulated by ►corticotropin-releasing factor (CRF) (or ►corticotropin-releasing hormone (CRH) or ►corticoliberin), a polypeptide hormone involved in the stress response, stress and hypoglycemia (Fig. 2b); (iv) ACTH initiates the release of adrenal corticosteroids and increases the growth of adrenal cells through actions on ►melanocortin receptors; (v) ACTH receptors are present on both B-cells (lymphocytes) and T-cells; (vi) it reduces antibody responses in vitro and reduces ►IFN-γ (interferon) production; and (vii) systemic injection of lipopolysaccharide (LPS) increases ACTH and corticosterone [1].

### *Gonadal Steroids*

Several lines of evidence implicate sex steroids in immune regulation and in the regulation of neuronal gene expression (transcriptional regulation) [1]. In general, ►androgens (hormones promoting the development and maintenance of male sex characteristics) exert suppressive effects on both humoral and cellular-mediated immune responses and seem to represent natural anti-inflammatory hormones; in contrast, ►estrogens (type of hormones that help develop and maintain female sex characteristics and the growth of long bones) exert immuno-enhancing activities, at least on humoral immune response.

This is based on the following observations: (i) sexual dimorphism exists within the immune system: females usually have higher concentrations of ►immunoglobulin (Ig)G, IgM and IgA than males; (ii) antibody responses to antigens are greater in magnitude and essentially more prolonged in females than males; (iii) females have a higher incidence of autoimmune disease (multiple sclerosis (MS), ►rheumatoid arthritis (RA), systemic lupus erythematosis (SLE),); (iv) manipulation of testosterone or estrogen alters autoimmune disease progression or onset in animal models; (v) sex steroids may influence the immune system, at least in part, via the thymus, where they play a role in development and atrophy; (vi) regulation of the immune system by estrogens is particularly important during pregnancy; in this case the balance between glucocorticoid and estrogen regulation probably plays a role in suppression of the maternal immune system to prevent rejection of the fetus; (vii) estrogen and testosterone can regulate IL-6 expression with loss of IL-6 effect in postmenopausal women and postandropausal men, thus resulting in increased IL-6 being associated with increased occurrence of inflammatory diseases with old age (RA, ►inflammatory bowel disease, osteoporosis); and (viii) in general, females are more sensitive to pain than males, and this is due, in part, to the presence of estrogen, which appears to be pronociceptive or of hyperalgesic nature [15].

Adrenocorticotrophic hormone (ACTH), glucocorticoids and gonadal steroids can also directly affect nervous system function. For example, corticosteroid

and estrogen receptors are found in discrete locations in the brain and spinal cord (►neuroinflammation – brain and spinal cord injury). Electrical properties of brain neurons are specifically regulated by glucocorticoid-receptor activation. β-Estradiol has been shown to inhibit L-type ►voltage-gated $Ca^{2+}$ channels in brain neurons. Estrogen receptors (a class of proteins found inside the cells of the female reproductive tissue, some other types of tissue, and some cancer cells; estrogen will bind to the receptors inside the cells and may cause the cells to grow) have been found to be coupled to ►metabotrophic glutamate receptors in the ►hippocampus of the brain and thus can affect second messenger systems involved in memory and learning [1].

## Immunological Surveillance of the Nervous System by Lymphocytes

Studies on the migration of labeled T cells following intravenous injection have shown that activated T lymphocytes of a rather broad specificity enter the normal CNS parenchyma as early as 3h following administration [1]. Thus, T-cell traffic in the CNS appears to be governed by the same principle as applies to other organs, namely that activated T cells preferentially migrate from the blood into tissues, whereas resting cells exit in lymph nodes via high-endothelial venules (HEVs) (found in lymphoid tissues, excluding the thymus; since endothelial cells are tall and lack tight junctions, this facilitates entry of lymphocytes into lymphoid tissue from the blood.) Low numbers of T cells are consistently demonstrable in normal human and rat brains, indicating that the CNS is continuously patrolled by activated lymphocytes [1].

## Conditioning of the Immune Response

Compelling evidence for the influence of the nervous system on the immune system arises from studies that indicate that behavioral conditioning can modify immune responses. A landmark study by Ader and Cohen [16] indicated that after the immunosuppressive drug, cyclophosphamide (a class of drugs known as alkylating agents; it slows or stops the growth of cancer cells), had been paired with the taste of saccharin (the oldest artificial sweetener; in the European Union also known as E954), subsequent ingestion of the saccharin prevented the production of antibodies in response to sheep red blood cell (SRBC) administration (serologic manifestation). This technique has been particularly used to prolong the lives of mice with systemic lupus. There can be little doubt that conditioning can alter immune responses, but the immunological specificity of the effects is not clear, and the mechanisms remain to be unraveled. It is possible that at least some of the immunosuppressive effects are from a conditioning of hormone and neurotransmitter secretion (e.g., glucocorticoids or catecholamines) [1].

## Effects of Brain Lesions on Immune Function

Although evidence has indicated that brain lesions may have effects on immunity, consistent coherence is, at best, fragmented, incomplete and complex. Effective lesions are most commonly located in the hypothalamus and are generally inhibitory. Lesions in other ►limbic areas may also be effective, notably in the ►septum, hippocampus and amygdala. Some studies have indicated that cortical lesions can affect immune responses and that the effects depend upon the laterality of the lesion [1]. Renoux and colleagues [17] have reported evidence that lesions of the left cortex, but not the right, produced pronounced immune deficits in spleen cell number, lymphocyte proliferation, and natural killer cell activity (►nervous, immune and hemopoietic systems – functional asymmetry). The lateral specificity indicates that the aforementioned observation cannot be from nonspecific effects of the lesion, and it could account for the greater number of left-handed individuals who exhibit diseases of the immune system. Lesions of the central noradrenergic systems have also been shown to impair various aspects of the immune response (►neurodegenerative diseases – MAPK signaling pathways: cytokine regulation and glial activation).

## Effects of Stress on the Immune System

It is established that stress may impair the immune system (see below) [1]. The dogma that stress suppresses immunity is to some extent based on the well-established immunosuppressive effects of glucocorticoids. However, the supra-physiological doses of the steroids used in most of the studies do not allow simple extrapolation to the normal physiological state. In fact, endogenous glucocorticoids at physiological doses are not universally immunosuppressive and actually may enhance immune function. Furthermore, glucocorticoids may not even be the major mechanism by which stress suppresses immune function. Experimental evidence has confirmed the immunosuppressive effect of stress. However, it is important to emphasize that there is considerable evidence to suggest the opposite.

### *The Role of the Adrenal*

Adrenalectomy (surgical removal of one or both adrenal glands) has been shown to prevent the immunosuppressive effects of stress, but other studies have indicated that stress-induced changes in immunity persist in adrenalectomized animals. Adrenalectomy appears to be effective in studies that have examined acute responses to brief stressors (for which the immunosuppressive effects are rapidly reversed), but may be less important for the effects of chronic stress. Adrenalectomy, furthermore, does not permit a distinction among the effects of steroids, catecholamines, or even of neuropeptides secreted by the adrenal gland. More recent studies

have suggested an important role for the circulating catecholamines, derived from the sympathetic nervous system and adrenal medulla [1].

The choice of immune parameters measured may also influence the results. Earlier studies relied heavily on mitogen-stimulated proliferation assays, which assess the responsivity (i.e., cell division measured by DNA synthesis) to lectin mitogens [such as concanavalin A (Con A), phytohemagglutinin (PHA), lipopolysaccharide (LPS), or pokeweed mitogen] in vitro (►anti-DNA antibodies against microbial and non-nucleic acid self-antigens). The interpretation of such assays is questionable, because the results are susceptible to a large number of extraneous influences, and the assays are conducted after several days of in vitro incubation separated from normal physiological influences [2]. A measure used more often has recently been that for natural killer cells. There is good evidence that natural killer cells are involved in the rejection of tumors, and therefore at least one of their immunophysiological functions is clear. Stressful treatments have been shown to suppress natural killer cell function. The major effector for the stress-induced effects on natural killer cell function appears to be ►opiates and catecholamines through β- ►adrenergic receptors. Because most of the studies of stress on immune function have used ex vivo procedures, another important factor is whether or not the population of cells sampled may be altered by the in vivo treatment. Cell trafficking, the movement of lymphocytes around the body, is known to be regulated by hormones and other secretions, including those secreted during stress, and it is likely, therefore, that the stressful treatments alter the population of cells harvested for the in vitro analysis [1].

### The Role of Glucocorticoids

The best-known mechanism for an influence of the nervous system on the immune system is circulating glucocorticoids secreted by the adrenal cortex (Fig. 2b). Glucocorticoids have long been known to have immunosuppressive effects. The data derive in part from the medical practice of using glucocorticoids postsurgically to decrease tissue inflammation and the rejection of transplanted tissues. However, considerable experimental data suggest that the effects of glucocorticoids are not exclusively immunosuppressive [18] (►neuroinflammation – LPS-induced acute neuroinflammation, rat model). Although it is well established, it is too often forgotten that glucocorticoids are essential for normal immune responses. For example, adrenally compromised individuals are more susceptible to infections. Of particular importance, it was also shown that corticosteroids were essential for normal recovery from infections in adrenalectomized animals [1].

Nevertheless, the extensive evidence for the immunosuppressive effects of glucocorticoids should not be ignored. It should, however, be viewed in the light that most of the data were generated using high doses of synthetic glucocorticoids (e.g., prednisolone, triamcinolone, or dexamethasone, amongst others), which are considerably more potent than the native steroids. The concentrations of these compounds used clinically can cause lysis of immune cells, especially immature ones. The more careful studies have used natural steroids at relatively physiological doses; these have noted stimulatory effects of steroids at lower doses. Inhibitory effects occur at higher (supra-physiological) doses, typically $10^{-6}$ M, which is close to the maximum concentration of free corticosterone or cortisol found in stressed animals after correcting for that bound by corticosteroid-binding globulins. It is also important that elevations of plasma glucocorticoids following acute stressors are short-lived [1].

Although there are direct effects of glucocorticoids on immune cells in vitro, there may also be indirect ones in vivo. One of the oldest known physiological correlates of stress is the involution of the thymus. This involution, which can decrease thymus weight by more than half (also ageing-related phenomenon), occurs largely because lymphocytes that normally reside there are driven out to the periphery. Stress-induced thymic involution is prevented by adrenalectomy and can be induced by administration of glucocorticoids. Thus glucocorticoids can alter the body's distribution of lymphocytes, which may in itself be an important factor marshalling the immune response to infection. Moreover, as mentioned above, the population of lymphocytes derived by harvesting tissues from animals subjected to experimental treatments may be altered by the redistribution of cells due to glucocorticoid secretion. This should be an important consideration in interpreting the results of ex vivo data [1].

### The Role of Catecholamines

Lymphocytes bear both α- and β-adrenergic receptors. Catecholamines appear in the circulation from both the adrenal medulla [noradrenaline (NA) and adrenaline] and from sympathetic terminals (NA). In addition, lymphocytes may be exposed more directly to neuronal secretions while they are resident in the thymus, spleen, and lymph nodes. Anatomical studies have clearly demonstrated a sympathetic innervation of immune structures, such as the bone marrow, thymus, spleen, and lymph nodes. Thus lymphocytes could be exposed to high local concentrations of catecholamines, as well as neuropeptides (►microglial signalling regulation by neuropeptides). A parasympathetic (i.e., cholinergic) innervation of these organs has not been confirmed [19].

In vitro studies have revealed adrenergic effects on lymphocytes. Early studies suggested separate α- and β-adrenergic effects; β-adrenergic receptors were largely inhibitory, whereas α-adrenergic receptors were

stimulatory. This generalization has endured to some extent, but the detailed results are very complex. There appear to be separate α- and β-adrenergic stimulatory effects on antibody production in vitro, whereas natural killer cell activity appears to be inhibited by β-adrenergic stimulation. The results of in vivo studies have been of bewildering complexity. Depending on the parameters used, sympathectomy has been shown to impair, enhance, or not change immune responses. In general, sympathectomy in adult animals depresses immune reactivity, but there are also paradoxical effects on lymphocyte proliferation and B-cell differentiation. Among the confounding factors that may contribute to the complexity are compensatory increases in adrenomedullary output, redistribution of lymphocytes, compensatory changes in the number and kind of adrenergic receptors, and the coexistence in sympathetic terminals of peptides, such as NPY [1]. Several studies have suggested that a major mechanism by which natural killer cell activity is regulated in vivo involves catecholamines released by the sympathetic nervous system. For example, the inhibitory effect of intra-cerebroventricular injection of corticotropin-releasing factor (CRF) on natural killer activity is blocked by the ganglionic blocker, chlorisondamine, as is the immunosuppressive effect of IL-1. There is also direct evidence that β-adrenergic receptor blockade can prevent stress-induced effects on natural killer cell activity [19].

### The Role of Peptides

Sympathetic nerve terminals contain not only noradrenaline, but also neuropeptides, including endorphins, which may act on the immune system. The presence of NPY, substance P (SP) and vasoactive intestinal peptide (VIP) in the thymus, spleen and lymph nodes, as well as calcitonin gene related peptide (CGRP) in the thymus and lymph nodes, enkephalin and somatostatin in the spleen, tachykinin in the thymus, and peptide histidine isoleucine in lymph nodes have been described [1]. It has been shown that lymphocytes can synthesize and secrete certain peptides. The spectrum of peptides synthesized is large, and includes many of the known peptide hormones, as well as the hypophysiotropic factors. The peptides include ACTH, CRF, growth hormone (GH), thyrotropin (TRH), prolactin, human chorionic gonadotropin, the endorphins, encephalin, SP, somatostatin and VIP. The quantities of the peptides produced are typically very small, and their biochemical characterization has often been perfunctory. Sometimes their existence has been inferred only from the results obtained in the very sensitive assays used to detect their messenger ribonucleic acids (mRNAs), which should not be construed as unequivocal evidence for the presence of the peptides themselves. More careful analyses have not always substantiated the original claims, especially for the endorphins. There is probably considerable variability in the ability of lymphocytes from different sources to produce a specific peptide, but this issue has received no serious attention in the literature [1].

The physiological significance of this production of peptides is not at all clear. Because in many cases lymphocytes display receptors for these same peptides, they may function as chemical messengers within the immune system. However, Blalock has suggested that the peptides may also have systemic functions; for example, ACTH could activate the adrenal cortex. Although there is no good experimental support for this specific example, it is possible that there may be a local bidirectional communication between lymphocytes and other cells. One example of this communication may be in the spleen, where CRF appears to be present in the innervating neurons and CRF-receptors are present on resident macrophages. Another example involves endorphins; β-endorphin produced by lymphocytes in an area of inflammation may exert an analgesic action directly on sensory nerve terminals. Such a mechanism is attractive, because the concentrations of the peptides produced locally may be adequate to exert such effects, and the metabolic lability of peptides would ensure that the effect was localized [1] (see Fig. 2a and b).

### Other Hormones of the Hypothalamo–Pituitary–Adrenocortical Axis

Many other hormones are known to affect the immune system. Firstly, there are the hormones of the HPA axis, each of which has been reported to affect immune function: CRF, ACTH, and the endorphins. Corticotropin-releasing factor (CRF) itself has been reported to have a variety of effects. The reported direct effects of CRF on immune cells have generally been stimulatory. For example, CRF has been shown to stimulate B cell proliferation and natural killer activity, as well as IL-1, IL-2, and IL-6 production. Receptors for CRF have been found on immune cells, providing a mechanism for these effects. Although it seems unlikely that CRF in the general circulation ever achieves concentrations high enough to stimulate these receptors, it is possible that local actions may occur, for example, in the spleen. By contrast, CRF injected intra-cerebroventricularly (icv) has largely inhibitory effects on immune function. A major effect of icv CRF is evident on natural killer cell activity and appears to be mediated through the sympathetic nervous system. The footshock-induced reduction of natural killer cell activity appears to be mediated by cerebral CRF, because an antibody to CRF injected icv but not peripherally prevented the shock-related response [1].

Although ACTH has been shown to have some direct effects on immune function, including an inhibition of antibody production and modulation of B cell function, the effects have not been striking. On the

other hand, the endorphins have been shown to exert a plethora of effects on immune function. Lymphocytes possess binding sites for opiates, but at least some of these are not sensitive to the opiate antagonist, naloxone. Interestingly, binding sites have been found for N-acetyl-β-endorphin, which is the commonest form of β-endorphin secreted from the anterior pituitary and has no opiate activity. β-Endorphin and other opioid peptides can exert effects on lymphocytes in vitro. By and large, the effects are facilitatory. Such effects have been observed on natural killer cell activity as well as on proliferative responses. Opioid peptides are also chemoattractants for lymphocytes. In contrast to the enhancing effects in vitro, in vivo opiates are largely inhibitory, especially on natural killer cell activity. This apparent contradiction can be explained, because, at least in the case of morphine, the site of opiate action appears to be in the CNS. Moreover, the effects appear to be mediated by the adrenal gland, most probably by catecholamines [1].

### *Other Hormones*

Perhaps the most interesting effect of a pituitary hormone on the immune system is that of prolactin; its effects are largely stimulatory. Reduction of pituitary prolactin secretion (e.g., by dopaminergic agonists or opiate antagonists) impairs immune function and increases susceptibility to infections, such as by *Listeria monocytogenes,* whereas stimulation of prolactin secretion (e.g., by D2 dopaminergic antagonists or opiates) can enhance it. It is postulated that prolactin may be the counter-regulatory hormone to glucocorticoids and thus acts by opposing interactions between these two hormones on immune function as can be demonstrated in vivo. Direct effects of prolactin on lymphocyte function have been difficult to demonstrate, but prolactin antibodies do impair proliferative responses in vitro. Lymphocytes can produce a prolactin-like protein, although its identity with prolactin has not been demonstrated. Thus it appears that prolactin is yet another example of a multifunctional peptide produced by both the pituitary and the lymphocytes [1].

## Immune System Signaling of the Brain – Infection as a Stressor

Not that many would technically challenge the notion that sickness is stressful. In his autobiography, Hans Selye (Selye János (1907–1982) was a Canadian endocrinologist of Austrian-Hungarian origin who did much important theoretical work on the non-specific response of the organism to stress.) indicates that it was the common characteristics of sickness regardless of the underlying disease, i.e., "the syndrome of just being sick," that first interested him in stress research and led him to advance his much maligned proposal of the *non-specificity* of stress. That the HPA axis is activated following infections has long been known. During World War I, it was noted that fatalities from infections were associated with striking morphological changes in the adrenal cortex. It was later discovered that endotoxin (lipopolysaccharide, LPS), a potent stimulator of the immune system, stimulated the HPA axis. Subsequently, it was shown that infection of rats with *Escherichia coli* increased the secretion of ACTH [1].

## Cytokines, Neuropeptides and the Mechanics of Neuroimmune Interactions

Cytokines are mediators of inter- and intracellular communications [20]. These peptides contribute to a chemical signaling language that regulates development, tissue repair, hemopoiesis, inflammation and the specific and non-specific immune responses [21].

Potent cytokine polypeptides (such as IL-1, IL-6, IL-8 and tumor-necrosis-factor-α (TNF-α)) have pleiotropic (redundant) activities and functional redundancy [1]; in fact, they act in a complex, intermingled network where one cytokine can influence the production of, and response to, many other cytokines. It is also now clear that the pathophysiology of inflammatory ►hyperalgesia, infection and autoimmune and malignant diseases can be explained, at least in part, by the induction of cytokines and the subsequent protracted cellular responses [21]. Of note, cytokines and cytokine antagonists have also exhibited therapeutic potential in a number of chronic and acute diseases [1].

The mechanisms, from both the neural and immunological perspective, involved in stress-induced alteration of immune function are being studied. The immune system is regulated in part by the CNS, acting principally via the HPA axis and the sympathetic nervous system [1]. In recent years, our understanding of the interactions between the HPA axis and immune-mediated inflammatory reactions has expanded enormously. This section outlines the influences that the HPA axis and immune-mediated inflammatory reactions exert on each other and discusses the mechanisms whereby these interactions are mediated. Furthermore, I discuss HPA interactions and oxidative stress evolution within the context of a potential role for the ►transcription factor NF-κB (►NF-κB – activation in the mouse spinal cord following sciatic nerve transection), which regulates a plethora of cellular functions including pro-inflammatory mediated processes [22], and the role of gaseous transmitters (►brain aging and Alzheimer's disease).

## Cytokines in the CNS: Neuro-Immune-Endocrine Interactions

The communication between the neuroendocrine and immune systems is bidirectional (see Fig. 1a). The neuroimmune-endocrine interface is mediated by cytokines, such as IL-1 and tumor-necrosis-factor-α

(TNF-α), acting as autocrine/paracrine or endocrine factors regulating pituitary development, cell proliferation, hormone secretion, and feedback control of the HPA axis [1]. Increasing evidence supports the hypothesis that there are bi-directional circuits between the CNS and the immune system. Soluble products that appear to transmit information from the immune compartment to the CNS include ►thymosins, ►lymphokines and certain complement proteins.

Opioid peptides, ACTH and ►thyroid-stimulating hormone (TSH) are additional products of lymphocytes that may function in immunomodulatory neuroendocrine circuits. It was proposed that the term "immunotransmitter" be used to describe molecules that are produced predominantly by cells that comprise the immune system but that transmit specific signals and information to neurons and other cell types [1].

Several cytokines are known to affect the release of anterior pituitary hormones by an action on the hypothalamus and/or the pituitary gland. The major cytokines involved are IL-1, IL-2, IL-6, tumor-necrosis-factor-α (TNF-α) and interferon (IFN) (see Fig. 2a). The predominant effects of these cytokines are to stimulate the HPA axis and to suppress the ►hypothalamic-pituitary-thyroid (HPT) axis and gonadal axis, and growth hormone (GH) release. However, the relative importance of systemically and locally produced cytokines in achieving these responses and their precise sites of action have not been fully established [1]. There is accumulating evidence that there are significant interactions between the immune and neuroendocrine systems which may explain, at least in part, some of the effects on growth, thyroid, adrenal and reproductive functions which occur in acute and chronic disease (►central nervous system disease in primary sjögren's syndrome). During stimulation of the immune system (e.g. during infectious diseases), peculiar alterations in hormone secretion occur (hypercortisolism, hyperreninemic hypoaldosteronism, euthyroid sick syndrome, hypogonadism). The role of cytokines is being elucidated [1,23].

### *IL-1/IL-6/TNF-α and HPA Responses*

The bilateral communication between the immune and neuroendocrine systems plays an essential role in modulating the adequate response of the HPA axis to the stimulatory influence of interleukins and stress-related mediators [24] (see Fig. 2a) (►neuroinflammation – IL-18). It is thus reasonable to assume that inappropriate responses of the HPA axis to interleukins might play a role in modulating the onset of pathological conditions such as infections and related pathologies [1]. Ever since two distinct molecules of IL-1 (IL-1α and IL-1β) were cloned, sequenced and expressed, it has been a matter of investigation whether these two forms of IL-1 possess an identical spectrum of biological activities (►immunomodulation – brain areas involved).

In situ histochemical techniques were used to investigate the distribution of cells expressing type I IL-1 receptor mRNA in the CNS, pituitary and adrenal gland of the mouse. For instance, hybridization of $^{35}$S-labeled antisense cRNA probes derived from a murine T-cell IL-1 receptor cDNA revealed a distinct regional distribution of the type I IL-1 receptor, both in brain and in the pituitary gland [1]. In the brain, an intense signal was observed over the granule cell layer of the ►dentate gyrus, over the entire midline ►raphe system, over the choroid plexus and over endothelial cells of postcapillary venules throughout the neuraxis. A weak to moderate signal was observed over the pyramidal cell layer of the hilus and CA3 region of the hippocampus, over the anterodorsal ►thalamic nucleus, over ►Purkinje cells of the ►cerebellar cortex and in scattered clusters over the external-most layer of the ►median eminence. In the pituitary gland, a dense and homogeneously distributed signal was observed over the entire anterior lobe. Furthermore, no autoradiographic signal above background was observed over the posterior and intermediate lobes of the pituitary, or over the adrenal gland, providing evidence for discrete receptor substrates subserving the central effects of IL-1, thus supporting the notion that IL-1 acts as a neurotransmitter/neuromodulator in the brain. It also supports the fact that IL-1-mediated activation of the HPA axis occurs primarily at the level of the brain and/or pituitary gland [1].

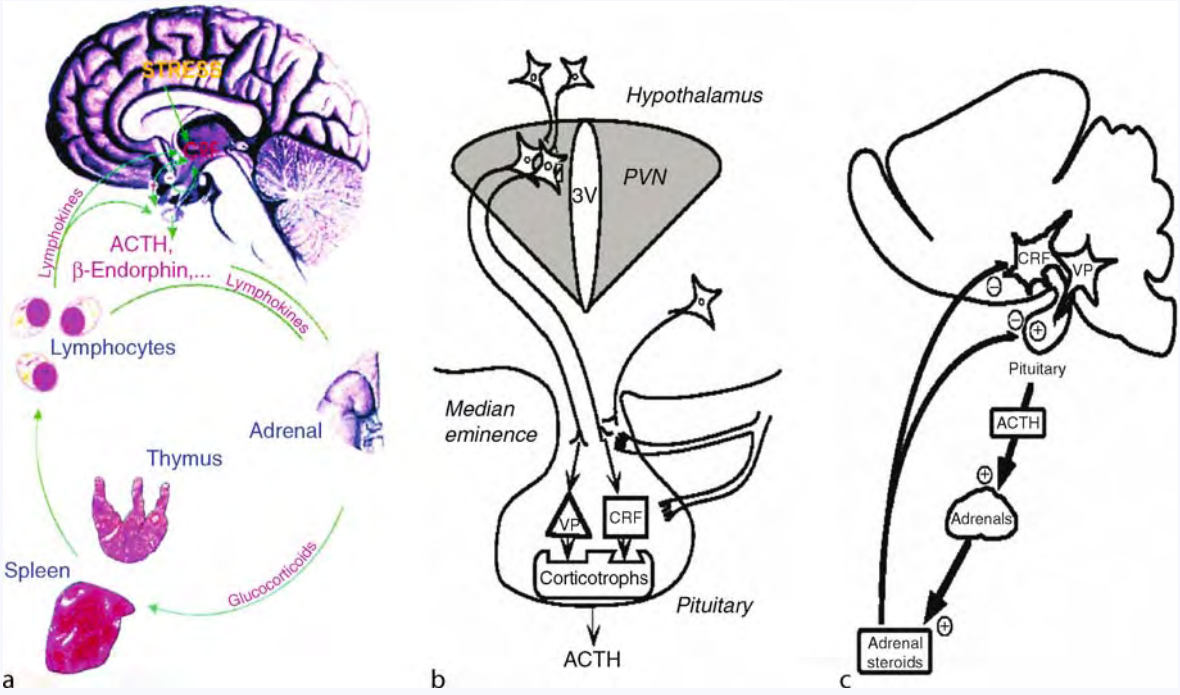
IL-1 and other related pro-inflammatory cytokines are potent activators of the HPA axis [1]. Current studies of IL-1 and its involvement in the HPA axis have indicated that there is a clear-cut differential response to IL-1α and IL-1β. For example, the intravenous injection of human recombinant IL-1β in conscious, freely-moving rats significantly increased the plasma concentrations of ACTH in a dose-related manner, whereas IL-1α did not, suggesting that the two members of the IL-1 family may have a different spectrum of biological actions.

Furthermore, additional investigations clarified the mechanism by which IL-1 activates the HPA axis. For example, the ACTH response to IL-1 was completely abolished by pre-injection of rabbit antiserum generated against corticotrophin-releasing factor (CRF) but not by normal rabbit serum [1]. The IL-1-induced ACTH release did not seem to be caused by a general stress effect of IL-1 because plasma prolactin (PRL) concentrations, another indicator of a stress response, were not altered by IL-1 injection, suggesting that IL-1 acts centrally in the brain to stimulate the secretion of CRF, thereby eliciting ACTH release, and that a direct action of IL-1 on the pituitary gland is unlikely. In addition, it has been reported that intra-peritoneal injection of recombinant IL-1 into mice increased the cerebral concentration of the noradrenaline (NA) catabolite,

3-methoxy-4-hydroxyphenylethyleneglycol (MHPG), probably reflecting increased activity of noradrenergic neurons [1]. This effect was dose-dependent and was largest in the hypothalamus, especially the medial division. Of note, ►tryptophan concentrations were also increased throughout the brain and the increase of MHPG after IL-1 administration paralleled the increase of plasma corticosterone (►neurodegenerative diseases – tryptophan metabolism). In contrast to prior observations [1], both the α- and β-forms of IL-1 were effective, but the activity was lost after heat treatment of the IL-1 [25].

Noradrenergic neurons with terminals in the hypothalamus are known to regulate the secretion of CRF, thus suggesting that IL-1 activates the HPA axis by activating these neurons. Because the initiation of an immune response is known to cause systemic release of IL-1, this cytokine may be an immuno-transmitter communicating the immunologic activation to the brain. The IL-1-induced changes in hypothalamic MHPG may explain the increases of electrophysiological activity, the changes of hypothalamic noradrenaline metabolism and the increases in circulating glucocorticoids reported to be associated with immunologic activation and frequently observed in infected animals [25]. In support of these observations, ACTH secretion by the anterior pituitary has been shown to be stimulated by catecholamines in vivo and in vitro [1] (Fig. 3).

In concert, it has been reported that intracerebroventricular injections of IL-1 can cause the release of ACTH. For instance, IL-1β produced an immediate increase in plasma corticosterone and ACTH [1]. Using a potent steroidogenic dose of IL-1β, intra-cerebroventricular injection resulted in the suppression of splenic macrophage IL-1 secretion following stimulation by lipopolysaccharide-endotoxin (LPS) in vitro. Macrophage ►transforming growth factor (TGF)-β secretion, however, was not affected, indicating a differential action of IL-1β on macrophage cytokine production. Following adrenalectomy, the suppressive effect of IL-1β was reversed and resulted in the stimulation of macrophage IL-1 secretion, indicating that the suppression was



**Neuroimmunology. Figure 3** The HPA doctrine. (a) Classic components of the HPA-CNS-immune systems. (b) Neurons of the hypothalamus that synthesize CRF and vasopressin are found in an area called the paraventricular nucleus (PVN). These cell bodies send axons to the median eminence, here peptides are released from the nerve terminals and are transported through vessels of the portal system. When they reach the anterior pituitary, these peptides act on their respective receptors, thereby stimulating ACTH secretion. (c) Following its release into the general circulation, ACTH acts on the cortex of the adrenal glands, which manufacture and secrete glucocorticoids (corticosterone in rodents and cortisol in humans). These glucocorticoids exert a classical negative feedback influence on the pituitary, where they inhibit the effect of CRF and VP, and on the PVN, where they inhibit the synthesis of CRF. Thus after a stimulus stimulates CRF and ACTH release, the production of glucocorticoids will eventually terminate this release, thereby ensuring the maintenance of homeostasis [1].

mediated by adrenocorticol activation. However, surgical interruption of the splenic nerve to eliminate autonomic innervation of the spleen also prevented the macrophage suppressive signal.

Further conflicting reports, however, have been published with regard to a crucial role of catecholamines in IL-1-mediated regulation of the HPA axis [1]. The hypothalamus seems to be an important site of action of IL-1 on the HPA axis, thereby inducing CRF secretion (catecholamines are important modulators of CRF secretion); in turn, IL-1 stimulates catecholamine release from the hypothalamus. In this respect, using an in vitro rat hypothalamic continuous perfusion system, the possible involvement of hypothalamic catecholamines in the effect of IL-1β on hypothalamic CRF secretion was investigated. For instance, neither in vivo pretreatment with an inhibitor of catecholamine synthesis nor in vitro exposure to α- or β-adrenoceptor antagonists (phenoxybenzamine or propranolol, respectively), nor combination of both treatments altered the effect of IL-1 on CRF secretion from superfused hypothalami, indicating that catecholamines are not involved in the in vitro stimulatory action of IL-1 on hypothalamic CRF secretion. In contrast, IL-1-induced corticosterone release was shown to occur by an adrenergic mechanism from rat adrenal gland [1].

An interesting mechanism was reported for IL-1-mediated regulation of the HPA axis. A primary route of peripheral cytokine signaling was proposed through the stimulation of peripheral vagal afferents rather than, or in addition to, a direct cytokine access to the brain. Sub-diaphragmatic, but not hepatic vagotomy, blocked IL-1β-induced hypothalamic norepinephrine depletion and attenuated IL-1β-induced increases in serum corticosterone, suggesting that IL-1 activates the HPA axis via the stimulation of peripheral vagal afferents and further support the hypothesis that peripheral cytokine signaling to the CNS is mediated primarily by stimulation of peripheral afferents [1].

Another major mechanism reported for the action of IL-1 on the HPA axis involves the amygdala. For example, bilateral ibotenic acid lesions of the central amygdala substantially reduced ACTH release and hypothalamic corticotropin-releasing factor and oxytocin cell c-fos expression responses to IL-1 and IL-8, suggesting a facilitatory role for this structure in the generation of HPA axis responses to an immune challenge [1]. Since only a small number of central amygdala cells project directly to the ►paraventricular nucleus, the authors then examined the effect of central amygdala lesions on the activity of other brain nuclei that might act as relay sites in the control of the HPA axis function. It was found that bilateral central amygdala lesions significantly reduced IL-1β-induced c-fos expression in cells of the ventromedial and ventrolateral subdivisions of the bed nucleus of the stria terminalis and brainstem catecholamine cell groups of the ►nucleus tractus solitarii (A2 noradrenergic cells) and ventrolateral medulla (A1 noradrenergic and C1 adrenergic cells). These findings, in conjunction with previous evidence of ►bed nucleus of the stria terminalis and catecholamine cell group involvement in HPA axis regulation, indicated that ventromedial and ventrolateral bed nucleus of the stria terminalis cells and medullary catecholamine cells might mediate the influence of the central amygdala on the HPA axis responses to an immune challenge. Thus these related data established that the central amygdala influences HPA-axis responses to a systemic immune challenge but indicate that it acts primarily by modulating the activity of other control mechanisms [1] (see Fig. 3).

Similarly, an interesting mechanism implicates the vagus nerve. For instance, direct electrical stimulation of the central end of the vagus nerve induced increases in the expression of mRNA and protein levels of IL-1β in the hypothalamus and the hippocampus. Furthermore, expression of CRF mRNA was increased in the hypothalamus after vagal stimulation. In addition, plasma concentrations of ACTH and corticosterone were also increased by this stimulation, indicating that the activation of the afferent vagus nerves can induce production of cytokines in the brain and activate the HPA axis. Therefore, the afferent vagus nerve may play an important role in transmitting peripheral signals to the brain in infection and inflammation. In concert, dorsal and ventral medullary catecholamine cell groups were reported to contribute differentially to systemic IL-1β-induced HPA axis responses. Medial parvocellular paraventricular corticotropin-releasing hormone (mPVN/CRH) cells are critical in generating HPA axis responses to systemic IL-1β. However, although it is understood that catecholamine inputs are important in initiating mPVN/CRH cell responses to IL-1β, the contributions of distinct brainstem catecholamine cell groups are not known [1] (Fig. 4a and b).

The in vivo release of ACTH by IL-1 is reportedly blocked by acute treatment with indomethacin, a non-steroidal anti-inflammatory drug (NSAID), suggesting an involvement of endogenous ►prostaglandins in the effect of cytokines on the HPA axis [1]. However, indomethacin also increases plasma corticosterone concentrations, raising the possibility that inhibition of ACTH release is due to suppressive effects of hypercorticolemia rather than to blockade of the stimulatory effects of IL-1α. It was observed that the intraventricular administration of indomethacin completely abolished the rise in plasma ACTH levels caused by the peripheral injection of this lymphokine to intact rats. In contrast, implantation of intact rats with indomethacin pellets only partially interfered with IL-1-induced ACTH secretion. To determine whether the effect of indomethacin was due to corticosteroid feedback

or represented a modulating action of prostaglandins themselves, a similar series of experiments were carried out in adrenalectomized rats. In the absence of corticoid replacement therapy, acute treatment with indomethacin did not measurably interfere with the stimulatory effect of IL-1α. In contrast, indomethacin blunted, but did not abolish, the effect of IL-1α in adrenalectomized rats pretreated with cortisone or dexamethasone to normalize basal ACTH levels. Thus, the acute ability of indomethacin to totally block IL-1-induced ACTH secretion by intact rats appears to be primarily mediated through corticosteroid feedback. However, results obtained when a similar experiment was carried out in adrenalectomized/corticosteroid-treated rats suggested that the ability of IL-1α to activate the HPA axis might be partially dependent on the release of prostaglandins. In concert, the effects of various cyclo- and lipoxygenase inhibitors on the neuro-chemical and HPA responses to IL-1 indicated a role for prostaglandins in IL-1-mediated activation of the HPA axis (►neuroinflammation – PDE family inhibitors in the regulation of neuroinflammation). For example, pretreatment of mice with the cyclo-oxygenase (COX) inhibitors indomethacin or ibuprofen failed to prevent the elevations of plasma cortisone, or hypothalamic MHPG or tryptophan that followed intraperitoneally administered IL-1 [1].

In contrast, pro-inflammatory cytokines can reduce glucocorticoid receptor translocation and function. Specifically, several studies have found that cytokines induce a decrease in glucocorticoid receptor function, as evidenced by reduced sensitivity to glucocorticoid effects on functional end points [26]. These observations clearly suggested that cytokines produced during an inflammatory response may induce glucocorticoid-receptor resistance in relevant cell types by direct effects on the glucocorticoid receptor, thereby providing an additional pathway by which the immune system can influence the HPA axis [1].

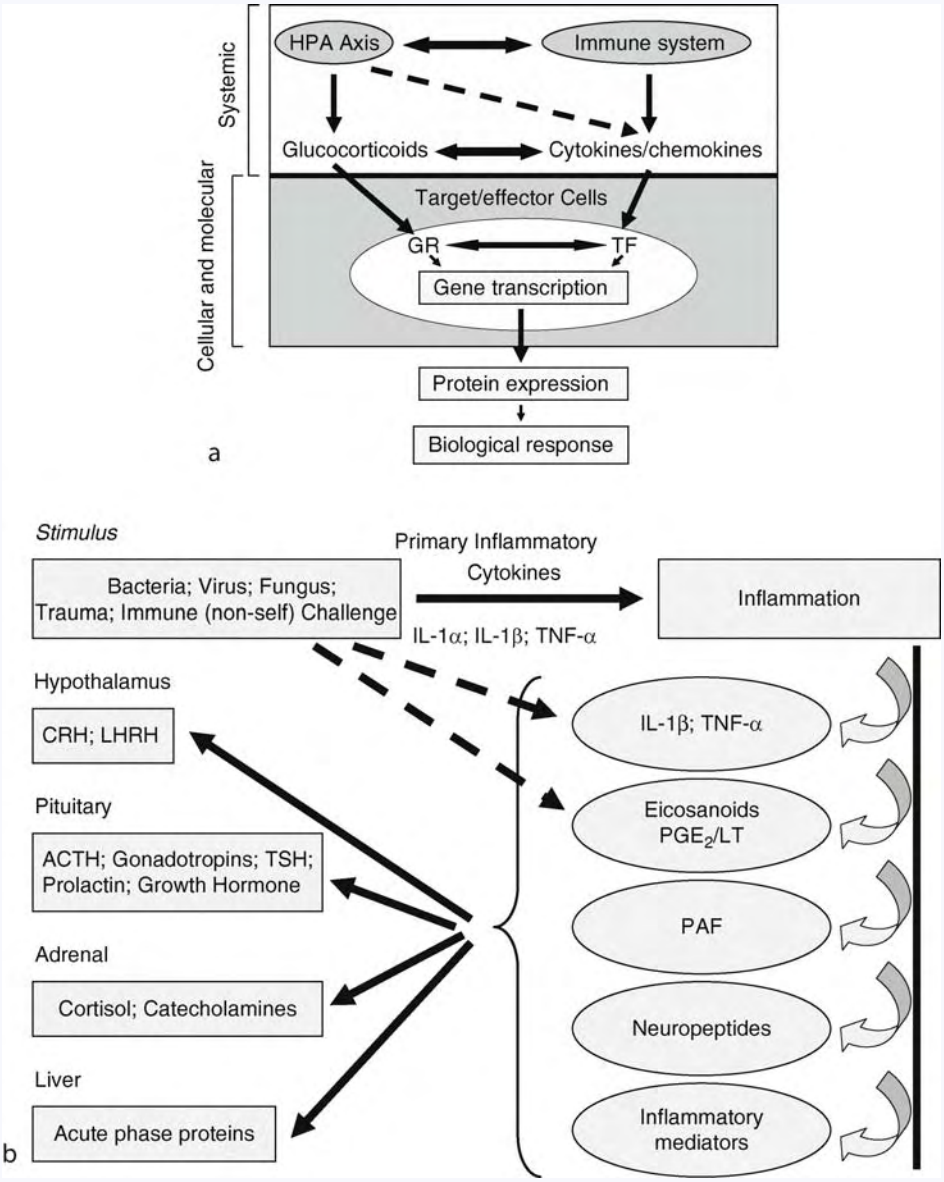
Administration of lipopolysaccharide (LPS) (and other inflammatory mediators) results in the activation of the HPA axis [1] (Fig. 4b). The mechanisms through which LPS stimulates the HPA axis are not well understood, however. In initial studies, the hypothesis that LPS increases plasma ACTH levels by releasing IL-1 was tested. Two experimental tools reported to interfere with the biological activity of IL-1 were used: antibodies directed against IL-1 receptors and α-melanocyte releasing hormone (α-MSH) [27] (►melanin and neuromelanin in the nervous system). The results suggested that LPS activates the HPA axis through a mechanism involving the activation of IL-1 receptors and that the effect of IL-1β, but not IL-1α, on ACTH secretion can be partially blocked by α-MSH. Therefore, LPS acts both at the level of the brain and the gonads to stimulate the HPA axis and inhibits the hypothalamic-pituitary-gonadal (HPG) axis [1].

Exogenously administered IL-1 mimics most of the effects of LPS on pituitary activity. In addition, antibodies against IL-1 receptors can interfere with LPS-induced ACTH secretion, indicating that at least part of the ability of LPS to alter endocrine functions appears to depend upon endogenous IL-1. Of interest, IL-1 and IL-6 share a number of biological functions. Because IL-1 induces IL-6 in vivo, the extent to which IL-6 mediates the effects of IL-1 has come under investigation. The stimulation of the HPA axis by IL-1 and IL-6 is recognized as a critical component of the inflammatory response. In this respect, it was demonstrated that the administration of IL-6 alone did not duplicate the stimulatory effect of IL-1α on ACTH release. On the other hand, sub-optimal amounts of IL-1α and IL-6 synergized to induce an early (30–60 min) ACTH response and produce a later (2–3h) response that was similar to the one observed after IL-1α was administered alone, suggesting that the late response to IL-1 may be dependent on synergy with the endogenous IL-6 it induces systemically and in the CNS (including the hypothalamus and the pituitary gland) [1].

Another mechanism implicates histamine receptors in LPS/IL-1-induced activation of the HPA axis and ACTH release [1]. Lipopolysaccharine (LPS) and LPS-derived cytokines stimulate the release of histamine. Histamine is a known hypothalamic neurotransmitter and activates the HPA axis. To elucidate the role of histamine in LPS- and cytokine-induced ACTH release, Perlstein and colleagues [28] evaluated the effects of several histamine H1 and H2 receptor antagonists on the ACTH response to LPS, IL-1α and histamine in mice. Although all three of the H1 receptor antagonists administered (mepyramine, diphenhydramine or promethazine) were able to block the 10-min ACTH response to histamine, only promethazine (a less selective H1 receptor antagonist than mepyramine) was able to reduce the LPS- or IL-1α-induced ACTH responses. In addition, ranitidine, a powerful and selective H2 receptor antagonist, had little effect on the LPS- and IL-1α-induced ACTH responses, while metiamide, a much less potent first-generation H2 receptor antagonist, substantially diminished ACTH release. It was concluded that the greater effectiveness of promethazine, in contrast to mepyramine or diphenhydramine, probably relates to the ability of phenothiazine derivatives to inhibit non-HA-dependent pathways involved in the stimulation of the HPA axis by cytokines [1].

### IL-2 and HPA Responses

The cytokine IL-2 exerts numerous effects within the immune as well as the central nervous system and is thought to serve as a humoral signal in their communication. A major role for IL-2 has been noted in the regulation of the HPA axis responses. Brain-derived or blood-borne



**Neuroimmunology. Figure 4** (a) Scheme depicting systemic and cellular/molecular interplay between the HPA axis and the immune system in the regulation of glucocorticoid/cytokine secretion and gene expression. *GR*, glucocorticoid receptor; *TF*, transcription factors. (b) The inflammatory response and the HPA axis. Some of the effects of the inflammatory response on the neuroendocrine system are illustrated. A stimulus such as trauma, stress, immune challenge, or bacterial, viral and fungal toxins acts to provoke the inflammatory process. Inflammatory cells respond by secreting inflammatory mediators such as cytokines. A profound process of inflammation ensues and propagates itself with the auto-induction (autocrine) of inflammatory mediators, including cytokines, eiconsanoids, platelet activating factor, neuropeptides and various other mediators. These agents, particularly inflammatory cytokines, act either directly or indirectly to increase the production of releasing hormones in the hypothalamus (HPA axis), pituitary hormones, cortisol and catecholamines. In addition, the liver participates in this inflammatory-HPA axis by releasing acute-phase proteins. *ACTH*, adrenocorticotropic hormone; *CRH*, corticotropin releasing hormone; *LT, IL*, leukotriene, interleukin; *LHRH*, luteinizing hormone releasing hormone; *PAF*, platelet activating factor; *$PGE_2$*, prostaglandin; *TSH*, thyroid stimulating hormone; *TNF*, tumor necrosis factor [1].

IL-2 may also control the activity of the HPA axis at various levels of regulation. IL-2, for example, caused a dose-dependent stimulation of secretion of arginine vasopressin (AVP; also called antidiuretic hormone, ADH) from both the intact rat hypothalamus in vitro and hypothalamic cell cultures [1]. IL-2, however, did not increase the secretion of corticotrophin-releasing factor (CRF) in either preparation, nor did it prime

the cells to respond to a subsequent dose of IL-2. Both preparations, nevertheless, were able to respond to known CRH secretagogues, such as ►serotonin (5-HT) and $K^+$. This may provide yet another line of communication between the immune and neuroendocrine systems. In another study [1], it was investigated whether persistently elevated concentrations of central IL-2, which are associated with several diseases or induced during immuno-therapeutic use of this cytokine, could induce long-term activation of the HPA axis. Adult male *Sprague–Dawley* rats received an intra-cerebroventricular infusion of the recombinant cytokine; control animals received heat-inactivated IL-2. IL-2 caused a significant increase in ACTH concentrations during the later portion of the dark phase of the cycle.

Plasma corticosterone concentrations were significantly elevated over almost the whole diurnal cycle. In addition, measurements of corticosterone-binding globulin concentrations revealed IL-2-induced decreases during the dark phase, resulting in a marked increase in free corticosterone. Furthermore, after prolonged chronic infusion, both groups of animals underwent restraint stress. For instance, IL-2-treated animals showed stress-induced increases in plasma ACTH and corticosterone that were not significantly different from those of animals treated with heat-inactivated IL-2. Along with the alteration of HPA activity seen in the IL-2-treated animals, chronic delivery of the cytokine caused periventricular tissue damage and gliosis. Taken together, the data reflected the capacity of IL-2 to modulate neuroendocrine activity over an extended period of treatment [1].

### IL-3/IL-6 and HPA Responses

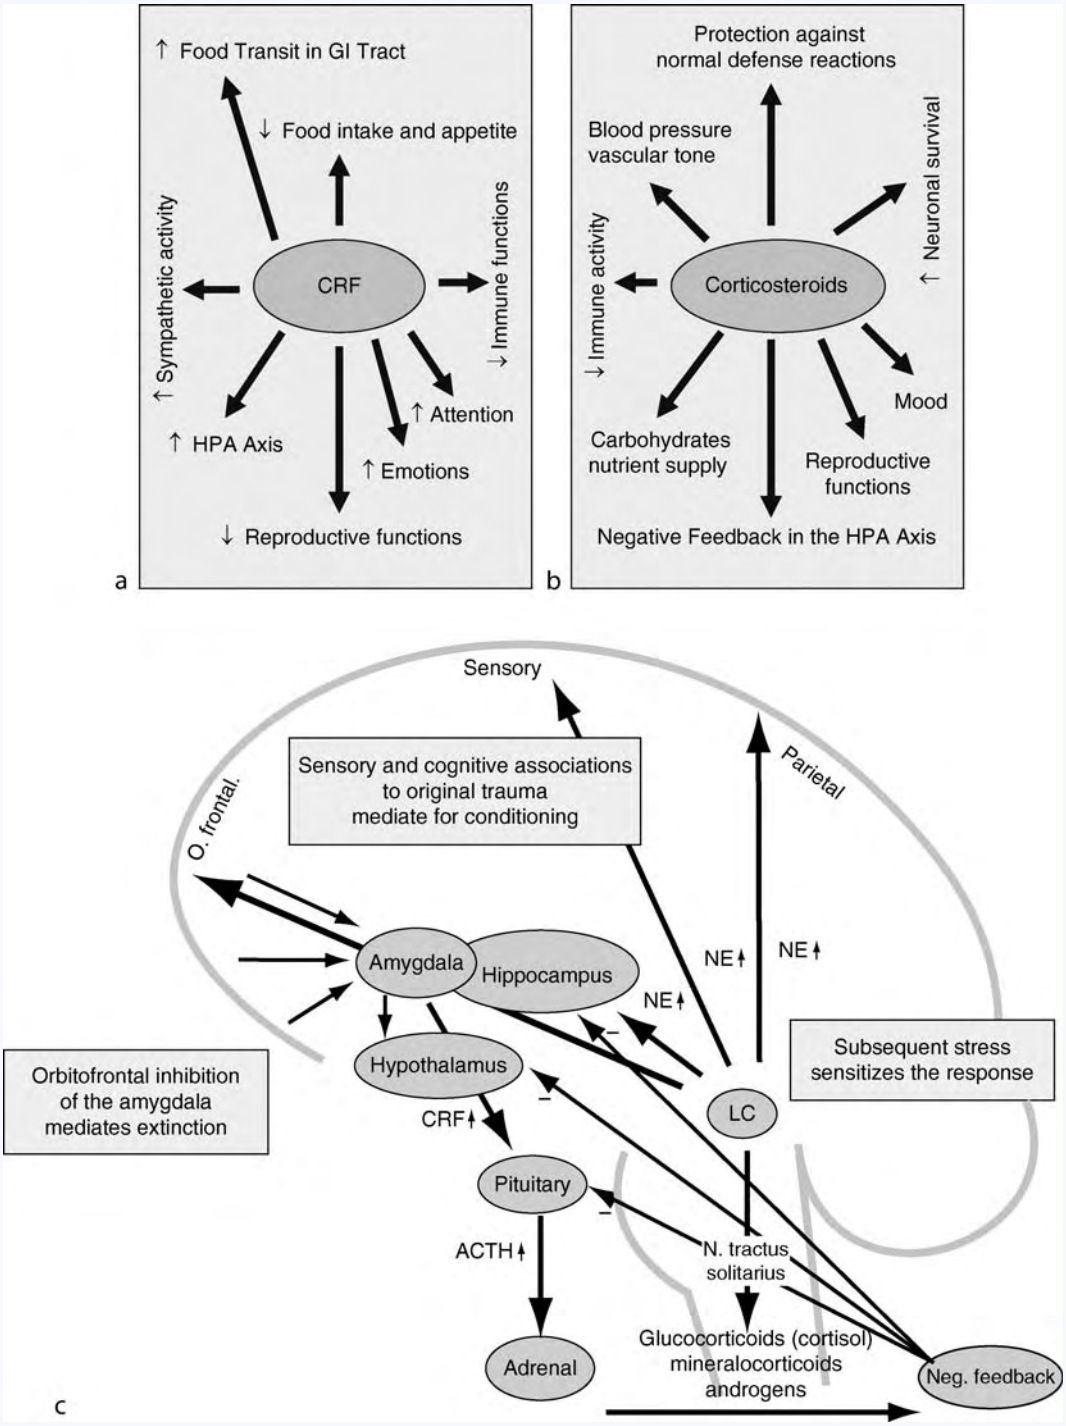
Accumulating evidence indicate that IL-3 can activate the HPA axis [1]. For example, IL-3 and IL-6 equipotently stimulated basal cortisol secretion. The stimulatory effect was significant and maximum cortisol levels were induced later. In contrast to ACTH, which significantly induced cAMP levels in parallel to its steroidogenic effect, IL-3 (or IL-6) had no significant effect on cAMP. Furthermore, the authors showed that specific inhibition of the cyclo-oxygenase (COX) pathway by indomethacin completely blocked the steroidogenic effect of IL-6 while the effect of IL-3 was not affected. In contrast, co-incubation with nordihydroguaiaretic acid (NDGA), a specific inhibitor of the lipoxygenase system, abolished IL-3-stimulated steroidogenesis but had no effect on IL-6-stimulated cortisol secretion, indicating that IL-3 and IL-6 directly stimulate the steroidogenesis at the adrenal level through activation of different, cAMP-independent pathways.

While the stimulatory effect of IL-6 on cortisol secretion from adult human adrenocortical cells seems to be mediated through the cyclo-oxygenase (COX) pathway, the effect of IL-3 on adrenocortical cortisol secretion is dependent on the lipoxygenase pathway. Similarly, the effect of IL-3 and IL-6 on cortisol secretion of bovine adrenocortical cells in primary culture under serum-free conditions was further explored. For instance, both IL-3 and IL-6 stimulated basal cortisol secretion dose-dependently to a similar extent at a similar time course [1]. After incubation with IL-3 or IL-6, a maximum 4.1-fold increase of the cortisol secretion was reached after 12h. Co-incubation of IL-3 and IL-6 revealed, however, no significant synergism. To elucidate a possible involvement of arachidonic acid metabolites in the signal transduction, IL-3 or IL-6 were co-incubated with indomethacin or nordihydroguaiaretic acid. Co-incubation with indomethacin completely abolished the stimulatory effect of IL-6 but had no effect on IL-3-stimulated cortisol secretion. In contrast, specific inhibition of the lipoxygenase system by nordihydroguaiaretic acid blocked IL-3-stimulated steroidogenesis while the effect of IL-6 was not affected. Neither IL-3 nor IL-6 altered cAMP levels significantly, whereas ACTH significantly induced cAMP levels in parallel to its steroidogenic effect. While the stimulatory effect of IL-3 seems to be dependent on the lipoxygenase pathway, the effect of IL-6 on adrenocortical cortisol secretion is mediated through the cyclo-oxygenase (COX) pathway [1].

### IL-4/IL-5/IL-10 and HPA Responses

Glucocorticoids are widely used in the therapy of inflammatory, autoimmune, and allergic diseases [1] (Fig. 5a and b). As the end-effectors of the HPA axis, endogenous glucocorticoids also play an important role in suppressing innate and cellular immune responses. The influence of dexamethasone on IL-10 production and the type 1 (T1)/type 2 (T2) T cell balance found in rheumatoid arthritis was studied to determine a possible role for IL-4 in HPA-related responses to rheumatoid arthritis. Peripheral blood mononuclear cells (PBMNC) were isolated from 14 rheumatoid-arthritis patients both before and 7 and 42 days after high-dose dexamethasone pulse therapy. The ex vivo production of IL-10, IFN-γ (T1 cell) and IL-4 (T2 cell) by PBMNC was assessed, along with parameters of disease activity (erythrocyte sedimentation rate, C reactive protein, Visual Analogue Scale, Thompson joint score).

The pro-inflammatory cytokines, IL-1 and tumor-necrosis-factor-α (TNF-α), were among the first to be recognized in this regard. A modulator of these cytokines, IL-10, has been shown to have a wide range of activities in the immune system. IL-10 is produced in pituitary, hypothalamic and neural tissues in addition to lymphocytes [29]. IL-10 enhances CRF and ACTH production in hypothalamic and pituitary tissues, respectively. Further downstream in the HPA axis,



**Neuroimmunology. Figure 5** (a, b) The effects of CRF and corticosteroids (glucocorticoids) on a variety of body mechanisms. These wide-ranging effects underscore the significance of HPA axis interactions and the mechanisms involved. (c) Neurochemical-imunologic mechanisms and their sites of action. *ACTH*, adrenocorticotropic hormone; *CRF*, corticotropin-releasing factor; *LC*, locus ceruleus; *NE*, norepinephrine [1].

endogenous IL-10 has the potential to contribute to regulation of glucocorticosteroid production both tonically and following stressors. Evidence indicated that IL-10 might be an important endogenous regulator in HPA axis activity and in CNS pathologies [30]. Thus, in addition to its more widely recognized role in immunity, as anti-inflammatory cytokine, IL-10's neuroendocrine activities point to its role as an

important regulator in communication between the immune and neuroendocrine systems (see Fig. 3a).

### IL-12 and HPA Responses

Recent studies have indicated that IL-12 promotes Th1 (T helper lymphocytes type 1) cell-mediated immunity, while IL-4 stimulates Th2 (T helper lymphocytes type 2) humoral-mediated immunity [1]. The regulatory effect of glucocorticoids on key elements of IL-12 and IL-4 signaling were further examined. On the analysis of the effect of dexamethasone on IL-12-inducible genes, it was shown that dexamethasone inhibited IL-12-induced IFN-γ (interferon) secretion and IFN regulatory factor-1 expression in both natural killer and T cells. This occurred even though the level of expression of IL-12 receptors and IL-12-induced Janus kinase phosphorylation remained unaltered. However, dexamethasone markedly inhibited IL-12-induced phosphorylation of Stat-4 (a transcription factor) without altering its expression. This was specific, as IL-4-induced Stat-6 phosphorylation was not affected, and mediated by the glucocorticoid receptor, as it was antagonized by the glucocorticoid receptor antagonist RU-486. Moreover, transfection experiments showed that dexamethasone reduced responsiveness to IL-12 through the inhibition of Stat-4-dependent IFN regulatory factor-1 promoter activity. It was concluded that blocking IL-12-induced Stat-4 phosphorylation, without altering IL-4-induced Stat-6 phosphorylation, appears to be a new suppressive action of glucocorticoids on the Th1 cellular immune response and may help explain the glucocorticoid-induced shift toward the Th2 humoral immune response [1] (see Fig. 3b).

### IL-18 and HPA Responses

Vertebrates achieve internal homeostasis during infection or injury by balancing the activities of pro-inflammatory and anti-inflammatory pathways (►central nervous system infections – humoral immunity in arboviral infections). The CNS regulates systemic inflammatory responses to lipopolysaccharide (LPS), for instance, through humoral mechanisms (see Fig. 2b). Activation of afferent vagus nerve fibers by LPS or cytokines specifically stimulates HPA anti-inflammatory responses. In this respect, it was described that a previously unrecognized, parasympathetic anti-inflammatory pathway, by which the brain modulates systemic inflammatory responses to LPS, is active at the level of the HPA axis [1,21]. Acetylcholine, the principal vagal neurotransmitter, significantly attenuated the release of pro-inflammatory cytokines, including IL-18, but not the anti-inflammatory cytokine IL-10, in lipopolysaccharide-stimulated human macrophage cultures. Furthermore, direct electrical stimulation of the peripheral vagus nerve in vivo during lethal endotoxemia in rats inhibited tumor necrosis factor (TNF) synthesis in liver, attenuated peak serum TNF amounts, and prevented the development of shock. Similarly, increased parasympathetic tone and acetylcholine significantly attenuate the release of TNF-α, IL-1β, IL-6 and IL-18 [1].

## Neuro-Immune Interactions and Oxidative Stress: A Role for the Transcription Factor NF-κB

The mammalian stress response evokes a series of neuroendocrine responses that activate the HPA axis and the sympathetic nervous system (Fig. 5c). Coordinated interactions between the stress response systems, occurring at multiple levels including the brain, pituitary gland, adrenal gland, and peripheral tissues, are required for the maintenance of homeostatic plateau. Adaptation to stress evokes a variety of biological responses, including activation of the HPA axis and synthesis of a panel of stress-response proteins at cellular levels. For example, expression of thioredoxin (TRX), a non-thiol antioxidant, is significantly induced under oxidative conditions. In this regard, it was demonstrated that either antisense TRX expression or cellular treatment with hydrogen peroxide ($H_2O_2$) negatively modulated glucocorticoid-receptor function and decreased glucocorticoid-inducible gene expression. In addition, impaired cellular response to glucocorticoids is rescued by overexpression of TRX, possibly through the functional replenishment of the glucocorticoid receptor. Moreover, not only the ligand-binding domain but also the DNA binding domain of the glucocorticoid receptor was also suggested to be a direct target of TRX [1]. Together, these observations presented conclusive evidence showing that cellular glucocorticoid responsiveness is coordinately modulated by redox state and TRX level and, thereby, it was proposed that crosstalk between neuroendocrine control of stress responses and cellular antioxidant systems may be essential for mammalian adaptation processes.

Employing primary neurons and clonal cells, it was demonstrated that corticotropin-releasing hormone (CRH; or factor, CRF) has a neuroprotective activity in corticotropin-releasing-hormone-receptor type 1 (CRH-R1)-expressing neurons against oxidative cell death [1]. The protective effect of corticotropin-releasing hormone was blocked by selective and nonselective CRH-R1 antagonists and by protein kinase A (PKA) inhibitors. In addition, overexpression of CRH-R1 in clonal hippocampal cells lacking endogenous CRH-receptors established neuroprotection by corticotropin-releasing hormone (central nervous system disease – natural neuroprotective agents as therapeutics). The activation of CRH-R1 and neuroprotection were accompanied by an increased release of non-amyloidogenic soluble Aβ precursor protein, characteristic of Alzheimer's disease [1] (►brain aging and alzheimer's disease).

At the molecular level, corticotropin-releasing hormone caused the suppression of the DNA-binding activity and transcriptional activity of the oxygen- and reduction-oxidation (redox)-sensitive transcription factor, ►nuclear factor (NF)-κB [31]. Suppression of NF-κB (an inflammatory transcription factor) by overexpression of a super-repressor mutant form of inhibitory-κB (IκB)-α, a specific inhibitor of NF-κB, led to protection of the cells against oxidative stress (►Nf-κB – potential role in adult neural stem cells; NF-κB – activation in the mouse spinal cord following sciatic nerve transection). These observations strongly demonstrated a novel cytoprotective effect of corticotropin-releasing hormone that is mediated by CRH-R1 and downstream by suppression of NF-κB and indicate corticotropin-releasing hormone as an endogenous protective neuropeptide against oxidative cell death in addition to its function in the HPA-system. Moreover, the protective function of corticotropin-releasing hormone proposes a molecular link between oxidative stress-related degenerative events and the CRH-R1 system. Further elaborating on the role of transcriptional regulation in HPA responses, dysregulation of the serotonergic system and abnormalities of the HPA axis function have been implicated in ►neuropsychiatric disorders. Corticosteroid hormones in a variety of animal models suppress serotonin-1A receptors. This effect may play a central role in the pathophysiology of depression. However, little is known about the molecular mechanism underlying this suppressive effect of corticosterone [1].

In this respect, Wissink and colleagues [32] showed by functional analysis of the promoter region of the rat serotonin-1A receptor gene that two NF-κB elements in the promoter contribute to induced transcription of the rat serotonin-1A receptor gene. Furthermore, it was shown that corticosterone represses this NF-κB-mediated induction of transcription. Remarkably, only the glucocorticoid receptor and not the mineralocorticoid receptor was able to mediate this repressive effect of corticosterone, thus arguing that negative cross-talk between the glucocorticoid receptor and NF-κB may provide a basis for the molecular mechanism underlying the negative action of corticosterone on serotonin signaling in the brain [1].

## Neuro-Immune Interactions and Oxidative Stress: A Role for Gaseous Transmitters

Recent work has demonstrated that the brain has the capacity to synthesize impressive amounts of the gases nitric oxide (NO) and ►carbon monoxide (CO) [1]. There is growing evidence that these gaseous molecules function as novel neural messengers in the brain. Abundant evidence is presented which suggests that NO has an important role in the control of reproduction due to its ability to control ►gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus. Nitric oxide potently stimulates GnRH secretion and also appears to mediate the action of one of the major transmitters controlling GnRH secretion, glutamate (►glutamate-mediated injury to white matter – mechanisms and clinical relevance). Evidence suggests that NO stimulates GnRH release due to its ability to modulate the heme-containing enzyme, guanylate cyclase, which leads to enhanced production of the second messenger molecule, cGMP. A physiological role for NO in the pre-ovulatory ►luteinizing-hormone (LH) surge was also evidenced by findings that inhibitors and antisense oligonucleotides to ►nitric oxide synthase (NOS) attenuate the steroid-induced and pre-ovulatory luteinizing hormone (LH) surge.

Carbon monoxide (CO) may also play a role in stimulating GnRH secretion as heme molecules stimulate GnRH release in vitro, an effect that requires heme oxygenase activity and is blocked by the gaseous scavenger molecule, hemoglobin. Evidence also suggests that NO acts to restrain the HPA axis, as it inhibits HPA stimulation by various stimulants such as IL-1, vasopressin (VP) and inflammation (►neurogenesis and inflammation). This effect fits a pro-inflammatory role of NO as it leads to suppression of the release of the anti-inflammatory corticosteroids from the adrenals. Although not as intensely studied as NO, CO has been shown to suppress stimulated corticotropin-releasing-hormone release and may also function to restrain the HPA axis [1].

Evidence implicating NO in the control of prolactin (PRL) and growth hormone secretion is plausible, as is the possible role of NO acting directly at the anterior pituitary. Taken as a whole, the current data suggest that the diffusible gases, NO and CO, act as novel transmitters in the neuroendocrine axis and mediate a variety of important neuroendocrine functions. To recapitulate, NO is an unusual chemical messenger. NO mediates blood vessel relaxation when produced by endothelial cells. When produced by macrophages, NO contributes to the cytotoxic function of these immune cells. Nitric oxide also functions as a neurotransmitter and neuromodulator in the central and peripheral nervous systems. The effects on blood vessel tone and neuronal function form the basis for an important role of NO on neuroendocrine function and behavior. NO mediates hypothalamic portal blood flow and, thus, affects oxytocin and vasopressin secretion; furthermore, NO mediates neuroendocrine function in the hypothalamic-pituitary-gonadal (HPG) and hypothalamic-pituitary-adrenal (HPA) axes. Nitric oxide influences several motivated behaviors including sexual, aggressive and ingestive behaviors. Nitric oxide also influences learning and memory (►neuroinflammation – chronic neuroinflammation and memory impairments). Thus, NO is emerging as an important chemical mediator of neuroendocrine function and behavior [1].

Nitric oxide synthetase (NOS), the enzyme responsible for NO formation, is found in hypothalamic neurons containing oxytocin, vasopressin and to a lesser extent corticotropin-releasing factor. Because NO is reported to modulate endocrine activity, the hypothesis that endogenous NO participates in ACTH release by various secretagogues was investigated in vivo. In the adult male rat, the intravenous injection of IL-1β, vasopressin and oxytocin increased plasma ACTH and corticosterone levels [1]. Pretreatment with the L-form, but not the D-form, of *N*-omega nitro-L-arginine-methylester (L-NAME), a specific inhibitor of NOS, markedly augmented the effects of these secretagogues. Blockade of NOS activity also caused significant extensions of the duration of action of IL-1β, vasopressin and oxytocin. In contrast, L-NAME did not significantly alter the stimulatory action of peripherally injected corticotropin-releasing factor, or centrally administered IL-1β. In addition, administration of L-arginine, but not D-arginine, used as a substrate for basal NO synthesis and which did not by itself alter the activity of the HPA axis, blunted IL-1-induced ACTH secretion and reversed the interaction between L-NAME and IL-1β. Then, following prenatal alcohol exposure, immature offspring showed blunted ACTH released in response to the peripheral administration of IL-1β (►prenatal brain injury by chronic endotoxin exposure). Further studies were conducted to investigate the role of changes in corticosteroid feedback (measured by altered adrenal responses to ACTH), corticotropin-releasing-factor content of the median eminence (ME) and the influence of endogenous NO. For instance, the injection of several doses of ACTH failed to indicate measurable differences between the corticosterone responses of offspring born to dams fed *ad libitum* [control (C)], pair-fed (PF), or fed alcohol [ethanol (EtOH)]. Corticotropin-releasing-factor content in the median eminence, taken as an index of the amount of releasable peptide, showed a small, but statistically significant, decrease following prenatal alcohol exposure. A comparable change, however, was also noted in PF rats. As expected, the subcutaneous injection of IL-1β induced smaller increases in plasma ACTH levels of EtOH than C pups. The response of PF animals was intermediate between that of EtOH and C rats. It was also observed that inhibition of NO formation by the administration of the arginine derivative L-NAME augmented ACTH secretion in all three experimental groups and reversed the decreased corticotrophs' response to IL-1β caused by prenatal alcohol [1,33].

## Conclusions and Future Prospects

The foregoing indicates that there is now substantial evidence for bidirectional communications between the nervous and immune systems. Communication occurs via chemical messengers, just as it does within the nervous and immune systems. Many of the messengers are already familiar as hormones, neurotransmitters, and cytokines, but presently the messages are poorly understood. Certain messengers from the neuroendocrine system appear to facilitate or inhibit the functions of immune cells, but the specificity remains to be elucidated. Cytokines are clearly potent activators of the HPA axis, but also exert a variety of other physiological effects. In all likelihood, many other messengers remain to be discovered [1,7,8,15,18].

Although our current understanding of the system is limited, it may be important to distinguish local from systemic effects. Whereas circulating concentrations of catecholamines and steroids are probably adequate to exert physiological effects, and this also appears to be true for cytokines, the role of the peptides is less clear. Their systemic concentrations are very low and are unlikely to be sufficient to modulate immune system function in a general way. However, it is possible that peptides secreted by nerve terminals in the thymus, spleen, and lymphoid tissue may achieve local concentrations sufficient to affect immune cells. Such effects may also be possible locally in tissue at sites of inflammation [1,8].

Messengers that can travel more readily and are more stable metabolically may be active systemically, whereas the less stable peptides may be confined to local actions. The chemical nature of the messengers may be suited to their functions. As lipophilic molecules, the glucocorticoids can readily penetrate membrane barriers and affect cells in all bodily tissues, whereas the hydrophilic catecholamines are more labile and their action may be limited to the circulatory systems. Our present knowledge indicates that the glucocorticoids and catecholamines predominantly inhibit immune responses, whereas the peptides are largely facilitatory. When the organism is threatened, the systemic activity of the glucocorticoids to limit immune responses may be important to depress immune activity to prevent undesirable autoimmune actions [1]. By contrast, peptides could facilitate immune responses in small areas close to the site of their release, for example, in an area of inflammation induced by infection or tissue damage. Catecholamines may occupy an intermediate position, existing in sufficient concentrations to have systemic actions but not having broad access to tissues and having relatively short durations of action, except when chronically elevated. Such an arrangement would permit focusing of the activation of immune response in local areas of inflammation, while preventing potentially damaging autoimmune actions that could be triggered by widespread activation (►brain inflammation – biomedical imaging).

The neuroimmune systems communicate bidirectionally (see Fig. 5c). The neuro-immune-endocrine interface is mediated by cytokines acting as auto/paracrine or endocrine factors regulating pituitary

development, cell proliferation, hormone secretion and feedback control of the HPA axis. Soluble products that appear to transmit information from the immune compartments to the CNS act as immunotransmitters and function in immunomodulatory neuroendocrine circuits. The relative importance of systemically and locally produced cytokines in achieving these responses and their precise sites of action have been the focus of a burgeoning number of investigations over the past few decades. There is now accumulating evidence that there are important interactions between the immune and neuroendocrine systems, which may explain, in part, some of the effects on growth, thyroid, adrenal and reproductive functions that occur in the pathophysiology of acute and chronic disease [1].

# Neuroimmunomodulation

## Definition

Neuroimmunomodulation is the modulation of the immune system through the nervous system.

►Neuroimmune Interactions – Serotonin
►Neuroimmunomodulation: The brain areas involved
►Neuroimmunology

# Neuroinflammation

## Definition

Neuroinflammation is the inflammation of a nerve or of the nervous system.

►Neurogenesis and Inflammation

# Neuroinflammation – DNA Vaccination Against Autoimmune Neuroinflammation

Anna Lobell
Department of Medical Sciences, Uppsala University, University Hospital, Uppsala, Sweden

## Synonyms

DNA immunization; Naked DNA vaccination; Genetic vaccination

## Definition

To prevent or treat ►autoimmune neuroinflammation by ►vaccination with DNA encoding one or more autoantigen(s) (►DNA vaccination against autoimmune neuroinflammation). The autoantigen, usually a myelin autoantigen, is transcribed and translated *in vivo*, processed and presented to T cells in the context of major histocompatibility complex after vaccination. Toll-like receptor (TLR) 9 ligand CpG DNA within the plasmid backbone acts as adjuvant to activate the innate immune system. Presence of CpG DNA and the expressed autoantigen are both essential for the protective immune reaction to occur.

## Characteristics

### Introduction

Failure of immunologic self-tolerance often leads to development of autoimmune disease, which is estimated to afflict up to 5% of the human population. Genetic factors, such as both major histocompatibility complex (MHC) and non-MHC genes, contribute to the risk for most autoimmune diseases. The same non-MHC gene may predispose for several different organ-specific inflammatory diseases such as rheumatoid arthritis and multiple sclerosis (MS). Environmental factors also play an important role in the risk for autoimmune disease. Many infectious agents have been investigated for crossreactivity towards self antigens, potentially leading to an autoimmune disease (molecular mimicry). Dysregulation of inflammatory cells or regulatory T cells has also been suggested as a cause of autoimmunity.

MS is a common disabling disease characterized by inflammation, neurodegeneration and demyelination in the central nervous system (CNS). The major hallmark of MS is the presence of sclerotic plaques in the CNS that are characterized by demyelination, which is associated with an inflammatory reaction that is orchestrated by activated lymphocytes, macrophages and glial cells. The etiology of MS is unknown, necessitating research into the mechanisms underlying

pathogenesis. Myelin autoantigens such as myelin basic protein (MBP), proteolipid protein (PLP) and myelin oligodendrocyte glycoprotein (MOG) are candidate autoantigens in MS. Because it is difficult to study CNS autoimmunity in humans, experimental models such as experimental autoimmune encephalomyelitis (EAE) are used. EAE is actively induced by injection of myelin proteins or encephalitogenic myelin peptides together with a proinflammatory adjuvant such as complete Freund's adjuvant (CFA). EAE was previously thought to be a T helper 1 cell (Th1)-mediated autoimmune disease whereas Th2 cells were thought to suppress EAE by inhibiting the Th1 responses. However, interleukin (IL)-23-driven proinflammatory IL-17-producing T cells mediate EAE. The IL-17-producing Th cell (Th17) is a distinct lineage from Th1 and Th2 cells and naïve CD4 T cells surprisingly differentiate into IL-17-producing T cells in the presence of soluble TGF-β or regulatory T cells if IL-6 is present. Th17 cells are then maintained by IL-23. Differentiation of naïve CD4 T cells into Th17 cells is inhibited by Th1, Th2 and regulatory T cells. Thus, the characteristics of the pathogenic T helper cell response in EAE is different from what was previously thought. As a consequence, Th1/Th2 ratios are no longer relevant, as both these T cell lineages suppress pathogenic Th17 cell responses. However, most of the studies described herein were done before the role of Th17 cells in EAE was discovered and Th1/Th2 ratios are therefore discussed.

DNA vaccines can induce antigen-specific CD4 T helper cell and CD8 cytotoxic T cell responses as well as antibody responses. Initially, ►DNA vaccination was thought to prime cytotoxic T cells in a unique manner through intracellular processing of antigen produced in transfected somatic cells. However, ►antigen-presenting cells prime cytotoxic T cells both by direct transfection and by cross-priming after endocytosis of antigen upon DNA vaccination. In fact, antigen-presenting dendritic cells in the spleen process and present the antigen encoded by the DNA vaccine.

DNA vaccines are plasmids produced by *E. coli* and all bacterial DNA contains unmethylated CpG DNA motifs. CpG DNA are pathogen associated molecular patterns (PAMP) which specifically binds the pattern recognition receptor TLR9. The recognition of PAMP by TLR triggers intracellular signaling pathways resulting in the induction of proinflammatory ►cytokines, type I ►interferon (IFN), chemokines and dendritic cell maturation that leads to activation of adaptive immunity. Each TLR recognizes different PAMP: TLR4 recognizes LPS and TLR2 plus TLR1 or TLR6 recognizes bacterial lipopeptides. TLR3 and TLR9 are expressed in endosomes and are involved in the recognition of double-stranded RNA and unmethylated CpG DNA respectively. Because the intracellular pathways of the TLR differ, TLR9 ligation mainly induces type I IFN production, whereas e.g., TLR4 ligation induces IL-12 and IFN-β production. CpG DNA is essential for efficient DNA vaccination and is currently used in therapeutic trials against allergy and as vaccine adjuvant. Furthermore, DNA vaccines coding for antigens can be combined with plasmids encoding various cytokines or ligands important for the ensuing immune response, thus providing methods to specifically modulate the vaccine effect.

In this essay, the effects of DNA vaccination against rodent EAE will be described.

## The DNA Vaccine

Mammalian expression vectors, e.g., pCI, pTarget and pcDNA3, are used as plasmid backbones for DNA vaccines. A strong promoter such as the human CMV immediate/early enhancer-promoter controls the transcription of the autoantigen and a Kozak box is introduced around the start codon to enhance transcription. DNA encoding myelin autoantigens or immunodominant myelin protein-derived peptides are ligated into the plasmid backbone. Minigenes encoding myelin protein-derived peptides can be inserted in tandem [1,2]. The DNA insert encoding the myelin autoantigen can be expressed in all mammalian cells, when a strong promoter such as CMV promoter is used. Additionally, presence of CpG DNA within the plasmid backbone of the DNA vaccine is required. Common plasmids such as pCI, pTarget and pcDNA3 all contain at least two immunostimulatory CpG DNA motifs.

## Immunization Protocols

The DNA vaccine is either injected before or after induction of EAE. In successful preventive trials in rats, the vaccine is administered in PBS as a single injection either intra muscularly or intra dermally three to eleven weeks before induction of EAE [1,3,4], whereas in therapeutic trials the DNA vaccine is given as weekly intra muscular injections after the onset of EAE [5,6]. If the DNA vaccine is injected intra muscularly, the muscles are often pretreated with compounds such as cardiotoxin, to enhance DNA uptake.

## Protection from EAE After Vaccination with DNA Encoding Myelin Autoantigens

DNA vaccination prevents EAE [1–4,6–8] with few exceptions [9] (Table 1). Vaccination with DNA encoding myelin peptides or proteins suppresses EAE induced with the corresponding peptide [1,4,7]. Treatment of ongoing EAE has been successful in murine EAE models [5,6]. Despite similar clinical outcomes, the ensuing immune response after DNA vaccination differs in rat and murine EAE models, which suggests that the protective mechanism differ in the two species. Antigen specificity, impact of CpG DNA and the protective mechanism are discussed below.

**Neuroinflammation – DNA Vaccination Against Autoimmune Neuroinflammation. Table 1** EAE prevention or treatment using DNA vaccines encoding myelin proteins or peptides

| Animal | DNA vaccine | Main findings | Reference |
|---|---|---|---|
| *Rat EAE* | | | |
| Lewis | MBP68-85 | Improvement | [1] |
| Lewis | MBP86-85 and MBP89-101 | High antigen specificity | [2] |
| Lewis | MBP68-85 +/- CpG DNA MBP68-85 + IL-4, IL-10 or TNF-α | CpG DNA is required, cytokine coinjection inhibits the suppressive effect | [3] |
| Lewis 1Av1, DA, Lewis 1N | MOG91-108 +/- CpG DNA | Improvement, CpG DNA is required | [7] |
| Lewis 1Av1 | MOG91-108 | Higher IFN-β expression, lower MHC II expression, lower IL-23p40 expression | [8] |
| *Murine EAE* | | | |
| SJL/J | PLP139-151 | Improvement, lower B7 expression | [4] |
| SJL/J | MOG | Worsening | [9] |
| SJL/J | PLP139-151 + IL-4 | Improvement | [6] |
| SJL/J | PLP, MOG, MBP, MAG cocktail + IL-4 | Treatment, improvement in relapses | [5] |
| SJL/J | PLP, MOG, MBP, MAG cocktail + IL-4 + GpG DNA | Treatment, improvement | [10] |

## Antigen Specificity of DNA Vaccination

Epitope spreading defines the expansion of antigen-specific immune responses beyond those targeted in the initial immunization. EAE and other autoimmune diseases are associated with spreading of autoreactive T and B cell responses. Treatment with a cocktail of DNA vaccines encoding several myelin proteins reduces the number of relapses in EAE and reduces spreading of the autoreactive B cell response, although the treatment does not affect disease severity [5].

Local production of IL-4 or TGF-β is instrumental for a regulatory immune response inhibiting pathogenic T cells of any specificity (bystander suppression) in oral tolerance or altered peptide ligand therapy. Is DNA vaccination acting through bystander suppression, or is the effect antigen specific? A single amino acid exchange in position 79 from serine (non-self) to threonine (self) in MBP68-85 dramatically alters the protective effect of a DNA vaccine encoding MBP68-85 in rats. Furthermore, the DNA vaccine encoding MBP68-85 does not protect from MBP89-101-induced EAE and vise versa [2]. Thus, the protective effect is highly specific and there is no evidence for bystander suppression, nor epitope spreading of tolerance.

## The Impact of CpG DNA

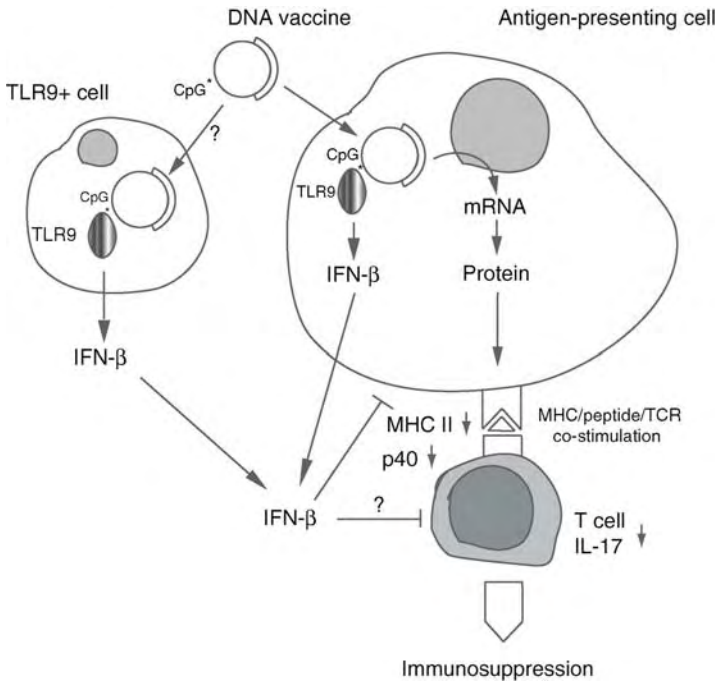
DNA vaccines are produced by bacteria and thus contain unmethylated CpG DNA that specifically binds TLR9 and thereby promotes innate immunity and type I IFN production. Treatment with a DNA vaccine containing two CpG DNA motifs suppresses clinical signs of EAE, while a corresponding DNA vaccine without such CpG DNA has no effect [3,7]. Moreover, there are no reports on successful DNA vaccination using plasmid DNA that lacks CpG DNA. Thus, the presence of CpG DNA is decisive for protective DNA vaccination against EAE.

In contrast, co-administration of an antagonist to CpG DNA, GpG DNA, enhances the suppressive effect of DNA vaccination against murine EAE by promoting Th2 immunity [10].

## Protective Mechanisms of DNA Vaccination Against EAE

The immune mechanisms involved in protective DNA vaccination are not fully understood, and differ between rat and murine EAE models. Also, the previous work done may have to be re-evaluated in the light of the recent discovery that Th17, but not Th1, responses are responsible for disease. A summary of the main findings is presented in Fig. 1 and Table 1.

The nature of the attenuated T cell function after DNA vaccination against rat EAE has until recently remained elusive since no induction of Th2 or regulatory T cells is observed, and neither the secretion of IFN-γ, nor the proliferative response, can be correlated to the suppressive capability of the DNA vaccine [7]. Instead, coinjection of IL-4 or IL-10 gene with the DNA vaccine inhibits the protective effect, which suggests that Th2 immunity is not involved in the protective mechanism. However, the antigen-specific IL-17 production by T cells is significantly reduced after DNA vaccination and subsequent induction of EAE, compared to controls. Moreover, T cells do not express IL-17 after DNA vaccination – but before induction - of EAE (A. Lobell et al., unpublished). Thus, priming of myelin-specific Th17 cells is indeed impaired after induction of EAE in DNA vaccinated rats which likely contributes to the reduced EAE symptoms (Fig. 1).



**Neuroinflammation – DNA Vaccination Against Autoimmune Neuroinflammation. Figure 1** Illustration of the proposed mechanism for suppressive DNA vaccination against rat EAE. Administration of a DNA vaccine encoding a myelin self peptide results in transcription and translation of the self peptide by antigen-presenting cells. The self peptide is processed and presented on MHC II to Th cells. In either the same antigen-presenting cell or other TLR9-expressing cells, CpG DNA motifs of the DNA vaccine binds TLR9 in the endosome, which induces IFN-β production. Priming of DNA vaccine-induced myelin-specific T cells in the presence of IFN-β results in suppression of subsequently induced EAE and dampened encephalitogenic Th17 responses. IFN-β may act via downregulation of antigen-presenting cell activation and maturation via reduced IL-23 and MHC II expression, and/or directly on encephalitogenic Th17 cells. Lines with bars represent inhibition.

IFN-β expression is upregulated after DNA vaccination, both before and after induction of rat EAE [8]. Silencing of IFN-β *in vivo* reveals a crucial role for the cytokine in suppressive DNA vaccination (A. Lobell et al., unpublished). It is unclear how the CpG DNA-induced IFN-β leads to impaired Th17 responses and protection from EAE. Antigen-presenting cell function may be altered. Indeed, the MHC II and IL-23/IL-12p40 expression are lower in DNA vaccinated rats compared to controls [8], which indicates impaired maturation and activation of antigen-presenting cells.

In contrast, induction of Th2 immunity increases the efficacy of DNA vaccination in mice. Coinjection of IL-4 gene with a DNA vaccine suppresses EAE. The IL-4 gene delivery activates STAT6 locally which shifts the antigen-specific T cells to a protective Th2 phenotype [6]. Th2-promoting CpG DNA antagonist GpG DNA enhances the suppressive effect [10]. *In vitro* exposure of a DNA vaccine to murine splenocytes slightly reduces the expression of costimulatory B7 molecules, which may suggest that anergy is induced by DNA vaccination [4].

## DNA Vaccines Targeting Chemokines/Cytokines

Substantial data support the notion that coinjection of cytokine-coding cDNA with DNA vaccines can selectively modulate the ensuing immune response. However, other reports suggest that vaccination with DNA encoding cytokines or chemokines can induce the production of specific antibodies directed against the gene product which in turn suppress EAE.

Nathan Karin and coworkers demonstrate that injection of DNA encoding rat chemokines MIP-1α or MCP-1 suppresses subsequently induced rat EAE, whereas the same strategy for MIP-1β slightly aggravates disease. Likewise, injection of DNA vaccines encoding the proinflammatory cytokine TNF-α confers resistance to EAE and induces antibodies directed against TNF-α. In contrast, production of the respective cytokine seems responsible for the effects in other DNA vaccine trials. Injection of DNA encoding TGF-β1 or an IL-4-IgG1 fusion into rats prior to induction of EAE leads to detectable *in vivo* production of these cytokines and prevention of EAE. An immunization regimen with multiple injections could account

for the autoantibody production in the former cytokine/chemokine experiments.

## Conclusion

Autoimmune neuroinflammation can be prevented or treated by DNA vaccination. The effect is highly antigen specific and requires CpG DNA within the plasmid backbone of the vaccine.

## Synonyms

Interferon (IFN)-γ inducing factor (IGIF)

## Definition

►Interleukin (IL)-18 is a member if the IL-1 family of pro-inflammatory ►cytokines. It was first cloned in the late 1980s and originally designated "interferon (IFN)-γ inducing factor" (IGIF). ►IL-18 is synthesized as an inactive precursor which is cleaved into its active form by ►caspase-1 for functional activity. IL-18 is an important mediator of innate immune responses against infection and has been shown to be critically involved in the pathogenesis of autoimmune diseases [1]. Resident cells of the central nervous system (CNS) express IL-18 and caspase-1 constitutively, thus providing a functional IL-18-dependent immune response in the intracranial compartment. Several studies in recent years have highlighted a crucial role of IL-18 in mediating ►neuroinflammation under a variety of pathological conditions in the CNS, such as bacterial and viral infections, autoimmune demyelinating diseases, hypoxic-ischemic, hyperoxic and traumatic brain injury [5,9].

## Characteristics

IL-18 is initially synthesized as an inactive 24 kD precursor protein (pro-IL-18) which is subsequently processed by ►caspase-1 (ICE) (IL-1β converting enzyme) into its mature and biologically active form with a molecular weight of 18 kD. In addition, the secreted pro-form of IL-18 can also be processed into its active form by a variety of extracellular enzymes which

are constitutively expressed by leukocytes, such as proteinase-3 (PR-3). The active form of IL-18 can either bind to its heterocomplex IL-18α/β receptor (IL-18Rα/β) or be neutralized by its natural antagonist, IL-18 binding protein (IL-18BP). At least ten IL-1 gene family members have been discovered, which all map to the same region on human chromosome 2, with the notable exception of IL-18, which is encoded for by a single gene located on human chromosome 11q22.2-q22.3.

## Biology

As a member of the IL-1 family of cytokines, IL-18 possesses a wide variety of inflammatory and immunoregulatory properties [4]. Human and murine IL-18, which show 65% sequence homology, are secreted by first-line immune cells capable of antigen presentation, such as macrophages, dendritic cells, and Kupffer cells. Other cell-types reported to express IL-18 include T- and B-lymphocytes, vascular endothelial cells, smooth muscle cells, keratinocytes, osteoblasts and synovial fibroblasts. In the rodent brain, IL-18 and its receptor were shown to be constitutively expressed by astrocytes, microglia, neurons and by ependymal cells [2,3]. Different studies have emphasized the important role of IL-18 expression and LPS-dependent up-regulation in microglia. IL-18 was also shown to induce signal transduction pathways in microglia. The IL-18 promoter includes binding sites for the transcription factor nuclear factor κB (NFκB). Furthermore, the proteasome inhibitor MG-132 – which regulates NFκB signaling – was found to block LPS- and IFN-γ-mediated IL-18 up-regulation in microglia. These findings imply an important role in IL-18-mediated activation of NFκB in the brain. The IL-18 activating enzyme, caspase-1, was also found to be constitutively expressed in microglia and astrocytes. Thus, maturation and activation of IL-18 can occur in the brain under physiological and inflammatory conditions [7]. The biological effects of IL-18 receptor binding include the induction of other inflammatory mediators, such as IFN-γ, tumor necrosis factor (TNF), IL-1β, IL-8, and of the so called "death proteins" of the extrinsic apoptotic pathway, such as TNF and Fas ligand (FasL). Thus, IL-18 represents a "key" cytokine which controls two distinct immunological regulatory pathways. These include the regulation of monocyte/macrophage function by induction of IFN-γ synthesis by T- and B-lymphocytes, as well as the induction of ►apoptosis through up-regulation of TNF and FasL. Both mechanisms may lead to extensive local inflammation and tissue destruction mediated by IL-18 under pathological conditions, as reported for various autoimmune and inflammatory diseases of the CNS.

## Function

IL-18 was first identified as an essential factor promoting IFN-γ production by T cells in the presence of IL-12. This is the most salient biologic property of IL-18 that separates it from IL-1. IL-18 enhances T cell maturation (Th1 > Th2), cytokine production, and cytotoxicity [4]. Other major targets of IL-18 include macrophages, NK cells, B-cells, basophils, and neutrophils. A wealth of data indicate that IL-18 contributes to host defense and inflammation through synergism in a cascade of cytokines associated with innate responses, including IL-12 and IL-15.

The action of IL-18 appears to go beyond immune regulation, as IL-18 (like IL-1) appears to induce sleep in mice, rats and rabbits. IL-18 injected into the brain increases non-rapid eye movement sleep. The sleep effects of IL-18 introduced directly into the brain coincides with increased brain temperature. In contrast, intraperitoneal IL-18 fails to induce fever or sleep. IL-18 mediates its biological functions through binding of a widely expressed heterodimeric receptor consisting of α- and β-chains expressed on many different cell-types including T-lymphocytes, natural killer (NK) cells, monocytes/macrophages, neutrophils, and endothelial cells. Receptor activation by binding of IL-18 leads to the activation of the transcription factor NFκB via a complex intracellular signaling cascade. While the receptor's α–chain (IL-18Rα) is essential for signaling, it binds IL-18 at a relatively low affinity. In contrast, the IL-18Rβ chain, also termed "IL-1 receptor accessory protein-like" (AcPL), binds to the complex formed by IL-18 and the IL-18Rα chain, thus generating a high affinity tricomplex interaction. Both IL-18Rα and IL-18Rβ are structurally related and belong to the extended IL-1 receptor family. The signal transduction pathway subsequent to ligand binding of the IL-18 receptor complex is virtually identical with that of the IL-1 receptor complex. Both IL-18Rα and IL-18Rβ chains are required for signal transduction through the "myeloid differentiation factor 88" (MyD88), the serine-threonine "interleukin-1 receptor-associated kinase" (IRAK), and the "TNFα receptor-associated factor 6" (TRAF6) adapter molecules and involves a series of phosphorylation events that take place during the first few minutes after IL-18R binding. These steps ultimately result in the phosphorylation of the "inhibitor of κB kinase" (IKK) complex, as well as specific "mitogen-activated kinase kinases" (MKKs). The IKKs phosphorylate the NF-κB inhibitor IκB, leading to its ubiquitination and subsequent degradation by the proteasome. This allows NF-κB to translocate to the nucleus and bind to specific promotor sequences. Activated MKKs phosphorylate and activate members of the "c-Jun N-terminal kinase" (JNK) and p38 "mitogen-activated protein kinase" (MAPK) family. These also translocate to the nucleus where they can phosphorylate several transcription factors of the basic leucine zipper family, like c-Jun and c-Fos.

## Pathology

### CNS Autoimmune Disease

The implication of IL-18 and caspase-1 in contributing to autoimmune neuropathology was investigated in patients with ►multiple sclerosis (MS) and its animal model, ►experimental autoimmune encephalomyelitis (EAE). Caspase-1 was shown to be elevated in EAE brain tissue as well as in peripheral blood mononuclear cells from MS patients, where expression levels correlated with disease activity. In addition, IL-18 levels were found to be slightly elevated in MS patients as compared to healthy controls. In the experimental setting of EAE, the importance of IL-18 on generation of Th1 response has been validated by demonstrating a significant attenuation of disease by administration of neutralizing anti-IL-18 antibodies. Similarly, the neuropathological sequelae of EAE were attenuated by either pharmacological inhibition of caspase-1 or in caspase-1 gene knockout mice. IL-18 and caspase-1 mRNA expression in the CNS was shown during the acute stage of EAE and implicated the IL-18/caspase-1 pathway in the amplification of Th1-mediated immune response in autoimmune CNS disease. This notion was supported by recent findings of resistance to EAE in IL-18 gene-deficient mice, whereas the administration of recombinant IL-18 enhanced the severity of EAE in wild-type mice and restored the ability to generate Th1 immune responses in the IL-18−/− mice.

In human MS patients, IL-18 levels were detected in cerebrospinal fluid taps only in about 3% of all patients studied. However, postmortem brain tissue section analysis from MS patients revealed an increased local expression of IL-18 and IFN-γ in demyelinating cerebral lesions, suggesting that cerebrospinal fluid levels do not accurately reflect the local tissue expression of these mediators in autoimmune CNS disease. This hypothesis is corroborated by a clinical study on patients suffering from the relapsing-remitting form of MS, where individuals with acute exacerbations and active gadolinium-enhancing lesions in MRI had significantly elevated IL-18 levels in serum and cerebrospinal fluid, as compared to MS patients without positive MRI lesions and to control patients without neurological disease. Furthermore, the enhanced expression of IL-18 and its receptor was reported on oligodendrocytes of human tissue samples from patients with active MS, as compared to brain sections from patients with silent MS or from neuropathologically normal subjects. Altogether, these findings imply an important involvement of IL-18 and caspase-1 in the pathogenesis of active stages of autoimmune CNS disease.

### Ischemic and Traumatic Brain Injury

IL-18 has been involved in the development of ischemia-induced inflammation in experimental models of middle cerebral artery occlusion (MCAO). As such, focal ischemic brain injury in rats has been shown to induce IL-18 expression in microglia and monocytes/macrophages in the infarcted cortex [6]. In those studies, both mRNA and protein levels increased within 24 hours and reached peaks at 6 days post injury. Interestingly, the expression profile of caspase-1 paralleled the increase of IL-18 levels, but not of IL-1β, suggesting a temporal diversity of expression within cytokines of the IL-1 family and implying a role of the IL-18/caspase-1 pathway in late-stage neuroinflammatory responses to focal cerebral ischemia. In ►stroke patients, elevated IL-18 levels in serum were shown to correlate with the extent of hypodense area volumes in craniocerebral CT scans and with functional disability. Moreover, serum IL-18 levels were shown to be higher in patients with a non-lacunar stroke subtype than in those with lacunar types of stroke. Affirmative data in an experimental model of hypoxic-ischemic brain injury in rats and mice reported the up-regulation of IL-18 and caspase-1 both at the mRNA and protein level within 12 h to 14 days after stroke. While microglia were determined as the major cell-type expressing IL-18 and caspase-1 in the injured hemisphere, IL-18 receptor expression was detected mainly on neurons in the cortex and thalamus. Interestingly, post-injury infarction area and neuropathological scores were significantly decreased in IL-18−/− mice, as opposed to wild-type littermates, suggesting that IL-18 may by functionally involved in the development and exacerbation of hypoxic brain injury.

Similarly to the demonstrated role of IL-18 in contributing to detrimental secondary effects in the injured brain after hypoxic-ischemic injury, IL-18 was shown to represent a "key player" in the pathophysiology of ►traumatic brain injury (TBI) [5]. First evidence of upregulated IL-18 gene and protein expression following optic and sciatic nerve crush injury was reported in rodent models. Interestingly, the constitutive levels of IL-18 mRNA expression were found to be higher in the CNS (optic nerve) than in peripheral nerve tissue (sciatic nerve). After experimental axonal crush injury, IL-18 expression dramatically increased both on injured optic and sciatic nerves. The cellular sources of increased IL-18 levels were determined to be mainly constituted by infiltrating ED1-postive macrophages within two to eight days after axonal injury. In addition, local resident microglia were shown to exhibit enhanced IL-18 expression mainly at sites of myelin degradation, suggesting an involvement of IL-18 mediated microglial neurotoxicity. This notion was confirmed by clinical and experimental data based on studies of severe closed head injury in humans, rats, and mice [8,10]. Significantly elevated IL-18 protein levels were reported in cerebrospinal fluid samples of patients with severe closed head injury for up to 10 days after trauma, as compared to normal controls. Notably, the peaks of intrathecal IL-18 levels in brain-injured patients were almost 200-fold higher than in

cerebrospinal fluid from control subjects without neuroinflammatory disease [10].

### CNS Infection

Several studies have highlighted a role of IL-18 in mediating the inflammatory response to bacterial, viral and fungal infections of the CNS. In models of pneumococcal and cryptococcal meningits, IL-18 was shown to be up-regulated in the infected brain and to contribute to the neuroinflammatory response. IL-18 −/− mice with pneumococcal meningitis had a prolonged survival and a decreased neuroinflammatory response compared to infected wild-type littermates. These data were supported in a model of fungal infection of the CNS, where mice with cryptococcal meningoencephalitis had increased IL-18 mRNA expression in the infected brain with associated potent neuroinflammatory events. In models of viral CNS infection, IL-18 was shown to play a key role in activating microglial functions by inducing neuronal IFN-γ release in brain parenchyma and thus supporting the viral clearance of infected neurons.

The different roles and pathological effects of IL-18 in the immature and adult brain are outlined in Table 1.

### Therapy

Several functional antagonists and inhibitors of IL-18 have been described, which neutralize its pro-inflammatory effects. The most important naturally occurring antagonist is IL-18 binding protein (IL-18BP), a secreted protein which displays high-affinity binding to mature IL-18, but not to the IL-18 precursor. A single copy of the IL-18BP gene exists for humans, mice, and rats. The highest expression of IL-18BP was detected in the spleen

**Neuroinflammation – IL-18. Table 1** Role of IL-18 in neuroinflammatory diseases

| Neuroinflammatory disease | IL-18 levels in the CNS | Functional role of IL-18 |
|---|---|---|
| Experimental autoimmune meningo-encephalitis (EAE) | Increased IL-18 gene expression in EAE spinal cord and brain | Neutralizing anti-IL-18 antibodies block the development of EAE |
| Multiple sclerosis | Elevated IL-18 and receptor protein expression in active MS lesions | n.d. |
| Experimental dopaminergic neurodegeneration | Increased microglial IL-18 in substantia nigra | Reduced susceptibility to dopaminergic neuronal loss and reduced microglial activation in IL-18 gene-deficient mice |
| Bacterial meningitis | Increased IL-18 levels in cerebrospinal fluid of bacterial meningitis patients, upregulation of IL-18 protein and gene expression in infected murine brain tissue | Prolonged survival and reduced neuroinflammation in IL-18 gene-deficient mice |
| Viral encephalitis | Induction of IL-18 and caspase-1 gene expression in murine brains | Protective effect of IL-18 by enhanced clearance of neurovirulent Influenza A infection |
| Cryptococcal meningoencephalitis | Increased IL-18 gene expression in infected brains | n.d. |
| Ischemic stroke | Increased intracerebral IL-18 and caspase-1 gene expression in injured brain, elevated IL-18 serum levels | IL-18 levels in serum are predictive of outcome |
| Axonal injury | Enhanced IL-18 expression on infiltrating macrophages after nerve crush injury | n.d. |
| Traumatic brain injury (TBI) | Elevated IL-18 protein levels in cerebrospinal fluid and brain tissue | Inhibition by IL-18BP is neuroprotective |
| Neonatal hypoxia-ischemia | Elevated IL-18 and receptor, IL-1β, caspase-1 protein and gene expression in the injured brain | Reduced infarct volume and neuropathology score in IL-18−/− mice. IL-18 contributes to white matter injury in neonatal brain |
| Neonatal hyperoxic injury | IL-1β, IL-18 and receptor/caspase-1 protein and gene expression | Inhibition by IL-18BP is neuroprotective |

n.d., not determined; CNS, central nervous system; IL-18BP, IL-18 binding protein; MS, multiple sclerosis; EAE, experimental autoimmune encephalomyelitis; TBI, traumatic brain injury.

and intestinal tract which are both immunologically active tissues. Four distinct isotypes of human IL-18BP and two isotypes of murine IL-18BP have been described which are formed by alternative splicing of the respective genes. Two of the four human isotypes and both murine isotypes are biologically functional by neutralizing IL-18. Experimental studies on TBI models revealed that the systemic administration of recombinant IL-18BP after trauma resulted in a significantly improved neurological recovery, both in the adult and immature brain [8, 10]. This neuroprotection was associated with an IL-18BP-dependent downregulation of intracerebral IL-18 levels in mice. Furthermore, hyperoxia-induced neonatal brain injury was largely attenuated by administration of recombinant IL-18BP. Based on these findings, the pharmacological administration of IL-18BP may represent a promising future therapeutic strategy for attenuating the IL-18-mediated neuroinflammation and neurodegeneration in the immature and adult brain.

# Neuroinflammation – LPS-induced Acute Neuroinflammation, Rat Model

Mehrnaz Jafarian-Tehrani
Laboratoire de Pharmacologie (UPRES EA2510), Université Paris Descartes - UFR Pharmacie, Paris, France

## Definition

Characterization of a rat model to study acute neuroinflammation induced by ►lipopolysaccharide (LPS), based on histopathological and biochemical outcomes.

Acute neuroinflammation is a common process accompanying acute brain injuries such as traumatic brain injury (TBI) and cerebral ischemia [1]. Acute inflammatory response due to central nervous system (CNS)-specific glial response within the injured brain exerts detrimental effects by releasing neurotoxic mediators. The model described here mimics some aspects of acute brain injuries with a specific regard to acute neuroinflammation *in vivo*. Lipopolysaccharide (LPS), a known potent immunostimulant, a cell constituent of the cell wall of Gram negative bacteria, is used to induce the inflammatory response within the brain [2]. This model is a powerful tool for mechanistic studies and evaluation of the potential neuroprotective strategies.

## Characteristics

### Quantitative Description

In the model described here, the LPS used is from *E. Coli* (serotype 0127:B8, Sigma L-3129). The intensity of inflammatory response may differ depending on the dose and source of LPS (*Salmonella versus E. Coli* and the LPS serotype) used, and also the site of the LPS injection. Therefore, caution should be taken in the interpretation and comparison of the data available from the literature.

### Description of the Structure

In the model described here, the site of the LPS injection is located in the right hippocampus, precisely in the dentate gyrus at the ►stereotaxic coordinates [3] relative to the ►bregma (Fig. 1).

The hippocampus is a part of the brain which is involved in memory and learning. It belongs to the limbic system and its name is due to its seahorse shape. Dentate gyrus is a part of the hippocampal formation containing granule cells, the principal excitatory neurons of the denate gyrus, which project to the pyramidal cells and interneurons of the CA3 subfield of hippocampus.

### Description of the Conditions

Rats are anesthetized with chloral hydrate and placed on a stereotaxic frame. During surgery, animals are placed

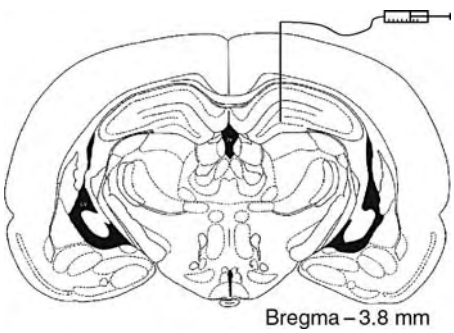
on a heating blanket system, the scalp is incised and a craniotomy is made following the coordinates described above. The injection cannula is implanted unilaterally (Fig. 1), and maintained in the site of injection for 5 min before and after LPS or vehicle (NaCl, 0.9%) infusion. Finally, the scalp is sutured and the animals are returned to their home cage in a room warmed to 26–28°C to recover from the anesthesia.

## Description of the Process

Following LPS injection, tissue damage and induced-inflammatory mediators are evaluated by ►cresyl violet staining, ►immunohistochemistry (IHC) and biochemical methods. Brains are removed at different times after LPS injection to establish a time course study. For histological studies, brains are quickly frozen in isopentane at −40°C. Brain sections (20 µm) are prepared at −20°C (Cryostat Jung CM3000) every half-millimeter at six coronal planes, from 2.8 to 5.3 mm posterior to the bregma, to establish a spatial study. Some sections are stained with cresyl violet to assess the tissue damage. Adjacent sections are processed for IHC after being dried and fixed in chilled acetone for 5 min [2].

To assess the inflammatory response, inducible nitric oxide synthase (iNOS) [4] can be used as a marker of inflammation. In fact, iNOS is one of three isoforms of NOS which is inducible under inflammatory conditions and produces a high amount of NO and has a detrimental role especially at the acute phase [5].

Other markers such as Neuronal Nuclei (NeuN), Glial Fibrillary Acidic Protein (GFAP), and OX-42 can be used to visualize the damage to neurones, astrocytes and microglia, respectively. NeuN is a marker of neuronal cell nucleus, GFAP is a marker of astrocyctic cytoplasm and OX-42 (or complement receptor 3, CR3) is a marker of microglial cell membrane.

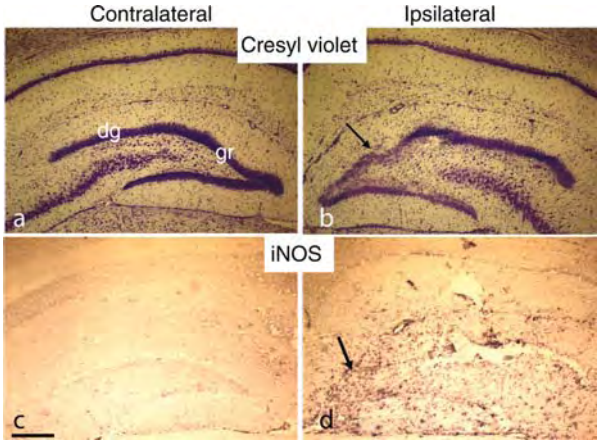


**Neuroinflammation – LPS-induced Acute Neuroinflammation, Rat Model. Figure 1** Illustration of LPS injection site in the dentate gyrus at the level of Bregma −3.8 mm [3]. LPS is dissolved in sterilized physiological saline and infused at the dose of 15 µg in a volume of 2 µl, at a rate of 1 µl/min, by using Hamilton syringe (10 µl) and syringe pump.

For biochemical studies, ►ipsilateral and ►contralateral hippocampi are dissected out and quickly frozen to perform one of the following assays. They include NOS activity evaluating iNOS activity [2,6] and also ►myeloperoxidase (MPO) activity which represents an index of monocyte/neutrophil infiltration [7]. The samples can be processed online for tissue NO end products assay, nitrate plus nitrite (NOx) which is an indirect index of NO production [8]. For brain MPO activity assay, caution should be taken to wash out the blood cells from the vasculature by transcardial perfusion through the aorta with NaCl 0.9%. The study of inflammatory mediators can also be extended to pro-inflammatory cytokines such as interleukin-1β (IL-1β), IL-6 and tumor necrosis factor α (TNFα) by using commercially available rat ►ELISA kits.

## Regulation of the Structure: Histopathological and Biochemical Outcomes After LPS Infusion

Saline infusion in the hippocampus does not lead to tissue damage and iNOS induction except at the site of injection due to the cannula penetration. In contrast, LPS infusion causes tissue damage, characterized by loss of cresyl violet staining, due to cell necrosis, in the ipsilateral denate gyrus compared to contralateral side (Figs. 2a and 2b). Furthermore, the cellular loss is due in part to neuronal cell loss observed by a marked decrease



**Neuroinflammation – LPS-induced Acute Neuroinflammation, Rat Model.**
**Figure 2** Representative photomicrographs of coronal brain sections for cresyl violet staining (a, b) and iNOS immunoreactivity (c, d) at 0.5 mm posterior to the LPS injection site. Contralateral (a, c) and ipsilateral (b, d) sections to injection site in rats submitted to LPS after 15h. At the site of LPS injection, cell loss was accompagnied by an intense iNOS immunoreactivity. Arrows show the site of brain damage (b) and iNOS immunolabeled cells (d). *dg*, dentate gyrus; *gr*, granular layer. Scale bar = 400 µm.

in NeuN immunolabeling [2]. An intense iNOS immunolabeling is also detected in the lesion area compared to contralateral side (Fig. 2c and 2d). This observation is consistent with intense iNOS activity and brain NOx levels indicating that iNOS is active in the brain parenchyma [2,9]. Following LPS infusion, induction of iNOS is acute and transient, peaked at 24h, with a coronal expansion of 2 mm around the injection site, preceding the peak of cellular loss in the hippocampus at 48–72h [2]. A high level of MPO activity is also observed in the hippocampus showing the infiltration of monocyte/neutrophil in the brain parenchyma following LPS infusion [2]. This model leads to an intense inflammatory response *in vivo* causing neuronal cell loss restricted to the hippocampus. It is a very reproducible model with no mortality over a week post-LPS infusion.

### *Function Alterations After LPS Infusion*

Neuroinflammation induced by LPS in this model is accompanied by some alterations in neurological functions such as impairment in sensorimotor function [2] and spatial memory [9]:

1. Contralateral sensorimotor functions are examined by assessing placing reactions (leg hanging and visual), grasping reflex (left forepaw and left hindpaw), and righting reflex (head tilted; left side and right side) in rats placed on a table [10]. Abnormal postures (thorax twisting and left forelimb flexion) are also examined. The scores for each item are summed and used as a global neurological score. The maximum score is for non-operated rats; the lower the neurological score the more severe the deficit.
2. Spatial memory is a more specific function to examine the function of hippocampus after tissue damage. This function is assessed by both spontaneous alteration behavior in a Y-maze and performance in the Morris water maze task.

## Therapy

LPS-induced tissue damage and neuronal dysfunction are limited by reducing the production of inflammatory mediators at its acute phase. One strategy is based on the use of iNOS inhibitors reducing iNOS-derived NO. It is noteworthy that treatment with an iNOS inhibitor prevents LPS-induced spatial memory dysfunction showing the detrimental role of iNOS in LPS-induced brain injury [9]. Since the early and late post-injury inflammatory response may play dual roles, detrimental vs. beneficial, caution should be taken on the timing of anti-inflammatory strategy [1].

# Neuroinflammation – PDE Family Inhibitors in the Regulation of Neuroinflammation

Tetsuya Mizuno
Department of Neuroimmunology, Research Institute of Environmental Medicine, Nagoya University, Furo-cho, Chikusa, Nagoya, Japan

## Definition

►Phosphodiesterase (PDE) is a group of enzymes that degrade key second messengers, cyclic AMP (cAMP) and cyclic GMP (cGMP). ►Phosphodiesterase inhibitors (PDEIs) inhibit the function of PDE and elevate

cAMP, thereby upregulating PKA/CREB signaling and downregulating NF-κB signaling. Consequently, PDEIs have anti-inflammatory and neuroprotective effects and may ameliorate the neuroinflammation accompanying demyelinating, ►neurodegenerative, and neuroinfectious diseases.

## Characteristics

### Quantitative Description

Neuroinflammation is involved in the demyelinating diseases, neurodegenerative diseases and neuroinfectious diseases. Activated ►microglia play a key role in the inflammatory processes of these diseases by releasing inflammatory mediators. PDEIs that inhibit the function of phosphodiesterases and elevate cAMP have anti-inflammatory and neuroprotective effects. PDEIs are one of the effective drugs capable of suppressing inflammatory functions of activated microglia.

### Involvement of Activated Microglia in Neuroinflammation

Neuroinflammation is a component of demyelinating diseases such as multiple sclerosis (MS) and is observed in an animal model for this disease, experimental allergic encephalomyelitis (EAE). Activated microglia play a key role in inflammatory process by releasing proinflammatory mediators including interleukin (IL)-1β, IL-6, tumor necrosis factor (TNF)-α, nitrite oxide (NO), and reactive oxygen species (ROS). These molecules damage myelinating oligodendrocytes to produce demyelinating lesions.

There is increasing evidence that inflammatory mechanisms are also involved in the pathogenesis of neurodegenerative diseases, such as amyotrophic lateral sclerosis (ALS), Parkinson's disease (PD) and Alzheimer's disease (AD). An immunological mechanism of ALS pathogenesis has been proposed and is supported by the presence of activated microglia within the gray matter of the spinal cord and motor cortex of patients with ALS. In PD, neuroinflammation contributes to the degeneration of neurons in the substantia nigra. Activated microglia and increased levels of inflammatory mediators have been detected in the striatum of PD patients and a large number of animal studies support a role for inflammation in the loss of dopaminergic neurons. In AD, neuroinflammatory mediators are upregulated in affected areas of the brain while fibrillar and oligomeric forms of amyloid β peptide (Aβ) stimulate activation of microglia.

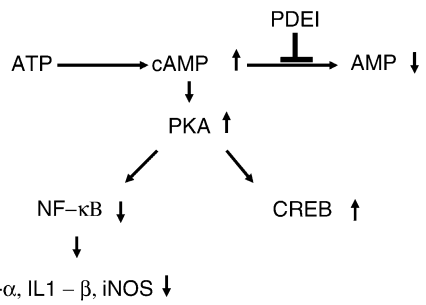
Activated microglia have a key role in chronic neuroinfectious diseases such as human immunodeficiency virus (HIV) encephalitis and prion diseases. Microglia are major targets of infection by HIV-1, and infected microglia are activated to produce inflammatory mediators. The pathogenic isoform of prion protein also stimulates microglia to produce inflammatory mediators. Therefore, inhibiting the release of inflammatory mediators by microglia may be an effective strategy for treating neuroinflammatory, neurodegenerative and neuroinfectious diseases. As PDEIs suppress the inflammatory response of activated microglia, these drugs are good candidates for therapeutic intervention.

### Anti-Inflammatory Mechanism of PDEIs

PDEs hydrolyze cyclic nucleotides, and may be specific for cAMP/cGMP or both cAMP and cGMP. There are 11 families of proteins with this enzymatic activity (PDE1-PDE11) and more than 50 isoforms in total [1]. Cyclic nucleotides are second messengers for several G proteins. PDEIs that block one or more PDEs enhance the function of cyclic nucleotides to promote a variety of pharmacologic actions. For example, some PDEIs elevate intracellular cAMP and activate the protein kinase A (PKA) signaling pathway. This suppresses NF-κB-mediated transcription without preventing nuclear translocation of NF-κB complexes [2]. Consequently, PDEIs inhibit the production of inflammatory mediators regulated by NF-κB such as IL-1β, IL-6, TNF-α, and NO (Fig. 1).

PDEIs block one or more phosphodiesterases and elevate intracellular cyclic AMP. Subsequently, they activate PKA signaling pathways that suppress NF-κB-mediated transcription and upregulate CREB. Consequently, PDEIs limit the production of inflammatory mediators and promote LTP that is regulated largely by CREB.

PDE4 and PDE10 are highly expressed in the central nervous system (CNS). The PDE4 inhibitor rolipram has anti-inflammatory, anti-depressant, and memory-enhancing effects. Ibudilast, which has been used in Japan to treat both bronchial asthma and cerebrovascular disorders since 1989, is a broad range PDEI that inhibits PDE3A, PDE4, PDE10 and PDE11(1). Inhibiting of PDE3A and PDE4 may affect tracheal smooth muscle contractility while inhibiting PDE4 and PDE10 has positive effects on neurological conditions.



**Neuroinflammation – PDE Family Inhibitors in the Regulation of Neuroinflammation.**
**Figure 1** Mechanisms of action of PDEIs.

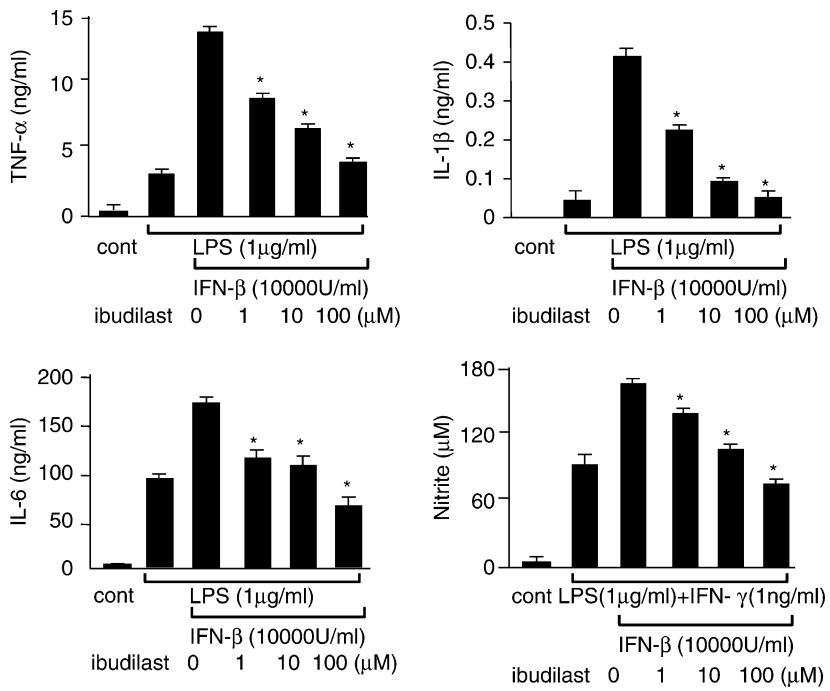
## The Effect of PDEIs on Demyelinating Diseases

Activated microglia perform several functions in the inflammatory process. They are antigen-presenting cells that present myelin-specific antigens to invading T cells in the induction phase of MS and EAE. In addition, they are effector cells that damage oligodendrocytes and neuronal cells by secreting inflammatory cytokines, radicals, and glutamate during the effector phase. However, these cells may also protect neural functions by producing neurotrophic factors. Ibudilast suppresses the production of IL-1β, IL-6, TNF-α, NO, and reactive oxygen species (ROS) by activated microglia. Moreover, it enhances the production of the inhibitory cytokine, IL-10, and neurotrophic factors including nerve growth factor (NGF), glia-derived neurotrophic factor (GDNF), and neurotrophin (NT)-4 by these cells [3].

MS is a T-helper 1 (Th1) lymphocyte-mediated disease. Th1 cells initiate proinflammatory activity while Th2 initiate anti-inflammatory activity. Ibudilast suppresses differentiation of Th1 cells in the CNS, and can shift the cytokine profile such that is dominated by Th2 rather than Th1 cells. Ibudilast significantly suppresses the production of IL-12 by microglia; this cytokine is critical for Th1 differentiation. In addition, ibudilast also suppresses the production of interferon-gamma, but not IL-4 or IL-10, by myelin oligodendrocyte glycoprotein (MOG)-specific T cells reactivated with MOG in the presence of microglia. Thus, PDEIs suppress the activities of activated microglia that contribute to the pathology of MS and EAE.

PDEIs have been examined in clinical studies of MS. The combination of three PDEIs suppresses the frequency of relapse in relapsing remitting MS (RRMS) at the standard therapeutic doses [4]. A randomized, double-blind, placebo-controlled multi-center Phase II clinical trial of ibudilast in patients with RRMS was initiated in Eastern Europe in July, 2005. Enrollment of 297 patients was completed in February, 2006. Interferon (IFN)-β is the first approved therapy for RRMS. However, IFN-β treatment causes several common side effects such as flu-like symptoms (fatigue, chills, and fever) which may be a consequence of elevated levels pro-inflammatory cytokines. PDEIs suppress the upregulation of inflammatory mediators induced by IFN-β. The PDE3 and PDE4B inhibitor pentoxifylline synergistically functions with IFN-β to reduce the production of inflammatory cytokines and upregulate the anti-inflammatory cytokine IL-10 in peripheral blood mononuclear cells from patients with active MS [5]. Ibudilast also suppresses the production of the inflammatory mediators TNF-α, IL-1β, IL-6, and NO concurrent with IFN-β treatment [6] (Fig. 2).

LPS treatment activates microglia to produce TNFα, IL-1β and IL-6. IFN-β enhances the production of these cytokines. Ibudilast significantly suppresses this effect in a dose-dependent fashion. Similarly, LPS and



**Neuroinflammation – PDE Family Inhibitors in the Regulation of Neuroinflammation. Figure 2** Ibudilast suppresses the enhanced production of inflammatory cytokines and NO induced by IFN-β.

IFN-γ induce the production of NO and its derivative nitrite. Addition of IFN-β enhances the production of these factors as well. Ibudilast significantly inhibits the upregulation of NO in a dose-dependent fashion.

## The Effect of PDEIs on Neurodegenerative Diseases

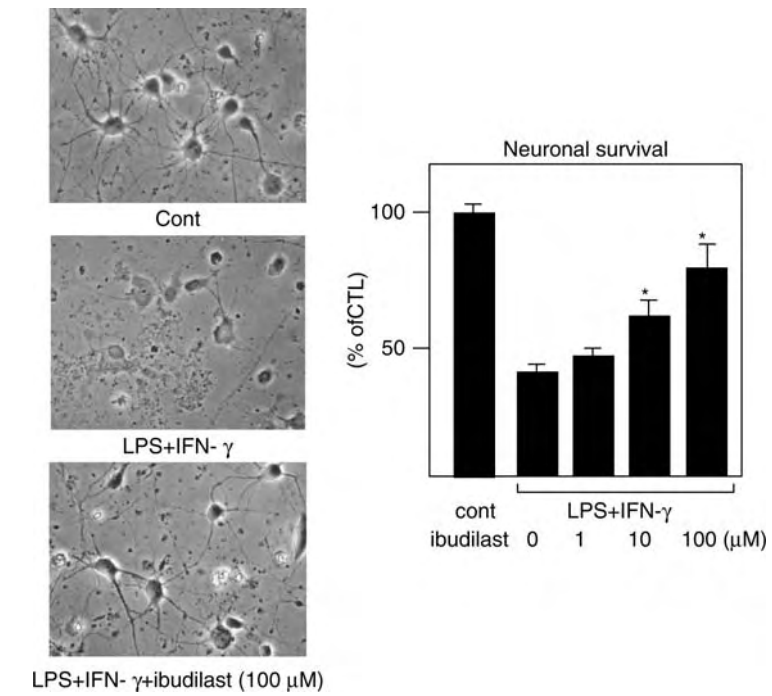
Activated microglia contribute to neuronal degeneration by producing proinflammatory cytokines, glutamate, and peroxynitrite, a product of NO and superoxide. As neuronal degeneration is related to the functional prognosis in MS, suppressing the production of these factors by activated microglia with PDEIs may be an effective strategy for treating the neuronal degeneration associated with MS. For example, ibudilast inhibits the neuronal cell death induced by activated microglia with lipopolysaccharide (LPS) and IFN-γ (Fig. 3).

Microglia activated with LPS (1 μg/ml) and IFN-γ (100 ng/ml) induce neuronal cell death. Addition of ibudilast inhibits this neuronal cell death.

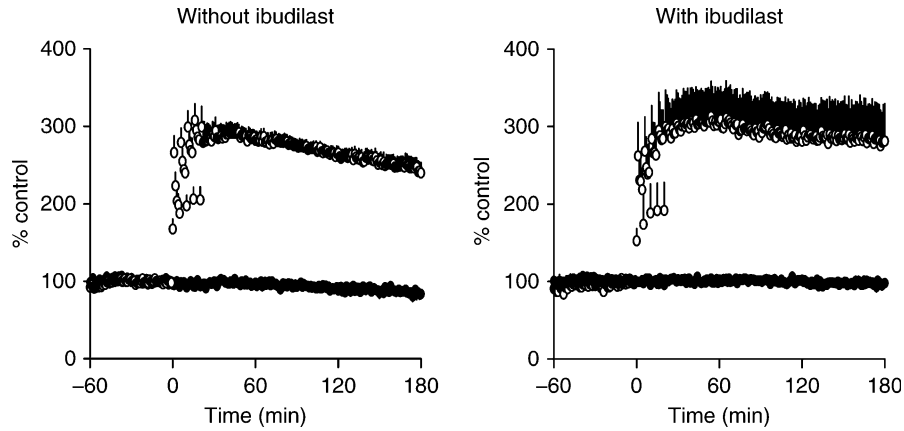
Experimental evidence supports a model for ALS neurodegeneration in which microglia contribute to the cell death of motor neurons. It is generally believed that oxidative stress and glutamate-mediated excitotoxicity are important mechanisms in ALS. NADPH oxidase, the main ROS-producing enzyme during inflammation, is activated in the spinal cord of ALS patients as well as in the spinal cord of animals with a genetic animal model of this disease. Inactivating NADPH oxidase in ALS mice delays neurodegeneration and extends survival [7]. A double-blind, randomized, multicenter, placebo-controlled trial of the PDE4B inhibitor, pentoxifylline, has been conducted with ALS patients. Unfortunately pentoxifylline had a negative effect on survival [8].

Activated microglia play a key role in the initiation and progression of PD. Exposure to a common herbicide, rotenone, induces features of parkinsonism. Rotenone stimulates the release of superoxide from microglia, resulting in the selective destruction of the nigrostriatal dopaminergic system. In animal models, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) damages the nigrostriatal dopaminergic pathway to induce parkinsonism. Neuronal damage induced by MPTP is mediated by activated microglia, and postmortem examination of human subjects exposed to MPTP reveals the presence of activated microglia decades after drug exposure. In contrast, PDEIs are reported to stimulate the uptake of dopamine and enhance intracellular dopamine levels in rat mesencephalic neurons.

Neuroinflammation is a characteristic of AD, with activated microglia being the driving force. As nonsteroidal anti-inflammatory drugs (NSAIDs) are the most commonly used of all anti-inflammatory agents, many studies have examined whether NSAIDs might have protective effects on AD. Cyclooxygenase (COX)-1 is upregulated in activated microglia and



**Neuroinflammation – PDE Family Inhibitors in the Regulation of Neuroinflammation. Figure 3** Neuroprotective effects of ibudilast.



**Neuroinflammation – PDE Family Inhibitors in the Regulation of Neuroinflammation. Figure 4** Effect of ibudilast on the suppression of LTP by LPS and IFN-γ.

NSAIDs that block this enzyme could have an ameliorating effect on the disease [9]. Similarly, the effects of PDEIs on activated microglia may also slow the progression of AD.

In addition to its roles in limiting the proinflammatory activity of microglia, PDEIs also affect neuronal activity. PDEIs that activate PKA and the cAMP responsive element-binding protein (CREB) pathway promote ►long-term potentiation (LTP) (Fig. 1). LTP in hippocampal CA1 neurons is essential for memory acquisition. Treating cultured hippocampal neurons with Aβ inactivates the PKA/CREB pathway and inhibits LTP. The PDE inhibitor, rolipram, reverses this inhibition. Moreover, rolipram ameliorates deficits in both LTP and contextual learning in the double-transgenic AD mice [10]. Treating hippocampal slices with LPS and IFN-γ prior to inducing LTP activates microglia and causes the magnitude of LTP decrease gradually. Ibudilast reverses this inhibition (Fig. 4). Thus, PDEIs may have the potential as therapeutics for treating dementia. Recently, novel PDE4 inhibitor, MEM-1414 was developed for treating AD, mild cognitive impairment and depression.

The mean population EPSP slope after tetanic stimulation was gradually attenuated with LPS (1 μg/ml) and IFN-γ (100 ng/ml) (A). Addition of 100 μM ibudilast during LPS and IFN-γ stimulation returned LTP to normal levels (B). The horizontal line indicates control levels at unstimulated sites.

## The Effect of PDEIs on Neuroinfectious Diseases

The HIV-1 virus infect macrophages and microglia in the CNS and frequently cause neurocognitive impairment. HIV-1 infected microglia are activated and inflammatory mediators. The HIV-1 envelope glycoprotein 120 (gp120), which is shed from the virus, can cause neuronal cell death. HIV-1 gp120 inhibits LTP, and HIV-1 replication is enhanced by TNF-α. Therefore, PDEI treatment could inhibit cytokine secretion associated with HIV-1 infection and transcriptional regulation of HIV replication. Rolipram is reported to inhibit HIV-1 replication in vitro.

Activated microglia are a predominant feature prion-related encephalopathy. The pathogenic isoform of prion protein causes microglial activation and has a crucial role in neuronal cell death. However, there are few reports examining whether PDEIs are effective in prion diseases.

Cell death after CNS trauma

## Definition

### Inflammation and Apoptosis after Brain and Spinal Cord Injury

Central Nervous System (CNS) destruction in traumatic brain (TBI) and ►spinal cord injury (SCI) is caused by a complex series of cellular and molecular events. Recent studies have concentrated on signaling by receptors in the interleukin 1 (IL-1) (►interleukin (IL)) and tumor necrosis factor receptor (TNFR) family that mediate diverse biological outcomes. From the basic science research perspective, understanding how receptor signaling mediates these divergent responses is critical in clarifying events underlying irreversible cell injury in clinically relevant models of CNS trauma. From a clinical perspective, this work also provides novel targets for the development of therapeutic agents that have the potential to protect the brain and spinal cord from irreversible damage and promote functional recovery. Here, we discuss how the formation of alternate signaling complexes and receptor membrane localization after TBI and SCI can influence life and death decisions of cells stimulated through IL-1 and TNFR superfamily.

## Characteristics

The pathophysiology of acute TBI and SCI is characterized by the shearing of cell membranes and axons, disruption of the blood-spinal cord barrier, cell death, immune cell transmigration, and myelin degradation [1–3]. Deleterious factors such as pro-inflammatory cytokines, proteases up-regulated by immune cells and toxic metabolites, and neurotransmitters released from lysed cells can induce further tissue damage [1–3]. These molecules can also stimulate an inflammatory reaction, with the subsequent release of neurotoxic molecules [1,3]. This subsequent damage, termed the "secondary injury," causes neuronal cell death and progressive axonal loss over time (days to weeks) laterally and longitudinally to areas undamaged by the initial trauma [2,3]. A primary goal of CNS trauma research has been to prevent or limit secondary cell death that produces further axonal degeneration and creates a significant barrier to the regeneration of descending and ascending fibers [3].

## Description of Process

IL-1 family members are known to alter the host response to an inflammatory, infectious, or immunological challenge [1,4]. The best-known members of this family are IL-1α/β, IL-1Ra, and IL-18. IL-1α/β, IL-18 and IL-33 are highly inflammatory cytokines, and dysregulation of their expression can lead to severe pathobiological effects. Accordingly, the expression of these cytokines is highly regulated via soluble receptors (type 2 IL-1 receptor) and natural antagonist proteins (IL-1Ra and IL-18 binding protein), as well as alternatively spliced forms of both ligands and receptors [4]. IL-1 cytokines exert their function through the Toll-like receptor (TLR)-IL-1 superfamily that can be divided into two groups, the TLRs and receptors of the IL-1 family. Currently there are 10 members of the IL-1 receptor family, and IL-1 ligands typically bind to a cellular receptor complex that consists of two members of this family. For example, the receptor complex for IL-1α/β consists of IL-1R and Il-1RAcP, with IL1Ra acting as a natural antagonist of IL-1α/β by trapping IL-1R1 molecules. The hallmark of IL-1 receptor signaling is the activation of the mitogen-activated protein (MAP) kinases p38, JNK and ERK 1/2 and the transcription factor ►nuclear factor kappa beta (NF-κB) [4].

Excessive levels of the proinflammatory cytokines IL-1β and IL-18 are associated with secondary damage following SCI and TBI [3]. Both IL-1β and IL-18 are synthesized as inactive cytoplasmic precursors that are proteolytically processed as biologically active mature

forms in response to proinflammatory stimuli by caspase-1, a cysteine protease. IL-33 has also been described as being processed by caspase-1. The processing of pro-IL-1β involves the activation of a multiprotein caspase-1-activating complex termed the ►inflammasome [5,6]. The inflammasome is formed by a member of the NALP protein family, such as NALP1, NALP2 or NALP3, and the adaptor protein ASC that connects the NALPs with caspase-1 [5]. Activation of the inflammasome ultimately results in activation of proinflammatory IL-1β that is secreted by macrophages and triggers another cascade of molecular events that result in inflammation [4]. To date, only neurons have been reported to contain the inflammasome in the CUS [6]. Thus, there is a need to establish the events critical to the assembly and activation of the inflammasome, and to determine if these principles apply to inflammatory processes within the CNS.

## Higher Level Structures

CNS inflammatory responses that occur after SCI and TBI are initiated by peripherally-derived immune cells (macrophages, neutrophils, and T-cells), and activated glial cells (astrocytes and microglia) that proliferate or migrate into the lesion site following injury [2,3]. T-cells are essential for activating macrophages and mounting a cellular or immune response. Macrophages and neutrophils have also been proposed to participate in tissue destruction and enlargement of the lesion [2,3]. Macrophages and microglia contribute to the secondary pathological and inflammatory response, in part through the release of cytokines, tumor necrosis factor (►tumor necrosis factor (TNF)), interleukin-1 (IL-1), IL-6, and IL-10, interferon [4], and activation of interleukin receptors (IL-4R and IL-2R) [4]. Cytokines facilitate CNS inflammatory responses by inducing expression of additional cytokines, chemokines, nitric oxide (NO), and reactive oxygen [3]. Since inflammation contributes to both constructive and neurodestructive processes, a more thorough understanding of the autoimmune events that occur following CNS injury may allow us to develop strategies that will harness the beneficial effects of inflammation and, hopefully, help to promote functional recovery [3].

## Therapy

Prevention of production of inhibitory proinflammatory molecules by activated mononuclear phagocytes has been demonstrated to be neuroprotective [3]. Various strategies including drug delivery as well as mild hypothermia [3] have been shown to reduce the inflammatory cascade after SCI and provide neuroprotection and improvement in functional outcome. Another strategy has concentrated on targeting selections on the surface of endothelial or inflammatory cells [3]. Interactions of endothelial cell-adhesion molecules with integrins on the white blood cell surface have been shown to promote leukocyte extravasation through the blood-spinal cord barrier and movement into the injured spinal cord.

It is likely that other agents that prevent the synthesis and secretion of IL-1 family members will be effective in CNS trauma. These are the IL-1 Trap, IL-1β-specific monoclonal antibodies, and the caspase-1 inhibitor [4]. It is also possible that agents that target IL-1β secretion may function to limit inflammation after CNS trauma. Moreover, once released, IL-1β must compete for receptor occupancy with the naturally occurring IL-1Ra, the binding and neutralization by the IL-1 type II decoy receptor and the formation of inactive complexes with constitutively secreted soluble IL-1 accessory protein, each of which also limit IL-1β responses. Moreover, we have recently found that therapeutic neutralization of the inflammatory after SCI reduces IL processing, resulting in significant tissue sparing and functional improvement [6]. Thus, continued investigations into the mechanisms underlying the activation of IL-1β inflammatory cascades after SCI and TBI could lead to new strategies to inhibit secondary injury and thus to promote recovery in injured patients.

## Regulation of Processes

TBI induces upregulation of TNF-α protein and mRNA in the injured cortex [7,8], and increased levels of TNF-α have been reported in plasma and cerebrospinal fluid of human head injured patients [7]. Gene-targeting studies indicate that the presence of TNF-α in the acute posttraumatic period may be deleterious, whereas this cytokine may play a beneficial role in the chronic period after TBI [7,9]. In a similar fashion, spinal cord trauma leads to increased expression of TNFR1 and TNFR2 receptors and their ligands as well as activation of ►caspases and calpain, but there are conflicting reports as to the role of TNF signaling after SCI that probably reflect the known capacity of TNF to be both pro and anti-apoptotic [7,9]. A solution to this paradox has been proposed in the recent findings that tumor necrosis factor receptor (TNFR) submembrane localization and the formation of alternate signaling complexes can alter the fate of cells stimulated through TNFRs [10].

Mammalian TNF-α signals through two cell surface receptors, TNFR1 (CD120a), and TNFR2 (CD120b). Most cells constitutively express TNFR1 while TNFR2 expression is highly regulated. Activation of TNFR1 leads to the recruitment of the adaptor ►TRADD (TNFR-associated death domain protein) that serves as a platform to recruit additional signaling adaptors [9]. TRADD binds the Ser/Thr kinase receptor-interacting protein (►RIP) and TNF-receptor-associated factors 2 (►TRAF2) and 5 (TRAF5). This TRADD-RIP-TRAF complex causes activation of NF-κB, through an unknown mechanism

[9]. TRAF2 can also recruit secondary adaptors that modulate signaling, i.e. TRAF1 and cellular inhibitor of ►apoptosis protein-1 (►cIAP-1) and -2 (cIAP-2) [9]. cIAP-1 supports ubiquitination and proteasomal degradation of TRAF2 [8], while TRAF2 inhibits signaling through TNFR2 by an unknown process [8]. Additionally, TNFR1 can recruit caspase-8 via TRADD and Fas-associated death domain protein (►FADD) to induce apoptosis [9].

Redistribution of TNFR1 in the plasma membrane is one possible mechanism for regulating efficiency of TNF signaling. Recent *in vitro* evidence suggests that redistribution of TNFR1 into specialized microdomains (►lipid rafts) may account for the outcome of some TNF-α-activated signaling pathways [7,8,9], but TNFR1 localized to nonraft regions of the plasma membrane are capable of initiating different signaling responses [7]. Recently, the role of microdomains in signal transduction emanating from the TNFR family *in vivo* has been addressed [8].

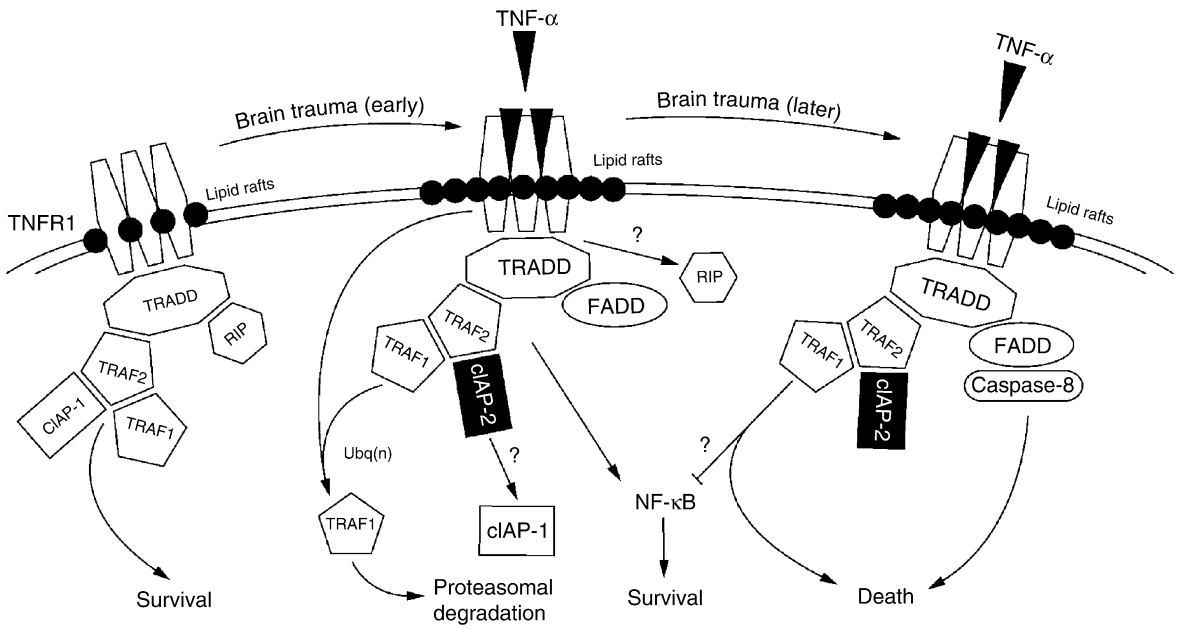
## Higher Level Processes

The TNFR superfamily mediates a wide spectrum of important cellular functions ranging from acute inflammation and lymphocyte co-stimulation to apoptosis and other forms of programmed cell death [7,9]. The divergent cellular signaling responses orchestrated by these receptors are dependent on cell-type and environmental factors [9]. In most instances, TNFR1 triggers cellular activation via NF-κB. However, when new protein synthesis is inhibited prior to TNF stimulation, TNFR1 can initiate apoptosis by activation of apical caspases [7,9]. Recent experimental evidence has provided information about how receptor submembrane localization and the formation of alternative signaling complexes by two members of the TNFR family, TNFR1 and Fas, can alter the fates of cells [8,10]. Here, we discuss how programmed cell death after CNS trauma is a tightly regulated process that can be initiated by activation of a specific TNFR family member TNFR1. Deletion of TNFR1 or blocking ligand interactions with different TNFR family members has emerged as a clinically effective therapy for experimental CNS injury.

In cells of the immune system, TNFR1 signaling involves assembly of two molecularly and spatially distinct signaling complexes that sequentially activate NF-κB and caspases [10]. Early after TNF binding to TNFR1, a TNFR1 receptor-associated complex (complex I) forms and contains TRADD, RIP1, TRAF1, TRAF2 and cIAP-1. Complex I transduces signals that lead to NF-κB activation through recruitment of the I-κB kinase "signalsome" high molecular weight complex [10]. TNFR1-mediated apoptosis signaling is induced in a second step in which TRADD and RIP1 associate with FADD and caspase-8 to form a cytoplasmic complex (complex II) that dissociates from TNFR1. However, when complex I triggers sufficient NF-κB signaling, anti-apoptotic gene expression is induced and the activation of initiator caspases in complex II are inhibited. If NF-κB signaling is deficient, complex II transduces an apoptotic signal. Thus, early activation of NF-κB by complex I serves as a checkpoint to regulate whether complex II induces apoptosis at a later time point after TNF binding.

Our recent study has shed new light on how membrane proximal events control fate decisions in signaling by TNFR1 in the CNS after TBI [8]. The results support a model in which a small amount of TNFR1 is constitutively expressed in the lipid raft microdomains. It has been proposed that lipid rafts serve as signaling platforms for variety of receptors including TNFR1 and Fas. TNFR1 signaling complexes in the normal CNS contain adaptor molecules TRADD, RIP, TRAF1, TRAF2 and cIAP-1 (Fig. 1) [8]. Since the TNFR1-TRADD-RIP-TRAF2 complex initiates the pathway leading to survival [9], it is probable that the TNFR1 signaling complex in the normal CNS initiates a survival signal. Moreover, this signaling complex is devoid of FADD, cIAP-2 and caspase-8 [8].

CNS trauma induced rapid translocation of TNFR1 to lipid rafts, altered associations with signaling intermediates, and induced transient activation of NF-κB. RIP and cIAP-1 dissociate from TNFR1, whereas FADD and cIAP-2 increase association with this receptor-signaling complex in lipid rafts. Because the TNFR1-TRADD-FADD complex initiates the pathway leading to apoptosis [9], it is possible that alterations in association of adaptor molecules in the signaling complex are responsible for the switch in the signal transduction pathway from survival in the normal CNS toward apoptosis after trauma (Fig. 1). Dissociation of RIP from the TNFR1 signaling complex induced by trauma may ablate or downregulate the NF-κB pathway and facilitate cell death. Additionally, cIAP-1 and cIAP-2 and TRAF1 have been identified as NF-κB target genes [9]. Trauma-induced interference of the NF-κB pathway may result in altered actions of the caspase-8 inhibitory TNFR1-TRAF-IAP complex to further promote apoptosis [9]. By 30 min after CNS trauma, caspase-8 was present in TNFR1 signaling complexes, supporting the idea that the association of FADD with TRADD initiates the apoptotic program by recruiting caspase-8. Thus, in contrast to TNFR1-mediated signaling in cultured cells, these *in vivo* studies do not reveal an essential role of complex II in the regulation of TNF-α responses after CNS trauma, but rather indicate that in both the normal and traumatized CNS, lipid rafts appear to promote the formation of a receptor-associated signaling complex (complex I) to produce different biological outcomes dictated by these complexes. Moreover, complex I in the traumatized CNS



**Neuroinflammation: Brain and Spinal Cord Injury. Figure 1** Model of lipid raft mediated TNFR1 signaling after CNS trauma. In a normal rat CNS low levels of TNFR1 are present in lipid rafts and are in complex with TRADD, TRAF1, TRAF2, RIP and cIAP-1 and signals survival. Early after trauma, increased levels of TNFR1 recruit into lipid raft microdomains (•), where they associate with the adaptor protein TRADD, FADD, TRAF2, TRAF1, and cIAP-2. TNFR1 and TRAF1 are polyubiquitinated (Ubq(n)) in lipid rafts after trauma, which leads to degradation via the proteasome pathway. In later stages after injury, RIP and cIAP-1 appear to dissociate from TNFR1 complex by an unknown mechanism, and this complex signals death by activating caspase-8 [8].

harbors activated caspase-8 by 30 min after insult, indicating involvement in downstream signaling cascades. Therefore, the death domain of TRADD may act as a central platform for the recruitment and activation of FADD after CNS trauma, leading to subsequent binding of caspase-8 triggering their activation. These studies support recent evidence that the roles for lipid rafts in Fas and TNFR1 signaling varies between cell types [8,10]. Thus, TNFR signaling is dependent on cell type and subject to influence of other signaling pathways, genetic and environmental factors.

The IL-1 and TNF family of cytokines have been mainly characterized in the immune system and are primarily involved in regulating inflammatory and apoptotic responses. However, these cytokines are detectable in other tissues, for example the normal and traumatized CNS, raising the possibility that these cytokines and their receptors have a role in neurological trauma and disease. There is increasing interest in the role of inflammatory processes in CNS injury, since inactivation neuroprotection in animal models of SCI, stroke and multiple sclerosis [3]. However, a true understanding of how reducing inflammation after CNS injury leads to inhibition of cell death and enhance functional recovery will require more detailed knowledge. For example, the signaling pathways initiated by the IL-1 and TNF receptors in CNS cells have not been delineated. It is not clear if CNS cells exhibit differences in the efficiency of IL-1 or TNF signaling and thus can be categorized as cells in the immune system. The cellular source and target of the ligand in damaged CNS tissues need to be identified, and protocols need to be developed to deliver antibodies to the lesion at later stages to clearly evaluate this therapeutic approach.

Recent experimental evidence has provided information about how receptor submembrane localization and the formation of alternative signaling complexes can alter the fates of cells *in vitro*, but whether these principles apply to signaling mediated by TNFR family members in the normal CNS and after trauma awaits further experimentation. Thus, activation of these signaling pathways might become promising therapeutic targets for the acute treatment of neurological trauma and disease.

## Acknowledgments

We would like to thank Dr. George Lotocki for the illustration. The work was supported in part by NIH PO1 NS 38665.

### Neuroinflammation and NSAIDs

Neuroinflammatory responses are characteristics of pathologically affected tissue in several neurodegenerative disorders, including Alzheimer's disease (AD). Epidemiological studies have shown that conventional long-term treatments with non-steroidal anti-inflammatory drugs (►NSAIDs) reduce the risk of AD, delay the onset of this disease, ameliorate symptomatic severity, and slow cognitive decline. A transgenic AD Tg2576 mouse has amyloid pathology and activated microglias. Daily intake of ibuprofen, a NSAID, reduces the levels of the inflammatory cytokine, reactive ►astrocytes with glial fibrillary acidic protein (GFAP), β-amyloid deposits, and activated microglia in these AD mice. Rats with intraventricular chronic infusion of β-amyloid or ►lipopolysaccharide (LPS; ►endotoxin) show microglial activation and ►memory impairment. NSAID treatments rescued memory impairment of these rats and lowered inflammatory responses. Thus, these anti-inflammatory agents can significantly delay inflammatory responses characterized by activated glial cells and increased expression of cytokines surrounding amyloid deposits of AD pathology and prevent cognitive decline, as inflammation clearly occurs in the AD brain.

## Characteristics

### Alzheimer's Disease and Neuroinflammation

AD typically leads to progressive and incapacitating memory loss followed by additional cognitive and behavioral impairments. A neuropathological diagnosis of AD is made upon the detection of amyloid plaques and neurofibrillary ►tangles (NFTs) in the limbic and neocortical areas of the brain. However, AD is now also characterized by neuroinflammatory changes and increased free radicals, as well as classic neuropathological features such as amyloid plaques, neuronal loss, and NFTs [1,2]. *In vivo* measurements of microglial activation using positron emission tomography (PET) and magnetic resonance imaging (MRI) show that inflammation is an early event in the pathogenesis of AD [3]. Further, a chronic inflammatory response characterized by activated microglia, reactive astrocytes, complement factors, and increased inflammatory cytokine expression is associated with amyloid plaques in the AD brain [4].

Chronic inflammatory processes play an important role in the pathogenesis of AD [4]. Clumps of activated microglias and reactive astrocytes appear on ►senile plaques [1]. The levels of inflammatory cytokine interleukin-1-alpha (IL-1α) are increased in the AD brain [5]. The increase in IL-1α might both underlie and be due to widespread astrogliosis in the AD brain. Additionally, IL-1α could induce the expression of the β-amyloid precursor protein (β-APP). Senile plaques contain both β-amyloid and reactive microglial cells that excessively express inflammatory cytokines, including IL-1α and tumor necrosis factor-alpha (TNF-α). Further, activated microglia is a source of free radicals and neurotoxic materials. One potential neurotoxin released by activated microglia is glutamate. Chronic increase of extracellular glutamate impairs the glutamatergic receptor function, leading to the entry of toxic amounts of calcium into neurons and subsequently potentiation of neurotoxicity [3].

There is now overwhelming evidence that a state of chronic inflammation exists in affected regions, although it must still be determined whether inflammation

merely occurs to clear the detritus of already existent pathology (plaques/tangles) or inflammatory molecules and mechanisms are uniquely or significantly elevated in the AD brain [6].

## Animal AD Model for Neuroinflammation

Well-characterized animal models with important neuropathological features seen in AD have significantly advanced our understanding of the molecular mechanisms of AD and are important in predicting future therapeutic intervention. In the following, I introduce two animal AD models currently used extensively by neuroscientists.

### *A Transgenic Mice Model for AD*

Targeted gene mutation technology represents a powerful new tool for biomedical research. A new gene or an additional copy of an existing gene is added to the genome in the transgenic mice and a gene is missed in the knockout (KO) mice. Transgenic mice expressing mutated human amyloid, human presenilin 1, or both show dramatic parallels to AD. However, none of the models appear to have the full pathological characteristics of human AD.

The most popular Alzheimer transgenic mouse model is the Tg2576 mouse, which carries a human familial AD gene (amyloid peptide protein; β-APP with the "Swedish" double mutation). The model displays age-related neuritic plaque pathology, activated microglias, and reactive astrocytes with increased GFAP (glial fibrillary acid protein) in the hippocampal and neocortical areas. More importantly, these mice show age-related memory deficits linked to defective ►long-term potentiation (LTP).

These AD transgenic models are being used to devise therapeutics strategies for AD. Specifically drugs or procedures that reduce the accumulation of β-amyloid in the mouse models are considered to be potential treatments for AD. One limitation of this approach is that such mice are only partial models of AD. They show abundant β-amyloid deposits, which are comparable to those observed in AD. However, in contrast with AD, the mice do not demonstrate the presence of NFTs. In the transgenic mice, complement staining of the deposits is weak, whereas as in AD it is very strong.

With the emergence of the transgenic/KO mouse models, the need for behavioral studies measuring the cognitive abilities of the mouse has become more urgent. Despite this, few studies to characterize cognitive behaviors with many different mouse strains have been reported. Furthermore, because the behaviors of mice are different from those of the rat, direct comparison of results for mice with those for rats is not fruitful. Therefore, much caution is needed in conducting behavioral experiments measuring memory impairment or enhancement by a given treatment when working with transgenic mice (for example background strains or wild-type littermate controls for a null mutation).

On the contrary, behavioral tasks for measuring cognitive abilities with rats have been well studied and characterized. Conclusive and reliable decisions regarding rat behavioral data can be easily reached through comparison with the results of reported studies. On this basis, an AD rat model has been introduced.

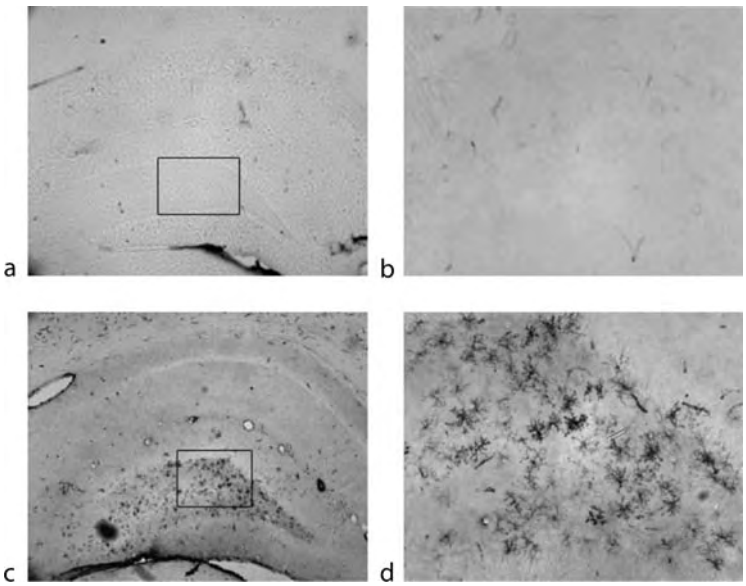
### *Chronic LPS Infusion Rat Model*

β-Amyloid or proinflammagen (such as LPS and interleukin (IL)-2) was chronically infused into the rat ventricle at a very low dose. LPS is a component of the cell wall of gram-negative bacteria and has been used experimentally to stimulate production of endogenous IL-1, β-APP and complement proteins. The chronic infusion of LPS into the brain via the fourth ventricle for 4 weeks reproduces important aspects of the pathology of AD.

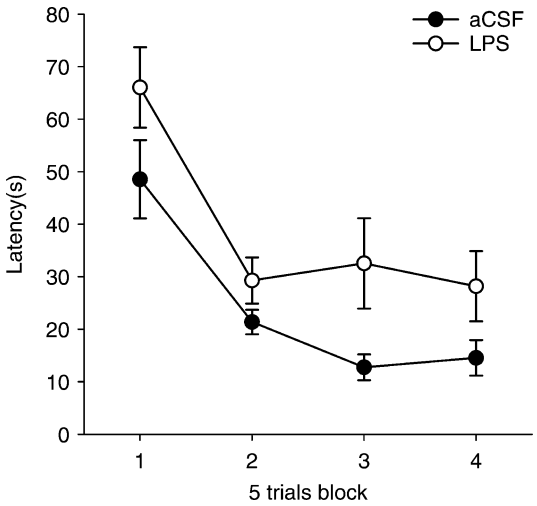
Chronic LPS infusions increased the number and density of OX-6-positive reactive microglia, the immune competent cells of the CNS, in the hippocampus of Fischer-344 rat (see Fig. 1). The number and density of astrocyte, observed by GFAP, was also affected. Rats with chronic LPS infusion take longer to find a hidden platform in the Morris water maze, relative to rats with artificial cerebrospinal fluid (aCSF) (see Fig. 2). *Arc* is an immediate-early gene that was cloned from the brain and is a good indicator of neuronal activation by physiological stimuli including LTP induction and seizures. Exploration-induced Arc protein expression within the dentate gyrus (DG) is altered in the hippocampus of rat with cognitive impairment by neuroinflammation. LPS activates microglia to initiate a series of inflammation-induced changes within the hippocampus and entorhinal cortex. The inflammation leads to a reduction in the number of NMDA glutamate receptors within the DG and CA3 hippocampal area without neuronal loss. Furthermore, LPS-induced neuroinflammation impairs the induction of LTP. According to MRI results, the size of the hippocampal formation and the temporal region was decreased. These aspects of the chronic LPS infusion model make it useful for testing potential pharmacotherapies for the prevention of AD [3].

## Neuroinflammation of AD and NSAID

Because the inflammatory process is the pathological hallmark associated with AD, it is not surprising that conventional anti-inflammatory therapy using NSAIDs has been shown to slow the progress, or delay the onset, of AD. Untreated elderly demented patients with senile plaques have almost three times more activated microglia than do those patients with senile plaques chronically taking NSAIDs. Neuronal cyclooxygenase (COX)-2 is elevated in the AD brain: long-term



**Neuroinflammation: Chronic Neuroinflammation and Memory Impairments. Figure 1** Reactive microglia stained with OX-6 in the hippocampus. Fischer-344 rats infused with aCSF have only a few activated microglias (a, b). Chronic infusion of LPS into the fourth ventricle produces activated microglias distributed throughout the hippocampus of the Fischer-344 rat brain. Activated microglias were expressed highly in dentate gyrus (c, d). (courtesy of Jung-Soo Han).



**Neuroinflammation: Chronic Neuroinflammation and Memory Impairments. Figure 2** Assessment of spatial learning in rats with LPS infusion and rats with aCSF infusion. Mean latency (±) to reach the escape platform across four blocks of five training trials during the spatial learning task. Fischer-344 rats with LPS or aCSF infusion received three trails/day trainings (1 min intertrial interval, maximum trail duration of 90 s with 30 s on the platform at the end each trial) in the hidden platform training. Rats with LPS infusion perform more poorly in the spatial learning task than rats with aCSF. (courtesy of Jung-Soo Han).

inhibition of this enzyme might underlie the beneficial effects of NSAID therapy in AD [7].

Ibuprofen is a NSAID, and is widely used to reduce pain, fever, and inflammation. The drug inhibits COX enzymes and activates peroxisome proliferators-activated receptors gamma (▶PPARγ); both of these actions result in reduced inflammation. In addition, ibuprofen suppresses cerebral plaque formation and inflammation in a mouse model of Alzheimer's disease [8]. However, a major limitation of NSAIDs, such as ibuprofen with respect to the prevention of AD is gastrointestinal and occasional liver and kidney toxicity caused by cyclooxygenase (COX-1) inhibition. These side effects have stimulated a search for alternative anti-inflammatory drugs and, alternatively, attempts to structurally modify existing NSAIDs so as to eliminate their COX-1 inhibition. Many modified NSAID or natural products are tested in animal models or clinically. Two alternatives among them are introduced below.

NO-flurbiprofen, a novel NSAID that lacks gastrointestinal side effects, attenuated the neuroinflammatory reaction and reduced inflammation-induced memory deficit in the chronic LPS infusion rat model [3]. β-Amyloid is also reduced in doubly transgenic (Tg) amyloid precursor protein plus presenilin-1 mice when NO-flurbiprofen is administered between 7 and 12 months of age [9].

Oxidative damage and neuroinflammation are closely associated with the progression of AD and

other neurological diseases. In the search for antioxidant and anti-inflammatory agents to reduce ROS and inflammation, the phenolic antioxidant ►curcumin, a yellow curry spice derived from turmeric, has proved to be of interest. This spice is used as a food preservative and herbal medicine in India, where the prevalence of AD in patients between 70 and 79 years of age is 4.4-fold less than that of the United States. In comparison with vitamin E used clinically [10], curcumin is several times more potent as a free radical scavenger. Based on these considerations, curcumin has been evaluated in some animal studies. In an AD transgenic Tg2576 mouse model, curcumin lowers oxidized proteins and IL-1β. The astrocytic marker GFAP and β-amyloid is also reduced by curcumin treatment [11]. Preventive effects of curcumin on the cognitive deficits have also been tested in a rat model with intracerebroventricular infusion of β-amyloid peptides. Dietary intake of curcumin prevents β-amyloid-infusion induced spatial memory deficits in the Morris Water Maze [12].

## Summary

Inflammation clearly occurs in the AD brain. In the periphery, degenerating tissue and the deposition of insoluble materials are classical stimulants of inflammation. Likewise, in the AD brain, damaged neurons, neuritis, deposits of insoluble β-amyloid, and neurofibrillary tangles stimulate the inflammation. Direct and bystander damage in AD is cumulated over many years and significantly exacerbates the pathological process. Thus, animal models and clinical studies suggest that inflammation in AD contributes to AD pathogenesis. While anti-inflammatory approaches (for example, NSAID) may not cure AD, it is possible that they will delay onset and slow the progression of this disease as well as slow cognitive decline.

## Synonyms

Biomagnification: high environmental persistence; Reactive oxygen species: superoxide anions; Hydroxyl free radicals; Pesticide: insecticide; Herbicide

## Definition

The term ►pesticide describes a chemical capable of being used to control pests to humans, agricultural crops, commercial operations, and households.

Promoting research in this area has resulted in a clear understanding of pesticide toxicological properties. Today, pesticides are considered to be one of the most thoroughly understood chemicals from a toxicological standpoint. Modern strategies in pest control have attempted to design compounds of high selectivity and low ►environmental persistence. Ideally, a pesticide would be selective only to the targeted species and would be non-persistent in the environment. However, these attempts have not been entirely successful. Non-persistent insecticides, such as carbamates and organophosphates, are currently in use but they are not considered as truly selective compounds. Most pesticides currently in use are toxic to humans, and present an environmental and occupational hazard [1].

Many of the used pesticides, whether applied as systemics, aerosols, baits, or fumigants, have been associated with some form of nervous toxicity. Moreover, increasing indications suggest that the pathogenesis of a number of chronic neurodegenerative diseases such as Idiopathic Parkinson's disease (PD), Alzheimer's disease (AD), multiple sclerosis, trauma, and stroke, may be influenced by exposure to infectious agents and pesticides. On the other hand, emerging evidence indicates that the development of these neurological disorders may be mediated by a complex cycle of atypical inflammation steps involving brain immune cells, mainly astrocytes and microglia.

Microglias, considered as the macrophages of the central nervous system (CNS; brain), are normally present in a down-regulated state, and serve the role of immune surveillance. When exposure to an environmental toxicant takes place, microglia change morphology and become active in phagocytosis and in producing inflammatory molecules. In parallel, astrocytes, which normally maintain neuronal homeostasis, also become active and serve in up-regulating the expression of neurotrophic factors and local mediators, and limiting the area of injury. Astrocytes are believed to react whenever the brain is injured by putting down glial scar tissue as part of healing. This whole process, mechanistically distinct from peripheral tissues inflammation, is known as neuroinflammation.

Whether neuroinflammation is harmful or protective to the nervous system, especially in cases of exposure to pesticides, is still a controversial issue. Studies using strategies aimed at both suppressing and inducing the process of neuroinflammation may be successful in identifying new treatments for common neurodegenerative diseases.

## Characteristics

### Description of Neuroinflammation

Inflammation is the first response of the immune system to infection or irritation. It is characterized by redness (*rubor*), heat (*calor*), swelling (*tumor*), and pain (*dolor*), and constitutes the body's initiation of healing. Although inflammation is considered a defensive mechanism, an exaggerated inflammatory response has been shown to cause additional injury to cells of the host. In the adult CNS, mainly the brain, damage often leads to persistent deficits due to the inability of mature post-mitotic axons to regenerate after injury [2]. This makes host cells in this particular area highly susceptible to injury and inflammatory processes. Inflammation associated with the CNS, known as neuroinflammation, differs from that found in the periphery. It does not involve any pain due to absence of pain fibers in the brain, and does not show any classic signs of inflammation such as redness, swelling, or heat. The process is usually mediated by cytokines following a direct injury to the nervous system, and systemic tissue injury in rare cases. Neuroinflammation involves neural-immune interactions that activate immune cells, glial cells, and neurons in response to injury [3].

### Activation of Astrocytes and Neurons

Astrocytes are considered as the most abundant cells in the brain. They are involved in maintaining the functional integrity of neuronal transmission and general activity. Astrocytes become activated in response to brain injuries and produce many pro-inflammatory molecules such as interleukins, prostaglandins, leukotrienes, thromboxanes, coagulation factors, complement proteins, and proteases. In addition, activated astrocytes promote repair of damaged tissues. Certain chemokines released by activated astrocytes attract microglia, which amplifies production of pro-inflammatory molecules. On the other hand, neurons themselves participate in the production of inflammatory molecules, mainly complement proteins.

An increasing amount of data has shown that the production of these molecules by astrocytes and neurons may in fact create an oxidative stress microenvironment that leads to neuronal toxicity and cell death. Studies on neuro-immune-endocrine interactions have shown that the hypothalamic-pituitary-adrenal axis (HPA) plays a key role in protecting cells from oxidative stress through suppression of redox-sensitive transcription factor, nuclear factor (NF)-$_k$B [4]. Several studies have demonstrated that the accumulation of pro-inflammatory and cytotoxic factors by activated glia induces ►neural degeneration. Neurotoxicity has been associated with high levels of nitric oxide (NO), superoxide anions, and other toxic intermediates [5]. Reports on lipid-derived mediators of inflammation, mainly prostaglandins $E_2$ and $I_2$, were shown to induce edema, which is deleterious to neuronal function and survival. In addition, several ►reactive oxygen species, such as superoxide anion and hydroxyl radical, were found to be released as byproducts of cyclooxygenase Cox-2 catalytic activity, a key enzyme in inflammatory response, thus leading to brain damage [6]. Emerging experimental evidence demonstrates that the inhibition of the inflammatory response can slow down degeneration of

dopamine-containing neurons in PD models. In fact, the use of anti-inflammatory steroids was reported to decrease the production of cytokines and NO, and consequently attenuating degeneration of dopamine-containing neurons in models mimicking PD [7]. Another study conducted in rat animal models has shown that inhibition of neurotoxic factors production, such as tumor necrosis factor alpha (TNF-α), superoxide, and NO, reduces damage to dopamine-containing neurons [8].

### Role of Reactive Microglia in Neuroinflammation

The activation of microglia is seen as a major step in brain inflammation. Microglial cells support and protect neurons of the CNS. They are mainly composed of mesodermally-derived macrophages and are able to release a number of inflammatory molecules including pro-inflammatory cytokines, chemokines, superoxide anions, and complement proteins. In addition, microglia have phagocytic and surveillance properties. Studies have shown that microglias are sensitive even to minor disturbances in CNS homeostasis [9]. More importantly, microglia play a key role in cellular responses to pathological lesions such as those of dopaminergic neurons in PD, and such as extracellular deposits of β-amyloid and intracellular neurofibrillary plaques seen in AD. These lesions can recruit and activate microglia around them in the brain. In addition, microglia can express scavenger receptors that facilitate their adhesion to injury sites [10,11].

Reactive microglia exert a protective role through clearance of cellular debris, destruction of foreign particles and release of neurotrophic factors such as the glia-derived neurotrophic factor (GDNF), and the insulin-degrading enzyme (IDE) that destroys damaged protein deposits. However, several studies have demonstrated that the production and buildup of pro-inflammatory and cytotoxic factors may have a negative impact on neurons leading to neurodegeneration. Resulting neurotoxicity is thought to be caused by increased production of NADPH-derived superoxide anions, which leads to additional neuronal damage. In addition, neurotoxicity is aggravated by microglial release of interleukins IL-1, IL-6, IL-8, tumor necrosis factor alpha (TNF-α), and other inflammatory proteins. In addition, increased levels of nitric oxide (NO) have been associated with neurotoxicity [12].

## Association between Pesticide Exposure and Neurodegeneration

All chemical pesticides in use today are poisonous to the nervous system of the target species. Pesticides are not highly selective and may affect humans. Exposure to pesticides has long being suspected as a risk factor for a number of neurodegenerative diseases including PD and AD [13]. The identification of chemicals inducing neurodegeneration symptoms, as in the case of 1-methyl-4-phenyl-1,2,3-tetrahydropyridine MPTP-induced Parkinsonian symptoms, is in support of the search for environmental factors at the basis of neurodegenerative diseases. Extensive literature suggests that exposure to pesticides is a risk factor for PD and AD. Many studies have established an association of PD risk with living in rural areas, drinking well water, and farming.

### Neurotoxicity of Organochlorines in PD

Organochlorines are a diverse group of agents belonging to three distinct chemical classes that include dichlorodiphenylethane, chlorinated cyclodienes, and chlorinated benzenes. Organochlorines are effective pesticides due to low volatility, chemical stability, lipid solubility, and slow rate of biotransformation and degradation. As a result, these compounds have high persistence and high biomagnification which makes them a serious hazard. Several studies have linked exposure to organochlorines and increased risk of neurodegeneration [14].

One organochlorine, dieldrin, has been detected in postmortem brain samples from PD patients. Studies have shown that dieldrin exhibit selective dopamine-depleting neurotoxicity effects by causing superoxide formation and ►lipid peroxidation. Similarly, dichlorodiphenyl-trichloroethane (DTT), another commonly used organochlorine, has been detected in postmortem brain samples from AD patients. Studies on other members of the organochlorine family showed that production of a direct toxic effect is a function of individual genetic factors, mainly drug-metabolizing enzymes such as cytochromes P-450 (►cytochrome P-450) genetic polymorphism, in addition to frequency of exposure to pesticides [15].

### Description of Organophosphates-Induced Neurodegeneration

Currently used organophosphorus ester insecticides (OP) are at least four generations of development away from the early nerve gases. Organophosphates elicit their toxicity through inhibition of acetylcholinesterase AChE, the enzyme responsible for terminating the activity of the neurotransmitter acetylcholine at the level of post-synaptic neurons. Case reports have associated development of Parkinsonism with exposure to organophosphate insecticides.

In addition to general central nervous toxicity symptoms, OPs have been shown to cause a persistent neuropathy with a delayed onset known as organophosphate-induced delayed neuropathy (►OPIDN). This involves slow degeneration of the nervous system seven to fourteen days after exposure to certain OPs at high doses. Causes of OPIDN are still not very well understood; it is hypothesized that OPIDN is caused by the inhibition of Neuropathy Target Esterase (NTE), an enzyme involved in lipid metabolism. In cases of chronic exposure, initial binding of the pesticide to the enzyme is reversible. However, the AChE-OP complex might undergo what

is commonly known as "aging." This occurs when the complex dealkylates itself to form an irreversibly inhibited AChE enzyme ultimately leading to neurodegeneration in the axons [16].

### Mechanisms of Neurodegeneration by Rotenone

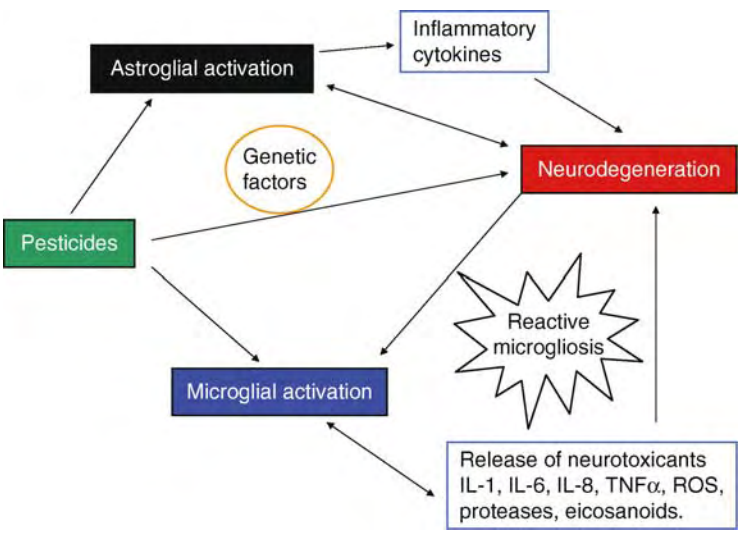
Rotenoids are another class of insecticide whose environmental exposure has been associated with increased neurodegeneration. The naturally occurring rotenone is a widely used rotenoid that inhibits complex I, the first enzyme of the mitochondrial respiratory chain. Complex I dysfunction is a feature of idiopathic PD and is linked to many other neurodegeneration disorders, such as that of retinal ganglion cells in ►Leber's optic neuropathy. Moreover, exposure to rotenone in rats has been shown to produce highly selective neural degeneration similar to that found in PD. In recent years, several studies have demonstrated that continuous exposure to rotenone in rats leads to degeneration of the nigrostriatal dopaminergic system accompanied by movement disorders. In addition, rotenone was shown to exhibit a markedly high toxicity by activating microglia, which releases superoxide free radicals and facilitates degeneration of dopaminergic neurons. Further studies using enzyme inhibitors suggest that rotenone-induced release of superoxide is mediated by microglial NADPH oxidase, a major superoxide generator in immune cells of the nervous system. In addition, rotenone and certain inflammogens have been reported to exert synergistic dopaminergic neurotoxicity [17].

### Association between Exposure to Paraquat and PD

Most herbicides are formulated to be toxic to plant biochemical systems that are absent in mammals. Human exposure to paraquat (PQ), a very commonly used weed killer, is known to cause lung fibrosis in addition to liver and kidney damage. Lately, studies on PQ have suggested that this herbicide may be an environmental factor contributing to PD. Paraquat was found to cause damage through generation of highly toxic superoxide anion. Although the biochemical mechanism is not yet fully understood, some evidence suggests that PQ-induced lipid peroxidation and resulting cell death of dopaminergic neurons may underlie the onset of the Parkinsonian syndrome or, to the least, influence the natural course of the disease [18].

## The Role of Inflammation in Modulating the Effect of Pesticides

The activation of microglia and astrocytes observed in patients with neurodegenerative disorders, mainly PD and AD, and in animal models suggest an involvement of neuroinflammation in the progression of these diseases. The observed synergism in neurotoxicity between pesticides and inflammogens, in addition to pesticide-pesticide interaction, may support



**Neuroinflammation: Modulating Pesticide-induced Neurodegeneration. Figure 1** Proposed mechanism of pesticides-induced neurodegeneration and deleterious glial modulation. Exposure to pesticides induces astrocytes and microglia activation while directly causing neuronal injury. Activated glia produce a wide array of pro-inflammatory factors and neurotoxicants, mainly cytokines, Interleukins, reactive oxygen species, proteases, and eicosanoids, which aggravate neuronal damage. This in turn will lead to further microglia activation. A self-propelling cycle is formed: microglial activation cause neurodegeneration while neuronal injury due to direct interaction with pesticides leads to additional glial activation; this further exacerbates neurodegeneration. Abbreviations: *IL*, interleukins; *TNF-α*, tumor necrosis factor-alpha; *ROS*, reactive oxygen species.

a multifactorial hypothesis underlying observed neurodegeneration. Experimental evidence showing that inhibition of inflammation correlates with attenuated neuronal damage supports such notion.

Following exposure to pesticides, microglia and astroglia are activated, thus releasing a wide range of neurotoxic endogenous factors, such as superoxide and cytokines. These factors bind directly to their receptors on the targeted neurons to activate an apoptotic pathway. In addition, cytokines lead to release of NO through the induction of NO synthase and Cox-2 within glial cells. Nitric oxide may react with superoxide to form a more potent intermediate: peroxynitrite ($ONOO^-$). Peroxynitrite can cross the cell membrane and cause neuronal injury. In addition, superoxide may convert to hydrogen peroxide ($H_2O_2$), thus adding to neuronal toxicity directly or by amplifying other neurotoxic factors in microglia [19]. Overall, activated glial cells produce a variety of pro-inflammatory and neurotoxic factors that aggravate neuronal damage. At the same time, direct interaction of pesticides with nerve cells causes neuronal injury. Damaged neurons stimulate an inflammatory response including reactive microgliosis and astrogliosis. These, in turn, will cause further neuronal damage. In fact, regardless of the origin of triggering factors, a vicious cycle is created. Pesticide-induced neuronal damage and neuroinflammation amplify each other in the form of a self-propelling vicious cycle (Fig. 1). Microglial activation leads to neurotoxicity while neuronal injury due to interaction with pesticides leads to additional glial activation; this further exacerbates neurotoxicity leading ultimately to neurodegeneration [20]. The progress of such cycle over a long period of time, especially in cases of chronic or occupational exposure to pesticides, in addition to potential genetically predisposing factors such as drug-metabolizing enzymatic pathway alterations, may lead to synergistic neurodegeneration and the development of symptomatic PD and AD [21].

Much remains to be investigated about the role of pesticides in neurodegeneration, and the potential role of microglial cells in the development of neurodegenerative diseases, mainly PD and AD. However, one thing is certain, the brain's immune system is deeply involved in both diseases, and further studies on neuroinflammation seems promising in contributing significantly to the discovery of new treatments.

# Neurology

William J. Spain
Department of Neurology, University of Washington, Veterans Affairs Puget Sound Health Care System, Seattle, WA, USA

## Introduction

Neurology is the main clinical branch of neuroscience. It is a medical discipline practiced by health care professionals. Neurology focuses on the diagnosis and treatment (excluding surgery) of people with afflictions of the central and peripheral nervous system and the skeletal muscles. As more is learned about the biological bases of disorders of thought and behavior, the boundaries between the practice of neurology and psychiatry are becoming less distinct. Medical doctors who practice neurology are called neurologists. To become a neurologist one must first complete a medical degree, followed by a general medical internship. Subsequent resident training normally entails at least 3 years of additional supervised training in providing care for people with neurological disorders. In most countries, there is a governing body that certifies a person as qualified to practice Neurology (boarding). This boarding organization typically sets the training requirements, administers an initial set of exams and periodic recertification exams to insure that those who have gone through the prescribed training have successfully incorporated a broad knowledge base of the elements of neurology and that they are capable of applying that knowledge base to the care of individuals with neurological diseases.

## A Brief History of Neurology

The history of neurology is ancient and colorful [1]. A few key milestones are listed here. The earliest known written reference to injury and treatment of the nervous system is contained in the Egyptian Edwin Smith Papyrus that was written around 1700 B.C. It is believed by some to be a copy of work done about a 1000 years earlier by Imhotep, the founder of Egyptian medicine. In ~400 B.C. Hippocrates wrote a treatise entitled *On The Sacred Disease* in which he debunked the idea that epilepsy is a spiritual affliction. He recognized that seizures come from abnormal functioning of the brain. About 200 years later Galen, another Greek physician, documented one of the earliest lesion studies to determine neurologic function. He noted that when the recurrent laryngeal nerve is cut, the "voice of the animal is damaged and its resonance is lost." However, it took about 2000 more years for Neurology to become a well defined and distinct medical discipline. The term neurology was coined by Thomas Willis in his 1664 book on the anatomy of the brain and nerves, *Cerebri anatomi*. This document laid the framework for modern neuroanatomic and neurophysiologic investigations. Neurology became a formal clinical discipline in the 1800's led by the writings and teachings of Jean-Martin Charcot in France, John Hughlings Jackson in England and Silas Weir Mitchell in America. Their observations and methods of clinical evaluation of malfunction of the nervous system formed the basis for the current practice of neurology.

## How Neurology is Practiced

A neurologist begins the process of diagnosis by first *talking* to a person who has experienced some set of symptoms, thus obtaining their medical history. The history is obtained in a question and answer format starting with general, open ended questions designed to screen a wide variety of potential problems, followed by more specific questions customized to a person's specific complaints. To paraphrase the great American neurologist H. Houston Merritt of The Neurologic Institute of New York, "the medical history when applied diligently is the most important and revealing tool a doctor has. In the vast majority of cases, a detailed history obtained by a knowledgeable neurologist will usually provide a good idea about the etiology of a person's symptoms. The physical exam and laboratory tests are for the most part confirmatory."

Armed with the information obtained from the history, the neurologist can then form a set of testable hypotheses as to the etiology of the person's complaints. With such a framework, the neurologist makes a set of predictions as to what will be observed on the physical exam and on further laboratory testing. During the physical exam, the neurologist first observes the body structure for asymmetries and abnormalities. Next is a systematic check of mental function, speech, sensory perception and motor functioning obtained by having the patient perform a standard set of simple behaviors or tasks. Because the nervous system is organized through interconnecting circuits, the neurologist (like an electronics repairman) can draw on their detailed knowledge of the nervous system's organization to localize and identify the abnormal structures, cell types and molecules. The logic of diagnosis relies on recognizing common denominators that cause the patients constellation of signs and symptoms from which the neurologist makes a list of the most probable etiologies. This list is called the differential diagnosis.

Sometimes, laboratory testing is needed to narrow the list or confirm the suspected diagnosis. Because there are literally hundreds of tests to choose from, it is essential that the neurologist have a well formed and justified hypotheses in order to keep the workup focused and thereby avoid a lengthy and expensive fishing expedition. The spectrum of tests routinely available include: examining the blood and cerebral spinal fluid for chemical abnormalities, infection and acquired or inherited molecular changes, tissue biopsy for histological

examination of cells and molecules, imaging of the internal structures using x-rays, nuclear magnetic resonance signals and scanning techniques for tracer uptake, and physiological testing which can measure electrical activity and the dynamics of metabolism or blood flow in the central nervous system. The results of such testing usually either confirm or confute the initial hypotheses. Throughout the evaluation of the patient, the neurologist draws on prior experience and knowledge of the published experience of others (both anecdotal and results of controlled studies) in order to weigh the historical information, physical findings and results of testing to determine the most probable cause of the disease. Finally, the neurologist chooses the best available course of treatment.

## Treatment of Neurological Disease

In the mid 1900s, neurology was primarily a discipline of diagnosis. Knowledge of the chemical and molecular basis of neurologic disease was so limited that only a few effective pharmacologic agents were available for treatment. As a consequence, neurologists were frequently the butt of jokes and sarcasm amongst other physicians; that all they were good for was informing their patients what was wrong with them and what type of suffering and deterioration to expect over what remained of their waning existence. Fortunately, the vast advances in basic and applied neuroscience research in the past 20 years have resulted in numerous effective remedies for diseases of the nervous system. There is, of course, still a long ways to go, as there are no effective means for altering the course of Alzheimer's disease, amyotrophic lateral sclerosis, glioblastoma multiforme and other debilitating diseases of the nervous system.

The treatment of neurological disorders falls into two broad categories; curing the underlying disease and alleviating the symptoms that result in suffering and loss of function. Choosing the best course of treatment is a mixture of applied science, empathy and common sense. The scientific component of treatment is based on the results of controlled studies of the various treatment options in specific situations. The empathy and common sense components of providing care to individuals are sometimes referred to as "the art of medicine." In addition, there is another important aspect to treatment of neurological diseases, namely prevention. Regrettably, patients rarely contact neurologists until they are ill, so that preventative treatment is only a small part of what the typical neurologist does in practice (except for the small number of neurologists involved in public health and education).

## Development of Knowledge in Neurology

Until recently much of the knowledge encompassed by the discipline of neurology was derived from the observation of human beings (i.e., uncontrolled experience and "chance experiments of nature"). As such, the descriptions of neurological diseases are often phenomenological. This stands in marked contrast to the basic neurosciences that are founded in the scientific method of asking questions and then drawing conclusions from the results of controlled, hypothesis driven experimentation. Although neurology and basic neuroscience have these fundamental differences, many of the questions asked by basic neuroscientists are motivated by observations that were initially made by neurologists. Further, the comparison of how things work during disease versus during times of health forms a powerful foundation for forming hypothesis. For example, the observation of overactive deep tendon reflexes in patients with motor weakness due to stroke compared to the underactive reflexes in people with weakness due to polio has led to numerous studies of the mechanisms underlying the coupling of somatosensory input to motor output. Similarly, posing the question "why do people who suffer from Alzheimer's disease have problems remembering things?" has motivated many basic studies that have provided insight into how animals learn and remember things. Progress in our understanding of how the brain works has been driven by the combination of innate curiosity and pragmatics.

Classically, the development of knowledge about the normal and abnormal workings of the nervous system followed a method of careful observation of people with neurologic illness for correlative symptoms. These methods are still in practice and complement the modern revolution in laboratory based methods of obtaining knowledge. First, people with similar constellations of signs and symptoms are grouped into syndromes or categories of disease. Then correlations with these abnormal phenotypes are looked for in two main arenas. One involves careful pathological examination of the structures of the nervous system at a gross, cellular and (now with modern techniques) at a molecular level. If differences are found between diseased and normal individuals, they can be correlated with the syndromic grouping and thus, serve to define structures and molecules that are essential to a particular function. So for example, the observation that a lesion in the cerebellum leads to problems with the coordination of motor activity provided insight into the function of the cerebellum. This method of correlation has been advanced by non-invasive methods for high resolution imaging of structures in living patients. The quality of imaging has advanced such that it can provide information formally obtained only from pathological specimens after death (e.g., like Hypocrites did more then 2000 years ago when he correlated the occurrence of epilepsy in individuals with injury to the brain).

Another method of gaining insight from correlation is to find common patterns of behavior and culture within a syndromic grouping (i.e., epidemiology). A notable example of this type of analysis [2] concerned

a recent incident when more than one hundred people on Prince Edward Island in Canada became similarly ill with headaches followed by confusion, loss of memory, disorientation, and (in some cases) seizures, coma and death. Their common experience was the recent consumption of cultured blue mussels. This "clue" led to some laboratory-based detective work that identified the accumulation of demoic acid in the mussels as the cause of the illness. Further experimentation revealed that demoic acid is a powerful excitotoxin that activates glutamate receptors. The hippocampus is particularly susceptible to the actions of demoic acid thus explaining the loss of memory and the seizures. (Interestingly, this syndrome which is now known as "amnesic shellfish poisoning" is thought to have caused the 1961 attack of the seaside town of Capitola, California by hundreds of crazed birds – the incident that inspired Alfred Hitchcock's movie *The Birds*.)

Occasionally, a single dramatic case unlocks a mystery of how the nervous system works. Perhaps the most famous is the oft cited case of Phineas P. Gage [3]. In 1848 Gage, while doing railroad work, was the victim of a mishap in which a tamping iron passed through his skull, and the frontal lobes of his brain. This injury changed his personality so much so that his friends said he was "no longer Gage." The scientific reporting of Gage's behavioral changes and associated pathology led to changes in perception about the function of the frontal lobes, particularly with regards to their role in emotion and personality. Before Gage's accident, most scientists thought the frontal lobes had little or no role in behavior. A limitation of the knowledge that comes from such chance "experiments" is that interpretation is confounded by the lack of controls performed in parallel. The case of Phineas Gage was partially responsible for simplistic reasoning behind frontal lobotomies as a cure for unwanted behavior. Lobotomy as a medical treatment has been abandoned, but not before it resulted in many undesirable and irreversible outcomes. Fortunately, neurology has moved beyond the insights it gained as a primarily observational scientific discipline. Now there is a large academic branch of experimental neurology that uses animal-based models of disease and modern methods of analysis of population data.

# Neuroma

## Definition

Tumor in the nervous system. Here referred to the tumor-like structure formed at the end of an injured peripheral nerve, in which some or all of its axons are unable to regenerate to the target tissue. Many lesions formerly called neuromas are now given more specific names such as ganglioneuroma, neurilemmoma, or neurofibroma.

►Neuronal Changes in Axonal Degeneration and ►Regeneration

# Neuromalacia

## Neuromelanin

### Definition

Neuromelanin is a brown-black intracellular polymeric pigment derived from dopamine or norepinephrine found within catecholaminergic neurons.

►Melanin and Neuromelanin in the Nervous System

## Neuromelanosome

### Definition

Neuromelanosome denotes an aggregate of brownblack intracellular pigment granules of varying sizes (0.5–2.5 μm) associated with tightly bound protein and lipid components found within some dopaminergic and noradrenergic neurons.

►Melanin and Neuromelanin in the Nervous System

## Neuromere

### Definition

Segmental unit of the developing brain. In vertebrates, constrictions seen along the neuraxis. Neuromeres in the hindbrain region are called rhombomeres and have been shown to be lineage restriction units. In insects neuromeres of the thorax and abdomen are largely stereotypical and correspond to the body segments.

Neuromeres of the head are more complex structured.

## Neuromimes

### Definition

Electronic circuits or instruments that mimic the action of neurons or brains.

## Neuromodulation

### Definition

Actions that change the baseline intrinsic properties of neurons and synapses. Neuromodulators alter the firing properties of neurons (for example, from silent to bursting) and change the strength of synapses. They often act through second-messenger mechanisms such as protein phosphorylation.

## Neuromodulation in the Main Olfactory Bulb

Nathalie Mandairon, Anne Didier
Neurosciences Sensorielles, Comportement, Cognition, Université de Lyon, Université Claude Bernard Lyon1, Villeurbanne, France

### Synonyms

Centrifugal or feed-back connections to the main olfactory bulb

### Definition

Centrifugal connections to the main olfactory bulb refer to the fiber systems originating from central structures, projecting to main olfactory bulb and contributing to olfactory processing.

## Characteristics

### Noradrenaline

#### Anatomical Organization

The mammalian main olfactory bulb (MOB) receives a significant noradrenergic input from the ►locus cœruleus. In fact, studies in rat show that approximately 40% of locus cœruleus neurons project to MOB. Noradrenergic fibers are localized in the subglomerular layers where they terminate densely in the internal plexiform and the granule cell layers, and moderately in the external plexiform and mitral cell layers. There are three known classes of noradrenergic receptors: α1, α2 and β. α1 receptors are particularly dense in the external plexiform layer, and moderate in mitral cell layer and granular cell layer. Cellular localization studies demonstrate that mitral/tufted and granule cells express α1, α2 and β receptors.

#### Cellular Effects

Dendrodendritic reciprocal synapses between mitral and granule cells in the MOB have been recognized as a critical locus where noradrenaline influences the processing of olfactory information.

In the turtle or rat dissociated MOB cultures, noradrenaline disinhibited mitral cells. This effect was attributed to α2 receptor-mediated presynaptic inhibition of granule cell dendrites. Moreover, it has been shown a direct excitatory action on mitral cells by iontophoretic application of noradrenaline in the MOB or by activation of α1 adrenergic receptors in rat [1]. However, field potential studies suggested that noradrenaline, acting at α1 receptors, depolarized granule cells, an effect that would inhibit mitral cells. Finally, in the rat, locus cœruleus activation decreases spontaneous mitral cell discharge but enhances the responses to weak olfactory input.

Locus cœruleus stimulation was also reported to initially decrease and then increase paired-pulse depression of mitral cell-evoked field potentials in the granule cell layer via activation of β receptors in the MOB [2]. It was concluded that noradrenaline release initially decreases then increases mitral cell glutamate release onto granule cells. It should be noted however, that other studies have reported that β receptor agonists have no effect on mitral cells or mitral-to-granule cell transmission. Noradrenaline may thus support opposing actions on the output neurons depending on the type or subtype of activated receptors.

#### Functional Implications

It now well established that the action of the noradrenaline on the MOB is critical for different kinds of olfactory learning. Olfactory cues trigger rapid increases in noradrenaline levels in the olfactory bulb. Noradrenaline release in the main and accessory OB is critical for the formation and/or recall of specific olfactory memories, pheromonal regulation of pregnancy, postpartum maternal behavior and rapid learning of conditioned odor preferences thought β receptor activation in early postnatal rodents [3]. In addition, noradrenaline levels are increased by sensory deprivation, possibly in order to increase the sensitivity of the mitral cells, in line with their increased response to weak stimuli reported under locus cœruleus stimulation (see above).

### Acetylcholine

#### Anatomical Organization

The cholinergic innervation of the MOB is exclusively extrinsic and originates in the horizontal limb of the ►diagonal band of Broca (Ch3) as demonstrated by the absence of choline acetyl transferase (ChAT)-positive cells revealed by immunohistochemistry or *in situ* hybridization. Using either of these markers or localization of binding to high-affinity uptake sites, cholinergic fibers are found throughout the different layers of the MOB but with great laminar variations: the highest density is found in the glomerular layer and the lowest in the subventricular layer. The cholinergic innervation develops during the first three postnatal weeks in rodents. It is present at birth first in a subset of posterior and medio-dorsal glomeruli, the so called atypical glomeruli, which remain particularly rich in cholinergic fibers in adult and whose function remains unknown [4]. Cholinergic fibers synaptically target dendrites of periglomerular and granular bulbar interneurones. No cholinergic synapses could be identified on mitral cells but rather cholinergic varicosities in close apposition to secondary mitral cell dendrites in the external plexiform layer.

Both nicotinic (ionotropic) and muscarinic (G protein-coupled) receptors are present in the MOB. Nicotinic receptors are pentameres of various subunits (α2–10; β2–4) whose combinations form cationic channels with distinct functional properties. High affinity heteromeric receptors, among which the abundant α4β2 combination, and low affinity α7 homomeric receptors are retrieved in the MOB and show a specific laminar distribution. Quantitative autoradiography indicates that heteromeric receptors are found at high levels in the granular cell layer. In contrast, α7 receptors are concentrated in the glomerular layer and to a lesser amount in the deeper layers of the MOB. Less is known about the cell types expressing the different nicotinic receptors. α2 subunit is expressed by a small group of neurons in the internal plexiform layer and additional rare neurons of the glomerular and external plexiform layers. The β2 subunit strongly labels mitral cells and cells located in the superficial part of the external plexiform layer.

Five subtypes of muscarinic receptors (M1–5) have been cloned in the brain that can be grouped in two

families based on their G-protein coupling mechanism and ligand's binding selectivity. The M1 family (M1, 3 and 5) is positively coupled to the activation of phospholipase C and receptors of the M2 family (M2, 4) are negatively coupled to adenylate cyclase and classically act as presynaptic auto- or heteroreceptors. In the MOB, M1-like and M2-like receptors are most abundant in the external plexiform layer compared to the deeper layers while their expression is low in the glomerular layer. Accordingly, M2 receptors have been localized by immunocytochemistry presynaptically on the dendrites of granule cells at synaptic loci in the external plexiform layer and post synaptically on soma of second order bulbar interneurons in the inframitral layers. In the glomerular layer, M2 receptors are expressed by a subset of GABAergic/dopaminergic periglomerular neurons.

### Cellular Effects

In line with the heterogeneous distributions of cholinergic fibers and receptors in the MOB, the cellular effect of Ach in the MOB proved to be complex [5]. Through nicotinic receptors, acethylcholine facilitates olfactory information transmission by directly exciting mitral cells in a paracrine manner. Nicotinic receptors activation also induces an increase in periglomerular cells activity which in turn inhibits mitral cells thus supporting an effect opposed to the direct action of Ach onto mitral cells. These two actions are likely mediated by heteromeric high affinity and low affinity α7 containing receptors respectively, in accordance with their laminar distribution (see above).

Through muscarinic receptors, acethylcholine also exerts two distinct actions on two compartments of granule cells. On the soma, it reduces their firing rate, thus producing a disinhibition of mitral cells. Pre-synaptically, through M1 receptors acethylcholine enhances GABA release by granule cells onto mitral cells, thus reinforcing inhibition of the output neurons. Through the several loci at which it influences the bulbar network, acethylcholine actions regulate both the entry and the output signals of the MOB, and is thus a key modulators of olfactory processing.

### Functional Implications

Given the well known implications of acethylcholine in memory processes in cortices, most of the studies on the role of acethylcholine in the MOB focused on odor memorization using pharmacological approaches. Systemic administration of scopolamine, a muscarinic antagonist impairs short term olfactory memory in rats and lamb recognition by parturient ewes without affecting olfactory detection.

In addition, a model of cholinergic modulation of the bulbar network suggested that cholinergic inputs may sharpen mitral cell receptive fields, allowing for better discrimination abilities [6]. This assumption was confirmed by the demonstration that intrabulbar administration of a nicotinic antagonist abolished spontaneous discrimination between perceptually close odorants and muscarinic receptors blockade impairs discrimination performances. In both cases, at the doses used in this study, a reward-associated discrimination task was left unaffected [7]. Taken together these data suggest that acethylcholine influences olfactory perception and memorization and thus interdependence between these two aspects of olfactory processing is likely.

## Serotonin

### Anatomical Organization

The olfactory bulb receives a dense serotonergic input from the ►raphe nuclei. In rats, serotonergic fibers display specific laminar and regional distributions in the MOB. The density of 5-HT fibers in the glomerular layer is 2–3 times greater than in any other layer in MOB. Some serotoninergic fibers were observed in the external plexiform layer, internal plexiform layer, mitral cell layer and granule cell layer. Several types of serotonin receptors are expressed in the MOB, including 5HT1A and 5HT1B and 5HT2C. 5HT2 receptors are mainly distributed in the glomerular, granular cell layers and in the mitral (M) cell layer. By contrast, 5HT1A and 5HT1B receptors are mainly present in the external plexiform and granular cell layers respectively.

### Cellular Effects

Serotonin inhibits a subset of mitral cells through an indirect mechanisms involving GABA release by granule or periglomerular cells, an effect that might be modulated by the vigilance states. In contrast, another subset of mitral cells is directly depolarized by serotonin acting at 5HT2A receptors. In addition, serotonin depolarizes some periglomerular cells through 5HT2C receptors [8].

### Functional Implications

In the MOB, 5HT has been demonstrated to be involved in olfactory learning. In the literature there is evidence that damage to the MOB or to his serotoninergic innervations may alter olfactory coding and/or memory. For instance, neonates with serotoninergic denervation of the MOB exhibit altered acquisition or expression of an olfaction-based learned behavior. Pharmacological studies indicated that 5HT2 receptors are more likely involved in promoting conditioned olfactory learning in neonatal rats although, it is not clear whether 5HT2A or 5HT2C subtypes are predominantly involved. 5HT2 receptors seem to be required in the acquisition stages but not in the consolidation and retrieval ones [9].

Rats with 5,7-dihydroxytryptamine (5,7-DHT) lesions of serotonergic fibers lose their ability to discriminate odors. It was also shown that damage to serotonergic afferents of the MOB does not induce complete anosmia and does not disrupt the basic mechanisms of olfactory recognition. 5HT depletion caused glomerular layer atrophy. Moreover, the 5HT innervation was hypothesized to act in collaboration with the noradrenergic (NA) innervation in olfactory learning, even if NA alone seems to be able to compensate for the deficit of 5HT in certain learning conditions.

### Orexin

Centrifugal orexin-containing fibers originating from the hypothalamic feeding centers (lateral and posterior hypothalamic areas and perifornical area) terminate in the glomerular and mitral cell layers. In addition, a few fibers are seen in the granular layer. Receptors to orexin (G-protein coupled receptors, ORX1–2) are localized to mitral cells principally and to subsets of periglomerular and granular cells. Oxerin indirectly hyperpolarize mitral cells through an increase in GABA release by granule cells while it seems to directly depolarize a small fraction of mitral cells [10]. Orexin infused in the brain stimulate food intake. In the MOB, it is proposed to participate in the regulation of olfactory perception by the feeding status but this remains to be assessed.

### Neuromodulators Interfere with Neurogenesis

Bulbar neurogenesis consists of the permanent renewal in the adult of the two populations of interneurons, periglomerular and granular cells. Nicotinic receptors activation increases the death rate of newborn granular neurons, while other studies have shown that Ach promote their survival, possibly then through muscarinic receptors. Chronic administration of a selective 5HT1A and 5HT2C receptor agonists induces an increase in the rate of neurogenesis. Similarly, stimulation of the noradrenergic system by an α2 antagonist promotes adult born cell survival. Neuromodulators are thus able to modulate olfactory processing not only by influencing the existing network but also by regulating the permanent maturation of the MOB circuits.

# Neuromodulation of Central Pattern Generators

►Neurotransmitters and Pattern Generation

# Neuromodulators

### Definition

A neuromodulator is a chemical compound released by particular neurons modulating the activity of targeted cells. In contrast to classical neurotransmitters, a neuromodulator is not reabsorbed by the presynaptic cell. Thus, it can diffuse more widely in the tissue and act on several neurons. Neuromodulators are typically amines or peptides that can phosphorylate ion channels, alter second messenger pathways and intracellular calcium. These modulatory effects change ion channel properties, which in turn lead to the alteration of neuronal discharge patterns.

They can enhance or decrease the activity of neurons or the efficiency of excitatory or inhibitory synapses

mediated by classical neurotransmitters as GABA or glutamate.

►Neuropeptides

## Neuromodulators in Nociception

### Definition

In the transmission from primary nociceptive afferents to central neurons, the combination of glutamate (transmitter) and calcitonin gene related peptide (CGRP) and Substance P (neuromodulators) are most important. Neuromodulators modify and enhance the synaptic transmission.

## Neuromorphic Device

### Definition

Electronic chip that emulates biological neural systems by means of analog and/or digital Very Large Scale of Integration (VLSI) technologies. Existing systems have been used to reproduce the functionality of biological sensors (such as silicon retinas and cochleas) and/or implement single neocortical processing modules (such as selective attention modules). Several single-chip neuromorphic systems have been developed, mainly focusing on the sensory periphery (e.g. silicon retinas, silicon cochleas, motion sensors, etc.). More recently, the development of general, standard communication infrastructures also enabled the creation of complex multi-chip systems.

►Computer-Neural Hybrids

## Neuromuscular

### Definition

Affecting or characteristic of both nerve and muscle.

## Neuromuscular Junction

Mark M. Rich
Department of Neuroscience, Cell Biology and Physiology, Wright State University, Dayton, OH, USA

### Synonyms

Endplate; NMJ

### Definition

The synapse between a lower motor neuron and a skeletal muscle fiber.

### Characteristics

Quantitative Description: The neuromuscular junction in mammals is, on average, 20–40 μm wide and 20–150 μm long.

Higher Level Structures: Neuron, muscle fibers.

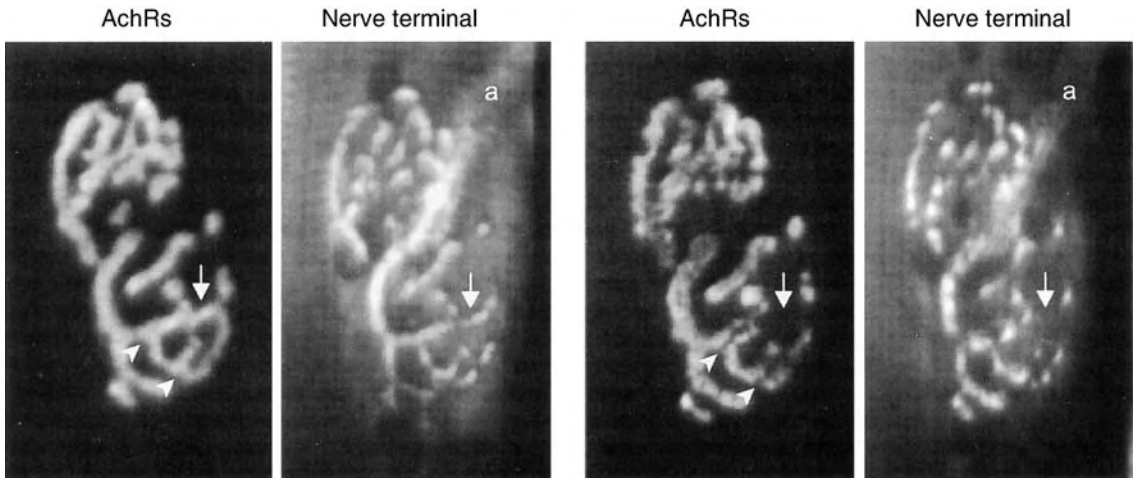
Lower Level Components: Synaptic vesicles, sodium channels, calcium channels, acetylcholine receptors, synaptic cleft.

Structural Regulation: The neuromuscular junction consists of a presynaptic motor nerve terminal that contacts the skeletal muscle at a single point along its length. Directly underneath the nerve terminal is a region of specialized postsynaptic muscle membrane in which there is a high concentration of acetylcholine receptors (Fig. 1).

Within the neuromuscular junction there are a number of specialized release sites known as active zones where synaptic vesicles fuse and release acetylcholine (the neurotransmitter at the neuromuscular junction). Between the pre- and postsynaptic cells is extracellular space in which there are a number of structural proteins. This extracellular collection of proteins is known as the basal lamina. The enzyme that breaks down acetylcholine (acetylcholinesterase) is located in the basal lamina and serves to terminate signaling between the pre- and postsynaptic cells.

During development, there is rearrangement of synaptic connections at the neuromuscular junction that is mediated by synaptic activity [2]. This rearrangement results in the mature structure in which only one presynaptic axon innervates each muscle fiber. In the adult, little further rearrangement occurs and the structure of the neuromuscular junction is thought to remain fairly stable. However, the capacity for rearrangement persists at the adult neuromuscular junction and such rearrangement may become important when synaptic function is disrupted in diseases of ►neuromuscular transmission (Fig. 1).

Higher Level Processes: Motor unit function, force generation.



**Neuromuscular Junction. Figure 1** Regions of acetylcholine receptors (AChRs) and nerve terminal staining are lost from the neuromuscular junction in autoimmune myasthenia gravis. Shown are images of the AChRs and nerve terminal from an individual mouse endplate before, and 1 week after an immune attack on the postsynaptic AChRs. Prior to immune attack (*on the left*) the structure of the endplate is normal. The postsynaptic AChRs are stained uniformly and precisely align with the nerve terminal. One week after exposure to antibody against AChRs (images of AChRs and nerve terminal on the *right*), regions of AChR staining present in the first view, have been eliminated (*arrows*). Nerve terminal overlying the eliminated regions of AChRs has retracted. In addition, regions of faint AChR staining are present throughout the endplate. Synaptic plasticity of the neuromuscular junction, such as that shown in this figure, may play an important role in various disease states that affect the neuromuscular junction. Each image is 40 μm wide. The presynaptic axon can be seen entering the endplate from the *upper left* in the image of the nerve terminal (a). From [1].

Lower Level Processes: Synaptic vesicle fusion, action potential propagation.

Process Regulation: Synaptic activity regulates function of the neuromuscular junction on both short and long timescales. There is regulation of synaptic function over a millisecond timescale in which the number of synaptic vesicles that fuse following a presynaptic action potential is modulated by previous activity. This category of synaptic plasticity is termed short-term synaptic plasticity and consists of depression, ►facilitation and ►post-tetanic potentiation [3]. In normal calcium there is thought to be a depletion of vesicles that are release-ready by previous pulses, such that fewer vesicles are released during subsequent presynaptic action potentials. This is termed ►synaptic depression and is used clinically to diagnose diseases of neuromuscular transmission such as myasthenia gravis [4]. When extracellular calcium is lowered (or calcium entry is lowered), an opposite response occurs to repetitive stimulation and more vesicles are released following each presynaptic action potential. This is known as facilitation and is a hallmark of diseases of neuromuscular transmission such as Lambert Eaton Myasthenic syndrome in which presynaptic calcium entry is decreased. The cause of facilitation is thought to be summing of the calcium signal from each pulse of the train. A third type of short-term plasticity is known as post-tetanic potentiation and can last for 10s of seconds after a train of pulses given at a high frequency. Post-tetanic potentiation is thought to be due to residual calcium following a train of stimuli.

There is also activity-dependent regulation of neuromuscular function that occurs over the time period of days to weeks. When neuromuscular activity is blocked for several days, nerve terminals at inactive junctions grow new processes that grow over the muscle and form new connections. This process is known as ►sprouting and serves to increase synaptic strength.

Function: The neuromuscular junction's function is to cause the postsynaptic muscle fiber to fire an action potential every time the presynaptic motor neuron spikes. This function differs from that of synapses in the central nervous system. In the central nervous system synapses integrate signals to process information. At the neuromuscular junction there is no information processing. The only time that abnormalities of neuromuscular transmission cause problems is when they become severe enough to cause the muscle fiber to no longer faithfully follow trains of action potentials fired by the presynaptic terminal.

The series of events necessary for neuromuscular transmission occur as follows. An action potential enters the presynaptic nerve terminal. During the action potential there is opening of presynaptic calcium channels, which allows calcium entry. Calcium binds

to a calcium sensor (thought to be synaptotagmin) and this leads to fusion of the membrane of synaptic vesicles to the nerve terminal. The precise series of molecular events that underlie vesicle fusion is currently an area of intensive study. The total number of synaptic vesicles that fuse during a presynaptic action potential at mammalian neuromuscular junctions varies between species and ranges from 20 to 100. Following fusion of synaptic vesicle there is release of acetylcholine which diffuses across the synaptic cleft and binds to acetylcholine receptors, causing them to open. Opening of acetylcholine receptors allows for flow of sodium and potassium ions, with the net result being depolarization of the postsynaptic muscle membrane. This depolarization opens muscle sodium channels and triggers a muscle action potential. The total amount of time for this cascade of events is 1 ms.

Pathology: The three diseases most commonly responsible for failure of neuromuscular transmission are myasthenia gravis, botulism, and Lambert-Eaton myasthenic syndrome (LEMS). These diseases present with weakness in the absence of sensory symptoms. Prominent symptoms often include difficulty swallowing as well as double vision. One of the primary diagnostic tests is repetitive nerve stimulation which reveals failure of neuromuscular transmission.

Weakness in myasthenia gravis is most often caused by an autoimmune attack directed at postsynaptic acetylcholine receptors. The result of the attack is that postsynaptic acetylcholine receptor density is reduced (Fig. 1). Thus, when a synaptic vesicle releases acetylcholine, there are fewer acetylcholine receptors available to respond and a smaller postsynaptic current is generated. This reduces the postsynaptic depolarization following a presynaptic action potential. If the postsynaptic depolarization is still large enough, the muscle fiber fires an action potential and there is no weakness. However, during trains of action potentials there is synaptic depression (see above). Depression of acetylcholine release during trains (a normal phenomenon) cause the postsynaptic depolarization caused by opening of acetylcholine receptors to become insufficient to trigger a muscle fiber action potential. Failure to activate muscle fibers causes weakness and a decrement on EMG that is diagnostic of a failure of neuromuscular transmission [4].

In botulism, failure of neuromuscular transmission is caused by cleavage of synaptic proteins that are critical for fusion of synaptic vesicles [5]. The synaptic protein cleaved in botulism depends on the subtype of botulinum toxin. Botulinum A and E cleave SNAP-25, botulinum B and D cleave synaptobrevin (also known as VAMP), and botulinum C cleaves syntaxin. Cleavage of these proteins greatly reduces the number of vesicles that fuse during a presynaptic action potential. This results in reduced release of acetylcholine and failure of neuromuscular transmission.

LEMS is caused by an autoimmune attack on presynaptic calcium channels that reduces calcium entry into the presynaptic terminal. Reduced calcium entry causes a reduction in the number of vesicles that fuse and thus reduces acetylcholine release. During repetitive stimulation of the neuromuscular junction in LEMS, there is dramatic facilitation of the EMG signal due to facilitation of release of synaptic vesicles [4].

Although the three diseases described above are thought to be the primary diseases in which there is failure of neuromuscular transmission, evidence has begun to emerge that neuromuscular dysfunction may be an important contributor to weakness in motor neuron disease as well. The most common form of motor neuron disease is amyotrophic lateral sclerosis (ALS). It has been thought that motor neuron cell death is the sole cause of weakness in ALS. In large part, this is due to the relative ease with which motor neuron cell death can be demonstrated with routine histological examination of autopsy material. Human autopsy results, however, are dominated by disease end stage phenomena, and while there is no doubt that cell death explains the permanent loss of motor units and paralysis of ALS, it remains uncertain whether cell death fully accounts for weakness in earlier stages of the disorder.

Evidence that dysfunction at the neuromuscular junction causes weakness in advance of cell death comes from studies of animal models of motor neuron disease. In both mouse and canine models of motor neuron disease, there is emerging evidence suggesting that loss of neuromuscular innervation (denervation) occurs before motor neuron cell death has begun. In the canine animal model there is further evidence that physiological dysfunction occurs at an even earlier stage of the disease, when no denervation is apparent histologically [6]. The cause of the failure of neuromuscular transmission is a reduction in the number of vesicles that fuse following a presynaptic action potential. If the sequence of events is similar in human motor neuron disease this would suggest that weakness in patients is initially caused by failure of neuromuscular transmission in the absence of a clear structural abnormality. This is then followed by degeneration of the presynaptic terminal, and only at very late stages, when a motor unit is generating almost no force, is there death of the motor neuron. Such a sequence of events would have important treatment implications, since it would mean that treatments aimed at slowing the progression of neuromuscular dysfunction may be important in helping patients with ALS.

Therapy: There are two categories of treatments for diseases of neuromuscular transmission. The first

is symptomatic treatment that is aimed at improving neuromuscular transmission and the second is aimed at the underlying disease process. The drug most commonly used to improve neuromuscular transmission is an inhibitor of acetylcholinesterase (usually pyridostigmine). By slowing breakdown of acetylcholine in the synaptic cleft pyridostigmine increases the amplitude and prolongs the time-course of the postsynaptic current. The increase in postsynaptic current allows increased depolarization of the muscle fiber, and thus allows more muscle fibers to reach threshold for action potential initiation. Block of acetylcholinesterase is most appealing on a theoretical basis for disorders such as botulism and LEMS where the underlying problem is a reduction in release of acetylcholine; however, pyridostigmine is most commonly used in treating myasthenia gravis. Another drug, 3,4 diaminopyridine, is used to treat LEMS. This agent inhibits presynaptic potassium channels, and thus prolongs the action potential to allow for increased calcium entry. Treatment for botulism is primarily supportive.

In both myasthenia gravis and LEMS the underlying problem is an autoimmune attack on the neuromuscular junction. Thus, in both of these disorders reversing the underlying disease process by reducing the immune attack on the endplate is the most important part of treatment. LEMS is often a paraneoplastic syndrome in which the antibodies to the neoplasm cross-react with the neuromuscular junction. In these cases, treatment of the neoplasm often results in improvement. Corticosteroid treatment, azathioprine, plasmaphoresis and treatment with intravenous immunoglobulin are all methods of immunosuppression used to treat myasthenia gravis and LEMS. In addition, in myasthenia gravis, thymectomy is often performed to treat more severe cases. For further details on treating these disorders see [7,8].

## Definition

NMO belongs to the group of ►idiopathic inflammatory demyelinating diseases of the central nervous system and has been distinguished from ►multiple sclerosis (MS) by the presence of (usually bilateral, simultaneous, and often severe) ►optic neuritis, spinal cord abnormalities (extending contiguously over three or more vertebral segments), absence of brain abnormalities, and often rapid progression to debility and even death. Pathologically, an antibody-dependent, complement-mediated process is thought to underlie the axonal loss, demyelination and necrosis. A specific serum biomarker, neuromyelitis optica immunoglobulin G (NMO-IgG), which distinguishes neuromyelitis optica from ►multiple sclerosis, targets the blood brain barrier and the water channel aquaporin-4, which is lost in

neuromyelitis optica lesions and classifies NMO as an autoimmune ►channelopathy. NMO-IgG is the first specific marker for a central nervous system demyelinating disease. Corticosteroids are used to treat acute attacks and immunosuppressants are the treatment of choice.

►Multiple Sclerosis

## Neuromyopathy

### Definition

Any disease of both muscles and nerves, especially a muscular disease of nervous origin.

## Neuron

### Definition

A late nineteenth century Greek term, refers to highly specialized "nerve cells". A neuron exhibits a highly complex repertoire of specialized membranous structures, embedded ion channels, second messengers, genetic and epigenetic elements and unique complements of various proteins such as the receptors.

Neurons are excitable cells (i.e., able to conduct electrical impulses of action potentials), which form elaborate networks through axons and dendrites. This ensemble is responsible for integrating, processing and transmitting information, and forms the basis for e.g., coordinated muscle movements and brain functions, including learning and memory formation.

## Neuron–Astrocyte Interactions

Yoshihisa Kudo
School of Life Science, Tokyo University of Pharmacy and Life Science, Tokyo, Japan

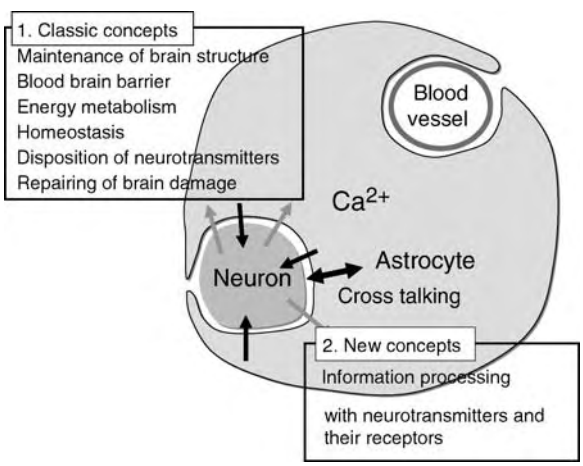
### Synonyms

Tripartite synapse

### Definition

Classically the roles of astrocytes in neuron–astrocyte interaction in the central nervous system (CNS) have been as passive and supportive elements, which remove the released neurotransmitters by specific transporters (such as GLT-1, a glutamate transporter), maintain the ionic environment in the ►extracellular space via ion channels and transporters ($K^+$ channels, $Na^+/K^+$ exchanger, etc.), supply the energy source through blood vessels to neurons and limit the passage of some toxic substances as a ►blood brain barrier, all optimizing the conditions for neurons and synapses in the CNS (Fig. 1).

However, since the expression of neurotransmitter receptors on astrocytes has been revealed by the dynamic responses in intracellular $Ca^{2+}$ concentration ($[Ca^{2+}]i$) to neurotransmitters, the possibility of cross-talking between neurons and astrocytes has been emphasized as a much more important interaction between those cells. The possibility became much more probable after the discovery of the ability of astrocytes to release neurotransmitters, such as glutamate and ATP. The finding of dynamic interaction between neurons and astrocytes urged the renewal of the concept of astrocytes as possible elements participating in the information processing mechanisms in the brain. Now neuron–astrocyte interaction has been accepted as one of the important systems for establishing higher order brain functions, which had been investigated based



**Neuron–Astrocyte Interactions. Figure 1** Classic concepts and new concepts of neuron–astrocyte interaction. According to classic concepts astrocytes are recognized as passive and supporting elements in the brain. Since the discovery of neurotransmitter receptors on astrocytes and the release of transmitters from them, new concepts of neuron–astrocyte interaction as information processing elements have been established.

upon a "neuroncentric" concept until the end of the twentieth century [1,2] (Fig. 1).

## Characteristics

### Quantitative Description

Astrocytes were named after their stellate shape observed under the light microscope after staining with silver. The cytoskeleton stained by such methods was only 15% of the total volume of the cell. The astrocytes located in the gray matter, called ►protoplasmic astrocytes, have profuse processes that give the cells an appearance that has been referred as to "spongiform." The average volume of a single astrocyte has been calculated to be about 66,000 $\mu m^3$. Together with a study that showed that there are about 213 synapses/100 $\mu m^3$ in the adult rat hippocampal CA1 subfield, it is estimated that a single astrocyte would be in contact with about 140,000 synapses. A recent 3D high voltage electron microscopic study on protoplasmic astrocytes in the hippocampal CA3 subfield demonstrated the average surface volume ratio as 26.2/μm and taking this value into account, the surface area of a single astrocyte would be about 2,000,000 $\mu m^2$. Since the density of astrocytes in the cerebral cortex is high (12,000–30,000/$mm^3$) and the number of astrocytes in the mammalian brain is estimated to be 1.3–1.4 times larger than the number of neuronal cells, the surface of neuronal cells would be almost completely covered with astrocytes [2].

The percentage of the coverage of astrocyte processes on a single synapse has been estimated by 3D reconstruction studies on electron microscopic images. According to these studies, percentages of all synapses associated with astrocytes have been estimated as 57% in hippocampus, 29% in visual cortex, 69% of parallel fiber–Purkinje cell synapses in the cerebellum and 94% of ascending fiber–Purkinje cell synapses [3]. However, these values may be low estimates because of the difficulty of reproducing the real shape of astrocytes in the preparation for electron microscopy.

### Description of the Structure/Process/Conditions

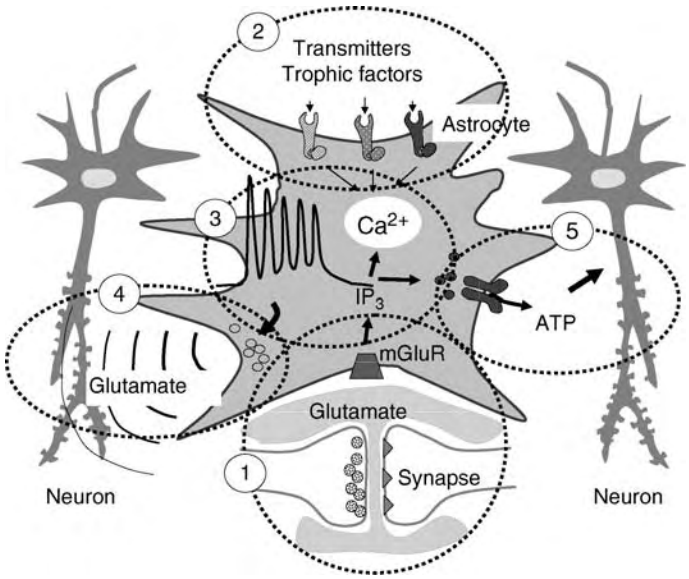
As mentioned above, the fine processes of a single astrocyte envelop numerous synapses in the brain. This structural association strongly suggests possible interaction between neurons and astrocytes, not only in structural and metabolic support but also in information processing. To establish the information processing between them, astrocytes should express some receptors for detecting the molecules released from neighboring neurons and should also release some factors to talk back to neuronal cells. Neurotransmitter receptor expression and dynamic responses were found as early as 1986, in C6Bu1, a clonal astrocyte in culture. The clonal astrocytes responded to serotonin by an increase in intracellular $Ca^{2+}$ concentration ($[Ca^{2+}]i$), which was measured by a specific $Ca^{2+}$ indicator, fura-2. Since then increases in $[Ca^{2+}]i$ induced by glutamate, GABA, noradrenalin, ATP and acetylcholine have been demonstrated in astrocytes isolated from hippocampus and other brain regions in culture [4]. The majority of receptors expressed on the astrocytes that cause an increase in $[Ca^{2+}]i$ have been classified as Gq-type G-protein coupled receptors, which will cause $IP_3$ production and thus stimulate the $IP_3$ receptors on endoplasmic reticulum to release stored $Ca^{2+}$ into the cytosol. However, the Bergman glia cells in the cerebellum express $Ca^{2+}$ -permeable alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptors assembled without the GluR2 subunit [5]. When the increase in $[Ca^{2+}]i$ induced by neurotransmitters was found in astrocytes, researchers expected the role of the $[Ca^{2+}]i$ to be as an activator for transmitter release from the cells. Activation of astrocytes sometimes induces the release of ATP, but the response is not always $Ca^{2+}$ dependent. Although $Ca^{2+}$ dependent release has been found in astrocytes, the processes are shown to be distinct from exocytosis in neuronal terminals. Recently ►gap junction hemichannels have emerged as an additional molecular pathway for transmitter release from astrocytes [6]. The hemichannel of the gap junction has been shown to be activated by lowering the concentration of extracellular divalent cation. The other important pathway is P2X7, a purinergic receptor, which seems to be modulated by intracellular divalent cations (Fig. 2).

Using such multiple machineries, astrocytes can release glutamate, ATP, ►D-serine and some other substances. These substances can send information to neurons by the activation of receptors expressed on their pre- and post-synaptic sites. The structure consisting of astrocyte and pre- and post-synaptic neurons has been emphasized by the coining of the term "►tripartite synapse" [7] (Fig. 3).

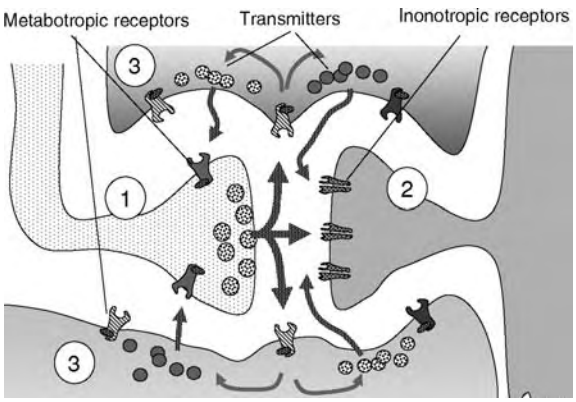
### High Level Structure/Process/Conditions (Fig. 4)

#### *Astrocyte–Astrocyte Intercommunication*

As mentioned above a single protoplasmic astrocyte in gray matter has profuse processes referred to as spongiform, which will make contact at its boundaries with other astrocytes. The processes of adjacent astrocytes do not project into neighboring domains. Thus each astrocyte seems to occupy a separate anatomic domain. Each astrocyte domain makes connections with others using specific gap junction proteins called connexins, which can mediate the passage of current and of rather large molecules (up to 1,000 molecular weight) between astrocytes. This structural feature stabilizes and equalizes membrane potential among groups of astrocytes and ensures common levels of ions and presumably other molecules as well.



**Neuron–Astrocyte Interactions. Figure 2** Neuron–astrocyte interactions. (a) Diffusion of neurotransmitter in extracellular space (spill over). Before disposal of the released neurotransmitters by specific transporters, they diffuse into the extracellular space and activate neurotransmitters expressed on the astrocytes. (b) Expression of many kinds of receptors. Astrocytes have been demonstrated to express receptors for neurotransmitters, such as glutamate, noradrenalin, serotonin, GABA and acetylcholine and also for trophic factors. Activation of these receptors induces the increase in $[Ca^{2+}]i$. (c) Characteristic $Ca^{2+}$ increase. The activation of astrocytes through receptors results in an oscillatory increase in $[Ca^{2+}]i$. (d) Neurotransmitter release. Activation of astrocytes sometimes causes release of neurotransmitters, such as glutamate and ATP. Released glutamate will activate neuronal cells. (e) Inhibitory regulation by ATP released from astrocytes has been demonstrated to depress neuronal activities.



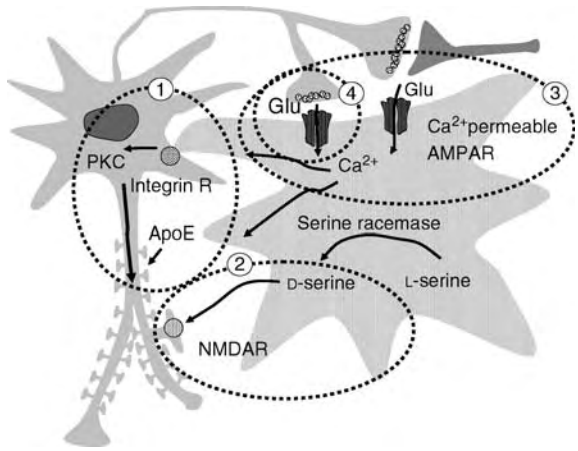
**Neuron–Astrocyte Interactions. Figure 3** Tripartite synapse. The structure consisting of (a) pre-, (b) post-synaptic neurons and (c) astrocytes has been emphasized by the coining of the term "tripartite synapse." Information processing between pre- and post-synaptic neurons receives further modulation from astrocytes, which express neurotransmitter receptor and release neurotransmitters.

### *Astrocyte–Vascular Interaction*

New lines of work have shown that receptors and channels essential for the function of astrocytes are densely concentrated in their vascular end-feet. Especially intriguing is the observation that the water channel aquaporin-4 and purine receptors – mediators of astrocytic $Ca^{2+}$ signaling – are expressed primarily at the ►gliovascular interface [2]. The array of these astrocyte-delimited microdomains along the capillary microvasculature allows the formation of higher-order gliovascular units, which serve to match local neural activity and blood flow while regulating neuronal firing thresholds through coordinative glial signaling. By these means, astrocytes might establish the functional as well as the structural architecture of the adult brain.

### *Neuron–Astrocyte Intercommunication*

Activation of astrocytes by neurotransmitters released from the neighboring neuron can evoke the increase in $[Ca^{2+}]i$ and the increase can propagate as $Ca^{2+}$ waves for several hundred micrometers [4]. The propagation, however, was found to be limited within a certain area, suggesting the existence of a local circuit. Intercellular communication among astrocytes using $Ca^{2+}$ waves provides astrocyte networks by which astrocytes can signal each other independently from the neuron network and can modulate the activities of neurons over a relatively wide range within the network. The brain structure as an information-processing machine should be recognized as an extraordinarily refined system consisted of the neuron network into



**Neuron–Astrocyte Interactions. Figure 4**
Interactions among astrocytes, synapses and vasculature. The $[Ca^{2+}]i$ increase in astrocytes induced by neurotransmitter propagates intra- and inter-cellularly. The propagation may be promoted by two mechanisms. One is diffusion of IP3 inside the cell and also through the gap junctions formed between astrocytes. The other is the response mediated by released ATP and its receptor (purinergic receptor). ATP released through the gap junction hemichannel diffuses to adjacent astrocytes and activates their ATP receptors. Functional molecules for regulating the astrocytes, such as purine receptor and aquapolin-4 are expressed mainly on the endfoot of astrocytes, which makes tight contact with a blood vessel. Since synaptic activities give and receive information between astrocytes, the size of the blood vessel may also be regulated depending upon the neuronal activities. The structure consisting of astrocyte, blood vessel and neuron will provide dynamic regulation of information processing in the brain. The gap junction hemichannel will participate in the release not only of ATP but also of some other transmitters and of trophic factors.

which the astrocyte network may be woven tightly and widely. Higher order brain function may be dependent upon this highly sophisticated structure. Although the participation of the "neuron astrocyte network" in the expression of higher order brain functions has not been established yet, these marvelous structures must be taken into account for further understanding the brain function [8].

## Regulation of the Structure/Process/Condition

Although the developmental profiles of the regulation of neuron–astrocyte interaction seem to be important in understanding the structure and functions of the brain, only ►synaptogenesis will be discussed in this essay. Some instances of the regulation of the neuron–astrocyte interaction in adult brain will be described (Fig. 5).

### Regulation of Synaptogenesis by Astrocytes

The co-culture of purified neurons with astrocytes has been demonstrated to facilitate synaptogenesis. Although the mechanisms of this facilitation have not been elucidated yet, some diffusible factors such as cholesterol complexed with apolipoprotein E-containing lipoproteins have been identified as candidates. Recently astrocytes have been demonstrated to affect neuronal synaptogenesis by the process of adhesion. Local contact with astrocytes via ►integrin receptors elicited protein kinase C activation, which was initially focal but soon spread throughout the entire neuron. This suggests that the propagation of PKC signaling represents an underlying mechanism for synaptogenesis [9].

### Regulation of NMDA Receptor Activation by D-Serine Released from Astrocytes

The activation of NMDA receptor by glutamate requires to be co-activated by glycine, which binds a specific binding site. Recently several lines of evidence indicate that D-serine, the stereo-isomer of L-serine, is an endogenous co-activator for NMDA receptor and is three times more potent than glycine in activating its binding site. The D-serine degrading enzyme has been shown to attenuate NMDA mediated transmission. D-serine and serine racemase, a D-serine synthesizing enzyme, have been found to be localized only in astrocytes. Since NMDA receptor is recognized as participating in synaptic plasticity, its regulation by D-serine suggests the important participation of astrocytes in higher order brain functions.

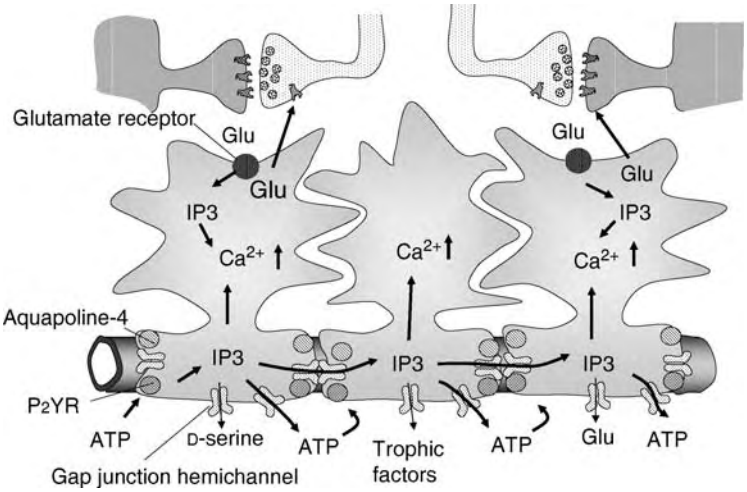
### Structural Regulation by the Activation of $Ca^{2+}$ Permeable AMPA Receptors in Bergmann Glia

As mentioned above, Bergman glia cells in the cerebellum express $Ca^{2+}$ -permeable AMPA-type glutamate receptors assembled without the GluR2 subunit [5]. Conversion of these $Ca^{2+}$ permeable receptors into $Ca^{2+}$ impermeable ones by adenoviral mediated delivery of GluR2 results in the retraction of glial cell processes from the spine of Purkinje cells and also the multiple innervation of Purkinje cells by the ascending fibers. The glial $Ca^{2+}$ -permeable AMPA receptors are indispensable for proper structural and functional regulation of Bergmann glia and glutamatergic synapses. Transfer of information from the ascending fiber to the Bergman glia has been shown to depend on the "►ectopic release" of glutamate from the ascending fiber to the receptor expressed on the Bergman cell. This means the existence of active and specific transmission between neuron and astrocyte.

## Function

### Functions Estimated by In vitro Preparations

Many important findings on neuron–astrocyte interaction have been demonstrated in primary culture or



**Neuron–Astrocyte Interactions. Figure 5** Regulatory neuron–astrocyte interaction. (a) Synaptogenesis Astrocytes play important roles in synaptogenesis during development. Apoprotein E released from astrocytes has been shown to be a factor facilitating synapse formation. Direct contact of astrocytes and neuronal cells through integrin receptor induces drastic synaptogenesis, which is mediated by protein kinase C (*PKC*) activation. (b) Activation of N-methyl-D-aspartic acid (*NMDA*) receptor by D-serine. D-Serine is produced from L-serine inside astrocytes by a specific enzyme, serine racemase. The amino acid is an effective activator for NMDA receptor, a key receptor for synaptic plasticity. (c) Regulation of neuron–astrocyte interaction by $Ca^{2+}$ -permeable AMPA receptors $Ca^{2+}$ -permeable AMPA-type glutamate receptors expressed on the Bergman glia are indispensable for proper structural and functional regulation of the Bergmann glia and glutamatergic synapses. (d) Ectopic release of glutamate from neuron to astrocyte. The ascending fiber terminal releases glutamate and directly activates $Ca^{2+}$ permeable AMPA receptor expressed on the Bergman cell.

organotypic culture preparations. These studies showed the wide range of inhibitory effects of ATP released from an astrocyte, the facilitatory and inhibitory interactions between astrocytes and neurons due to glutamate released from either cell [10] and facilitation of synaptogenesis [9]. However, since the functions of astrocytes are structure- and environment-dependent as mentioned in this essay, real functional profiles of the neuron–astrocyte interaction in in vivo brain may be difficult measure in such simple in vitro experiments. One possible breakthrough for this difficulty may be provided by in vitro study of retina, which has a closely similar structure to brain. The synapses in the retina are contacted by Müller cells (astrocyte-like radial glia) and make regulatory configurations with neuronal networks similar to those in brain.

### *Functions Estimated from Pathological Conditions*

Recent pathological studies demonstrate that dysfunction of "neuron–astrocyte interaction" is an important causal factor in the development of schizophrenia, depression and some other psychiatric disorders. The activities of a glutamate transporter (GLT-1 type) in astrocytes obtained from schizophrenic patients were significantly higher than in those obtained from normal brain. Furthermore the level of D-serine, a coactivator for NMDA receptor and a product of astrocytes is significantly lower in the schizophrenic brain than in normal brain. These facts suggest that appropriate activities of glutamatergic synapses required for expression of higher order brain functions are regulated by astrocytes.

Many other brain dysfunctions due to abnormality of astrocyte functions, such as epilepsy and dementia, have demonstrated the importance of neuron–astrocyte interactions for the establishment of higher order brain functions.

# Neuron/Cell

## Definition

The neuron is the functional unit of the nervous system, specialized for the conduction of electrochemical impulses along neuron processes, and the transmission of information from one neuron to another usually by the release of a neurotransmitter from one neuron onto another that expresses receptors for that neurotransmitter.

# Neuron/Cellular Doctrine

## Definition

The neuron cell doctrine states that the neuron with its processes is a single cell and forms the functional unit of the nervous system. In this doctrine nerve networks (interconnections) and pathways (connections from one collection of neurons to another) are made by synaptic contacts between neurons.

## Synonyms

Neuronal imaging; *in situ* microscopy

## Definition

►Neuron-glia-imaging means videocamera, ►confocal or ►multi-photon microscopy of dynamic changes in the activity and/or morphology of living ►neurons and ►glia at the (sub) cellular level. A rapidly increasing number of cellular processes is being monitored with neuron-glia-imaging *in vitro* and *in vivo* using genetically encoded fluorescent dyes expressed in targeted cells.

## Purpose

For most central nervous tissues, the relation between structure and function is largely unknown at the cellular level. Brain structures are monitored *in vivo* with powerful techniques such as ►positron emission tomography (PET). However, analysis of fast activity in central nervous micro-networks is not feasible with such functional brain imaging due to a low temporal and spatial resolution. Rather, video, confocal or multi-photon microscopy (mostly ►two-photon microscopy) is used *in vivo* and *in vitro* for simultaneous imaging of brain cell activity and morphology. Optical techniques are being developed further in conjunction with engineering of genetically encoded fluorescent dyes to allow for neuron-glia-imaging of nervous structures in deeper brain layers of freely moving mammals. This may allow for future endoscopic investigation of neuron-glia networks plus microcirculation in the almost intact mammalian brain and spinal cord, possibly with the attractive option to diagnose and treat nervous diseases such as focal epilepsy.

## Principles

### Biological Activity Dyes

Biochemical, physiological and morphological features of ►brain cells can be assessed with a variety of (fluorescent) dyes [1–4]. In a morphological study on living ►taste organs of frogs [5], the $H^+$ - thus, pH-sensitive dye BCECF and the $Ca^{2+}$-sensitive dye Indo-1 stained glia-like cells, while ►type-II receptor cells were stained with the $Cl^-$-sensitive dye MQAE. In contrast, ►Merkel-like basal cells were only stained with the membrane-labeling dye FM1–43 that is also used for recording synaptic processes such as ►vesicle recycling. The above ion-sensitive dyes as well as the $Na^+$ -sensitive dye SBFI and the $K^+$-sensitive dye PBFI are well suited to image nervous activity which is typically associated with notable changes of cellular ions [2–4,6,7]. Neuronal signals in the upper µs-lower ms range are well resolved with high-speed video-microscopy using voltage-sensitive dyes, e.g., Di-8-ANEPPS [1,4] or $Ca^{2+}$ -sensitive dyes [1–4,6–9] (see below). Some dyes stain quite selectively organelles. Amongst these, Rhodamine-123 is used to monitor both mitochondrial structure and membrane potential [1,4]. Dual dye labeling allows for ►ratiometric measurements for a better signal-to-►noise ratio and/or calibration of concentrations of cellular factors [1,3,4]. Ratiometric measurements can

also be done with single indicators showing an excitation or emission spectral shift upon ion binding. If ratiometric [$Ca^{2+}$] measurements are not possible, the change in ►fluorescence can be calculated as $\Delta F/F$, i.e., as the background-corrected change in fluorescence ($\Delta F$) divided by resting fluorescence ($F$). This calculation allows comparison of fluorescence transients in cellular compartments with different thickness, for example, ►soma or ►spines and/or indicator concentration [1,3,4,7].

Molecular techniques offer a most powerful approach for neuron-glia-imaging [2,4]. For example, cameleons are protein-based, resulting from the fusion of calmodulin with a calmodulin-binding peptide with cyan and yellow mutants of ►green-fluorescent-protein. They utilize ►fluorescence-resonance-energy-transfer for coupling $Ca^{2+}$ binding to changes in fluorescence. In general, this spectroscopic technique allows to monitor changes in both, distance (20–100 nm) and orientation of two ►fluorophores. In addition to $Ca^{2+}$-sensitive cameleons, specific macromolecule pairs have been designed to use fluorescence-resonance-energy-transfer to record biochemical or physiological signals such as ►membrane potential, ► cyclic-adenosine-monophosphate or protein-protein heterodimerization. Besides, some mutants of green-fluorescent-protein are sensitive to pH and/or $Cl^-$. Genetically encoded fluorescent probes are being targeted to different tissue and cell types and/or various subcellular structures such as ►endoplasmic reticulum or ►synapses, using ►viral transfection and transgenic techniques [2,4].

## Labeling Neurons and Glia

Cultured brain cells form a thin layer and can thus be visualized at reasonable optical resolution with a standard fluorescence microscope attached to a videocamera-based imaging system [1,4]. Neurons and glia in culture can easily be labeled with morphological dyes of the "Alexa Fluor" or "BODIPY" families, or with ►$Ca^{2+}$-sensitive dyes for ►$Ca^{2+}$ imaging [1,2,4]. Loading with $Ca^{2+}$-sensitive dye is achieved by adding to the culture medium the membrane-permeant, acetoxymethyl ("AM") form of the dye, which is cleaved into the impermeant, fluorescent form by cellular esterases [1,4]. In contrast to cultures, cells in acute ►brain slices remain in their natural environment *in situ* and thus show often features close to *in vivo* (Fig. 1) [4,6,7]. However, in particular in mature brain structures *in situ*, loading of neurons by addition of the AM form of the $Ca^{2+}$-sensitive dye to the superfusate may not be successful due to diffusional or uptake problems. In such cases, ►pressure injection of the AM dye can provide adequate loading of glia and neurons in both brain slices and *in vivo* (Fig. 1) [4,6].

In a different *in situ* approach, the membrane-impermeant form of the $Ca^{2+}$-sensitive dye is injected into a brain cell via the recording ►patch- or ►micro-electrode (Figs. 1, 2) [4,6,7,9]. With this method, morphological features and/or activity-related [$Ca^{2+}$] rises can be correlated with electrophysiologically recorded biophysical parameters, such as membrane potential, resistance or capacitance. In brain tissue *in situ*, visualization of cellular structures with conventional light microscopy is usually restricted to depths of ~50 µm.

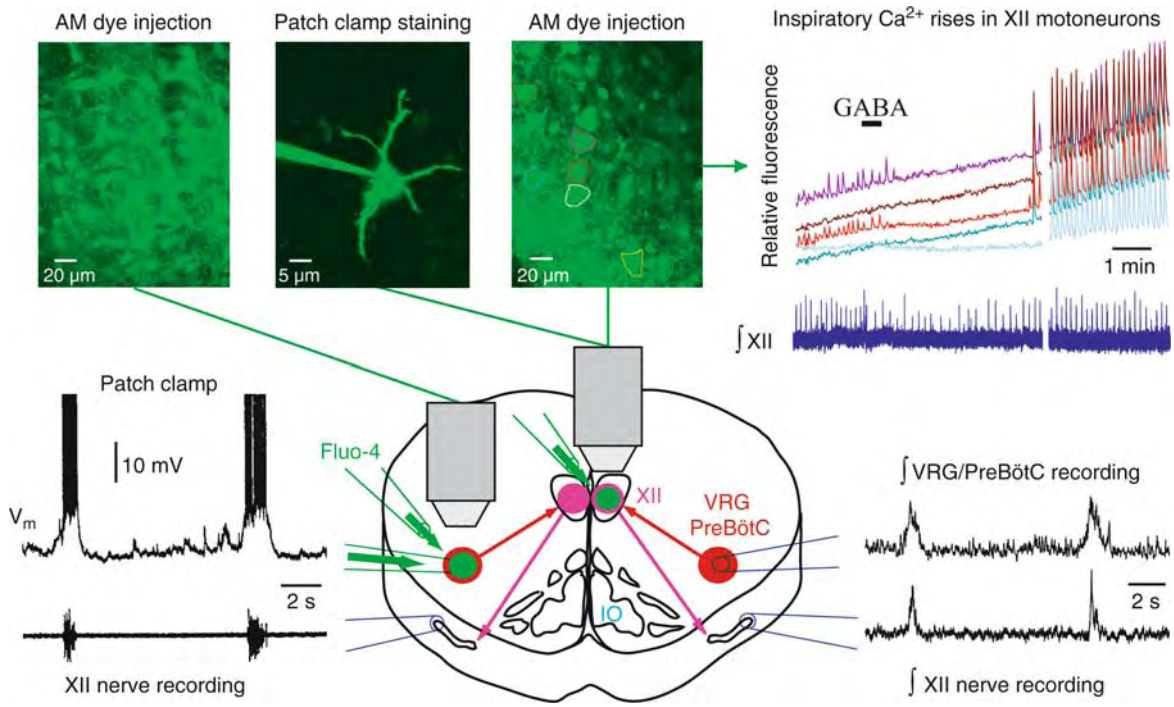
## Confocal and Videocamera Microscopy

The spatial resolution of fluorescence imaging is greatly improved by one-photon-excitation ►confocal laser-scanning microscopy, which eliminates out-of-focus and stray light via a pinhole aperture (Figs. 1–4) [4,7,8].

Confocal techniques do not principally improve neuron-glia-imaging in deeper tissue layers, in contrast to one specific subtype of two major video-microscopy techniques [4,8]. Intensified video-microscopy involves imaging a specimen when light levels are too low for standard cameras, while enhanced video-microscopy is used when the specimen is invisible to the eye, either due to lack of contrast or due to its spectral characteristics, i.e., ultraviolet or infrared [4]. As infrared light enters deeper into tissues [4,8,9], infrared ►differential-interference-contrast enhanced video-microscopy produces images of almost three-dimensional quality from cells in tissue depths of 50–100 µm. Besides, the technique allows for dynamic recording of (re)organization of cellular structures [4]. Infrared darkfield video-imaging can be used in brain tissue *in situ* to monitor neuronal activity as cellular ion fluxes and subsequent volume changes affect light scattering. Such imaging of intrinsic optical signals can, e.g., provide cortical activity maps, although not at cellular resolution [1,4].

## Two-Photon Microscopy

Two-photon-excitation laser-scanning fluorescence microscopy enables *in situ* visualization of brain cells in tissue depths up to ~2 mm [4,6,9]. For two-photon-excitation, femtosecond pulses from a mode-locked Ti: sapphire infrared laser at megahertz repetition rates are focused to a point in the tissue and scanned over a horizontal optical plane (Figs. 2–4). Within a focus of only about one femtoliter in the tissue, two infrared photons can be simultaneously absorbed by the fluorophore and produce an excited state similar to that from the absorption of a single photon of twice their energy. The fluorescence is collected by a photomultiplier and fed into a computer. Specific software is used to reconstruct a plane of fluorescence intensity reflecting the activity and/or morphology of brain cells within that plane. As for ►confocal microscopy, three-dimensional images can be produced if consecutive image planes are scanned while a stepmotor moves the objective or specimen stage along the z-axis (Figs. 2–4) [4,8,9].



**Neuron-Glia-Imaging. Figure 1** Confocal and two-photon ►$Ca^{2+}$ imaging in respiratory neurons. The schematic shows a newborn rat transverse ►brainstem slice containing the neuronal network that initiates and controls inspiratory-related breathing movements. Rhythmogenic ►interneurons are located within the ►pre-Bötzinger Complex (preBötC), a subregion of the bilateral rostrocaudal columns of the ventral respiratory group. preBötC neurons transmit their inspiratory activity to motoneurons of the ►hypoglossal (XII) ►nucleus whose axons project within the same transverse plane to XII ►nerve rootlets. The left lowermost trace shows two bursts of inspiratory XII nerve activity, while the right lowermost trace displays the integrated form of such activity in a different slice. An integrated extracellular signal of preBötC ►neuron population activity is shown above the latter recording, while the trace on top of the XII nerve recording in the left part of the figure shows rhythmic ►membrane potential ($V_m$) fluctuations of a single VRG-preBötC neuron. Individual respiratory neurons can be labeled via the recording ►patch-electrode with fluorescent dye as exemplified in the central ►confocal image of the upper part of the figure for an inspiratory XII motoneuron stained with the ►$Ca^{2+}$-sensitive dye Fluo-4. In addition, the activity and morphology of multiple VRG- preBötC neurons (*left*, ►two-photon image) and XII motoneurons (*right*, confocal image) can be visualized with $Ca^{2+}$ imaging. For that purpose, the membrane-permeant form of Fluo-4 (0.5 mM) is ►pressure-injected (0.5–1 psi, 5–15 min) into the VRG- preBötC or XII nucleus. The upper right part of the figure illustrates that two of seven XII motoneurons show $Ca^{2+}$ rises in phase with inspiratory XII nerve activity. Bath-applied (1 mM) ►γ-aminobutyric acid (GABA) slightly depresses respiratory rhythm and abolishes inspiratory $Ca^{2+}$ rises. Upon washout of GABA, $Ca^{2+}$ oscillations of the two cells are potentiated severalfold while pronounced rhythmic activity is induced in further XII motoneurons, probably due to decrease of tonic extracellular GABA levels by stimulated ►GABA-uptake. All recordings from A. Ruangkittisakul and K. Ballanyi, unpublished.

Two-photon microscopy can easily be combined with electrophysiological recording of single brain cell or neuronal population activity, even *in vivo* (Figs. 1, 2), while miniature two-photon-microscopes enable neuron-glia-imaging in freely moving animals [4,6]. Currently, optical fibers and lenses with a diameter <1 mm are being developed for two-photon microscopy. This enables visualization of deep brain structures, such as the ►hippocampus, which is crucial for memory processes while its dysfunction can constitute a focus for ►epilepsy [4,6]. Besides revealing brain cell properties, ►two-photon imaging enables visualization of brain ►microcirculation, which is involved in various nervous diseases such as ►angiopathy or ►stroke [4,6]. The high spatial resolution of two-photon microscopy, but also of other types of neuron-glia-imaging, is further improved by image processing and deconvolution techniques [1,4,8]. Computer power is steadily growing while ultra-fast scanning techniques, such as acousto-optical tuning deflectors, are currently being implemented into modified two-photon microscopy (Fig. 3) [4,8,10]. Thus, four-dimensional imaging of deeper brain structures in real-time is becoming feasible soon. This opens the

The fates of typical excitation (*blue* and *red lines*) and fluorescence (*green* lines) photons are shown to illustrate the advantages of two-photon microscopy. The sample consists of a scattering neural tissue permeated by blood vessels (*red ovals*) and containing a labe0000led neuron. In the confocal case (*left*), the short-wavelenth excitation photons have a relatively high chance of being scattered (*1,3*) or absorbed (*2*). Only unscattered fluorescence photons originating at the focus contribute to the signal (*4*). Scattered (*5*) and out-of-focus (*6*) photons are blocked by the pinhole, which is necessary to reject out-of-focus fluorescence. Spurious excitation, and hence photobleaching and phototoxicity, occur throughout a large part of the cell (*green region*). In the two-photon case (right), the long-wavelength excitation photon have a relatively low chance of being scattered or absorbed; scattered photons are too dilute to excite (*7*) and excitation is therefore localized to the tiny focal volume. Since no pinhole is necessary to reject out-of-focus fluorescence, all fluorescence photons entering the objective contribute to the signal. Reproduced from Svoboda, Tank, Stepnoski and Denk in [4], with kind permission.

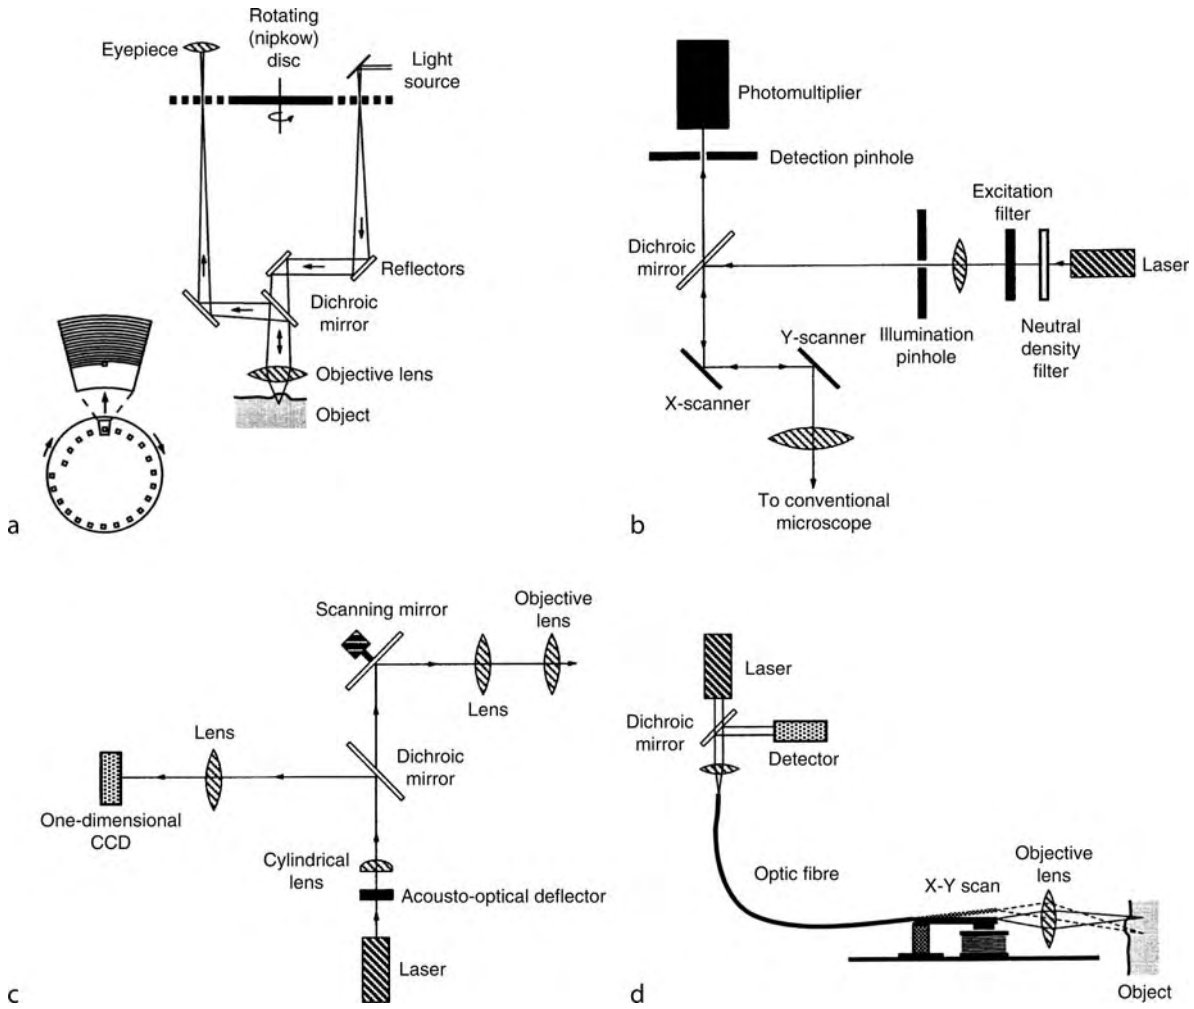
is currently studied by various groups in transverse brainstem slices of newborn and juvenile rodents (see also essays on "brain slices" and "isolated respiratory centers"). These brain slices contain a kernel of rhythmogenic interneurons within the ►pre-Bötzinger Complex (preBötC), a subregion of the bilateral rostrocaudal columns of the ventral respiratory group (Fig. 1). The preBötC has a rostrocaudal extension of about 200 μm and provides within the slice an inspiratory excitatory drive to ►hypoglossal motoneurons whose axons exit the preparation in the same transversal plane (Fig. 1). This kernel of the ►inspiratory network is devoid of afferent influences from ►sensory systems mediating, e.g., peripheral ►chemosensitivity or the ►lung-stretch reflex. Despite this, the respiratory active brain slices retain central chemosensitivity for $CO_2$, thus pH, and $O_2$ and respond to ►neuromodulators in a fashion very similar to that in more intact *in vitro* preparations, and even in (preterm infant) humans. In slices with a rostrocaudal thickness of 500–700 μm, a regular inspiratory rhythm can be recorded at physiological superfusate [$K^+$] (3 mM) for several hours from hypoglossal ►nerve roots or within the preBötC. Such recording can routinely be combined with ►patch-clamp measurement of oscillatory membrane properties of rhythmogenic preBötC ►interneurons or hypoglossal motoneurons (Fig. 1).

Figure 1 shows that the activity and structure of the cellular elements of this neuronal network can be analyzed with two-photon or confocal microscopy. Individual respiratory neurons are labeled via the recording patch-electrode with fluorescent dye as exemplified for a hypoglossal motoneuron stained with the $Ca^{2+}$-sensitive dye Fluo-4. Also the activity and morphology of populations of ventral respiratory group/preBötC neurons or hypoglossal motoneurons can be visualized with $Ca^{2+}$ imaging. For that purpose, the membrane-permeant form of Fluo-4 (0.5 mM) is pressure-injected (0.5–1 psi, 5–15 min) into the ventral respiratory group/preBötC or the hypoglossal nucleus. Figure 1 also illustrates that two of seven hypoglossal neurons show $Ca^{2+}$ rises that are in phase with inspiratory hypoglossal nerve activity. Bath-applied ►γ-aminobutyric acid (GABA) slightly depresses the ►respiratory rhythm and abolishes the inspiratory $Ca^{2+}$ rises. Upon washout of GABA, the $Ca^{2+}$ oscillations of the two cells are potentiated severalfold while pronounced rhythmic activity is induced in further hypoglossal motoneurons, probably due to decrease of tonic extracellular GABA levels by stimulated ►GABA-uptake.

## Advantages and Disadvantages

### Imaging Systems

The choice of hardware for neuron-glia-imaging depends on whether speed or spatial resolution of the acquired image series is more relevant. Digital videocameras with a high pixel number provide a lateral resolution that is indistinguishable from fine-grain photography [1,4].



**Neuron-Glia-Imaging. Figure 4** Confocal implementation. (a) A two-dimensional image can be generated by spinning a spiral array of illumination apertures (a Nipkow disc) over a window on the specimen, thereby illuminating points on sequential lines (*insert*). A confocal image of the illuminated points is viewed through a similarly moving array in a conjugate image plane. (b) A spot of light from a fixed point source can be scanned across the specimen by mirrors; longer-wavelength fluorescence from the point is reflected back along the same light path through a dichroic reflector to a conjugate fixed-point aperture. The time-varying signal from the detector behind this aperture is converted by computer into a two-dimensional image. (c) Scanning can also be performed by an acousto-optical deflector, but the wavelength dependency of these devices prevents their use for de-scanning the longer-wavelength fluorescence. Instead, a linear detector array can be used, sampling each element in sequence corresponding to the moving point. (d) A simpler configuration uses a fiber optic, vibrating in an image plane, as both point source and detector aperture. Reproduced from A. Fine in [4], with kind permission.

But, the large amount of digital data limits the sampling rate. Conversely, recording with high-speed videocameras provides full-frame sampling rates >1 kHz at the cost of a low spatial resolution due to digital chips with a low pixel number. A further type of intensified videocameras is optimized to sample fluorescence or luminiscence, at low light intensities, often down to the single-photon level. For example, some voltage-sensitive dyes produce a <0.1% change in fluorescence in response to nervous activity, on top of a high background fluorescence [1,4].

For all its virtues, confocal microscopy has a major flaw in that it excites fluorophores in excess, but detects only a small fraction of the generated fluorescence light [4,8]. Two-photon microscopy reduces problems associated with scattering and absorption of fluorescence compared to one-photon-excitation (confocal) techniques for several reasons. (i) The use of longer excitation wavelengths leads to a better tissue penetration; (ii) The two-photon excitation wavelengths for most useful fluorophores fall into a range (800–900 nm) characterized by low absorption due to water, blood or

other intrinsic tissue fluorophores; (iii) Scattered excitation photons are too dilute to excite and, hence, produce negligible background or damage (see below); (iv) In two-photon microscopy, three-dimensional sectioning and resolution are due to the localization of excitation alone. Thus, scattered fluorescence photons constitute useful signals, permitting greatly increased collection efficiencies (Fig. 3) [4,8,9].

In commercial confocal or two-photon microscopes, the sampling rate is limited by the mass of the galvanometric scanning mirrors (Figs. 2–4) [4,8]. It can be increased, at the cost of spatial resolution, to the hundred-millisecond or low millisecond range by acquiring only a small portion of the image plane or a line scan, respectively (Fig. 2) [4]. Considerably higher scan speed can be achieved with acousto-optical tunable filters (deflectors), which use sound to induce refraction waves that behave like a refraction grating (Fig. 4) [4,10]. Imaging of many points at once at rates >100 Hz can also be achieved by coordinated scanning of apertures, e.g., arranged in a spiral pattern of a Nipkow disc (Fig. 4) [4,8]. However, adequate simultaneous illumination of the multiple points is difficult to achieve, thus limiting sensitivity. While two-photon-excitation makes ratiometric measurements with dual-excitation dyes unfeasible, dual-emission rationing is possible. For confocal imaging, the choice of $Ca^{2+}$-sensitive or other dyes is determined by the availability of lasers operating at the required wavelength [4,8]. This potential limitation for use of dyes can be overcome by Nipkow-disc confocal microscopy (Fig. 4) or videocamera imaging. The latter techniques do not critically depend on dye excitation via a laser and can rather make use of conventional light sources such as a xenon or halogen lamp, often in combination with a monochromator [4,8].

## Dye Properties

Due to the limited format of this article, technical considerations will be exemplified only for $Ca^{2+}$-sensitive dyes (in addition to those properties of such dyes already outlined above) [1,4,7]. $Ca^{2+}$-sensitive dyes are most powerful tools for neuron-glia-imaging, as they allow simultaneous assessment of (sub)micrometer structures and millisecond electrical activities. Neuronal activity can rapidly increase cytosolic $[Ca^{2+}]$ due to $Ca^{2+}$ influx from the interstitial space via voltage-activated $Ca^{2+}$ channels and/or $Ca^{2+}$-permeable neurotransmitter receptors, often in conjunction with $Ca^{2+}$ release from intracellular stores. As intracellular $Ca^{2+}$ is a ►second messenger of ultimate importance, $Ca^{2+}$ imaging is pivotal to the understanding of nervous functions [2–4, 6–9]. $Ca^{2+}$-sensitive dyes should be chosen according to the primary aim of a study. For assessment of morphological features, e.g., spine formation, it is important that the dye fluoresces brightly already at low nanomolar, thus resting intracellular $[Ca^{2+}]$ levels. For that purpose, Fura-2 can be used with most videocamera imaging systems and two-photon microscopy. Confocal laser-scanning microscopy is often not possible with Fura-2 as most commercial systems cannot use ultraviolet light, while Calcium-Green or Fluo-4 can be used with most imaging systems. Due to its relatively high resting fluorescence, Calcium-Green has a decreased dynamic range for $[Ca^{2+}]$ measurements compared to Fluo-4, while the latter dye fluoresces less brightly at resting $[Ca^{2+}]$ (Fig. 1). Fura-2 has a large dynamic range despite a bright fluorescence at low $[Ca^{2+}]$, as intracellular $Ca^{2+}$ rises decrease its fluorescence intensity [1,3,4,7–9].

The dynamic range of activity-related $Ca^{2+}$ imaging depends greatly also on the dissociation constant ($K_d$), which describes $Ca^{2+}$ binding to the dye. $K_d$ is affected by many factors, including pH, temperature, protein binding and ions such as $Mg^{2+}$. Indicators have a detectable response in the concentration range from approximately $0.1 \times K_d$ to $10 \times K_d$. A dye with a low $K_d$ value binds most $Ca^{2+}$ already at low $[Ca^{2+}]$ levels and is saturated at higher values. For example, Fura-2 with a $K_d$ of 145 nM measures effectively $[Ca^{2+}]$ in brain cells at levels between 20–2,000 nM. In contrast, Fura-FF ($K_d$ = 5,500) is predestined for measurements of micromolar $[Ca^{2+}]$ transients that are observed, e.g., during repetitive or pathological neuronal activity, in particular in small compartments such as dendrites or spines [1,3,4,7,9].

The fact that $Ca^{2+}$ is bound to the dye means that the dye acts as a $Ca^{2+}$ buffer. Accordingly, the magnitude of activity-related $[Ca^{2+}]$ transients is attenuated and the kinetics prolonged. In AM $Ca^{2+}$ dye-loaded cells, the artificial $Ca^{2+}$ buffer adds up to intrinsic $Ca^{2+}$ buffer systems, such as calbindin or parvalbumin. In contrast, in single brain cells loaded with the dye via a recording patch- or micro-electrode, the dye can substitute for endogenous $Ca^{2+}$ buffers that are eventually washed out from the cell. It should be noted that different cell types express substantially different levels of endogenous buffer [1,3,4,7].

The latter considerations show that it is important to choose the right intracellular dye concentration. A high concentration may, on the one hand, provide a better resolution of structures or improve the signal-to-noise ratio for activity measurements. On the other hand, it may distort fast activity related $[Ca^{2+}]$ transients, which often have immediate second messenger function such as activating ►$Ca^{2+}$-gated $K^+$ channels. If neuronal networks in AM $Ca^{2+}$ dye-loaded systems are studied, such as a respiratory brainstem slice (see above and section on brain slices) (Fig. 1), it must be considered that not only the excitability of the imaged cells, but rather major parts of the network, may be affected by high intracellular $Ca^{2+}$ dye concentrations [1,3,4,6,7].

## Photobleaching, Phototoxicity, Auto-Fluorescence

A number of natural peptides is auto-fluorescent when excited at wavelengths well into the ultraviolet region. This may cause interference with probes used to measure intracellular ion concentrations requiring excitation in that range of thr spectrum [1,4]. Apart from that, all fluorescent probes will photobleach to a greater or lesser extent when excited with a suitable wavelength, at a rate proportional to the intensity of the incident light. While this may not be a problem for some morphological applications, it does seriously affect any attempt to quantify intracellular concentrations using single-wavelength probes [1,3,4,7–9]. The most obvious practical way to reduce ►photobleaching is to minimize light reaching the probe. Since this reduces the amount of fluorescence, optimum conditions for image analysis must include, for example, optimal dye loading or sampling fluorescence with highly sensitive systems such as cooled CCD-type intensified videocameras or two-photon microscopes. Room light contributes to photobleaching already during the loading procedure and during storing the loaded cells prior to the actual experiment. Also oxygen plays a major role in photobleaching, at least during $Ca^{2+}$ imaging with Fura-2. Genetically encoded fluorescent proteins can have a remarkable resistance to photobleaching in addition to their large extinction ratios and quantum efficiencies [2,4,6].

Two-photon imaging may deteriorate living tissue by production of heat, in particular when a high power of the infrared laser is needed. Accordingly, two-photon microscopy of deeper brain structures *in vivo* may induce a caloric challenge not only to the studied brain region, but indirectly, to the entire animal [4,8,9]. Fluorescent molecules in their excited state react with oxygen to make ►free radicals, which can damage cellular molecules [1,4,7,8]. There are several strategies to reduce such phototoxic cell damage, specifically (i) Use of high numeric aperture lenses allows for collecting more light, thus enabling reduction of excitation light intensity; (ii) Reduction in the number and/or rate of scans. For example, Fluo-4-loaded cells of the ►respiratory network need to be confocally scanned at a rate of 0.3–1 seconds to visualize cytosolic [$Ca^{2+}$] oscillations. But, it is advisable to record only for several minutes during control and pharmacological treatment and stop scanning for the rest of time; (iii) Using two-photon microscopy, ►phototoxicity is reduced by focal excitation allowing for continuous recording of respiratory oscillations for >1 h at a rate of >2 Hz. For the latter approach, it is advisable to use an external, more sensitive photomultiplier that is located closer to the specimen to enable reduction of excitation light. In some preparations, it may be helpful to reduce potential toxicity chemically by adding antioxidants, such as oxyrase or ascorbic acid to the superfusate [1,4]. The toxicity does probably not solely depend on the intensity of the excitation light. For example, some voltage-sensitive dyes can only be used for a limited time period to monitor nervous activity, before activity of the preparation gets impaired. More recent dyes of that class, such as Di-4-ANEPPS, can be used for up to severely hours without severely impairing nervous functions [1,4,8].

Some of the limitations of conventional dyes can be avoided, or at least attenuated, by fluorescence-resonance-energy-transfer [2,4,8]. This spectroscopic technique is general, non-destructive and easily imaged and has thus proven to be one of the most versatile readouts available to the designer of new optical probes (see above). It is particularly amenable to emission rationing, which is more reliably quantifiable than single-wavelength monitoring and is better suited than excitation rationing for high-speed and laser-excited imaging. Two-photon microscopy can be easily combined with ►fluorescence-lifetime measurements for quantitative fluorescence-resonance-energy-transfer imaging. One major domain of fluorescence-lifetime measurements is the field of ion concentration imaging. This method is insensitive to intensity effects, such as shading, photobleaching, absorption or light source noise. This can be an important advantage, especially in confocal studies of brain cells *in situ*, where absorption effects and photobleaching are important limitations [2,4,8].

## Acknowledgments

The study was supported by AHFMR, CIHR and CFI-ASRIP. We thank Dr. A. Fine for comments.

## Definition

Neuron – a late nineteenth century Greek term, refers to highly specialized "nerve cells" that conduct electrical impulses (►Action potential). This innate propensity to generate and conduct electrical potentials is a unique hallmark of all "excitable cells" of which the neurons are the most specialized. A neuron exhibits a highly complex repertoire of specialized membranous structures, embedded ►ion channels, ►second messengers, genetic and epigenetic elements and unique complements of various proteins such as the ►receptors. A "►synapse," which is the functional building block of all communicating neurons, refers to the juxtaposed point of contact between two excitable cells. As the nerve impulse invades the "►presynaptic terminal," it elicits the release of chemical messenger/s – the ►neurotransmitter into the synaptic cleft. The diffused chemical neurotransmitter substance, such as ►dopamine, ►serotonin or a proteineous ►peptide (►substance P for example) then binds to its respective receptor located on the "postsynaptic" side of the terminal and invokes an electrical response. Synapses are analogous to electrical bulbs that light up when electric current traveling through the nerve ►cables (►Cable theory) is switched on by the neuron. Thus, synapses serve as the functional unit of all neuronal connectivity upon which hinge its marvelous attributes – ranging from the control of simple ►reflexes (Reflexes) to complex motor patterns, ►learning and ►memory, cognition, emotions etc. Perturbations – emanating from either genetic, cellular and molecular malfunction or an injury – disrupt lines of communications between neurons thus rendering the nervous system dysfunctional. Therefore, central to our comprehension of all brain functions and its repair lie an in-depth understanding of the cellular and molecular elements that make up the neuronal architecture.

## Characteristics

### From Wiring Together to Firing Together: The Marvelous Neuron

The astonishing structural and functional traits of the human brain have eluded many intriguing minds for centuries – and yet our understanding of even the very basic neuronal elements, such as the synapse, remains pedestrian. Notwithstanding tremendous efforts by the neuroscience community over the decades, the sheer numbers of brain cells (tens of billions) and the intricate nature of their connectivity continue to offer formidable challenges. While tools are being developed to visualize and record the activities of functionally active neurons embedded deep within the brain, an alternative paradigm is to understand how the nervous system is put together during ►development in the first instance. A developmental approach to understanding nervous system function and dysfunction is aimed at drawing up the road maps that were originally used to orchestrate the neuronal connectivity patterns. Once a blue print of all such essential, cellular and molecular components used to lay down the original neuronal maps are "decoded," one might be in a much better position to recapitulate these steps in an adult brain to help "rewire" its damaged connectivity.

A variety of animal model systems are being used to define elements that foster neuronal proliferation, migration and differentiation – steps that are central to the normal wiring of the brain. The steps that enable a neuron to get to its final and well-defined destination in the nervous system are highly complex and rely upon a variety of intrinsic cell-cell signaling and extrinsic factors. Having arrived at its final destination, a neuron begins to develop its axonal and dendritic architecture, which is highly ordered and equipped with navigational tools that would enable these newly born processes to reach out to select groups of target cells that are often located at some distance. Such "search and select" tasks are assigned by neurons to highly specialized structures, termed ►growth cones located at the tip of an extending neurite (axon or dendrite). Every growth cone, fueled by specific ►chemotropic molecules and ►growth factors, follows a precise roadmap, rarely deviating from its defined trajectory that is designed for it to seek out its specific target/s. Growth cones are assisted in their navigational tasks by a variety of cell-cell interacting and diffusible molecules comprising the extracellular milieu. A number of molecules, such as netrin, slit etc. and their interacting receptors are eloquently described and discussed in detail by Spencer et al. (►axonal pathfinding and network assembly).

In addition to various growth-permissive molecules described above, a growth cone's navigational ability is

also empowered by a number of well-defined growth repulsive factors that are either membrane-bound or diffused along its path, *en route* towards targets. These growth-repulsive molecules such as the Samaphorins, NI35 etc. will, on the one hand, deter growth cone's entry into the wrong territory, and on the other hand, they serve to prevent wiring among functionally "unrelated" neurons. An intriguing aspect of these growth-suppressive or -repulsive molecules is their continued presence in the adult brain – which incidentally offers formidable challenge to brain repair after trauma and injury. Numerous studies in which the activities of these ►growth-inhibitory molecules were neutralized have uncovered an innate regenerative capacity of the adult neurons – thus underscoring their therapeutic importance vis-à-vis functional recovery from stroke and injury. Metz and Faraji have defined some of these ►growth inhibitory molecules in nervous system development and regeneration and have identified their underlying mechanisms. These authors have also offered several therapeutic strategies that might involve perturbation of these growth-inhibitory molecules to ensure functional regeneration and recovery after nerve injury or neuronal degeneration.

In the vicinity of its target tissue, a growth cone slows its advance and makes physical contacts with potential target cells. Cell–cell interactions via a variety of membrane-bound molecules such as neuroligans and neuregulin etc. trigger inductive changes not only in the presynaptic cells but also its postsynaptic partner. On the presynaptic side, the growth cone undergoes dramatic structural changes that begin with the retraction of filopidia while lamellopodia transform into a club shaped structure. Transmitter vesicles and other related synaptic proteins descend into the bulbous ending, which comes to rest at the juxtaposed postsynaptic site. In addition, $Ca^{2+}$ channels (►Calcium channels – an overview) and other elements of the synaptic machinery specifically cluster presynaptically. At the postsynaptic site, neurotransmitter receptors and their respective second messenger molecules cluster – concomitant with the ►postsynaptic density (PSD). Initially, neurons make myriads of synaptic contacts, which are subsequently refined through ►activity-dependent mechanisms. The molecular machinery mediating cell–cell contact coupled with the activity-dependent mechanisms are central to establishing a precise balance between ►inhibitory and ►excitatory synapses and their respective partners. Interplay between various molecules mediating cell–cell interactions and the underlying mechanisms have been described by Arstikaeitis and El-Husseini (►synapse formation: neuromuscular junction vs. central nervous system) and Colicos (►activity-dependent synaptic plasticity). While El-Husseini's lab takes advantage of powerful molecular techniques to unravel various elements of the synaptogenic program, Colicos lab uses novel photoconductive stimulation techniques to decipher how activity-dependent mechanisms either strengthen or weaken certain synapses. Several recent studies from these and other labs have shed significant light on to the mechanisms by which neurons recognize their potential targets and establish synaptic connectivity. Because some developmental aspects of synapse formation are also recapitulated in the adult brain during ►synaptic plasticity that underlies ►learning and memory, many investigators are taking advantage of activity- or plasticity-related changes in the adult brain to understand how synapses may form and subsequently refine during development. The plasticity-related induction of new synapses or the awakening of the ►silent ►synapses has thus provided greater insight into mechanisms that regulate synapse formation during development (activity-dependent synaptic plasticity) This area of research is not only important for our understanding of the mechanisms underlying nervous system development but also synaptic plasticity that forms the basis for learning and memory in the intact animals.

Due in large measure to the complex nature of the neuronal connectivity in the adult brain where cell–cell interactions are often difficult to study at the level of single pre- and postsynaptic neurons, a number of labs have opted to explore various model system approaches to define mechanisms underlying synapse formation. For instance, the ►neuromuscular junction (NMJ) and various invertebrate models have been extensively used to define both the cellular and molecular mechanisms underlying target cell selection, specific synapse formation and synaptic refinement. As a result of these studies as highlighted by Feng in the chapter ►synaptic transmission: model systems we now know a great deal about various steps that determine the specificity of synapse formation both at the NMJ and between central neurons. Molecules such as ►Agrin that are synthesized and secreted by ►Motoneuron (motor neurons) have been shown to bring about specific inductive changes required for the assembly of the postsynaptic machinery at the NMJ. Similarly, postsynaptic cells have been shown to induce clustering of $Ca^{2+}$ channels and other elements of the synaptic machinery at the presynaptic terminal. Newly formed synapses have since been shown to undergo activity-dependent refinement and consolidation.

Among various proteins that are selectively targeted at both the pre- and postsynaptic sites are the ion channels. For instance, $Ca^{2+}$ (►Calcium channels – and overview), $Na^{+}$ (►Sodium channels) and $K^{+}$ channels (►Neuronal potassium channels) are specifically targeted at select synaptic sites, and this targeting is essential not only for normal synapse formation but also the synaptic transmission. In the chapter ►ion channels from development to disease Pham et al. demonstrate how various ion channel sub-types are selectively gated

at various synaptic and extrasynaptic sites to serve their well-defined roles in a wide variety of cell types. Perturbation or mutations to various ion channels subtypes either in non-excitable or excitable cells may result in pathologies, such as the neonatal diabetes and ►epilepsy, respectively.

In addition to ion channel targeting to specific synaptic sites, the function of various other synapse-specific and $Ca^{2+}$-dependent proteins are also highly regulated. Intricate interplays between myriads of ►synaptic vesicle-associated proteins have been an area of intense investigation recently. A combination of biochemical, molecular, imaging and electrophysiological approaches have served to identify how synaptic vesicles might be targeted, primed, docked, released and recycled at the synaptic sites. As outlined by Coorssen in the chapter ►synaptic proteins and regulated exocytosis newly synthesized synaptic vesicles leave the cell body by a series of well-defined pathways. These vesicles are then specifically targeted to select synaptic sites where they get tethered, docked and primed for release. An action potential-induced $Ca^{2+}$ influx through voltage-gated $Ca^{2+}$ channels (VGCCs) (Calcium channels – and overview) is a critical step, which triggers fusion and exocytosis. Following their release at the synapse, the synaptic vesicles undergo endocytosis and are recycled for subsequent re-release. Although the spatio-temporal patterns of the synaptic vesicle behavior have been well characterized, this area of research, however, continues to enjoy its fair share of controversies.

The opening of the VGCCs invokes $Ca^{2+}$ entry into the cytosol. This $Ca^{2+}$ is then rapidly taken up by the fast ►endogenous $Ca^{2\pm}$ buffers, the mitochondria as well as the ►SERCA – sarco-endoplasmic reticulum $Ca^{2+}$-ATPase pumps (Ion transport). These three steps thus exert a critical regulatory control over the magnitude of the rapid, $Ca^{2+}$-mediated signaling. In addition to these fast acting steps, the $Ca^{2+}$ ►homeostasis is also maintained by slower endogenous $Ca^{2+}$ buffers, such as the mitochondria, the SERCA pumps, the plasma membrane plasma membrane ►NCX – $Na^{+}$-$Ca^{2+}$ exchanger and the ►PMCA – plasma membrane $Ca^{2+}$-ATPase pumps (Ion transport) – all of which curtail subsequent $Ca^{2+}$ signaling. The role/s of these various $Ca^{2+}$-regulatory steps are not only cell type-specific, but they also vary within a cell from its somal to extrasomal compartments. Recent advances in various imaging and molecular techniques are enabling a greater understanding of the mechanisms by which various regulatory steps maintain $Ca^{2+}$ homeostasis and these are described by Amy Tse et al. (►influence of $Ca^{2+}$ homeostasis on neurosecretion).

In contrast to classical transmitters such a dopamine, serotonin and ►acetylcholine, much less is known about the secretary machinery that regulates the release of dense-cored vesicles containing neuro-►hormones or peptides. Fred Tse (►non-synaptic release) and colleagues have developed reliable carbon fiber ►amperometry approaches to define the kinetics of transmitters (such as ►catecholamines) release at the resolution of single granule cells. The Tse lab and others have also demonstrated the involvement of the ►SNARE complex in the release machinery to provide direct evidence that kinetics of release probability is highly variable from cell to cell and relies, in many important ways, on $Ca^{2+}$ sensitivity of the system. Because the release of polypeptides and peptidergic neurochemical substances occurs at a relatively slower time scale, a great deal is now known about the cellular and molecular mechanisms underlying their mode of release. A variety of peptide messengers have now been shown to regulate important neuronal programs in a number of species.

In their chapter ►neuropeptides in energy balance Chee and Colmers describe how ►neuropeptides modulate hypothalamic circuitry to regulate energy balance. Their work underscores the importance of peptides such as ►melacocortin, ►corticotrophin-releasing hormones (CRH) and CRH-like peptide and ►neuropeptide Y, ►agouti-related peptide (AgRP), ►melanin-concentrating hormone (MCH), ►orexin etc. in regulating food intake and body metabolism. This is an impressive list of candidate molecules that appear to be specifically released to regulate energy balance in various animal models. Deciphering their precise roles is the focus of many laboratories and the studies are deemed important for obesity research.

While it is generally believed that most proteins such as the neuropeptides destined for various extrasomal sites (axons, dendrites and synapses), are synthesized at the soma and then selectively transported to these regions, this dogma has however, been recently challenged. Specifically, several recent studies have provided ample convincing evidence that the extrasomal compartments are able to synthesize a host of synapse- and plasticity-specific proteins *de novo*. Support for this notion stems from earlier studies where a host of mRNA species were identified in dendrites and axons where they were selectively targeted to specific synaptic sites following an activity-dependent mechanism. Subsequent studies using a number of molecular and radio-labeling techniques demonstrated that the targeted mRNA was indeed able to translate specific protein locally. Furthermore, injection of foreign mRNA into the extrasomal compartments was also shown not only to result in the production of encoded proteins but also that these proteins were functional. The impact of this research, which is highlighted by van Minnen in ►extrasomal protein synthesis in neurons are far-reaching and perhaps will be one of the most exciting areas of neuroscience in the years to come.

Once the developmental program has established a complete repertoire of synaptic connectivity, the neuronal networks are put to work through myriad modes of neuronal communication. These range from excitatory to inhibitory to mixed excitatory/inhibitory connections. While the synaptic transmission in general is predominantly chemical, the role of ►electrically coupled networks cannot be underestimated. Specifically, in addition to conventional chemical synapses, many neurons may also connect to each other through ►gap junctions where the membranes of two neurons become contiguous. Current in one cell may pass unabated to another without the need for a ►synaptic delay. While such gap junctions are predominant during development, their presence in the adult nervous system is only beginning to be realized in most vertebrates. In invertebrates, however, electrically coupled networks are quite common where they are often recruited to trigger fast ►escape responses that are critical for their survival and thus cannot afford the synaptic delays which are the hallmark of most chemical synapses. The precise nature of both structural and functional attributes of gap junction/tight junction or electrically coupled cells is wonderfully described by Wildering in the chapter on ►electrical synapses. Blocking gap junctions during early development has been shown to perturb nervous system development; their precise functions in the adult mammalian brain are, however, yet to be fully understood. It is nevertheless generally agreed that one of the hallmarks of gap junctions is to synchronize pattern activity either during a patterned motor program or pathological discharges such as epilepsy.

One of the most fascinating aspects of the neuronal uniqueness is the ability of a network of central pattern-generating neurons to exhibit rhythmical activity in the absence of the peripheral feedback. These networks of neurons, often termed ►central pattern generators (CPG), control a variety of rhythmical behaviors such as ►locomotion, ►respiration, ►feeding, mastication etc. Because CPG neurons can generate fictive, patterned activity underlying a rhythmical behavior, even in an isolated preparation, a great deal is known about intrinsic membrane properties that generate a well-organized motor output. In some instance, neurons are known to possess ►pacemaker potentials, which can generate endogenous bursting patterns; however, the ►rhythmogenesis is always a network phenomenon in both vertebrates and invertebrates. In a serious of chapters written by Bell (►peripheral feedback and rhythm generation), Straub (central pattern generator) and Whelan (►neurotransmitters and pattern generation) we learn a great deal about various intrinsic membrane properties (pacemaker potential, ►endogenous bursters, ►conditional bursters, etc) and synaptic interactions (excitatory/inhibitory, ►half-center model, ►reciprocal inhibition, ►postinhibitory rebound excitation, ramp generators, recurrent inhibition etc.) underlying patterned motor activity. Even though the CPG neurons have been known to generate patterned activity in the absence of any peripheral feedback, Bell (peripheral feedback and rhythm generation) demonstrates how peripheral feedback could be critical for the initiation, modulation and termination of the patterned activity. He specifically focuses on the role of hypoxia-sensitive chemosensory drive from the carotid body chemoreceptors, and how it affects the patterned respiratory discharges. Bell then discusses how these networks of rhythm-generating neurons are similar in both vertebrate and invertebrate animals – assuring us that the fundamental building blocks of CPG neurons are likely conserved throughout the animal kingdom. While Straub (central pattern generator) illuminates various membrane and network properties that are the hallmark of pattern generation, Whelan (neurotransmitters and pattern generation) examines structural, functional and transmitter (serotonin, dopamine etc) organization of the CPG underlying locomotor behavior in mammals. Whereas in some invertebrate models, ►command neurons are thought to be sufficient and necessary to trigger a patterned discharge, it is generally believed that the rhythm generation is a function of polymorphic nature of the network. In this configuration, the network exhibits a highly dynamic repertoire of activity patterns thus allowing greater flexibility within the network. Neuronal networks are thus known not to be hardwired, rather they exhibit great flexibility – allowing a subset of neurons to switch between inter-related networks. A similar reorganization of the network behavior is observed following trauma and injury whereby uninjured neurons either take on additional assignments or switch their roles from one to another.

In contrast to their central counterparts, most peripheral neurons are able to regenerate their axonal projections after injury (►Regeneration). Although this regeneration appears to re-capitulate developmental patterns of growth, the ►reinnervation is often incomplete, mismatched and often accompanied with ►neuropathic pain. Tremendous efforts are therefore being made to improve the outcome of ►peripheral injuries by either manipulating the extracellular environment or the surgical interventions. Zochodne (►axon degeneration and regeneration of peripheral neurons) provides a very comprehensive account for cellular and molecular changes that occur immediately after a peripheral injury (►neurapraxia, ►axonotmesis, neurotemesis and how this signal is conveyed to the cell body to activate the "regenerative program." It is generally believed that an immediate injury response triggers a massive $Ca^{2+}$ influx, which in turn activates a cascade of events that lead to the ►microtubular

disorganization and ►neurofilament dissolution. Subsequent SC activation then results in microphage invasion, an upregulation of ►cytokines and ►chemokines – including IL-1β, IL-6, IFN-γ, TNF-α, MCP-1 (monocyte chemoattractant protein-1) and MIP-1α (►macrophage inflammatory protein 1α) followed by a complete breakdown of ►myelin. In the presence of appropriate trophic factors, ►nitric oxide, and various substrate adhesion molecules, a neuron then triggers its regenerative program, which begins with the initiation of new neurites and the re-establishment of synaptic connectivity. In contrast with the above described crush injuries, nerve transsections often result in ►Wallerian degeneration (neurotmesis or Sunderland Type V injury), which involves breakdown of axons and myelin distal to the injury site. It is interesting to note that the regeneration re-activates many but not all elements of the developmental program and as a consequence the functional recovery after nerve injury is often incomplete. Several novel approaches are being developed to enhance the clinical outcomes of nerve injury and are described in detail by Midha (►peripheral nerve regeneration and nerve repair). Specifically, Midha provides extensive overview vis-à-vis the pros and cons of ►nerve grafts, electrical stimulation paradigm and ►nerve conduits that are being used clinically. This chapter also provides a detailed account of various bio-engineering approaches that are being developed to create nerve conduits that may, in the future, play "active" rather than passive roles in promoting nerve regeneration. This approach most certainly holds tremendous potential and is being perused extensively by Zochodne and Midha labs.

### Summary

A neuron is considered as the functional unit of the nervous system, whereas a synapse serves as a gatekeeper of all neuronal communication. Over the past 50 years our understanding of both the structural and functional attributes of neurons and synapses has been enhanced tremendously. Specifically, a great deal is now known about the intrinsic membrane properties that contribute to neuronal excitability and shape its unique characteristics. Every unique neuronal trait in turn, makes specific contributions to synaptic properties of the network in which it is embedded. Neurochemical, electrochemical and/or electro-electrical properties empower a network to generate rhythmical patterns, which in turn control important behaviors – ranging from simple reflexes to complex motor patterns and learning and memory. These connectivity patterns are orchestrated early during development and are constantly re-organized and reconfigured throughout life. Perturbation to either the intrinsic membrane or synaptic properties renders the nervous system dysfunctional thus resulting in the permanent loss of neuronal function. Restoration of this connectivity is perhaps one of the greatest challenges facing the neuroscientists – an area that requires extensive efforts not only by the basic scientists, clinical investigators but also the bio-medical engineers and nano-engineers. A multidisciplinary approach is likely to yield bionic hybrids, which can then be interfaced with neurons to resort lost brain function. For instance, bio-compatible and neuron-friendly chips that can be interfaced with networks of brain cells will not only enhance our understanding of brain function but also regain the lost nervous system function. Although challenging – this appears to be the most promising avenue towards regeneration and functional repair of the injured nervous system.

## Neuron-to-neuron Communication

►Synapse Formation: Neuromuscular Junction Versus Central Nervous System

## Neuronal Cell Death and Axonal Degeneration: Neurofilaments as Biomarkers

Axel Petzold, Department of Neuroimmunology, Institute of Neurology, University College London, London, UK

### Definitions

The aim of this chapter is to explain why ►neurofilaments (Nf) are a useful ►biomarker for ►axonal degeneration and can be used as a surrogate endpoint in clinical and experimental research (►surrogate outcome).

Neurofilaments: Nf are proteins which are exclusively expressed in neurons and their adjacent axons. Nf are particularly abundant in the axon, where they are key building blocks of the axonal cytoskeleton. The complex protein chemistry of Nf is briefly described.

Biomarker: A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacological responses to therapeutic intervention.

Surrogate endpoint: defines a biomarker that is intended to serve as a substitute of a clinically meaningful endpoint and is expected to predict the effect of a therapeutic intervention or the evolution of disease.

## Characteristics

### Quantitative Description

Nf are obligate heteropolymers (►polymer) that are composed of four subunits: a light (NfL), a medium (NfM), a heavy (NfH) [1] chain and also ►alpha-internexin [2,3]. In some cases, peripherin may be added to the list [2]. These subunits differ not only in their molecular weight, but also in their functional properties, as discussed below.

### NfL

The ►neurofilament light chain (NFL) is coded on chromosome 8p21 and consists of 543 amino acids. The molecular mass corresponds to 61 kDa, but due to phosphorylation and glycosylation, migration in sodium dodecyl sulfate (SDS) polyacrylamide gels (PAGE) is slow, and most authors refer to a molecular mass of 68 kDa as determined in SDS-PAGE. NfL forms the back-bone of the Nf heteropolymer and can self-assemble. Mutations in the NfL gene have been associated with Charcot-Marie Tooth disease.

### NfM

The ►neurofilament medium chain (NfM) is also coded on chromosome 8p21 and consists of 916 amino acids. The molecular mass is calculated as 102.5 kDa, and runs at 150 kDa in SDS gels. NfM is important for the radial axonal growth. One mutation in the NfM gene has been associated with Parkinsons disease.

### NfH

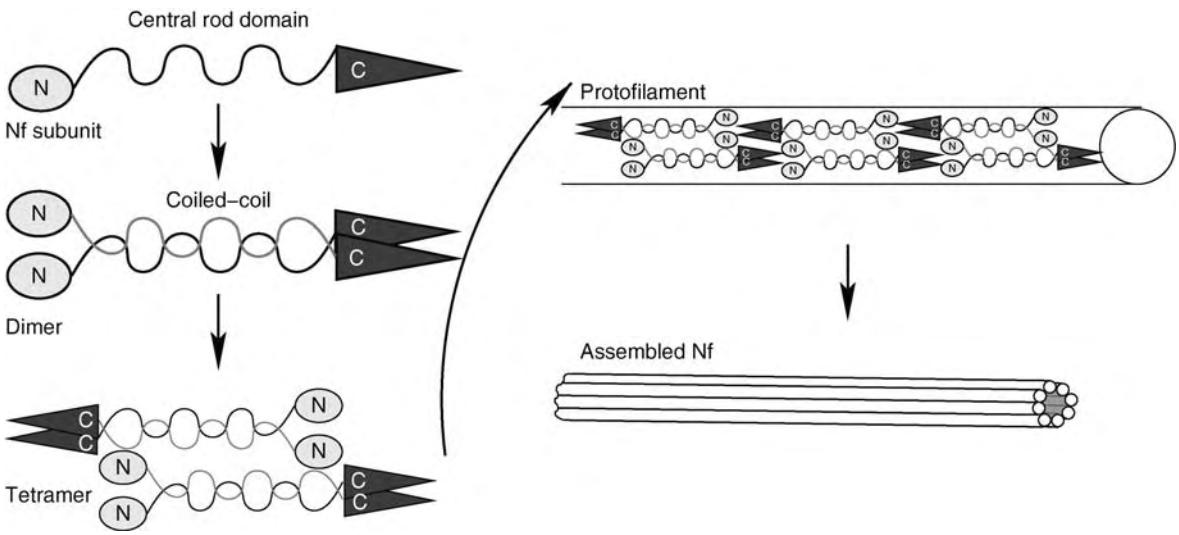
The ►neurofilament heavy chain (NfH) is coded on chromosome 22q12.2 and consists of 1,020 amino acids. The molecular mass of the amino acids corresponds to 111 kDa. Most authors however refer to the molecular mass derived from SDS gels which is also influenced by the charge/weight of bound phosphate and therefore ranges from 190 to 210 kDa for the various phosphoforms. NfH is important for protein-protein interactions which is regulated locally in the axon by phosphorylation. Mutations in the NfH gene have been associated with amyotrophic lateral sclerosis (ALS).

### Alpha-Internexin

The 66 kDa alpha-internexin protein is coded on chromosome 10q24.33 and able to form homopolymers. Alpha-internexin has only recently been rediscovered as one of the Nf subunits and the role of alpha-internexin is still poorly understood [3]. Extracellular deposits of alpha-internexin are an important hallmark of a newly discovered neurodegenerative dementia named neurofilament inclusion disease (NFID).

### Assembly of the Nf Heteropolymer

Figure 1 illustrated how NfL, NfM and NfH assemble to produce the Nf heteropolymer, which has a diameter of about 10 nm. Because of its size, which is intermediate



**Neuronal Cell Death and Axonal Degeneration: Neurofilaments as Biomarkers. Figure 1** Neurofilament assembly. The central rod domain of the Nf subunits is intertwined in order to form dimers. The dimers are arranged antiparallel to form tetramers. Tetramers combine to form protofilaments, which finally assemble to produce the 10 nm thick Nf (figure reprinted with permission from reference [4]).

between the smaller proteins, e.g. microfilaments (7 nm) and larger proteins such as microtubules (approximately 25 nm), the Nf heteropolymer belongs to the intermediate filaments.

## Stoichiometry of the Nf Subunits

The estimated in vitro molar ratio of isolated Nfs from the mouse optic nerve and spinal cord is 4:2:2:1 (NfL:a – internexin:NfM:NfH) [3]. The in vivo stoichiometry of Nfs in body fluids remains unknown.

## Classification of Nf

Nf are type IV intermediate filaments (Table 1).

## Nf are a Biomarker for Axonal Degeneration

Nf subunits are useful biomarkers for axonal degeneration, as illustrated in Fig. 2. Any insult causing neuronal death or axonal degeneration will inevitably result in disintegration of the axonal membrane. Subsequently the contents of the axonal cytoplasm are released into the ►extracellular fluid (ECF). From the ECF Nfs diffuse into other body fluid compartments such as the ►cerebrospinal fluid (CSF), blood or amniotic fluid. As explained above Nf are a major structural protein component of the axon and the quantification of Nfs from body fluids therefore allows estimation of the degree of axonal degeneration.

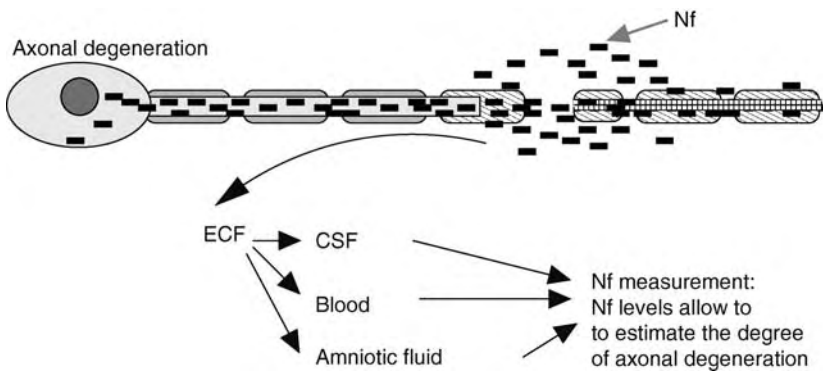
## The Measurement of Nf Body Fluid Levels

At present, high-throughput quantification of Nfs from body fluids and tissue homogenates is best achieved using enzyme linked immune assays (ELISA). In-house ELISAs have been developed for NfL and NfH [5–8]. These assays are highly robust and have been cross-validated [9,10]. A commercial NfH ELISA kit has recently been made available (Chemicon). Alternatively immunoblots or dot-blot assays have

**Neuronal Cell Death and Axonal Degeneration: Neurofilaments as Biomarkers. Table 1** Classification of intermediate filaments and cell-type specificity

| Class | Identity | Cell-type specificity |
|---|---|---|
| Type I | Acidic keratins | Epithelial |
| Type II | Neutral & Basic keratins | Epithelial |
| Type III | GFAP | *Astrocyte* |
| | Peripherin | Neuronal (peripheral) |
| | Vimetin | Mesenchymal |
| | Desmin | Muscle |
| Type IV | NfL, NfM, NfH | *Neuron and axon* |
| | Alpha-internexin | *Neuron and axon* |
| Type V | Laminin A, B, C | Most cells |
| Type VI | Nestin | CNS stem cells |

GFAP = glial fibrillary acidic protein.



**Neuronal Cell Death and Axonal Degeneration: Neurofilaments as Biomarkers. Figure 2** Neurofilaments are released into the extracellular fluid (ECF) following axonal disintegration. From the ECF Nfs equilibrate with the adjacent body fluid compartment. Quantification of Nfs is therefore possible from the cerebrospinal fluid (CSF), blood and amniotic fluid. The degree of axonal degeneration is related to the amount of Nf measured in these body fluids. For this reason body fluid Nf levels permit the estimation of the amount of axonal degeneration. Axonal degeneration is extremely important because the loss of axons is irreversible and may therefore lead to persistent disability.

been used, but generally they are not high-throughput and only semi-quantitative.

### *The Diseases Associated with High Body Fluid Nf Levels*

Neuronal loss and axonal degeneration are a key feature in numerous disorders and frequently represent the endstage of a pathophysiological cascade. Not surprisingly, body fluid levels of Nf subunits have been used to estimate the degree of axonal damage in a number of diseases (Table 2). It is important to remember that body fluid Nf levels are not a diagnostic test for one single disease. In contrast Nf are a biomarker and surrogate enpoint according to the initial definitions.

## Conclusion

Neurofilaments are complex proteins composed of four subunits, expressed exclusively in the neuro-axonal compartment. Nf are released into the extracellular fluid from degenerating axons. From the extracellular fluid they diffuse into adjacent body fluid compartments. Using standard ELISA techniques Nf subunits have been quantified from the cerebrospinal fluid, the blood and the amniotic fluid. Because body fluid levels of Nf are related to the amount of neuronal death and axonal loss, they provide valuable prognostic information and correlate with disability in a number of diseases.

**Neuronal Cell Death and Axonal Degeneration: Neurofilaments as Biomarkers. Table 2** Diseases in which Nf have been used as a body fluid biomarker for neuronal death and axonal degeneration

| Disease | Findings |
|---|---|
| AD | CSF NfL and NfH levels are elevated in AD. The difference from controls was marginal for CSF NfH levels and more impressive for NfL levels |
| ALS | CSF NfL and NfH levels are considerably increased in patients with ALS. Rapidly progressing ALS patients had the highest CSF NfH levels |
| CBD | CSF NfL and NfH levels are elevated in patients with CBD |
| FTLD | CSF NfL is elevated and CSF NfH marginally elevated in patients with FLTD. The degree of NfH phosphorylation is increased in FTLD compared to AD and controls |
| GBS | Elevated CSF NfH levels in patients with GBS are a poor prognostic sign, probably due to proximal axonal degeneration. Proximal axonal degeneration at the level of the nerve roots rapidly releases Nfs into the CSF. Proximal axonotmesis requires axonal regrowth over a long distance with the risk of losing chemical and anatomical guidance cues |
| ICH | CSF NfH levels are high in ICH, probably indicating direct axonal degeneration due to rupture and ischemia |
| DLB | CSF NfH but not NfL levels are elevated in DLB compared to AD and controls |
| MMC | Amniotic fluid NfH levels are elevated in mice with MMC and correlated with the size of the lesion |
| MS | CSF NfH and NfL levels are elevated in MS. CSF NfL levels are highest following a clinical relapse and return to baseline within about 3 months. CSF NfH levels are highest in the secondary progressive phase of the disease when axonal degeneration accumulates. The degree of NfH phosphorylation is increased in patient with more severe disease. High CSF NfH levels are a poor prognostic sign. Both CSF NfL and NfH levels correlate with disability |
| MSA | CSF NfL and NfH levels are markedly elevated in MSA compared to controls and patients with PD. This may be related to the greater degree and more rapid disease progression in MSA. The highest levels are found in patients with the cerebellar variant of MSA, which may be of help for the differential diagnosis of patients with cerebellar syndromes |
| NMO | CSF NfH levels are considerably elevated in NMO (synonymous with Devic's disease) suggesting that these patients suffer from substantially more axonal damage than patients with MS or ON |
| ON | Plasma NfH levels are increased in acute ON. CSF NfH levels are elevated in patients with subacute ON. Plasma and CSF NfH levels correlate with loss of visual function |
| PD | CSF NfH and NfL levels are increased in PD compared to controls |
| PSP | CSF NfL and NfH levels are elevated in PSP compared to controls and patients with PD. As with MSA this may be related to the greater degree of axonal loss and more rapid disease progression in PSP patients, who are also very resistant to pharmacological treatment |
| SAH | CSF NfL and NfH levels are elevated in SAH and correlated with the outcome. Importantly CSF NfH levels showed a secondary increase during the high risk period of vasospasm, probably indicating secondary axonal degeneration following an ischemic insult |

AD = Alzheimer's disease, ALS = amyotrophic lateral sclerosis, CBD = cortico-basal degeneration, DLB = Diffuse Lewy body disease, FTLD = fronto-temporal lobar degeneration, GBS = Guillain–Barré syndrome, ICH = intracerebral haemorrhage, MMC = meningo-myelocele, MS = multiple sclerosis, MSA = multiple system atrophy, NMO = neuromyelitis optica, ON = optic neuritis, PD = Parkinson's disease, PSP = progressive supranuclear palsy, SAH = subarachnoid haemorrhage.

## Synonyms

Excitotoxicity; Apoptosis; Necrosis; Virotexias; Encephalitis; Chemokines; Cytokines; Chemtaxis; Blood brain barrier; Matrix metallo Proteinases

## Definition

Exitotoxicity is a mechanism which often leads to Neuronal cell damage or death. Excitotoxicity occurs when glutamate receptors on neurons are overactivated. Neuronophagia occurs when nerve cells are phagocytosed or internalized by macrophages. This often happens to clear debris after the neurons have undergone apoptosis, but in some neuroinflammatory or neurodegenerative conditions, the neurons may be killed as the macrophages digest them. Necrosis is a process of cell death whereby cells swell, rupture, and release their contents, causing ►inflammation and damage to neighboring cells. In the nervous system, this usually happens in response to stroke or trauma. In contrast to necrosis, apoptosis is a form of cell death which does not cause inflammation, but, rather, is frequently the result of inflammatory processes. Therefore, the mechanism of neuronal cell death which usually occurs in the setting of neuroinflammatory and neuro-infectious diseases is apoptosis. Unlike necrosis, apoptosis occurs via a controlled sequence of events, starting with an initial trigger, then proceeding through a specific signaling cascade, resulting in breakdown of the chromatin and shrinkage of the nucleus and cellular contents without rupture of the cell membrane. See Table 1.

Neuronal cell death is the irreversible loss of function of a neuron. Neuroinflammatory diseases such as multiple sclerosis, transverse myelitis, and neurosarcoidosis are characterized by episodic immune activation, which results in nervous system injury. Although an infectious etiology has long been suspected in these diseases, none has been conclusively demonstrated. Other chronic neurodegenerative diseases, such as Alzheimer's disease, also have chronic glial cell activation. It remains unknown if this chronic activation is needed to provide trophic support for injured neurons or if ►cytokines and other host factors released by these cells may be injurious. ►Virotoxins and other infectious agents may trigger immune cascades that can persist long after the infection has been controlled or eradicated, a mechanism of injury that has been termed the "hit and run phenomenon." This persistent immune activation can lead to neuronal injury resulting in neurocognitive impairment. There are many in vitro and in vivo models of neuroinflammatory conditions which allow us to study the effects of immune responses on the nervous system. Although many different conditions produce a neuroinflammatory state, the host repertoire for immune response and the mechanisms for subsequent neuronal death or dysfunction are relatively limited. It is thus hoped that the study of any one of these diseases or model systems will be widely applicable to other autoimmune and neurodegenerative diseases in which immune activation is an important component.

Neuronal cell death is common in patients with both infectious and non-infectious neuroinflammatory

**Neuronal Cell Death and Inflammation. Table 1** Features of necrosis versus apoptosis

| Feature | Apoptosis | Necrosis |
|---|---|---|
| Cell size | Shrunken, small | Swollen, enlarged |
| Inflammation | Inflammation causes apoptosis | Necrosis causes inflammation |
| Leakage | Cell contents intact | Cell contents leak out |
| Membrane | Intact | Disrupted |
| Nucleus | Fragmented | Condensed |
| Role | Often physiological | Always pathological |

conditions. Even in many infectious conditions, such as HIV infection, neurons themselves are frequently not directly infected. Thus, in all of these conditions, the observed loss of neurons is likely due to indirect effects of inflammatory mediators and/or infectious proteins. A process called apoptosis is the primary mechanism through which neurons die. Apoptosis may also be seen in some other cells of the nervous system, including astrocytes and endothelial cells. Neuronal apoptosis correlates with microglial activation and axonal damage, suggesting that the inflammatory mediators secreted by microglia and other immune cells play a major role in initiating the apoptotic cascades.

Importantly, recent studies have shown that neuronal injury may occur without cell death. The clinical manifestations of neuroinflammatory conditions are likely due to neuronal dysfunction via multiple mechanisms. Although massive neuronal loss may occur in many neuroinflammatory conditions, it often occurs late in disease, and may not be the cause of early clinical manifestations. Some inflammatory pathways, and related dysfunction, may be reversible with strategic neuroprotective and immunomodulatory strategies. Pathological studies have demonstrated injury types which are likely to be reversible, including morphological changes in dendrites and loss of neurites without neuronal cell loss. Such dendritic injury and loss, without neuronal cell body loss, is often called dendritic pruning. Similarly, axonal injury can occur without death of neuronal cell bodies. This raises great hope for the potential use of neurotrophic modes of therapy for neuroinflammatory and neurodegenerative diseases.

## Characteristics

The mechanisms by which inflammatory conditions and infections lead to neuronal cell death and dysfunction, as well as associated clinical conditions like ►encephalitis, ►vasculitis, or dementia, remain elusive. In many cases, the inflammation generated by the host, in an attempt to combat a presumed or real infection, is itself implicated as a primary factor in causing neuronal dysfunction or degeneration. In this essay, we outline the current state of knowledge regarding the pathophysiology of central nervous system injury in infectious or inflammatory conditions. Understanding these mechanisms should ultimately enable development of immunomodulatory therapies for treating these conditions.

## Description of the Process

Inflammation in the nervous system is dependent on two main features: infiltration of monocytes from the peripheral blood into the brain, and activation of microglia, which are the immune cells that are always present in the brain. In viral infections, such as HIV, the virus itself or viral proteins can activate uninfected cells directly. In non-infectious conditions, the inciting agent(s) may be unknown, but these immune cells are likely activated in a similar fashion. Then, in an attempt to eradicate the presumed or real infection in the brain, these immune cells are likely most responsible for the neuroinflammatory and neurotoxic cascades which lead to brain injury. These cells express tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), interferon-α (INF-α), and nitric oxide synthase (NOS), among other inflammatory mediators [1]. It should be noted, however, that these cells may have neuroprotective properties as well. In fact, immune cells typically serve beneficial functions. This may suggest that the immune response does not become damaging until it becomes dysregulated and chronic.

Cytokines and ►chemokines are multifunctional proteins which regulate individual cells under physiological or pathological conditions. They are important mediators for communication between nervous tissues and immune cells and are thus very important in the induction and regulation of inflammation in the nervous system, and thus to the progression or inhibition of neurodegeneration [1]. They are expressed by the peripheral immune cells which have entered the brain often across a defective ►blood–brain barrier, by activated microglia, by astrocytes, and even by certain neurons. They include, but are not limited to, IL-1, IL-8, RANTES, TNF-α, SDF-1, and MCP-1. MCP-1 is a potent chemoattractant for monocytes, drawing them into the brain from the peripheral blood in a process called ►chemotaxis, so that they, in turn, can produce even more inflammatory cytokines. Many of these cytokines/chemokines have both deleterious and beneficial effects,

so the net effect is likely the result of a complex set of interactions and conditions and is very difficult to predict a priori or to determine experimentally.

Neuronal injury can be triggered by various mechanisms. Binding of various cytokines and chemokine receptors either by the cytokines/chemokines themselves (especially TNF-α) or by viral proteins or other neurotoxic agents will lead to increases of intracellular calcium. Similarly, inflammatory conditions may promote excitotoxicity. Neuroinflammatory proteins may either directly stimulate the neuronal glutamate NMDA receptor or may sensitize neurons to the effects of otherwise physiological levels of glutamate. Excessive or chronic stimulation of this receptor results in a long cascade, again leading to increased intracellular calcium. Increased calcium leads to loss of mitochondrial membrane potential, release of cytochrome c, activation of caspases, and apoptosis [2]. Excitotoxicity also leads to production of nitric oxide and free radicals which in turn produce oxidative damage, energy failure, and DNA damage.

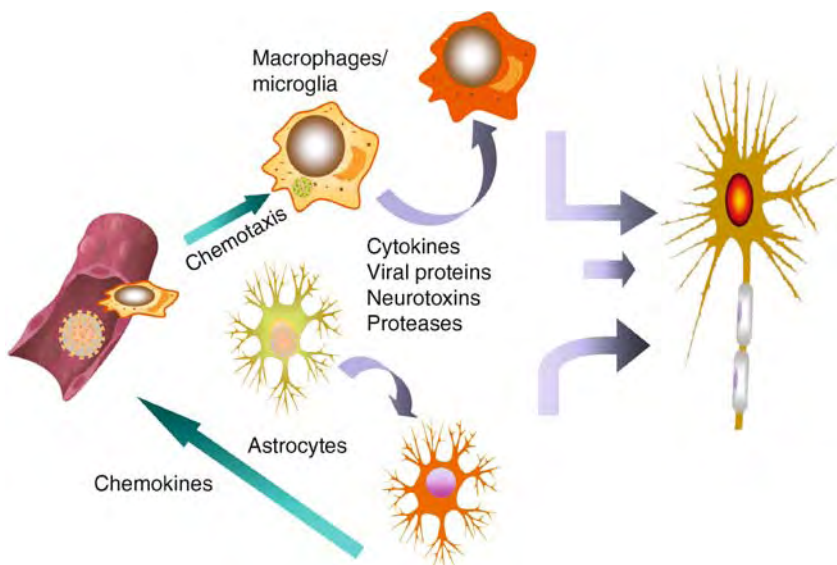
Figure 1 depicts the complex interactions between toxic cellular proteins, viral proteins, and the immune response, which lead to neurotoxicity in vitro and to the neurological complications of inflammatory and/or infectious conditions clinically.

## Higher Level Processes and Conditions

Reactive astrocytes are common in these neuroinflammatory conditions and they participate in the production of neurotoxic substances, such as TNF-α, and other inflammatory mediators. Activation of astrocytes can alter their function in other ways as well, leading to loss of support for neurons, in turn making the neurons more susceptible to injury or death.

Periventricular white matter pallor is also frequently observed in these conditions. Depending on the specific condition, this can be associated with damage to the oligodendrocytes and/or the myelin sheath which wraps around neuronal axons, or, alternatively, it can be associated with subtle changes of the ▶blood–brain barrier (BBB) secondary to inflammation. Inflammation can affect the expression and assembly of ▶tight junction proteins, leading to cytoskeletal disruption of endothelial cells and increased endothelial permeability. White matter changes on MRI seem to correlate with perivascular macrophage infiltrates, extravasation of protein, and blood–brain barrier compromise. Endothelial cells and astrocytes functionally form the blood–brain barrier, so injury to either of these cell types can compromise the blood–brain barrier. Endothelial cells may also increase expression of adhesion molecules [3], allowing easier entry of peripheral immune cells into the brain. A compromised blood–brain barrier allows immune cells, inflammatory mediators, and neurotoxins from the peripheral blood to enter the nervous system where they can participate in damaging and killing neurons. Sometimes, however, these white matter changes are reversible, with associated improvement in clinical manifestations.

Various viral infections have been used extensively as model systems for neuroinflammatory conditions,



**Neuronal Cell Death and Inflammation. Figure 1** Through multiple indirect mechanisms, neurons become dysfunctional and die in the setting of inflammatory and infectious conditions. Inflammatory mediators can be toxic to neurons directly, can alter glial function, and can further activate the immune response, all of which damages the nervous system. The arrows in the figure demonstrate the existence of these complex feed back loops.

and such studies have elucidated mechanisms which are widely applicable. Neurons may die upon interaction with viral proteins, while uninfected microglia, monocytes, and astrocytes are activated upon such interaction. These activated cells release a variety of proinflammatory factors, including cytokines, chemokines, free radicals, matrix metalloproteinases (MMPs), and prostanoids, which may result in secondary neuronal toxicity or further immune cell activation and reactive gliosis. This amplification of the immune cascade after an initial trigger has been termed the "domino effect" [4]. Once the domino effect has been initiated, the inflammatory process may be self-propogating, even if the initial trigger is no longer present, resulting in the "hit and run" phenomenon [5].

MMPs are a family of endopeptidases which enzymatically degrade extracellular matrix proteins and can thus disrupt the blood–brain barrier and neuronal synapses [6]. MMP levels are elevated in the spinal fluid and/or brains of patients with many neuroinflammatory or neurodegenerative conditions, suggesting they may contribute to the neuropathogenesis of these conditions. MMPs can cleave chemokines, such as SDF-1, with the cleavage products subsequently causing neurotoxicity, and they can interact with integrin receptors on neurons, initiating apoptosis. Furthermore, they can become nitrosylated and hyperactive, contributing to neurotoxicity under conditions of oxidative stress [7]. MMP expression in monocytes can facilitate monocyte transmigration through the extracellular matrix. However, it should also be noted that cleavage of the chemokine, MCP-3, by MMP-2 has been shown to decrease the inflammatory response [8], and cleavage of HIV Tat protein by MMP-1 attenuates Tat-induced neurotoxicity [9]. Thus, MMPs may be neuroprotective under certain conditions.

## Regulation of the Process

The brains of patients with many of the neuroinflammatory conditions demonstrate up and downregulation of numerous genes compared to control brains. These changes in gene expression profiles are consistent with changes in various neurotransmitter receptor levels and ion currents, which would be expected to alter neuronal excitability. Perhaps these changes in gene expression are in response to the changes in neuronal excitability which are induced by the inflammatory cascades and processes.

## Function

Although the mechanisms of inflammation and neuronal cell death and dysfunction may be quite similar in the various neuroinflammatory conditions, the clinical manifestations may be variable. For reasons which are not well understood, certain areas of the brain may be preferentially affected over other areas [10]. For example, as a result of the inflammation caused by HIV infection, the basal ganglia and hippocampus are preferentially damaged, with neuronal losses of up to 50–90% in patients with severe HIV encephalitis. The cortex is also affected with the frontal lobes having 40–60% neuronal loss, but parietal and temporal lobes having only 20% loss. The cerebellum has even less neuronal loss and the occipital lobe has the least. The locations of the predominant changes accounts for the predominant symptoms of HIV dementia, including psychomotor slowing and memory impairment.

It is not surprising that a prolonged, poorly controlled inflammatory reaction in the nervous system would result in neurodegeneration. Neurological outcome from these conditions depends on the interplay of a complicated network consisting of various cell types, pro- and anti-inflammatory factors, viral virulence factors, and host susceptibility factors. A successful therapeutic strategy to treat inflammation-mediated neurodegeneration will likely require a multi-faceted approach, aiming to not only inhibit proinflammatory factors but also to increase neuroprotective and neurotrophic factors.

# Neuronal Changes in Axonal Degeneration and Regeneration

Håkan Aldskogius
Uppsala University Biomedical Center,
Department of Neuroscience, Uppsala, Sweden

## Synonyms

Axon reaction; Retrograde neuron reaction; Chromatolysis

## Definition

Following injury to the ►axon, the affected nerve cell body (►soma) with its associated processes undergo a sequence of structural and molecular changes, collectively termed the ►axon reaction or ►retrograde neuron reaction. ►Chromatolysis is sometimes used as a synonym, but in a strict sense refers to the marked reduction (dissolution) of basophilic ►Nissl bodies caused by axon injury (Fig. 1).

Neuronal changes to axon injury are fundamental pathophysiological events in any neurological condition, which interrupts axons in the peripheral or central nervous system, or in which the normal peripheral or central target for the neuron is lost.

## Characteristics

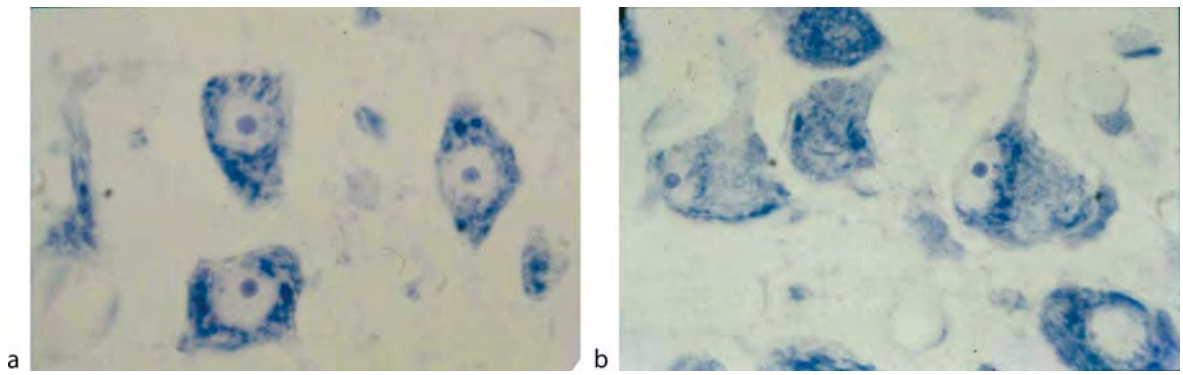
### General Characteristics

The neuronal changes to axon injury include responses to overcome the ►cellular stress imposed by the injury, as well as a reorganization of the overall cell morphology and cellular metabolism from a "transmitting" to a "growing" mode. The latter implies that the expression of genes involved in ►neurotransmitter synthesis and release are typically down-regulated, whereas those promoting ►neurite growth are up-regulated [1,2]. As a result of this phenotypic shift, injured neurons in many ways resemble developing neurons. Under the most favorable circumstances, the injured neuron survives, ►regenerates its axon, and restores functional contact with the ►denervated cells/tissue. A sustained up-regulation of ►growth-associated genes is considered necessary for successful regeneration and target ►reinnervation Neurons with axons in the peripheral nervous system, i.e. ►motoneurons ►sensory ganglion cells and ►autonomic neurons all have this ability, whereas neurons with axons entirely within the central nervous system usually do not.

Axon injury consistently affects ►glial cells in the surroundings of the injured nerve cell body and ►dendrites, as well as neurons with ►synapses on the injured neuron. Under certain circumstances, neurons, which are ►presynaptic or ►postsynaptic to the injured neuron undergo ►trans-synaptic changes [3].

### The Phases of Neuronal Changes and Their Regulation

The prototypic neuronal response to injury, as seen following injury to peripheral axons, can be schematically divided in three, overlapping phases. This sequence



**Neuronal Changes in Axonal Degeneration and Regeneration. Figure 1** (a) Normal rat motor neurons showing clumps of dark blue cytoplasmic Nissl bodies stained with a basophilic dye. (b) Rat motor neurons after injury to their axons showing that the Nissl bodies have disappeared, and the cytoplasm acquired a pale color, so-called chromatolysis.

of events applies only in part following injury to axons in the central nervous system (see below).

- The initial phase reflecting the immediate cell stress, and adaptation to loss of target contact; in this phase numerous ►sprouts are formed at the end of the proximal stump of the injured axons
- The phase of axonal elongation; in this phase a subset of the sprouts negotiate their way towards the denervated target; if conditions are sufficiently favorable, target contact is restored
- The phase of maturation of the ►regenerated axon and the return of the neuron to a "transmitting" (normal) mode; in this phase axonal diameter is growing, and ►remyelination of the larger axons is completed

Several factors mediate changes occurring during the initial phase. The injury causes an immediate ►depolarization of the neuron resulting in changes in intracellular ion homeostasis and the release of neurotransmitters and synaptic ►modulators. These early events lead to the induction of ►immediate early genes, which act as ►transcription factors. At a somewhat later point in time, the full transformation of the neuron into a growth state occurs by at least two different processes: (i) molecules from the extracellular environment enter the axon at the injury site and are ►retrogradely transported within the axon to the nerve cell body, and (ii) specific molecules produced by the target cells, so-called ►trophic factors, which normally reach the nerve cell body by retrograde axonal transport, are depleted. Concomitantly, growth promoting molecules, diffusible and associated with the ►extracellular matrix, are up-regulated in cells at the injury site, and in non-neuronal cells in the distal part of the axon. These molecules play a crucial role in the creation of a growth permissive pathway from the injury to the target tissue.

## Changes in Neuronal Morphology

The most striking morphological change in nerve cells following axon injury is the loss of Nissl bodies, making the cytoplasm appear paler than normal (chromatolysis). At the same time, the nerve cell bodies often appear round with their nucleus displaced towards the periphery (away from the exit point of the axon). The ultrastructural basis for chromatolysis is loss of granular ►endoplasmic reticulum. The diameter of the axon proximal to the injury gradually becomes thinner, axon collaterals are lost and the dendrites become shorter. Thus, the overall dimension of the injured neuron is reduced. Following target reinnervation, these changes are only partially reversed. The axon diameter and the normal shape of the ►dendritic tree are typically not restored.

## Changes in Neuronal Gene Expression

The list of changes in gene expression following axon injury is long. Genes involved in the synthesis of the classical neurotransmitters and with ►postsynaptic receptors are down-regulated, as are also genes contributing to structural stability of the neuron. The latter includes genes for proteins of ►neurofilaments, the major stabilizing component of the axon, and certain classes of ►microtubulus-associated proteins (MAPs), which provide structural support to dendrites. All these changes provide the basis for the morphological changes (see above). Genes belonging to the family of ►stress response (heat shock) protein, and the ►chaperon system are up-regulated, as well as genes supportive of axonal sprouting and extension. The latter includes intracellular molecules, which provide building blocks for the elongating axons, as well as membrane-bound and diffusible molecules, which are necessary for appropriate interactions with the environment. Important intracellular growth-associated molecules include ►actin, ►tubulin and several so-called ►growth-associated proteins (GAPs).

## Changes in Glial Cells and Synapses

Striking changes occur in adjacent glial cells as well as in ►synaptic terminals, which cover injured neurons [4–6]. In the central nervous system, non-synaptic neuronal membrane is covered by processes of ►astrocytes. As a result of axon injury, these cells hypertrophy, and increase their coverage of the neuronal membrane in parallel with the disappearance of ►presynaptic terminals. The predominating type of the lost terminals is ►excitatory. ►Microglial cells in the neighborhood of the affected neurons ►proliferate, migrate towards the nerve cell body of the injured neuron, and up-regulate molecules associated with ►immune and inflammatory responses. In autonomic and sensory ganglia of the peripheral nervous system, ►satellite cells, which normally cover nerve cell bodies, proliferate. In addition, monocytes enter from the vascular system, and become transformed to macrophages. In the central nervous system and autonomic ganglia, a large proportion of presynaptic terminals on the cell body and dendrites disappear. The overall result of these changes is that the nerve cell body and dendrites of the injured nerve cell are partially isolated from surrounding influences.

## Differences in Neuronal Changes Following Injury to Peripheral or Central Axons

Neurons with there axons confined to the central nervous system initially respond to injury or loss of target in a similar manner as those with axons in the peripheral nervous system [7]. Central neurons produce sprouts, which are capable of making novel synaptic connections

within a limited distance [8]. However, central neurons are in general unable to mount the sustained up-regulation of growth supporting gene expression necessary for axon elongation, unless their axons are allowed to grow in a peripheral nervous system environment. The failure to sustain a prompt and long-lasting up-regulation of growth supporting genes is the result of intrinsic neuronal factors, in combination with a powerful inhibitory influence of the environment at the injury site and distal to it.

## The Special Case of Sensory Ganglion Cells

Sensory ganglion cells are unique in having one axon projecting to peripheral target tissue, and one centrally, which terminates on postsynaptic neurons in the spinal cord or brainstem. Injury to peripheral sensory axons results in the same sequence of structural and molecular changes in their cell bodies, and proximal axon as described above. In addition, the central process and its terminals are affected. These include a reduction in the diameter of the central process, and changes in the morphology and chemical properties of its central terminals. As a consequence of these changes permanent alterations arise in the transmission of sensory impulses in the spinal cord and brainstem, which may contribute to long-lasting post-injury sensory ►neuropathies, e.g. ►neuropathic pain.

Injury to the central axon is associated with an attenuated neuronal response. The "transmitting" phenotype is essentially intact, and growth supporting gene expression is minimal. The injured axons sprout and elongate, but at a significantly slower rate than after corresponding injury to the peripheral axon. By combining central axon injury with a peripheral one, both axons elongate with the higher rate, and is capable of even moderate growth in the spinal cord itself [9]. The peripheral injury induces a growth state, and act as a ►conditioning lesion that amplifies axon outgrowth from the central process.

## Long term Consequences of Axon Injury in the Peripheral Nervous System

There are three principal outcomes of axon injury: (i) neuron survival, axon regeneration, and functional recovery; (ii) neuron survival, failure of axon regeneration, and no functional recovery; (iii) neuron degeneration.

Successful axon regeneration and functional recovery is possible following injury to axons in the peripheral nervous system. This outcome requires that injured axons are able to enter the distal stump unimpeded, and that the target tissue is not too distant. A prime goal in modern research on peripheral axon injury is to eliminate obstacles to axonal elongation, and to increase its rate. With reconnection to a target, the neuron down-regulates genes expressing growth promoting molecules, the dendritic tree expands, and synaptic coverage increase, i.e. the neuron resumes a mature, "transmitting" phenotype. A complete restoration of the pre-injury state is, however, achieved only under the most favorable circumstances.

In case injured axons fail to make functional peripheral connections, the growth state of the neuron will cease, and nerve cell body and its processes enter a state of prolonged, possibly permanent atrophy, which may be severe. Injury to the axon, e.g. by removal of the ►neuroma at the proximal stump, will re-activate the growth state, and a new attempt to regenerate the injured axon [10].

Degeneration and ►death of neurons is a common consequence of axon injury. The risk of this outcome is significantly increased if axon injury (i) affects immature individuals, (ii) the injury leads to complete separation of the proximal and distal parts of the axon, e.g. the nerve is sectioned rather than crushed, (iii) is close to the nerve cell body, (iv) is combined with injury to afferent axons, a common situation in the central nervous system, and (v) affects certain classes of neurons. Neuron degeneration after axon injury commonly occurs by an intrinsic cell death program, ►apoptosis. The relationship between neuron degeneration and regeneration is complex in the sense that injury circumstances that increase the risk of neuron death also leads to the most powerful growth response.

## Clinical Aspects

Axons in the peripheral nervous system are injured in trauma and many common disorders, e.g. diabetes. Trauma is also a common cause of axon injury in the central nervous system. More common there are axon injury because of disorders of the cerebral blood vessels (►stroke). Axon injury is at least in part a feature of many chronic disorders of the nervous system, e.g. ►Alzheimer's disease. Nerve cell survival is a prerequisite for functional recovery. Intense research is therefore underway to develop optimal strategies for promoting survival of injured neurons, and allow them to regenerate their axon and restore useful functional synaptic contacts.

## Neural Integrator – Horizontal

José M. Delgado-García
División de Neurociencias, Universidad Pablo de Olavide, Sevilla, Spain

### Definition

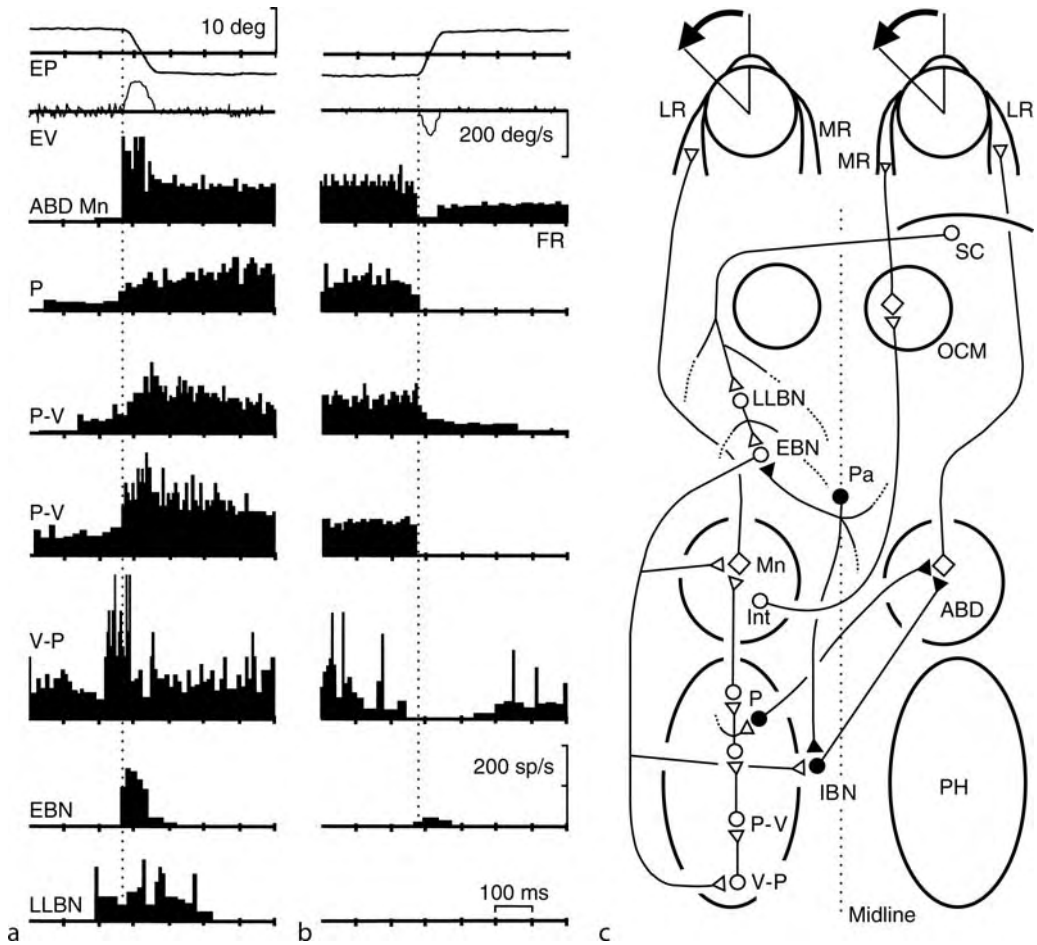
A neural network that receives input signals related to horizontal eye velocity and generates a signal proportional to horizontal eye position that it conveys to extraocular motoneurons.

### Description of the Theory

The eye moves in the horizontal plane under the action of two antagonist extraocular muscles: the lateral rectus and the medial rectus (see the entry devoted to extraocular motoneurons for a description of their source of innervation). To fully compensate for head movements activating vestibular or optokinetic reflexes, or to maintain a given eye position on a target following a voluntary saccade, motoneurons need to receive an eye position signal [1–5]. Although a common neuronal integrator capable of generating eye position signals for all kinds of eye movements was initially proposed [5], recent experimental data indicates that there are several integrators depending on the neural structure responsible for generating oculomotor commands and on the plane of the movement [6]. It is accepted that horizontal and vertical eye position signals are generated separately in the ►nucleus prepositus hypoglossi (PH) and in the interstitial nucleus of Cajal [2,4,7]. Other brainstem and cerebellar structures, such as the medial vestibular nucleus, the marginal zone between the latter and the PH nucleus, and cerebellar areas including the flocculus and the fastigial nucleus, also contain neurons carrying eye position signals (see [8] for references).

## How Horizontal Eye Position Signals are Generated

Permanent and transient blockage of the normal function of neuronal integration in the horizontal plane in both cats and monkeys [6,9–11], supports the assumption that it takes place inside the PH nucleus and/or in the functional interactions established by its reciprocal connections with the vestibular nuclei, the contralateral PH, and the cerebellum. However, a still – unanswered question is: how are eye position signals generated by neuronal centers or circuits? Although the intrinsic connectivity of PH neurons is not completely known, in particular regarding the presence of axon collaterals that project in a feedback (or feedforward) fashion onto other oculomotor-related neurons [3,5,6,8], one hypothesis is that the PH neuronal integrator could generate eye position signals from successive synaptic steps in cascade, lateral, or retrograde chain systems [1,2,8]. As illustrated in Fig. 1, the presence of cascade-like, polysynaptic connections could explain the experimental observation of neuronal types with a wide range of eye motor signals (velocity, velocity-position, position-velocity, position, etc.), and the high susceptibility of



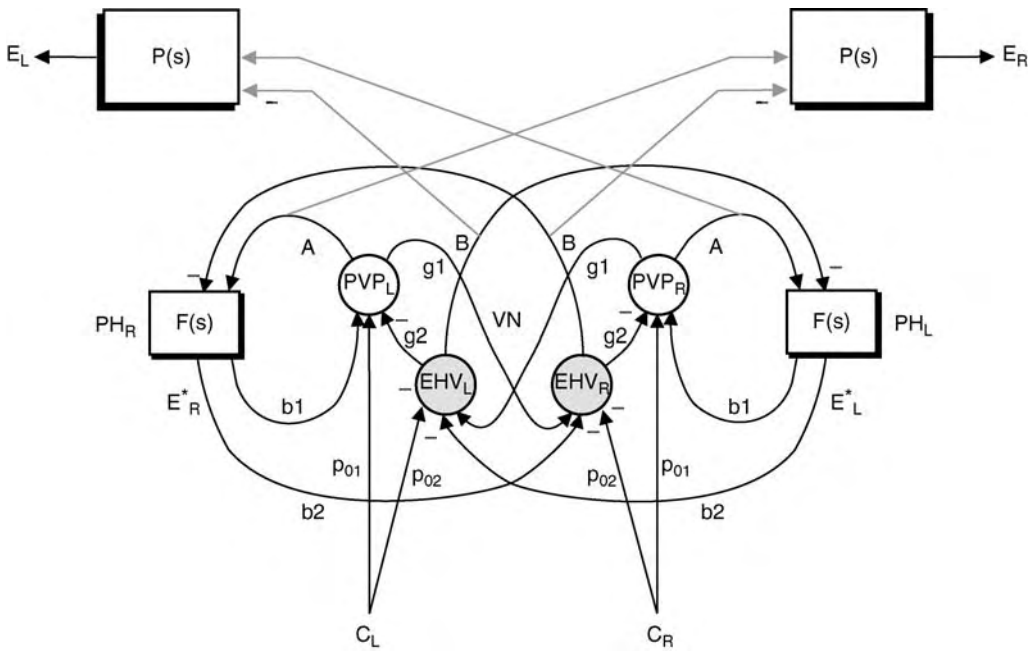
**Neural Integrator – Horizontal. Figure 1** Experimental support for a ►cascade model in the generation of eye position signals in the nucleus prepositus hypoglossi (PH). (a,b) Firing rate of seven different types of neuron recorded in alert cats during eye fixations before and after on- and off-directed saccades. From bottom to top are illustrated the firing rates (FR, in spikes/s) of a long-lead burst neuron (LLBN), an excitatory burst neuron (EBN), four PH neurons showing velocity-position (V-P), position-velocity (P-V), or position (P) signals, and an abducens motoneuron (ABD Mn). Abducens interneurons receive the same inputs as ABD Mns, and relay them to medial rectus Mns located in the oculomotor nucleus (OCM). Representatives horizontal eye position (EP, in deg.) and velocity (in deg/s) corresponding to these neuronal activities are illustrated in the two traces at the top. (c) A diagram illustrating the possible pathways generating eye position signals following a saccadic motor command triggered from the superior colliculus (SC). Abbreviations: *LR*, *MR*, lateral and medial rectus muscles; *IBN*, inhibitory burst neuron; *Pa*, omnipause cells. Modified from Escudero et al. [2], and reproduced with permission of the Physiological Society.

the eye position neuronal system to administration of drugs and anesthetics and to the mental state and attentive level [2,7,8,11]. Moreover, these cascade chains could be superimposed upon the shorter, direct pathways carrying eye velocity signals (Fig. 1c). Evidence supporting the participation of neuronal circuits in the generation of the persisting activity that underlies the integration of eye position signals in goldfish has been reported recently [12].

Pure horizontal eye position neurons seem to project monosynaptically from the PH nucleus onto abducens motoneurons [2]. However, other neuronal types carrying mixed vertical position-velocity signals have been reported to project monosynaptically on vertical motoneurons located in the oculomotor complex [3,4]. According to the available information [2,11,13], PH neurons classified as ►principal cells [13] are the ones responsible of the neural integration taking place in this nucleus, and/or of carrying eye position signals to oculomotor nuclei.

Once generated, horizontal (and vertical) eye position signals seem to arrive at extraocular motoneurons, where they are integrated with (i.e. added to) eye velocity signals arriving from specific reticular formation nuclei. The stabilizing role of the intrinsic membrane properties of ocular motoneurons should also be taken into account. The algebraic addition of eye velocity signals arriving preferentially onto motoneuron somata, and of these different sources of eye position signals impinging upon their distal dendrites, can still be further enhanced by the intrinsic active properties of the motoneuron membrane to produce the stable firing rate that these motoneurons display, mainly during eye fixation [1].

Since the seminal contributions of Robinson's group [5], many authors have attempted with the design of more or less realistic mathematical models simulating the generation of eye position signals in mammals. A recent example of implementation for brainstem circuits involved in oculomotor integration processes is illustrated in Fig. 2 [14].



**Neural Integrator – Horizontal. Figure 2** A bilateral implementation for brainstem circuits involved in supporting the central ►oculomotor integrator. This model allows merging of both vergence and version integrator functions in the dark. All sensory inputs converge on this circuit, with only semicircular canals ($C_{R,L}$) shown here on both sides. $E_R$,$E_L$ are monocular eye positions on the right and left; P(s) represent dynamics of each eye plant in Laplace domain (filters); F (s) represent low-pass filters in the PH, which approximately model the true eye-plant dynamics. ►Position-vestibular-pause (PVP) and ►eye-head-velocity (EHV) cells in the vestibular nuclei (VN) are interconnected ipsi- and contralaterally with the PH. All other variables are simply scalar weights on the paths. Each PH receives branches from the same cells eventually driving the contralateral eyeball muscles – as a result, PH cells produce ►monocular efference copies. Due to mirror symmetry, the distributed loops between PH and VN imbed two large time constants, one for vergence and the other for version (conjugate) eye control. Hence, there are actually two integrators available for the two dimensions of horizontal, binocular, eye movements. Modified from A. Green, Visual-Vestibular interaction in a bilateral model of the rotational and translational vestibule-ocular reflexes: An investigation of viewing-context-dependent reflex performance, PhD Thesis, Department of Biomedical Engineering, McGill University, January, 2000."

N

### Role of Neurotransmitters in the Generation of Eye Position Signals

As indicated above, the presence of separate integrators subserving the velocity storage mechanism and eye position signal generator has been proposed [7,13]. In fact, these two integrating mechanisms can be experimentally separated using some pharmacological tools. For example, injections of nitric oxide (NO) synthase inhibitors in the nucleus PH of conscious cats produce alterations of eye velocity, but not of eye position. In contrast, the injection of NO donors in the marginal zone close to the medial vestibular nucleus (i.e. an area rich in NO-sensitive guanylyl cyclase present on GABAergic afferent terminals) seems to affect the generation of eye position signals, a fact confirmed with lesion experiments in monkeys [7,8,14]. Thus, the integrative capabilities of distinct regions of the same PH nucleus subserve different eye-movement subsystems.

Other neurotransmitters (glutamate, acetylcholine) have been proposed to be related to neuronal operations taking place in the PH nucleus during eye fixation. An initial step for the integration of those early findings is represented by the suggestion that a cholinergic synaptically triggered phenomenon participates in the generation of eye position signals, subsequent to glutamatergic velocity signals arriving at the PH nucleus from the paramedian pontine reticular formation, i.e. from the site of excitatory burst neurons (Fig. 1c). It has been reported that the tonic firing present in PH neurons (►tonic neurons) that follows a velocity motor command are generated, or at least facilitated, by cholinergic inputs acting on post-synaptic muscarinic M1 receptors located on those PH neurons [10]. These findings indicate that eye position signals arriving at the abducens nucleus could be originated in the PH nucleus by the effect of cholinergic inputs, subsequent to the depolarizing effects of glutamatergic excitatory burst neuron inputs, besides the participation of cascade-like [1,2] and/or ipsilateral and contralateral reverberant circuits [12]. Thus, the PH nucleus has more than one control mechanism to transform transient velocity signals into eye position ones [10].

## Neuronal Migration

Mineko Kengaku
Laboratory for Neural Cell Polarity, RIKEN Brain Science Institute, Wako, Japan

### Definition

Cell migration is crucial for a variety of physiological and pathological processes, including leukocyte migration in the inflammatory response and tumor cell metastasis. During development, many cells migrate from their site of origin to their destination and reassemble with other cells for integration into functional tissues. Cell migration is a directional movement distinct from random dispersion and requires some mechanism for guiding cells to their destination. This essay focuses on migration of neurons in the developing brain, which is one of the most significant cell migration events in life.

## Characteristics

### Quantitative Description

The distance that a cell migrates varies widely from a few to a thousand cell-body diameters. Migration speed depends on the mode of migration. For instance, neurons in the cerebral cortex move at an average speed of 35 μm/h during locomotion and 60 μm/h during somal translocation [1]. Chain migration in the rostral migratory stream is as rapid as 120 μm/h [2].

### Description of the Process

Neuronal migration consists of three schematic steps:

1. The ►leading process extends in the direction of travel along the substratum (neuronal or glial processes).
2. The nucleus and other organelles in the cell body move into the leading process.
3. The trailing process at the back detaches from the substratum and retracts to restore the original cell shape.

Harmonious repetition of these steps causes a caterpillar-like movement called locomotion [1]. In another mode of migration called somal translocation, the steps are not typically synchronized so that the cell soma moves within the preformed leading process independently of its extension [1]. In addition, cortical neurons in the intermediate zone migrate irregularly with dynamic extension and retraction of multiple processes; this mode is referred to as multipolar migration [3].

### Higher Level Processes

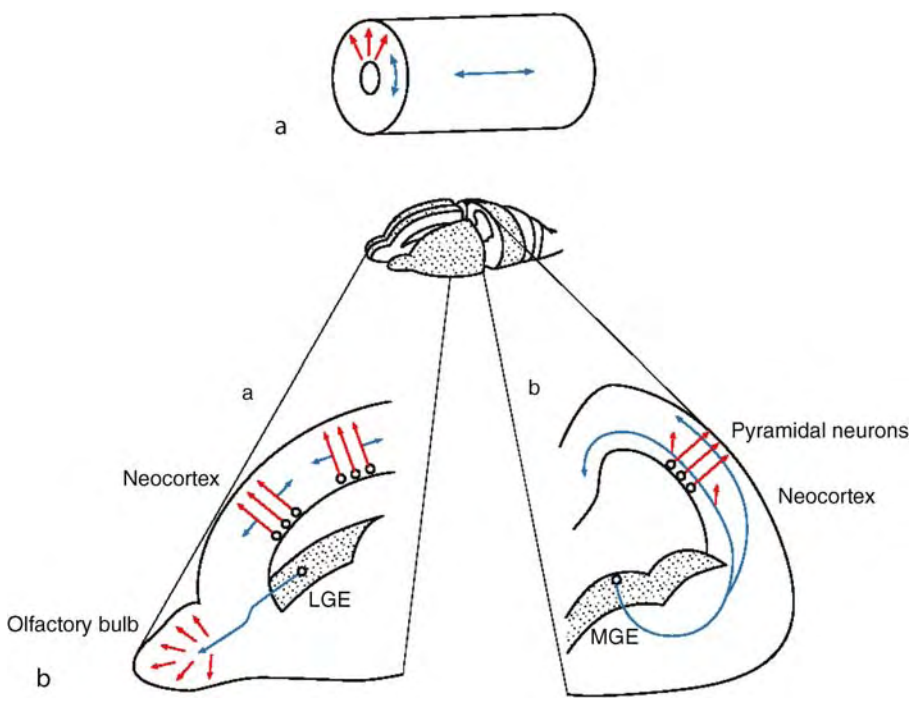
Neuronal migration is classified into two distinct modes by the direction of the travel within developing neural tissue (Fig. 1).

#### *Radial Migration*

The vertebrate brain originates from the cylindrical neural tube. Neurons develop in germinative regions on the inner surface of the tube wall (the ventricular zone). Thus, new neurons principally move orthogonally from the ventricular zone toward the outer pial surface. In this mode of migration, which is called radial migration, neurons typically move along the fibers of radial glia traversing the entire depth of the parenchyma. Typical radial migration is thus referred to as "gliophilic migration".

#### *Tangential Migration*

In tangential migration, neurons move parallel to the pial surface of the brain, often across segmental or



**Neuronal Migration. Figure 1** Two modes of migration in the developing brain. (a) Radial (*red*) and tangential (*blue*) migration in the neural tube (b) Neuronal migration in the developing telencephalon. N

regional boundaries. Tangentially migrating neurons are often "neurophilic" and extend their leading process along the axons of other neurons.

## Higher Level Structure

The following are the relevant brain structures undergoing active neuronal migration during development.

### Cerebral Cortex

The mammalian dorsal telencephalon develops into the six-layered cerebral cortex by radial migration of constituent pyramidal neurons. New neurons migrate from the ventricular zone towards the pia and accumulate below the margin of the cerebral wall to form the preplate. Subsequent neurons are deposited within the preplate to form the cortical plate and split the preplate into the superficial marginal zone and the deeper subplate. Cell dating studies have shown that neurons take their position in the cortical plate in an "inside-out" sequence, such that later developed cells migrate past the existing layers of earlier developed neurons and reside at the top of the plate (Fig. 2) [4,5].

Migration of cortical neurons can be classified into several modes with distinct kinetics. Neurons are generated from radial glia, which have a long process reaching the pial surface. Early neurons that inherit the long process from radial glia migrate into the cortical plate by translocation of their nucleus within their own processes independently of other cells. In contrast, later developing neurons often associate with other radial glia and migrate by locomotion in which the leading process moves in harmony with the cell body [1]. In addition, the later neurons have a multipolar shape and migrate in various directions (multipolar migration) in the intermediate zone, before they form a predominant leading process and enter the cortical plate by locomotion (Fig. 2) [3].

Inhibitory interneurons in the neocortex arise in the caudal and medial ►ganglionic eminences (CGE and MGE) of the ventral telencephalon and move to various levels of the developing neocortex in the dorsal telencephalon by tangential migration (Fig. 1) [4]. These neurons form one or two prominent leading processes, which follow the trajectory of axonal plexuses in the marginal zone and intermediate zone.

### Rostral Migratory Stream in the Olfactory Bulb

Periglomerular and granule interneurons of the olfactory bulb are generated in the subventricular zone of the lateral ganglionic eminence (LGE) and reach their destination by tangential migration with a rostral orientation (Fig. 1). This migration, known as the "rostral migratory stream," mostly occurs during the early postnatal stage in rodents, but some cells continue to migrate throughout life. Unlike classical neurophilic tangential migration, many of these rostrally migrating cells are mitotic and migrate in chains in a glial tunnel traversing the tissue [2]. Migration of tightly associated strands of neurons is referred to as chain migration.

### Cerebellar and Precerebellar Neurons

The developing cerebellum undergoes dynamic morphogenetic movements accompanying active cell migration. Most cell types in the three-layered cerebellar cortex migrate radially from the ventricular zone of the cerebellar anlage in the dorsal aspect of the hindbrain and caudal midbrain. In contrast, precursors of granule cells immediately take a tangential path from their origin in the rhombic lip, the anterior margin of a rhomboid-shaped roof plate lining the edge of the fourth ventricle. Granule cells undergo three successive phases of migration, each perpendicular to the others. First, precursors of granule cells undergo chain migration anteriorly to form the external granule layer over the dorsal surface of the cerebellum. After active proliferation, postmitotic granule cells extend bipolar axons and migrate tangentially following the trajectories of the preformed axons of other granule cells along the long (mediolateral) axis of the cerebellum. The third phase is radial migration along the radial fibers of Bergmann glia to reach the internal granule layer in the deep cerebellar cortex [6] (Fig. 3).

The different populations of rhombic lip cells migrate tangentially to form the precerebellar nuclei in the ventral hindbrain. These include the pontine, lateral reticular and inferior olivary nuclei, which provide the principal input to the cerebellum. The young precerebellar neurons first emit a long leading process circumferentially from the dorsal to the ventral hindbrain and then translocate the nucleus within their own leading process through a tangential migration [7].

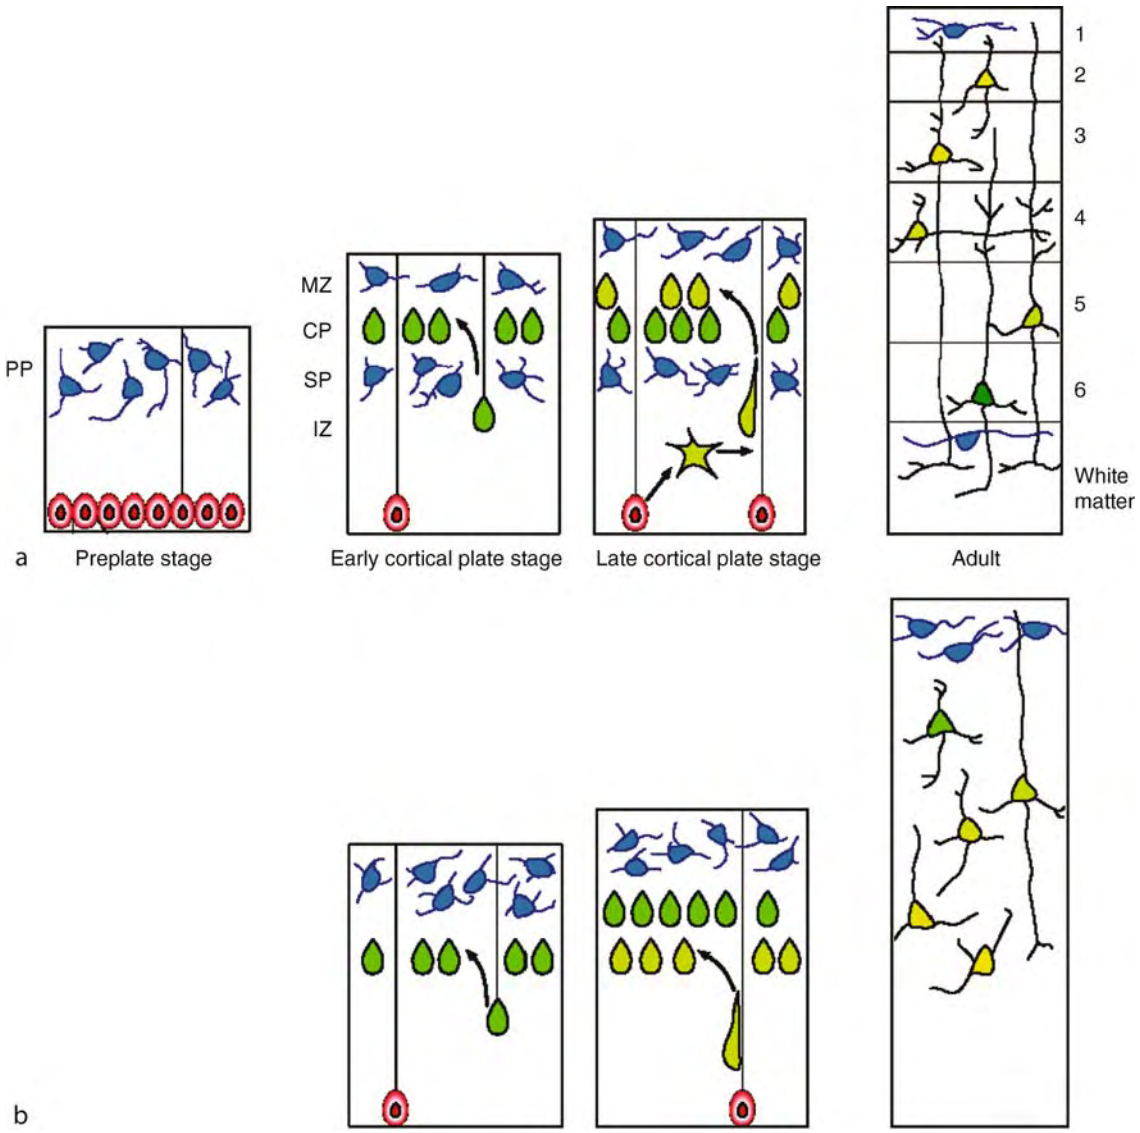
### Neural Crest

Neurons and glia in the peripheral nervous system arise from the neural crest and migrate dynamically to various regions of the embryo. See accompanying essay in this Encyclopedia.

## Regulation of the Process

### Leading Process Extension

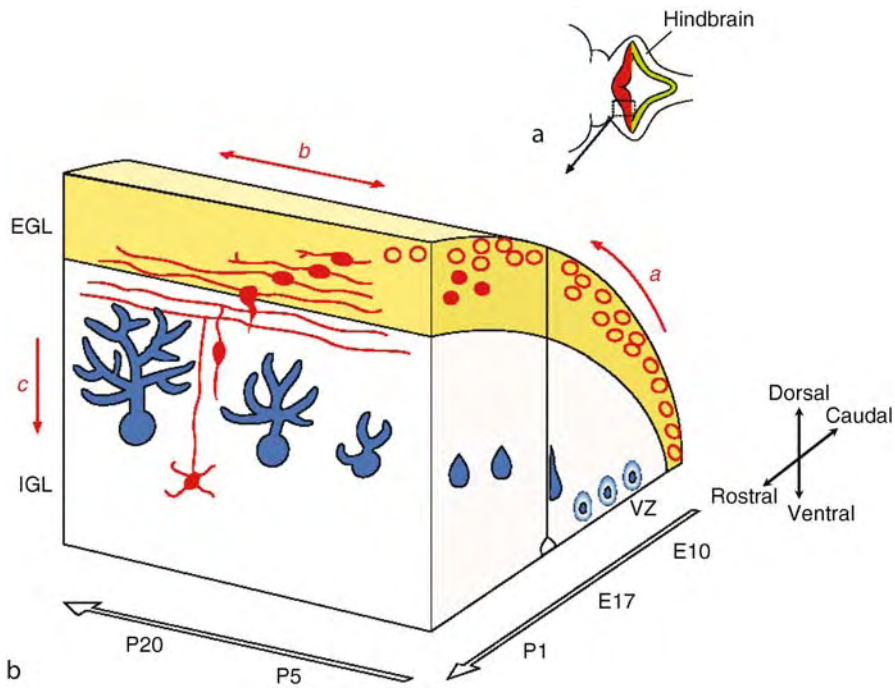
Leading processes have distinct characteristics depending on the mode of migration. Some tangentially migrating neurons including precerebellar neurons and cerebellar granule cells extend long leading processes tipped by a large growth cone. These tangential leading processes are destined to become axons and their extension is probably controlled by a mechanism similar to that of growth cone steering without cell migration (See accompanying essay in this Encyclopedia). In contrast, gliophilic radial migration is guided by a short, tapering leading process resembling a dendritic tip. Despite some fundamental differences, leading process



**Neuronal Migration. Figure 2** Radial migration and neocortical layer formation a normal cortical development. a The preplate (*PP*) is formed by the first wave of postmitotic cells (*blue*) differentiated from radial glia (*red*) in the ventricular zone (*VZ*). In the early cortical plate (*CP*) stage, new neurons migrate radially from the VZ and split the PP into the marginal zone (*MZ*) and subplate (*SP*). Many neurons adopt somal translocation within the process inherited from radial glia. In the late CP stage, new neurons first move randomly by multipolar migration in the intermediate zone (*IZ*) and then migrate radially toward the CP by locomotion along the fibers of other radial glia. Neurons migrate past their predecessors and expand the CP in an inside-out fashion. The adult stage is marked by the six-layered neocortex. b In *reeler* mice, neurons fail to migrate beyond earlier neurons and pile up underneath the PP. Cortical layering in the adult stage is inverted and disorganized.

extension appears to involve common steps regardless of the mode of migration.

As mentioned in Higher Level Processes above, migrating neurons typically attach to glia or neurons on the path and follow the trajectories of their processes. Cell-substratum attachment is formed by transmembrane adhesion molecules, which recruit actin filaments in the cytoplasm through actin-binding proteins, such as integrin and L1, which immobilize actin filaments at neuron-glia or neuron-neuron contacts. At the cell-substratum attachment, the growing end of the actin filaments orients toward the tip of the leading process and generates a protrusive force for its extension [8]. An actin cross-linking phosphoprotein filamin A has been implicated in the protrusion of leading processes in cortical neurons during the transition from

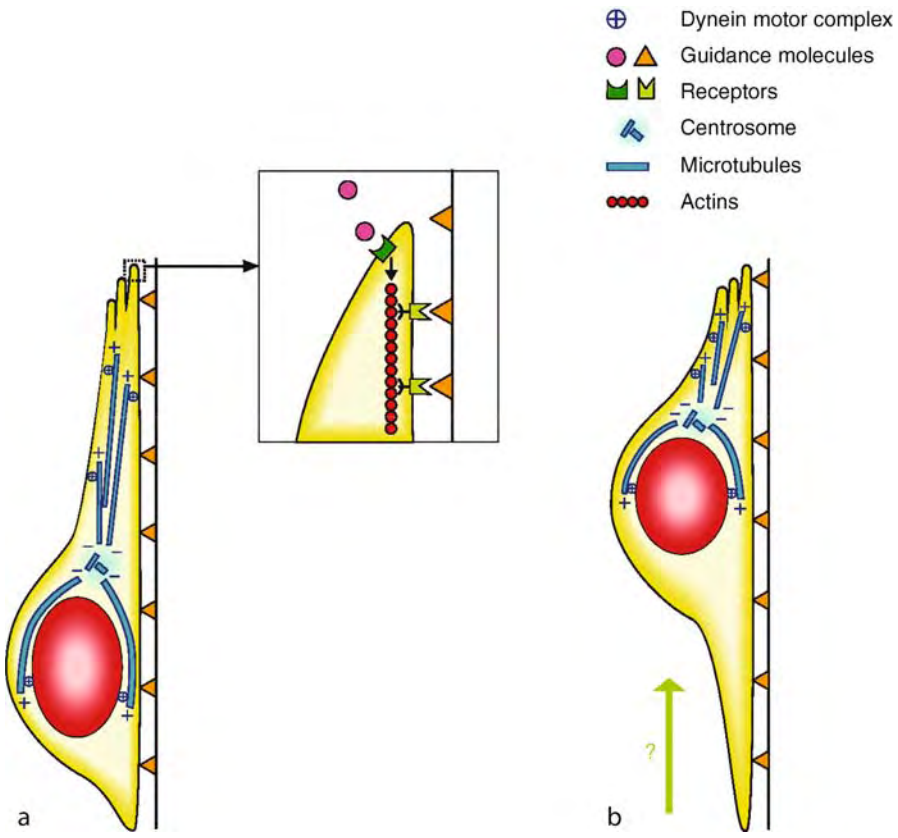


**Neuronal Migration. Figure 3** Migration of cerebellar neurons (a) Dorsal view of the developing rhombic lips. The anterior part of the lip (*red*) gives rise to granule cell precursors. Cells from the posterior part of the lip (*green*) migrate ventrally to form the precerebellar nuclei. (b) Embryonic and postnatal development of the cerebellum. Purkinje cells (*blue*) are generated in the ventricular zone (*VZ*) of the cerebellar anlage and reach the cerebellar cortex by radial migration. Granule cells (*red*) undergo three successive phases of migration en route to the internal granule layer (*IGL*) in the cortex: Mitotic precursors (*blank*) migrate rostrally in chains to form the external granule layer (*EGL*) on the dorsal surface (*a*); postmitotic granule cells first extend bipolar axons and tangentially migrate along the mediolateral axis (*b*); cells then make a vertical turn and move ventrally toward the IGL by radial migration (*c*). *Blank arrows* indicate approximate developmental stages in mice.

multipolar migration to locomotion. Actin polymerization can be promoted by guidance cues that include soluble chemicals and adhesive molecules on the path. Receptors for families of such guidance cues can directly or indirectly alter the activity of the Rho family small GTPases, which are key regulators of actin polymerization in various migrating cells (Fig. 4).

### Nuclear Migration

Migrations of neurons and other fibroblastic cells are clearly distinguished by their mechanisms of nuclear movement. In fibroblastic cells, nuclear migration is principally served by the actin cytoskeleton in the absence of microtubules; the actin-dependent extension of the leading edge generates a cortical tension that pulls the cell body in all directions. Traction then occurs at the back, because of preferential assembly of the cortex and adhesion to the substrate at the cell front. Finally the nucleus and cytoplasm are dragged forward passively by the traction force [8]. In contrast, some neuronal migration occurs by nuclear-driven cell migration termed "nucleokinesis" in which the nucleus moves within a highly protrusive leading process in a microtubule-dependent manner. In some migrating neurons, microtubules envelop the nucleus and also project into the leading process with the plus-end oriented toward the tip. It is hypothesized that the ►dynein motor complex is anchored to the cell cortex in the leading process and pulls the cell body forward by its minus-end-directed motor activity [9]. Dynein and its regulator LIS1 are colocalized in the cell cortex and ►centrosome and disruption of either of the genes leads to defects in nuclear migration in neurons. The centrosome is typically positioned in front of the nucleus and might mediate the pulling force from the leading process. The dynein complex on microtubules is also localized to the nuclear membrane, which could pull the nucleus toward the centrosome. The two-step nucleokinesis mediated by the centrosome – the movement of the centrosome toward the leading process followed by the movement of the nucleus toward the centrosome – is a favorable model especially for saltatory locomotion (Fig. 4).



**Neuronal Migration. Figure 4** Model for kinetics of neuronal migration. (a) Leading process extension is navigated by guidance molecules, which regulate actin polymerization in the leading edge. (b) Nuclear movement is driven by microtubules radiating from the centrosome. Activation of minus-end-directed motor activity of the dynein complex on the nuclear membrane leads to a displacement of the nucleus toward the centrosome. It is also provable that the dynein motor complex is anchored to the cell cortex in the leading process and pulls the centrosome forward. Additional forces may push the nucleus from the back. The retraction of the trailing process is not well understood.

### *Traction*

As mentioned above, traction of the posterior of the cell is less important for nuclear migration in neurons. Indeed, the trailing processes of some neurons (e.g. cerebellar granule cells) are retained and differentiate into axons after cell migration. The mechanisms of retraction and differentiation of the trailing process are not well understood.

## Function

Neuronal migration is required for the formation of defined cell patterns for the development of specific neural circuits.

### *Radial Migration*

Defects in radial migration cause disruption of cortical lamination. Layering of the cerebral cortex is inverted and indistinct in the naturally occurring mouse mutant *reeler*, as radially migrating neurons are able neither to traverse their predecessors nor to assemble into distinct layers (Fig. 2) [5,10]. Reelin, the protein defective in *reeler* mice, is a large extracellular matrix protein secreted by ►Cajal-Retzius cells in the marginal zone. Reelin is a high-affinity ligand for two members of the LDL family of lipoprotein receptors, VLDLR (very-low-density lipoprotein receptor) and LRP8 (low-density lipoprotein receptor-related protein 8, also known as ApoER2), which induce phosphorylation of the tyrosine kinase adaptor Disabled 1 (Dab1) in migrating cortical cells. Mutations in the *Dab1* gene (*scrambler* and *yotari)* or double homozygous null for the genes *VLDLR* and *LRP8*, show identical phenotypes to *reeler*. Reelin signaling might induce events related to the reorganization of microtubules and microfilaments in the cytoskeleton.

Mice deficient in cyclin-dependent kinase 5 (Cdk5), or its activator p35, display similar defects in cortical lamination. Although preplate splitting by early-developed neurons occurs normally, layering of the cerebral cortex is inverted due to the inability of later developed neurons to migrate past their predecessors. The broad substrate range of the Cdk5-p35 complex suggests that it could regulate multiple aspects of migration. Cdk5-p35

is likely to regulate cytoskeletal dynamics by phosphorylating actin- and microtubule-binding proteins. Cdk5 signaling could also regulate neuron-glia attachment. Interestingly, tangential migration of cortical inhibitory interneurons appears relatively unaffected in mice deficient in Cdk5 or p35, suggesting that the Cdk5-p35 pathway is mainly used for radial, gliophilic migration [5,10].

### *Tangential Migration*

Defects in tangential migration also disrupt the formation of specific brain structures and proper neural networks. Most cortical GABAergic interneurons arise in the MGE and CGE and reach the cortex in tangentially migrating streams. In *Dlx1/Dlx2* double-mutant mice, GABAergic interneurons fail to migrate from the MGE and drastically decrease in the neocortex, olfactory bulb and hippocampus [4]. On the other hand, neurons in precerebellar nuclei originate from the rhombic lip in the dorsal hindbrain and migrate tangentially toward the ventral midline secreting netrin 1. The loss-of-function mutant of netrin 1 causes defects in tangential migration of rhombic lip cells and hence the disruption of precerebellar nuclei [7].

### Pathology

Disturbances of neuronal migration are implicated in human brain malformations associated with neurological conditions including mental retardation and epilepsy [10]. Mutations in filamin 1 gene lead to X-linked periventricular heterotopia in which a subset of neurons fails to migrate from the ventricular zone. Defects in nucleokinesis by a LIS1 mutation cause type 1 lissencephaly ("smooth brain" without convolutions) characterized by abnormally thickened and incomplete neocortical layers. Another X-chromosome-linked lissencephaly locus has been identified and named doublecortin (DCX). DCX encodes a microtubule-binding protein that is thought to stabilize microtubules. Male patients with mutations in the DCX gene on their single X-chromosome give rise to a phenotype similar to type 1 lissencephaly. Female patients with a heterozygous DCX mutation exhibit double cortex syndrome (subcortical band heterotopia) in which a fraction of neurons expressing a mutant DCX gene halt migration and cluster halfway between the cortex and the ventricle.

# Neuronal Network

## Definition

A group of neurons that are connected by a specific set of synaptic interactions and fulfil a specific function (e.g. control of locomotion, processing of visual information, etc.). The boundaries of neuronal networks within the nervous system are often not very well defined as individual neurons can be part of a neuronal network under one set of circumstances, but not part of it under different circumstances. Entire networks can be reconfigured by modulatory influences, which enhance or suppress the activity in individual neurons and/or specific synaptic connections. These networks are described as polymorphic neuronal networks. Reconfiguration enables the nervous system to employ the same neuronal elements for the control of related, but different activities (e.g. walking, running, jumping, etc.), which is a more efficient use of resources than the existence of independent neuronal networks for each activity.

►Central Pattern Generator
►Rhythmic Movements

# Neuronal Oscillator

## Definition

A neuronal circuit or even a single neuron that, owing to the inherent electrical properties of the neuronal membranes and the synaptic connectivity of the

component neurons, produces a rhythmic pattern of activity. Central pattern generators (CPGs) include neuronal oscillators, and CPGs for segmentally distributed motor patterns often comprise of neuronal oscillators in each segment of the nervous system participating in the production of the motor pattern; they are then often called segmental oscillators.

### Synonyms

Asymmetry in neurons

### Definition

Neuronal polarity is the asymmetry in the distribution of cellular components (►cellular polarity) within ►neurons. In this essay, we first describe the development and maintenance of neuronal polarity and then demonstrate its function in the nervous system.

### Characteristics

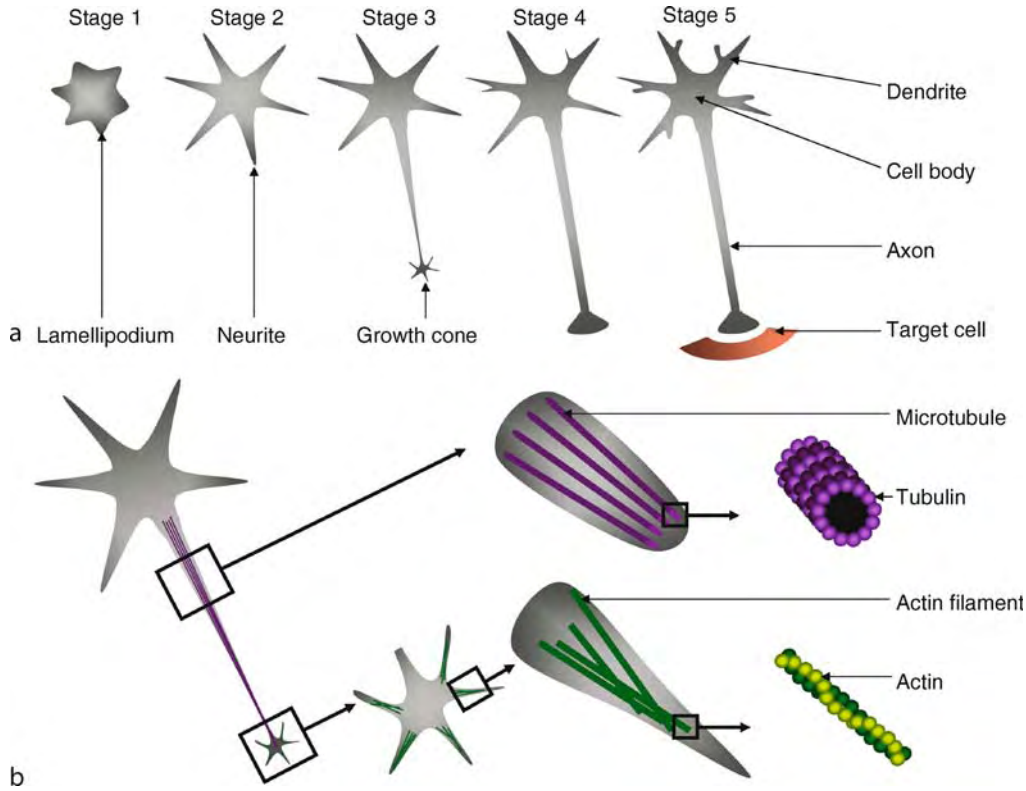
#### Development and Maintenance of Neuronal Polarity

Cells are the basic building blocks of multi-cellular organisms. Some cells appear morphologically and functionally homogeneous. For example, oxygen-carrying erythrocytes and infection-fighting leukocytes in human blood are round and even in shape. Other cells, however, display clear heterogeneity, where specialized regions within a single cell perform different biological functions. Epithelial cells in the vertebrate digestive system are an excellent example of the latter case. Each epithelial cell has an apical side that absorbs outside materials and a basal side that transfers the absorbed materials to the bloodstream. Epithelial cells are therefore termed "polarized."

Neurons are perhaps the most extensively-studied polarized cells. Each neuron performs two distinct functions: receipt of information from signaling cells and transmission of this information to target cells. To accommodate these different functions, neurons form multiple dendrites and in most cases, a single axon (Fig. 1a). Dendrites receive information from other neurons and relay it to the axon of the same cell. The axon then transmits the information to one or more target cells that can be neurons or tissue cells. The process of dendrite and axon differentiation is called neuronal polarization (Fig. 1).

Neuronal polarization has been well-characterized in the cultured hippocampal neurons of rat embryos [1]. This developmental process has been divided into five stages (Fig. 1a). In Stage One, newly-born neurons develop multiple outgrowth extensions called lamellipodia. Lamellipodia extend and elongate into neurites in Stage Two. In Stage Three, one of these neurites begins to grow faster than the others, adopting the axonal fate. Found at the tip of this neurite is a ►growth cone that leads the axon to its targets. In the fourth stage, while the growing axon matures, the remaining neurites become dendrites. In the fifth and final stage, the axon and dendrites make connections with other cells, forming a neuronal network [1].

These dramatic morphological transformations during neuronal polarization are accompanied by changes in the ►cytoskeleton structures of the developing neuron. The cytoskeleton supports membrane structure, maintains cell shape, and enables trafficking of organelles and proteins. The cytoskeleton is primarily comprised of polymers of tubulin (microtubules) and actin (actin filaments) (Fig. 1b). During neuronal polarization, microtubules and actin filaments are in highly dynamic states where their subunits assemble onto or disassemble from the filamentous structures, allowing rapid growth or shrinkage of neurites. Bradke and Dotti [2] have provided *in vitro* evidence that the one neurite destined to become the axon is associated with highly dynamic actin filaments. In addition, when a dynamic state was artificially created throughout a developing neuron with an actin-destabilizing drug, this neuron generated multiple axons. Conversely, local application of the drug to a single neurite designated axonal fate to that neurite [2], suggesting that actin dynamics in a neurite is necessary for its axonal fate. Accordingly, cytoskeleton dynamics is thought to be extensively regulated during neuronal polarization.



**Neuronal Polarity. Figure 1** Neuronal polarization. (a) Five different stages of polarization observed in the cultured rat hippocampal neurons. A mature neuron has multiple short dendrites and a single long axon. Information adapted from Dotti et al. (b) Cytoskeleton structures in the developing neuron. Microtubules are found along the neurite while actin filaments localize to the growth cone. Both microtubules and actin filaments are comprised of protein subunits.

A number of regulators of cytoskeleton dynamics in neuronal polarization have been discovered [3,4]. The first *in vivo* evidence for such regulator was provided by ►Synapses of Amphids Defective 1 (SAD-1) [5]. The SAD-1 protein was identified in ►*Caenorhabditis elegans* (*C. elegans*), a nematode model organism first developed by Nobel laureates Sydney Brenner, Robert Horvitz, and John Sulston and now widely used in the laboratory for its easy handling and amenable genetics. Animals with mutantions in thier SAD-1 gene showed shorter axon lengths in specific neurons. Further, axon-specific proteins were mislocalized to dendrites [5], suggesting that SAD-1 is required for accurate polarization of neurons.

Mammalian ►homologs of *C. elegans* SAD-1 have also been identified [6]. In the mouse, two SAD-1-like proteins were found and named SAD-A and SAD-B. Eliminating both SAD-A and SAD-B causes the cultured hippocampal neurons from embryos to develop multiple projections that are neither dendrites nor axons [6], strongly supporting an evolutionarily conserved role for SAD proteins in neuronal polarity. Another mammalian protein, LKB1, also regulates neuronal polarity [7,8]. Similar to mice lacking the SAD proteins, LKB1 mutant animals show neuronal projections without distinct dendritic or axonal characteristics. Biochemical analyses show that LKB1 regulates neuronal polarity through SAD-A and SAD-B [7,8].

How do the SAD proteins and LKB1 regulate the cytoskeleton dynamics in neurons? The various SAD proteins and LKB1 are ►protein kinases – enzymes that transfer phosphate groups to their target protein. In the mouse, LKB1 first phosphorylates and activates SAD-A and SAD-B [7]. The activated SAD proteins then directly or indirectly (i.e., through another kinase) phosphorylate TAU, a microtubule-associated protein (MAP) [6]. MAPs bind and subsequently stabilize microtubules. Phosphorylated MAPs on the other hand detach from microtubules, resulting in cytoskeleton instability and dynamics. Microtubule dynamics, as mentioned above, is essential for neuronal polarization. Therefore, the SAD proteins and LKB1 regulate the cytoskeleton dynamics by modulating the phosphorylation status of TAU and possibly other MAPs [6–8].

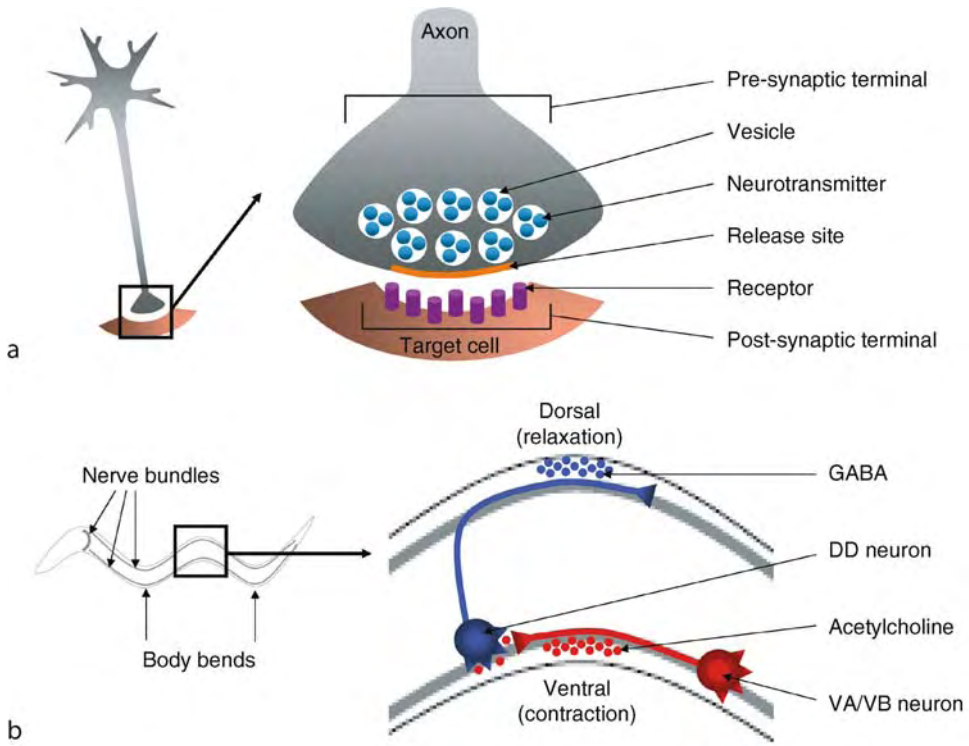
Once developed, neuronal polarity needs to be maintained throughout the animal's lifespan. Presently, little is known about the mechanisms of maintenance. Nevertheless, Hammarlund et al. [9] have identified an

essential component in the maintenance of membrane structure in *C. elegans* motor neurons. Supporting and organizing the membrane structure of mature axons is a complex called spectrin [9]. Made up of two protein subunits – alpha and beta spectrins – the spectrin complex maintains membrane integrity by stabilizing actin filaments associated with the membrane. In *C. elegans* animals with mutant beta-spectrin, neurons develop normally. However, mature axons of their motor neurons break in the adult stage [9]. When these animals were restricted from movement, no broken axons were observed, suggesting that breaks occur from the wear and tear of movements. Broken axons continue to regenerate, but fail to form functional axons due to repeated breaks. This study suggests that the membrane structure in mature axons needs to be maintained and that the development and maintenance of neuronal polarity may be governed by separate mechanisms.

## Function of Neuronal Polarity

The nervous system is essentially a network of neurons forming connections with each other and other tissues. Communication between neurons is achieved through specialized structures called synapses (Fig. 2a). Each synapse consists of a pre-synaptic terminal in the signaling cell and a post-synaptic terminal in the target cell. Pre-synaptic terminals contain signaling molecules known as ▶neurotransmitters in small membrane-bound compartments called vesicles. Upon stimulation, the vesicles release neurotransmitters outside the cell, which then diffuse to the target cells. The target cells contain post-synaptic terminals that are characterized by clusters of receptors for the neurotransmitters, often ion-channels, and other molecules required for signaling (Fig. 2a). Neurotransmitters bind the receptors in the post-synaptic terminals, trigger changes in the membrane potentials and cause subsequent effects in the target cells. In summary, information travels through the neuronal network via synapses formed by individual neurons.

What role does neuronal polarity play in synaptic functions? Dendrites and axons are different not only morphologically but also, more importantly, functionally. The dendrites of a neuron, as well as parts of its cell body, form post-synaptic terminals at the contact sites



**Neuronal Polarity. Figure 2** Synapses and neuronal connectivity. (a) Key components of pre- and post-synaptic specializations. Pre-synaptic terminals contain neurotransmitters in membrane-bound compartments called vesicles. Upon stimulation, neurotransmitters are released and bind the receptors in the post-synaptic terminal of a target cell, triggering changes in that cell. (b) Characteristic body bends generated by neuronal connectivity of motor neurons in *C. elegans*. The VA/VB axon releases acetylcholine which causes contraction of ventral muscles. Acetylcholine also triggers the release of GABA from the DD axon. GABA relaxes dorsal muscles. Information adapted from Schuske et al. [10].

with the axons of signaling cells (Fig. 2a). Axons on the other hand, form pre-synaptic structures that relay signals to target cells upon stimulation (Fig. 2a). Polarity in each neuron, therefore, defines the direction in which a signal travels.

Neuronal polarity and synaptic connections together determine the route by which signals travel throughout the nervous system. A simple example is provided by the *C. elegans* motor circuit [10] (Fig. 2b). The axon of a motor neuron called VA or VB forms synapses with the dendrite of another motor neuron, DD, on the ventral side of the animal. The VA or VB neuron releases neurotransmitters called acetylcholine. Acetycholine stimulates the DD neuron to release its neurotransmitters GABA, from its dorsally located axon. Signals continue to propagate throughout the neuronal network determined by neuronal polarity and synaptic connections.

The motor neurons also form synapses with muscle cells and control motor functions. The VA or VB axon forms synapses with ventral muscles. Acetylcholine, an excitatory neurotransmitter, causes contraction in these muscles (Fig. 2b). The DD axon, on the other hand, forms synapses with dorsal muscles. When these muscles receive GABA, they relax. The result of muscle contraction on the ventral side and relaxation on the opposite dorsal side is a body bend. This pattern of contraction and relaxation on the opposite sides is observed throughout the length of the animal's body, characteristic of roundworms. Alternating the pattern of body bends allows the forward and backward movement of the animal.

## Summary

Neuronal polarity refers to the asymmetrical distribution of cellular components within a neuron. In this essay, we described the development of neuronal polarity and its function in the nervous system. During neuronal polarization, a group of molecules work in concert to regulate the dynamics of the cytoskeleton. The cytoskeleton dynamics is essential for neurite extension and axon and dendrite formation. Once established, neuronal polarity needs to be maintained, which likely requires the stabilization of cytoskeleton structures. In the nervous system, neuronal polarity and synaptic connections determine the route by which information travels. The synapses between neurons and other cell types along this route lead to the complex sensory, motor, or cognitive functions of an organism.

# Neuronal Potassium Channels

Alistair Mathie, Emma L. Veale
Medway School of Pharmacy, Universities of Kent and Greenwich at Medway, Chatham Maritime, Kent, UK

## Definition

Potassium ($K^+$) channels are proteins which span the membrane of cells and are selectively permeable to $K^+$ ions.

## Characteristics

Potassium ($K^+$) channels are proteins which span the membrane of cells and which, when open, allow the selective flow of $K^+$ ions from one side of the membrane to the other (usually from the inside of the cell to the outside). They can be gated by a variety of stimuli including voltage, changes in intracellular $Ca^{2+}$ and certain other physiological mediators. In neurons, they have a number of functional roles related, primarily, to the electrical properties of the membrane. As such, they determine the neuronal action potential frequency, shape the neuronal action potential waveform (►Action potential) and control the strength of synaptic contacts between neurons [see 1]. Additionally, certain $K^+$ channels regulate the absolute excitability of neurons and set (or contribute to) the neuronal ►resting membrane potential [2] (►Membrane potential – basics). Their physiological importance has been exemplified

by the observations that mutations in $K^+$ channel sequences in particular individuals leads to such varied clinical disorders as ►epilepsy, episodic ataxia, unregulated insulin secretion and deafness [3].

## $K^+$ Channel Families

$K^+$ channels are members of the voltage-gated-like ►ion channel superfamily [4]. Since the first molecular cloning of $K^+$ channel subunits in the 1980s, over eighty different genes have been identified which each encodes for distinct $K^+$ channel α subunits [see, for example, [5]]. Each $K^+$ channel consists of a primary pore-forming α subunit often associated with auxiliary regulatory subunits. From the amino acid sequences of $K^+$ channel α subunits, it is possible to group them into three families (Fig. 1).
