Autonomic regulation occurs in an integrated manner across multiple peripheral systems and in parallel with somatic systems across sleep-wake states due to coordination by the central nervous system [1–3]. Nonetheless, the regulation of those systems across states can be most easily considered for each system, including principally cardiovascular [4,5], respiratory [6,7], thermal [8], endocrine [9] and digestive [10] regulatory systems.

### Cardiovascular Regulation

Heart rate and blood pressure as well as circulation are regulated during waking by the autonomic nervous system, such that they respond to the demands of activity to be high, stimulated by adrenergic sympathetic input, during walking or running, for example, and attenuated to be low by cholinergic parasympathetic input, during

resting. These autonomic responses occur in parallel with voluntary commands to the somatic system in association with different behaviors. For running, for example, excitation of particular sympathetic ganglia and inhibition of parasympathetic ganglia would stimulate an increase in heart rate and blood pressure and be responsible for an increase in blood flow to the skeletal muscles and decrease in blood flow to the viscera. Adjustments also occur as a function of feedback, positive and negative, to the central nervous system. Thus, a drop in blood pressure upon standing stimulates a compensatory increase in blood pressure through the sympathetic outflow to the heart and major arteries. Excessive increases in blood pressure on the other hand can evoke negative feedback to decrease pressure by inhibiting the sympathetic and exciting the parasympathetic outflow. Cardiovascular regulation during waking is thus a function of behavior and feedback control mechanisms that allow a physiological range of values for action while maintaining healthy homeostasis. An active waking state is stimulated and maintained by ►arousal systems in the brain which in turn promote activity in both the somatic and sympathetic motor systems. Of these, central noradrenaline (NA)-containing ►locus coeruleus (LC) neurons and ►orexin/hypocretin (Orx/Hcrt)-containing hypothalamic neurons are known to excite somatic motor and sympathetic (preganglionic) motor neurons, such that movement and activity are supported by increased cardiovascular function and appropriate circulation.

During SWS, heart rate and blood pressure are on average lower than during waking. It is a state of rest for the body and brain. The sympathetic input to the heart and blood vessels is dampened or silent. The parasympathetic input predominates. Sleep is generated by neural systems in the brain which act to dampen central arousal systems and promote peripheral parasympathetic activity. Of these, neurons in the solitary tract nucleus and surrounding region of the medulla, where vagal afferent and efferent fibers arrive and emerge, have the capacity to promote SWS by central projections, while also evoking decreases in heart rate and blood pressure through peripheral vagus outflow. This circuit can be reflexively triggered by extreme increases in blood pressure that by baroceptor feedback propagate a vagal-mediated drop in blood pressure and an associated loss of consciousness and muscle tone, or syncope. Neurons in the basal forebrain and ►preoptic area also promote sleep along with parasympathetic changes in heart rate and blood pressure, as evidenced by the effects of electrical stimulation of these regions.

During PS or REMS, heart rate and blood pressure are irregular and manifest sudden surges upon relatively low base levels continuing from SWS. These surges are caused by sudden increases in sympathetic nerve activity upon a background of more continuous parasympathetic activity. Interestingly, blood vessels to skeletal postural muscles are constricted by sympathetic nerve activity, whereas blood vessels to the viscera and genitals are dilated by inhibition of sympathetic nerve activity, indicating differential sympathetic control and resulting circulation during this state. PS is promoted in the ►brainstem by discharge of cholinergic neurons in the pontomesencephalic tegmentum while other neurons of the arousal systems, importantly the NA and Orx/Hcrt neurons, are silent. The cessation of activity in the latter neurons results in a disfacilitation of sympathetic as well as somatic motor neurons. Particular GABAergic and glycinergic neurons are additionally responsible for tonic inhibition of the somatic postural motor neurons. At the same time, other glutamatergic reticulo-spinal neurons discharge in phasic bursts, stimulating rapid eye movements and twitches of facial and distal flexor somatic motor neurons. Such phasic excitation is presumably also transmitted in parallel to certain sympathetic (preganglionic) motor neurons in the spinal cord to stimulate blood pressure surges and tachycardia.

## Respiratory Regulation

During ►waking, respiration is regulated as a function of activity and the corresponding need for oxygen uptake and carbon dioxide dissipation. With increasing use of muscles stimulated by locomotion, for example, respiration is increased. This response involves both the somatic and visceral motor systems; the diaphragm and intercostal muscles are striate muscles and under voluntary control through somatic motor neurons for breathing, and the bronchial dilator muscles are smooth muscles and under involuntary control of the autonomic nervous system. There is also feedback control through the vagus which stimulates respiration in response to changes in oxygen or carbon dioxide. During active wakefulness, arousal systems in the brain facilitate respiratory motor neurons in the spinal cord for increased ventilation and excite preganglionic sympathetic neurons to dilate the bronchial muscles for greater gaseous exchange in the lungs. There is also a facilitatory influence upon the respiratory rhythmic pattern generator neurons in the medulla. On the other hand, some behaviors can be associated with voluntary breath control and holding that can override to a certain extent the rhythm pattern generator and feedback control.

During SWS, respiration is rhythmic and slow. Feedback mechanisms function to increase rate in response to changes in oxygen or carbon dioxide, although the threshold for this response is slightly higher.

During PS or REMS, respiration can be irregular, somewhat like it can be during waking, particularly during periods of phasic twitches and rapid eye movements. In parallel with the atonia of the postural

muscles, there is also a relative loss of tone in the muscles of the air passages. And there is a relative inhibition of sensory-motor reflexes in the visceral as in the somatic systems, such that the threshold for arousal and increased ventilation with decreasing oxygen and increasing carbon dioxide concentrations in the blood is greatly increased. For these reasons, PS can be associated with relative hypoxia and hypercapnia. In normal animals or humans on the other hand, this state is perhaps not entirely different from certain waking periods in association with particular behaviors and thus might reflect dreaming activity.

## Thermal Regulation

In most mammals and birds, body temperature is maintained in a fairly narrow range. For this purpose, energy is expended and thus metabolism increased for warming the body in cold ambient temperatures or for cooling the body in hot ambient temperatures. These regulatory changes are effected through the somatic and autonomic nervous systems which by integral adjustments stimulate changes in behavior and physiological processes. These include included adoption of heat conserving postures (curled), shivering, cutaneous vasoconstriction and shallow breathing for warming in cool environments or adoption of heat dissipating postures (outstretched), cutaneous vasodilatation, sweating and panting for cooling in warm environments. All of these mechanisms function through feedback control during waking behaviors. Generally, increases in somatic motor activity are associated with increases in metabolic rate and temperature up to a point at which cooling mechanisms are activated. The regulatory centers and neurons for temperature sensing and adjustment are in the ►hypothalamus and preoptic area where they overlap with sleep-wake promoting systems.

During SWS, body and brain temperature along with metabolism are lower than during waking due not simply to reduced activity, but also to a change in the thermostatic set point of the thermal regulatory system. A thermal regulatory posture is adopted in SWS which is thus dependent upon the ambient temperature, curled in cold or outstretched in hot environments. Other autonomic adjustments to changing temperatures also function as during waking, however at a lower body temperature. In fact with the onset of sleep, cutaneous vasodilatation occurs and is associated with cooling of the body and brain by ~1° or so during SWS. These changes are promoted by warm-sensitive, sleep promoting neurons in the preoptic area.

During PS or REM sleep, thermal regulatory systems do not function in the same way they do in most periods of waking or SWS. The feedback circuits are closed and somatic along with many sympathetic motor neurons are inhibited, so that shivering or sweating cannot be induced during PS by changes in ambient temperature. On the other hand, given surface and muscle vasoconstriction and visceral vasodilatation (above), core body temperature is well conserved during PS and brain temperature actually increases along with the increases in activity and metabolism that occur in the brain during this state.

## Endocrine Regulation

Through multiple endocrine systems, which release various hormones into blood and body fluids to act on target cells in different organs, metabolism and temperature along with many functions of the body and organism are kept within a healthy range. Collectively, they maintain the nutrient, mineral and water fluxes of the internal milieu and also serve special functions for growth and reproduction. These hormonal systems are in turn regulated by the autonomic and central nervous systems. Several important hormones show sleep-wake, as well as circadian, changes or regulation in their release. The corticosteroids, cortisol in humans, which mobilize energy stores for catabolism to support increased metabolism for activity, are maximal in association with or anticipation of waking periods, starting in the early morning for humans, and minimal during sleep, particularly SWS in the first part of the night for humans. Conversely, release of growth hormone and prolactin, which mobilize energy stores for restorative protein synthesis and growth, is maximal during SWS in the first part of the night for humans. In hydromineral regulatory systems, plasma renin which stimulates through angiotensin, retention of sodium and water by the kidney, increases during periods of SWS in response to SWS-associated decreases in blood pressure and volume. ►Melatonin is high throughout the night, but is absent in daytime.

## Digestive Regulation

Digestion is obviously a function of eating, which is done during waking, but the gastrointestinal system and associated endocrine systems are regulated across the sleep-wake cycle as well. Digestion is controlled by the enteric nervous system, which is influenced by the autonomic nervous system but can also function almost independently in the process of digestion, particularly digestive peristalsis. Nonetheless, the parasympathetic system is importantly involved in the secretion of digestive juices, including saliva and gastric acid, and in visceral motility. Selective and reciprocal changes in sympathetic and parasympathetic components are also responsible for diverting circulation from the skeletal muscles to the smooth muscles of the viscera to support gastrointestinal activity. Similarly, the parasympathetic system through ►acetylcholine stimulates insulin release from the beta cells, whereas the sympathetic through noradrenaline inhibits insulin release from the beta cells and stimulates glucagon release from the alpha

cells of the pancreas. Insulin promotes uptake of glucose and its storage as ►glycogen in liver and muscle cells. Glucagon prevents these and stimulates glycogenolysis for mobilization and use of glucose. Thus during waking, dependent upon consumption of a meal, the parasympathetic system stimulates digestion and an anabolic state of replenishing energy stores during periods of rest, whereas the sympathetic system inhibits digestion and promotes a catabolic state of energy mobilization and expenditure during motor activity.

During SWS as during rest, when the parasympathetic system predominates, digestion of food can continue. Generally, however, food is digested prior to sleep onset, and digestive activity is relatively quiescent during sleep. Nonetheless, gastric acid secretion continues. Insulin release is quite high during the night in humans. Insulin release is highest in the early part of the night during SWS when growth hormone release is also high, rendering this period and state of rest a maximal anabolic state, since the release of insulin together with growth hormone would stimulate uptake of amino acids and protein synthesis in multiple tissues.

Relatively little is known concerning changes in digestive or metabolic processes during PS or REMS, relative to SWS. However, given the storms of sympathetic activity that occur during PS, many digestive and hormonal processes can be differentially affected during this state.

### Summary of Physiological Regulation Across Sleep-Wake States

During waking, homeostatic processes involving positive and negative feedback maintain the body in a relatively balanced state while permitting activity to modulate various systems within a healthy range. Under conditions of high activity involving locomotion, fight or flight, central arousal systems activate both somatic and sympathetic motor systems. These systems are also activated by hunger and promotion of food seeking behaviors. Blood pressure, heart rate, blood supply to muscles, respiratory rate, temperature, cortisol and glucagon release are all increased for supply of energy in these catabolic states. At the same time, blood supply to the viscera, digestive processes, growth hormone, prolactin and insulin release are all decreased and energy storage thus prevented. Following consumption of a meal, an anabolic state of rest usually follows during which the sympathetic nervous system is inhibited and the parasympathetic nervous system activated. This condition allows for digestion by facilitation of gastrointestinal activity along with secretion of acid and digestive juices. Release of insulin is stimulated and promotes uptake of glucose and replenishment of fuel stores.

SWS also is a state of rest but one which allows maximal rest and restoration of fuel stores. This anabolic state is characterized by somatic inactivity and a predominance of parasympathetic activity in the periphery, centrally promoted by sleep promoting systems in the brainstem and preoptic area. Blood pressure, heart rate, respiration, body temperature and basal metabolism along with corticosteroid release are all at their lowest levels. Digestive processes are relatively quiescent as digestion of food has usually been completed. On the other hand, insulin is high along with growth hormone and prolactin release which collectively stimulate amino acid uptake and protein synthesis for repair and growth along with replenishment of energy stores in multiple tissues. SWS is thus an anabolic state allowing for large homeostatic adjustments in all physiological systems for reestablishing and maintaining balance in energy stores and a healthy condition of tissue in adult organisms, as well as growth in immature organisms.

PS or REMS is truly a "paradoxical" state since it is also an anabolic state of sleep and continued rest for the antigravity skeletal muscles, yet is a catabolic state with high activity for the brain and some rapid or twitching muscles, along with the sympathetic nervous system through which surges in heart rate, blood pressure, and respiration occur. During this state, the feedback mechanisms which are fundamental to homeostasis are inhibited, such that cardiovascular, respiratory and thermal regulation are blunted. Such changes may reflect conditions which can also occur with active behaviors during waking and thus dream activity or processes during this "paradoxical" state.

# Sleep-Wake Cycle

Derk-Jan Dijk
Surrey Sleep Research Centre, University of Surrey, Guildford, Surrey, UK

## Synonyms

Sleep-wake rhythms; Wake-sleep cycle

## Definition

The rhythmic alternation between two behavioral states: sleep and wakefulness. The rhythmic regulation of the alternation between these two states usually refers to rhythms with a circadian period.

## Characteristics

### Sleep and the Sleep-Wake Cycle

The defining behavioral characteristics of sleep that are used to identify sleep in many animals are: (i) a species-specific posture; (ii) reduced responsiveness to external stimuli; (iii) rebound after deprivation see [1].

The assessment of a species-specific posture requires around-the-clock behavioral observations. In most species, sleep will be accompanied by behavioral quiescence. In some species, such as dolphins, sleep verified by electrophysiological recordings has been observed while the animal is behaving.

Variation in responsiveness across putative sleep and wake states can be assessed by quantification of arousal thresholds for standardized tactile, auditory, or other stimuli. Animals can be deprived from sleep by continuous stimulation through handling or engagement of the animal in activities such as exploration or forced locomotor activity. A rebound of the putative sleep state after a period of deprivation is indicative of homeostatic regulation of sleep and is considered a characteristic that differentiates between a simple circadian rhythm and a homeostatically regulated state.

### NREM and REM Sleep

In mammals and birds sleep can be subdivided in two very different sleep states: ►non-rapid-eye movement (NREM) sleep and ►rapid-eye movement sleep (REM) see [1,2]. The two states are identified by simultaneous recording of the ►electroencephalogram (EEG), the electroculogram (EOG) and muscle tone (►electromyogram, EMG). NREM sleep is characterized by low frequency, high amplitude EEG patterns and absence of rapid eye movements. In mammals, ►sleep spindles and slow waves (also referred to as ►slow-wave activity, SWA, or delta waves) are defining EEG characteristics of NREM sleep. In humans, NREM sleep is subdivided in stages 1–4 which contain progressively more SWA. During REM sleep, the EEG patterns resemble those of quiet wakefulness, while at the same time rapid eye movements and atonia in skeletal muscles are observed. The major neuromodulatory systems, including the noradrenergic, serotonergic, histaminergic, cholinergic, and orexinergic systems, are implicated in the alternation between the three vigilance states, NREM, REM and wakefulness. NREM and REM sleep alternate with an ►ultradian periodicity within the sleep episode. The period of this ultradian rhythm varies both within and between species and is proportional to brain size. The ultradian rhythm in REM sleep is generated by the reciprocal interaction of neuronal populations in the upper brain stem and hypothalamus.

### Homeostatic Regulation of Sleep and its Function

When animals are provided with *ad libitum* sleep opportunity following a period of enforced wakefulness, i.e., total ►sleep deprivation, an increase in sleep is observed see [3–5]. In mammals, total sleep deprivation leads to an increase in total sleep time, an increase in SWA in NREM sleep and an increase in REM sleep time. Selective deprivation of REM sleep is followed by an increase in REM sleep, and selective deprivation of ►slow-wave sleep (SWS) or SWA leads to a selective enhancement of SWA. SWA in NREM is under strict homeostatic control and mathematical models describing its dependence on the sleep-wake history are available for rats and humans. SWA is also affected by specific experiences during wakefulness, such as explorative behavior, intense somatosensory stimulation and learning. This accurate control of SWA has led to the hypothesis that slow waves are an important aspect of sleep and that they reverse non-specific detrimental effects of wakefulness on the central nervous system. Current hypotheses on the function of sleep for the central nervous system

emphasize the role of SWS in reversing the increase in synaptic strength and the role of both REM and NREM sleep in consolidation of procedural and declarative memories.

## Circadian Regulation of Sleep

In nocturnal species such as rats and mice, wakefulness predominates during the night and sleep during the day see [6–9]. In ►diurnal species, such as humans and fruit flies, wakefulness occurs primarily during the day and sleep at night. This association between the ►light-dark cycle and the predominance of sleep is, in itself, not sufficient to conclude that it is regulated by endogenous circadian rhythms. Involvement of circadian process in the regulation of sleep can be ascertained by quantifying its occurrence while the organism is studied under constant environmental conditions, i.e., in the absence of rhythmic variations in variables such as light and temperature. If sleep and wakefulness are not uniformly distributed but the probability of their occurrence varies with a periodicity in the circadian range, then it is safe to assume that circadian processes are involved.

In all species in which sleep has been identified, circadian processes play a role in its regulation. In mammals the role of circadian processes has been studied by ablation of the ►suprachiasmatic nuclei (SCN) of the hypothalamus, which are the locus of the ►pacemaker driving circadian rhythms in physiology and behavior. SCN lesions abolish neither the occurrence of sleep, nor its homeostatic regulation. Although specific aspects of sleep structure, such as REM sleep, and EEG phenomena, such as ►sleep spindles, are modulated by circadian processes, the circadian regulation of sleep primarily concerns its timing. Whereas in the intact animal the distribution of sleep and wakefulness is circadian, in the SCN-lesioned animals sleep and wakefulness are distributed uniformly across the 24 h period. The SCN exert its influence on sleep through indirect projections via the dorsal medial hypothalamus to areas involved in the generation of sleep and wakefulness which are located in the hypothalamus, the thalamus and the brainstem. The SCN also modulate sleep propensity through their influence on the circadian rhythms in other variables, such as body temperature and the pineal hormone ►melatonin.

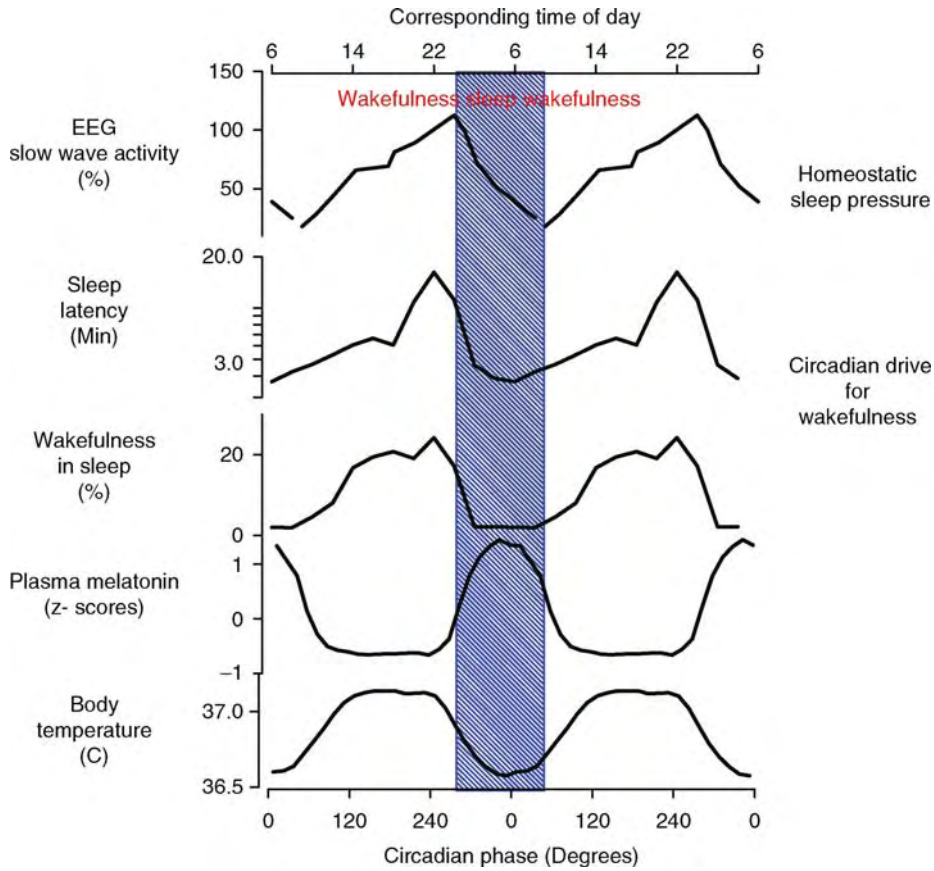
Alterations of some of the core ►clock genes involved in the generation of circadian process do not abolish sleep or the homeostatic response to sleep loss but lead to modifications in total sleep time, sleep structure and the homeostatic regulation of sleep in animals and humans. For example, in mice devoid of the *Cry1* and *Cry 2* genes, EEG SWA, which is a primary marker of sleep homeostasis, is enhanced and total sleep time is increased. In humans, a polymorphism in the *PER3* gene is associated with an enhancement of SWA in NREM sleep, and theta and alpha activity in the EEG in wakefulness and REM sleep.

## Interaction of the Homeostatic and Circadian Regulation of Sleep-Wake Cycles in Humans

The interaction of sleep regulatory and circadian processes has been studied in detail in humans see [6,10]. Early experiments by Aschoff and Wever in Germany and Czeisler and Weitzman in the US established that the human sleep-wake cycle persists with a near 24-h period in the absence of an externally imposed light-dark or clock time cycles. These observations demonstrated the endogenous circadian nature of the ►sleep-wake cycle also in humans. Furthermore, both research groups reported that the sleep-wake cycle can dissociate from the endogenous circadian rhythms of other variables, such as core body temperature and urine volume. This phenomenon, which was called spontaneous ►desynchrony, demonstrates that the sleep-wake cycle is generated by the interaction of two oscillatory processes, which in the two-process model of sleep regulation are referred to as a circadian and a homeostatic ►oscillator.

According to this standard model, the circadian oscillator regulates the preferred timing of sleep and the homeostatic oscillator tracks sleep debt, which increases during wakefulness and dissipates during sleep. The deep circadian oscillator is synchronized to the 24-h geophysical cycles primarily through circadian variation in its sensitivity to ocular light exposure. The mechanisms underlying the synchronization between the homeostatic and circadian oscillator are not well understood. Under normal, entrained conditions, when we are active during the day, and sleep at night, the two oscillators are in synchrony.

Desynchrony between the two oscillators occurs during ►shift work and ►jet-lag and has been induced in the laboratory in forced-desynchrony experiments. Under these conditions the circadian oscillator can be tracked by the rhythm of melatonin, and has been shown to oscillate with a period of approximately 24.2 h. Circadian wake propensity, as assessed by the latency to sleep onset (Fig. 1b), or the intrusion of wakefulness in scheduled sleep episode (Fig. 1c), is greatest just prior to the onset of nocturnal melatonin secretion, which under entrained conditions occurs at approximately 22:00 h (Fig. 1d). Circadian sleep propensity is strongest at the nadir of the core body temperature rhythm, which in healthy individuals is located at approximately 06:00 h (Fig. 1e). The homeostatic oscillator can be tracked by slow EEG oscillations in the sleep and wake EEG. Homeostatic sleep pressure increases during the waking day (Fig. 1a), in parallel to the increase in the circadian drive for wakefulness and declines during the nocturnal sleep episode, in parallel to the increase in the circadian



**Sleep-Wake Cycle. Figure 1** Circadian and homeostatic regulation of sleep and wakefulness in humans. Panel A: Increase of homeostatic sleep pressure during wakefulness and its dissipation during sleep as reflected in EEG SWA during daytime naps and nocturnal sleep. Circadian variation in wake/sleep propensity as reflected in the latency to sleep onset (Panel B) after 18 h:40 min of wakefulness and wakefulness (Panel C) in sleep opportunities, measured during forced desynchrony of the sleep-wake cycle and endogenous circadian rhythms of melatonin (Panel D) and core body temperature (Panel E).

drive for sleep. It is through these opposing homeostatic and circadian processes that the sleep-wake cycle remains consolidated when the two oscillators are sycnchronized during ►entrainment. During disruption of this desynchrony, as occurs during shift work, jet lag and in circadian sleep disorders, sleep consolidation and waking performance are compromised.

# Sleep-Wake Mechanisms

Barbara E. Jones
Department of Neurology & Neurosurgery, McGill University, Montreal Neurological Institute, Montreal, QC, Canada

## Synonyms

Sleep-wake neurochemical substrates

## Definition

Mechanisms comprising the neural systems and their neurotransmitters which generate the three major states of mammals: wake (W), slow wave sleep (SWS) and paradoxical sleep (PS) or rapid eye movement sleep (REMS).

## Characteristics

The sleep-wake mechanisms comprise the neural systems and their neurotransmitters which generate the three major states of mammals: ►wake (W), ►slow wave sleep (SWS) and ►paradoxical sleep (PS) or ►rapid eye movement sleep (REMS) (see Fig. 1). W is a behaviorally active and responsive state with phasic and tonic activity on the electromyogram (EMG) recorded from the postural muscles, and fast activity (gamma, 30–60 Hz) on the electroencephalogram (EEG) recorded from the cerebral cortex. SWS is a behaviorally quiet state with low muscle tone on the EMG and large slow waves (delta, 0.5–4 Hz) on the EEG. PS or REMS is a "paradoxical" state because it is characterized by muscle atonia on the EMG of the axial postural muscles, yet by rapid eye movements and small twitches of the facial and distal flexor muscles. It is also characterized behaviorally by a lack of responsiveness, typical of sleep, yet by fast (gamma) activity on the EEG, typical of cortical activation and W.

The neural systems generating these states are located through the ►brainstem, hypothalamus and basal forebrain (BF) and give rise to either descending projections to the spinal cord, by which they influence movement and muscle tone (recorded on the EMG), or ascending projections to the cerebral cortex, by which they influence cortical activity (recorded on the EEG) (see Fig. 1).

The different neural systems utilize different chemical neurotransmitters, which include most importantly: ►glutamate (Glu), GABA, ►acetylcholine (ACh), noradrenaline (NA), ►histamine (HA) and ►orexin (►Orx or ►hypocretin, ►Hcrt) (see Fig. 1). Since except for Glu and GABA, these chemicals serve as neuromodulators upon specific receptors on specific cells, they can generate specific states or the specific EMG or EEG activities of those states.

Specific neural groups with particular projections and neurotransmitters discharge during particular states or in association with particular EMG or EEG activities of those states such as to exert their influence in a state selective and determining manner (see Fig. 1).

## Neural Systems and Their Neurochemical Substrates

### *Arousal Systems*

#### *The Reticular Formation (RF) and Glutamate (Glu)*

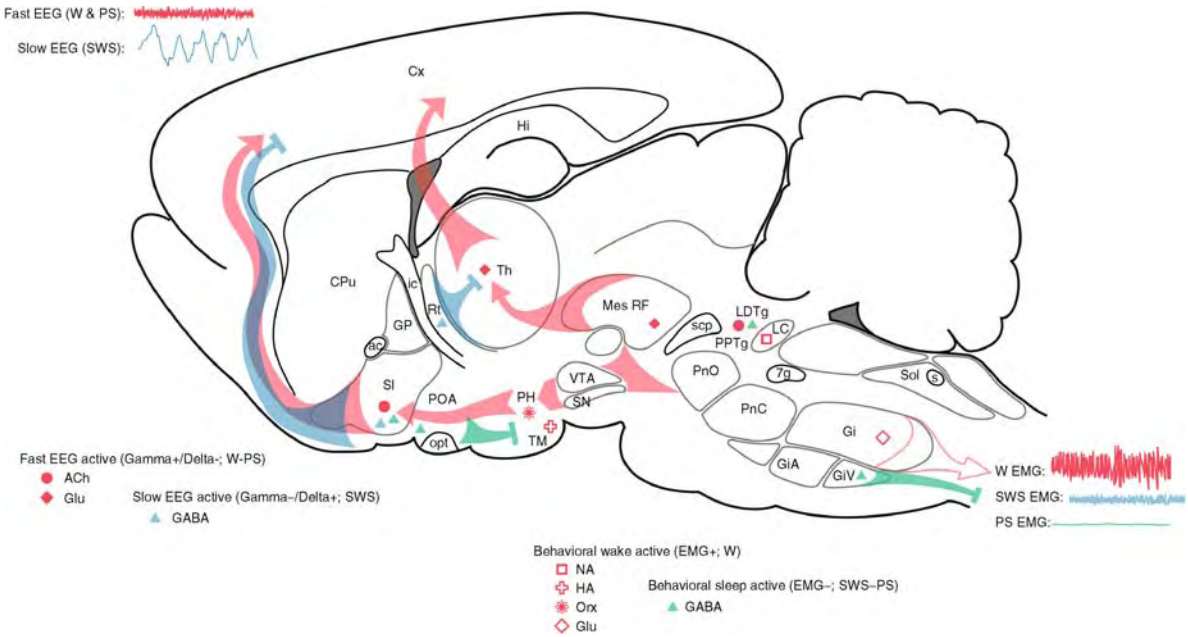
Since the early studies of Moruzzi and Magoun, it has been known that the RF, which is a netlike web of cells and passing fibers in the brainstem, is essential for the ►maintenance of wakefulness, as its destruction by large lesions results in a comatose state [2]. Neurons of the RF give rise to descending projections into the spinal cord by which they influence movement and muscle tone or to ascending projections into the forebrain by which they influence through other relays, cortical activity (see Fig. 1). Through a dorsal pathway, the RF neurons project onto midline and intralaminar neurons in the thalamus, which project in turn in a widespread manner to the cerebral cortex, as the nonspecific thalamo-cortical projection system. Through a ventral pathway, the RF neurons project to and through the hypothalamus and up to the BF from where other neurons also project in turn in a widespread manner to the cerebral cortex, as the basalo-cortical projection system.

Most projection neurons in the RF likely utilize Glu as a neurotransmitter and would accordingly excite their target neurons in the spinal cord or forebrain (Fig. 1).

Neurons in the caudal pontine and medullary RF with predominantly descending projections discharge maximally during waking and in association with movement and muscle tone. Those more concentrated in the oral pontine and mesencephalic RF with predominantly ascending projections discharge maximally during waking and in association with cortical activation. Collectively, these RF neurons stimulate and maintain by their activity and release of Glu, behavioral ►arousal with muscle tone and cortical activation.

#### *Cortical Activation and Acetylcholine (ACh)*

From very early studies, ACh has been known to play a very important role in cortical activation [1–3]. Drugs which enhance or mimic cholinergic transmission, such as physostigmine and nicotine, enhance cortical activation, whereas those which block ACh receptors, such as atropine, diminish fast cortical activity, which is replaced by slow wave activity. Interestingly, however, blocking cortical activation with atropine does not prevent movement or behavioral arousal and so produces a dissociation between cortical activity and behavior. Moreover, ACh release from the cortex is high in association with cortical activation during both W and PS. And, injections of the cholinergic agonist,



**Sleep-Wake Mechanisms. Figure 1** Sleep-wake state neurochemical substrates. Sagittal schematic view of the rat brain depicting neurons with their chemical neurotransmitters and pathways by which they influence cortical activity or behavior across the sleep/wake cycle. Wake (W) is characterized by fast gamma activity on the cortical EEG (upper left) and high postural muscle tone on the neck EMG (lower right); slow wave sleep (SWS) by slow delta EEG and low tone on the EMG; and paradoxical sleep (PS) by fast gamma EEG and atonia on the EMG. Neurons which are active during waking (red symbols) include cells with ascending projections toward the cortex which stimulate fast cortical activity and cells with descending projections toward the spinal cord which stimulate postural muscle tone and behavioral waking. Those with predominantly ascending projections discharge in association with fast EEG activity (gamma+) and cease firing with delta activity (delta−) to be active during both W and PS (filled red symbols); they include cholinergic (ACh) and glutamatergic (Glu) neurons. Those with more diffuse or descending projections discharge in association with behavioral arousal and EMG activity (EMG+) and cease firing with muscle atonia to be active during W and silent during PS (empty red symbols); they include noradrenergic (NA), histaminergic (HA), orexinergic (Orx) and some putative glutamatergic (Glu) neurons. Neurons which are active during sleep (blue and aqua symbols) include cells with ascending projections toward the cortex which dampen fast cortical activity and those with descending projections toward the brainstem and spinal cord which diminish behavioral arousal and muscle tone. Those with projections to the cortex discharge in association with slow EEG activity (gamma−/delta+) during SWS (blue triangles) and include certain GABAergic neurons in the basal forebrain (BF) and preoptic area. Also shown are GABAergic neurons of the nucleus reticularis in the thalamus that discharge in bursts with sleep spindles and slow waves to inhibit and pace thalamocortical relay neurons. In the BF and preoptic area, presumed GABAergic neurons with descending projections increase their firing as muscle tone progressively decreases (EMG−) during SWS and PS (aqua symbols). Also shown are GABAergic (and/or glycinergic) neurons in the ventral medulla that project directly to the spinal cord where they could inhibit neck and other motor neurons during sleep. carbachol into the brain and particularly into the oral pontine RF produce a state with cortical activation in association with muscle atonia or the state of PS. ACh and cholinergic neurons thus elicit cortical activation in the presence or absence of behavioral arousal and thus likely stimulate cognitive processes during both W and PS. They may even elicit attenuation of movement or muscle tone along with attentive immobility during waking or with dreaming during PS.

Cholinergic neurons are located in the brainstem, where they are clustered in the dorsolateral pontomesencephalic tegmentum within the laterodorsal and pedunculopontine tegmental nuclei (LDT and PPT). The LDT and PPT neurons project locally into the brainstem RF and rostrally to the thalamus, hypothalamus and BF. ACh excites thalamo-cortical projection neurons to promote their tonic discharge and thus to promote through them, fast cortical activity or cortical activation [4]. Cholinergic neurons are also located in the BF, where they comprise the magnocellular basal nucleus of Meynert within the substantia innominata (SI, see Fig. 1). In the rat brain, they are distributed as well within the magnocellular preoptic nucleus (MCPO), nucleus of the diagonal band of Broca (DBB) and medial septum (MS). Collectively, the BF cholinergic neurons innervate all of the neocortex and hippocampus. ACh excites pyramidal cells in the cortex and thus promotes therein fast cortical activity while blocking slow wave activity [4].

Immunohistochemically identified cholinergic neurons have to date only been recorded in the BF. The BF ACh cells discharge in association with fast cortical activity (gamma+/delta−) during W and PS (as W-PS active cells) (see Fig. 1). Presumed cholinergic neurons in the LDT and PPT discharge in a similar manner. They can thus collectively stimulate cortical activation during both W and PS.

### *Behavioral Arousal, Noradrenaline (NA) and Dopamine (DA)*

The catecholamines, NA and DA have been known to stimulate arousal since early pharmacological studies [2,3,5]. Amphetamine, which releases both NA and DA, evokes prolonged wakefulness characterized by cortical activation and behavioral arousal.

NA-containing neurons are located in the brainstem and clustered in the ►locus coeruleus (LC) in the pons (see Fig. 1). The LC neurons give rise to highly diffuse projections. They project into the brainstem and spinal cord and directly innervate and excite motor neurons. They project into forebrain subcortical relay stations of the thalamus, hypothalamus and BF and also directly up to the cerebral cortex. In the thalamus, NA excites the thalamo-cortical projection neurons and in the BF, it excites the cholinergic basalo-cortical neurons. In the cortex, it also excites pyramidal cells to stimulate fast cortical activity [4]. When NA neurons discharge and NA is released, they would thus stimulate both behavioral arousal and cortical activation. LC neurons discharge selectively during waking and at highest rates during active waking. They decrease and cease firing during SWS and PS.

DA-containing neurons are located in the diencephalon and mesencephalon, being most numerous in the substantia nigra (SN) and ventral tegmental area (VTA). The latter cell groups project into the forebrain, particularly the striatum, amygdala, BF and prefrontal cortex. Both through pharmacological studies and clinical studies of Parkinson's patients, suffering from degeneration of DA neurons, DA is known to play an important role in movement. However, their influence in this domain occurs through forebrain centers, including limbic structures and thus by promoting movement but not directly stimulating it through action upon motor neurons. Given its release by many addictive drugs, DA is also known to be positively rewarding. Upon recording, presumed DA neurons were surprisingly found to discharge during waking and sleep, although in different patterns. They discharge in bursts with rewarding stimuli during W and they do so during PS, perhaps underlying the emotional components of ►dream activity.

### *Behavioral Arousal and Histamine (HA)*

HA has been known to stimulate waking since antihistaminergic drugs diminish cortical activation and produce sleepiness [2,5,6]. The HA neurons are located in the ►tuberomammillary (TM) nucleus of the hypothalamus (see Fig. 1). They give rise to highly diffuse projections into the forebrain and also though to a lesser extent the brainstem and spinal cord. HA excites neurons in the thalamus, BF and cortex, stimulating cortical activation. They discharge during waking and cease firing during sleep.

### *Behavioral Arousal and Orexin (Orx)/Hypocretin (Hcrt)*

Following its discovery ~10 years ago, Orx/Hcrt was found to be essential for the maintenance of waking and behavioral arousal, since in its absence or that of its receptor, ►narcolepsy with cataplexy occurs in mice, dogs and humans [1,5–7]. In humans, this condition is characterized by excessive daytime sleepiness, sleep onset REMS, paralysis and hallucinations. Cataplexy or sudden loss of muscle tone is often triggered by strong emotions and particularly laughter. Given the almost direct entry into REMS or loss of muscle tone accompanied by hallucinations, this disorder is thought to be a disorder of REMS. Its appearance in absence of Orx/Hcrt indicates that Orx/Hcrt neurons sustain behavioral arousal with postural muscle tone, particularly under conditions of strong emotion when other systems, perhaps cholinergic (above), precipitate a loss of muscle tone. The neurons which contain Orx/Hcrt are located in the posterior hypothalamus (see Fig. 1) and like NA LC neurons give rise to highly diffuse projections through the forebrain, brainstem and spinal cord. In the spinal cord, they innervate and excite motor neurons. In the brainstem and forebrain, they innervate and excite the neurons of the other arousal systems, including the ACh LDT/PPT and BF neurons, the NA LC neurons, and the HA TM neurons, together with neurons of the diffuse

thalamo-cortical projection system and deep layers of the cortex. They also directly excite somatic and sympathetic motor neurons. Their discharge would thus be associated with cortical activation and behavioral arousal with increased muscle tone and sympathetic activity. Immunohistochemically identified Orx/Hcrt neurons were indeed found to discharge during active waking, decrease firing during quiet waking and cease firing during sleep, including PS.

## Sleep Systems

### GABA

GABA has long been known to be important in promoting sleep, since the major hypnotic drugs and many anesthetics act by enhancing GABAergic transmission [1,5,8]. GABAergic neurons are located through all regions of the brain and of course are critical for normal functioning during waking of all neural circuits. However, particular GABAergic neurons are responsible for inhibiting and/or shaping the discharge of neurons of the arousal and activating systems.

As learned in early studies, there are neurons concentrated in certain regions of the brainstem RF which through descending projections to the spinal cord inhibit movement and muscle tone (see Fig. 1). These RF neurons utilize the inhibitory neurotransmitters, GABA and glycine. These amino acids are responsible for inhibiting motor neurons in the spinal cord and brainstem during PS [9]. Such RF neurons discharge selectively during sleep and maximally during the muscle atonia of PS.

GABAergic neurons through the brainstem RF also become active with sleep and are likely responsible for inhibiting other RF projection neurons. GABAergic neurons in the oral pontine and mesencephalic RF can inhibit neighboring Glu forebrain projecting neurons to diminish their discharge with sleep. Such GABAergic neurons also inhibit the LC NA neurons to allow sleep and PS with muscle atonia to occur (Fig. 1).

In the thalamus, GABAergic neurons, located in what is called the thalamic reticular nucleus, surround and innervate the specific and nonspecific thalamo-cortical projection neurons (see Fig. 1). By their specific properties and pattern of discharge, they not only inhibit, but also shape the discharge pattern of the thalamo-cortical relay neurons [10]. When released from excitatory inputs from the RF, the GABAergic thalamic reticular neurons discharge in bursts to drive spindle and then delta activity in the thalamo-cortical neurons. This activity is transmitted through the thalamo-cortical-thalamic pathways to generate the slow wave patterns which characterize and define SWS.

Other GABAergic neurons are found in the BF and preoptic area (including the ventrolateral preoptic area), (POA) which also play important roles in generating sleep (see Fig. 1) [1,7,8]. Among these, some GABAergic neurons discharge in association with cortical slow waves which they could accordingly promote during SWS. The discharge of these SWS-active cells is negatively correlated with gamma EEG activity and positively correlated with delta EEG activity (gamma−/delta+). Some may project directly to the cortex, others locally onto neighboring cholinergic BF neurons, which have a reciprocal profile of discharge (above). Other presumed GABAergic BF and POA neurons discharge at progressively higher rates through SWS into PS, as SWS/PS-active cells. Their discharge is negatively correlated with EMG. Such cells likely correspond in part to GABAergic neurons giving rise to descending projections to the posterior hypothalamus and innervating Orx/Hcrt neurons, which are inhibited by GABAergic inputs during sleep.

### Adenosine

►Adenosine has long been thought to play a role in promoting sleep since one of the major stimulants, caffeine, acts as an antagonist of adenosine receptors [3]. It is potentially released from all nerve terminals, since it is a product of ATP, the major energy source contained in terminals and their synaptic vesicles. Its levels are progressively increased with sleep deprivation, presumably as more ATP would be utilized and metabolized by actively discharging neurons. Adenosine inhibits many neurons in the brain, including importantly the cholinergic BF neurons.

## Orchestration of Neural Systems Generating Sleep-Wake States

The three states of mammals are generated by concerted or reciprocal discharge of hodologically and chemically distinct cell groups through the brain. W is stimulated and maintained by spinally projecting and forebrain projecting Glu RF neurons, which are in turn facilitated and reinforced in their action by diffusely projecting NA, HA and Orx neurons. These systems collectively promote motor activity along with muscle tone for behavioral arousal with cortical activation. GABAergic neurons in the brainstem, preoptic area and BF inhibit the neurons of these arousal systems to shut them off during sleep and thus prevent behavioral arousal while diminishing muscle tone. Other GABAergic neurons in the thalamus and BF inhibit thalamo-cortical and cortical neurons respectively, while also pacing them to elicit spindle and slow wave activity in the cortex during SWS. Discharging during W and PS, cholinergic neurons in the brainstem and BF stimulate cortical activation along with attention during W and perhaps ►dreaming during PS, when in absence of the influence from other arousal systems, most importantly Orx/Hcrt neurons, they also provoke a loss of muscle tone.

## Sleep Walking

### Definition

Sleep walking, also known as Somnambulism, consists of a series of complex behaviors that are initiated during sudden arousals from Non-REM sleep, and usually from slow-wave (delta) sleep, which culminate in walking around with an altered state of consciousness and impaired judgment, with absent or poor subsequent recall. In some adults there is associated dreaming.

## Sleeping Sickness

### Definition

Infectious parasitic disease carried by tsetse flies and characterized by inflammation of the brain and the covering of the brain (meninges). An alternative name is African trypanosomiasis. Sleeping sickness is caused by two organisms, T. brucei rhodesiense and T. brucei gambiense.

## Slice Preparation

Haruyuki Kamiya
Department of Neurobiology, Department of Molecular Neuroanatomy, Hokkaido University School of Medicine, Sapporo, Japan

### Synonyms

Acute brain slice

## Definition

Thin sections (~400 μm thick) of part of the brain kept in oxygenated ►artificial cerebrospinal fluid.

## Purpose

In the mammalian central nervous system (CNS), pharmacological studies were seriously hampered by the presence of the blood brain barrier (BBB). Direct infusion of drugs into the small brain regions is technically difficult *in vivo*, and it is rather hard to estimate the actual concentration of the drug at the recording site. In order to develop alternative *in vitro* experimental systems enabling pharmacological studies in a quantitative manner, in the mid 1960s, Yamamoto and McIlwain, devised a novel way to keep intact neuronal networks in thin slices of anterior piriform cortex [1,2]. Afterwards, it was revealed that this method is applicable to many cortical areas including neocortex, cerebellum, hippocampus, *etc* (Figs. 1 and 2).

Slice preparation retains intact structures and functions of CNS synapses, and use-dependent synaptic plasticity such as LTP and LTD can also be induced in these experimental systems. Currently, slice preparation is one of the most widely-used techniques to study the mechanism of synaptic transmission and plasticity *in vitro*. It also provides useful experimental models for the study of the pathological mechanisms underlying epileptogenesis and generation of seizure discharges. Slices are also widely used for studies of ischemic cell damage following hypoxia and hypoglycemia.

## Principles

In principle, slice preparations can be made from any brain regions by cutting them into thin sections.

However, in practice there are several technical limitations to this method. Slices are usually continuously perfused with artificial cerebrospinal fluid (at a rate of ~2 ml/min) bubbled with 95% $O_2$ and 5% $CO_2$. Neurons in slice preparation are nourished with oxygen and glucose exclusively by penetration from the surface, and therefore the thickness of the slice is limited and must be thinner than ~400 μm. In addition, several conditions are critical for preparing "healthy" slices. Generally, slices should be cut quickly following removal from the skull in order to avoid ischemic neuronal damage. Cooling of tissues before and during slicing improves viability of neurons and is practically essential. Using a ►cutting solution also improves the viability of neurons, especially when slices are prepared from older animals. Since cell damage is mainly due to an influx of $Ca^{2+}$ from the cut end or by activation of $Ca^{2+}$ channels and NMDA receptor channels, a low $Ca^{2+}$ and/or $Na^{+}$ solution remarkably reduces cell death during slicing. After cutting slices, it takes approximately one hour to recover metabolisms of neurons from cooling and subsequent depletion of ATP. Slices can be kept alive for up to 10 h, but their activity gradually diminishes due to the breakdown of important molecules such as proteins, nucleotides and lipids, because artificial cerebrospinal fluid does not supply sources for synthesis of those macromolecules.

## Advantages and Disadvantages

Slice preparation offers innovative experimental approaches for cellular and molecular neuroscientists. As discussed above, the most important advantage of this method is that quantitative pharmacological experiments of CNS neurons become feasible. In addition to pharmacological application, slice preparation is well suited for detailed cellular neurophysiological studies of CNS. Neurons are readily visible under the

**Slice Preparation. Figure 1** Hippocampal slice preparation. *Left panel*: Surface image of the slices. Transverse slices of mouse hippocampus (~400 μm thickness) were prepared using a ►vibrating slicer (see Fig. 2) and viewed under microscope with DIC optics. A photograph was taken from the boxed area shown in the schematic drawing (*right panel*). Note that some of the neuronal cell bodies can be seen in the cell layer (translucent layer). Hippocampal slice retains intact neuronal networks of tri-synaptic circuit, which are thought to be important for mnemonic function of the hippocampus.

**Slice Preparation. Figure 2** Vibrating slicer. Conventional vibrating type slicers for fixed tissues can be used for cutting living brain slices. A block of brain tissue was glued to the bottom of some metal dishes, and continuously submerged in an ice-cooled artificial cerebrospinal fluid gassed with 95% $O_2$ and 5% $CO_2$. After slicing using a horizontally oscillating razor blade, the metal dishes were lifted for the desired thickness (~400 μm) and cut another plane to obtain the slice.

microscope with DIC optics, and movement due to pulsation is absent. Therefore, slice preparation is adopted for many *in vitro* neurophysiological studies of ion channels, synaptic transmission, and local neuronal networks. Patch clamp recordings are also possible [3], even from fine cellular processes such as dendrite [4], axon [5], and presynaptic terminal [6] (►blind patch-clamp, slice patch-clamp). On the other hand, serious disadvantages of this method are that slices are short-lived and cannot be used for longer period than days. Therefore, acute slices are not usually suited for the molecular biological experiments using heterologous gene expression. In order to overcome this disadvantage, Gähwiler developed an ►organotypic slice culture that enables cultivation of slices for many weeks to months [7]. Thereafter, a much simpler method was revised for cultivating slices [8]. Currently, organotypic slice culture has been widely adopted for experiments requiring gene delivery either by using virus vector or by biolistic method. Combining GFP imaging with multiphoton laser microscopy, movement of glutamate receptors following high-frequency stimulation can be monitored in a real time manner [9]. Recently, activity-dependent changes in spine shape were also shown using a similar experimental strategy [10]. Another inevitable limitation of slice preparation arises from the slicing procedure itself. Although slices retain cytoarchitecture of the tissue of origin, only a fraction of the neuronal networks is kept intact because of thickness limitation (~400 μm). Therefore, it should be noted that natural inputs from presynaptic neurons are largely diminished or abolished in slice preparation.

S

# Sliding Filament Theory

Walter Herzog
Faculty of Kinesiology, University of Calgary, Calgary, Canada

## Definition

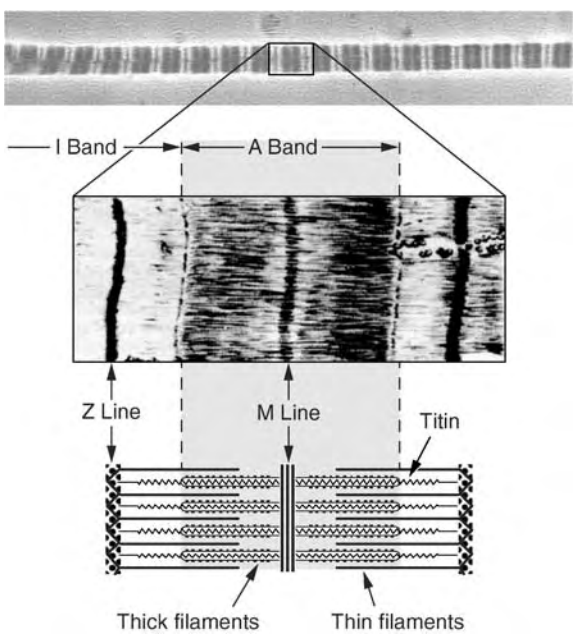
According to the sliding filament theory, muscle contraction occurs through the relative sliding of two sets of filaments (►actin and ►myosin). This sliding is produced by cyclic interactions of sidepieces from

the myosin filament (►cross-bridges) with specific sites on the actin filament. Each such interaction is associated with a cross-bridge ►power stroke whose energy is derived from the hydrolysis of adenosine-triphosphate (►ATP), one ATP per cross-bridge cycle.

## Characteristics

Prior to the 1950s, muscle contraction and force production was associated with the shortening of myosin filaments. Myosin filaments can be seen with microscopy as the dark bands (the so called A-bands) in the striation pattern typical for skeletal and cardiac muscle (Fig. 1).

However, in 1954, Andrew Huxley and Rolf Niedergerke [1] in single fibres and Hugh Huxley and Jean Hanson [2] in isolated myofibrils showed independently that the A-band was not shortening when their preparations were activated and contracted. They speculated that muscle contraction and shortening was not caused by A-band (or myosin) shortening, but rather by the sliding of actin filaments relative to the myosin filaments. This sliding was proposed to be powered by so called cross-bridges (sidepieces arising from the myosin filament) that attach cyclically to actin and pull the actin past the myosin filament.

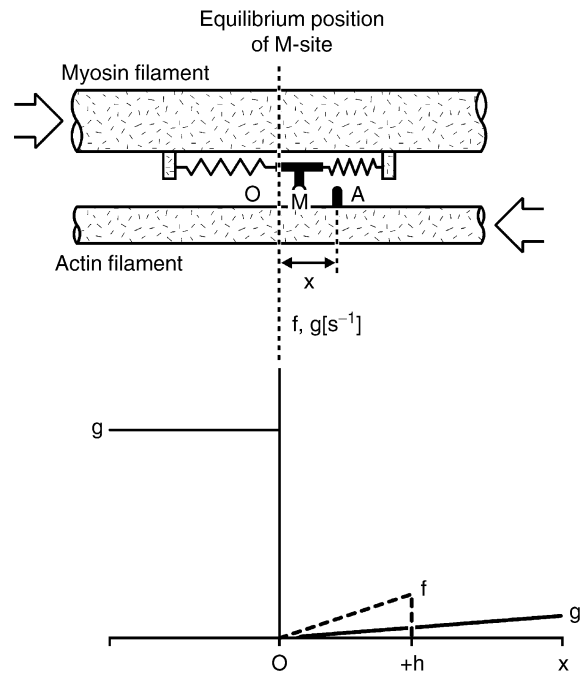


**Sliding Filament Theory. Figure 1** Micrograph of a series of sarcomeres from an single myofibril (*top panel*), an isolated sarcomere bordered by the z-lines and containing myosin (or thick filaments) in the A-band region and actin (or thin filaments) in the I-band region (*middle panel*), and schematic representation of an isolated sarcomere with z-lines, thick filaments, thin filaments and titin identified (*bottom panel*).

### The 1957 Cross-Bridge Theory

In 1957, Andrew Huxley [3] was the first to describe in precise mathematical terms how muscle contraction might occur and how the myosin and actin filaments might interact to cause muscle contraction. Huxley [3] proposed that cross-bridges were uniformly arranged along the myosin filament, and that there were uniformly arranged attachment sites for the cross-bridges on actin. Cross-bridges were assumed to be attached to myosin through a linearly elastic spring and they were moving around an equilibrium point through thermal agitation (Fig. 2).

Attachment and detachment of cross-bridges to actin was determined by a set of attachment and detachment rate functions that depended exclusively on the location of the cross-bridge equilibrium point relative to the nearest attachment site ("x" in Fig. 2). The attachment and detachment functions were asymmetric with respect to the cross-bridge equilibrium point, thus enforcing that force production was unidirectional, muscles can pull and exert tension, but they cannot push (Fig. 2). The 1957 theory contains

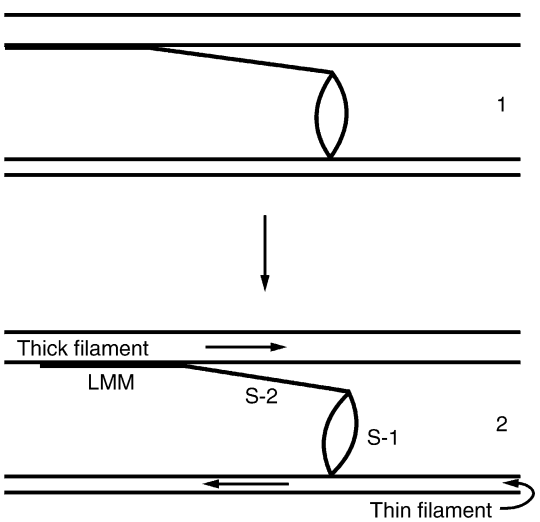


**Sliding Filament Theory. Figure 2** *Top*: Schematic illustration of the 1957 cross-bridge model with the cross-bridge head (*M*) oscillating around its equilibrium position through thermal agitation until it may become attached to its nearest attachment site on actin (*A*) *Bottom*: Rate functions of attachment (*f*) and detachment (*g*) as defined by Huxley [4]. Note that the rate functions are exclusive functions of x, the distance from the cross-bridge equilibrium position to the nearest actin attachment site. (Adapted from [3] with permission).

two cross-bridge states, an attached and a detached state. The action of each cross-bridge is independent of other cross-bridges and the force is given by the stretch of the elastic element that connects the cross-bridge to the myosin filament. Each cross-bridge cycle (attachment and detachment) was associated with the hydrolysis of one ATP.

### The 1969 Cross-Bridge Theory

Hugh Huxley [4] showed that the spacing between actin and myosin filaments behaves isovolumetrically, like that observed in whole muscle. Therefore, when ►sarcomeres are stretched from 2.0 to 2.8 μm, myofilaments approach each other and the distance between them decreases by about 18%. Huxley [4] argued that this is too great a range for protein interactions that must produce specific conformational changes associated with the regulation of enzyme activities. Based on further structural evidence, Huxley [4] suggested that the light meromyosin (LMM) part of the cross-bridge was bonded to the backbone of the filament (Fig. 3).The linear portion of the heavy meromyosin S-2 component (S-2) was assumed to be attached to the LMM portion through a flexible joint. The cross-bridge head (heavy meromyosin S-1) was also assumed to be attached to the heavy meromyosin S-2 portion through a flexible joint (Fig. 3), thus cross-bridges can interact with actin through a great range of ►lattice spacings without changing their orientation. Huxley [4] provided further structural evidence suggesting that the cross-bridge head could rotate and so produce force and sliding of actin. Thus the swinging lever arm theory was born.



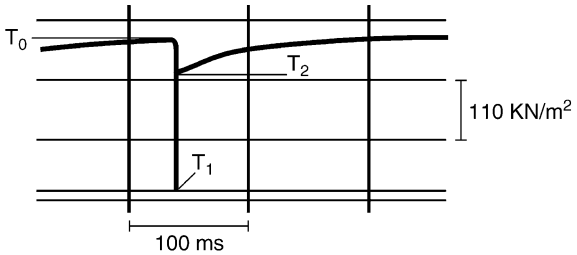
**Sliding Filament Theory. Figure 3** Schematic illustration of the mechanism of force generation according to Huxley [4]). Note that in the 1969 model, the cross-bridge head (S-1) can rotate around its attachment point on actin (thin filament).

### The 1971 Cross-Bridge Theory

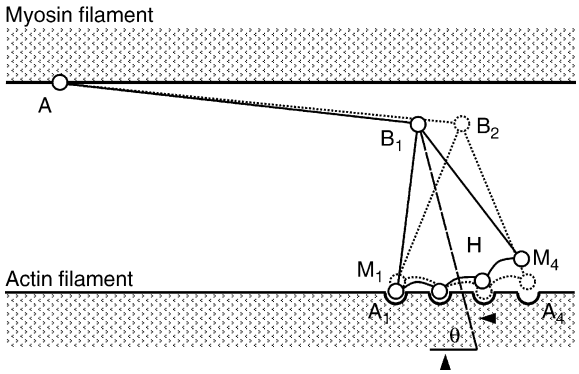
A characteristic of muscle contraction that could not be predicted adequately with existing models was the force transients following quick length changes. When a muscle fibre is shortened rapidly, force drops virtually simultaneously with the length change and then recovers quickly at first (1–2 ms) and more slowly later (Fig. 4).

In order to account for the force transients following stepwise length changes and to avoid losing the good predictive power of earlier cross-bridge models, Huxley and Simmons [5] introduced the concept of different attachment states for cross-bridges, thereby allowing the cross-bridges to perform work in a small number of steps. Going from one stable attachment configuration to the next was associated with progressively lower potential energy. Furthermore, Huxley and Simmons [5] assumed that there was an elastic element within each cross-bridge which allowed for cross-bridges to go from one stable attachment configuration to the next without a corresponding relative displacement of the actin and myosin filaments (Fig. 5).

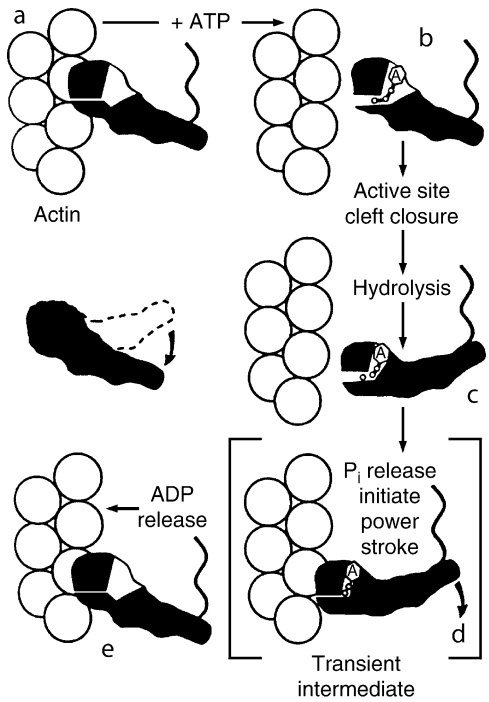
The force transients during a quick release could now be explained as follows. The virtually instantaneous drop in force with a quick shortening step was associated with the elastic cross-bridge element. The quick force recovery was associated with a rotation of the cross-bridge head from a position of high to a position of low potential energy, thereby stretching the elastic link connecting the cross-bridge to the filament and increasing force. Finally, the slow recovery of force was associated with the normal attachment/detachment



**Sliding Filament Theory. Figure 4** Force-time trace of an isolated muscle fibre preparation that is shortened rapidly by approximately 6 nm/half-sarcomere. When the fibre is shortened, force drops instantaneously because of the elastic attachment of the cross-bridge to the myosin backbone. Force then recovers, first rapidly because of a quick rotation of attached cross-bridge heads, then slowly in accordance with the normal attachment/detachment kinetics of cross-bridges (Adapted from Ford et al. (1977); with permission).



**Sliding Filament Theory. Figure 5** Schematic representation of the cross-bridge model according to Huxley and Simmons [5]. In this model, the cross-bridge head rotates about its attachment site on actin in several discrete steps (Adapted from [5] with permission).



**Sliding Filament Theory. Figure 6** Schematic representation of the mechanism of contraction according to Rayment et al. [6, 7]. In this model, the part of the cross-bridge that attaches to actin remains fixed, while rotation of the "cross-bridge" is associated with a conformational change of the light chain binding domain around a hinge in the myosin head (Adapted from Rayment et al. [6] (1993); with permission).

kinetics of the cross-bridges. Thus, cross-bridge models went from two states (attached and detached) to multiple state models with at least one detached and at least two attached states.

### *Current Thinking*

One further step in the development of cross-bridge models deserves attention. In their 1971 explanation of multi-state cross-bridge models, Huxley and Simmons thought that rotation involved the entire cross-bridge head and occurred around the attachment sites on actin. However, based on structural studies of the cross-bridge head (HMM S-1) and the corresponding attachment site on actin, Rayment et al. [6,7] suggested that the attachment of the cross-bridge head on actin was fixed, while the actual "cross-bridge" rotation was associated with a conformational change of the light chain binding domain around a hinge in the myosin head (Fig. 6).

## Slowly Adapting Type I Mechanoreceptors

### Definition

A mechanically sensitive sensory ending in the skin that adapts slowly to a sustained indentation and therefore is sensitive to static events; it is also dynamically sensitive. It has small, well-defined receptive fields and the sensory terminal is believed to innervate the Merkel-cell neurite complex. Also known as SAI (slowly-adapting type I) afferents in humans and SA receptors in the cat and primate.

## Smell Disorders

Basile Nicolas Landis
Unité de Rhinologie-Olfactologie, Clinique de Oto-Rhinologie-Laryngologie et de Chirurgie cervico-faciale, Hopitaux Universitaires de Genève, Genève, Switzerland

### Synonyms

Olfactory disorders; Dysosmia

### Definition

Olfactory disorders are states where the normal human olfactory function is altered. This might happen physiologically with age, but is mainly the consequence of a pathological event. The most frequent causes of olfactory disorders are head trauma, upper respiratory tract infections or sinunasal diseases. Other causes, assessing methods and therapy options are discussed.

### Characteristics

#### Anatomy

Olfactory perception starts at the level of the olfactory epithelium in the roof of the nasal cavity. ►Olfactory receptor neurons (ORN) are embedded within the respiratory epithelium and send their axons through the cribriform plate towards the olfactory bulbs. From there, most fibers directly project to the piriform and entorhinal cortices as well as to the amygdalae (all structures formerly subsumed under the term "limbic system") whereas a minority of fibers project through the thalamus towards the orbito-frontal cortex. Compared to other sensory modalities the olfactory system has some particularities. First, the majority of the olfactory fibers do not cross but project ipsilaterally in the brain. Second, most olfactory fibers bypass the thalamus and project very rapidly and directly in the pyriform cortex, amygdalae, and entorhinal cortex which are implicated in emotional and memory processing.

#### Chemicals Senses

Although this essay focuses on the olfactory system, it is necessary to mention briefly, taste and ►trigeminal function. Together with olfaction, taste and trigeminal function are called the "chemical senses." All three systems can be stimulated by chemicals, and they provide us with different information. The trigeminal system is the somato-sensory innervation of the nasal mucosa. The main modalities supplied by the trigeminal system are temperature, pain, touch, and irritation. Since most odorous compounds stimulate trigeminal nerve endings, at least at higher concentrations, this system is almost always co-activated in the perception of odors. With few exceptions almost all odorants have

been shown to exhibit trigeminal activation to some extent [1] (e.g., mint has a somewhat fruity odor, but also evokes a typical cooling effect which is mainly trigeminally mediated). The gustatory system provides the five basic tastes; sweet, sour, salty, bitter, and umami (glutamate). The latter, which resembles mainly the taste of chicken soup, has long been claimed in the Asian literature to be a basic taste quality, whereas the western scientific community considered umami mainly as a "taste enhancer." This controversy was resolved when monosodium glutamate receptors were found on the tongue surface acting as specific taste receptors [2]. Taste receptors are located within the taste buds, which are situated on all papillae except the filiform type. The highest densities of taste buds are found on the tongue and palate but they are also found throughout the entire oral cavity, hypopharynx and larynx. The facial, glossopharyngeal, and vagal nerves provide neural supply for these cells. Like olfaction, taste fibers project ipsilaterally into the brain stem. All gustatory fibers (facial, glossopharyngeal and vagus) innervating the oral-pharyngeal cavity converge into the nucleus solitarius within the brain stem. In most situations of the daily life (e.g., eating) all tree chemical senses are stimulated concomitantly.

## Retronasal Olfaction

"Retronasal olfaction" encompasses the perception of odors emanating form the oral cavity during eating and drinking. It is opposed to "orthonasal olfaction" which occurs during sniffing. The retronasal olfactory pathway, contributing to the flavor of foods or drinks, is commonly associated with "taste." Clinically, most patients with olfactory dysfunction complain of both, loss of smell and taste. Furthermore, this "taste" loss has been reported to affect quality of life of most patients with olfactory disorders [3].

## Measurement

Olfactory function, like most other sensory systems can be measured by psychophysical or objective techniques. Since the subjects' self assessment of olfactory function is unreliable, testing of olfactory function is necessary [3].

### *Psychophysical Methods*

The basic principle of psychophysical testing of olfaction is to expose a subject to an olfactory stimulus and to interpret the responses or reactions of the tested subject.

The most valuable advantage of psychophysical testing compared to objective testing methods is the rapidity which allows quick screening for olfactory dysfunction. More extensive testing sets, which can also be used for clinical research, allow graduation of the olfactory disorder. Fundamentally, every collection of odors is a potential olfactory test. Whatever a clinical test consists of, it should reliably distinguish between anosmic, hyposmic, and normosmic subjects. Most tests are based on a forced choice paradigm. An odorant is presented at supra-threshold concentration and the subject has to identify the odor from a list of descriptions of odors (e.g., the subject gets rose odor to smell, and is asked whether the perceived odor was "banana," "anis," "rose," or "lilac"). This forced-choice procedure controls the subjects' response bias. It also (potentially) allows the detection of malingerers since even anosmic subjects will produce a few "correct" answers provided in a random selection of items. The result of the test corresponds to the sum of the correctly identified items. This test design is called a ►smell identification test, and is the most widely used way of testing [4]. Another widely used test design are ►threshold tests. The idea of threshold tests is to expose a subject repeatedly to ascending and descending concentrations of the same odorant and to identify the least detectable concentration for this individual odor.

Besides the solid body of literature and its clinical convenience, the psychophysical tests have one main limitation. As soon as the patient's collaboration is not guaranteed, interpretation of test results becomes difficult or even impossible.

### *Objective Methods*

#### *Electro-Olfactogram (EOG)*

Electro-olfactograms (EOG) are electrical potentials of the olfactory epithelium that occur in response to olfactory stimulation. The EOG represents the sum of generator potentials of ORN.

#### *Chemosensory Event-Related Potentials (CSERP)*

Event-related potentials are EEG-derived poly-phasic signals. They are caused by the activation of cortical neurons which generate electro-magnetic fields. As the EEG is a noisy signal which contains activity from many cortical neurons, ERP need to be extracted from this background activity. The classical approach to this problem involves averaging of individual responses to olfactory stimuli such that random activity would cancel itself out while all non-random activation would remain. Olfactory ERP (i) are direct correlates of neuronal activation, unlike the signals that are seen, for example, in functional MR imaging, (ii) have an extremely high temporal resolution in the range of micro-seconds, (iii) allow the investigation of the sequential processing of olfactory information, and (iv) can be obtained independently of the subject's response bias

## Symptoms

Although this distinction is a matter of debate, the discrimination between qualitative and quantitative

olfactory disorder have proven helpful in clinical practice. This distinction is mainly based on the patient's history and psychophysical test results.

### Quantitative Olfactory Disorders

#### Normosmia/Hyposmia/Anosmia

►Normosmia (►Normosmia/Hyposmia/Anosmia) is the subjectively perceived normal olfactory function, usually defined as the ability to detect the great majority of tested odors in a given olfactory test. ►Hyposmia means the decrease of this olfactory function and ►anosmia the total loss of any olfactory function. Beside total anosmia, specific anosmias have been described, where only certain odors are not perceived and most odors are smelt normally [5].

#### Qualitative Olfactory Disorders

The term "qualitative olfactory disorder" reflects the qualitatively changed perception of odorous sensation. They are frequently, but not necessarily, associated with quantitative olfactory disorders.

#### Parosmia

►Parosmia describes the distorted perception of smells in presence of an odor source. In other words, parosmias are triggered by odors. This is a symptom occurring particularly often in post-URTI or posttraumatic olfactory disorders. Mostly odors are distorted into unpleasant odors. For example, to parosmic patients, coffee smells like burnt plastic. The exact explanation of the molecular modifications leading to parosmia is as yet unknown. Even the site of parosmia generation (olfactory epithelium, olfactory bulb, or other central-nervous olfactory structures) is not clear. Important clinically, is the observation that most parosmic impressions tend to diminish over months and finally disappear after years.

#### Phantosmia

►Phantosmia describes the distorted perception of smells in the absence of an odor source. Most often, phantosmias occur after trauma or URTI and consist of unpleasant odors occurring without being elicited through environmental odor sources. Phantosmias also have a tendency to disappear over the course of years.

## Causes/Etiologies

Methodological progresses made in the assessment of olfactory function allowed epidemiological studies, which demonstrated that the occurrence of olfactory disturbances is largely underestimated. Almost 15% of the general population suffers from a mild or severe olfactory dysfunction [6].

### Most Common Causes

#### Olfactory Loss Following Infections of the Upper Respiratory Tract (URTI)

Apart from posttraumatic and ►sinunasal origin, post-URTI olfactory loss is among the major causes of olfactory dysfunction. The patient's history typically starts with a cold, during which he loses his sense of smell. Not particularly bothered during the cold, the patient becomes suspicious about the smell loss when, one or two months after all sinunasal symptoms have abated, normal olfactory function does not return. Currently, no good data indicate which agent in such upper tract respiratory infections (URTI) leads to olfactory lesions. It is not even clear whether toxicity originates from a virus or bacteria, or from the immune response directed against olfactory neuroepithelium. In one third of those patients parosmia occurs two to three month after the URTI.

#### Posttraumatic Olfactory Loss

Posttraumatic olfactory disorders represent approximately 20% of the patients seen in "Smell and Taste Clinics" [7]. The current explanation is that "coup-contre-coup" lesions or tearing of the filae olfactoriae leads to anosmia or hyposmia. Olfactory loss seems to correlate with the severity of the trauma [8], although several authors pointed out the fact that there is considerable individual variability in terms of the vulnerability of olfactory structures. Thus, even minor trauma can lead to anosmia whereas severe brain injuries may not alter olfaction [8]. Probably, the injured parts of the olfactory system are most often the filae olfactoriae which cross the cribriform plate. Similar to post-URTI olfactory impairment, these patients are prone to develop parosmia and phantosmia several months after the trauma.

#### Sinunasal Causes

Approximately 20% of all patients in smell and taste consultations have lost or impaired olfactory function due to a nasal problem [7]. Chronic inflammatory processes within the nasal and paranasal cavities such as nasal polyposis probably lead to mechanical obstruction of nasal cavity restricting the airflow to the olfactory cleft. During the last two decades, as a result of better olfactory tests, mild olfactory impairments could also be identified in other groups of patients with sinunasal diseases such as allergic and uncomplicated chronic rhinosinusitis.

#### Neurodegenerative Causes

Olfactory loss is common in patients with idiopathic Parkinson's disease (IPD). This olfactory deficit is so reliable that it can be used as a marker of IPD [9]. In other words; if a patient with normal olfactory function presents

with IPD symptoms the diagnosis should be re-investigated [10]. It can also be assumed that olfactory loss precedes the onset of motor symptoms by 4–6 years so that IPD may be the reason for "idiopathic olfactory loss" in some patients. Olfactory loss is also observed regularly in Alzheimer's disease, but at a much lower frequency and is less pronounced in multiple system atrophy, Huntington's disease, and motor neuron disease. Little or no olfactory deficit is seen in cortico-basal degeneration, progressive supranuclear palsy, or essential tremor.

#### *Idiopathic*

In almost 20% of the patients with olfactory disorders, no origin is identified even after extensive workup. These idiopathic (unknown) olfactory disorders seem simply to reflect the poor understanding of factors interfering with olfaction. With further insight and research this percentage should logically decrease.

### *Less Frequent Causes*

#### *Endocrine Diseases*

Diabetes has been shown in most studies to cause slight olfactory deficiencies especially at threshold levels. Several other endocrine diseases have been reported to cause olfactory disorders.

#### *Epilepsy*

The general findings in epileptic patients were that they perform similar to controls with regard to odor thresholds. In contrast, more centrally believed tasks such as odor identification, discrimination or memory tests revealed that epileptic patients have olfactory impairments predominating on the side of the epileptic focus. This indicates that decreased olfactory function in epileptic patients is primarily due to centrally altered olfactory structures whereby the temporal lobe is the main lesion site.

#### *General Pathologies*

Long lists of general pathologies causing olfactory disorders can be found in most reviews and textbooks of smell and taste disorders, whereas only few large studies investigated general disease and olfactory function. Especially kidney and liver affections have been associated with decreased olfactory function.

#### *Drug-Induced/Toxic*

Numerous toxins have been implicated as causes of olfactory disorders. Nevertheless, this information has been mainly accumulated on the basis of case reports.

#### *Congenital*

Congenital anosmia occurring as an isolated defect or occurring within the context of a syndrome are distinguished. Isolated ►congenital anosmia seems to occur more often than previously believed. Apart from the typical patient history of no odor memories, only MR imaging leads to a more definitive diagnosis showing hypoplasia or aplasia of the olfactory bulbs. Among cases of congenital anosmia as part of a syndrome, the Kallmann-Syndrom is the disorder in which it is most frequently encountered. This is an anosmia associated with hypogonadotropic hypogonadism clinically characterized by infertility and anosmia. Congenital anosmia is typically discovered during early puberty.

## Consequences

Compared to deafness or blindness, anosmia is less disabling in terms of typical social functioning. However, beside the associated dangers like eating spoiled food or non recognition of fire and smoke, it considerably impairs quality of life. Recent studies underlined the potential alteration of quality of life consecutive to olfactory impairment [3]. In some patients olfactory dysfunction even leads to depression.

## Treatment

The treatments of olfactory disorders mainly depend of its origin. Neither treatment nor ►spontaneous recovery can be expected in age-related and congenital anosmia. Sinunasal smell disorders are mostly treatable with antibiotic and anti-inflammatory drugs such as systemic and topical corticosteroids. In general, treating the underlying nasal disease, either surgically or with medical treatment, improves olfactory function. Toxic- and drug- induced smell disorders may recover once the drug intake is interrupted. For two of the most important causes (post-URTI and posttraumatic) of olfactory dysfunction, no curative treatment exists. However, in contrast to other sensory neurons, olfactory neurons regenerate regularly. Thus, spontaneous recovery after olfactory loss is often observed after posttraumatic and post-URTI olfactory dysfunction. Recovery rates are much better in post-URTI (in ca. 60% of the patients) than in posttraumatic (ca. 15%) patients. Usually the main recovery takes place within the two years after the event causing the olfactory disturbance. Spontaneous recovery often remains partial and rarely complete. Although olfactory neurons have the ability to regenerate, the exact mechanisms favoring such spontaneous recovery are not understood. It is currently impossible to predict an individual outcome with regard to recovery. In contrast to the quantitative olfactory disorders, the qualitative disorders have a far better prognosis of spontaneous disappearance. Parosmias tend to decrease to a bearable level after approximately one year. To summarize, the best current therapeutic attitude towards post-URTI and posttraumatic olfactory disorders is to correctly inform the patient, without removing all hope of recovery.

# Smell Identification Test

## Definition

Testing olfactory function can be done by different means. The most popular and widespread one is to use an identification test. The subject is exposed to an odorant in a concentration which is far over threshold concentrations. Then the subject has to identify this odor. In order to facilitate the task he is presented a list of possibilities (usually four) of which he has to decide for one. The number of correct answers is the score of the identification test.

# Smooth Pursuit

## Definition

Continuous eye movements made to track a moving visual target.

# Smooth Pursuit Eye Movements

## Definition

Smooth pursuit eye movements are those where subjects intentionally track a smoothly moving object or target using their eyes. The smooth pursuit system attempts to match the velocity of subject's eye movements to that of the target so that the image of the target continuously falls on the fovea.

Because subjects rarely do this perfectly, accumulating position errors are corrected using saccadic eye movements, often called "catch-up saccades". Although movement of the image of the target on the retina (retinal slip) is often a stimulus for smooth pursuit, it is not a necessary one. Subjects can track a target with negligible slip if the target motion is highly predictable, and subjects can correctly track the perception of movement created by object moving behind a narrow stationary slit oriented perpendicular to the motion (i.e., the visible edges of the object also move perpendicular to the actual motion.

Smooth pursuit is distinct from the optokinetic response, which is involuntary and responsive to image motion anywhere on the retina. Animals lacking a fovea exhibit little or no smooth pursuit, but do exhibit an optokinetic response.

# Snapback Hairpin

## Definition

Snapback hairpin – A short hairpin RNA (shRNA) is a sequence of RNA that makes a tight hairpin turn that can be used to silence gene expression via RNA interference. This is when a single-stranded RNA folds back on itself by pairing with its own complementary strand. Snapback refers to this hairpin formation.

►GAL4/UAS

# Snapshot Memory

## Definition

The memory of the scene from a goal. Upon reaching a goal for the first time, a subject may make a survey of

the scene from the goal and store this in memory for subsequent use in returning to the goal. This snapshot may be used to mediate a form of navigation back to the goal. This involves moving to minimize the difference between the current snapshot and the one from memory.

A common form of insect navigation is based on snapshot memory, and there is also evidence that mammals use snapshot memory too.

►Spatial Learning/Memory

## SNARE Proteins

### Definition

Snare proteins are group of proteins located on the membrane of synaptic vesicles and the prejunctional nerve terminal that interact to mediate vesicle docking, fusion and exocytosis of neurotransmitters in a calcium-dependent manner. The proteins on vesicle membranes include synaptotagmin and synaptobrevin (v-SNAREs), with syntaxin and SNAP-25 located on the inner surface of the nerve terminal membrane (t-SNAREs).

►Postganglionic Neurotransmitter

## Sniff

### Definition

Sniffing is the drawing of air into the nasal cavity with the goal of odor detection. The flow rate observed during a sniff is usually higher than what is seen during quiet inspiration and the initial flow rate is very consistent from sniff to sniff. The higher flow is thought to direct more of the incoming air to the olfactory receptors and it facilitates olfaction by creating a more turbulent flow within the nasal cavity.

►Nasal Passageways

## Sniffing Behavior (Mammals)

►Odor-Sampling Behavior

## Snoring

### Definition

Sound produced by vibration of anatomic structures in the upper airway during sleep. Snoring can be caused by obstruction or narrowing of the upper airway (e.g., obesity, elongated soft palate, relaxation of tissues in the throat) and by sedative drugs (alcohol and some prescription medications including sleeping pills).

Snoring often disrupts the sleep of housemates more than that of the person snoring. However, loud snoring associated with pauses in breathing can be a sign of sleep breathing disorders referred to as sleep apnea and upper airway resistance syndrome. Snoring in children may be related to airway obstruction caused by large tonsils or adenoids.

# Social Chemosignal

Benoist Schaal
Centre Européen des Sciences du Goût, CNRS, Dijon, France

## Synonyms

Social odor [1]; Semiochemical [2]; Sociochemical [3]
Related terms: Social olfaction; Social chemosensation; Chemical communication; Semiochemistry [2]; Sociochemistry

## Definition

Social chemosignals encompass all types of stimulations exchanged among members of a given species and that are detected through the chemical senses (i.e., olfaction, vomerolfaction, taste, tarsal chemoreception). These are carried by chemicals derived from physiological processes and circumstantially learned as social cues, as well as by specialized signals, termed pheromones, which were evolutionarily selected for communicative purposes.

It should be noted that whereas all pheromones are social chemosignals, all social chemosignals are not pheromones. There is indeed a definitional confusion leading to the indiscriminate use of the pheromone concept to designate any communicative process involving odors. In fact, pheromones may be conceived more as regulating than as informative factors. Thus, the term pheromone should be kept separate to qualify *well-identified chemicals* that fulfill an operational set of functional criteria [4,5]. Pheromones have been proposed to belong to a subclass of (i) chemically simple compounds (single- or multiple-component pheromones made up with a limited set of active compounds in given ratio); (ii) that are exclusive in eliciting (iii) a well-defined and invariant behavioral/physiological response with obvious functional significance (iv) among individuals of the same species; finally, (v) the activity of these compounds should be minimally dependent on learning processes [4,5]. In sum, pheromones represent only a portion of social chemosignals; these latter include more or less additional compounds leading to mixtures that can be exceedingly complex in both chemical (sometimes composed by several hundreds of compounds) and semiotic terms. These social chemosignals elicit responses that can be highly variable as a function of the context or the interacting organisms' internal state, mingle individual as well as supra-individual (colony, caste, species, etc.) information, and depend on prior experience and cognitive processes.

## Characteristics

The chemical, physiological and behavioral principles of social olfaction mostly stem from studies in Insects and Vertebrates, especially Mammals [2,6]. Accordingly, these principles may be revised with incoming new knowledge from other taxa. As in any communication system, social odors may be described in the context of the functional loop between an emitting individual carrying the source of the chemosignal that impinges on a recipient organism responding either by attentional mobilization, by an immediate overt behavior or by a covert physiological reaction.

## Sources

Social chemosignals are derived from multiple sources, which are either distributed over the tegumentary surface (sebaceous, eccrine and apocrines sweat glands) or collected in more or less specialized scent glands. They can also be emitted by the way of various excretory carriers, such as tears, breath, saliva, mucus, milk, the genital discharges, urine, or feces [2,6]. These biological substrates may transmit an intrinsic distinctive odor or may gain their characteristic odor through the action of bacteria dwelling on the skin surface or in glandular recesses. They are composed of volatile and involatile fractions the interaction of which modulates the temporal dynamics and properties of the final odor stimulus.

These multiple secretory or excretory sources, and hence the odor quality and intensity derived from them, are regulated by the organism's genetic and immunogenetic constitution, but can also be induced by a multiplicity of factors, including endocrine status (linked with age, sex, reproductive stage), metabolism (diet, pathology), and psychobiological state (age, stress, dominance, fitness). The combined action of all these causal pathways leads to the formation of a specific chemical image or of an individual's olfactory fingerprint or signature.

## Signals

The chemistry that any organism presents to its conspecifics can be exceedingly complex and versatile, and its total chemical understanding may be unattainable [2]. Many classes of biologically emitted chemical compounds are physically and biologically compatible with chemosensory function. In terrestrial animals, a first partition in this complexity is between volatile and involatile fractions of the chemosignals, leading to ▶odor detection or ▶odor tracking from a distance or to the need for direct contact with the stimulus.

In this way, involatile proteins, lipids or cuticular hydrocarbon can act as fixatives or precursors of volatile cues, as well as contact chemosignals. In aquatic species, chemosignals generally need to be hydrosoluble, and bind with receptors from the olfactory as well as the taste system [7]. A second divide in the complexity of chemosignals is between individual-specific and species-specific compounds in the stimulus. Depending on the behavioral tests used to assess the responses, an

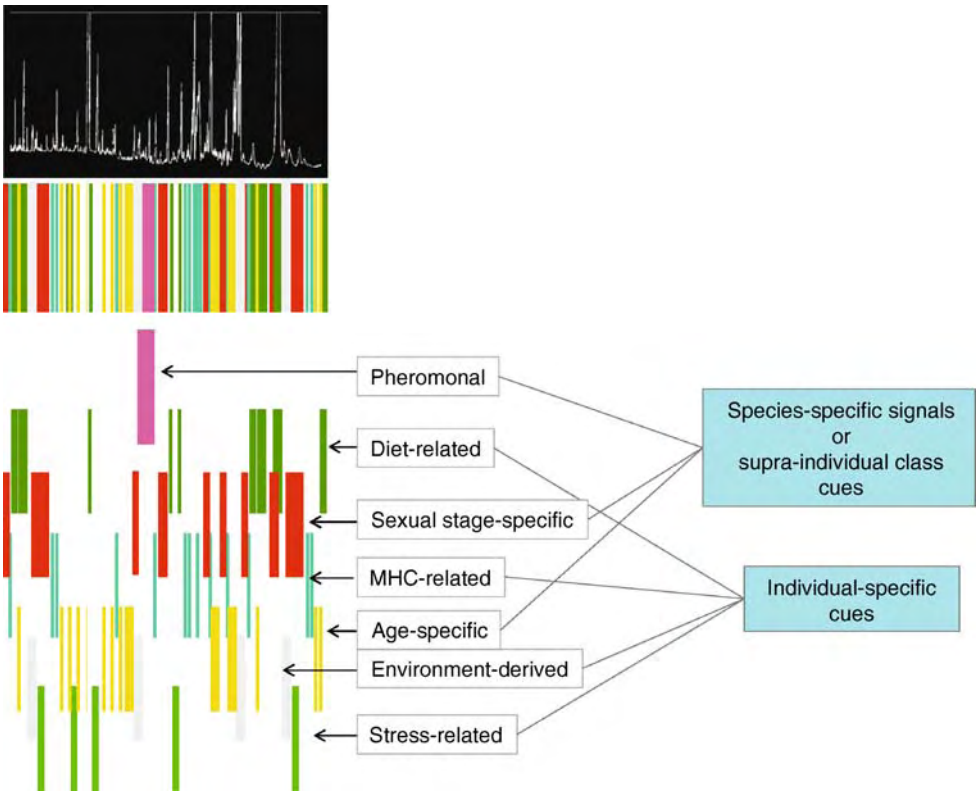
organisms' ability to extract individual or supra-individual meanings can be evidenced in a same chemosignal. Thus, social chemosignals may be conceived as more or less complex stimuli in which multiple levels of information can be nested (Fig. 1).

Little is known on the rules by which information is ciphered in social chemosignals [4,7,8]. A same biological secretion may code for one information or for several, or different secretions may code for the same information. Within a complex secretion, only one or several compounds, or groups of compounds, may carry the signal, the remaining compounds constituting background noise. The term "mosaic signal" has been proposed for such complex signals in which most of the individual compounds do not bear an effect by themselves [8], but are part of a multidimensional chemical signal classified in a multidimensional perceptual space.

## Reception and Integration

Animal organisms have evolved several neural systems to detect, analyze, extract and store information from social chemosignals [8,9]. In higher vertebrates, an array of different systems detects chemosignals depending on the volatility and concentration of ligand molecules. From the most to the least volatile stimuli, the main olfactory system, the accessory olfactory (or vomeronasal) system and taste system come into play. The trigeminal system may be drawn in the detection of higher intensity compounds. In these systems, recognition pathways can be narrowly or broadly tuned, leading to specialized versus generalist chemoreception [9]. It was long held in higher vertebrates that some of these neural pathways (e.g., the vomeronasal system) were dedicated to detect social chemosignals of the subclass pheromones. A strict functional exclusivity has been since questioned, and overlap and interactions between specialized and generalist systems of chemodetection now seems to be the rule.

The brain structures involved in higher level processing of social chemosignals remain poorly understood, and offer a promising ground for future advances in cognitive and behavioral neuroscience [9]. So far, we know in rodents some neural structures (e.g., medial area of the amygdala, hypothalamus) that react differentially to complex odors contrasted along sex or individuality,



**Social Chemosignal. Figure 1** A bar-code metaphor to nested chemical sources of meanings within a social chemosignal. The complex chromatographic pattern is translated in color bars representing levels of meanings. The decomposed bundles of bars represent compounds that are correlated with a given meaning, and hence with a given communicative function. Note that a pheromone is inclusive to a social chemosignal.

linking social chemosensory inputs to the brain areas involved in neuroendocrine, affective and cognitive processes.

## Functions

The chemical senses being operative throughout the animal kingdom, their involvement in social processes is well conserved [1,5,7,10]. This functional ubiquity is reinforced by the fact that chemosignals have specific advantages over visual or auditory signals in terms of pervasiveness: they can operate in obscure (night-time, burrows, turbid water) or noisy (dense colonies) environments, are distributable in space and time (scent-marking) and can outlast for long periods the emitter's presence. Further, these chemosignals can rally attention in other modalities (alerting function) and they can be integrated with the entries from the other sensory systems, leading to the multimodal appraisal of conspecifics (cognitive function) and redundant regulation of behavior.

Social chemosignals can convey a wide range of psychobiological meanings actualized in the varying types and rates of behavioral and physiological responses measurable in appropriate experimental situations [6,7]. The basic requirement of social life being the recognition of particular individuals, or classes of individuals, it is seminal that chemoreceptive cues encode such categories. ►Odor recognition of individuality, or of classes of individuals, has been repeatedly shown in vertebrates and insects, making olfaction a basic organizing system of social life. The recently established role of peptides from the major histocompatibility complex in individuality signals reveals how genotypic information can be externalized and traced in vertebrates. Similar abilities lead to discriminate social categories such as age or gender, or to differentiate kin, family and colony members from out-groups, inducing within-group social selectivity and more or less between-group closure, and strategies to avoid consanguinity.

Social odors are also used as situational cues inscribing the individual in space and time. This is best observed in the frequent marking behaviors involved in the establishment and maintenance of a territory, or trails within it, in the labeling of conspecifics, foods or objects with own odor, or even in self-anointing. Social chemosignals are also involved in the coordination of social interactions. They can elicit recruitment and aggregative responses (as in foraging and reproductive parties), as well as avoidance and dissociative responses (warning signals, *Angstgeruch, Schreckstoff*). Finally, chemosensory correlates can be traced to decode indices related to psychological state (mood, stress), fitness (dominance, aggressiveness), and diet and health status (pathologies, parasite load) [1,7].

Social chemosignals have been investigated most extensively in the context of reproductive processes [5–8]. They guide the appraisal of mate quality, and hence direct mate choice and recognition, provide mutual indications on male sexual state and female stage of receptivity, and in concert with the other senses orchestrate courtship and copulation. In species that take care from their young (social insects, mammals), females are sensitive to the odor cues emitted by their offspring. Brood, amniotic and neonatal chemosignals determine the rapid onset of selective responses of females directed toward the young [10]. Reciprocally, at least in mammals, newborns are attracted to odor cues from females, and rapidly develop selective attachment responses to their mother. Further, mammalian females emit odor signals near the mammary glands or in milk, which have the effect of boosting neonatal motivation and of providing guidance to the nipples. In addition to the orchestration of behavior, data from rodents, ungulates and primates also indicate that social chemosignals modulate the physiological coordination of reproduction within groups. For example, urinary volatiles of reproductively-active males accelerate the attainment of puberty in young females, or induce estrus, block pregnancy, or synchronize ovarian cycles in mature females [5,7,9].

Finally, it may be highlighted that social chemosignals remain active in species that have developed higher cognitive processes, ideation, and communication systems dominated by vision and audition. Although it has been proposed that improved visual abilities in primates made olfaction redundant, social chemosignals remain actively involved in inter-individual exchanges [10]. For example, men and women can distinguish gender and recognize their mates and genetic relatives. Likewise, infants single out the individual odor of their mother from that of other females; but, in addition, infants display general attraction to the breast odor of any lactating woman and to the odor of conspecific milk. This is a well documented situation where individual and supra-individual cues can be extracted from a same chemosignal. The fact that social chemosignals make a notable contribution to the perceptual world of humans is further underlined by their universal use of extraneous odorants, adding culturally shaped complexity to the odors produced by species-specific chemo-emission.

## Development: How Odors Become Social Signals?

The most obvious means by which odors become socially relevant is through acquisition processes, i.e., direct familiarization, associative learning, or conditioning [7,10]. Odor familiarization can be already set on in ovo or in utero, while embryos are exposed to genotype- or phenotype-related (dietary) compounds transmitted by the maternal organism. This explains how newly emerged insect larvae and vertebrate newborns can already be biased in their responses to maternal chemosignals against homologous signals from other conspecifics. Afterwards, the range of

stimuli that become salient in social contexts is rapidly, and sometimes lastingly, expanded through odor exposure during early sensitive periods. In this way, the females' constitutional odors, as well as circumstantial odorants from the environment associated with her, can be imprinted as chemical templates against which future allies or mates are selected. Further, indirect familiarization, by which familiar individuals (kin) can be used as standards against which others are compared, can also come into play in the discriminative value of chemosignals. In this case, individuals or categories of individuals are discriminated not because of previous contact, but as a function of phenotypic resemblance to relatives (or self) with whom one is acquainted (phenotype matching). Lifelong learning processes mediated by social interactions occur further in juveniles and adults, especially in emotion-primed contexts. Another recently-evidenced way to engage the learning of social chemosignals is through the intrinsic reinforcing impact of pheromones. In certain cases, these compounds promote the rapid learning of any odorant that is associated with them, rendering initially inactive odorants functionally similar to them, and thus engage circumstantial odorants into communicative actions. In this way, predisposed and plastic cognitive processes may cooperate in attuning individuals to the local conditions of their present and future social networks.

# Sodium Channels

Simon Rock Levinson
Department of Physiology and Biophysics, University of Colorado School of Medicine, Aurora, CO, USA

## Synonyms

Voltage-dependent sodium ($Na^+$) channel; Voltage-gated $Na^+$ channel; Voltage-sensitive $Na^+$ channel; Voltage-activated $Na^+$ channel

## Definition

Sodium ($Na^+$) channels are ►membrane glycoproteins (►Cell membrane – components and functions) that form $Na^+$-selective voltage-gated pores across the plasma membranes of excitable cells, such as neurons and muscle fibers. When these pores are in an open configuration, $Na^+$ cations flow through them. This flux is usually into the cell, and thus creates a voltage change across the cell membrane that is the basis of the propagating electrical signal known as the action potential (►Action potential; Action potential propagation). (Note: These voltage-gated channels are not to be confused with non-voltage-gated epithelial $Na^+$ channels (ENaCs) that are found in a variety of epithelial tissues, such as kidney, colon, and lung.)

## Characteristics

Voltage-gated $Na^+$ channels are the primary molecular entities that initiate the propagating action potential of nerve axons, the fundamental electrical signal that underlies communication in the nervous system. Due to their central role in the function of the nervous system, a variety of natural toxins have evolved that affect them, while several clinically important drug classes target $Na^+$ channels, such as local anesthetics, chronic pain medications, and anti-seizure (►Seizures) drugs. Finally, genetically-based changes in the function of $Na^+$ channels can give rise to a number of human diseases, e.g. certain forms of cardiac long Q-T syndrome and epilepsy (►Epilepsy), and the periodic paralyses of muscle (►Familial periodic paralysis). For these reasons, $Na^+$ channels have been well studied in the past and will continue to be a focus of major investigative efforts for some time to come.

As with many other proteins, within a given organism $Na^+$ channels are encoded by a number of genes, giving rise to channel ►isoforms. In addition, additional diversity in channel types may derive from variations in the RNA processing of any gene transcript, while posttranslational modifications can vary the functional properties of the expressed gene product itself [1,2]. Consideration of the biological significance

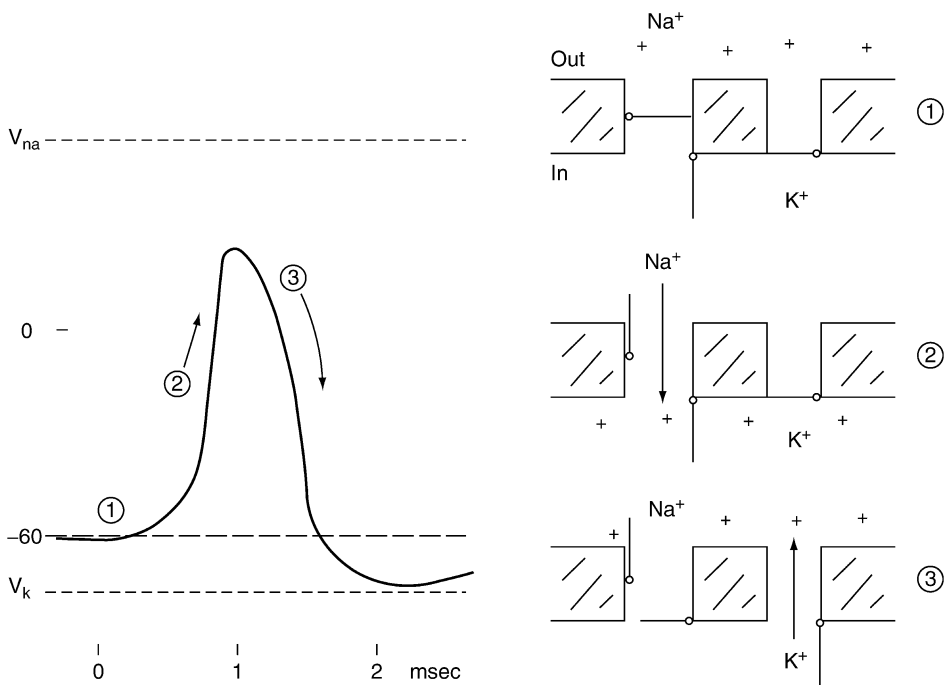
of such structural and functional variations among $Na^+$ channel isoforms is a major focus of current research.

## Basic Physiological Functions of $Na^+$ Channels

### *Role in Generation of Propagating Action Potentials (►Action potential)*

The study of the functional properties of $Na^+$ channels in generating action potentials has a long history and is described in detail in a number of texts (e.g. [3]). In its simplest terms, the action potential is a brief, propagating change in the transmembrane voltage across the neuron axon. As originally elucidated by the classic work of Hodgkin and Huxley (see [3]), this waveform is generated by the coordinated flux of $Na^+$ and $K^+$ ions across the cell membrane (Fig. 1). Subsequently it has been established that these ion fluxes are mediated by discrete molecular pores known as voltage-gated $Na^+$ and $K^+$ ►ion channels N euronal potassium channels). In particular, these channels are closed in the resting state, but are opened by any stimulus (e.g. by a ►postsynaptic potential at a ►synapse or a ►generator potential in a ►sensory receptor) that ►depolarizes the negative resting membrane potential (i.e. decreases it towards zero), past a characteristic threshold level. Initially, this voltage change causes $Na^+$ channels to open or ►activate, allowing $Na^+$ ions to flow passively into the cell driven by their ►electrochemical gradient (►Membrane potential – basics). This influx of positive charge further depolarizes the transmembrane voltage, and causes the initial rising phase of the action potential (Fig. 1), which goes toward $V_{Na}$ (i.e. the $Na^+$ ►equilibrium potential as approximated by the ►Nernst equation for $Na^+$). In reality, $V_{Na}$ is never quite reached because of two subsequent limiting processes: (i) $Na^+$ channels ►inactivate, thus shutting off the further influx of $Na^+$ ions; (ii) $K^+$ channels slowly open, which allows the outward flow of $K^+$ ions from the cell driven by their own electrochemical gradient, thus returning (►repolarizing) the membrane potential to its original resting level. After a brief delay (the ►refractory period), during which $Na^+$ channels recover from inactivation and $K^+$ channels close, another action potential may be generated.

The basic description above allows one to explain certain fundamental properties of the action potential, namely the "all-or-none" nature of its amplitude and its propagation. Both phenomena are related to the fact that in excitable tissues the influx of $Na^+$ ions through the



**Sodium Channels. Figure 1** Ionic flows involved in generation of the action potential. The left part of the panel shows the action potential waveform, while the right part shows the gating state changes in $Na^+$ and $K^+$ channels that shape the action potential. Thus in the resting state (i), both $Na^+$ and $K^+$ channels are in the closed, nonconducting states. In (ii), a suprathreshold voltage stimulus causes $Na^+$ channels to open rapidly (i.e. activate), and the resultant influx of positively charged $Na^+$ ions causes the positive-going "►depolarizing" phase of the action potential. In (iii), the upstroke of the action potential ceases due to the entry of $Na^+$ channels into their "►inactivated" state, while the delayed opening of $K^+$ channels allows the efflux of $K^+$ cations to return the membrane potential to its starting value.

first few opening $Na^+$ channels causes an increased local depolarization that accelerates the opening of some of the surrounding channels; influx of $Na^+$ through these channels in turn further depolarizes the membrane, thus increasing the opening rate of more $Na^+$ channels, and so on. This "regenerative" effect quickly becomes the dominant stimulus for $Na^+$ channel activation, hence overwhelming the influence of the original stimulus. As a result, all subsequent processes in the action potential (e.g. $Na^+$ channel inactivation, $K^+$ channel opening) are obligatorily entrained by the regenerative phenomenon, and thus the action potential amplitude and shape are independent of the initial depolarizing stimulus. This explosively regenerative upswing in the membrane potential also propagates in a domino-like fashion, as channels adjacent to this activation zone are recruited into a conducting state (►Action potential propagation). In addition to this the process of "continuous conduction" characteristic of unmyelinated nerve fibers found in most animals, $Na^+$ channels also mediate the process of fast saltatory ("jumping") conduction that is found in the ►myelinated axons of vertebrates through the formation of very high densities of channel clusters at nodes of Ranvier.

### *Role of $Na^+$ Channels in the Initiation of Action Potentials and in Integrating Multiple Synaptic Signals at Dendrites*

In addition to their classical role in generating action potentials, it has more recently been appreciated that $Na^+$ channels also are involved in initiating action potentials and in responding to more graded signals such as stimuli transduced by sensory receptors or synaptic potentials in neuron dendrites.

One essential role of $Na^+$ channels is to reinitiate the action potential on the postsynaptic side as a result of synaptic transmission. Thus in the motor endplate, $Na^+$ channels are located in the folds of the postsynaptic membrane (►Neuromuscular transmission). Both the high density of channels and the geometry of the folds themselves allow endplate potentials to initiate reliably a propagating action potential in the postsynaptic membrane. In neurons, $Na^+$ channels are present at high density in the ►axon hillock and ►initial segment of the axon. These channels initiate an action potential only when synaptic inputs at dendritic synapses summate sufficiently to depolarize the membrane potential in the peri-somatic axonal membrane. Clearly, in both of these cases the voltage-sensitivity of the $Na^+$ channels will determine the strength of synaptic signal required to fire an action potential in the postsynaptic cell. In addition, a very low and non-uniform density of $Na^+$ channels has been inferred to exist in the dendrites themselves. These channels are thought to be part of the mechanism by which dendrites perform signal processing of multiple synaptic inputs to produce an appropriate output at the axon hillock. Finally, $Na^+$ channels are found in certain sensory receptors, e.g. those for pain (►Pain), taste (►Chemical senses), and sound (►Hearing), where they are part of the transduction mechanisms that amplify weak sensory stimuli.

In summary, recent work shows that $Na^+$ channels play a number of important yet different roles in neuronal communication and sensory transduction. The multiplicity of such functions suggests that functionally distinct $Na^+$ channel types (i.e. isoforms) will serve in these different roles.

## The Molecular Basis for $Na^+$ Channel Function

### *Basic Functional Properties of $Na^+$ Channels*

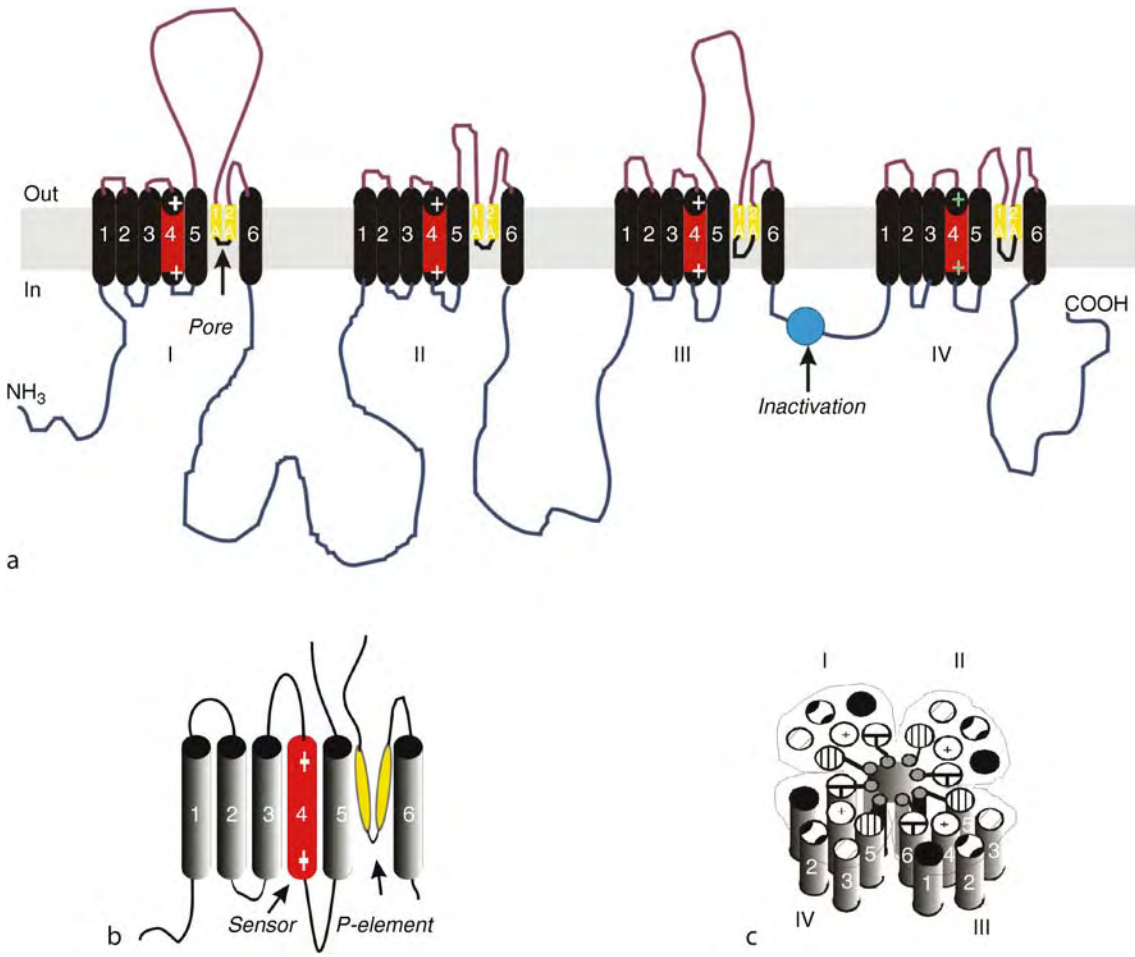
The microscopic functional properties of individual $Na^+$ ion channels that underlie its role in electrical signaling phenomena may be conveniently broken down as follows. First, $Na^+$ channels must have a *transmembrane aqueous pore* that allows the passage of ions across the plasma membrane. Second, access to this pore pathway must be regulated by a mechanism for *ion selectivity* that allows the channel to choose $Na^+$ over other ions in physiological solutions (e.g. $K^+$, $Cl^-$, $Ca^{2+}$). Lastly, there must be *voltage-sensitive activation and inactivation gates* that allow channels to assume the various closed, open, and inactivated states that occur in response to changes in membrane voltage (Fig. 1).

### *Subunit Composition and Amino Acid Sequence of $Na^+$ Channels*

The basic molecular mechanisms of $Na^+$ channel operation (i.e. that which forms voltage-gated, ion selective pores) are contained within a single large polypeptide (usually designated as an "$\alpha$" subunit). These are very large proteins of approximately 2,000 amino acid residues in length whose amino acid sequences have been determined largely from cloned cDNAs (see [1] for a description of the strategies and methods used). Naturally, models of the secondary and higher order structure could then be constructed from a combination of ►hydropathy and secondary structure prediction analysis.

Such a predictive model for the $Na^+$ channel structure is shown in Fig. 2. First, hydropathy and ►secondary structure constraints predict that $Na^+$ channels consist of four transmembrane domains (I, II, III, IV), each of which consists of six hydrophobic α-helices (S1–S6). Second, this architecture suggests that the four domains might contain segments (i.e. the α-helices) of highly (but not completely) conserved sequence homology to one another. These "internal repeats" have been confirmed by homology analysis.

In addition to these primary α subunits, many channels are associated with one or several "accessory" β subunits. While not directly part of the actual pore, selectivity or gating structures, there is increasing evidence that such



**Sodium Channels. Figure 2** (a) Predicted secondary structure of a typical $Na^+$ channel α subunit. (b) Enlarged view of a transmembrane homology domain, showing segments postulated to comprise the voltage sensor and the selectivity filter in the pore lining ("p-element"). (c) Transmembrane "staves of a barrel" tertiary architecture involved in pore formation by α subunit homology domains.

subunits play important roles in regulating channel numbers, localization, and gating [4].

### Sodium Channel Molecular Mechanisms

*Pore formation:* The four-fold pseudo-symmetry of $Na^+$ channel domains has been taken to imply that transmembrane pores are formed by an arrangement in which each internal repeat domain forms one quarter of the pore structure (Fig. 2). This architecture is highly similar to that of many other ion channels as described in other articles, e.g. $K^+$ channels that are formed by a four-fold association of individual subunits shown (►Neuronal potassium channels). A variety of ►mutagenesis studies have confirmed this "staves of a barrel" architecture.

*Ion Selectivity*: Classic biophysical studies provided evidence for thinking that the ion selectivity apparatus lay within the lining of the transmembrane pore itself, and consisted of a narrowing of the pore to form a "selectivity filter" (see [3]). It is currently thought that fully hydrated ions are too large to pass through the filter by themselves, and that the role of the selectivity filter is to remove their associated water, thus the naked ion would then be small enough to move past the barrier. Selectivity among ions would thus occur through differences in their relative affinity for water-removing selectivity filter. Such a view has largely been confirmed for other ion channels, and such a mechanism is assumed to operate for $Na^+$ channels.

The amino acid sequences responsible have been identified in $Na^+$ and other voltage-gated channels, and reside in the sequences between helices S5 and S6 termed the "P-element" or "P-loop" (Fig. 2). Thus $Na^+$ channels are postulated to contain four such loops, each one of which forms a quarter-sector of the cylindrical pore lining, and mutagenesis of the four P-loop segments in $Na^+$ channels has identified the region as crucial to the selectivity properties. In particular, two negatively charged glutamate residues have been

localized in this region that are thought to be responsible for binding the $Na^+$ cation, causing the $Na^+$ water of hydration to dissociate and allowing the ion to pass the selectivity barrier [5].

*Voltage-sensitive gating* (►Ion channel gating): The transmembrane segment S4 contains a strikingly unusual motif that consists of a repeated triad of two very hydrophobic amino acids (usually leucine, isoleucine, or valine) followed by a positively charged amino acid (arginine or lysine) [1,3,6]. This structure is found in all voltage-gated cation channels, and it is highly suggestive of a ►voltage sensor lying within the transmembrane electrical field. The basic idea is that sufficient changes in transmembrane potential will cause motion of the S4 structure in the membrane, and it is this motion that is then mechanically coupled to other parts of the channel structure to open (i.e. activate) the pore. Thus mutagenic substitution of the positively charged amino acids for either neutral or negatively charged residues usually alters the voltage-dependence of channel opening. More recently, elegant biophysical experiments have been done in which fluorescent reporter probes have been introduced into these segments and surrounding structures [6]. These studies provide strong support for the identification of these S4 segments as voltage sensors in $Na^+$ channel gating, while they illuminate the actual molecular movements that give rise to activation gating.

The mechanism of $Na^+$ channel inactivation has also been successfully addressed in structure-function mutagenesis studies (see [6]). Evidence from a large number of classic electrophysiological studies suggested that inactivation for ion channels generally occurred through a mechanism in which the inactivation gate is a protein "ball" that enters and blocks the open channel from the inside of the membrane. For $Na^+$ channels, this "ball" lies in a highly conserved cytoplasmic sequence between domains III and IV, and is thus tethered to the channel by a "chain" formed by amino acid residues at both ends. This model has been elegantly confirmed in a series of mutagenesis experiments that have identified the critical residues this "ball and chain" mechanism. Mutagenesis and biophysical experiments have also identified candidate sites within the channel to which the ball binds to occlude the pore.

## Molecular Diversity of $Na^+$ Channels: Isoforms

As described earlier, $Na^+$ channels consist of a large polypeptide "α subunit" that forms the pore and gating structures, along with a variable number of accessory β subunits. Nine genes that code for $Na^+$ channel α subunits and four β subunits have been identified in mammals. The nomenclature that evolved for the different α isoforms was awkward and inconsistently used, thus a simpler nomenclature has been proposed that is now accepted in which individual α polypeptides are designated as $Na_v1.x$, where "x" ranges from 1 to 9. In addition, a rather mysterious $Na^+$ channel-like protein has been identified from cDNA clones and has been termed an "atypical" $Na^+$ channel, or $Na_v2$ in the current nomenclature. Based on difficulties in studying its functional properties, it is still uncertain whether it is a functional $Na^+$ channel in vivo. Lastly, the four β subunits, designated as β1 through β4, have similar structures consisting of a single transmembrane domain with a short cytoplasmic tail and an extracellular domain that has ►immunoglobulin-like motifs [4].

Finally, although there has been no systematic study describing all the molecular isoforms generated by each $Na^+$ channel gene, it is likely that each gene gives rise to a geometric increase in protein isoforms due to alternative splicing and editing of mRNA, to posttranslational modifications, and to different combinations of subunits. The physiological significance of such potentially great molecular diversity of $Na^+$ channels has only recently started to become clearer.

## Physiological Significance of $Na^+$ Channel Diversity

### *Functional Variations Among $Na^+$ Currents in Cells and Tissues in vivo*

In addition to their central role in mediating the propagating action potential, $Na^+$ channels have been recently recognized to play an increasing number of roles in sensory transduction and in signal processing events (see above). These different roles would seem to require different functional forms of $Na^+$ channels to serve each one of them. However, it has been difficult to study the functional properties of different channel isoforms in actual nervous tissues because multiple isoforms are nearly always co-expressed in a given neuron. Thus such studies have often utilized ►heterologous expression systems in which cDNAs encoding a specific channel isoform are introduced into a cell line that has no (or nearly no) $Na^+$ channels of its own.

In any case, significant functional differences in basic voltage gating behavior have been found among isoforms. For example, the $Na_v1.6$ isoform generally displays very rapid kinetics, which is assumed to be adapted to its role as the primary isoform involved in fast *saltatory conduction* of frequency-encoded information over myelinated fibers (►Action potential propagation). On the other hand, peripheral nervous system isoforms such as $Na_v1.7$ and $Na_v1.8$ display slow kinetics of gating, which are thought to be somehow important to their role in the transmission of pain information from the site of injury [7] (►Voltage-gated sodium channels: multiple roles in the pathophysiology of pain).

In addition, when co-expressed with various α isoforms, β subunits cause significant alterations to $Na^+$ channel function to occur, the details of which depend on the specific combination of α and accessory subunits in the complex [4]. For example, association of β4 with

$Na_v1.6$ results in a $Na^+$ channel with highly unusual inactivation properties that appear to be required for the spiking behavior of the ►Purkinje neurons in which it is expressed. Thus differential association of accessory subunits is a basis for generating additional functional diversity among $Na^+$ channel isoforms.

### Sodium Channel Isoforms are Differently Modulated by Intracellular Signaling Cascades

Sodium channels are substrates for biochemical modification by protein kinases (i.e. PKC, PKA, RPTPβ), and such modifications result in significant changes to the functional properties of channels in vivo [2]. Such dynamic, cell signaling-related changes are known collectively as ►ion channel modulation. Recent work has established that modulation effects are isoform-specific. For example, PKA appears to reduce the number of $Na^+$-conducting $Na_v1.2$ channels while it otherwise specifically affects the gating kinetics of the $Na_v1.8$ isoform. Overall, it appears that $Na^+$ channel isoforms may indeed be differentially modified by a variety of mechanisms, and this may serve as the basis for the specific regulation of $Na^+$ currents within individual cell types and tissues.

## Differential Expression and Localization of $Na^+$ Channel Isoforms in Tissues: Targeting and Clustering

The above suggests that functional and regulatory differences among $Na^+$ channel isoforms allow the tissue-specific expression and modulation of electrical signaling properties. Thus it has been found that $Na^+$ channel isoforms are differentially expressed among excitable tissues. Figure 3 summarizes information derived from ►immunocytochemical studies (►immunocytochemistry) regarding the selective localization of $Na^+$ channels in excitable tissues. It would seem that the expression of individual $Na^+$ channel isoforms is highly tissue/cell specific (see Fig. 4 for examples). Thus two isoforms are selectively expressed in muscle, while three appear to be peripheral nervous system specific. Nonetheless, there are a few recent reports of expression of these isoforms in the central nervous system, so the tissue-selective expression of some isoforms is still uncertain.

In addition, even within a given cell, different isoforms are usually selectively targeted to different specializations, such as dendrites or the axon hillock. For example, in retinal ganglion cells (►Retinal ganglion cells), the $Na_v1.2$ isoform is expressed in the unmyelinated segment of the neuron axon within the retina itself, whereas $Na_v1.6$ is selectively clustered at ►nodes of Ranvier in the ►optic nerve. Thus there must be cellular targeting mechanisms to achieve the differential distribution of these two isoforms in the same axon. At present the mechanisms behind the selective targeting of $Na^+$ channels are being actively investigated.

The formation of high-density clusters of $Na^+$ channels at nodes of Ranvier is one aspect of $Na^+$ channel targeting and clustering that is being actively studied by a number of laboratories. These clusters are essential to the mechanism of high-speed saltatory conduction in myelinated nerve axons (►Action potential propagation). Here the neuron must precisely target the $Na_v1.6$ isoform to the minute domains of the nodal gaps, and it must do this for nodes that may be many thousands of cell diameters remote from the soma where the channels are synthesized. How might such a spectacular process of transport, targeting, and clustering be achieved?

Sodium channel isoforms

| | |
|---|---|
| $Na_v1.1$ (Type I) | *Dendrites* |
| $Na_v1.2$ (Type II/IIA) | *Unmyelin. initial segments* |
| $Na_v1.3$ (Type III) | *Early neuronal development* |
| $Na_v1.4$ (SkM1, μ1) | *Skeletal muscle (mature)* |

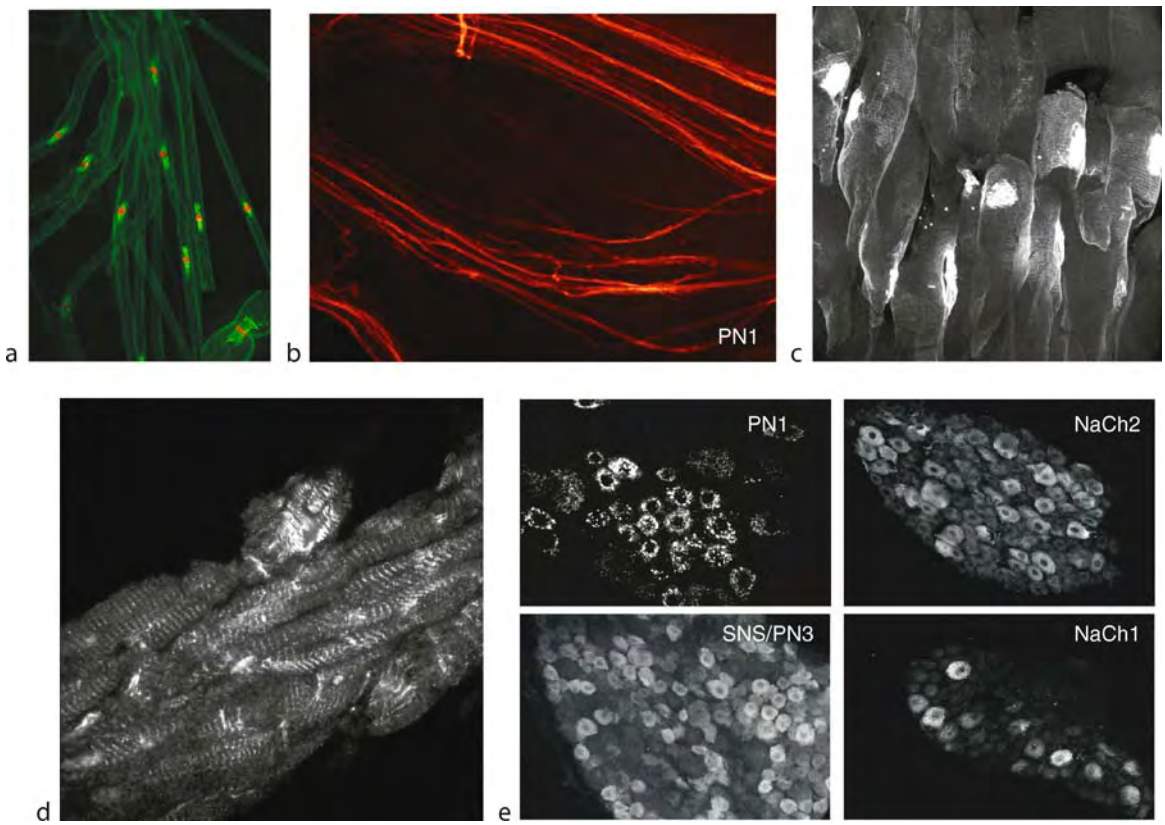
**Sodium Channels. Figure 3** Sodium channel isoforms and their known distributions in excitable tissues. Also given are older alternative isoform protein designations: Genomic nomenclature is also sometimes used, but is not shown here.



**Sodium Channels. Figure 4** Images of the subcellular localization of various $Na^+$ channel isoforms as seen using isoform-specific immunofluorescence techniques. (a) $Na_v1.6$ channels (red fluorescence) at nodes of Ranvier. These are mouse sciatic nerve axons co-labeled for caspr (green), a protein found in paranodal glia-axonal junctions. (b) $Na_v1.7$ (a.k.a. PN1) isoform expression in unmyelinated fiber bundles of mouse sciatic nerve. (c) $Na_v1.4$ expression in rat skeletal muscle. Note the intense labeling of postsynaptic $Na^+$ channel clusters, while weaker labeling of t-tubules is also apparent (as seen in the z-line labeling pattern). (d) $Na_v1.5$ expression in rat cardiac ventricular myocytes. Note intense staining of intercalated discs between myocytes and the t-tubule staining pattern. (e) Expression of isoforms in the dorsal root ganglion. Isoforms are identified by the older nomenclature. Note that expression of isoforms varies among different sized subpopulations of neurons, i.e. smaller neurons express PN1 and SNS ($Na_v1.7$ and 1.8), while larger neurons express $Na_v1.1$ and $Na_v1.2$.

Part of the answer to this question appears to be that myelinating glia (i.e. ►Schwann cells in the peripheral nervous system, ►oligodendrocytes in the central nervous system) assist the neuron by specifying where nodal clusters are to be formed. In particular, immunocytochemical studies show that when glia start to form compact myelin during development, $Na^+$ channel clusters quickly form at the ends of the myelinating glial cell. Further, as the myelin sheath extends along the axon, these clusters appear to move with it at the edge of the growing glial processes. This motion continues until adjacent myelin sheaths come close to one another; at this point the adjoining clusters appear to fuse to form a stable nodal cluster [8].

At the other end of the nodal clustering process, a number of proteins have been described that define the nodal membrane domain, while others have been identified as being part of the actual $Na^+$ channel cluster complex (see [9]). In particular, ►ankyrinG is thought to be the link that joins $Na^+$ channels to the axonal cytoskeleton, but this interaction seems to take place between ankyrinG and the β1 subunit.

## Roles of $Na^+$ Channels in Human Disease: $Na^+$ Channelopathies

Finally, a growing number of human disorders have been identified with defects in $Na^+$ channel function or expression [10] (see ►Channelopathies; ►Voltage-gated sodium channels: multiple roles in the pathophysiology of pain). Best characterized are the periodic paralyses (►Familial periodic paralysis) and certain myotonias (►Myotonia) of muscle and certain heritable forms of long Q-T syndrome of the heart; these involve $Na_v1.4$ and $Na_v1.5$ isoforms, respectively. In the

S

nervous system, several forms of ►epilepsy and pain disorders have been linked to genetic defects in the functional properties of $Na^+$ channel isoforms, particularly $Na_v1.1$ and $Na_v1.7$ (►Voltage-gated sodium channels: multiple roles in the pathophysiology of pain). In addition, a form of epilepsy has been associated with a defect in β1 expression. No doubt other human disorders will be identified as $Na^+$ channelopathies of other isoforms, especially since animal diseases have been associated with such defects (e.g. $Na_v1.6$ channelopathies in mice).

## Somatic Features

### Definition
For a diagnosis of major depression with somatic features, the individual must display at least four of the following: marked loss of interest or pleasure in activities that are normally pleasurable; lack of emotional reaction to events or activities that normally produce an emotional response; waking in the morning 2 hours or more before the usual time; depression is worse in the morning; marked psychomotor retardation or agitation (observed by other people); marked loss of appetite; weight loss (5% or more of body weight in the past month); marked loss of libido.

►Major Depressive Disorder

## Somato-Autonomic Reflex

Sae Uchida, Brian Budgell
Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan

### Synonyms
Somato-visceral reflex

### Definition
A somato-autonomic reflex is a reflex elicited by stimulation of somatic tissue (strictly speaking, tissue of

the musculoskeletal system and the dermis of the skin), and manifesting as an alteration in autonomic nervous system function. Altered autonomic nervous system function may or may not subsequently lead to changes in the function of dependent organs, in which case one could properly refer to the phenomenon as a somato-visceral reflex. However, one should also keep in mind that somatic stimulation may evoke mechanisms external to the autonomic nervous system which, nonetheless, impact visceral function and would therefore constitute somato-visceral reflexes. Such mechanisms include humoral, immune and non-autonomic neurological processes. Thus, while the terms somato-autonomic and somato-visceral are often used interchangeably, there are differences in nuance.

## Characteristics

### Quantitative Description

A great variety of somato-autonomic reflexes has been described in the research literature, and a number of these reflexes have considerable clinical importance. In conscious subjects, somatic stimulation is likely to lead to somatic sensation and to emotional responses that add a further level of complexity to somato-autonomic interactions. Hence, it is extremely challenging to isolate somato-autonomic reflexes in conscious humans and animals. In anesthetized animal preparations, however, somatic stimulation has been clearly shown to elicit responses in autonomic efferent nerves and, thereby, in the functions of various organs. Indeed, a comprehensive review of the literature [1] has revealed somato-autonomic reflexes arising from noxious and innocuous thermal, mechanical and chemical stimulation of virtually all somatic structures investigated, and manifesting in, for example, the cardiovascular, digestive, urogenital and endocrine systems.

### Higher Level Structures

►Central structures regulating autonomic function [link to essay "Central Regulation of Autonomic Function" by Dr. Benarroch] have been described comprehensively elsewhere in this text. Important centers for autonomic output, such as the nucleus tractus solitarius (►NTS [link to glossary item "Nucleus of the Solitary tract" by Dr. Benarroch]) and rostroventrolateral medulla (►RVLM [link to glossary item "Rostral Ventrolateral Nucleus (RVLM)" by Dr. Kannan]), receive inputs from higher centers and thus are influenced by, for example, emotional state. These same centres also receive visceral sensation which contributes to the generation of ►viscero-visceral reflexes [link to glossary item "viscero-visceral reflex" by Dr. Budgell] such as the ►baroreceptor reflex [link to glossary item "Baroreceptor reflex" by Dr. Dampney]. Additionally, autonomic nuclei in the brain stem receive relays from centres which receive noxious input, including noxious input from somatic tissues. Thus, somatic pain influences central autonomic function indirectly, through emotional responses to pain, and also through less circuitous relays [2]. Important within the context of somato-autonomic reflexes, is the more recent demonstration of direct inputs from somatic afferents to central autonomic motor nuclei; see, for example [3].

### Lower Level Structures

The lower level structures contributing to somato-autonomic reflexes are somatic afferents, and sympathetic, parasympathetic and enteric motor neurons. The afferent limbs of somato-autonomic reflexes include group II, III and IV afferent fibers entering the spinal cord via the spinal nerves, and entering the brainstem via the trigeminal nerve. There is also emerging evidence to suggest that group Ia or Ib afferents (from muscle spindles and Golgi tendon organs) modulate some autonomic reflexes [4].

### Higher Level Processes

The importance of central regulation of autonomic function is brought into sharp focus by the distressing and even life-threatening manifestations of ►disease effecting these structures [link to essay "Autonomic Insufficiency" by Budgell]. Furthermore, while a simplified view would hold that noxious stimulation increases sympathetic output, while innocuous stimulation decreases it (with the inverse effects on parasympathetic output) [5], clinical observations and laboratory experiments demonstrate that the higher autonomic centres are much more discriminating. As mentioned above and described in detail elsewhere in this text [link to essay "Central Regulation of Autonomic Function" by Dr. Benarroch], ►autonomic centres in the brain receive divergent input allowing the integration of emotion, information concerning the internal environment, and somatic sensory information. This permits them to generate not simply stereotypical responses, such as "►fight or flight response" [link to glossary item "fight-or-flight response" by Dr. Passatore], but rather responses which are specific to the immediate needs of the organism. Hence, by way of example, there will be occasions on which the higher level structures dampen what might otherwise be exuberant sympathetically-mediated hypertensive responses to pain. The adaptive importance of this discriminative potential becomes obvious in patients with high spinal cord injuries, and in laboratory animals subjected to experimental spinal cord lesions.

### Lower Level Processes

In subjects with an intact nervous system, autonomic reflex responses may include excitation or inhibition of motor neuron activity, depending, in part, on the somatic afferent modalities involved; see for example [6]. Classically, noxious somatic stimulation has been

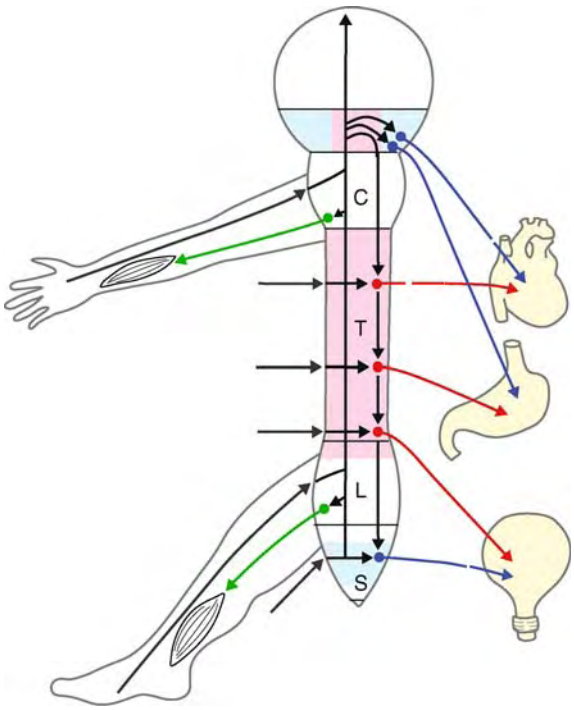
thought to increase the activity of peripheral autonomic nerves, and any number of experimental studies support this generalization; see, for example [7]. However, in animals subjected to spinal lesions, one can observe the native reflex activity of peripheral autonomic nerves below the level of the lesion in the absence of modulating influences from autonomic centres in the brain. In such animals, the peripheral autonomic motor neurons seem to be capable of only excitatory responses to stimuli [6]. Furthermore, these reflexes exhibit a clear segmental organization [7,8]. That is to say the reflex output of an autonomic motor neuron is likely to be greatest when the stimulation is conveyed by a sensory nerve which enters the same spinal cord segment. By way of example, noxious pinching of upper thoracic skin may preferentially excite the cardiac sympathetic nerves which originate in the upper thoracic region, and this leads to reflex ►tachycardia [link to glossary item "tachycardia" by Budgell]. On the other hand, noxious pinching of abdominal skin may preferentially excite the renal sympathetic nerves which originate in the lower thoracic and upper lumbar spinal cord of the rat, and this leads to increased blood pressure.

## Process Regulation

It would appear that there are a number of parallels between somato-somatic and somato-autonomic reflexes. To use the patellar reflex as an example of a somato-somatic reflex, when one strikes the patellar ligament and stretches the quadriceps muscles, somatic information enters the spinal cord, synapses immediately with somatomotor neurons at the same level(s), producing an excitatory response – the leg jumps. Furthermore, it appears that this reflex is normally dampened by inhibitory influences descending from the brain, such that the reflex often becomes exhuberant with brain or spinal cord injury. Similarly, it appears that somatic information entering the spinal cord may synapse with autonomic motor neurons originating in the same region of the cord, producing an excitatory response – for example, an increase in heart rate or blood pressure. As with the somato-somatic reflex, it appears that such somato-autonomic reflexes are often dampened by inhibitory influences descending from autonomic centres in the brain.

This model of somato-autonomic reflexes is both attractive and logical, but has been slow to emerge due to the complexity of autonomic anatomy and physiology. In particular, early experimentation into somato-autonomic reflexes often employed noxious stimulation of limb afferents; a model which obscures the segmental organization of autonomic function. This is because somatic sensory information from the forelimbs and hind limbs enters the spinal cord at the cervical and lumbar enlargements, respectively. In these regions of the spinal cord, there are many somatic motor neurons to control limb movement, but relatively few autonomic motor neurons. Hence, autonomic reflex responses to limb stimulation are necessarily mediated primarily at the supraspinal level, and so are abolished by transection of the upper cervical spinal cord. It was only with systematic investigation of thoracolumbar stimulation that the segmental organization of somato-autonomic reflexes became apparent.

The thoracolumbar region of the spinal cord (exclusive of the lumbar enlargement) and the sacral region contain abundant ►preganglionic autonomic motor neurons [link to glossary item "preganglionic neurons" by Dr. Gabella]. In humans, preganglionic sympathetic neurons are concentrated in the intermediolateral and intermediomedial columns between, approximately, the first thoracic and the second or third lumbar segments. Preganglionic parasympathetic neurons form the intermediate columns in the second to fourth sacral segments. Hence, somatic afferents entering the spinal cord at these segmental levels have the potential to elicit local, spinally-mediated reflex responses, and may also synapse with projections to higher supraspinal centers (Fig. 1).



**Somato-Autonomic Reflex. Figure 1** Schematic diagram of the reflex pathways for the somato-somatic and somato-autonomic reflexes (from Sato A. et al. 1997 [1]). Somatic stimulation of limb tissues elicits reflexes mediated primarily at the supraspinal level (in the brain), whereas somatic stimulation within the distribution of the thoracolumbar spinal nerves (the trunk region) has the potential to elicit both spinally-mediated and supraspinally-mediated reflexes.

Thus, stimulation within the distribution of the thoracolumbar and second to fourth sacral spinal nerves may elicit "segmentally-organized" somato-autonomic reflexes. That is to say, the stimulation may preferentially elicit responses in visceral organs receiving autonomic efferent innervation from the same (or adjacent) segmental level(s) as the involved afferents. Moreover, the segmental organization of these reflexes is likely to manifest itself more clearly when released from descending inhibitory influences, as for example when the cervical spinal cord is transected.

### Clinical Implications

A number of somato-autonomic reflexes have well established roles in clinical practice. For example, ►paralytic ileus [link to glossary item "Paralytic Ileus" by H. Katayama] may be an important clue to the presence of local disease such as an occult fracture of the lumbar spine. Similarly, the ciliospinal reflex may be used to assess the extent of injury to the cervical sympathetic trunk. More recently, ►autonomic dysreflexia, [link to glossary item "autonomic/enteric dysreflexia" by Budgell] exhuberant autonomic reflex activity in patients with spinal injury, has emerged as an important clinical challenge. Historically, somatic stimulation has also been used in a variety of health care practices, including acupuncture and spinal manipulation, to manage visceral disease. Clinical and basic scientific studies suggest that somato-autonomic reflexes may account for at least some of the therapeutic effects achieved with these therapies [9].

## Somato-cardiovascular Reflexes

►Cardiovascular Reflexes

## Somatosensory Cortex, Plasticity

Jon H. Kaas
Department of Psychology, Vanderbilt University, Nashville, TN, USA

### Definition

Somatosensory ►cortex is the part of neocortex of the forebrains of mammals that is activated exclusively or mainly by somatosensory stimuli. Somatosensory cortex is plastic in the sense that it can change in internal organization so that the response properties of neurons in the cortex are altered. Most notably, neurons that lose their major source of somatosensory activation following nerve or nervous system injury typically become responsive to remaining sources of activation.

### Characteristics

Somatosensory cortex is divided into a number of functionally distinct regions called areas. Typically, each area represents cutaneous or (and) deep tissue (muscle and joints) receptors of the contralateral body in a systematic (somatotopic) pattern. Areas depend on inputs from the somatosensory ►thalamus and other somatosensory areas for activation. The loss of a source of activation, such as afferents from the hand, is typically followed by neurons developing responsiveness to remaining inputs, such as those from the face or arm. Sensory experiences can also alter the response properties of neurons, often in ways that they become more selective for the experienced stimuli. These plastic changes in somatosensory cortex are mediated by the growth of axons and the formation of new synapses

in the somatosensory system, as well as by cellular changes that influence the sensitivities of neurons to neurotransmitters.

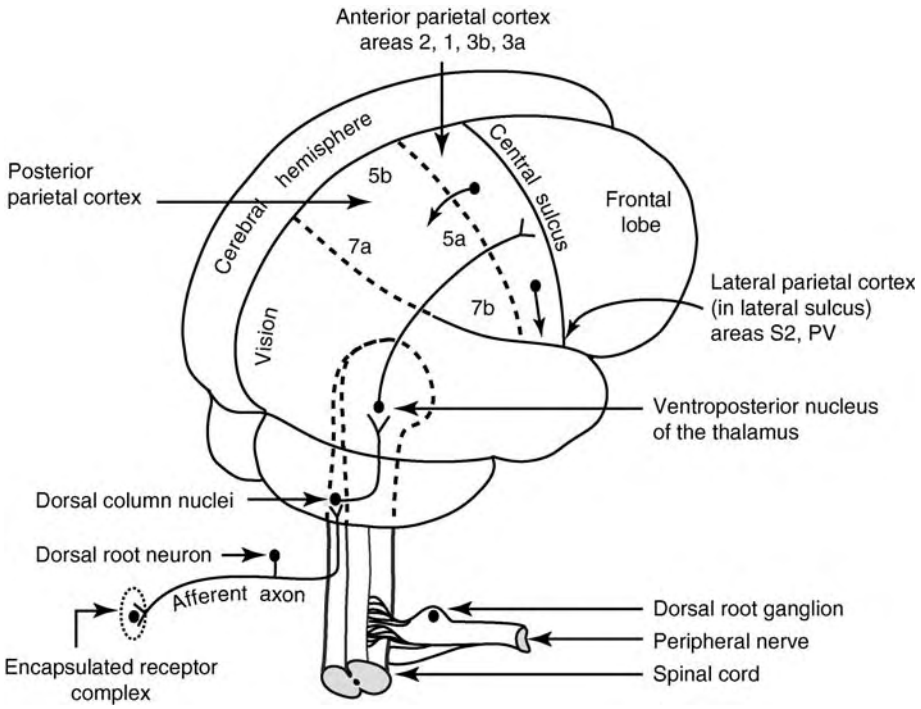
## Plasticity in the Somatosensory System

Neural ►plasticity has often been observed during the development of the nervous system, in that the early loss of some input, such as that from the whiskers of the face in rats, will alter the course of development so that parts of somatosensory cortex that represent the whiskers fail to develop properly. Thus, sensory experience is essential for the normal development of the somatosensory system and somatosensory cortex.

The somatosensory systems of mature mammals are also plastic, but the mature system responds somewhat differently. In adult mammals, the response properties of cortical neurons are reversibly altered by sensory experience, often in ways that makes them more sensitive to relevant stimuli. Such changes in neuron response characteristics appear to mediate long-lasting improvements in sensory and perceptual abilities that are called ►perceptual learning. In addition, damage to the mature nervous system usually results in some reorganization of the system so that remaining neurons partially compensate for the loss, allowing some behavioral recovery. However, a major loss of sensory inputs results in an extensive reactivation of deactivated portions of somatosensory cortex by remaining somatosensory inputs in ways that result in misperceptions, such as feeling ►touch or pain in a missing (phantom) limb. Researchers are trying to understand the mechanisms of neural plasticity so that useful forms of plasticity can be promoted, and harmful types of plasticity can be prevented.

## The Organization of the Somatosensory System and Somatosensory Cortex

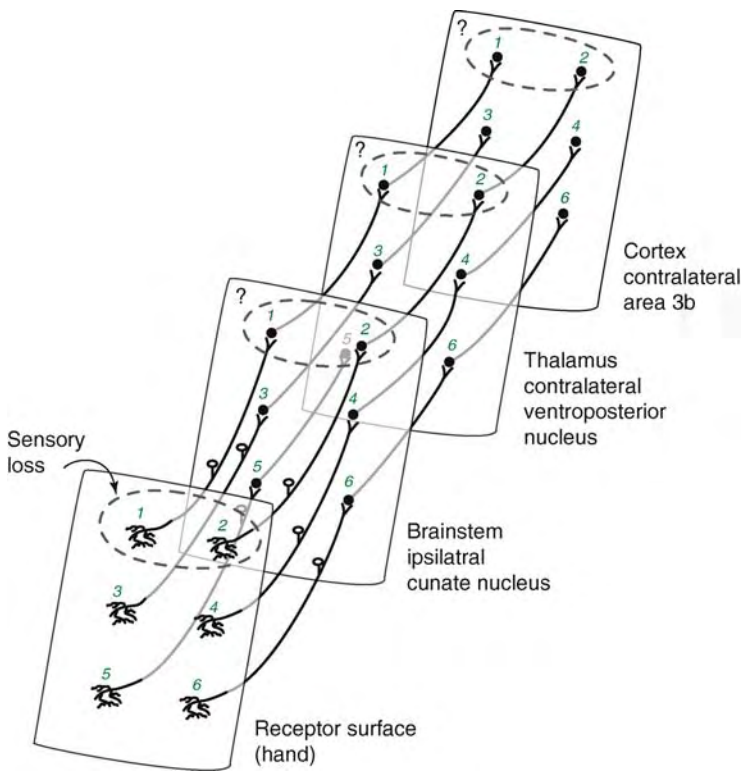
While the somatosensory system is complex, and involves several afferent pathways [1] nearly all of the studies of plasticity in the somatosensory system have focused on the major pathway that starts with encapsulated, low-threshold mechanoreceptors in the skin and reaches primary somatosensory cortex via the dorsal column-trigeminal nuclear complex in the ►brainstem and the ventroposterior ►nucleus in the thalamus (Fig. 1).



**Somatosensory Cortex, Plasticity. Figure 1** The somatosensory system for tactile discriminations in humans. Afferents in peripheral nerves enter the spinal cord or brain stem and send branches to the dorsal column-trigeminal nuclear complex where the contralateral body surface is represented somatotopically. Neurons in these nuclei project to the ventroposterior nucleus of the thalamus of the contralateral cerebral hemisphere, where neurons project to primary somatosensory cortex (area 3b). Information is then relayed to other somatosensory areas. Cortical regions are numbered according to current use of the numbering system of Brodmann. *S2,* the second somatosensory area; *PV,* the parietal ventral area.

Much of the research in the plasticity of the mature somatosensory system after injury has involved alterations of the representation of the glabrous hand in area 3b (primary somatosensory cortex) of anterior parietal cortex. According to Bolanowski and coworkers [2], tactile experience in humans depends on combinations of neural activity in four peripheral nerve channels that appear to correspond to the two slowly adapting and two rapidly adapting classes of low-threshold mechanoreceptor afferents. These afferents enter the spinal cord and course rostrally in the dorsal columns to the dorsal column nuclei, including the cuneate nucleus for afferents from the upper limb, the gracile nucleus column nuclei for the lower body, and the trigeminal nucleus for the head. These nuclei of the lower brainstem project to the ventroposterior nucleus (VP) in the contralateral thalamus. The ventroposterior nucleus, in turn, projects densely to layer 4 of area 3b, and to layer 3 of area 1 in anterior parietal cortex. Area 3b distributes tactile information to areas 1, 2, and 3a of anterior parietal cortex, and to the second somatosensory area, S2, and the parietal ventral area, PV, of lateral parietal cortex in the lateral sulcus. These areas distribute tactile information to additional areas in lateral parietal and posterior parietal cortex, as well as to motor cortex. The subcortical nuclei and most of the ►cortical areas of the somatosensory system contain systematic, topographic (somatotopic) representations of the body, including the glabrous hand. Thus, at least the early stages of the ascending somatosensory processing hierarchy of nuclei and areas can be portrayed schematically as a series of surfaces where the order of the distribution of receptors in the skin is preserved in representations of the skin at each level (Fig. 2).

While the representation of the fine grain of the receptor array is degraded somewhat from level to



**Somatosensory Cortex, Plasticity. Figure 2** A schematic of the early stages of the portion of the somatosensory system that processes tactile information from the mechanoreceptor of the skin. In this schematic, the surface of the hand is portrayed as a simple sheet, with subsequent targets in the nervous system as similar sheets. The important point is that the order of afferents subserving receptors of the hand is preserved as they terminate in the cuneate nucleus of the brainstem, and the order is further preserved as neurons project successively to the thalamus and cortex. Thus, removing some of the afferents, such as those from positions 1 and 2 (*dashed lines*) immediately deprives neurons at the 1 and 2 positions at subsequent levels of their sources of tactile activation. Plasticity is demonstrated when any of these deprived zones of nuclei or cortical areas recover responsiveness to any of the preserved inputs.

level, as receptive fields for neurons become larger, orderly ►somatotopic representations are found at each stage up to and beyond area 3b to also include the representations in areas 3a, 1, 2, S2, PV and elsewhere. In rats, and many other mammals, similar processing hierarchies exist, but they are less elaborate at the cortical level. In rats and other mammals, primary somatosensory cortex, S1, corresponds to area 3b of primates.

## The Immediate Consequences of Sensory Loss

In either monkeys [3] or rats [4], the immediate consequence of removing a portion of the tactile afferents from the body is to completely deactivate the corresponding portions of each successive representation in the hierarchy. Thus, if afferents from skin locations 1 and 2 in Fig. 2 are eliminated by sectioning them in the dorsal columns of the spinal cord, neurons in locations 1 and 2 in the brainstem, thalamus, and primary somatosensory cortex will no longer respond to tactile stimulation on skin locations 1 and 2, or any other place on the body. In some higher order representations such as S2, where the convergence of inputs creates larger receptive fields that include locations 3 and 4 as well as 1 and 2, neurons in partially deprived cortex will respond only to touch on locations 3 and 4 and not 1 and 2, thereby having smaller receptive fields. This complete or partial deactivation of neurons is exactly what one would expect from the diagram in Fig. 2, but the brain is not stable like the diagram, and the somatosensory system immediately starts to recover from the damage. What occurs depends in part on the species (rat or monkey) and the age of the animal at the time of injury. Also, the type of recovery is more dependent on the magnitude of the sensory loss rather than the way the loss occurred. Thus, similar recoveries can occur after damage to peripheral sensory nerves, the section of the dorsal roots of sensory serves as they enter the spinal cord, section of ascending branches of afferents in the dorsal columns of the spinal cord, or even the loss of a limb via therapeutic amputation.

## Plasticity after Sensory Loss in Mature Primates

After a sensory loss in primates, a process begins that starts to reactivate the deactivated neurons via remaining afferents [5]. If the loss is limited, such as the loss of afferents from part of the glabrous hand via section of the median nerve, reactivation proceeds rapidly over the course of 2–3 weeks, with most of the deprived neurons acquiring new receptive fields on the dorsal, hairy surface of the hand and digits. The reactivation is complete or nearly complete at the level of the cortex, nearly complete at the level of the thalamus, and partial, but extensive, at the level of the cuneate nucleus in the brainstem. As afferents from the back of the hand terminate in the cuneate nucleus very close to those from the glabrous hand, the critical mechanism of reactivation is likely to be the local sprouting of preserved afferents in the cuneate nucleus to synapse on and activate denervated neurons. Although the reactivation of neurons in the cuneate nucleus is incomplete, these reactivated neurons project to the ventroposterior nucleus of the thalamus where the activity is amplified to include more neurons at the thalamic and cortical levels via the divergence of projections in each relay, and the lateral (horizontal) connections in cortex. In addition, there is likely to be some axon sprouting and the formation of new connections at the thalamic and cortical levels to further promote reactivation. Reactivation is also promoted by self-regulatory cellular mechanisms such that deprived neurons produce less inhibitory neurotransmitters and fewer receptors for inhibitory neurotransmitters, thereby making them more sensitive to remaining inputs.

If the sensory loss is such that all inputs are sectioned from some digits, but at least a few inputs remain from other digits, deprived cortex becomes completely or nearly completely reactivated by preserved inputs from the hand, including those that were so sparse that initially they failed to activate any cortical neurons [3,6]. This reactivation results in a considerable recovery of hand use in skilled behavior, such as in retrieving food. Thus, the cortical reactivation is clearly useful. This recovery of cortical activation and behavior occurs over a period of weeks to several months, and again it depends on the growth of new connections in the dorsal column cuneate nucleus, and possibly in the thalamus and cortex.

A greater sensory loss, such as the loss of all the afferents from an arm after an injury and therapeutic amputation, or after extensive damage to the dorsal roots of nerves subserving the arm, is followed after months of recovery in the reactivation of the deprived parts of somatosensory cortex. Cortex that is normally devoted to the hand can be reactivated by inputs from the stump of the amputated limb or from the face [7,8]. Similar, but possibly less complete reactivations of the deactivated portions of the ventroposterior nucleus of the thalamus have been observed in both monkeys and humans. As with more limited sensory losses, the growth of new connections at the level of the brainstem, and the amplification of those effects at higher levels, seems to be critical to the cortical reactivation. Such extensive reactivations appear to be largely maladaptive, as patients with arm amputations report feeling touch on the fingers of the missing hand after being touched on the face or arm stump. A similar reorganization of the pain system could account for the feeling of pain in missing limbs of patients after amputations (phantom pain). Thus, not all outcomes of brain plasticity are good, and

we need to learn how to promote types of plasticity that restore lost abilities while preventing types of plasticity that lead to misperceptions and pain.

## Plasticity of the Somatosensory System in the Developing Brain

The effects of sensory loss can be quite different in developing and mature brains. The section of somatosensory afferents of the forelimb in the spinal cord of the developing brain of rats around the time of birth can cause a rapid degeneration of the relay neurons in the cuneate nucleus of the brainstem and a loss of the normal modular organization of the nucleus that reflects the normal somatotopy [9]. Most of the deprived neurons in the brainstem apparently die before they are reinnervated by the sprouting of preserved tactile inputs. As a result, the deprived portion of the ventroposterior nucleus fails to develop, and even much of deprived primary somatosensory cortex (S1) fails to histologically develop or acquire a source of somatosensory activation. However, preserved afferents from the anterior upper arm may activate forelimb cortex, and these afferents typically activate a larger than normal portion of S1, including some of the deprived forepaw region, demonstrating that preserved afferents also enlarge their cortical territory in the developing somatosensory system. Similar results have been obtained after forelimb amputation in neonatal rats. In addition, after forelimb amputation, some hind limb afferents grow into the cuneate nucleus to activate and preserve neurons.

Presently, little is known about what happens to the somatosensory system after sensory loss in newborn primates. However, the degeneration of the deprived portions of the brainstem relay nuclei would remove one site that is important in the reactivation of cortex in adults.

## Plasticity Following Somatosensory Experience

Sensory experience and learning produce changes in somatosensory cortex that are often called "use-dependent plasticity." During development, the extensive use of a part of the sensory surface can lead to an over-representation of that surface, while the disuse of a surface can result in an under-representation of that part. Such sensory experience, or lack of experience, can alter the course of development so that changes in representation are difficult or impossible to reverse after the brain matures.

Sensory experience also changes the organization of the somatosensory system in mature mammals. In contrast to the usual outcome of developmental plasticity, changes induced by experience in the mature somatosensory system can be rapidly reversed. The changes are largely at the level of single neurons and small groups of neurons, and therefore they are not expressed as large changes in somatotopy. For example, neurons in somatosensory cortex of rats that respond mainly to the movement of a single whisker on the face typically increase their responsiveness to an adjoining whisker, if the two whiskers are repeatedly stimulated together (called whisker pairing). Similar changes in the response properties of neurons in somatosensory cortex of monkeys have been shown to follow training and sensory experience. Over periods of disuse or altered use, the changed properties of cortical neurons typically reverse. The ability of neurons to change how they respond to stimuli apparently depends cellular mechanisms that alter synaptic strengths, and they often depend on co-activations of neurons by sensory inputs and by neurotransmitter systems that modulate neural activity [10]. As perceptual skills improve with training, and training changes the properties of cortical neurons in ways that would enhance the detection of the stimuli rewarded during training, such perceptual learning is often attributed to local regions of experience induced plasticity in somatotopic cortical representations.

# Somatosensory Cortex I

Yoshiaki Iwamura
Department of Sensory Science, Kawasaki University of Medical Welfare, Kurashiki, Okayama, Japan

## Synonyms

Primary somatosensory cortex; First somatosensory cortex, SI

## Definition

The cortical area first found to be specifically involved in somatosensory processing. It is in the postcentral gyrus in primates and in the postcruciate gyrus in cats. The human somatosensory cortex was defined earlier as the regions where electrical stimulation provoked subjective somatosensory experiences. In animals, cortical evoked potentials were recorded by electrical stimulation of the body surface to determine the location of the somatosensory cortex.

## Characteristics

The somatosensory cortex I (SI) was located in the postcentral gyrus in primates. In humans, electrical stimulation of the postcentral gyrus evoked subjective somatic sensation and the somatotopic maps of the body representation over the cortical surface were drawn. In monkeys, cortical evoked potentials were recorded with shortest latency after stimulation of the periphery, either skin or nerves. Analogous somatotopic maps of the body representation were also drawn in various other mammals [1].

### Cytoarchitectonic Subdivisions of SI

Brodmann assigned three different cytoarchitectonic areas in the postcentral gyrus of primates, areas 3, 1 and 2. Later area 3 was subdivided into areas 3a and 3b.

### Thalamic Inputs to SI

SI receives direct projections from the thalamic ventrobasal complex, the specific somatosensory relay nuclei that mainly convey somatosensory signals from the periphery through the dorsal column-lemniscal system, and some through the spinothalamic tract. Sensory signals from deep tissues, muscles or joints project mainly to area 3a, while those from the skin or intra-oral mucous membrane, project mainly to area 3b. The projections from the ventrobasal complex also go to areas 1 and 2, but less heavily than to area 3. Area 2 receives some additional projections from the thalamic association nuclei such as the posterior nuclei.

### Cortico-Cortical Association Connections of SI

The gray matter of the neocortex is composed of six layers. Axons of neurons in layer III project to other cortical areas as cortico-cortical association fibers. In SI, areas 3a and 3b project to areas 1 and 2, and area 1 to area 2. Areas 3a, 1 and 2 project anteriorly to the motor cortices. Areas 1 and 2 project posteriorly to areas 5 and 7. Areas 3b, 1 and 2 project to the second somatosensory cortex (SII) [2].

### Callosal Connections of SI

Among neurons in layer III, some neurons send axons to the other hemisphere through the corpus callosum. Through these callosal fibers homotopic cortical regions of two hemispheres are connected. Generally speaking, the callosal fibers are scarce in the primary sensory areas. In SI, it is in 50 area 3b, the hand or foot region, in particular. They are seen only in the face or trunk region in area 3b. The callosal connections are denser in area 2 and more posterior in area 5, seen even in the hand or foot region [2].

### Corticofugal Connections from SI

Neurons in the cortical layers V and VI send axons down to subcortical structures. Neurons in layer V send axons to the brain stem and spinal cord while those in layer VI send axons to the thalamus [2].

### Somatotopic Representation of the Body Surface

SI is characterized by a topological (somatotopic) representation of the body over the cortical surface. In SI of the primate, the oral cavity, face, hand, arm, trunk, leg, and foot are represented orderly in the lateral-medial direction over the postcentral gyrus. Penfield and Boldrey (1937) invented a homunculus to describe such an arrangement. Maps of somatotopic representation of the body over the cortical surface were demonstrated in various other mammals by recording evoked potentials. The cortical tissue devoted to each body-part representation is not equal. The part of the body which is most exaggerated in the somatotopic map differs among animals. In primates, the cortical region for the oral cavity, face, hand, or foot is much larger compared to that of the trunk or the proximal part of the arms or legs.

### Plastic Changes in the Somatotopy

It has been reported that amputation of a digit in macaques resulted in modification of the cortical representation map in a way to cover the representation area of the lost digit by that of adjacent digits. After extensive training to use certain digits this resulted in the enlargement of the representation of adjacent digits. Furthermore, in owl monkeys after extensive use of three digits together, neurons emerged with multidigit receptive fields, which were never seen in untrained animals in area 3b [3].

Blind persons who use three fingers together to read Braille frequently misperceive which of the fingers

actually touches the text. In these subjects an expansion and dislocation of SI hand representation were found by magnetic source imaging techniques [4]. The representation area of fingers measured by magnetic source imaging increased in the left hand in string players possibly as the result of extensive training [5].

## Columnar Structures of SI and Diversity of Neuronal Receptive Field along a Perpendicular Array

There has been a hypothesis that the neocortex is columnar in its structure. The idea of columnar organization of the cortex in a physiological sense was first proposed in the cat somatosensory cortex by Mountcastle (1957). He described that neuronal receptive field locations tended to be similar among neurons recorded along an electrode track perpendicular to the cortical surface. He thought the phenomenon reflected the anatomical structure of vertical neuronal arrays in the cortex proposed by Lorente de No (1949). The columns were thought to be basic and elementary structures for the localization of functions in the neocortex.

The columnar structure in its original proposal was based on the assumption that a cortical locus represents a locus in the periphery faithfully, that is, the cortex is somatotopic. Receptive field characteristics of neurons in a single column could share a common thalamocortical input. It was thought that the barrel cortex in the rodent is a typical example: each barrel represents a single whisker hair there. However, recent studies show that it is not so simple in the barrel field (ref to Essay by Ebner). In other cortical areas in SI of monkeys that are more associative, such as areas 2 or 5, what is represented in the putative unitary structure is not clear-cut, because receptive field characteristics are not necessarily the same nor are they similar among neurons in a vertical array. Neurons in deep layers tend to have larger and more complex receptive fields [6,7].

Receptive fields of neighboring neurons diversify in conjunction with an increase in receptive field size and the complexity of neuronal properties in the crown of the postcentral gyrus, areas 1 and 2. In that sense, some investigators doubt that the cortex is modular. There are synonyms of column: mini-columns, modules, slabs, stripes, bands, barrels, beads, blobs, patches, puffs, lattices etc.

## Hierarchical Processing in the Hand Region

Modern microelectrode techniques to record single neuronal activity in waking animals enabled scientists to analyze detailed organization of the enlarged cortical finger representation in the monkey [1]. The most important principle of information processing in SI is a hierarchical processing, that is, information each neuron bears becomes progressively more complex along the rostro-caudal axis of the postcentral gyrus [6]. In the finger region of area 3b in the monkey, the neuronal receptive field is small, often representing only a part of a phalange of a single finger. Functionally unique parts of fingers (i.e. tips, ventral glabrous surfaces, and dorsal surfaces) are represented separately, forming different subdivisions of area 3b. These subdivisions provide a basis for inter-digital integration of information in the more caudal regions of SI, areas 1, 2 and 5.

In areas 1 and 2, progressive inter-phalangeal or inter-digital integration takes place, and receptive fields of neurons become larger, covering more than one phalange of a finger, or more than one finger. The inter-digital integration is more remarkable in the ulnar fingers than in the radial ones. There are unique types of neurons in areas 1 and 2 with selectivity to specific features of stimulus, such as the direction of a moving stimulus; the presence of an edge or rough surface; those that are activated better or solely by the monkey's active hand movements, including reaching; or those facilitated or inhibited by attention.

## Vertical Neuronal Arrays Representing Active Touch

Diversity in the receptive field of cortical neurons was also pointed out in conjunction with a perpendicular array of neurons [7]. Receptive fields of neurons recorded along a perpendicular penetration were often variable, but the largest receptive fields usually covered the others, and were found mostly in the infragranular layers. Often they included inhibitory receptive fields that were arranged side-by-side to the excitatory ones, and also some of them responded to both skin stimulation and joint manipulation. The key stimulus common to neurons in a perpendicular penetration was the contact of an object to the receptive field achieved during an animal's active behavior to manipulate objects. Thus the largest receptive field was designated as functional surfaces. They could be regarded as a functional assemblage that deals with a set of information concerning one of various aspects of active touch.

## Bilateral Representation of the Body in SI

The hierarchical integration proceeds to combine information from the bilateral sides in the higher stages of hierarchical processing: a substantial number of neurons with bilateral or ipsilateral receptive fields are found in the caudalmost part (areas 2 and 5) of the postcentral finger region, and also in other body parts.

Neurons in SI usually have receptive fields on the contralateral body. Several studies reported the presence of neurons with bilateral receptive fields (Manzoni et al. 1989). According to these studies, these exceptional bilateral activities were limited to the body midline including the dorsal or ventral trunk, occiput, perioral face, or oral cavity. The midline structures are activated bilaterally in normal body use and thus have good reason to be represented bilaterally. From the

same functional standpoint however, even the distal and other body parts such as hands, shoulders, or feet should also be represented bilaterally. It had been generally thought such bilateral integrations were postponed to SII and the parietal association cortices.

Indeed, such bilateral activities have been found in the postcentral gyrus of macaque monkeys (Iwamura et al. 1994, 2001) [8]: bilateral hands, arms/shoulders and trunk, girdles, and feet neurons have been found in the caudalmost part of the postcentral gyrus (areas 2 and 5) in the dorsal bank of the intraparietal sulcus. These neurons were found systematically and nearly somatotopically. The bilateral receptive fields are large and the most complex types found in this gyrus. The distribution of the bilateral receptive field neurons roughly corresponds to that of callosal connections in this gyrus.

## Hierarchical Processing in the Hand Region of Human Somatosensory Cortex

Recent progress in technology of investigating human brain activity such as MEG, PET, fMRI, TMS etc. enabled the confirmation that the organization of the human somatosensory cortex (SI) is based on the same principles as those found in macaque as described in the previous section. Precise cytoarchitectonic structures of the human SI have been described. Representation of single finger in multiple sites of the hand region, overlapping representation of different fingers, the increasing rostral to caudal convergence of finger representation, integration of cutaneous and kinesthetic information in the caudal region were described, and thus the presence of hierarchical processing of information was confirmed in the hand region of the human somatosensory cortex [9]. Inui et al. (2004) compared the latency of SEF potential and found that it becomes progressively longer as the recording site moves caudally in the postcentral gyrus, from area 3b to 1 and 2, and areas 5 and 7.

## Attributes of Tactile Perception Represented in Cortical Activity

Cortical activities representing spatio-temporal patterns of tactile skin stimulation such as flutter-vibration, motion, direction, length, velocity of tactile stimulus, surface texture, spatial form, and so on, have been studied [1]. Studies of single cells in the somatosensory cortex SI have shown that responses reproduce essential object features presented to the skin and show response patterns similar in many cases to the primary afferent input signals. For example, the configuration of embossed dot ensembles is clearly evident in the response patterns across arrays of single cortical units. Some single cortical units have characteristics that appear to combine response characteristics of more than one afferent type, e.g. SAI and FAI afferents, providing an additional layer of information. DiCarlo et al. (1998) indicated that area 3b neurons act as local spatio-temporal filters and may contribute to form and texture perception.

Lesions placed in the caudal postcentral region cause disturbances in the discrimination of size, form and roughness of tactile objects. Neurons were found in the caudal part of the SI of monkeys that were activated by the contact of either round or elongated objects with edges (Iwamura & Tanaka 1978). These neurons were considered as neuronal correlates of stereognosis.

In human brain the presence of systematic and hierarchical organization to discriminate texture or object shape was shown [9].

## Representation of Pain in SI (See Pain Section)

Single-neuronal recordings in the monkey established that nociceptive pathways project to area 3b and 1 of the somatosensory cortex SI. SI may be involved in the sensory-discriminative aspect of pain, especially stimulus localization. Intensity may be coded in other somatosensory cortical areas as well [10]. Pain has a strong emotional component, in addition to the sensory component, and is therefore processed by further distributed multiple cortical loci.

## Pathology

Lesions of SI produce deficits in somaesthesia, including simple light touch, two-point discrimination, position sense, vibration sense and complex perceptual abilities such as tactile object recognition and visuo-tactile matching. In contrast, patients with lesions of the posterior parietal cortex (posterior S1 and areas 5 and 7) are particularly impaired on complex tasks. Some of these patients also show difficulties in generating exploratory and manipulative finger movements within the context of active touch, called limb kinetic apraxia (Liepmann 1910). Such observations suggest that the posterior parietal cortex is a key station in generating and executing exploratory movements utilizing both efference copy and sensory feedback.

# Somatosensory Cortex II

Yoshiaki Iwamura
Department of Sensory Science, Kawasaki University of Medical Welfare, Kurashiki, Okayama, Japan

## Synonyms

Secondary somatosensory cortex; The second somatosensory cortex; SII

## Definition

The cortical area involved in the somatosensory processing in the parietal operculumin in primates and in the lateral cortical region in the cat. It has been defined as a separate cortical region from SI based on the presence of an independent somatotopic representation of the body. The extent of SII and its functional role are still in debate.

## Characteristics

Adrian (1940, 1941) found the second representations of the contralateral paw and toe being close to each other in a small portion of the lateral cortex of the cat. Penfield suggested the presence of the second somatosensory cortex (SII) in the human in the parietal operculum, in the Sylvian fissure (Rasmussen & Penfield 1947, Penfield & Rasmussen 1950): somatic sensations referred to the limbs or other body parts of either side (though more often the contralateral side) were obtained by electrical stimulation of the cortex. Woolsey (1958) later confirmed the presence of SII in various mammals [1].

### Location of SII in Terms of Brodman's Cytoarchiteconic Areas

SII can be included in Brodmann's area 43, but they do not correspond to each other since the area 43 encompasses the postcentral face region of areas 3 and 1, and reaches the insula. Posterior to area 43, Brodmann identified area 40. Area 40, known as the posterior parietal association cortex, could include a part of SII [1].

### Thalamic Projections to SII

Major thalamic nuclei projecting to SII are VPI (nucleus ventralis postero-inferior in the ventrobasal complex), PO (the posterior nuclei), and CL (nucleus centralis lateralis in the intralaminar nuclei). Sensory modalities reaching to the SII region are innocuous cutaneous, proprioceptive, and nociceptive.

### Cortico-cortical Inputs to SII

SII in the primate receives ipsilateral cortico-cortical projections from each of the three cytoarchitectonic subdivisions of SI, areas 3b, 1 and 2, and areas 5 and 7 in the parietal cortex [1]. SII receives callosal inputs from the contralateral SI and SII.

### Subdividing of SII Region

#### *Monkey Studies*

Based on single neuronal recording in monkeys (after halothene administration was discontinued), Whitsel et al. (1969) divided the second somatosensory area into two parts, rostral and caudal. They defined the rostral area as a true SII (SII/r) where neurons were activated solely by one modality of somatic stimuli from the contralateral side (thus the body representation was somatotopic), while in the caudal area the neuronal receptive fields were large (thus the body representation was not somatotopic) and some neurons were activated by visual or auditory stimuli. Robinson & Burton (1980) did more extensive microelectrode mapping in unanesthetized monkeys in SII and the surrounding areas. They found a rather complex somatotopic representation of the contralateral body in SII. Burton et al. (1995) divided SII into two parts, based on the labeled corticocortical connections from area 3b and 1 to the SII region: two somatotopic maps were in mirror image. Krubitzer et al. (1995) recorded multi-units in anesthetized monkeys and proposed that the lateral somatosensory cortex should be divided into two parts, SII and PV (parietal ventral area). One of the common findings in these mapping studies was that the distal limbs occupy the central and largest part of the SII region [1].

Recently, Fitzgerald et al. (2004) reported that the SII hand region comprises of three adjoining fields: posterior, central and anterior, by receptive field

analysis of single units recorded from unanesthetized macaque brain [2]. The central field receives cutaneous inputs only while the other two fields receive both cutaneous and proprioceptive inputs. The authors speculate that the three fields play different roles in tactile perception.

### *Human Studies*

Disbrow et al. (2000) based on fMRI data proposed that the subdividing of SII cortex with the nomenclature of SII and PV proposed by Krubitzer et al. (1995) for monkeys was applicable to the human SII region. Mima et al. (1997) demonstrated two representations of the hand by recording SEPS and SEFS directly from the cortical surface of the human perisylvian cortex (SII).

Eickhoff et al. (2006) histologically mapped the SII cortex of human postmortem brains and identified four cytoarchitectonic areas: OP1–4 (for Operculum, 1–4 in caudal to rostral sequence) [3]. The authors claim that this cytoarchitectonic heterogeneity corresponds to results of fMRI studies on the human SII cortex.

## Bilateral Body Representation

Earlier studies in monkeys pointed out the presence of neurons with bilateral receptive fields (Burton 1986, Manzoni et al. 1986, Whitsel et al. 1969), but survey for the bilateral representation have not been extensive. More recent studies in human using magneto-encephalography or neuroimaging techniques confirmed that the representation is bilateral in SII [4].

## SII is a Higher Stage of Serial Information Processing

### *Monkey Studies*

The notion that SII is hierarchically higher than SI in the information processing network was proposed on the basis of their anatomical relationships: SI sends projections to SII, while SII projects back to the superficial layers of SI (Burton et al. 1995, Caulier et al. 1998) [1]. Physiological studies have shown that SII neurons tend to have larger and more complex receptive fields, including bilateral ones [1]. SII has been viewed as being composed of at least two parts, with area 3b having greater connections to the anterior part (Burton et al. 1995). It was proposed that there is a hierarchical relationship between the two parts of SII with regard to the receptive field properties of their neurons. Jiang et al. (1997) have shown that neurons in SII signal a change in texture but not its magnitude; thus, SII neurons are of a higher-order than SI neurons, which show a graded change in discharge when the spatial periods of test gratings are increased [5].

On the other hand, neural activity in SII of the marmoset monkey and cat is not completely abolished by reversible inactivation of SI (Zhang et al. 1996, Rowe et al. 1996), leading to the suggestion that the strict serial processing scheme might be in need of revision. Zhang et al. (2001) concluded that SI and SII occupy a hierarchically equivalent network for tactile processing [6].

### *Human Studies*

Inui et al. (2004) compared the latency of SEFs evoked by transcutaneous electrical stimulations applied to the dorsum of the left hand, just on the first metacarpal bone, and found that it becomes progressively longer as the recording site moves caudally in the postcentral gyrus, from area 3b to 1 and 2, and areas 5 and 7. The latency was even longer further in SII, indicating the presence of serial hierarchical processing from SI to SII [7].

SEFS evoked by median nerve stimulation have been recorded in SI, posterior parietal, parietal opercular (SII), and frontal regions (Mauguiere et al. 1997). On the basis of latency differences, it was assumed that the higher-order areas receive signals from SI through serial feedforward projections.

Huttunen et al. (1996) recorded SEFs in response to median nerve stimulation so as to measure changes in responsiveness during finger movements. The changes did not parallel those in SI, suggesting that the changes depended on additional modulatory inputs to SII rather than those from SI. The long latency component of SEF in response to stimulation of the posterior tibial nerve is affected by movement imagery of a toe in bilateral SII. Painful stimulation first activates contralateral SI and then bilateral SII, although it is not clear whether SII receives signals through SI or directly from the thalamus. SEFS in response to median nerve stimulation in SII are enhanced during thenar muscle contraction, possibly by decreasing inhibition from SI. Enhanced SII activation might be related to the tuning of SII neurons towards the relevant tactile input arising from the muscle.

Young et al. (2004) found that separation of hand and foot representation was clear in SI but less and less clear in SII in the order of OP4, OP2 and OP1. Instead, the rostralmost area (OP4) showed task-related enhancement [8].

## Attention to Tactile Objects Alters Responsiveness of SII

Recent studies have identified neurons in the monkey somatosensory cortex with enhanced sensitivity and selectivity for stimuli to which an animal is directing its attention (Sinclare & Burton 1993, Hsiao et al. 1993, Burton et al. 1997). The authors argue that SII, rather than SI, plays a role in tactile attention because a larger number of neurons in SII is related to attention. Burton et al. (1997) found that tactile and auditory cues correlate with enhanced or suppressed average firing rates of SII or area 7b neurons (45–50% of neurons) in response to vibrotactile stimuli. These modulations are consistent with a model of possible neural mechanisms associated

with selective attention and confirm earlier suggestions that SII plays a role in tactile attention. The authors also suggest that area 7b might play a similar role.

Nelson et al. (2004) confirmed in a human fMRI study that SII was activated more often during an attention demanding tracking task compared with passive vibration.

Chapman et al. (2005) in the study to record neurons in monkeys that were activated by a texture discrimination task, concluded that the attentional mechanisms were dual, one involved both SI and SII, while the other was more specific to SII [9].

### SII Neurons Activated by Decision-Making

Romo et al. (2002) found that some SII neurons were activated specifically at decision- making. They trained monkeys to compare two mechanical vibrations applied sequentially to the fingertips and to report which of the two had the higher frequency.

Activity of some SII neurons were correlated with monkey's decision-making to judge which of two stimuli (remembered and current) is higher in their vibration frequency [10].

### SII for Proprioception

Fitzgerald et al. (2004) [2] reported by receptive field analysis of single units recorded from unanesthetized macaque brain, that the central field receives cutaneous inputs only while the other two, the anterior and posterior fields, receive both cutaneous and proprioceptive inputs. The authors speculate that three fields play different roles in tactile perception. Alary et al. (2001) in a human SEF study suggested that human left SII plays a predominant role in proprioceptive processing.

### Projection of Pain in Human SII

Feretti et al. (2003) found in an fMRI study that the activity for the painful stimulation was localized more posteriorly compared to that for the nonpainful stimulation. Bingel et al. (2004) in an fMRI study showed that both SI and SII encode spatial information of nociceptive stimuli independent of tactile ones, and proposed the concept of a redundant representation of discriminative stimulus in somatosensory cortices. Marihofner et al. (2006) in an fMRI study concluded that SII plays an important role in the discrimination dimension of pain rather than the affective-motivational ones.

# Somatosensory Projections to the Central Nervous System

Mark J. Rowe
Department of Physiology and Pharmacology, School of Medical Sciences, The University of New South Wales, Sydney, NSW, Australia

## Synonyms

Somatic Sensory Projections to the Central Nervous System

## Definition

►Somatosensory projections arise from ►sensory receptors and nerve fibers distributed throughout the body as a whole, as distinct from those arising from the highly specialized sense organs for vision, hearing, balance, taste and olfaction. They are therefore concerned with the sensory modalities of touch, pain and thermal sensation, and the kinaesthetic sense which is the sense of body position and movement.

## Characteristics

### The Sources of Somatosensory Information

Much of the information contributing to the different modalities of somatic sensation is derived from sensory

receptors or nerve endings in the skin, in particular, for touch and thermal sensations. However, for kinaesthesia, the information is derived from receptors in muscles and joints, and to some extent, from those within the skin because, as fingers or limbs are moved, the cutaneous mechanoreceptors are subject to perturbation in association with the stretch or compression of the skin in the vicinity of the joints being moved. In the case of pain sensations, the input may be derived from almost any site in the body, including, of course, the skin, but also from muscles and joints, for example, in association with muscle injury or inflammatory diseases of joints. Inputs for pain sensation may also arise from pathophysiological disturbances in our internal organs and give rise to ►referred pain in which the pain is associated with an external body part, such as the left shoulder or arm, in the case of coronary-induced cardiac pain. The pattern of pain referral is crucial for differential diagnosis at a clinical level, and, in terms of its explanation, is thought to reflect convergence or overlap within the central nervous system (CNS) projections of nociceptive afferent nerve fibers arising from the affected visceral organ and from the somatic site to which the pain is referred.

## The Nature of Somatosensory Receptors and Associated Afferent Nerve Fibers

The receptors and sensory nerve fibers responsible for the four modalities of somatic sensation fall into two broad groupings. First, the mechanoreceptors for tactile and kinaesthetic sensation are specialized transducer structures in which the sensory nerve ending has a complex association with non-neural cells. In contrast, thermal and pain information appears to be derived from naked sensory nerve endings in which the peripheral endings of the sensory nerve fibers, whether in the skin, muscles, joints or viscera, have some physicochemical specialization that enables them to act as transducers that convert the thermal or a variety of noxious stimuli into the electrical signals that are conveyed over the sensory nerve fibers to the CNS. A further distinction among these four modalities of somatic sensation exists over the diameter and conduction velocity of the sensory nerve fibers responsible for each modality of somatic sensation. These somatic sensory nerve fibers are usually classified into four major groups on the criterion of the cross-sectional diameter of the nerve fiber (or axon) and range from as fine as <1 μm in diameter (the group IV fibers, or C fibers as they are also known, that lack a fatty-insulating layer of ►myelin around the conducting cable of the nerve fiber) up to diameters of ~20 μm (the Group I fibers, which, like the Group II and III fibers, are said to be myelinated, because the nerve axon is ensheathed by a myelin layer that helps confer a faster signaling speed on the fiber. The largest and fastest conducting fibers (Gr. I and II) carry kinaesthetic and tactile information, whereas the Gr. III and IV fibers carry information for pain and thermal sensations. Fiber diameter correlates with the conduction velocity at which impulses are propagated along these somatic sensory nerve fibers, with velocities exceeding 100 m/s in Gr. I fibers, and ranging from ~40–70 m/s in Gr. II fibers, ~10–30 m/s in Gr. III fibers, and ~0.5–2 m/s in Gr. IV fibers. It should be emphasized that a peripheral somatic nerve such as the ulnar nerve (which is the one that passes close to the humerus bone near the elbow, and which, if bumped, generates pain and the pins-and-needles sensation) contains thousands of individual nerve fibers and includes not just the sensory, or afferent fibers, but also nerve fibers that convey signals outwards from the CNS to bring about muscle contraction, and others, the autonomic efferent fibers, that control blood vessel diameter and sweat gland activity.

## The Projection of Somatosensory Information From the Periphery to the CNS

Somatosensory information for touch, kinaesthesia, pain and thermal sensations is carried from all parts of the body to the CNS via vast numbers of nerves that finally enter either the spinal cord or the brainstem, depending on their source in the body. Those arising below the head enter the spinal cord via a series of paired posterior nerve roots that extend all the way from the upper cervical levels of the cord down through thoracic, lumbar and sacral levels. Each pair of spinal nerves supplies a particular band of skin, known as a ►dermatome, and associated subcutaneous somatic or visceral structures. Inputs from the feet and legs enter at lumbo-sacral levels while those from the trunk, arms and hand enter at progressively higher levels of the spinal cord. Somatosensory information from craniofacial regions enters the brainstem directly via the fifth cranial nerve, known as the trigeminal nerve, and therefore mediates tactile and kinaesthetic sensations upon which we rely for the complex sensori-motor mechanisms involved in facial expression, speech and eating, together with pathophysiological ones associated with toothache and headache.

## Projection of Somatosensory Information Within the CNS

Upon entering the CNS, somatosensory nerve fibers may project, as a result of branching in their axons, into more than one target site at which they make synaptic connections with neurones of the CNS. In this way, incoming signals may be distributed in parallel for different processing purposes, supplying, first, intraspinal nerve networks for the reflex regulation of posture and movement; second, central structures, such as the cerebellum, for the regulation of voluntary movements; and third, ascending pathways, crucial for conscious

sensory and perceptual experience, that convey the information to somatosensory areas of the cerebral cortex, in particular, the primary and secondary somatosensory areas of cortex (SI and SII respectively) located in the postcentral gyrus and the Sylvian fissure of the human cerebral cortex. In each of these cortical areas, the somatic inputs are projected in a so-called ►somatotopic pattern that retains the spatial relations of the body parts, but with the area of representation of those body regions being proportional to the density of somatosensory innervation of the region.

## CNS Pathways for Ascending Projections of Somatosensory Information

There appear to be at least three major pathways within the spinal cord for conveying somatosensory information to higher centers of the brain for somatic sensation and perception. The first of these is the Dorsal Column (DC) system, made up, to a great extent, of Gr. I and II tactile and kinaesthetic sensory axons that project directly up the spinal dorsal columns before synapsing with neurones in the ►dorsal column nuclei (DCN) at the junction of the spinal cord and brainstem. Although inputs from the upper body, including the hand, project directly to the cuneate nucleus division of the DCN, those from the leg are conveyed over both direct and indirect paths to the gracile nucleus division of the DCN and a further division, known as nucleus Z, located just in front of the gracile nucleus [1]. Output from the DCN is projected across the midline of the brain and ascends via the medial lemniscus to the level of the ►thalamus, in particular, the ventralposterior (VP) nucleus, for further synaptic processing before the next stage of projection takes place to the SI and SII areas of the cerebral cortex.

The second principal ascending spinal cord pathway for ascending somatosensory information is the ►spinothalamic tract (STT) which arises from neurones of the spinal dorsal horn, and which, in contrast to the DCN, receives direct input from Gr. III and IV afferent nerve fibers responsible for signaling pain and thermal information [2]. However, there are also substantial inputs to this STT system from collateral branches of larger tactile afferent fibers. STT axons project from the dorsal horn across the midline of the spinal cord, ascending in the anterolateral columns of the cord, and project to a number of different nuclei of the thalamus.

The third of the major ascending somatosensory pathways at the spinal level is the ►spinocervical tract (SCT) system which, like the STT, arises from dorsal horn neurones [3]. However, the SCT axons project into the ipsilateral dorsolateral columns to the upper cervical cord where they synapse with neurones of the lateral cervical nucleus whose axons, in turn, project across the midline to ascend in association with the dorsal column-lemniscal pathway to the thalamus. The SCT system, whose input comes predominantly from tactile and nociceptive sources, is most prominent in carnivores, but is present in primates, including human beings [1,3].

Somatosensory information may also be conveyed to higher centers of the brain over less direct pathways, in particular, involving spino-reticular pathways (►spinoreticular tracts) whose functions are not entirely clear, but are probably not of major importance for the signaling of detailed discriminative information for sensory experience.

## Role of Ascending Somatosensory Pathways Based Upon Experimental Surgical or Clinical Evidence

Lesions, whether in experimental animals, or in human patients, do not provide an unequivocal account of the functional role of each of the major ascending somatosensory pathways, principally because of the difficulty of confining the disruption selectively to the intended ascending pathway. Nevertheless, observations of this type, coupled with a knowledge of the inputs reaching each of these systems, have identified the DC system as the principal ascending pathway for tactile and kinaesthetic information, while the STT appears to be the principal path for pain and thermal signaling. This knowledge has been utilized at times for the alleviation of intractable pain in patients, by means of surgical interruption of the spinal anterolateral tracts [2]. Inferences about the function of the SCT system are especially difficult to derive from lesion data as the dorsolateral columns of the cord contain a mixture of different fiber tracts.

## Function of Ascending Somatosensory Pathways Revealed by Electrophysiological Studies

Electrophysiological recordings from STT neurones, in particular, by Willis' group in Texas [2], have demonstrated that a great many are involved in nociceptive processing. However, some are responsive to gentle touch and may therefore contribute to the residual tactile sensory capacities that can survive if the DC pathway is damaged [4]. However, as the SCT is also involved in processing innocuous tactile information [3,5], it also remains a candidate for this role.

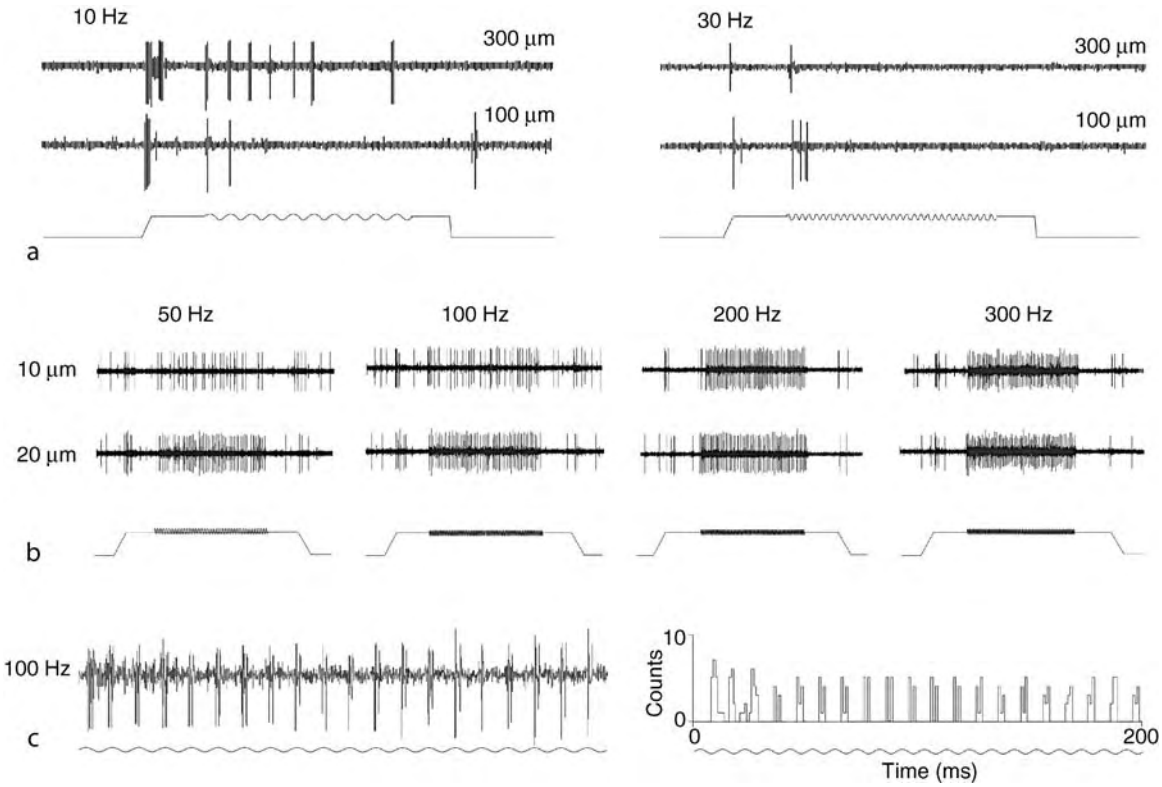
## Differential Representation of Different Body Regions Within Ascending Somatosensory Projection Pathways

Recent detailed analysis of the function of these ascending tactile systems has clarified to a great extent the differential capacities of these pathways and why such marked differences exist among them in their contributions to tactile sensibility. *First*, it is now

recognized that there are important differences in the regional representation of the body within the different ascending systems. For example, there is a restricted representation of glabrous skin inputs from the limb extremities in both the SCT [3] and STT systems [2], in contrast to the DC system which clearly serves as the pre-eminent pathway for tactile information from these crucial prehensile regions of the limb extremities [6–8]. However, for tactile inputs from the more proximal, hairy regions of skin on the limbs and trunk, there is a prominent representation within all three of these ascending pathways [2,3,5,8–10]. One might therefore ask whether there are differences in the signaling of tactile information from these sources over the three parallel pathways. In order to evaluate this issue in a quantitative way it has been necessary to employ reproducible forms of cutaneous stimulation, for the most part involving precise step indentations or sinusoidal vibrotactile stimuli delivered to the skin by means of feedback-controlled mechanical stimulators (Fig. 1).

## Quantitative Analysis of Tactile Coding Capacities for Neurones of the DC Ascending Somatosensory Pathway

In the case of the DC system, the individual neurones display a striking capacity to code reliably for the various parameters of tactile stimuli whether these are applied to the glabrous skin [6,7] or to hairy regions of skin [9,10] (Fig. 1b and c). These DCN neurons display sensitively graded stimulus-response relations as a function of changes in the intensity of both vibrotactile stimuli and static forms of skin indentation, and, in addition, retain a tightly phaselocked pattern of response to vibrotactile stimuli over a broad bandwidth of vibration frequencies extending up to ~400 Hz [6–8,10] (Fig. 1c). The high security of synaptic transmission between tactile afferent fibers and their DCN target neurons [7,10] enables the DCN neurons to retain, in their rates and patterns of impulse activity, a reliable signal of the intensity and periodicity parameters of vibrotactile perturbations encountered in either the glabrous or hairy skin.



**Somatosensory Projections to the Central Nervous System. Figure 1** Vibrotactile responsiveness of representative neurones of the SCT system (a) and DCN-lemniscal system (b and c). (a) the paired impulse traces show the limited responsiveness of a typical SCT neurone to 1s-long trains of skin vibration at 10 and 30 Hz, at the indicated amplitudes. (b) paired impulse traces show the response behavior of a DCN neurone to 1s trains of skin vibration at 50, 100, 200, and 300 Hz, at the two indicated amplitudes. (c) the expanded impulse trace (on the left hand side) and response histogram of accumulated impulse counts (on the right) show the precise phaselocking of DCN responses to the waveform of a 100 Hz train of skin vibration. (Figure modified from Fig. 1 in [9], and Figs. 5 and 9 in [8]).

### Quantitative Analysis of Tactile Coding Capacities for Neurones of Somatosensory Pathways Arising in the Spinal Dorsal Horn

Within the parallel ascending projection systems arising in the spinal dorsal horn, such as the spinocervical tract (SCT) pathway, there have also been reports of secure transmission between tactile afferent fibers and the post-synaptic neurons [3,5]. However, these studies of transmission characteristics were based upon very brief input signals. With recent study using vibration stimulus trains that generate a sustained input, it has become clear that SCT and other dorsal horn projection neurons are fundamentally limited in their capacity to sustain a response beyond the transient, onset component (Fig. 1a), in contrast to the neurones of the DCN [8,9]. Furthermore, as a consequence, the response levels of these dorsal horn neurones are very low and stimulus-response relations display only a very coarse and poorly-graded signal of vibrotactile stimulus intensity, in contrast to DCN neurones [8,9], demonstrating that their capacity to signal intensive changes in vibrotactile disturbances is vastly poorer than that of individual neurones of the DCN-lemniscal pathway. As spinal dorsal horn neurones are limited in their bandwidth of vibrotactile responsiveness to no more than 5–10 Hz [9] (Fig. 1a) there is a dramatic difference in functional properties, with DCN neurones displaying a vibrotactile bandwidth effectively 40 times broader than that of dorsal horn neurones in systems such as the SCT and STT [2,6,7–10] (Fig. 1). In addition, DCN neurones retain great precision in the temporal patterning of their impulse activity in a way that enables them to reliably signal information about the periodicity inherent in vibrotactile stimuli, at least up to frequencies of several hundred Hertz [6–8,10] (Fig. 1c). In contrast, even at very low vibration frequencies (up to 5–10 Hz) that SCT and other dorsal horn neurones can follow, the phaselocking of responses is poorer than in DCN neurones [9]. The limitations revealed by these quantitative measures suggest that ascending pathways from the dorsal horn, such as the SCT system, could, in contrast to the DCN system, serve as little more than coarse *event detectors* for tactile sensory experience [9].

### Evolutionary and Comparative Roles of Dorsal Horn and DC Tactile Projection Systems

The limited capacities of SCT and other dorsal horn neurones in tactile signaling raises the question of why these ascending systems should operate in parallel with the far more discriminative DC system. From an evolutionary perspective, one finds that both systems appear to be present in amphibians, reptiles and birds, as well as in mammals. However, it is unclear whether the tactile signaling capacities of the dorsal horn somatosensory projection systems and those of the DC-lemniscal systems have remained consistently different across generic and species borders. Perhaps the existence of both these major systems represents, at least in the tactile signaling capacities of the dorsal horn outflow projection system, a form of redundancy in the evolution of sensory systems. Alternatively, subtle differences in projection targets of each system at higher levels of the nervous system may confer some differential and unique role in tactile sensibility upon the two systems.

# Somatosensory Reorganization

Ben Godde
Jacobs Center on Lifelong Learning and Institutional Development, Jacobs University Bremen, Bremen, Germany

## Synonyms

Somatosensory representational plasticity; somatosensory remodelling

## Definition

Tactile inputs from the body surface are sequentially processed at various subcortical stages (spinal cord,

brain stem, thalamus) before this information reaches the primary somatosensory cortex (SI) and the following other cortical areas.

Each of these processing levels is characterized by a topographic representation of their respective sensory epithelial surfaces. The result is a somatotopic map of the body surface (called ►homunculus), where neighbouring neurons respond to tactile stimuli at neighbouring skin sites. The size of the representations of different body parts within these maps is related to their behavioural relevance, the receptor density, and the amount of tactile sensations within these body parts. Consequently, certain body parts, like the tongue and single fingers, are over represented relative to much larger body parts like the abdomen.

However, cortical representations are not fixed but continuously modified throughout life in response to use, learning, skill acquisition, or lesions. Thus, somatosensory reorganization describes lasting changes in the layout of topographic representations of the body surface, allowing developmental and adult adaptation to individual and dynamically changing sensory input patterns that are not specified by genetic constraints.

Although somatosensory reorganization is best described for the ►primary somatosensory cortex (SI), which is located in the postcentral gyrus, it occurs at all afferent subcortical levels and is not restricted to cortical areas.

## Characteristics

### Higher Level Structures

The classical experiments in monkey somatosensory cortex, performed by Merzenich and colleagues, demonstrated that immediately after peripheral nerve section or digit amputation a large portion of the respective cortical representation was unresponsive to any stimulation, but over the course of a few weeks, this unresponsive area came to be excited by inputs from neighbouring skin surfaces. The recent development of ►non-invasive imaging techniques made it possible to perform similar studies in humans. These studies consistently revealed that neurons in the SI hand or forelimb representation, having lost their inputs due to amputation, became reactivated by inputs from the stump or the face [1].

Other experiments demonstrated that the somatosensory cortex could dynamically allocate areas in a use-dependent manner. In monkeys, extensive training in a tactile discrimination task resulted in an expansion of the respective cortical representation of the trained skin surface [2]. In professional string players, the cortical representation of the left string-fingers are substantially enlarged as compared to the fingers of the right hand. Similarly, blind Braille readers have increased representations of their reading fingers, which are accompanied by superior tactile spatial acuity with these fingers [3].

Moreover, it is also possible to induce lasting changes in sensory performance by passive induction of cortical reorganization without conscious attention and feedback. For example, in humans, a few hours of synchronous tactile stimulation of separated ►receptive fields on single fingers also leads to an increase of the related representational areas and their overlap in primary somatosensory cortex, paralleled by improvement in spatial two-point discrimination [4]. However, the improvement is completely reversible within hours after termination of the stimulation protocol. Therefore, stability of the reorganization is closely related to the time course of induction, and original representations reoccur after exposure to the original sensory input statistics.

### Lower Level Components

Topographic changes as well as changes in single neuron response characteristics, synaptic properties, and biochemical processes can be found months or years after peripheral deafferentiation at all subcortical afferent stages [1]. However, it seems to be most pronounced at the somatosensory cortex. One reason for that might be the system of divergent and convergent afferents, leading to increasing ►magnification factors from the periphery to the cortex. Thus, small changes at the brain stem level would induce much larger changes in the cortex. However, the extent of cortical reorganization goes far beyond the boundaries of thalamocortical afferents favouring far-reaching intracortical horizontal connections in being the substrate for these effects. Moreover, tactile training experiments in monkeys revealed cortical receptive field changes, which were not paralleled by similar changes in the thalamus [1]. Using microstimulation to induce short-term plasticity in the SI cortex and thalamus, without involving more peripheral levels of sensory processing could demonstrate that reorganization in the thalamus can be induced by stimulating the cortex, but in contrast, no thalamocortical transfer was found. What is more, the largest map changes were observed in the cortex after ►intracortical microstimulation. These results direct to the cortex as main substrate for somatosensory reorganization.

### Higher Level Processes

►Hebbian-based learning rules relate to the detection of temporally correlated inputs and are often used to explain the formation and plasticity of representational maps. In the case of topographic representations of sensory epithelia, peripheral inputs that fire in close temporal proximity are more likely to represent neighbouring points on the peripheral sensory sheets.

Animal and human data have always pointed to the behavioural significance of input timing [1]. In monkeys, artificially induced ►syndactyly, aimed to

enhance indirectly the degree of synchronicity of inputs across two merged fingers, led to a fusion of the respective cortical representations. In human subjects, after surgical reversal of congenital syndactyly, and therefore reduction in synchronous tactile inputs, cortical representations of the respective fingers that had been strongly overlapping before surgery, became rapidly separated.

Even enhancement of synchronous usage of different fingers in monkeys during training in a tactile discrimination task, resulted in an integration of the representations of those parts of the fingers that received temporally coincident inputs [1]. In humans, examination of the cortical hand representations of blind Braille readers who use three fingers of each hand in synchrony for reading [3], revealed a distortion of the normal cortical topography due to an increase of overlap of the respective finger representations.

On the neuronal level, in freely moving rats, clipping and pairing whiskers for several days led to increased neuronal responses to the paired surround receptive field whiskers which had experienced temporally correlated activity, and decreased responses to the clipped whiskers in which activity was temporally de-correlated to the neuron's principle whisker [5].

More recently, imaging experiments in humans [4] revealed consistent effects of synchronous coactivation characterized by an enlargement of the respective somatosensory cortical representations and their overlap. On the other hand, segregation of cortical representations could be induced by asynchronous coactivation [6].

Interestingly, coactivation-induced somatosensory reorganization was accompanied by alterations in perceptual capacities: after synchronous coactivation, two-point discrimination performance was improved, while frequency discrimination and localization became impaired. On the other hand, segregation of cortical representations induced by asynchronous coactivation was paralleled by an impairment of two-point discrimination, but an improvement of localization abilities on the stimulated skin sites.

## Lower Level Processes

Reorganization can be observed on different time scales from minutes and hours to days, weeks, months, and even years, indicating different mechanisms being involved. After extensive remodelling of sensory afferents and cortical representational areas during maturation, only very few changes in the anatomical connections can be observed in the adult individual. Local growth of axons and dendrites, as found months or years after severe central or peripheral lesions, cover only very short distances (several micrometers) and cannot account for far reaching map reorganization of several millimetres to centimetres. Possible other mechanisms are the unmasking of previous silent, subthreshold, or actively inhibited synaptic connections. Increased numbers of $GABA_A$-receptors after chronic injury might be interpreted as response to immediately decreasing levels of the inhibitory neurotransmitter ►GABA, leading to disinhibition and hyperexcitability extending over several millimetres within minutes after deafferentiation [1].

Changes within the existing network based on cellular and synaptic mechanisms may play a crucial role, also underlying short-term somatosensory cortical reorganization after training or extensive tactile stimulation. This might be alterations in synaptic strengths and efficacy, changes in the balance of excitatory and inhibitory intracortical connections, as well as structural processes resulting in the formation of new synapses and an increase in spine density. In a Hebbian sense, the importance of stimulus timing and the amount of synchronicity of different stimuli point to the relevance of spike timing-dependent processes like ►long-term potentiation (LTP) and ►long-term depression (LTD) [7]. This view is supported by the finding that input-dependent plasticity can be facilitated or blocked by either ►NMDA-agonists or antagonists, respectively [7].

## Process Regulation

Cortical plasticity allows adaptation to changing sensory environments and demands. However, sensory reorganization influences perception and may interfere with the need for stable percepts of the outer world. Thus, it is important that changes in the amount of sensory inputs causing reorganization are behaviourally relevant. Interestingly, Recanzone and co-workers found changes in the somatosensory hand representation of monkeys after extensive tactile finger stimulation only when the monkey had to attend the stimuli to get a reward but not with passive stimulation [2]. The ►nucleus basalis (NB), a subcortical structure receiving inputs from limbic and paralimbic regions and sending excitatory projections to the entire brain, seems to play a key role in estimating the behavioural relevance of particular stimuli and the control of selective attention [8]. Nevertheless, as shown above, cortical plasticity is controlled not only by top-down directed processes like attention or reinforcement, but somatosensory reorganization can also be induced in a bottom-up fashion purely by the statistics of the sensory inputs. The application of tactile stimuli with high frequency for several hours, resulting in a total number of stimuli that is much larger than that used in most training experiments, might yield an intrinsic behavioural significance of these stimuli relative to others.

## Function

Functional recovery after damage seems to be one major role of somatosensory reorganization. However,

since processes of axonal and dendritic sprouting, as occurring after deafferentiation, are very slow and would not have direct evolutionary advantages, the main role of somatosensory reorganization might be founded on its strong relationship to tactile learning processes. Further, whereas physical growth during maturation establishes the gross layout of the somatosensory map, adult plasticity allows the ongoing adjustment of cortical information processing to changing demands.

### Pathology

Somatosensory reorganization not only takes part in tactile learning or rehabilitation after lesions. It may also be related to maladaptive phenomena like ►phantom limb pain (PLP) or ►focal dystonia [3].

In upper arm amputees, the neighbouring representations of the face and shoulder invade the representational area of the lost arm. A significant relationship was found between the amount of reorganization in the primary somatosensory cortex, and the occurrence of phantom sensations and even phantom limb pain that were perceived to be emanating from the now missing extremity.

Focal dystonia – a motor disorder often leading to loss of motor control of one or more fingers – is frequently observed in musicians like pianists or string players who extensively do repetitive, synchronous movements of their fingers. Motor impairment is associated with somatosensory cortical reorganization: Assumable as a consequence of synchronous inputs from multiple skin sites at unusually high rates, topographic order is disturbed and cortical representations of the fingers are more overlapping than in controls.

### Therapy

One kind of therapy for patients suffering from PLP as well as from focal dystonia is to reverse cortical reorganization. Huse and colleagues treated upper arm amputees suffering from PLP with asynchronous tactile stimulation of the stump and the face for several months, and found a decrease in PLP accompanied by a disintegration of the face and stump representations [9]. Tactile discrimination training had a similarly beneficial effect on both the cortical topography and PLP [10].

Whereas some researchers also suggested sensory discrimination training for the treatment of patients suffering from focal dystonia, Elbert and co-workers used a different approach: they fixed single fingers with a splint so that the other fingers could be moved independently. After both kinds of therapy, a normalization of the map layout and a decrease of dystonic symptoms occurred [3].

# Song Control System

## Definition

An interconnected chain of brain areas that controls song production and sensory-motor learning.

►Song Learning of Songbirds

# Song Learning

## Definition

Bird calls are, in general, acquired by inheritance. However, two orders of birds are able to learn vocalizations: parrots and passerines. These birds inherit only a very general motor program. They modify this program in two steps: first they hear their father singing. They store this information in a template. When they start to sing by themselves they compare their own singing with the stored template.

# Song Learning of Songbirds

Manfred Gahr
Department of Behavioural Neurobiology, Max Planck Institute for Ornithology, Germany

## Definition

Songs of songbirds (order Passeriformes, suborder oscines) are sequences of frequency-amplitude-modulated sounds and intervening silent intervals. First, songs can be characterized by the phonology of the sounds, which are named elements. Second, songs can be characterized by its syntax, the rules with which elements and silent intervals are combined to form longer temporal sequences. For example, in some species such as the great tit the songs of a male can be classified into distinct song types, characterized by unique sequences of elements. In other species such as the sedge warbler songs consist of sequences of randomly assembled elements, rarely repeated in the same order. Intra- and interspecies differences in song phonology and syntax are in part due to auditory-motor learning, i.e., songs are cultural trades much like human language.

## Characteristics

### Song Learning: Consideration from Behavioral Experiments

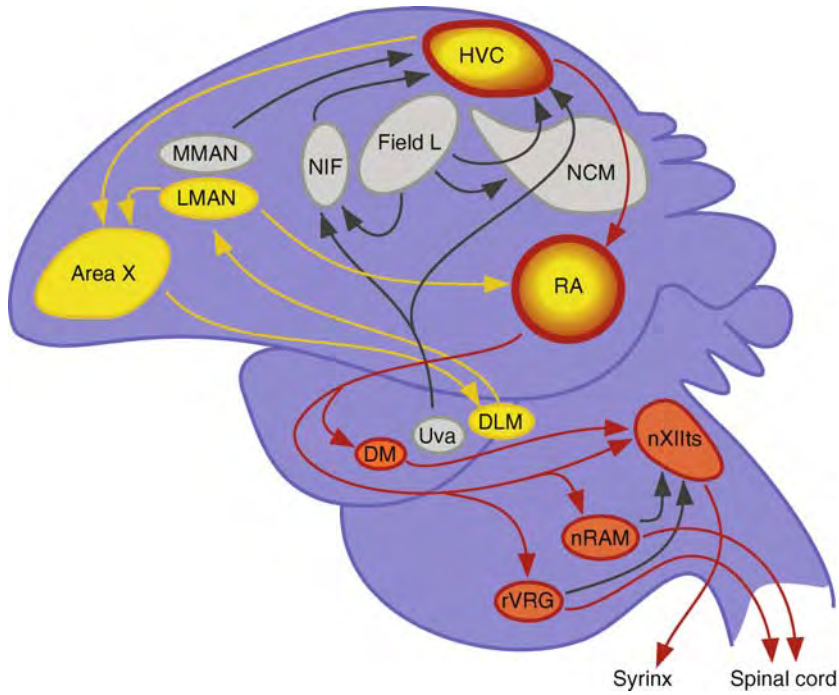
During development young birds first listen, guided by innate auditory preferences for conspecific song, and memorize the song of an adult tutor during the ►sensory phase. The overlapping or subsequent sensory-motor phase starts with the onset of singing at a species typical age. In the sensory-motor phase, the juveniles first produce immature vocalizations that they gradually refine and approach towards the memorized tutor song. Konishi [1] developed the concept of an acquired auditory ►template or memory as the basis of song learning in songbirds. He showed that deafening of non-learning species (e.g., chicken) shortly after hatching had no effect on their vocal development. In contrast, deafening in songbirds such as the white-crowned sparrow disturbed song development dramatically depending on the age at which the surgery took place. Males that were operated upon before onset of singing developed highly abnormal songs, while those deafened after establishing of a stable (crystallized) song pattern maintained their songs. This pioneering and subsequent works [1,2,3] suggest that: (i) innate motor programs are only sufficient for the development of parts of the song, (ii) a combination of innate and acquired auditory templates guides song development, and (iii) self-generated auditory feedback is essential for the conversion of innate and acquired templates into songs. Although the timing and the amount of learning from external models might vary considerably between species, vocal learning appears a general feature of songbirds while the song features (e.g., the phonology, the syntax) to be learned are species-typical.

These behavioral studies suggest neural circuits for the following processes [3–5]: (i) the generation of the motor commands that give rise to the songs, (ii) the sensory learning of sounds, and (iii) the comparison of self-generated sounds and auditory memories and subsequent error correction mechanisms during sensory-motor learning. Despite the large diversity of song pattern among songbirds, the neurobiological mechanisms of vocal learning detailed below are derived, mainly for technical reasons, from a few species, primarily the zebra finch.

### The Song Control System Produces Learned Vocalization

In songbirds, neural vocal control is achieved by a chain of anatomically discrete, interconnected brain areas in the fore-, mid-, and hind-brain [6] (Fig. 1).

These areas can be subdivided in the descending motor pathway (HVC, RA, nXIIts) and the anterior forebrain pathway (AFP). The AFP is a forebrain-basal-ganglia loop that connects HVC with RA via three intervening areas (LMAN, DLM, Area X). Besides



**Song Learning of Songbirds. Figure 1** A schematic parasagittal view of the song system of songbirds indicating the major projections (*arrows*). The descending motor control pathway (*red*) includes the HVC, RA and syringeal motonucleus nXIIts as well as respiratory premotor areas. HVC and RA are further the beginning, respectively, and the end of the anterior forebrain pathway (▶AFP) (including Area X, LMAN, DLM) (*yellow*) that is likely involved in sensory-motor learning. Thus, HVC and RA (*red* + *yellow*) might be involved in motor control and sensory-motor learning. Sensory input (*grey*) comes via the UVA (somatosensory) and via the Field-L complex and NIF (auditory) into the HVC. Song perceptual learning might first take place in the Field-L complex and NCM. The role of MMAN is not studied in detail. Abbreviations: *DLM*, nucleus dorsolateralis thalamis, pars medialis; *DM*, nucleus dorsomedialis; *HVC*, Nucleus HVC of the nidopallium; *LMAN*, Lateral magnocellular nucleus of anterior nidopallium; *L*, Field L; *MMAN*, Medial magnocellular nucleus of anterior nidopallium; *NCM*, Caudal medial nidopallium; *NIF*, Nucleus interface of the nidopallium; *nRAM*, nucleus retroambigualis; *nXIIts*, pars tracheosyringealis of hypoglossal nucleus; *RA*, Robust nucleus of arcopallium; *rVRG*, rostroventral respiratory group; *UVA*, nucleus uvaeformis.

the AFP, there are further recursive loops between song areas and sensory input comes from the somatosensory and the auditory system. Although the flow of auditory information into the vocal areas is not entirely worked out, the avian primary auditory cortex (Field L-complex) appears to connect with NIF and HVC (Fig. 1) [4,6].

The production of learned vocalizations correlates with the differentiation of forebrain vocal control areas [6] (Fig. 1). These forebrain areas are rudimentary in females of those songbird species such as the zebra finch, in which females produce only innate vocalizations (calls). In suboscine passerines such as the tyrannid flycatchers and in those non-passerine species that do not learn its vocalizations, these forebrain areas are missing entirely. Interestingly, in parrots (order Psittaciformes) and hummingbirds (family Trochilidae, order Apodiformes), the other two avian taxa with vocal learning, the vocal control system too comprises multiple forebrain areas. Since the three groups of song learning birds (songbirds, parrots and hummingbirds) are not closely related, vocal learning evolved independently at least three times among birds.

### *The Descending Motor Pathway Generates the Motor Commands of Song*

Singing involves inspiratory airflow (silent intervals) and expiratory airflow, during which the frequency-modulated sounds are produced involving activity of the syrinx and of suprasyringeal structures such as the trachea, tongue, and beak. The descending motor pathway consists of the HVC, RA and hindbrain areas that innervate the syringeal muscles (nXIIts) and expiratory and inspiratory motoneurons of the spinal cord (Fig. 1) [6]. This pathway generates the motor commands of the song with a hierarchical organization. The premotor activity of HVC correlates with larger vocal sequences and that of RA with the motoric details.

### *Is the Template Memorized in the Auditory or the Song System?*

Despite the comparative evidence that implicates forebrain areas in the production of learned vocalizations, the location of the template, probably a distributed function, is unclear. Since auditory learning is a general characteristic of birds and not linked to the production of learned vocalizations, template formation might occur in the auditory system and/or in the ►song control system. The best experimental attempt to involve the song system, in particular the AFP, in sensory learning has been to reversibly inactivate the LMAN by infusing a NMDA-receptor antagonist during tutoring periods but not during periods of active singing of young zebra finches. Although song learning is somewhat reduced in these males, template formation was not prevented [4,5]. A recent study employing markers of neuronal activity suggests that some auditory responses in the caudomedial nidopallium reflect the song learning experience of individual male zebra finches (Fig. 1). This finding and the lack of song control neurons that are tuned to the ►tutor song before the onset of sensory-motor learning indicates that sensory learning of song occurs first in the auditory cortex rather than in the song system [4,5].

### *Where does Sensory-Motor Learning Take Place?*

During sensory-motor learning, motor circuits need to be gradually shaped by singing-based feedback in order to transform an auditory map into a muscle map. The electrophysiological finding of auditory neurons that become tuned to features of the tutor song, or of the ►birds-own-song,or of both in vocal areas gives anatomical grounds for sensory-motor learning in the song system [4,5]. Such neurons are found in the descending motor pathway (HVC, RA) and in the AFP. Lesion experiments of the AFP suggest that the integrity of this loop is necessary for sensory-motor learning. Although lesions do not locate function and AFP-lesions affect the differentiation of the descending motor pathway, such lesions inhibit the development of aberrant songs that can be induced through certain experimental conditions [5]. This suggests the AFP as part of a comparator that generates a correction signal. Another candidate for sensory-motor learning is the HVC [4]. The auditory properties of HVC (neurons tuned to birds-own-song and tutor song), the separate projections of HVC into the descending motor pathway and into the AFP, and the properties of the local HVC-circuitry put this area in a central position for sensory-motor integration. Thus, we need to consider that sensory-motor learning is a distributed function with various tasks located in various brain areas or neural assemblies.

## Hormone-Dependent Differentiation of the Song Control System and Song Learning

The evolution of forebrain song control areas in songbirds is paralleled by the evolution of estrogen (only HVC) and androgen receptor (all song areas) expression [7,8]. During ontogeny, expression of these hormone receptors is one of first neurochemical features of song areas to emerge, i.e., the song system is sensitive to gonadal hormones during periods of sensory and sensory-motor learning.

Androgens and estrogens specify the sexual differentiation of brain and behavior upon brain-intrinsic genetic mechanisms. In this process, the hormones first specify the global development of the song control system, which provides the crude substrate for song development. Some of these hormone-sensitive global anatomical features, in particular the size of the vocal areas and its neuron numbers, are proposed to relate to the amount of song motor memories, i.e., to the amount of ►sensory motor learning [7,8]. However, since the overt motor memories do not in all cases represent the total learned repertoire such correlations are controversial. For example, adult male canaries sing some of their song elements in certain seasons while others are produced year-round. Similarly, the selective production of song units after initial overproduction due to socio-sexual interactions, coined action-based-learning by Marler [2], does not mean that unused motor memories are deleted.

Next to the overall differentiation of a functional song system, androgens and estrogens modify many neural phenotypes (synapse density, synaptic proteins, neurotrophins, neurotransmitter receptors) that are potentially involved in the formation of neural circuits during song learning. In relation, circumstantial evidence suggests hormonal modification of sensory-motor learning: High levels of testosterone induces premature crystallization, i.e., ends sensory-motor learning, while depletion of testosterone delays the closure of sensory-motor learning. Similarly, seasonal periods of sensory-motor learning in adult canaries coincide somewhat with periods of low testosterone production. These findings need, however, to consider that testosterone increases singing activity. Thus, it remains to be seen if sex hormones affect the production of motor commands, or auditory properties or the comparison between birds-own-song and the song template. The presence of further types of hormone receptors (e.g., melatonin) in the song system as well as the expression of receptors of the ascending monoaminergic systems (e.g., dopamine receptors) suggest that song learning is modulated by a number of signaling systems that reflect environmental conditions. Such modulatory action is to be expected since learned songs are under sexual selection pressure [7,8].

## Sensory and Sensory-Motor Learning at the Circuit Level

After the onset of singing, i.e., during the period of sensory-motor learning, neurons that are tuned to birds-own-song or to the tutor song or to both emerge in various parts of the song control system. Thus, it is likely that the template is first formed outside the song control system and subsequently shifted to (multiple) sites of the vocal system during the sensory-motor period of song learning, a process reminiscent of memory translocation in visual imprinting. Syringeal deafferentiation that hampers the birds to gradually copy the tutor model indicates that the neural representation of the tutor song in vocal areas requires the process of sensory-motor learning [5].

The transformation of the auditory template into a motor representation in the song system requires comparison. The comparator circuit would evaluate auditory feedback of the birds-own-song in the context of the template. Differences between the actual song and the model would result in an error signal that modifies the song control system so that subsequent song better matches the template. One scenario is that premotor-linked inhibition and auditory-evoked excitation of Area X-projecting HVC neurons might constitute an estimate of the error signal. The inhibition is through inhibitory HVC interneurons, which are activated by RA-projecting HVC neurons. In relation, Area X-projecting HVC neurons can respond to various sounds including birds-own-song, but are silent during the singing of adult males, i.e., these neurons might only be active in the case of non-matching auditory feedback but otherwise cancel out auditory feedback. Such error estimates could also be produced in the AFP, since the AFP also contains neurons tuned to the birds-own song and/or the tutor song and is active during singing. The song related activity of the AFP might constitute an efference copy of premotor activity, which results (as detailed above) from the patterned inhibition of X-projecting HVC neurons during singing. This inhibition of the input to Area X could activate LMAN circuits through disinhibition of a thalamic relay (DLM), similar to mammalian cortex-basal-ganglia circuitry. Although there is much progress in understanding the properties of the vocal circuitry in relation to song learning, the central problem of how an error signal modifies the motor network is unsolved [4,5]. However, since the AFP and the HVC excite the same RA neurons with a time difference of about 60 msec, delayed excitation could be used as a reinforcement signal to the descending motor pathway. Lastly, since song areas of sleeping animals show discharge patterns that are remarkably similar to patterns generated during singing, off-line rehearsal might play a role in sensory-motor learning or maintenance of motor memories [3–5]. This would solve some problems of the above scenarios resulting from fast sound production.

## Cellular Mechanisms of Sensory and Sensory-Motor Learning

In general, we don't need to expect any "songbird-special" cellular mechanisms of learning, seen in the similarities of song learning to other types of sensory-motor learning [9]. Thus, the songbird-specific feature is grounded in the anatomy and connectivity of the vocal system itself. One speciality of song learning might, however, be seen in the ample recruitment of new neurons into certain song areas (see below) [10].

Changes of the vocal system during sensory-motor learning have been best studied in the AFP. Refinements of topographic projections between LMAN and RA, elimination of synaptic contacts in LMAN, faster NMDA currents at the DLM to LMAN synapse, and loss of activity-dependent synaptic potentiation and depression in LMAN have been reported. It is difficult to establish if such regression and refinement underlie sensory-motor learning, since the song system still undergoes maturation during the sensory-motor period that is independent of learning. To separate maturation from learning related events, zebra finches are raised under special conditions, e.g., without tutor. Although this approach indicates that certain developmental observations such as synapse elimination in LMAN are linked to song learning, the findings might rather reflect the social isolation than the lack of learning [9].

An unusual type of mechanism involved in sensory-motor learning might be the recruitment of new neurons during both development and adulthood [10]. Various factors including testosterone, auditory input, or singing are thought to affect the addition of new neurons in HVC. Although, fascinatingly, these new neurons are integrated into neural circuits, clear evidence that they are required for song learning is missing. In female canaries, the number of new neurons can be increased by testosterone treatment, which is otherwise known to induce song crystallization. If the new neurons indeed play a role in this behavioral process needs to be seen since neuron recruitment is subsequent to testosterone-induced angiogenesis in HVC. The latter certainly has a number of consequences next to facilitating neuronal recruitment that could underlie song development [10].

## Function of Song Learning

Song learning might facilitate the adjustment of vocal development to local ecological demands or socio-sexual experiences. However, evolutionary related groups of birds (the ►suboscines) are successful without the evolution of song learning. Among ►songbirds, song learning is an additional criterion upon which sexual selection works, seen in the function of learned song in the realm of reproduction (mate choice, territorial defence). Mate choice based on singing not only considers the actual physiology such as high levels

of sex hormones of the advertiser, but also considers the life history of the singer, i.e., its physiological conditions during song learning periods [7].

## Spasticity

### Definition

Spasticity results from damage to motor nerve fiber systems descending from supraspinal to brainstem and spinal structures. However, lesions limited to the pyramidal tract (e.g., the pyramids in the medullar oblongata) entail a Babinski reflex and paresis (i.e., temporary weakness and loss of dexterity), but neither spastic dystonia nor permanent weakness. The pathophysiology is complicated, therefore, also due to the fact that (i) depending on damage site, there are several clinical syndromes with potentially different pathogenic mechanisms (cerebral spasticity vs. spinal spasticity, which can be symmetric or asymmetric), (ii) descending fibers and afferent sensory fibers show a complex convergence onto motoneurons and interneurons in brainstem and spinal cord. In varying combinations, symptoms include *positive symptoms* such as *hypertonia* (velocity-dependent resistance of skeletal muscle to stretch); *hyperreflexia* (enhanced tendon reflexes and clonus); *enhanced cutaneous reflexes*; *contractures*; *autonomic hyperreflexia*; and *negative symptoms* including *paresis*; *synkinesia*; *lack of dexterity and enhanced fatiguability. Hypertonia* probably has several intertwined causes. First, muscle compliance may change due to changes in collagen tissue, tendons and joint capsules, thus entailing a higher passive stiffness. Second, the histochemistry and morphometry of spastic muscle may change. *Hyperreflexia:* The tendon reflexes and the fast dynamic reflex responses to maintained muscle stretches, as well as the H-reflex (Hoffmann reflex), are enhanced. *Clonus* is thought to result from increased stretch reflex excitability and consequent tendency towards oscillation. The *enhanced tendon jerk* can probably not be accounted for by augmented γ-motoneuron activity. α-Motoneurons might become hyperexcitable due to changes in biophysical properties or synaptic inputs. Recurrent inhibition has been found changed in spastic patients, but in different ways, partially dependent on disease state. Reciprocal inhibition is often disrupted and mostly reduced in spastic patients, which might disrupt the orderly alternation of agonist/antagonist activity during rhythmic movements such as locomotion. Changes in reflex pathways from Golgi tendon organs could alter reflex excitability. The presynaptic inhibition of group Ia fibers from muscle spindles appears reduced in amyotrophic lateral sclerosis, multiple sclerosis and patients with spinal cord injury. Spinal *reorganization*: Short- to long-term plastic changes may re-organize spinal operations so as to increase the cord's excitability. Mechanisms might include the unmasking of existing but hitherto ineffective synapses, collateral sprouting, reductions in pre- and postsynaptic inhibition, and changes in postsynaptic sensitivity ("denervation hypersensitivity"). *Flexor spasms:* Flexor spasms are another facultative sign that occurs especially in spinal cord-injured patients. They probably represent the augmented form of normal flexion reflexes as they are used during locomotion and the withdrawal reflex. They may be elicited by excitation of small-diameter, mechanically sensitive muscle afferents (maybe including group II muscle spindle afferents), joint and cutaneous afferents. In cerebral spasticity, short-latency cutaneous reflexes may be suppressed, while spinal spasticity often goes along with a particularly prominent enhancement of the

long-latency flexor withdrawal reflexes, with a reduced threshold, prolonged duration and irradiation. *Spastic Gait:* The traditional concept of spastic gait disorders envisages exaggerated reflexes as the primary change underlying spastic movement disorders and thus promotes anti-spastic drugs as means to reduce the reflex activity. The new concept emphasizes the loss of functionally more important long-latency reflexes (leading to reduced muscle activity during movements despite increased short-latency stretch reflexes) and changes in non-neural factors that compensate for the loss of supraspinal drive, which would argue against anti-spastic drugs in mobile patients. In children with early supraspinal motor lesions, e.g., in *cerebral palsy* children, the usual maturation of gait does not take place so that the co-activation of antagonist leg muscles persists. In adults with spasticity acquired after the age of four years, the reciprocal pattern is developed, but temporal overlap of antagonist muscle activities is pronounced. Functionally important polysynaptic and long-latency reflexes are diminished, leading to reduced proprioceptive contributions to the leg muscle activations, which are less well modulated and less well adapted to the ground conditions. One problem in making spastic patients walk more easily is to overcome the destructive flexor spasms. Modern treatment strategies rest on combinations of physiotherapy, locomotor training, electrical stimulation (e.g. of spinal cord and peripheral afferents), and drug therapy (e.g., with $\alpha_2$-agonist clonidine) to support rhythmic spinal activity generation, provided by spinal central pattern generators (CPGs), while attempts at repairing the spinal lesions are in the experimental phase.

## Definition

The representation of location, orientation, and action with respect to the self, others, objects, or the environment. Spatial cognition may be studied in the context of sensory information, motor control, frames of reference, scale, maps, imagery, attention, language, and memory. Approaches include developmental, neural, cognitive, and cognitive neuroscience investigations of both humans and nonhuman animals. The study of spatial cognition crosses disciplines of psychology, ethology, geography, information science, and computer science.

## Characteristics

### Multiple Sources of Spatial Information and Integration

There are multiple sources of information for spatial orientation. External, or allothetic, information includes visual, auditory, olfactory, or tactile cues for position. Internal, or idiothetic, information includes proprioceptive and vestibular sources that change as a result of self-movement. Research has addressed the relative contribution and integration of sensory information for

the perception of self-motion and spatial localization within one's environment. Nonhuman animals have been shown to integrate allothetic and idiothetic cues in a flexible manner, using both route-based and landmark-based references. For example, given an environment with visual, olfactory, and internal motion cues, rodents will rely first on vision, next on olfaction, and third on motion-based path integration (see below). However, given unreliable or the lack of visual and olfactory cues, the animals will navigate through path integration alone [1]. Humans have been shown to dynamically calibrate perceptual and motor information. There is consistent covariation between action and perception as an observer navigates through space. For example, when a person walks along a straight path (translation), visual perspective translates as well. Rieser and colleagues [2] demonstrated that changing this perception-action coupling will lead to systematic recalibration of representation-action coupling, or how one dynamically updates spatial orientation without vision.

## Action, Path Integration, and Spatial Updating

A common goal for all organisms is to act in their environment, making action critical to defining spatial cognition. Moving in space provides information about spatial location through efferent feedback of the motor system, afferent proprioceptive cues linked to limb movement, and vestibular cues of linear acceleration and rotation. ►Spatial updating is the process of updating representations of the locations in the environment with respect to the self and others. It potentially involves two broad sources of information. The first is path integration, in which velocity- or acceleration-based self-motion information from the visual, vestibular, and proprioceptive systems is used to update one's spatial displacement. The second is the recognition and use of landmarks within the environment. Path integration is typically tested in both human and nonhuman animals with a return-to-origin or path completion task in which the observer follows an outbound path and then travels back (or points or turns) to the origin of the path without the use of positional landmarks. Although organisms such as the desert ant and rodents are quite skilled at path integration, it has been suggested that humans are imprecise when navigating by path integration alone. In contrast, tasks referred to as visually directed actions, in which an observer typically walks without vision to a previously viewed target, are performed on average, quite accurately up to approximately 20 m.

It has also been proposed that transient action-based responses (necessarily egocentric, see next characteristic) involve a distinct representation of space as opposed to longer-lasting spatial representations that use other spatial frames of reference (►spatial frame of reference) [3]. This "two visual systems approach" suggests that spatial characteristics may be processed independently depending on the goal of the observer, defining a long-term conscious system for "what" or identification versus an immediate unconscious system for "how" or guiding actions. However, other research supports the claim that some visually directed actions and cognitive response measures are informed by the same spatial representations.

## Frames of Reference and Structure of Space

Spatial frames of reference are a means of representing spatial locations relative to some spatial framework. Generally, frames of reference are defined relative to the viewer, *egocentric*, or relative to something other than the viewer, *allocentric*. More specifically, the egocentric frame of reference involves a ►first person perspective and may be subdivided into spatial relations to body-parts, such as oculocentric, headcentric, and bodycentric, specifying spatial locations relative to the eye, head, and body, respectively. Allocentric representations include the object-relative frame which defines space relative to two or more objects and the environmental frame which defines space relative to cardinal directions of north, south, east, and west. The gravitational frame of reference specifies up and down relative to gravity.

Regions of space defined relative to the observer have been characterized in the context of the utility of information for space perception and action-relevant goals. In the context of space perception, Cutting and Vishton [4] defined *personal space*, which extends slightly beyond an arm's reach from the observer, *action space*, within which we can rapidly locomote and extending from the boundaries of personal space to approximately 30 m from the observer, and *vista space* beyond 30 m from the observer. In a somewhat different context of how people think about space, Tversky [5] categorized *space of the body* as the understanding of positions and relations of body-parts, *space around the body* as the space within which one can immediately see and reach to things, and *space of navigation* as space that is explored and too large to see all at once.

## Imagery and Spatial Transformations

The human ability to imagine spatial transformations is important for accomplishing many daily goals such as action planning, object recognition, spatial navigation, and problem solving. Much of the early work on ►spatial imagery and mental rotation focused on the human ability to make a decision about the congruency of one rotated object with respect to another. Shepard

and Metzler [6] found that the time required to make a decision about the similarity of the structure of two rotated objects was a function of the angular disparity between the two objects. This monotonic rotation function was upheld for rotations in the picture plane and in depth. Much mental rotation work has focused on 2D or 3D objects but other related research has involved imagined transformations of hands and bodies using both cognitive and neuroimaging approaches.

Mental transformations of bodies and body-parts may serve to facilitate planning of actions, predicting or understanding other's behavior, or other complex tasks of spatial reasoning. Parsons' [7] work with imagined spatial transformations of biological objects such as hands, feet, and bodies indicated that the response time to make a left-right decision about the hands or feet (given no explicit instructions on a strategy to use) was highly correlated with the time required to imagine a limb movement (without the left-right decision). Both types of judgments were also highly correlated with participant's ratings of the awkwardness of moving into a given limb orientation. This work relates to the concept of body schema, knowledge of the spatial relations among the parts of the body that can be used to represent oneself and others, as well as ►self perception.

A related paradigm has compared object- and perspective-based transformations in the context of spatially updating external objects. Several studies have directly compared both cognitive and neural mechanisms involved in mental transformations of objects versus egocentric (or viewer) perspective [8]. When participants are given a spatial updating task to name an object in a given location after a specified imagined transformation, a large systematic performance advantage has been found for viewer versus object/array transformations.

## Spatial Attention

►Spatial attention is the process of selecting stimuli on the basis of spatial location. Often this process relies on visual stimuli and is referred to as ►visuospatial attention. Items in the selected region then receive further cognitive processing. Attentional mechanisms may operate early or late in processing. In a spatial cuing paradigm, a "cue" preceding a target either predicts (valid trial) or does not predict (invalid) the target's spatial location. Typically, valid trials lead to facilitation of responses to the target, although this effect can be reversed when the time interval between the cue and the target is increased. Neglect is a disorder of spatial attention typically a result of damage to the right posterior parietal lobe. Patients with neglect fail to attend to the side of space opposite the brain lesion are typically unaware of stimuli falling on the left side of egocentric or object-centered space.

## Spatial Language

►Spatial language uses verbal description to represent objects and locations with respect to multiple coordinate systems or frames of reference. Both the scene characteristics and the speaker's perspective and goals influence schematization of spatial relations in language. Spatial language can be used effectively to communicate spatial layout and directions. Furthermore, mental representations of space based on verbal descriptions have been shown to be functionally similar, and accessed and updated as those based on visual information [9]. However, some recent work has shown that language-based responses of direction lead to different spatial updating performance than body-based responses such as turning or pointing.

## Cognitive Maps, Place Cells, and Spatial Knowledge

Historically, the term ►cognitive map has been used to refer to a mental map of space represented in an allocentric framework. The hippocampus is one brain region which has been defined as integral to spatial memory and a cognitive map theory in animals. Identified within the hippocampus were place cells, neurons that fire in response to specific locations in an environment regardless of the animal's movement or perspective. This pattern of neural activity specific to spatial positions led to the proposal of the hippocampus as supporting an allocentric environmental map, distinguished from other brain regions that might support more egocentric representations of space. Recent data shows that in addition to place cells, neurons throughout the limbic system encode nonspatial experiences and viewing orientation (head direction cells), suggesting a more general navigation system. This conjecture is also supported by human lesion research in which patients with hippocampal damage are impaired in path integration. More generally, human cognitive mapping defined from cognitive psychology and geography involves extracting information from large-scale environments to store in some type of mental representation of space [10].

A distinction between route and survey perspectives has been made both in spatial learning and memory. Route-based perspectives involve egocentric representations from the viewpoint of the observer navigating in an environment. Survey-based perspectives involve map-like or global "birds-eye" spatial representations without a specific viewer orientation. Although these types of representations may be distinguished clearly in spatial cognition, human neuroimaging data suggests that the neural substrates supporting these representations overlap.

### Neural Representations of Space

Two dominant regions of the brain that are implicated in spatial cognition are the parietal cortex and the hippocampus. Evidence for the strong role of the parietal cortex in spatial cognition comes from a variety of domains such as single-unit recording of neurons in the monkey for different spatial frames of reference, lesions in humans associated with neglect and other spatial deficits, and functional neuroimaging of spatial decisions, imagery, and navigation with healthy humans. The hippocampus has been implicated in large-scale spatial navigation, allocentric representations and spatial memory for the configuration of objects. Hypotheses differ in how the parietal cortex and hippocampus interact.

## Synonyms

Navigation

## Definition

Spatial learning and memory refers to the set of behaviors and processes through which information about external environmental space is acquired, stored, organized, and used. These phenomena provide a paradigm to systematically study the neural basis of cognition.

## Characteristics

### Background

While gathering nuts, a squirrel spots a threatening hawk overhead. Quickly, it runs at top speed in a direct path towards the safety of the nest. How is this done? How does the squirrel process its current sensory information, combine that with memory, and rapidly choose the best path for survival?

Animal ►navigation has been studied for over 100 years in the laboratory. For several decades in the early twentieth century, animal psychologists argued about whether rats solved complex maze (►maze learning) tasks by means of "place" or "response" strategies. Tolman, the leader of the "place" group argued that the maze behavior of rats could only be explained if a rat possessed a "cognitive map" of the maze. Such a map would describe the spatial relations among major ►landmarks.

The brain has two types of representations of space: egocentric and allocentric. An egocentric spatial representation refers to a representation using body-centered coordinates (the ego or self). Examples of egocentric neural maps are ►retincocentric (retina-centered) maps in the ►visual and ►parietal cortices, and ►somatotopic (body-centered) maps in the ►somatosensory or ►motor cortex.

Allocentric representations have coordinate frames that are not centered on the body. The simplest example is a road map. Significantly, Tolman's cognitive map is allocentric. Later in this article we will describe several examples of neuronal representations that are allocentric. Since the data the brain uses to construct these maps enters via body-centered sensory channels, allocentric representations seem complex in that they involve transforms to-and-from egocentric frames. Although allocentric representations are difficult to construct, they permit important efficiencies.

### Spatial Navigation Strategies

Navigation is the process of planning and going to a specific location. Its function is to make efficient use of scattered resources. There are four principal mechanisms: (i) ►Beaconing is taxic movement towards a landmark. Animals may use a wide variety of strategies to reach a beacon, ranging from simple ►chemotaxis to complex processes such as ►echolocation. One form of beaconing may involve moving to minimize the difference between the current visual snapshot and a previously memorized snapshot taken from the goal. (ii) Homing is the process of returning to a place by reverse summation of the outbound movement vectors. (iii) Route learning is a memorized series of ►local cue response rules. An example might be "at the big rock, turn left; next, at the fallen tree bear right…". Route learning is also called "response chaining" and in animals is typically acquired through operant conditioning. Route learning can work effectively in a static environment, but is inflexible. (iv) Cognitive mapping is a navigational strategy where behavior is optimized by using a two- or three-dimensional representation of the environment.

A cognitive map can be thought of as a bird's-eye representation. These are economical representations of the many relationships among environmental features. Importantly, unless we are referring to birds, these global representations of relationships among landmarks have never been seen; that is, they are transformations of sensory data. Using a cognitive map permits taking direct paths from any location to any other location on the map. Start and stop points may or may not be the locations of important landmarks. The gold-standard test of whether an animal is using a mapping strategy has been to see whether it can take a novel route to an unmarked goal. Such a route would rarely occur if the animal is navigating with other strategies.

This article will focus on neural mechanisms that contribute to map-based navigation. The mapping strategy is sometimes referred to as the locale navigation strategy in contrast to a ►route navigation (►or taxon navigation) strategy. We will be focusing on the mechanisms that have been studied in the laboratory over the past 30 years, chiefly in the hippocampus and chiefly in rats. There are other well-studied aspects of animal navigation whose neural substrate is being explored. These include trail following in a variety of animals, ►chemotaxis, path integration and snapshot navigation in insects, migration in birds and other animals, ►magnetic sensation, food caching, and flocking. These will not be covered.

There are two parts to the cognitive mapping process: creating the map and using the map. The process of map creation is associated with ►exploratory behavior. At the neuronal level, this is the plastic stage when the map is created, filled out and stabilized. Usage is when an animal can take an efficient route or exhibit other behavioral efficiencies. Presumably, during usage the brain map is read-out and utilized.

It is important to note that the hippocampus, the focus of this article, is commonly associated with the plasticity during the storage of ►declarative (generic) memories. Although it seems likely that map learning and ►declarative learning have much in common, the relationship remains problematic. Nonetheless, it is clear that modification of hippocampal circuits is involved in both declarative learning and spatial learning. In addition, long-term potentiation (►LTP), the favored model for memory, is a prominent feature of hippocampal circuits and is involved in both declarative learning and acquiring spatial maps.

## Measuring Spatial Learning and Memory in the Laboratory

Three sets of techniques comprise the great majority of laboratory approaches to navigational behavior. For the first half of the twentieth century, studies of rat cognition employed a wide variety of alleyway mazes. Some of the most familiar are the Hebb-Williams maze set, the sunburst maze, the T maze and the plus maze. Famously, Tolman and Hull used a variety of these to demonstrate that rats either did or did not use a cognitive map in navigation. In 1976 Olton and Samuelson introduced the ►radial-arm maze. In this, apparatus arms are baited at the ends, and a rat or mouse will forage using an innate win-shift strategy to visit each arm only once. Although a number of effective strategies are possible, such as a rat avoiding its own odor trace, rats spontaneously use an apparent mapping strategy, avoiding a previously-visited arm because of its association with the spatial arrangement of distal landmark cues. Although an inherent problem with the radial-arm maze is that it can be solved by a variety of strategies, it remains popular due to ease of use and the relative ease of combining navigational problem solving with electrophysiological recordings. The water maze, introduced by Morris in 1981, is a circular swimming pool with a stationary slightly-submerged escape platform [1]. On initial trials a rat is introduced near a wall and swims until it bumps into the submerged platform. On subsequent trials when the rat is introduced from various start locations it will take shorter times and more direct routes to the platform. After a few dozen trials a typical rat will take direct escape paths from any start location. The water maze provides the clearest example that a rat can take a novel route to an unmarked goal.

In ship navigation, two strategies are commonly used to determine a vessel's location: The first is "►fixing a position by sighting", where the navigator records angles and distances to distal objects (stars, landmarks), and, with the aid of a map, determines the ship's position. The second is "►dead reckoning" where the navigator uses knowledge of the ship's motion (speed, direction, time) to update position on the map. Although sightings are critical, in certain situations, such as fog, navigators rely completely on dead reckoning. Rodents appear to use both types of strategy for navigation. In rats ►self-motion cues (►idiothetic cues) are generated from motor commands and sensory cues generated from self motion, such as vestibular activity, optic flow and proprioception. Sighting cues (allothetic cues) are not exclusively visual, as rodents also rely heavily on their auditory, tactile and olfactory senses.

## The Spatial Theory of the Hippocampus

A salient clue that the hippocampus might be involved in navigation was provided by the ►theta rhythm, a highly regular 6–10 Hz EEG oscillation generated in the ►hippocampus. In rats, theta is present whenever the animal walks or interacts with external objects [2]. Both hippocampal principal cells and interneurons fire in register with the theta rhythm, with the firing of certain interneurons (►theta cells) dramatically entrained. Several theories have suggested that the theta rhythm plays a role in navigational behavior, but all are speculative. It was the subsequent observation of place cells in the hippocampus [3] and the ►cognitive map theory that followed, which first convincingly linked the hippocampus to navigation.

In 1978 O'Keefe and Nadel published the cognitive map theory as a book ►The Hippocampus as a Cognitive Map [4]. The book was the birthing event in the neuroscientific approach to navigation. This book contained five important features. First, it summarized O'Keefe's discovery of hippocampal ►place cells. Place cells initiated the notion that the hippocampus was part of navigational machinery. Second, it placed navigational problem solving in a historical/philosophical context, notably invoking Kant and Tolman as the sources for the idea that the brain had an inborn, map-like representation of the world. Third, most remarkably, it reviewed the rat hippocampal lesion literature and made a convincing argument that the deficits reported in virtually all studies could be attributed to failures of a brain map. Fourth, it established the first of many computational models for how hippocampal place cells are formed and how they might aid in route finding. And, finally, it speculated on the relationship of the hippocampal map to learning. Although there remains intense debate over the degree to which the rat or human hippocampus is devoted to spatial problem solving, this book,

and the questions it raised, remains the touchstone of these key issues.

Hippocampal lesions have been the principal tool of establishing a causal relationship between this structure and navigation. In the 1970s and 80s it was repeatedly established that hippocampal lesions eliminated use of locale (mapping) strategies on the plus maze, the radial arm maze and the water maze. After hippocampal damage rats either relied on cue strategies, response strategies or apparently random goal selection. Particularly stark, early results were obtained with the water maze. After several training sessions an intact rat will swim directly towards the goal from any start location. A rat given hippocampal lesions and similar training is more likely to swim in circles [5]. It is important to realize that lesions to several other parts of the brain, including the ►subiculum, and the ►entorhinal, ►medial prefrontal, ►parietal, and ►cingulate cortices also impair navigation in the water maze, suggesting a network of structures mediate navigation by mapping. Lesion studies have provided additional insights. For example, when rats are trained in a plus maze, they will initially use hippocampus-dependent locale strategies (e.g. go to a particular part of the room). After more extensive training, rats will switch to a hippocampus-independent response strategy (e.g. turn right). Another important line of work involves ►acoustic fear conditioning. Several labs have demonstrated that a rat requires an intact ►amygdala to form a tone-shock association. On the other hand, a rat must have an intact hippocampus for the global environment (►context) to influence the tone-shock association or for the rat to learn a direct relationship between context and shock. Although these fear-conditioning studies do not involve navigation directly, there is a fascinating connection. If we view the enclosure that a rat is tested in as a large "place", rats with hippocampal damage are exhibiting a form of spatial deficit. These studies suggest a continuity between place and context.

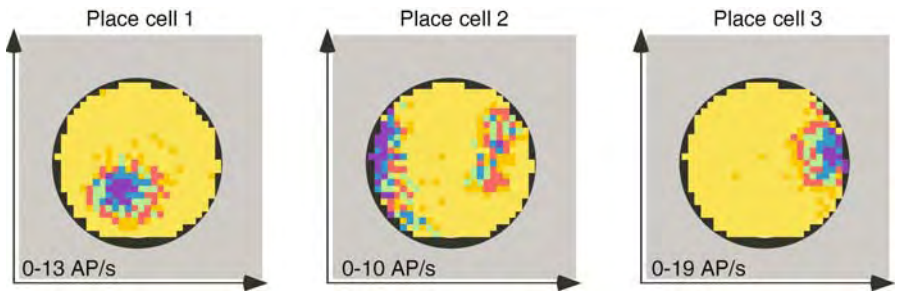
Pharmacological, genetic, and molecular imaging studies also implicate the hippocampus in navigation. Anticholinergic drugs like atropine disrupt the theta rhythm. Like other manipulations that disrupt theta, such drugs also impair spatial navigation in the water maze. Similarly, specific forms and phases of spatial learning are impaired by drugs and genetic manipulations that interfere with the induction of ►LTP such as treatments that impair *N*-methyl-D-aspartate (►NMDA) glutamate receptor function. The imaging of memory-related and activity-related molecules like immediate early genes also suggest the hippocampus is a key structure in spatial learning and memory. However, it is important to keep in mind that to-date essentially all pharmacological and genetic treatments that impair spatial behavior also interfere with both the information processing and storage functions of the brain, and thus far, molecular imaging has not distinguished between the potentially distinct processing and storage functions of a brain area.

## The Neurophysiology of Allocentric Spatial Information

The specific information processed by a part of the brain can be discovered by recording the action potential discharge of individual neurons from a freely-behaving subject and then by correlating the neural activity with well-defined sensory, motor, and cognitive variables. Projecting neural discharge onto representations of a freely-moving subject's position and direction revealed that the activity of individual neurons in three connected mammalian brain networks contain allocentric positional and directional information that may be the basis of the cognitive map.

### *Place Cells*

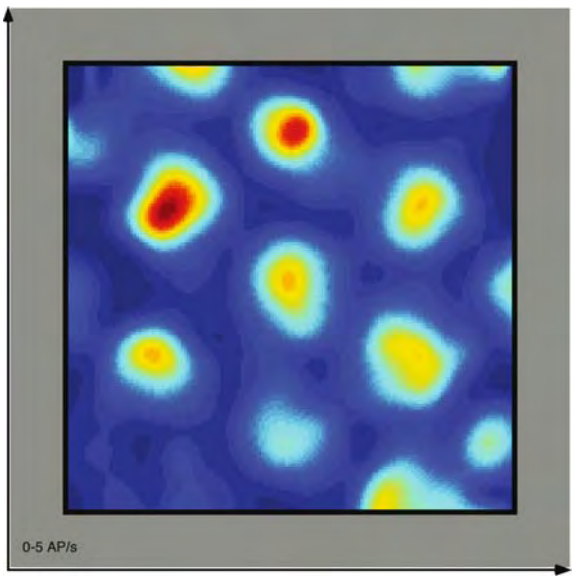
Place cells are hippocampal ►pyramidal neurons with strong location-specific firing. An individual place cell fires rapidly almost only when the animal is in discrete regions of the environment termed "►firing fields". Typically, a place cell will have zero, one or a few firing fields in a few scattered locations (Fig. 1). An animal's location can be predicted, within a few centimeters, from the activity of an ensemble of a few hundred place cells [6].



**Spatial Learning/Memory. Figure 1** Firing rate maps from three simultaneously recorded place cells. The recording was made while the rat was foraging for food on a 82-cm disk. The maps are depicted in real-world space; thus, they are allocentric. The color code is that yellow codes regions of zero firing rate, while the colors orange, red, green, blue and purple represent higher rates. The range of rates is given for each cell in units of action potentials/sec.

### Grid Cells

Grid cells, discovered by the Moser lab in Norway, are cells that show intense location-specific firing. Unlike the firing patterns of place cells, however, grid cells firing patterns are spread over an environment [7]. The pattern appears as a regular, hexagonal grid (Fig. 2). Grid cells are found in the dorso-caudal part of the medial ►entorhinal cortex.

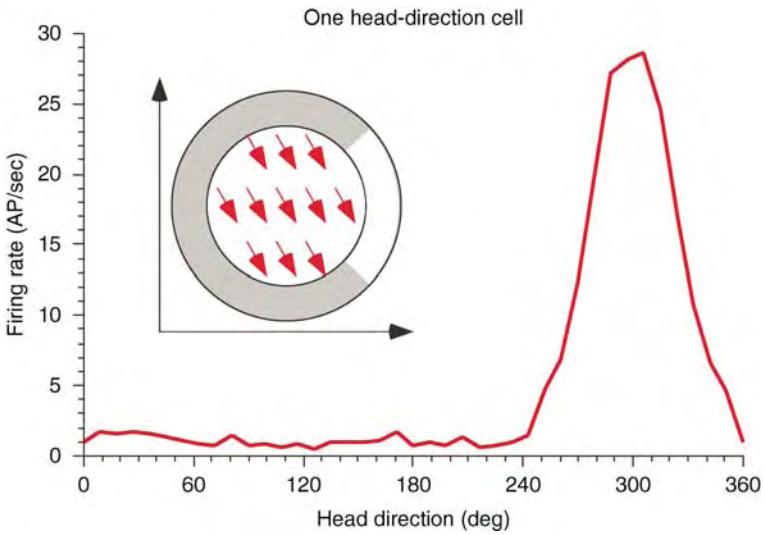


**Spatial Learning/Memory. Figure 2** The firing rate map from a grid cell recorded from a rat foraging in a 1.5 m square black box with a white card on one wall. Again, the map coordinates are in real-world, allocentric space. The color code is blue for 0 AP/s and red for 5 AP/s. Figure courtesy of Jonathan Whitlock, May-Britt Moser and Edvard Moser.

### Head-direction Cells

Head-direction cells are neurons that fire when the rat's head is pointed in a particular direction with different cells tuned to different directions (Fig. 3). The directional tuning is independent of a rat's location. (Therefore, if mapped on a floor projection, the tuning of a head-direction cell is a set of parallel vectors). Originally discovered by Ranck [8] during recordings of the post-subiculum (part of the hippocampal formation), head-direction cells can be recorded in several areas including the anterior and lateral dorsal thalamus and mammillary bodies. These regions, which resemble the Papez circuit, have interconnections with various parts of the hippocampal formation.

Place cells, grid cells and head-direction cells have important similarities. The best spatial discharge correlate of each cell class is a map-like feature of allocentric space. Activity within each class of representation tends to be internally coherent so that the firing of individual neurons is constrained to remain in register with the discharge of other neurons in the representation. The spatial discharge of each cell class also tends to stay in register with external sensory orientation cues, but firing is also controlled, at least in part, by other inputs like self-motion. Several models describe how these three neuron classes together represent an animal's location and orientation in allocentric space [9].



**Spatial Learning/Memory. Figure 3** This plot of data from a head-direction cell depicts firing rate as a function of head angle. Data were collected while the rat collected food pellets in a 76-cm gray cylinder with a white card on the wall. Head angle is with respect to east, and is therefore allocentric. The inset is an idealized representation of the preferred head angle at different regions of the cylinder.

### *Local and Global Space*

We've described the fundamental local spatial discharge correlates of place cells, grid cells, and head-direction cells, as animals move within a single environment, but additional features of these networks can be revealed by comparing their discharge in distinct environments. The across-cell pattern of place cells and grid cells in two distinct environments can "remap", meaning the spatial relations amongst place fields and grid peaks is scrambled, as if reset between environments [10]. ►Remapping radically changes which principal cells can be simultaneously active. In contrast, conditions that trigger remapping typically cause all head-direction cells to reorient as a cohesive unit, perpetually preserving which cells do and do not discharge together. As a rat moves within a single environment, the rat's local position and direction is signaled by a unique across-cell, ensemble discharge pattern that changes smoothly within the place cell, grid cell, and head-direction cell networks. Remapping implies that the ensemble activity of each cell class can switch abruptly when a rat is moved between two environments. Under special conditions this switch may also occur within a single environment, suggesting these networks may signal global space or context as well as local space.

## Conclusion

Returning to our initial question, how does the squirrel know the best path? How does the map work? We still do not know. Over the past three decades scientists have used ingenious methods and advanced tools to observe the map in action. We now have a good description of the brain map and how it is formed. We see a rich ever-changing array of spatial data. But we don't know how brain networks use these data to calculate an optimal path and organize behavior. A few simple models have been developed, but they need extensive work. Understanding how the brain solves spatial challenges like the squirrel's appears to be a tractable cognitive problem. Understanding the operation of the cognitive map is a challenge for the next decade.

## Synonyms

Spatial cognition; Spatial abilities; Spatial navigation; Cognitive map; Way finding

## Definition

From an evolutionary perspective, spatial memory is crucial to foraging and reproduction but, at the same time, multiplies the risks of getting lost, being killed or consumed by other animals (predation). Thus, survival of mobile species depends on their ability to reach a feeding location, return home quickly and safely, find shortcuts and avoid dangerous places. These basic behaviors are crucial for successful interactions with the environment and call upon effective spatial navigation skills.

The capacity to move through space may appear to be a very simple behavior consisting in maintaining a body trajectory from a place to another. However, getting from place to place is more than a body displacement. Indeed, ►navigation is an action oriented by a goal that at least involves knowing where I am and where I go. Such knowledge requires the encoding and the gathering of multimodal information concerning our body position relative to the position of other objects. This ability – called spatial memory – is now considered as analogous to human ►episodic memory (memory of personal, experiential events) since both rely on the coding, storing and retrieving of events in a spatio-temporal context (e.g. [1]).

Characterizing spatial orientation and spatial memory skills requires an understanding of how cognitive and neural mechanisms underlie adaptive behavior to environmental requirements. The following section summarizes the basic concepts and findings issued from this research effort.

## Characteristics

### Reference Frames

Fixing and maintaining a trajectory from place to place is done through the establishment of a relationship between subject and object. This relationship is commonly categorized in egocentric and ►allocentric reference frames.

Frameworks centered on the subject (e.g. body parts such as head, trunk, arm, or receptor surfaces such as retina) are called ►egocentric reference frames. Such ►reference frames allow the subject to directly estimate the position of an object relative to their own body. However, the egocentric bearing is not invariant with respect to the subject's orientation and position. Frameworks centered outside of the body, on a fixed point in the environment (e.g. mountain, corner of a room or individual object), are allocentric reference frames. Such reference frames provide two main advantages: (i) to be invariant with respect to the subject's position and orientation in the environment, and (ii) to represent the relative location of objects independently from the subject's viewpoint.

Although these two systems of knowledge allow navigation, their respective weight depends on learning. Indeed, if a local or egocentric frame is immediately available even for naive subjects, a relational or allocentric frame depends on the development of spatial skills.

### Spatial Navigation Strategies

Spatial cognition is assumed to be a hierarchical set of reference frameworks -or maps- containing landmarks, routes, locations, and configurations that integrate relative information about landmarks, routes and locations in a coherent structure. It is based on what information is perceived, represented and processed by the subject to solve navigation tasks. Adaptive spatial behavior relies on the flexibility in the use of reference frames depending on the problem to be solved. This involves the capability to choose among different cognitive possibilities that are referred to as spatial strategies.

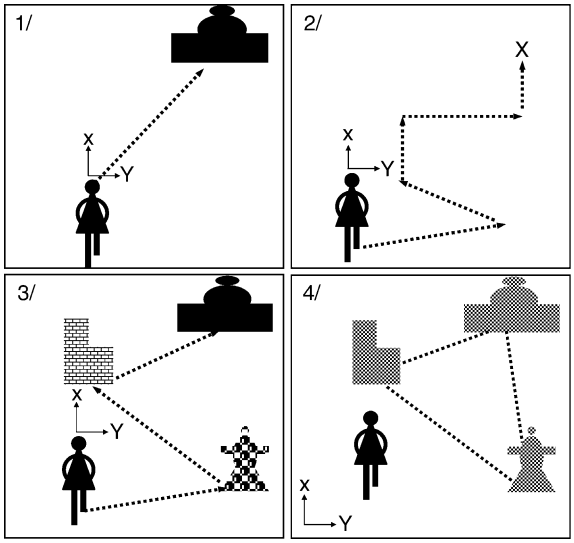
A four-level hierarchy of ►spatial navigation strategies based on a large range of researches [e.g. 2–4] can be resumed as following (fig. 1):

►Taxon navigation strategy (level 1) is used when a location coincides with a conspicuous cue. In such case, approaching a goal location is easy if the latter is either directly visible or identified by a visible cue. Such behavior does not require spatial memory per se, but rather an association between the cue and the goal to initiate a guided movement.

►Praxis navigation strategy (level 2) is used when a subject can navigate towards a hidden goal by executing a specific motor sequence acquired by extensive training. For example, if the goal is never moved and the individual always starts at the same location and with the same orientation, it can easily learn the appropriate of taxon and sequence of movements leading to that goal.

►Route navigation strategy (level 3) is a more complex strategy where the subject has learnt to associate a direction of movement to each sensory view. This strategy is appropriate, when a goal is identified by a sequence of specific sensory cues. Then, instead of single cue guidance, the subject can use more elaborate chaining sequences of taxon and praxis strategies.

Relational or configural strategy (►Relational or configural navigation strategy) (level 4) is based on the coding of relations between attributes of the environment into an internal ►spatial representation. An important property of this representation is that it offers a flexible spatial behavior adapted to each situation. In a familiar environment for example, subjects can get to a place from different starting points, as well as choose a novel path when the usual one is unavailable.



**Spatial Memory. Figure 1** Egocentric and allocentric reference frames. The egocentric reference frame (1 taxon, 2 praxis and 3 route navigation strategies) is centered on the subject (x and y arrows) whereas the allocentric reference frame is centered outside the body (4 relational or configural strategy).

To summarize, taxon, praxis and route navigation strategies are based on an egocentric frame of reference

S

depending on sensory-action associations where the position of the goal is directly estimated with respect of body-based references. They are inflexible in the sense that they prevent the taking into account that different paths may join the same place. Relational or configural strategy is based on an allocentric reference frame (a spatial representation of the environment) where the relationships between stimuli are maintained invariant with respect to the subject's position.

### Multimodal Sensory Information

The establishment of an efficient spatial representation relies on the integration of multimodal sensory information that has been divided into allothetic (►allothetic information) and idiothetic (►idiothetic information) categories.

Stimuli provided by environment-like visual, olfactory, sound, tactile stimuli- are allothetic signals providing spatial information to the subject. Orientation based on allothetic stimuli allows, for example, identifying a place through visual features of a particular object.

Stimuli provided by the body-like vestibular, proprioceptive and motor command efferent copies are idiothetic signals providing information about continuous changes of the subject position and orientation. Orientation based on idiothetic stimuli allows deriving the subject's current position in relation to a starting position by the integration of its angular and linear displacements. This ability to keep track of spatial location relying on self-motion information is referred to as ►path integration (e.g. [5]). Although path integration is available in all types of environments (unknown, absence of landmarks, darkness), its use is limited by its vulnerability to cumulative non-systematic errors over distance. However, when allothetic landmarks are available, path integration can be reset in order to maintain orientation.

Therefore, prevention of ambiguous information relies on the combination of different sensory information that is encoded within different reference frames. Thus, multisensory integration requires the integration of different reference frames into a unified spatial framework, and the hippocampus appears to be the brain region in charge of such process.

### Spatial Coding and Hippocampal Brain Area

Studies of the hippocampal formation occupy a central position in the advance of theories concerning episodic and spatial memory. Early experimental evidences for location-sensitive neurons in the rat hippocampus called "place cells," and the "►cognitive map theory" promoted by O'Keefe and Nadel [6] make out the hippocampus as the brain area that mediates allocentric spatial coding. Hippocampal function appears to be required in spatial representation, path integration and exploration (e.g. [7]) concerning the encoding of trajectories, single cell recording data suggests that the hippocampus represents the animal's position in the context of a trajectory through space while the enthorinal cortex represents regularities across different trajectories that could allow for generalization across experiences. Apart from the hippocampal area, the posterior parietal cortex seems to be in charge of egocentric spatial coding that represents body location related to subject's environment. It has been hypothesized that the multiple egocentric representations from sensory receptors and motor effectors converge from the parietal cortex onto the hippocampal formation where they are translated into an allocentric spatial reference frame. This postulate is based on findings showing strong neuronal connections between the posterior parietal cortex and the hippocampal formation, and between the hippocampal formation and the parahippocampal region. Thus, it could be postulated that spatial memory and flexible navigation requires the combination of both egocentric and allocentric components of the task, which is based on the cooperation of parietal cortex and the hippocampus respectively. This hypothesis is supported by a large convergence of data from experimental psychology, comparative anatomy and field research (for reviews see for example [8–10]).

## Spatial Navigation

►Spatial Memory

## Spatial Orientation

**Definition**

Orientation of the head and body in space. Inputs from the vestibular, visual and somatosensory systems provide critical information about the spatial orientation. Once information from two sensory inputs conflicts, disorientation and vertigo are brought about.

►Anti-Motion Sickness Drugs
►Vertigo

## Spatial Receptive Field (SRF)

**Definition**

The region of space from which a sound can evoke a response in auditory neurons.

►Neuroethology of Sound Localization in Barn Owls

## Spatial Representation

**Definition**

Synonym of cognitive map, internal representation where the coding of relations between attributes of the environment are maintained invariant with respect to the subject's position.

►Spatial Memory

## Spatial Resolving Power

**Definition**

The detection of light energy by the eye based on the spacing of the detector elements i.e. photoreceptors, retinal ganglion cells. Typically expressed in either cycles per degree or minutes and seconds of arc, spatial resolving power may be partly dependent on the optical resolution of the lens.

►Photoreceptors
►Retinal Ganglion Cells

## Spatial Rule of Multisensory Integration

**Definition**

The principle that multisensory stimuli from will be integrated depending on their relative spatial locations. Typically, stimuli presented from the same spatial location will result in enhanced multisensory integration, while stimuli presented from different spatial locations result in decreased multisensory integration, or multisensory inhibition.

►Multimodal Integration

## Spatial-temporal Transformation

**Definition**

Many sensory regions of the cerebral cortex and brain stem receive information from the outside world via a topographic and in many cases a point-to-point relationship between the physical stimulus (e.g., visual, auditory, somatosensory, etc) and the target neural structure. However, the actions of the organism are carried out by effectors (e.g., muscle) that require temporal signals to control the rate and amplitude of the movement as well as maintain its final position. Exactly how the brain performs the conversion from topographic maps into the appropriately timed neural signals is under intensive investigation. This transformation from spatial coordinates (i.e., topographic maps) to temporal

activity (e.g., muscle contraction) is called the spatial to temporal transformation. It has been studied extensively in the oculomotor system.

## Spatial Updating

### Definition

The process of updating representations of the locations in the environment with respect to the self and others after the observer or objects have moved.

►Spatial Cognition

## Spatial Vision

### Definition

Information about the structure of the visual scene as opposed to unstructured information like overall light levels.

►Blindsight
►Visual Space Representation for Action
►Visual Space Representation for Reaching
►Vision

## Spatiotemporal Learning Rule LTP STLR

►Synaptic Plasticity

## Spatiotopic

### Definition

It makes reference to topographic arrangements of sensory pathways that reflect the spatial localization of sensory stimuli.

►Evolution of the Optic Tectum: In Amniotes

## Species-specific Defense Reaction (SSDR)

### Definition

Bolles (1970) first characterized SSDRs as innate defensive reactions in response to aversive stimuli. Bolles stated that animals undergoing aversive conditioning are more likely to learn reinforced responses related to their innate SSDRs then other behaviors (e.g., freezing vs. lever pressing). The Blanchards experimentally validated the SSDR theory, broadening the spectrum of known defense reactions and redefining the term as "species-typical defense reactions," due to a cross-species generality of defensive behaviors.

►Aversive Learning

## Specific Anosmia

### Definition

Specific anosmia is selective inability to smell one particular odor. This anosmia may be genetically based.

►Smell Disorders

## Specificity of Learning

### Definition

The improvement of discrimination, classification, or discrimination achieved through training does not transfer to similar (classes of) stimuli.

►Sensory Plasticity and Perceptual Learning

## Spectral

### Definition

Refers to the frequency (pitch) aspects of the speech signal.

►Hearing Aids

## Spectral Reflectance

### Definition

In vision, the proportion of photons at different wavelengths in the visible spectrum which are reflected by a given object in the visual field. Spectral reflectance is the inverse of spectral absorption.

►Color Processing
►Retinal Color Vision in Primates

## Spectral-shape Cues in Hearing

### Definition

In the ear canals of humans and other mammals, certain frequencies are attenuated or boosted in a manner that is highly characteristic of the position of the source along the midsagittal plane. For instance, when a sound with a flat spectrum at the speaker is placed overhead, the 8 kHz band is found to have been boosted in the ear canal, due to the shape of the human head and ear. Humans appear to use these bands, collectively called spectral shape cues, for vertical sound localization. (Humans use interaural differences in time and level to localize sounds in the horizontal plane).

## Spectrin

### Definition

A membrane-associated protein that interacts with a number of other proteins, including actin and ankyrin, to form and maintain the cytoskeletal network or "mesh" found near intracellular membrane surfaces.

►Synaptic Proteins and Regulated Exocytosis

## Spectrogram

### Definition

A pattern for sound analysis that provides a three-dimensional display of time on the horizontal axis, frequency on the vertical axis and intensity on a color or gray scale.

►Speech Perception

## Spectrum in Acoustics

### Definition

A description of the relationship between magnitude (pressure or sound intensity), frequency and starting phase of the sinusoidal components of a complex sound wave.

►Acoustics

## Speech Perception

Keith R. Kluender
Department of Psychology, University of Wisconsin, Madison, WI, USA

### Synonyms

Human speech recognition; Human speech understanding

### Definition

Speech perception encompasses an array of sensory and perceptual processes through which listeners can recognize words using sensory signals from the ears and sometimes the eyes.

### Characteristics

#### Speech Production

In many ways, perception of speech is much like other perceptual tasks. However, there is one aspect of speech communication that is not typical of most perception. A tree does not strike a pose that deliberately conveys strength and longevity, but talkers do speak so that they can be understood. Speech sounds are created especially for listeners.

Owing primarily to unique characteristics of supra-laryngeal anatomy, the adult human's sound-producing abilities are unrivaled among other organisms. This capacity is revealed in a grand assortment of over 850 different speech sounds used contrastively by the more than 5,000 distinct languages around the world. In contrast to this diversity, collections of consonants

and vowels used by individual languages are anything but random. One factor that may help determine what combinations of vowels and consonants are commonly used is the ease with which the sounds are produced either in isolation or in sequence with other sounds. Most important for perception is the fact that speech sound repertoires of all languages have developed over generations toward greater communicative effectiveness, with inventories of sounds optimized for acoustic and auditory distinctiveness [1].

Another factor that makes differences between speech sounds perceptually dependable is the complexity and consequent redundancy of the speech signal. Speech ►articulation has multiple acoustic consequences. Often, multiple acoustic attributes are effortless consequences of passive interactions between articulators and/or airflow. Talkers also systematically vary relatively independent articulatory maneuvers to enhance auditory distinctiveness.

## Speech Perception

Performances of listeners detecting tones in quiet and detecting small differences in pitch are poor predictors of ability to understand speech. Perceiving distinctions between speech sounds does not rely upon the ability to make fine-grained discriminations bordering on sensory or perceptual thresholds of auditory systems. Differences between even relatively similar vowels, such as [æ] (as in "bat") and [ɛ] (as in "bet"), are easy to detect on the basis of gross spectral and temporal differences. Hence, speech recognition shares little in common with the types of discriminations presented in psychoacoustic studies that demonstrate humans' ability to detect tiny changes between simple signals. Listeners who suffer significant hearing loss can, nonetheless, manage to understand speech until the level of impairment becomes severe. The ability of normal hearing listeners to understand severely degraded speech is particularly impressive.

Because talkers exploit auditory capacities, several observations follow. First, human infants are quite proficient at discriminating differences between speech sounds from a very early age. Three decades of studies document impressive abilities of human infants, some less than one week old, to discriminate a wide variety of consonants and vowels from across many languages. Second, discrimination of speech contrasts by nonhuman animals is quite good, with multiple demonstrations that animals can distinguish human speech sounds with facility. These findings for human infants and for nonhuman animals can be expected, based on the tendency of languages to use acoustically and perceptually robust distinctions [2].

Because nonhuman animals appear to provide an adequate model for simpler aspects of speech perception, many neurophysiological studies have been conducted in the interest of describing neural representation of speech sounds. Most of this work has focused upon neural responses in the auditory (VIIIth) nerve, but there have been a number of studies concerning successive stages of the auditory system such as ventral cochlear nucleus, inferior colliculus, medial geniculate and auditory cortex.

Enough is known about the ability of humans and animals to use the acoustic information necessary for speech perception to make it clear that apparent limitations on the separate contributions of individual neurons, especially at the periphery, do not present obstacles to understanding speech. In part, this is because ample information is conveyed across 15,000 auditory nerve fibers and increasing numbers of neurons at successive levels of the auditory system. In addition, high fidelity representations are unnecessary to convey acoustically robust distinctions between sounds. Subsequent research should better illuminate the contributions of populations of neurons at low and at higher levels in processing the information contained in speech sounds.

Producing and perceiving differences between speech sounds is only a part of understanding how speech is perceived. Speech production gives rise to a host of acoustic attributes; however, matters are complicated by the fact that no single acoustic attribute by itself dependably signals any given consonant or vowel. This is referred to as the classic problem of "lack of invariance," the fact that there are no individually necessary and sufficient cues that uniquely identify speech sounds. Multiple acoustic attributes of the speech signal must be combined to identify speech sounds.

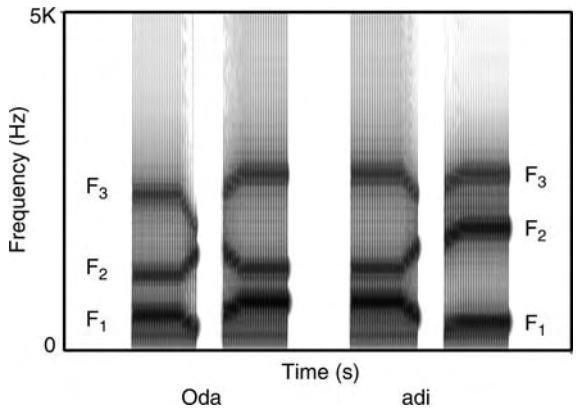
The ability to discriminate speech sounds on the basis of one or more acoustic attributes is *not* synonymous with the functional use of speech sounds. Speech perception requires treating acoustically different complex sounds as linguistically equivalent. Among the many variations in the speech signal, some are relevant to the linguistic message, but many are not. Speech perception requires ignoring irrelevant variation and focusing on linguistically relevant changes. For example, listeners must identify sequences of consonants and vowels despite substantial changes to the speech signal owing to differences in talkers. Other sources of variability that do not affect the linguistic content of speech include acoustic consequences of distance, room reverberation or competing sounds in the environment including the voices of other talkers.

Because so very many speech sounds are used across the languages of the world, perceiving distinctions in one's own language requires becoming tuned to the important distinctions in that language. Acoustic differences that matter critically for one language may be irrelevant or even distracting in another language. Perception must become tuned in such a way that most of the many possible differences between speech

sounds are relatively ignored, while at the same time the relatively few important distinctions between speech sounds that are used by a specific language are preserved or even enhanced.

Even for utterances by the same speaker, acoustic qualities of consonants and vowels vary. Production of consonants and vowels is altered by articulation of consonants or vowels that precede and follow. This process, known as ►coarticulation, results in temporal and spatial overlap in production of successive sounds. One example is the pattern of spectral peaks (►formants $F_1$, $F_2$, $F_3$) for the stop consonant [d] following the vowel [o] ("oh") and preceding [a] ("ah", left) and following [a] and preceding [i] ("ee", right) as depicted schematically in Fig. 1. Due to overlapping production of vowels and consonants, there is no single acoustic quality that signals [d] in both [oda] and [adi].

Explaining perception in the face of context sensitivity and lack of invariance is central to understanding speech perception. It has been shown that auditory processes that increase spectral contrast between successive speech and nonspeech sounds contribute to reversing the assimilative effects of coarticulation [3]. Also, in a way that bears a striking resemblance to visual perceptual constancies, multiple aspects of the speech signal come to be used together through experience with systematic covariation among attributes. One of the things that neural systems do best is to exploit multiple sources of modestly reliable information to reach a highly reliable conclusion. Simulations of neural connectivity and activity in artificial neural networks or connectionist models are designed to mimic the use of multiple attributes and associations between attributes as a function of experience with natural covariation [4]. Some of the most interesting findings to come out of computer simulations of vision have been demonstrations that performance can remain very robust across severe degradations of the signal such as adding noise, spectral filtering or deleting portions of the signal – a close analogy to the robustness of speech perception.



**Speech Perception. Figure 1** Pattern of spectral peaks.

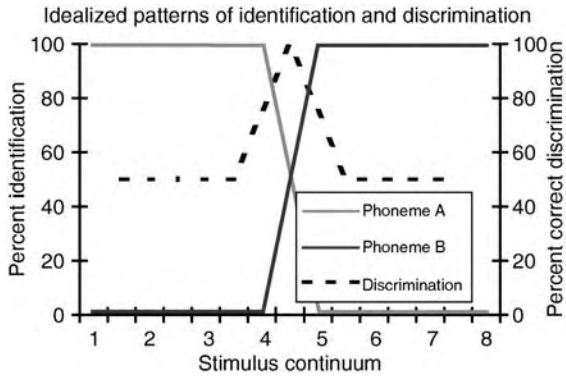
## Effects of Experience

Studies on development of speech perception address some of the same issues. Infants' perception of individual speech sounds and words is shaped by statistical regularities across speech sounds heard within even a single listening session. In addition, there have been a small number of studies in which animals, instead of infants or computers, have served as surrogates to reveal how experience with natural covariation between acoustic attributes of speech help to maintain perceptual constancy for speech sounds. In each case, perceptual performance reveals sensitivity to experience with the frequency with which particular sounds occur and with the ways acoustic properties co-occur.

During the first year of life before infants produce much speech, they become increasingly attuned to the differences between vowels and consonants that are functionally appropriate to their language environment [5]. They begin to respond only to acoustic differences that distinguish two sounds in their native language, but not to acoustically equivalent differences that do not distinguish sounds in their language even when those differences are used by other languages. Adult difficulties perceiving differences between sounds in a non-native language develop early. There have been many studies of adult perception and production of contrasts when learning a second language and these show that ease of perception can be predicted on the basis of similarity or dissimilarity with sounds experienced in the native language.

Among experimental phenomena related to speech perception, perhaps none is more widely known than categorical perception. This classic perceptual process is studied using a series of stimuli that vary systematically in one or more acoustic attributes that distinguish between two speech sounds. Listeners label each stimulus as one or the other speech sound, and they discriminate between pairs of speech sounds drawn from different points along the series. Three features define categorical perception, a labeling (identification) function with an abrupt transition between the two categories, discontinuous discrimination performance (near perfect across the identification boundary and near chance when both stimuli are from the same side) and the ability to predict discrimination performance on the basis of labeling data (Fig. 2).

These patterns of data stand in contrast to perception of simple stimuli continuously varying along dimensions such as frequency, intensity, etc. Many additional findings indicate that categorical perception is not unique to humans' perception of speech. As might be expected given the major role of experience in



**Speech Perception. Figure 2** Idealized Patterns of Identification and Discrimination.

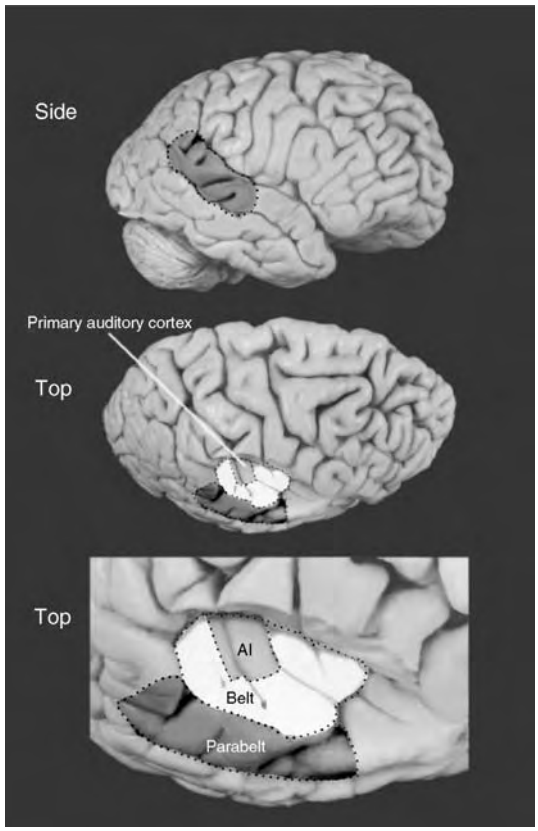
perception of speech, when experience is simulated using artificial neural network models, signature response patterns for categorical perception are emergent properties of learning following exposure to distributions of speech sounds [6]. Consistent with this conclusion, categorical perception has been observed with a number of visual and nonspeech auditory stimuli with which observers and listeners have much experience.

## Cortical Processing of Speech

Modern methods of electroencephalography (EEG), magnetoencephalography (MEG), positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) are contributing to a greater understanding of cortical functions related to speech perception.

Presentation of sounds of any kind results in activation of primary auditory cortex (AI). Beyond AI, ventral, anterior and posterior, there is a belt of cortex that is activated by more complex sounds (Fig. 3). Ventrally, a second belt, sometimes referred to as a parabelt, can be described. For these belt areas, often referred to as "secondary" or "associational" areas, there is decreasing activation in response to very simple sounds such as sine waves and white noise, particularly when stimuli do not change much over time. In addition to responding to more complex acoustic structure, there is greater evidence of cross-modal encoding (e.g. auditory and visual), particularly in parabelt areas. Activation in response to speech in core, belt and parabelt areas of auditory cortex has most often been found to be relatively balanced bilaterally in the absence of higher-level linguistic effects [7].

Some very recent research suggests that, when listeners discriminate speech sounds such as "ba" and "da", brain areas anterior and ventral to parabelt areas on the superior temporal lobe are more activated relative to very similar nonspeech sounds and this activation is relatively stronger in the left hemisphere [8]. When listeners understand whole meaningful sentences, activation is more clearly lateralized to the left



**Speech Perception. Figure 3** Cortical processing of speech.

hemisphere in regions yet further anterior and ventral in the temporal lobe [9].

Although evidence for strong lateralization of cortical speech processing – absent higher linguistic content – is relatively limited, this does not imply that there is nothing special about processing of speech in the human cortex. There are other ways in which processing of speech can be distinguished from perception of other sounds. Cortical organization is critically linked to the amount and nature of experience and there are no acoustic signals with which humans have more experience than speech. One may well expect that, as more becomes known about cortical processing of complex sounds, cortical areas that appear more exclusively dedicated to speech sounds may be revealed.

Evidence for two types of cross-modal organization might also be expected in cortex. First, owing to a wealth of experience simultaneously hearing speech and viewing talkers' faces, one may expect substantial interaction between auditory and visual speech. The so-called McGurk effect, achieved by placing auditory and visual speech information in conflict, provides a powerful behavioral demonstration of this interaction, and there is some brain imaging evidence for cortical areas related to these perceptual effects [10]. Second,

there is some reason to expect evidence of interactions between speech production and perception. In addition to the more dorsal route between posterior temporal and motor cortex via the arcuate fasciculus, there is another connection between temporal and frontal areas of cortex via the uncinate fasciculus, which extends from anterior temporal cortex to inferior frontal gyrus. Thus, anatomical connections are in place to support associations between areas involved in perception of speech with areas involved with production. Given that speech provides an unusual case for which, at least when one is talking, there are simultaneous activities for producing and perceiving one's own speech, the potential for such as an association existing and being significant for speech perception is substantial.

## Spike

### Definition

Spike – (also discharge, impulse): another term for the most rapidly changing portion of the action potential.

►Action Potential
►Sensory Systems

## Spike Sorting

### Definition

Class of techniques and algorithms that use the shape of waveforms collected by one or more electrodes in a neural preparation to distinguish the activity of one or more neurons from background electrical noise – this is also known as "spike detection" – and to assign spikes to different neurons. Extra-cellular electrodes often detect action potentials generated by several neurons in their vicinity. Since the spike shapes are unique and quite reproducible for each neuron, classification of these shapes can be used to distinguish spikes produced by different neurons.

►Computer-Neural Hybrids

## Spike Train

### Definition

Series of action potentials (or spikes).

►Action Potential
►Sensory Systems

## Spin Tensor

### Definition

The skew symmetric part of the velocity gradient. Also called vorticity tensor.

►Mechanics

## Spina Bifida

### Definition

Developmental abnormality resulting from the failure of the caudal ►neural tube to close, which in turn results in disruption of the functions of the lumbar and sacral spinal segments.

►Neural Tube

## Spinal Animals

### Definition

"Acute Spinal" refers to an animal whose spinal cord is surgically cut with a scalpel on the day of an experiment and is used to record electrophysiological data from muscles, nerves or spinal neurons "Chronic Spinal" refers to spinal animals whose spinal cord is cut at various levels (usually T13 in cats and T8 in rodents) and the animal is kept for a varying number of days, weeks and months to record kinematics, kinetics or EMGs.

►Locomotor Training

## Spinal Autonomic Circuit

### Definition

Segmental or propriospinal reflex circuit consisting of primary afferent neurons (mostly with small-diameter Aδ- or C-fibers), interneurons and preganglionic neurons. These spinal autonomic circuits are functionally defined by the function of the final autonomic (sympathetic or parasympathetic) pathway (e.g. muscle vasoconstrictor, urinary bladder etc) and the functional type of primary afferent neuron.

►Medulla spinalis; Pars thoracica

## Definition

Thoracic cord. The part of the spinal cord comprising the spinal nerves of the thoracic vertebral column.

►Medulla Spinalis

## Spinal Ganglion

### Synonyms
►Ganglion spinale

### Definition
Spinal ganglion is formed by the cell nuclei of vicero-sensory, bi- or multipolar neurons, which project across the dorsal root into the spinal cord, where they mostly synapse directly on viscero-efferent fibers, thus creating the basis for autonomic reflex arcs.

## Spinal Hyperexcitability

### Definition
Sensitization of spinal cord neurons for peripheral input.

►Hyperalgesia and Allodynia

## Spinal Muscular Atrophy

### Definition
Disease of spinal ►motoneurons (with some ►demyelination of the ►corticospinal tracts) presenting with wasting and weakness of skeletal muscles, loss of reflexes and ►fasciculations; may be the same disease as ►amyotrophic lateral sclerosis.

►Amyotrophic Lateral Sclerosis
►Corticospinal Tract
►Fasciculations

## Spinal Nerve

### Synonyms
►N spinalis

### Definition
A spinal nerve originates in the spinal cord, unlike the cranial nerve which arises from the cerebrum. A distinction is made between 31 pairs: 8 cervical (C1–C8), 12 thoracic (Th1-Th12), 5 lumbar (L1–L5), 5 sacral (S1–S5), and 1 coccygeal. Each segment pair provides sensory innervation for a clearly delineated skin area ( = dermatome). Close to the spinal cord, the spinal nerve divides into a sensory dorsal root and a motor ventral root. External to the intervertebral foramen it divides again into a ventral branch and a dorsal branch.

►Medulla Spinalis

## Spinal Nucleus of the Trigeminal Nerve

### Synonyms
►Nucl. spinalis n. trigemini

### Definition
This nucleus extends from the principal nucleus of the trigeminal nerve to the dorsal column of the cervical cord, which it enters. Afferents are the axons from the trigeminal ganglion, which convey somatotopically organized impulses from the face via the spinal tract of the trigeminal nerve. Efferents come from the caudal nuclear region, decussate to the contralateral side and pass as the lateral trigeminothalamic tract to the ventral posteromedial thalamic nucleus.

►Myelencephalon

## Spinal Reflex

### Definition
A reflex mediated via neuronal pathways located entirely within the spinal cord.

## Spinal Respiratory Neurons and Respiratory Control

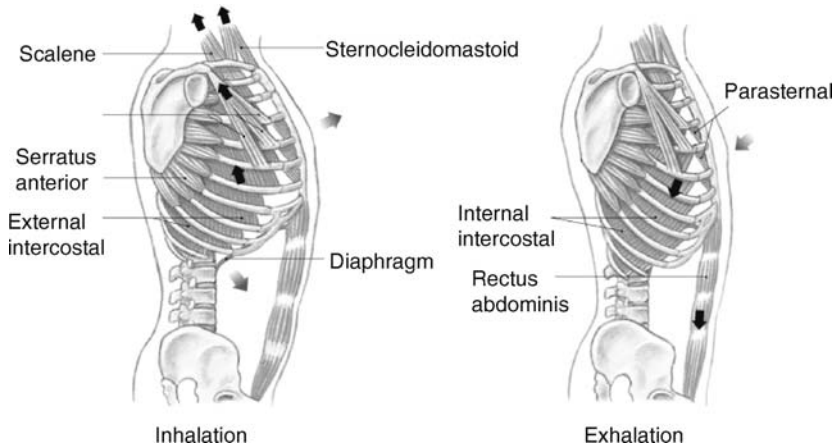
Department of Physiology, Centre for Neuroscience, University of Alberta, Edmonton, AB, Canada

### Definition
Air flow in and out of the lungs is regulated by mechanical action of the ribcage moving in axial and radial directions. Inspiration is an active phase controlled by the



**Spinal Respiratory Neurons and Respiratory Control. Figure 1** Respiratory muscles innervated by spinal respiratory motoneurons that are recruited during inhalation and exhalation. Levator costae (occupying most rostral regions of each intercostal space), triangularis sterni (underlie parasternal muscles) and other abdominal muscles besides rectus abdominis not shown.

contraction of the diaphragm, levator costae, scalene, parasternal and external intercostals muscles. In addition, the sternocleidomastoid, pectoralis, serratus anterior and trapezius muscles are recruited during forceful inspiration. Expiration is largely passive, except for the recruitment of levator costae muscles. During forced expiration, rib cage movements are also controlled by abdominal and internal intercostal muscles (Fig. 1). Further, the thoracoabdominal muscles play a role in vocalization, various gastrointestinal activities, as well as ribcage stabilization and postural adjustments, particularly during locomotor activities and exercise. Thus, their contribution to airflow generation will vary from breath to breath as it is adjusted to best meet these multiple demands. The motoneurons innervating and controlling these muscles are located within the ventral horn of the spinal cord. This section will provide an overview of the anatomical and physiological properties of spinal respiratory motoneurons. The primary focus will be on ►alpha motoneurons, those that innervate extrafusal muscle fibers. A brief discussion of ►gamma motoneurons which innervate intrafusal fibers of muscle spindles will appear at the end. There a number of excellent reviews that provide more in depth discussions of spinal respiratory motoneurons and the muscles they innervate [1–4].

## Characteristics

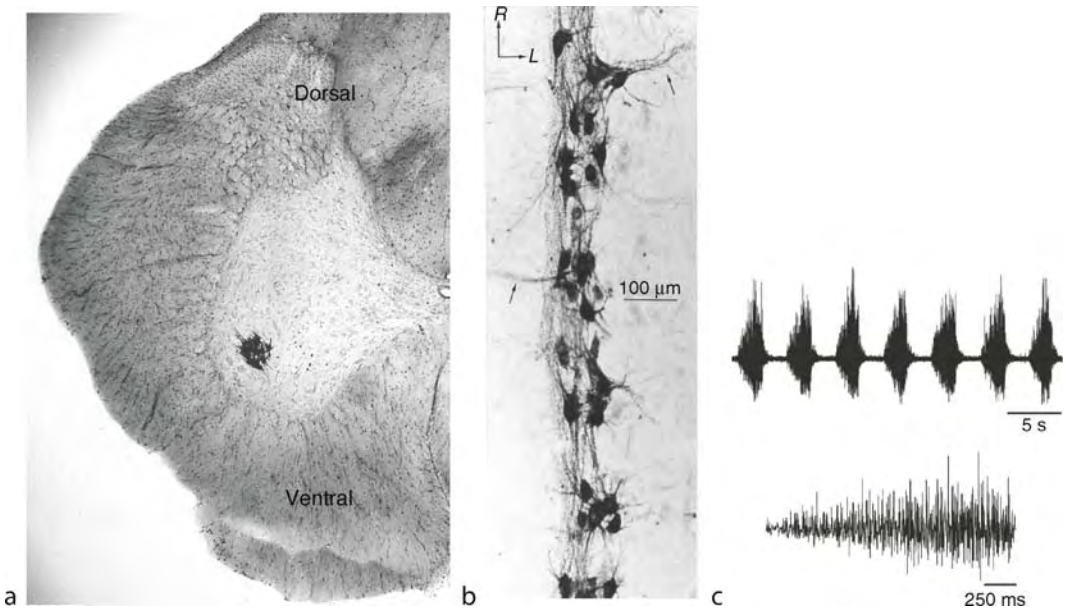
### Phrenic Motoneurons

Phrenic motoneurons (PMNs) are the sole source of efferent innervation of the diaphragm muscle, the primary inspiratory muscle controlling thoracic expansion. PMNs have been studied in much more detail compared to other spinal respiratory motoneurons.

*Anatomy:* PMNs are located in the ventral horn of cervical (C)3-C5 segments of the human and rodent spinal cord. The relative proportion of PMNs residing within each cervical segment varies with species. The PMN nucleus is readily recognizable by its medial position in the ventral horn and the extensive rostrocaudally-oriented dendritic branches (Fig. 2). It has been suggested that these dendritic bundles assist in coordinating respiratory movements by synchronizing the activity of groups of motoneurons. The diaphragm originates from a single embryological structure but is functionally compartmentalized into costal and crural regions via selective recruitment of motor units. PMNs innervating the costal diaphragm are located rostral relative to those innervating the crural diaphragm.

*Synaptic input and discharge characteristics:* PMNs receive inspiratory drive from bulbospinal neurons located in the ventral nucleus of the solitary tract, referred to as the ►DRG (dorsal respiratory group), and rostral region of the ventrolateral column of respiratory neurons called the rostral ventral respiratory group (rVRG). In the rat, however, the DRG contribution is minor. The connections from the medulla to PMNs are both mono- and poly-synaptic, but monosynaptic connections predominate.

Glutamate is the main neurotransmitter mediating transmission of synaptic inspiratory drive to PMNs. The majority of the glutamate-mediated action is via non- ►NMDA (N-methyl-D-aspartic acid) receptors. However, there is an NMDA-receptor mediated component that accounts for ~10% of the baseline drive and that component may be further enhanced via reflex-mediated synaptic input. PMNs are silent during the expiratory phase due to the combined withdrawal of inspiratory drive and the activation of GABAergic inhibitory synaptic drive. The primary source of inhibitory drive to PMNs arises from expiratory bulbospinal neurons located in the caudal VRG and ►Bötzinger



**Spinal Respiratory Neurons and Respiratory Control. Figure 2** (a) HRP labeled PMNs showing distinct clustering and bundling of rostrocaudal projecting neurites. Figures provided by Dr. H. Goshgarian, Wayne State U. (b) Cat phrenic nerve recording showing characteristic ramp-like burst pattern. Figures provided by Irene Solomon, University of New York at Stony Brook.

complex (BötC) located at the rostral end of the ventral respiratory column. Further, PMNs receive GABAergic inhibitory drive concomitant with excitatory glutamatergic inspiratory drive; the balance of each being adjusted to shape PMN discharge pattern and subsequent drive to the diaphragm muscle.

In addition to the fast excitatory and inhibitory inspiratory drives mediated, respectively by the amino acid transmitters glutamate and GABA, a dense plexus of synaptic varicosities converge onto the PMN pool that contain a multitude of neurotransmitters, including serotonin, thyrotropin releasing hormone, noradrenaline, Substance P, metenkephalin, cholecystokinin, galanin, neuropeptide Y and adenosine. The neuromodulators regulate PMN excitability on a slower time scale relative to the amino acid transmitters. In addition, the activity of these modulatory neurons often varies between states (e.g., sleep-wake cycling).

The pattern of phrenic discharge increases in a ramp-shaped pattern during each inspiratory burst (Fig. 2). The increasing discharge is due to the increase in discharge frequency of individual PMNs and recruitment of previously silent PMNs. There is also post-inspiratory discharge amongst a sub-population of PMNs that works in concert with activation of laryngeal expiratory motoneurons to provide a smooth transition from inspiration to expiration by limiting early expiratory airflow. In addition, PMNs receive endogenous rhythmic inspiratory currents with prominent oscillations in the 20–50 Hz and 80–150 Hz ranges. It has been hypothesized that these oscillations control the precise timing of ▶action potentials, helping to maximize synaptic drive efficiency by constraining MN firing frequencies to those optimal for muscle contraction [5].

Details of how PMN output in the form of action potentials are determined by the complex interaction of intrinsic and synaptic properties is largely unknown. This requires specific knowledge of several factors including neuronal morphology, type and distribution of multiple types of voltage- and ligand-gated channels, ▶second messenger systems and their actions, associated endogenous neurotransmitters and their location on the somatodendritic and presynaptic membranes, and the interactions between various neuromodulators and ionic channels (see [3,10] for review).

*Development:* Most mammalian motor systems do not become fully functional until they undergo significant postnatal development. While the neuronal and muscular components of the respiratory system mature postnatally, they must be developmentally advanced and functional by birth to generate a rhythm and motor behavior that is sufficient for gas exchange in a highly compliant chest wall but can also to integrate swallowing and other behaviors with breathing. The development of rat PMNs during the perinatal period has been systematically examined (see [7] for review).

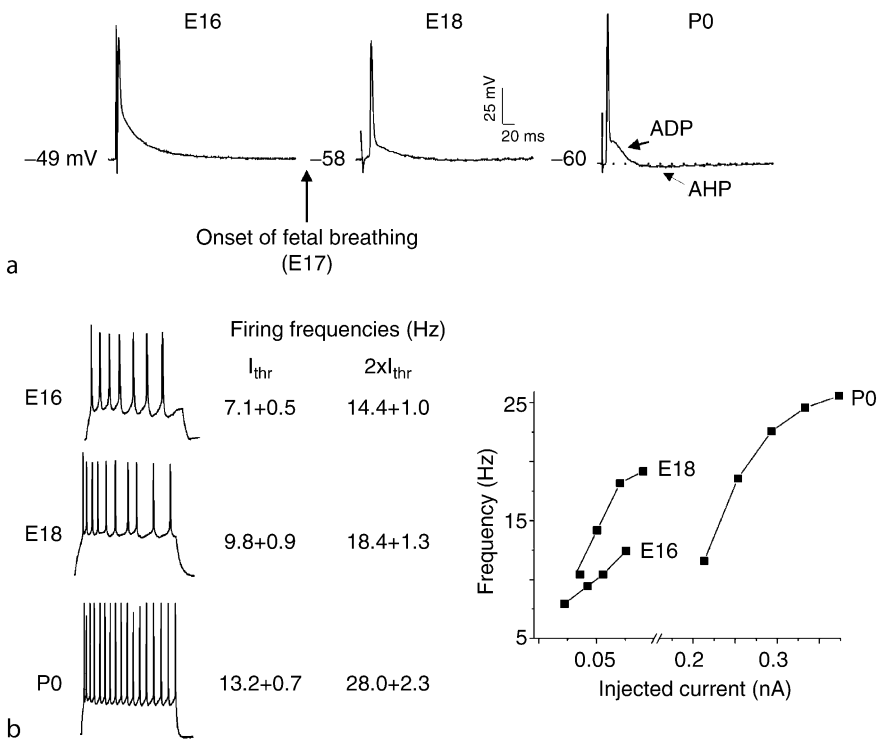
PMNs differentiate and proliferate within the ventricular zone of the neural tube. They are organized into

tightly packed clusters, linked by gap junctions, as they migrate to reach their final position in the ventral horn. During these early stages, the PMN somata and their simple mediolateral neurites align along the processes of radial glia that provide a guiding substrate. The specification of motoneuron identity is thought to be controlled, in part, by the combinatorial actions of transcription factors. The detail of how these operate to specifically define phrenic versus brachial phenotype has not been examined. The axons of phrenic and brachial motoneurons exit via cervical ventral roots and migrate together toward the primordial diaphragm. Under the influence of currently unidentified guidance cues, the two populations, led my pioneer axons, diverge. Phrenic axons continue to grow ventrally toward the diaphragmatic primordium; brachial axons turn laterally to grow into the limb bud. The phrenic nerve initiates branching within the diaphragm when myoblasts in the region of contact with the phrenic nerve begin to fuse and form distinct primary myotubes. As the nerve migrates through the various sectors of the diaphragm, myoblasts along the nerve's path begin to fuse and form additional myotubes.

During these early stages of development from the time of initial axon outgrowth until the diaphragm is fully formed, PMNs are recruited as part of a robust, regular rhythmic motor pattern that is generated along the entire developing spinal cord and brainstem. It has been hypothesized that the spontaneous embryonic rhythmic activity plays a key role in regulating the early development of neuronal circuits and motoneuronal phenotype.

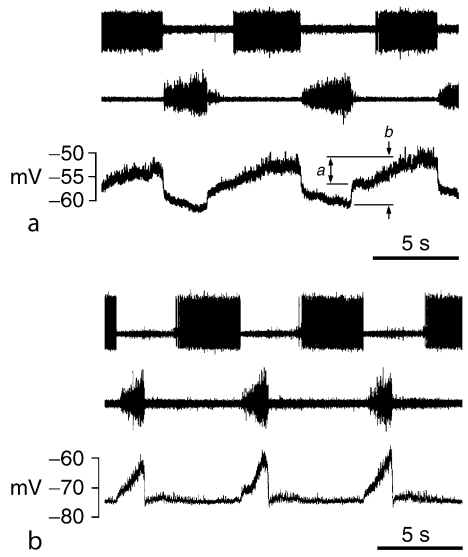
The phrenic nerve intramuscular branching and concomitant diaphragmatic myotube formation is largely complete by embryonic day 17 in the rat and the 10th week of gestation in the human. This is also the time of the commencement of inspiratory drive transmission to PMNs, the inception of fetal breathing movements (FBMs) and the arrival of phrenic afferents to the motoneuron pool.

During the period spanning the inception of FBMs to birth there is dramatic change in PMN morphology, passive membrane properties, action potential characterises and firing properties (Fig. 3). Changes include the following. (i) PMN dendritic branching is rearranged into the rostrocaudal bundling characteristic of mature PMNs, and gap junctions between PMNs decrease. (ii) PMN ►resting membrane potential becomes significantly more hyperpolarized (~10 mV) without a significant change in action potential threshold, whereas



**Spinal Respiratory Neurons and Respiratory Control. Figure 3** (a) Typical action potentials recorded from embryonic day (E16), E18 and postnatal (P)0 rat PMNs. (b) *Left panel* shows examples of repetitive firing patterns generated following injection of a depolarizing square pulse. *Right panel* shows representative current frequency plot for PMNs at various ages studied. Adapted from [7].

there are significant decreases in the input resistance (►membrane resistance) (~three times lower) and ►time constant (~1.4 times shorter). Thus, PMNs require significantly less depolarizing current to reach threshold at the inception of inspiratory drive compared with more mature states (i.e., rheobase current is ~2.5 times less at E17 than at birth). Functionally, the increased propensity for reaching firing threshold will compensate for a relatively weak descending inspiratory drive at this age, and thus facilitate the production of fetal breathing movements. (iii) Action potential characteristics change markedly. The amplitude increases by ~12 mV and the duration decreases by ~50%. Calcium conductances emerge which play a large role in the development of after-depolarizing and -hyperpolarizing potentials. (iv) Concomitant with changes in the duration and shape of action potentials, there is a marked change in the repetitive firing properties of PMNs. By birth, PMNs fire at ~ two times the maximum discharge frequency achieved at the onset of FBMs. The net results of the changes in the passive and action potential properties are that by birth, PMNs, while requiring a stronger synaptic drive to initiate firing, are capable of driving the diaphragm musculature to produce greater contractile forces in comparison to those generated in utero.



**Spinal Respiratory Neurons and Respiratory Control. Figure 4** Examples of central respiratory drive potentials (CRDPs) in intercostal motoneurons. Records in each panel, from the top: extracellular discharge from an expiratory bulbospinal neuron; efferent discharge in an external intercostal nerve, used to define inspiration; intracellular recording from a motoneuron. (a) expiratory motoneuron, (b) Inspiratory motoneuron. Adapted from [6].

## Respiratory Motoneurons Innervating Thoracic Muscles

Motoneurons innervating thoracic muscles are phasically active during inspiratory or expiratory phases to control ribcage expansion. Further, they regulate ribcage stability and therefore improve the efficiency of the diaphragm muscle.

*Anatomy:* Internal and external intercostal, as well as triangularis sterni and parasternal motoneurons are located in the ventromedial region that corresponds to the intercostal space in which the muscle is located. In the transverse plane, levator costae motoneurons are located in the ventromedial region of the ventral horn, while the parasternal and triangularis sterni motoneurons are located primarily along the lateral edge of the ventral horn. Internal and external intercostal motoneurons are located between these motoneuron groups with external intercostals motoneurons generally being more medial than internal intercostals motoneurons.

*Synaptic input and discharge characteristics:* Inspiratory drive transmission to thoracic respiratory motoneurons arises from the rVRG and ►DRG. Expiratory drive arises from the cVRG, but likely not the BötC which does not project beyond the cervical spinal cord. Unlike PMNs, there seems to be very little monosynaptic input to thoracic respiratory motoneurons from the medulla. Rather, there is a segmental interneuronal network transmitting reciprocal inhibition between inspiratory and expiratory intercostals motoneurons that provides spinal integration of supraspinal and segmental synaptic inputs (Fig. 4). The neurochemical control of respiratory motoneurons controlling thoracic musculature has not been studied in detail. However, it would appear that the primary inspiratory drive is via glutamatergic synaptic input.

Parasternal, external intercostal and levator costae motoneurons are activated during the inspiratory phase. There is a rostrocaudal gradient of the strength of inspiratory activity in external intercostals muscles. In contrast, there is a tendency for the levator costae motoneurons innervating caudally located muscle to be recruited strongly during inspiration.

Internal intercostal and triangularis sterni motoneurons are activated during the expiratory phase. The majority of triangularis sterni motoneurons commence firing mid-expiration. There is a caudorostral gradient of the strength of expiratory activity in internal intercostals muscles.

Motoneurons innervating muscles in the neck, shoulder and chest region can also contribute to movements of the thorax during respiration. Scaleni motoneurons, located in segments C2-C7, are activated during inspiration. Scalene muscle activity assists with the lifting of the upper ribcage. The sternocleidomastoid, pectoralis, trapezius and serratus anterior motoneurons are not rhythmically active at rest but can be recruited during forced inspiration. Sternocleidomastoid motoneurons are located in segments C1-C3 and trapezius motoneurons extend from C2-C6; both send axons via the spinal

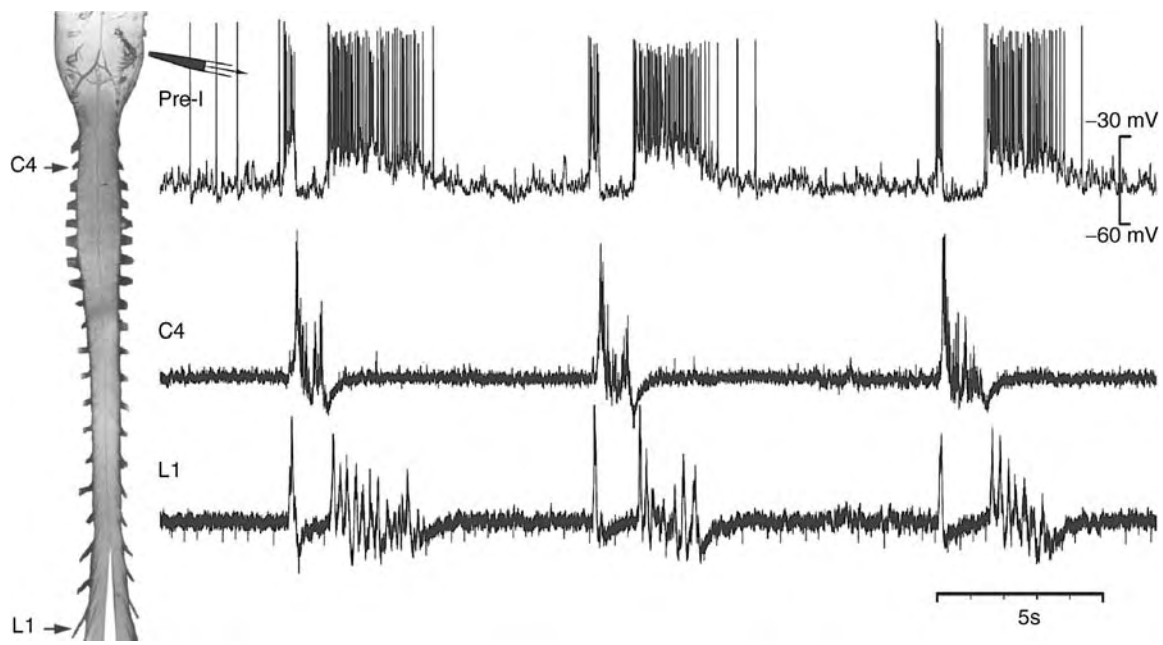
accessory nerve. Notably, there is overlap in the location of caudally located trapezius and PMNs. Pectoralis motoneurons are located within the medial to ventromedial tip of the ventral gray matter of C6-C7. The majority of serratus anterior motoneurons are from C6, with a smaller component located at C7.

### Abdominal Motoneurons

The respiratory abdominal muscles comprise two outer (external oblique, EO, and rectus abdominis, RA) and two inner (internal oblique, IO, and transversus abdominis, TA) muscles. Abdominal muscles are primarily innervated by motoneurons located in the lower thoracic and upper lumbar spinal cord; external oblique (T6-L3), internal oblique (T13-L3), transverse abdominis (T9-L3) and rectus abdominis (T4-L3). There is considerable overlap in the positioning of those motoneurons within the ventrolateral region of the ventral horn. Abdominal motoneurons are recruited during forced expirations. Premotoneurones supplying abdominal motoneurones are localized in the caudal part of the ►VRG (ventral respiratory group), within or close to the nucleus retroambiguus. It has been recently hypothesized that preinspiratory neurones located in the rostral ventrolateral medulla close to the ventral surface at the level of the rostral half of the nucleus retrofacialis provide rhythmic drive to those premotoneurons (Fig. 5).

### Gamma Motoneurons

Muscle spindles respond to changes in muscle length. The sensitivity and firing rate of muscle spindles is modulated by fusimotor axons. Most fusimotor axons derive from γ-motoneurons that exclusively innervate spindles, but a minority are β-fibers (α-motoneurons that innervate spindle intrafusal muscle fibers and skeletal muscle fibers). Intercostal muscles have a rich complement of muscle spindles and gamma motoneuron innervation (reviewed in [9]). Inspiratory activity of external intercostals is markedly reduced in the absence of feedback onto intercostal motoneurons from muscle spindle afferents. In contrast, the diaphragm and triangularis sterni muscle have very few muscle spindles and consequently a low number of gamma motoneurons in their motoneuron pools. Perhaps reflex activity mediated via muscle spindles would be functionally inappropriate for the diaphragm, the major muscle controlling inspiration. For instance, reflex activation of PMNs by spindle afferents could occur when the diaphragm is passively lengthened either due to trunk rotation of pressure applied by adjacent abdominal organs. Likewise, heightened fusimotor activity that can occur in association with certain states of alertness, would result in increased muscle spindle afferent discharge and reflex activation of PMNs. These occurrences could theoretically lead to disturbances in diaphragm function and breathing pattern.



**Spinal Respiratory Neurons and Respiratory Control. Figure 5** Expiratory activity of lumbar motoneurons. Activity of the preinspiratory neuron located in the parafacial nucleus region projecting to the nucleus retroambiguus and traces of C4 and L1 root activity generated in an vitro neonatal rat brainstem-spinal cord preparation. The firing pattern of the preinspiratory neurons and L1 root in vitro consisted of two distinct bursts bracketing C4 root activity. Adapted from [8].

# Spinal Shock

## Definition

Spinal shock results from a complete transaction of the spinal cord and denotes a state of reduced or absent spinal reflexes, which gradually recover within weeks and months and then often are enhanced.

# Spinal Trigeminal Nucleus

## Definition

The spinal trigeminal nucleus receives input from the pain and temperature (and some tactile) afferents in the trigeminal nerve (Vth cranial nerve). This nucleus is in the lateral brainstem and extends from the pons through the medulla to the spinal cord where it is continuous with the substantia gelatinosa region of the dorsal gray.

# Spinal Trigeminal Tract

## Definition

The spinal trigeminal tract is made of primary afferent fibers of the trigeminal nerve (Vth cranial nerve) that carry pain and temperature (and some tactile) information. The cell bodies of these fibers are in the trigeminal ganglion. The tract begins at the Vth nerve entry in the pons and courses lateral to the spinal Vth nucleus in its descent to the spinal cord where it is continuous with the tract of Lissauer.

## Definition

### Dendritic Spines and Filopodia

Spiny protrusions of dendrites that receive excitatory synaptic inputs. Dendritic spines possess a bulbous head, at which stable synaptic contact with a presynaptic terminal is formed. Dendritic ▶filopodia do not manifest a bulbous head and are often longer than spines as well as highly motile and unstable. Filopodia are numerous in neurons of young animals but are sparse in those of adults. It is often difficult to distinguish filopodia from thin spines. Filamentous (F) actin is highly enriched in spines

and filopodia, whereas microtubules are absent; in contrast, F-actin is less abundant and microtubules are present in the parental dendritic shaft.

## Characteristics

### Quantitative Description

Spines are present on a variety of neurons, but they are especially numerous (1–15 spines per micrometer) and prominent in the major projection neurons of the vertebrate brain, including cerebellar Purkinje cells, ►pyramidal neurons in the cerebral cortex, and medium spiny neurons in the basal ganglia. In pyramidal neurons, the morphology of spines is highly variable; spine–head volume varies from 0.005 $\mu m^3$ to 0.5 $\mu m^3$ (head diameter of 0.2–1 μm), spine–neck length from 0 μm to 1.1 μm, and spine–neck diameter from 0.04 μm to 0.26 μm. Spine structure is less variable in Purkinje neurons, with head volume ranging between only 0.06 $\mu m^3$ and 0.18 $\mu m^3$ [1]. The structure of spines, especially that of the neck, is difficult to study, even with serial reconstruction by electron microscopy, because the thickness of tissue sections (~0.06 μm) is similar to the diameter of spine necks. High-voltage electron microscopy allows examination of a large number of spines without serial sectioning (Fig. 1), and may prove useful for detailed quantitation.

Direct imaging of spines in living brain tissue is possible by ►two-photon excitation microscopy. With this fluorescence imaging technique, spine–head volume ($V_H$) can be determined by measurement of the total fluorescence intensity of the spine head. Spine–neck geometry can be similarly quantified from fluorescence images or can be determined by quantitative $Ca^{2+}$ imaging [2], and expressed as a parameter, spine–neck $Ca^{2+}$ conductance ($g_N$) (Fig. 2).

Spine–neck $Ca^{2+}$ conductance varies by a factor of up to 1,000, and is approximately proportional to the second power of spine-head volume in hippocampal pyramidal neurons. This nonlinear relation may be essential for the plasticity of small spines and the stability of large spines [2]. Similar head-neck relations are also apparent by electron microscopy (Fig. 1). Three typical types of spine – thin, stubby, and mushroom – have been distinguished (Fig. 2), but these types reflect three extremes of one continuous population of spines.

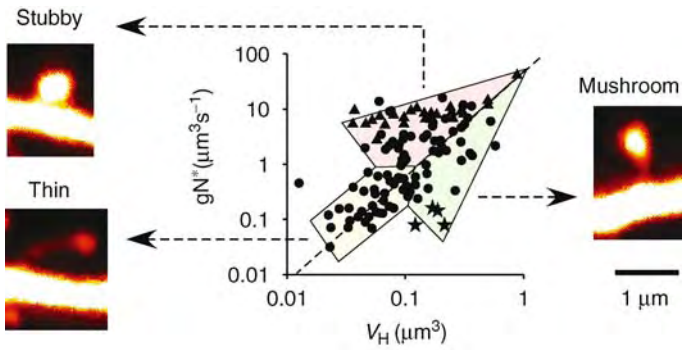
### Higher Level Structures

Spines are components of dendrites and of excitatory synapses. They are also one of the major constituents of the ►neuropile.

### Lower Level Components

Synaptic contact is made at the region of a spine at which a ►postsynaptic density (PSD) is identifiable by electron microscopy, at the cytoplasmic face of the plasma membrane. Most spines also contain a ►spine apparatus, a structure thought both to function as a $Ca^{2+}$ store and to house the machinery for protein synthesis. The spine apparatus is more prevalent in larger spines. Polyribosomes are also present in spine heads, where they are

Methodology is described in Microscopy Research and Technique 29(1994) 357–367.



**Spine, Morphological Change. Figure 2** Distribution of spine–head volume ($V_H$) and spine–neck $Ca^{2+}$ conductance ($g_N$*) for 115 spines, in four dendrites, in slice-culture preparations of rat hippocampal CA1 pyramidal cells. Values of $g_N$ were obtained from fluorescence images as described in [2]. The yellow, green, and red regions contain thin, mushroom, and stubby spines, respectively. Stars represent typical mushroom spines with long narrow necks and relatively large heads, and triangles typical stubby spines without a neck. Modified with permission from [2].

thought to participate in protein synthesis, and their prevalence is increased after tetanic stimulation.

## Structural Regulation

Spines are either formed from dendritic filopodia after establishment of a stable synapse or emerge directly from a dendritic shaft. The dynamics of transitions among spines with different structures has been partly understood. Rapid enlargement of spines with a small head is induced by tetanic stimulation of presynaptic fibers, and gives rise to long-term potentiation (LTP) [3]. Spine enlargement and LTP can be induced at the level of a single spine by direct stimulation of the spine, indicating that individual spines are able to serve as memory elements at the cellular level. In addition, large spines ($V_H$ of >0.1 $\mu m^3$) are resistant to long-lasting enlargement and LTP [3], and they can stably exist in living animals for months or more than a year [4,5], suggesting that large spines might represent physical traces of long-term memory.

Spines also change their shape sporadically with a time constant of minutes to hours, a process that can be detected as fluctuations in spine–head fluorescence and which possibly reflects treadmilling of actin. Indeed, many molecules that regulate the actin cytoskeleton affect spine structure [6]. Abnormal spine shape, or spine dysgenesis, is associated with various forms of mental retardation [7]. Spines are thus unusually numerous and tortuous in individuals with fragile X syndrome, the most frequent form of hereditary mental retardation. Many hormones, especially sex steroids, alter spine density.

## Higher Level Processes

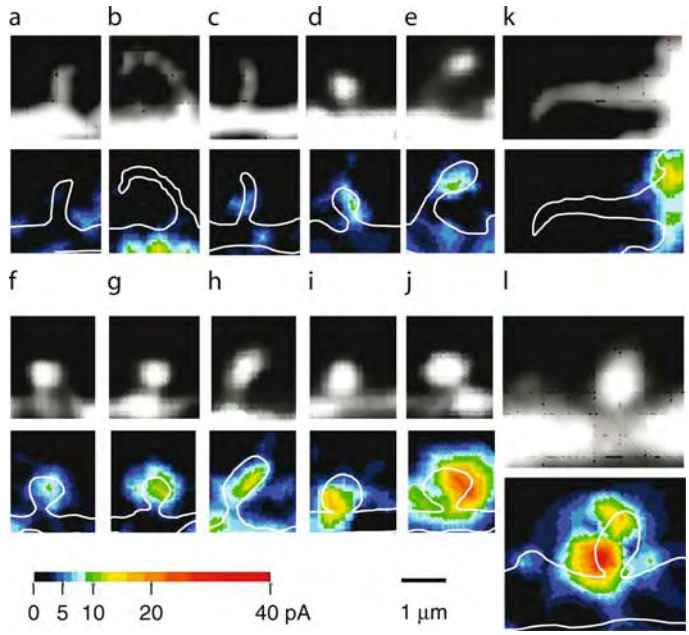
Spines are basic functional units of higher order brain activities, such as learning and memory as well as cognitive and executive processes. Spines are thus more prominent in higher animals and are absent from most invertebrate neurons. Spines are also present at extremely high density on the major projection neurons, which play a central role in mental functions, and are postsynaptic to most excitatory synaptic inputs. In addition, spine density and shape are affected by various environmental factors and are abnormal in individuals with various mental disorders. Spines also undergo extensive reorganization during the critical period of ocular dominance plasticity. Finally, spines detect coincidence of pre- and postsynaptic neuronal activities and respond with rapid structural and functional plasticity [3].

## Lower Level Processes

Spine structure underlies the major spine function, the sensing of glutamate released from presynaptic terminals. It is now possible to measure the function of individual spines by two-photon uncaging of a caged-glutamate compound [2, 3, 8]. This approach has revealed that expression of glutamate receptors sensitive to α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) in spines is approximately proportional to spine–head volume [8] and that these receptors are absent from filopodia (Fig. 3).

The abundance of glutamate receptors sensitive to *N*-methyl-D-aspartate (NMDA) is also greater in larger spines than in smaller ones. Whereas expression of NMDA receptors is significant even in small spines, however, that of AMPA receptors is not, suggesting that small spines form silent synapses [2]. Small spines are also preferential sites for LTP [3]. The differential distribution of NMDA and AMPA receptors in small spines may reflect the abundance of binding partners for NMDA receptors in PSDs and the dependence of AMPA receptor function on F-actin [6].

The spine neck is a critical determinant of $Ca^{2+}$ diffusion from the spine head into the dendritic shaft



**Spine, Morphological Change. Figure 3** Spine geometry and expression of functional AMPA receptors. Fluorescence images (*upper panels*) and glutamate-sensitivity maps (*lower panels*) are shown for various dendritic spines of CA1 pyramidal neurons in fresh hippocampal slices prepared from adult (a–k) or 9-day-old (l) rats. The fluorescence profiles were obtained from stacked images containing the respective spine. The glutamate-sensitivity maps are based on AMPA receptor-mediated current, the amplitude of which is pseudocolor coded as indicated. The maps were smoothed by linear interpolation. White lines indicate the contours of dendritic structures. Representative data from thin spines (a–e), mushroom spines (f–j, l), and filopodia (k) are shown. Reproduced with permission from [8].

during NMDA receptor-mediated responses [2]. Furthermore, increases in the concentration of $Ca^{2+}$ within spines are greater and more confined in those with a narrow neck. Given that the spine neck tends to be narrower in smaller spines (Fig. 2), increases in cytosolic $Ca^{2+}$ concentration are larger and more confined in such spines, whereas they are smaller and spread into the parental dendritic shaft in large spines. The spine neck may also restrict the movement of large structures such as the spine apparatus and polyribosomes. In contrast, the diameter of even the smallest spine necks is not sufficiently small to substantially affect the propagation of excitatory postsynaptic currents.

NMDA receptor-dependent $Ca^{2+}$ influx into the spine head induces enlargement of the head in a manner dependent on calmodulin and on actin polymerization [3]. The long-lasting phase of spine enlargement further requires the action of $Ca^{2+}$- and calmodulin-dependent protein kinase II. Spines also express metabotropic glutamate receptors and receptors for brain-derived neurotrophic factor (BDNF), which trigger the activation of various protein and lipid kinases (such as cyclic AMP-dependent protein kinase, protein kinase C, mitogen-activated protein kinase, phosphoinositide 3-kinase, and Src), protein phosphatases (such as calcineurin), and small GTPases (Ras, Rap, Rac, Rho) as well as stimulate protein synthesis. Such intracellular signaling is thought to alter spine morphology through regulation of the actin cytoskeleton as well as exo- and endocytosis. Spine molecules thus regulate spine structures and vice versa. The reciprocal relationships between spine molecules and structures may underlie the high stability of spines in the brain, and their characterization is important for an understanding of spine function at the molecular level.

## Process Regulation

### *LTP and Dendritic Spines*

LTP is induced at glutamatergic synapses on spines in an input-specific manner. In aspiny interneurons, however, LTP is either absent or spreads along dendrites [9]. Spines thus appear to support the induction and input specificity of LTP. Induction of LTP is input specific even at the level of the individual spine [3] as a result of the confined increase in cytosolic $Ca^{2+}$ concentration within the spine head. LTP is associated with spine enlargement and actin polymerization, which results in accumulation of scaffold proteins and AMPA receptors through lateral diffusion and exocytotic insertion into the spine membrane.

Given that spine–head volume is correlated with AMPA receptor expression in the steady state [8], long-lasting plasticity would be expected to lead to an alteration of spine structure. The extent of immediate structural change, however, may be variable, depending on the specific synapse and experimental conditions. Structural plasticities of spines include phenomena other than LTP, since LTP is mainly associated with enlargement of small spines into medium-sized spines [3]. Such plasticities include the emergence of new filopodia or spines, reflecting the generation of new connections, and the maturation of large spines, reflecting the formation of highly stable connections.

### Function

The reason why spines are necessary for the function and plasticity of synapses in the brain awaits further investigation. It has long been thought that the persistence of memory traces in a biological system requires their storage in a structural form [10]. If this is the case, then the structure and density of spines appear well suited for the rapid induction and maintenance of memory at the highest density, in a manner that satisfies Hebb's learning principle.

### Pathology

Abnormalities in spine density or morphology, which are associated with various mental disorders, may partly reflect abnormal neuronal activities [7]. Dendritic spines, however, may be the primary sites of diseases, since mutations in proteins expressed in spines are identified in certain types of mental retardation [7]. Spine dysfunction likely underlies a broader range of mental disorders, given that glutamatergic synaptic transmission is impaired in many such conditions, including schizophrenia.

Split-brain patients present with neurological pecularities yielding insights into the functional asymmetries between the two hemispheres.

►Corpus Callosum

## Split Rhythms

### Definition

A dissociation of circadian components induced by appropriate environmental conditions. In some species, exposure to constant light causes the usual 24 h activityrest cycle to dissociate into two components. These “morning” (M) and “evening” (E) components run at slightly different periods before coupling in a stable (antiphase) relationship. In hamsters induced to split, clock gene expression in the left and right Suprachiasmatic nucleus (SCN) assume an antiphase relationship as well. Related dissociations, which may not be mechanistically similar, may be induced by exposure to ultradian (much shorter than 24 h) light-dark cycles or to light-dark cycles with periods at the limits of entrainment for the organism. This latter type of dissociation may involve one oscillator that entrains to the light-dark cycle and another that is unable to entrain and therefore essentially free-runs.

►Circadian Rhythm

### Synonyms

Static posturography; Stabilography; Computerized stabilometry

### Definition

Stabilometry is the objective study of body sway during quiet standing, i.e., stance in the absence of any voluntary movements or external perturbations. Conventionally, the study focuses on the properties of body sway during upright standing, thus far primarily measured by means of force plates. Sometimes, upper body sway is studied in sitting postures.

### Purpose

Stabilometry aims at collecting information indicative of the steady-state functioning of the postural control system, and of its success in stabilizing the body against gravity, by examining the properties of measures, directly or indirectly related with ►postural sway.

### Principles

Stabilometry is a valid, objective and functional evaluation of the postural control system in its steady-state behavior [1]. Quiet, upright stance is the basic, representative posture that is traditionally investigated in stabilometry although a few studies concentrate on sitting postures.

During the test, the subject is asked to stand upright in a stationary environment where, depending on the protocol, one or more sensory afferences can be made unavailable or manipulated. Upright stance is inherently unstable. Small deviations from an upright body position result in a gravity-induced torque acting on the body, causing it to accelerate further away from the upright position. Many muscles become tonically and phasically active, in a largely automatic way, to generate appropriate, corrective torques to oppose the destabilizing torque due to gravity. As a result of such an active process, even when visual, somatosensory, and vestibular systems are all active, a standing individual will sway slightly. This sway will increase, as sensory input is distorted or removed, as it may happen, e.g., (i) when vision is not available or is sway-referenced, (ii) when the support surface is compliant or sway-referenced, and (iii) when vestibular information is distorted. Similarly, this sway will decrease, when (i) sensory input is augmented or reinforced, (ii) by repetitive balance training, (iii) by an artificial biofeedback device, or (iv) by threat of a fall.

Postural sway during quiet standing reflects this interplay between gravity destabilizing the body and actions by the postural control system to prevent a loss of balance, and can be modeled with an inverted pendulum model of the body [2]. The regulatory mechanisms underlying postural sway are not fully understood yet, and controversy remains regarding the organization of sensory and motor systems contributing to spontaneous sway.

Balance impairments caused by altered sensory, motor, or central nervous function related to such factors such as older age and pathology (e.g., cerebellar ataxia, peripheral neuropathy, Parkinson's disease) will be reflected in characteristic, altered characteristics of postural sway [3–4]. The influence of different factors on postural sway

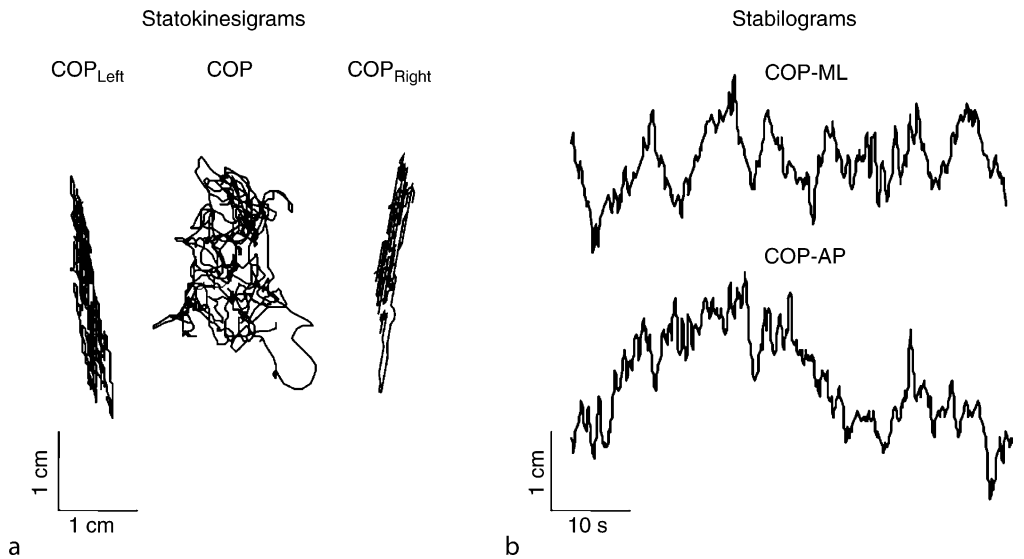
during quiet standing has been the focus of much clinical and basic scientific study.

Due to its complexity, the postural control system is challenging to measure with simple methods, although simple methods are needed, especially in clinical practice. Since a direct, multisegmental analysis of postural sway during stance may require complex kinematic trackers such as motion analysis systems, postural sway is most often described indirectly by the fluctuations of the ►center of pressure (COP) on the ground, measured with a force platform. By means of a set of mechano-electrical force transducers (strain gages or piezoelectric crystals), force platforms act as dynamometers and record the interaction between the feet and the ground, i.e., the ground-reaction, and the COP. Ground-reaction force and COP are related to postural sway, more precisely, to the motion of the body ►center of mass (COM), and consequently provide important insights into the process of controlling balance [2]. In the future, portable systems, based on miniaturized, inertial sensors (accelerometers, gyroscopes), may allow a direct, multisegmental analysis of body sway. Several studies are in progress to determine procedures to make measurement of sway with portable inertial sensors robust and valid [5].

The vast majority of studies in stabilometry have been limited to force plate studies using only one force platform. In that case, the COP reflects the net effect of the ankle muscles and the loading/unloading of each limb [2] as well as the movement of the COM of the entire body, and displays as a random-looking pattern when its antero-posterior (AP) coordinates are plotted against its medio-lateral (ML) coordinates. This plot is commonly referred to as statokinesigram (Fig. 1a). Alternatively, each COP coordinate can be represented as a function of time, to obtain the so-called stabilograms (Fig. 1b) [1].

If two force platforms are available, one for each foot, distinct left and right COP displacements can be measured (Fig. 1a) [2]. Since the ankle muscles are important controllers of the COP, the location of the COP under each foot is an outcome from concerted efforts of the ipsilateral, individual ankle muscles. Increasing plantarflexor activity (e.g., triceps surae, peroneii) moves the COP anteriorly; increasing dorsiflexor activity (e.g., tibialis anterior) moves the COP posteriorly. Increasing invertors' activity (e.g., triceps surae, tibialis anterior and posterior) moves the COP laterally; increasing evertors' activity (e.g., peroneii) moves the COP medially. Individual ankle muscle actions on the COP can be investigated through in-vitro studies [6] that demonstrated that the calf (plantarflexor group) is the most efficient COP controller in the anterior direction, while the tibialis anterior muscle and dorsiflexor group are the major COP controllers in the posterior direction. Two force platforms also disclose the lateral loading and unloading mechanism, and the consequent pressure modulation under each foot, controlled by the activity of the hip abductor/adductor muscles (e.g., tensor fascia latae, gluteus maximus, semimembranosus). In this case, the location of the total body COP either in the AP or ML directions can be computed by using Varignon's theorem that states that in equivalent force systems the sum of moments equals the moment of the resultant.

Several methods exist to describe postural sway using the COP statokinesigram and/or stabilograms. In general, measures that are most commonly used are



**Stabilometry. Figure 1** Representative quiet stance recordings through a force platform. (a) AP vs ML coordinates of the COP in presence of a two force platform set-up (COPleft, COPright) and resultant, whole-body COP. (b) Time series of ML and AP coordinates of whole-body COP.

S

those that describe statistical properties of the COP, treated as a stationary signal, in the time and frequency domain [7]. Time domain measures estimate a parameter associated with either the displacement (expressed in mm) or the velocity of the COP trace, and include parameters such as: mean distance from average COP position (mm), root mean square distance from average COP position (mm), total distance traveled by the COP (mm), peak-to-peak COP displacement (mm), mean velocity of the COP (mm/s), area of the 95% confidence circle or ellipse ($mm^2$), swept area ($mm^2/s$).

Frequency domain measures characterize the power spectral density of the COP, and include parameters as: total power ($mm^2$), power in selected bandwidths ($mm^2$), median frequency (Hz), 95% power frequency (Hz), centroidal frequency (Hz), frequency dispersion (dimensionless).

Many studies in force platform stabilometry characterized postural sway based on a single COP-based measure, but more recent studies usually include multiple measures [4,7]. Depending on the cause of the postural instability, velocity-related measures were often reported to separate stable postural control from reduced stability better than displacement-related measures [4,8]. No general rule of thumb is available, however, to select the best subset of measures needed in force platform stabilometry. Since many and varied sway measures exist, feature selection has to be preliminary performed to keep only independent measures and avoid redundancy, make statistical analyses stronger, and facilitate interpretation of the results.

The ideal set of measures to recommend for practical use should be minimally influenced by spurious sources of within- (e.g., non-stationarity, fatigue) and between-subject variability (e.g., anthropometry) that may peculiarly influence the characteristics of the COP. In addition, selected measures should be sufficiently sensitive to changes in hypothesized physiological determinants of postural sway and hence able to identify actual, significant changes in posture control across patients' or treatments' groups or across experimental conditions [9]. Several recent studies, using different methodologies, have recommended and justify different subsets of three to four COP-based measures, e.g., see [8].

Interestingly, COP displacements during quiet stance display a fractal behavior. This important property, common to many physiological processes, can be expressed in terms of statistical self-similarity. Such self-similarity implies that there is a scaling relationship describing how the measured value of a statistical property depends on the scale in which it is measured. The simplest scaling relationship determined by self-similarity has a power law form, leading to a straight line on log–log plots.

In the analysis of COP experimental data, the existence of scaling comes to light, for example, if the variance of the displacements (i.e., the distances between consecutive points of the statokinesigram) is examined over different time scales. One main implication of fractality is that scaling functions that describe how the values change with the resolution tells more about the data than the value of the measurement at any one resolution (in particular, at the higher resolution as it is commonly done by the summary statistic scores, working with the original sampled time series). For this reason, to obtain more significant parameters about the postural control system, techniques postulating the time-scale dependence of COP statistical properties have been proposed [10]. These techniques show that COP fluctuations have a structure that is dependent upon the time-scale of observation and not simply random. This result was interpreted by proposing different modes of postural control taking place over different periods of time and opened the way to more sophisticated tools in postural sway analysis.

## Advantages and Disadvantages

Platform stabilometry is a simple and easy tool to objectively investigate the function of the postural control system in its steady-state behavior. To date, stabilometry undoubtedly suffers, however, from several limiting factors including (i) the absence of a definite "normal pattern"; (ii) the lack of standardization in the measurement protocols; (iii) the large number of highly coupled variables that are computed from the force platform recordings.

Most COP-based measures have in common a medium to large variability, both between- and within-subjects, and this may be a limiting factor when wishing to determine whether a postural performance is abnormal or whether it is sensitive to change from a treatment or a therapy [1,9]. The inherent variability of such measures in normal subjects has been the object of several studies. Within-subject variability has been partially explained by a learning effect that leads to an optimization of the energy expenditure by means of a progressive reduction in body sway over repeated trials. The large between-subject differences prevents defining normative values for stabilometric parameters [1]. This is a major restriction of stabilometry, which limits its routine use in clinical practice or as a first-level examination of postural control. For this reason, it is important to cope with all the potential sources of spurious variability that may mask or overwhelm control-related information. To this aim, first, a significant role can be ascribed to inconsistencies in the measurement procedure (between experimental sessions within the same lab and, more so, between different laboratories) including, e.g., reproducibility of the experimental protocol such as foot placement and duration of testing, environmental conditions, random errors, and signal processing. A second source of

variability is related to the intrinsic differences between subjects in terms of their biomechanics. Subject morphology, together with joints and muscle function, has been identified, in a systems approach, as the main biomechanical factors involved in balance control. Body size and foot placement are known to influence postural stability and their impact on COP-based measures can be at least partly removed through normalization [9].

## Stain

### Definition

A stain is any number of chemical compounds which when applied to tissue appropriately will color cellular components. Thus details of particular cellular structure can be studied under a microscope. A variety of stains are used to study nerve tissue. Some, such as Nissl stains, mark cytoplasmic detail and show cell bodies. Others, such as the Weigert stains, mark the myelin and show myelinated axons. Still others, such as Nauta silver stains, show axons and their terminals, while Golgi stains show a few neurons in their entirety.

## Staircase Method

### Definition

A psychophysical procedure by which the stimulus intensity is changed according to an observer's response to bracket the threshold; an interactive variant of the method of limits.

►Psychophysics

## Standing Wave

### Definition

A periodic wave having a fixed distribution in space that is the result of interference. Such waves are characterized by the existence of nodes and antinodes that are fixed in space.

►Acoustics

## Stapedius Muscle

### Definition

One of two muscles in the middle ear of mammals that is involved in the middle ear muscle reflex. (The other middle ear muscle is the tensor tympani muscle.) The stapedius muscle arises from the auditory tube and inserts onto the stapes, or stirrup, which is the middle ear bone directly connected to the round window of the inner ear. The stapedius muscle is innervated by the facial nerve. Its contractions dampen sound-induced oscillations of middle ear bones and reduce sound amplitude, thus protecting the ear from intense sound signals.

## Definition

The point in time at which a sound wave starts relative to the period of the sound wave, expressed in degrees or radians.

►Acoustics

# Startle Response

Joseph R. Fetcho
Department of Neurobiology and Behavior, Cornell University, Ithaca, NY, USA

## Synonyms

Escape behavior

## Definition

Startle responses are rapid movements that occur very quickly following an abrupt, unexpected, strong sensory stimulus, such as a loud sound produced by a slamming door. Startle or escape responses are shared by almost all animals, including both invertebrates and vertebrates [1]. In many cases, they are thought to serve protective functions such as avoiding the attack of predators. The form of the response varies across species. In humans, it usually consists of closing of the eyes and a hunching of the head and body. Extension of the legs in some mammals can lead to a jumping movement that might serve to move the animal away from an attacking predator. In fish, the startle (escape) response involves a rapid bend of the body that turns the fish away from the stimulus. This is usually followed by rapid swimming to avoid capture by a potential predator. In invertebrates, startle might consist of a rapid jump followed by flight in a fly, or a tail flip in a crayfish.

## Characteristics

### Quantitative Description

Perhaps the most characteristic feature of a startle response is the very short time between the stimulus and the start of the movement. This occurs in about 14 milliseconds (ms) in humans, 10 ms in rats and as little as 5 ms in larval fish [1]. Typically, the magnitude of the response is measured as the force or amplitude of the movement. In mammals, such as rats, this is accomplished by measuring the force generated by limb movements in specialized cages fitted with accelerometers. In fish, the angular velocity and magnitude of the bending of the body are measured using high-speed imaging because the movements are very fast. Startle responses can vary in magnitude depending upon the strength of the stimulus and its source, as well as the history of exposure to other stimuli. For example, responses are increased following induction of fearful states and are reduced in amplitude following prior exposure to a weak stimulus that does not elicit a startle response [2].

### Higher Level Structures

Startle responses are typically produced by relatively large, fast conducting neurons. These are the giant neurons in invertebrate systems such as flies, crayfish, and squid. In vertebrates, the cell bodies of the giant neurons are in the hindbrain ►reticular formation and their axons have outputs in the brain and spinal cord. There are relatively few of these neurons in fishes and amphibians, where they include the well- studied giant ►Mauthner cells [3]. A larger number of neurons located in the ►caudal pontine reticular nucleus in the hindbrain mediates the startle response in mammals [4]. Among vertebrates, the pathways for sound elicited startle responses are strikingly similar, with very short pathways from the ear to giant neurons in the hindbrain,

and direct pathways from hindbrain to motoneurons and interneurons in the spinal cord.

### Lower Level Components

Startle or escape responses typically engage local circuits controlling a variety of muscle groups, including muscles in the head responsible for eye blinks and jaw clenching, as well as axial (trunk) and limb muscles. Some of the networks for these circuits have been well described in fishes and invertebrates where the giant neurons connect directly to motoneurons, as well as to excitatory interneurons that drive motoneurons and inhibitory interneurons that control antagonistic muscle groups [5,6]. Evidence from mammals indicates similar patterns of output to local motor circuits in the head and spinal cord [4].

### Structural Regulation

The patterns of recruitment of the giant hindbrain neurons vary in conjunction with variation of the behavior. This is best documented in fishes, where the form of the escape response varies depending upon the source of the sensory stimulus that elicits it [7]. This variation is associated with different patterns of activation of the giant neurons in the hindbrain [8]. The gradations of the magnitude of escape responses in mammals are also likely to be a consequence of changing patterns of recruitment of hindbrain neurons, because reductions of the number of neurons in lesioning experiments is associated with a reduction in response amplitude [9].

### Higher Level Processes

The rapid nature of the startle response is reflected in a circuit designed for speed. There are only a few neurons in the path from sensory input to initial motor output – four in the pathway for auditory startle in fish and five in mammals. These pathways generally contain ►electrical synapses, which are associated with speed and synchronous activation of circuits. The giant neurons in the hindbrain of vertebrates also have some of the largest and fastest conducting axons in the central nervous system, designed to quickly relay the sensory signals to the spinal cord to produce a motor response.

### Lower Level Processes

The rapid, powerful drive to the spinal cord is associated with a large pulse of activation in muscles that results from a synchronous activation of motoneurons. This may be important for overwhelming any ongoing muscle activity that might interfere with initiation of the startle or escape response.

### Process Regulation

The magnitude of the startle/escape responses changes in conjunction with prior experience. Most notably, the response shows simple forms of learning such as ►habituation and ►sensitization [2]. Cellular data indicate that there is plasticity of synaptic connections onto the giant neurons in the form of ►long term potentiation and ►long term depression, which might underlie the simple forms of learning associated with the response [3]. Innervation of giant neurons by ►serotonergic and dopaminergic systems is consistent with evidence that changing levels of serotonin and dopamine can alter the startle response, with serotonin usually attenuating responses and dopamine elevating them [2]. Importantly, the startle response shows ►prepulse inhibition, with a reduced startle response to a strong stimulus when it follows a stimulus too weak to elicit a startle. Prepulse inhibition occurs broadly among species. In invertebrates, a neuron that produces it by ►presynaptic inhibition of sensory neurons has recently been identified [10]. As many neuropsychiatric diseases are associated with disruption of serotonergic and dopaminergic modulatory systems or with changes in prepulse inhibition, the startle system is becoming a model for identifying genes that might underlie diseases of the brain [11].

## Function

Startle or escape responses appear to serve a protective function that is most obvious in invertebrate animals and aquatic vertebrates, where the circuits are recruited in response to predatory attacks. A similar anti-predatory role might occur in quadupedal mammals. In humans, the function is less obvious, although the tensing of the body and the closing of the eyes in response to a loud sound might serve to protect the body from possible injury, as these sounds might naturally occur in hazardous situations produced by breaking or falling objects such as rocks and branches.

## Pathology

Abnormal prepulse inhibition of the startle response is associated with neurological disorders including ►schizophrenia, obsessive-compulsive disorder, and ►Huntingtons disease [11]. Some of these deficits are thought to result from problems in the control of the flow of sensory information through central circuits to motor output – a process called sensorimotor gating. This has led to studies of deficits in prepulse inhibition of startle in genetic models such as mice, as a tool to identify the genetic basis of neuropsychiatric diseases [11]. Mutations in receptors and transporters involved in serotonergic and dopaminergic transmission alter prepulse inhibition of the startle response and also contribute to psychiatric disorders. Exaggerated startle responses and a lack of habituation are associated with a disorder called hyperekplexia, or familial startle disease, which occurs as a consequence of a mutation

in the alpha subunit of the glycine receptor [12]. This is consistent with the known important role of inhibitory pathways in controlling startle responses and in sensorimotor gating more generally.

### Therapy

Drugs that are known to alter serotonergic and dopaminergic transmission also have effects on startle behavior. The known circuitry and reproducible responses of the startle behavior, make it a good system for testing the effects of drugs that might serve to alleviate the neuropsychiatric disorders associated with changes in startle pathways [13]. Drugs that improve deficits in startle responses in animals or humans might also alleviate the more severe neuropsychiatric symptoms associated with these deficits.

# State

### Definition

Particulars can be in different states. "State" can mean a state token, e.g. a concrete occurrence of molecular motion in a body or of a neural activity in a person's brain. Alternatively, "state" can mean a state type. This is either a property that can be shared by several things or persons, such as being hot or being in pain, or a kind of state tokens, such as a certain kind of molecular motion or neural activity. In control theory, a state is defined by a collection of variables that describes system behavior. Present state, together with the future inputs to the system, uniquely determines future states.

►Argument
►Control
►Logic

# State, Functional

### Definition

A functional state is a higher-order property of a particular system: the property of being in some inner state or other that plays a certain functional role, i.e. that bears certain (causal) relations to outer affections of the system (inputs), its outer behavior (outputs), and to other inner states. Different systems can be in the same functional state, although the inner states that play the functional role in question radically differ in nature.

►Argument
►Logic

# State, Mental

### Definition

A mental state is a state of the kind that is typically attributed by mental predicates such as "is in pain" or "believes that it is raining." In a narrow sense, only

long-term mental attitudes like beliefs (Belief) or desires are states. But mental events (sensations, feelings, thoughts) (Consciousness) are called states, too. Mental states may be physical states (identity theory), functional states (ontological functionalism), or sui generis (dualism).

►Argument
►Logic

## State, Physical

### Definition

States that can be attributed by a detailed description in the language of the physical sciences are physical states. If a state is of the same kind as these, it counts as physical even if that particular state cannot be described by current science. In a very narrow sense, only states describable by physics are physical. When contrasted with mental states, "physical state" often means "a state that is either physical or functional or a mixture thereof.

►Argument
►Logic
►State, Functional

## State, Representational

### Definition

Postulating representational states in order to account for a certain psychological achievement carries two main commitments: different representational states can occur independently of each other, and only their contents and functional roles, but not their intrinsic natures are of mental significance. It is often further assumed that such states form sentencelike or image-like complexes and that they are related to their contents one by one rather than holistically.

►Argument
►Logic
►State, Functional

## State Estimation

### Definition

The process of estimating the plant state from sensory feedback and knowledge of the plant dynamics and effector activations.

►Neural Networks for Control

## State of Activation

### Definition

Theory that states that the modulation of GABAergic synaptic connections between nucleus tractus solitarii (NTS) and dorsal motor nucleus of the vagus (DMV) is controlled by the levels of cAMP (cyclic AMP) in the NTS terminals. In "resting" conditions, the GABAergic synapse is unresponsive to neuromodulators, when the levels of cAMP are increased by hormones released following a meal, the synaptic connection is "primed" and available to modulation.

►Cyclic AMP
►Nucleus Tractus Solitarii
►Dorsal Motor Nucleus of the Vagus (DMV)
►GABA

## State of Affairs

### Definition

A situation, something that might be the case, if a state of affairs obtains it becomes a fact.

►Possible World

## State Space

### Definition

The space, which contains all the possible states of a system, e.g. all the possible values of its variables.

►Signals and Systems

## State Variables (SVs)

### Definition

Express relationships inherent in natural laws (e.g., forces and kinematic variables in Newton's laws of motion); any variables that cannot be changed independently of SVs (e.g., in the intact neuromuscular system, stiffness, damping, and the magnitude of muscle activation since they are coupled to changes in muscle force, a SV); constrained by natural laws, can only be changed indirectly by neural control levels, by regulating control variables.

►Equilibrium Point Control

## Static

### Definition

Static implies that there are no changes over time (*i.e.*, a steady-state has been reached). For skeletal muscle, static refers to the state when no length or force changes are occurring.

## Static Air Pressure

### Definition

The air pressure at a point in space that would exist in the absence of sound waves.

►Acoustics

## Static and Dynamic Sensitivity of Sensory Receptors

### Definition

Static and dynamic sensitivity are qualitative terms aimed to characterize the sensory receptor response to external stimuli. Static sensitivity describes the capacity for the receptor to signal the persistence of a (constant) stimulus, for some time after stimulus onset. Dynamic sensitivity describes the capacity for the receptor to signal when the stimulus intensity changes over time.

►Autonomic Control of Sensory Receptors
►Sensory Systems

## Static Posturography

►Stabilometry

## Static (Steady-State) Stiffness

### Definition

The proportionality constant that relates the change in force (or torque), produced by displacement from an initial stationary position to a final stationary position, to the displacement.

►Impedance Control

## Statics

Marcelo Epstein
Schulich School of Engineering, University of Calgary, Calgary, AB, Canada

### Definition

Statics is the science of equilibrium.

### Description of the Theory

The fundamental equations of ►mechanics (q.v.) are differential equations, whose solution determines the motion of a mechanical system. A mechanical system is said to be in *equilibrium* if there exists an inertial frame for which the motion vanishes identically. In all other inertial frames, therefore, the motion can at most consist of a uniform translation, namely, each and every particle of the system moves with a constant ►velocity, equal

for all particles. A useful subdivision of classical mechanics from this point of view is into *statics* (the science of equilibrium) and *dynamics* (the science of motion). Although the first is clearly a particular case of the second, it is useful sometimes to regard it as an independent discipline. This point of view not only facilitates the treatment for those many applications in which motion is not of interest, but it also provides an intuitive basis to regard, somewhat paradoxically, dynamics as a particular case of statics, whereby the so-called *forces of inertia* are brought to bear.

The concept of equilibrium applies equally well to classical mechanics (q.v.) and to continuum mechanics (q.v.). This article will however, concentrate on the statics of a rigid body, leaving for the article on the ▶principle of virtual work (q.v.) a re-consideration of statics from a more general point of view. The first task is to obtain a set of necessary conditions for the equilibrium of a rigid body. Since, by definition, equilibrium can be regarded as the absence of motion (in an inertial frame), a direct application of Eqs. 6 and 7 of ▶Newtonian mechanics (q.v.) yields the following two vectorial *equilibrium equations*:

$$\mathbf{F}^{ext} = \mathbf{0}, \tag{1}$$

and

$$\mathbf{M}_0^{ext} = \mathbf{0}. \tag{2}$$

In words, a necessary condition for the equilibrium of a rigid body is that the sum of all the external forces and the sum of all the moments of the external forces with respect to a fixed point be equal to zero. Notice that, while Eq. 1 guarantees that the center of mass of the system will move at a constant velocity, the satisfaction of Eq. 2 is not sufficient to guarantee that the rigid body will be at rest from the rotational point of view. It is only for this reason that these equations are not also sufficient for equilibrium. To guarantee equilibrium, at some instant of time the angular velocity vector must vanish. From the point of view of statics as an independent discipline, however, these two vectorial equations are considered as the very definition of equilibrium.

Considering a system of rigid bodies interconnected perhaps by means of joints (such as the skeletal system), it is possible to mentally split this system into its component members (each bone, say) and to draw a *free-body diagram* of each member. This diagram must include not only the external forces directly applied to the member (such as weight, ground reaction, etc.), but also the forces transmitted by the other members from which it has been detached (joint forces and muscle forces transmitted through tendons and ligaments, for example). It is to the totality of these forces that Eqs. 1 and 2 are to be applied, resulting in a system of six *algebraic* equations for each member, involving just the forces and the geometry of the system. A system is called *statically determinate* if the number of equations obtained in this way is exactly equal to the number of the statical unknown quantities of the problem. These statical unknowns usually represent the forces of interaction (such as muscle and joint forces and ground reaction forces). If the number of statical unknown quantities is larger than the number of equations of statics, the system is said to be *statically indeterminate* and its solution will in general fall into the domain of continuum mechanics (q.v.) or require the incorporation of extra information (conveying, for example, the assumed *force sharing* conditions of agonistic muscles). Cases in which the number of equations of statics is larger than the number of statical unknown quantities (*statical* under-determinacy) may also occur, indicating that there are extra conditions to be satisfied between the geometry and the applied forces. To illustrate the various situations just described, the simple example of a two-bone planar system may suffice (e.g., the femur and the tibia). The planarity of the system manifests itself in the assumption that all forces involved belong to the plane in which the system is assumed to be constrained to move. Assume that the bones are rigid and that they are connected by an ideal frictionless hinge (the knee, say). Assume, moreover, that one of the bones is hinged at the other end to a fixed joint (e.g., a fixed hip). Assuming the plane of the system to be identified with an $x$-$y$ coordinate plane, Eq. 1 reduces, for each bone, to two scalar equations (the sum of the $x$- and $y$- components of the external forces, respectively, equal to zero), while Eq. 2 becomes a single scalar equation (the sum of the $z$-components of the moments equal to zero), the other component equations vanishing trivially by the assumed planarity of the system. There is thus a total of six equations of statics, three for each member. Considering first the case in which there are no muscles involved and the system is subjected just to its own weight (hanging, as it were, as a skeleton in the closet), the unknown quantities are: the angular deviations of each bone from the vertical position (two quantities), the reaction force at the hip (two quantities) and the interaction force at the knee (two quantities). When drawing the free-body diagrams, the interaction force at the knee will appear in each of the diagrams, with opposite senses, as required by Newton's third law, the so-called principle of action and reaction (see the article on Newtonian mechanics). The system is, therefore, statically under-determinate, indicating that the geometry of the system is to be determined as part of the solution. It has, in fact, two solutions, only one of which (the one corresponding to the bones lying vertically directly *under* the hip) is stable. Assume now that the bones are connected by a single muscle, which is assumed to be perfectly articulated at the points of insertion. For simplicity, also assume that the muscle is of a known length (say, when fully activated). There is now a situation in which the bone-muscle system forms roughly the shape of the letter *A*, hanging from the hip. Again, the

system is statically under-determined, although less so than before. The number of statical unknowns has increased by one (the internal force in the muscle), while the number of geometrical unknowns has decreased by one. Suppose now that the free end of the tibia rests, in a frictionless manner, on the ground, thus eliciting a vertical reaction (assuming the ground to be below the hip at a distance strictly smaller than the sum of the lengths of the bones). The system becomes statically determined, its geometry being completely prescribed by the data. (There are actually four geometric ►configurations compatible with the given data). Suppose now that the free end of the tibia is anchored to the ground, by means of an ideal hinge, thus requiring both a horizontal and a vertical component of the ground reaction. The system becomes statically indeterminate. The statical indeterminacy can be exacerbated by adding more muscles in parallel with the one already in place.

As mentioned above, the idea of free-body diagram can be also applied beyond the domain of statics to derive the equations of motion of a system by incorporating the forces of inertia. This point of view, sometimes called ►*D'Alembert's principle*, requires that the right-hand sides of Eqs. 6 and 7 of Newtonian mechanics (q.v.) be regarded as some kind of negative external forces and moments. Defining, therefore, $\mathbf{F}^{ext}_{inertia} = -\dot{\mathbf{P}}$ and $\mathbf{M}^{ext}_{0,inertia} = -\dot{\mathbf{H}}_{\mathbf{0}}$, and incorporating these new "external" forces into our free-body diagrams, statics Eqs. 1 and 2 may be applied to the formulation of the dynamical problem.

In the case of continuum mechanics (q.v.), the problem of continuum statics consists of solving the system of partial differential equations obtained from the ►balance laws (q.v.) when all the time-derivatives are regarded as zero. In a more restricted sense, however, continuum statics applies mainly to the purely mechanical aspects, leaving thermodynamic considerations aside. Thus, a problem of continuum statics will usually involve only the balances of momentum and of ►angular momentum and a constitutive equation for the ►stress in terms of kinematical quantities only (see the articles ►Kinematics of Deformation and ►Constitutive Theory), while temperature, ►heat flux and ►internal energy are not taken into consideration.

An alternative formulation of statics can be obtained by means of the principle of virtual work (q.v.).

Serious condition of prolonged and repetitive ►seizures that tend to be self-sustaining. The definition of prolonged has varied from 5 to 30 min. There are various clinical forms: subtle SE, impending SE, established SE, non-convulsive SE, and generalized convulsive SE. The transition from isolated seizures to SE probably involves changes in ►$GABA_A$ (►γ-aminobutyric acid) receptors, ►AMPA (►α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) and ►NMDA (N-methyl-D-aspartic acid) receptors, as well as changes in neuropeptides. These changes may explain the hyperexcitability of cortical neurons, the tendency of seizures to become self-sustaining, and the development of resistance to antiepileptic drugs.

►Anticonvulsants

## Steady (also Equilibrium) State

### Definition

State of the system comprised of the organism and the environment, when neurons influencing the motor

outcome generate stationary (tonic) activity or remain silent, all torques and forces including those resulting from the interaction of the organism with the environment are balanced and do not change, and the body and its segments cease to move; may be changed by external forces or control variables causing motor actions.

►Equilibrium Point Control

## Stellate Cell

### Definition

Multipolar neuron whose dendrites project in all directions. Also used to describe multipolar neurons with less uniform dendritic fields.

## Stellate Cell in Cochlear Nucleus

### Definition

Neurons that occupy all parts the ventral cochlear nucleus, receive auditory nerve terminals in their dendrites, and project to the inferior colliculus or to the cochlear nucleus on the other side. They may have different functional roles depending on their targets.

►Cochlear Nucleus

## Stem Cell

### Definition

Immature undifferentiated cell endowed with endless capacities of self-renewal, i.e., to reproduce itself identically, and the ability to generate multiple mature cell types. It can be produced both during the embryonic development and in the adult age. Whereas embryonic stem cells can give rise to virtually all the cell types in the body, adult stem cells only generate a limited number of cell types depending on the tissue from which they are originated.

For instance, stem cells residing in the subventricular zone of the mammalian brain can be isolated and cultured. One single stem cell can proliferate to form a spherical aggregate of cells called a neurosphere containing both stem and progenitor cells. Plated onto an adherent support, cells differentiate into neurons, astrocytes and oligodendrocytes. Stem cells are, therein, multipotent cells as they produce a wide range of cell type.

Moreover, the stock of multipotent stem cells is maintained during the lifespan of the organism. According to their capacities, stem cell therapies are under investigation as they could replace dead cells and may provide successful cures for neurodegenerative and demyelinating diseases, heart failure, spinal cord injuries, among others.

►Adult Neurogenesis
►Neural Development
►Neurogenesis and Inflammation

## Stem Cell Transplantation

### Definition

Medical procedure in the field of hematology, oncology or regenerative medicine that involves transplantation of stem cells of different origins (e.g., neural stem cells, hematopoietic stem cells, mesenchymal stem cells, cord blood stem cells, etc.). It is most often performed on people with diseases of the blood or bone marrow, certain types of cancer or diseases of the central nervous system [e.g., multiple sclerosis (MS), Parkinson disease (PD), Huntington's disease (HD), etc.]. Transplanted stem cells are usually administered either locally (e.g., intraparenchymally), intravenously or intrathecally (e.g., trough the cerebrospinal fluid circulation). The main aims of the procedure are either the repopulation of the host bone marrow and the production of new blood cells (e.g., in the case of hematopoietic vs. cord blood stem cell transplantation), the replacement of lost vs. injured neural cells (e.g., in the case of neural stem cell transplantation) or the induction of peripheral immune tolerance (e.g., in the case of mesenchymal and neural stem cell transplantation).

## Stepping Strategy

### Definition
A change in support reaction to postural perturbation in which one or more rapid stepping movements are used to restore equilibrium.

►Postural Strategies

## Step Response

### Definition
The output of a system when a Heaviside (step) function is input into it.

►Signals and Systems

## Stereocilia of Vestibular Hair Cell

### Definition
Cilia projecting from the apical surface of the receptor hair cell. The cilia are connected to each other by small actin filaments and vary in stiffness. Stereocilia deflection leads to mechanoelectrical transduction in the kinocilium.

►Peripheral Vestibular Apparatus

## Stereognosis

### Definition
The ability to perceive the properties of an object by touch.

►Active Touch
►Haptics
►Processing of Tactile Stimuli

## Stereogram

### Definition
A set of objects seen by both eyes such that their fusion results in binocular disparity detection and stereoscopic vision.

►Binocular Vision

## Stereopsis

### Definition
The combination of image information from left and right eyes via binocular disparity provides the basis for stereoscopic depth perception.

►Binocular Vision

## Stereoscopic Acuity

### Definition
►Binocular Vision

## Stereotaxy

### Definition

Stereotaxy is a method for locating deep brain structures that can be reached from the surface with the use of electrodes or other probes. The probes can them lesion or electrically stimulate the target region or inject a drug or tracer. Usually a stereotaxic instrument is attached to the skull and deep structures are reached with the use of stereotaxic brain atlases prepared with standard coordinates based on skull landmarks and deep midline structures seen in scans of different types (e.g., X-ray or Magnetic Resonance Images).

## Steroid Hormones

►Neuroendocrinological Drugs

## STG

►Stomatogastric Ganglion

## Stiff-man Syndrome

### Definition

Uncommon disease consisting of several forms, with the severity of evolution differing in each individual case. It is characterized by symmetrical muscle ►rigidity and painful ►spasms of the lumbar paraspinal, abdominal, and occasionally proximal leg muscles, which often lead to skeletal deformity (e.g., lumbar hyperlordosis). There is continuous motor unit activity with abnormal exteroceptive reflexes. Variants may involve one limb only (stiff leg syndrome), and other symptoms and signs such as eye movement disturbances, ►ataxia, or ►Babinski sign, or concur with malignant disease. Antineuronal autoimmunity (against glutamic acid decarboxylase, GAD) and accompanying autoimmune diseases are characteristic features. Patients remain ambulant.

►Babinski Sign

## Stiffness

### Definition

The strict definition in physics is: change of force per unit change of length, or the slope of the force-length curve of a structure (df/dl). In motor control, the term characterizes the ability of the neuromuscular system to resist deviations from an equilibrium or current position elicited by external perturbations; required, together with damping, for stability of posture and movement; the ratio of the change in the static values of forces (torques) to a small ("infinitesimal") change in position elicited by an external load provided that control variables remain the same; measurements are comparatively easy for steady states of the system but are unreliable for transitional states (e.g. during movements) because of the necessity to extrapolate dynamic muscle forces and torques to static values, delays in the position-dependent muscle force regulation, and changes in control variables underlying active movements.

## Stimulant Drugs

►Stimulants

## Stimulants

Stephen J. Kish
Human Neurochemical Pathology Laboratory, Centre for Addiction and Mental Health, Toronto, ON, Canada

### Synonyms

Psychostimulants; Stimulant drugs; Analeptics; Excitants; Activators; Energizers; Awakening agents; Tonics

## Definition

Stimulants are chemical substances that temporarily activate the nervous system. In common usage, stimulants are generally understood as chemicals that increase activity of the ►central nervous system (i.e. psychostimulants) although such substances may also activate the ►sympathetic nervous system. The temporary effects of stimulants can include increased ►alertness, wakefulness, a feeling of well-being, euphoria, and increased ►heart rate and ►blood pressure. The substances may be derived from natural products (e.g. caffeine from the coffee plant) or can be synthesized (►methamphetamine). Stimulants are used both for therapeutic and recreational purposes.

## Characteristics

### Examples of Stimulants

The Table 1 provides representative examples of common stimulants used by humans.

### Overview: What We Know and Do Not Know About Stimulants

This essay focuses to the extent possible on stimulant actions in the human, as it is the human stimulant user, rather than the experimental animal, that can best report on many of the key effects of the drugs. Good information is available on the acute (temporary) behavioural effects of stimulants in humans. However, there is much uncertainty regarding mechanisms that explain their behavioural effects.

**Stimulants. Table 1** Examples of stimulant drugs used by humans

| Classical stimulant drugs | "Atypical" stimulant drugs |
|---|---|
| Amphetamine and structurally related compounds | Caffeine |
| | Modafinil |
| D-amphetamine | |
| methamphetamine | |
| methylenedioxymethamphetamine (mdma, ecstasy) | |
| methylenedioxyamphetamine (mda, "love drug") | |
| phentermine | |
| ephedrine | |
| cathionine | |
| Fenfluramine | |
| Nicotine | |
| Cocaine | |
| Methylphenidate (Ritalin) | |

Stimulant drugs known or suspected to have a major action as monoamine neurotransmitter releasers are **boldened**. Stimulants having a major action as monoamine neurotransmitter transporter inhibitors are *italicized*. Caffeine and modafinil are listed as "atypical" stimulants as the primary mechanism of action of some of the key acute effects of the drugs is probably different from that of the classical stimulants (caffeine: adenosine receptor antagonism) or is unknown (modafinil).

### Acute Behavioural Effects

The typical acute (minutes to hours) effects of a low to moderate dose of a stimulant drug in a normal human include feelings of ►alertness, wakefulness, energy, well-being (euphoria at higher doses), and suppression of appetite. As a consequence, stimulants have been used to improve concentration and attention, counteract fatigue and excessive sleepiness (e.g. in ►narcolepsy), cause feelings of pleasure, and induce weight loss. Many stimulants also activate the cardiovascular system (cause increased ►heart rate and ►blood pressure).

The ►central and ►sympathetic nervous system effects are typically observed to some degree with all of the classical stimulant drugs with the differences in drug intensity and duration explained by drug pharmacokinetic properties, route of administration characteristic of the drug (e.g. oral vs. inhalation), and probably, drug maximal response. Unlike the classical stimulants (e.g. ►methamphetamine), the atypical stimulant modafinil can induce wakefulness with no or little accompanying activation of the cardiovascular system (►Nootropic Drugs).

In addition to the acute stimulant effects described above, one of the amphetamine derivatives, mdma (►ecstasy), is claimed by many stimulant users to promote feelings of openness, sociability, and talkativeness (and possibly empathy) to a greater extent than that caused by the parent drug ►methamphetamine, although this has yet to be verified.

### Chronic Behavioural Effects Following Repeated Exposure

It is generally assumed from animal findings that partial ►tolerance will develop in the human to some or perhaps all of the acute behavioural effects of stimulant drugs following repeated exposure – but this has been somewhat difficult to prove in humans (►Tolerance and Dependence). The question of ►tolerance is best addressed by prospective studies of chronic drug exposure in previously drug-naïve humans. However, for many of the representative stimulants (e.g. ►methamphetamine, ►cocaine), data from such prospective studies are still too limited [1] because of the ethical problem of exposing humans repeatedly to drugs that might cause harm.

Findings from chronic stimulant users suggest that partial ►tolerance to some of the effects of stimulant drugs (e.g. drug liking, cardiovascular activation) most likely develops following repeated exposure to moderate to heavy stimulant doses, especially during a drug "binge" characterized by rapid dose escalation.

However, the extent to which such ►tolerance carries over to the next drug use that might occur a week or two later is still unclear. In the case of ►ecstasy, many users report some persistent (weeks to months or longer after last use) tolerance to the pleasurable effects of the drug with repeated drug use. This probably represents a combination of a true ►tolerance and some decrease in novelty of the drug experience.

Animal findings indicate convincingly that repeated intermittent doses of stimulant drugs can induce an *increase* in ►locomotion as compared with that produced by the first exposure to the drug. However, it is still quite uncertain [2] whether ►sensitization (reverse ►tolerance) to any of the behavioural effects of stimulant drugs reliably occurs in the human (possible examples being emerging ►psychosis and stereotyped movements in ►methamphetamine users) and the specific counterpart in humans to the motor sensitization reported in experimental animals is unknown.

A ►withdrawal syndrome, which can include ►depression, ►anhedonia, and ►anxiety, can develop within hours or days following drug cessation after repeated exposure to moderate to heavy doses of stimulant drugs, or to a single high dose of the drug. Typically, ►withdrawal features are the opposite of some of the acute effects of the drug (e.g. unpleasant vs. pleasant feelings; increased vs. decreased appetite) and can last a few hours to days or even weeks (see ►Tolerance and Dependence).

In some individuals, chronic exposure to stimulants leads to a state of drug ►addiction characterized by a ►compulsive wanting or ►craving for the stimulant drug and a loss of control. ►Addiction is not an obligatory component of a ►withdrawal syndrome.

## Mechanism of Action of Some of the Acute Behavioural Effects of Classical Stimulants

Stimulant drug targets. Brain neuronal systems have been identified that are acted upon by stimulant drugs. However, not yet established is the extent to which these drug targets are critically involved in stimulant actions.

In brain, stimulant drugs act *inter alia* on neurones that utilize ►dopamine, ►noradrenaline, and ►serotonin as ►neurotransmitters. Studies of patients with the dopamine deficiency condition ►Parkinson's disease show that ►dopamine in the ►putamen and ►caudate subdivisions of the ►striatum is involved in ►motor control and probably in aspects of ►cognition [3] (►Drug Treatment for Motor Disorders and Antipsychotics). Dopamine, localized to the ►ventral striatum/►nucleus accumbens portion of the ►striatum has often been considered to mediate feelings of pleasure. However, this is likely an oversimplification and debate continues on re-defining this aspect of the role of ►dopamine from such possibilities (all related) as "liking," "wanting," and "►incentive salience" [4].

The precise roles of brain noradrenaline and ►serotonin are less certain as there does not exist any human conditions characterized by selective loss of either of the ►neurotransmitters. However, the ►antidepressant actions of fairly selective serotonin and noradrenaline ►transporter inhibitors suggest involvement of both ►neurotransmitters in ►mood and an extensive animal literature suggests an involvement of noradrenaline in arousal and ►attention [5] (►Antidepressants).

►Classical stimulants activate monoamine neurotransmitter systems. A primary action of the "►amphetamine-like" stimulants (see Table 1) is to elevate brain extracellular ►monoamine neurotransmitter (►dopamine, ►serotonin, noradrenaline) levels by enhancing ►neurotransmitter release from the nerve endings [6]. Although the mechanism by which ►amphetamine stimulants cause release is still under investigation, it likely involves (i) redistribution of the neurotransmitters from the synaptic vesicle (via the ►vesicular monoamine transporter [VMAT2]) to the neuronal cytoplasm and (ii) reverse transport of the ►neurotransmitter through the plasma membrane transporter into the extracellular space [7]. A primary action of "cocaine-like" stimulants is to increase extracellular ►monoamine neurotransmitter concentrations by binding to plasma membrane ►transporter proteins (►dopamine transporter, ►serotonin transporter, ►noradrenaline transporter) and thereby blocking reuptake of the ►neurotransmitter from the ►synapse into the nerve ending [6]. Some (but not all) data in the human suggest that cigarette smoking can cause a slight increase in release of ►dopamine in the ►striatum – an action attributed to ►nicotine. The ►dopamine-releasing action of ►nicotine is considered to be mediated, at least in part, by activation of ►nicotinic receptors of the $\alpha_4$ and $\beta_2$ subtypes [8].

Since the stimulant drugs act, to a varying degree, depending on the stimulant, on all three ►monoamine neurotransmitter systems [6], it is difficult to ascribe specific behavioural effects of the drug to involvement of a single ►neurotransmitter. Speculations, mentioned below, on mechanism are primarily based on animal findings.

►Cardiovascular activation. Activation of ►heart rate and blood pressure caused by some stimulants (e.g. ►methamphetamine) has been commonly explained by a drug-induced release of noradrenaline from ►sympathetic nerve endings and subsequent activation of ►adrenergic receptors. However, the situation is probably much more complicated with some data suggesting involvement of ►monoamine neurotransmitters (►dopamine and/or noradrenaline) in brain as well as in the ►sympathetic nervous system.

►Alerting and attention. Animal data suggest that the ►alerting and improved ►attentional effects of

the prototype ►monoamine neurotransmitter releaser (►amphetamine) and uptake blocker (►methylphenidate) could be explained in large part by enhancement of brain noradrenergic function. This is also suggested by the efficacy of ►atomoxetine, reputedly a selective ►noradrenaline transporter blocker, in treatment of patients with ►attention deficit/hyperactivity disorder (►ADHD) (explained as a disorder of ►attentional control). Comparison of the maximal clinical response of ►amphetamine and methylphenidate (activate both ►dopamine and noradrenaline systems) vs. atomoxetine in treatment of ►ADHD may help to establish extent of involvement of ►dopamine.

►Liking. It is commonly assumed that "all roads lead to ►dopamine" when explaining the feelings of well-being and euphoria associated with a moderate stimulant dose.

This is supported by brain imaging findings in the human strongly suggesting that administration of a variety of stimulants (►amphetamine, ►nicotine, cocaine, methylphenidate) cause increased synaptic levels of ►striatal dopamine and that, in some studies, the extent of increase in ►dopamine correlates with subjective measures of ►mood [9].

At odds with the ►dopamine hypothesis, however, is the simple observation that the positive effects of stimulants in humans are not antagonized by dopamine receptor blocking agents. In contrast, preliminary data (requiring confirmation) indicate that the "positive" effects of at least three stimulant drugs (amphetamine, cocaine, ►nicotine [cigarette smoking]) are partially antagonized by non-selective ►opioid receptor antagonists (naloxone or naltrexone). This suggests that the "liking" effect of some stimulants might be mediated through a process involving activation of an endogenous ►opioid.

►Increased sociability with ecstasy vs. amphetamine The mechanism explaining this reputed drug effect is unknown but likely involves the ability of ►ecstasy to preferentially release the ►neurotransmitter serotonin as compared to ►dopamine, whereas ►dopamine (vs. ►serotonin) is preferentially released by ►amphetamine.

## Mechanism of Acute Effects of Some Atypical Stimulants

►Adenosine is considered to be an inhibitory neuromodulator involved in regulation of the ►sleep-wake cycle. The mechanism of the modest stimulant action in humans of caffeine, an "atypical" stimulant found in coffee, tea, and cola, is likely related to its ability to block the action of ►adenosine at its adenosine $A_{2A}$ receptor as suggested by the lack of stimulant effect of caffeine in mice lacking this receptor.

Modafinil is an atypical stimulant, structurally unrelated to the ►amphetamines, currently used clinically for the treatment of excessive ►sleepiness. This is an example of a stimulant in which animal data implicate many different drug targets, but insufficient information is presently available to identify those targets likely to be critically involved in its stimulant action.

## Mechanism of Action of Some Chronic Behavioural Effects

►Withdrawal. Some of the unpleasant behavioural features of ►withdrawal to repeated exposure to stimulants are likely related to a "deficiency state" for those ►monoamine neurotransmitter systems that are activated acutely by the stimulants [6]. In the case of ►ecstasy, for example, the ►depression-like features during drug ►withdrawal are most likely due in part to an actual deficiency of brain ►serotonin. Similarly, the postmortem ►brain finding of low ►striatal dopamine in chronic ►methamphetamine users suggests that some features of ►methamphetamine withdrawal, including ►anhedonia and problems with ►cognition, can be explained by loss of this ►neurotransmitter [10]. It is also highly likely that diverse ►adaptations downstream from the ►monoamine neurotransmitter receptors underlie the ►withdrawal syndrome associated with stimulant drug taking.

►Addiction. Speculations on possible mechanisms explaining stimulant-induced ►addiction can be found in the Chapter on Tolerance and Dependence. This reviewer finds attractive the model proposing that ►addiction is a form of "pathological ►learning" for which ►dopamine (perhaps critically) helps facilitate the ►learning process and in which ►memories, once formed, are rather resistant to change [2].

No single neuronal system in brain has yet been identified which is critical in explaining the transition from stimulant "liking" to "wanting" or "►craving" in the human, including ►dopamine. Certainly, ►dopamine is somehow involved, at least initially, as stimulants that (rapidly) elevate extracellular levels of this ►neurotransmitter in human ►brain can be abused. However, the evidence for ►dopamine receptor blocking drugs influencing drug ►craving and ►relapse in humans is not compelling. Those stimulants that have a preferential action on the ►serotonin (vs. dopamine) system (►fenfluramine, ecstasy) appear to have a lower risk of ►addiction.

Clinical pharmacological studies testing potential anti-addiction medications in humans are key to identification of neuronal targets likely involved in stimulant addiction. Although such data are still preliminary, not always consistent, and no "magic bullet" has yet been discovered, some interesting findings have emerged:

In the case of ►nicotine addiction (as an example), emerging pharmacological data show that drugs blocking ►opioid and CB1 ►cannabinoid receptors help some tobacco smokers quit the drug, suggesting possible involvement of ►endogenous opioids and

►cannabinoids in ►craving and ►relapse in humans. Using also the example of ►nicotine, a rational approach in development of a drug to block relapse incorporates a "drug substitution" strategy in which the drug therapeutic is a "dual action" ►partial agonist drug that acts as an agonist at the ►nicotine $\alpha_4\beta_2$ ►receptor, but has lower (e.g. 30–70%) maximal response than ►nicotine (but still sufficient to reduce ►craving during drug ►withdrawal) and also acts as an antagonist in the presence of ►nicotine. Preliminary data suggest that such a ►nicotine partial agonist drug improve smoking quit rates in humans [8].

### Do Stimulants Cause Persistent Brain Damage?

A variety of structural brain abnormalities have been reported in some chronic users of ►methamphetamine, ►ecstasy, and cocaine; however, to date the findings are too inconsistent and anecdotal to provide a definitive conclusion.

Good evidence exists in the animal literature that neurochemical markers of brain ►dopamine nerve terminals (►dopamine, ►dopamine transporter, ►VMAT2) are persistently decreased in experimental animals given high doses of ►methamphetamine (see [10]) whereas markers for ►serotonin neurones (►serotonin, ►serotonin transporter) are decreased in nerve terminal regions following high dose exposure to ►ecstasy. Oxidative damage due to formation of oxy-radicals derived from ►dopamine and ►serotonin is a plausible mechanism for the toxicity.

In the human literature decreased ►striatal concentration of the ►dopamine transporter in some abstinent (months to years) ►methamphetamine users has been reported (see [10]). Although low ►dopamine transporter does not necessarily equal actual loss of ►dopamine nerve terminals, the human data do suggest that some (likely dose-dependent) "damage" could occur to dopamine neurones in ►methamphetamine users that persists some months or longer after the last exposure to the drug. Similarly, emerging, though still preliminary, data describe a brain serotonin transporter decrease in the cerebral cortex of abstinent ►ecstasy users. The question whether these changes are associated with any functional impairment is still debated.

# Stochastic Resonance

## Definition

Stochastic resonance refers to a nonlinear dynamical interaction of a periodic signal and noise appearing in multistable systems (e.g. a neuron) near a bifurcation. The noise can be either random or fractal and exist internal to the system or be externally applied. Information flow (the periodic signal) through the system is optimized by a particular noise intensity, thereby actually increasing the signal-to-noise ratio. Stochastic resonance is a strictly nonlinear effect, not accessible within the framework of linear signal processing theories.

# Stomatogastric Ganglion

Ronald M. Harris-Warrick,
Bruce R. Johnson
Department of Neurobiology and Behavior, Cornell University, Ithaca, NY, USA

## Synonyms

STG

## Definition

The stomatogastric ►ganglion (STG) in lobsters, crabs and other crustaceans is one of the premier systems for studying how neural networks generate rhythmic motor patterns [1]. It is an important model system for more complex behaviors such as respiration, locomotion, rhythmic scratching, and mastication, and has given insights into the mechanisms underlying behavioral flexibility. The STG is part of the stomatogastric nervous system (STNS), which controls movements of the crustacean foregut (Fig. 1a). The STNS includes the STG, the oesophageal ganglion, and the paired commissural ganglia.

## Characteristics

The STG is a small ganglion of about 30 neurons (Fig. 1b), all individually identifiable (Fig. 1c). It contains two complete ►Central Pattern Generator (CPG) networks that drive rhythmic movements of the foregut: the gastric mill and the pyloric networks. In the spiny lobster, *Panulirus interruptus*, the gastric mill network contains eleven identified neurons: one interneuron and ten neurons that act both as CPG neurons and as motoneurons. The gastric mill network generates slow rhythmic movements of the three internal teeth that masticate food inside the foregut (Fig. 2a).

The pyloric network contains fourteen identifiable neurons in six major classes (Fig. 2b). One is an interneuron while thirteen are dual function CPG/motoneurons. This network organizes more rapid rhythmic pumping, mixing and filtering movement in the pylorus, or posterior region of the foregut. These

From ref. [1].

networks vary only slightly between different crustaceans, showing their evolutionary conservation.

## Upstream Events/Conditions

When isolated from the rest of the nervous system, both of the CPGs in the STG cease to function. Descending modulatory inputs from the commissural, oesophageal and other ganglia are essential to activate the motor patterns. In the lobster, there are about 120 central neurons as well as a number of sensory/modulatory neurons that affect the ganglion [2]. The CPG motor patterns vary markedly, depending on which modulatory inputs are active. A number of these modulatory neurons have been identified; when selectively stimulated, each can elicit a distinct variant of the gastric and/or pyloric motor patterns. Most of these modulatory neurons release two or more co-transmitters; often one is a fast-acting neurotransmitter like glutamate, while the others are slower acting neuromodulators including peptides (such as proctolin) or amines (such as dopamine) [3]. In addition, a number of circulating ▶neurohormones (such as serotonin) act on the STG over longer times and at lower concentrations. More than 20 modulatory substances have been identified that affect the STG networks.

Modulatory inputs reconfigure the CPGs in several ways. First, they determine which cells are actively firing in the network. Second, they alter the cycle

frequency, intensity of firing and phasing of the component neurons. Third, they can shift the allegiance of neurons to fire with a different CPG for an entirely different behavior. Finally, they can fuse two or three networks into a new motor network for a novel behavior.

## Downstream Events/Conditions

Much work has gone into understanding how the pyloric network, and to a lesser extent the gastric mill network, generates its rhythmic output. In brief, the motor pattern is shaped by the interaction between two complementary processes: the intrinsic firing properties of the different neurons, and the pattern and kinetics of their synaptic interactions. Due to space considerations, in this paper we discuss how these processes interact to generate the pyloric rhythm. The gastric mill rhythm is more complex and more integrated with other STNS networks than the relatively independent pyloric network.

## Intrinsic Properties of Pyloric Neurons

The six classes of neurons in the pyloric network each have a unique firing pattern during the pyloric rhythm. Each neuron can be studied in isolation from all synaptic input by a combination of photoablation of synaptically connected neurons and pharmacological blockade of pre-synaptic inputs. A number of distinct intrinsic electrophysiological properties shape the neurons' firing patterns [1].

With intact modulatory inputs, all of the neurons are capable of rhythmic ►bursting of different kinds and at different rates. However, this is lost when modulatory inputs from other ganglia are blocked: all of the neurons fall silent or fire slowly. Thus, these neurons are ►conditional bursters which oscillate only in the appropriate modulatory environment. The Anterior Burster (AB) typically oscillates at the highest frequency and thus acts as the primary pyloric ►pacemaker (Fig. 2b). The AB neuron is electrically coupled to the two Pyloric Dilator (PD) neurons, which oscillate more slowly and constrain the AB oscillatory frequency. These three neurons form the pacemaker group and play the major role in setting the cycle frequency.

The remaining follower neurons are all inhibited by the pacemaker group. All the follower neurons possess ►post-inhibitory rebound, where after synaptic inhibition they rebound to fire a burst of action potentials. Some of the neurons also show ►delayed excitation, such that they rebound more slowly after inhibition, and begin firing only after a delay. This delay is due to the activation of a subthreshold transient potassium current, $I_A$, which competes with a slow hyperpolarization-activated inward current, $I_h$, to set the rate of post-inhibitory rebound. Many of the neurons also express ►plateau potentials, where a short depolarizing input, or post-inhibitory rebound, can trigger prolonged action potential firing that lasts until synaptic inhibition or the slow development of outward currents repolarizes the neuron.

## Synaptic Interactions

The pyloric network is highly interconnected (Fig. 2b) top. All the neurons make chemical inhibitory synapses, using either acetylcholine or glutamate which, unlike vertebrate systems, act as fast inhibitory transmitters. Release of transmitter is not only spike-evoked but also graded, with continuous release as a function of membrane potential during the neurons' oscillations. These synapses are highly susceptible to depression during normal oscillations: the synapses weaken as the cycle frequency accelerates [4]. In addition, several of the neurons make rectifying or non-rectifying ►electrical synapses with partner neurons, which help to synchronize or initiate activity.

## Generating the Pyloric Rhythm

With modulatory inputs intact, the 14 neurons in the pyloric network fire rhythmic bursts of action potentials in a characteristic triphasic pattern (Fig. 2b). The major pacemaker, AB, and the electrically coupled PD neurons, burst synchronously in the first ►phase. This pacemaker kernel inhibits all the follower neurons. As the endogenous burst terminates, the follower cells repolarize by ►post-inhibitory rebound to resume firing, but at different rates, due to different amounts of subthreshold outward currents that cause delayed excitation. The IC (Inferior Cardiac) and VD (Ventricular Dilator) neurons rebound most quickly. However, the LP (Lateral Pyloric) neuron is not far behind, and it silences the VD due to a very strong synaptic inhibition, and inhibits PD. The LP then fires tonically, while the PY (Pyloric Constrictor) neurons depolarize more slowly by post-inhibitory rebound from their pacemaker inhibition and begin firing. In turn the PY neurons inhibit the LP and IC neurons, disinhibiting the VD neurons, which fire a second burst. These neurons fire until they are inhibited by the next pacemaker kernel burst, and the cycle repeats. The rebound burst of action potentials in follower cells is supported by their plateau properties.

The pyloric rhythm shows ►phase constancy, a general feature of rhythmic behaviors: while the cycle frequency can vary over time, the neurons adjust their burst durations to retain a constant phase relationship with one another. The neural mechanisms underlying phase constancy remain unclear, but frequency-dependent synaptic depression as well as the kinetics of activation, inactivation and deinactivation of voltage-sensitive ion channels play important roles [4]. The phase relations do change when the modulatory milieu is altered.

## Nonlinear Muscle Responses to the Neuronal Motor Pattern

The muscles driven by the pyloric network have different kinetics of contraction: many of them are very slow, and exhibit a large tonic contracture with only small superimposed oscillations in response to the rhythmic pyloric neural drive. Subtle changes in the numbers of spikes per burst, however, can alter this resting contracture. The pyloric network receives inputs from the slower gastric mill CPG and the cardiac sac CPG, another network that causes slow rhythmic contractions of the foregut sac. These minor inputs cause subtle changes in cycle frequency and spikes per burst in some of the pyloric neurons. These small changes are magnified at the muscle level, so when both gastric and cardiac sac rhythms are simultaneously active, the major pyloric muscle contractions are in time with the much slower gastric mill and cardiac sac rhythms, despite the fact that only pyloric motoneurons innervate these muscles [5]. In addition, some pyloric muscles are themselves conditional oscillators whose intrinsic contractions interact with the oscillatory neural input; the motoneuronal drive entrains the muscle's rhythmic oscillations but does not affect their amplitude.

## Neuromodulation

A large number of modulatory neurons act to reconfigure the STG networks over the short term, and the actions of applied neuromodulators such as amines and peptides has been studied in detail [1,2,6] (Fig. 3a).

These modulators alter the pyloric motor pattern by three mechanisms:

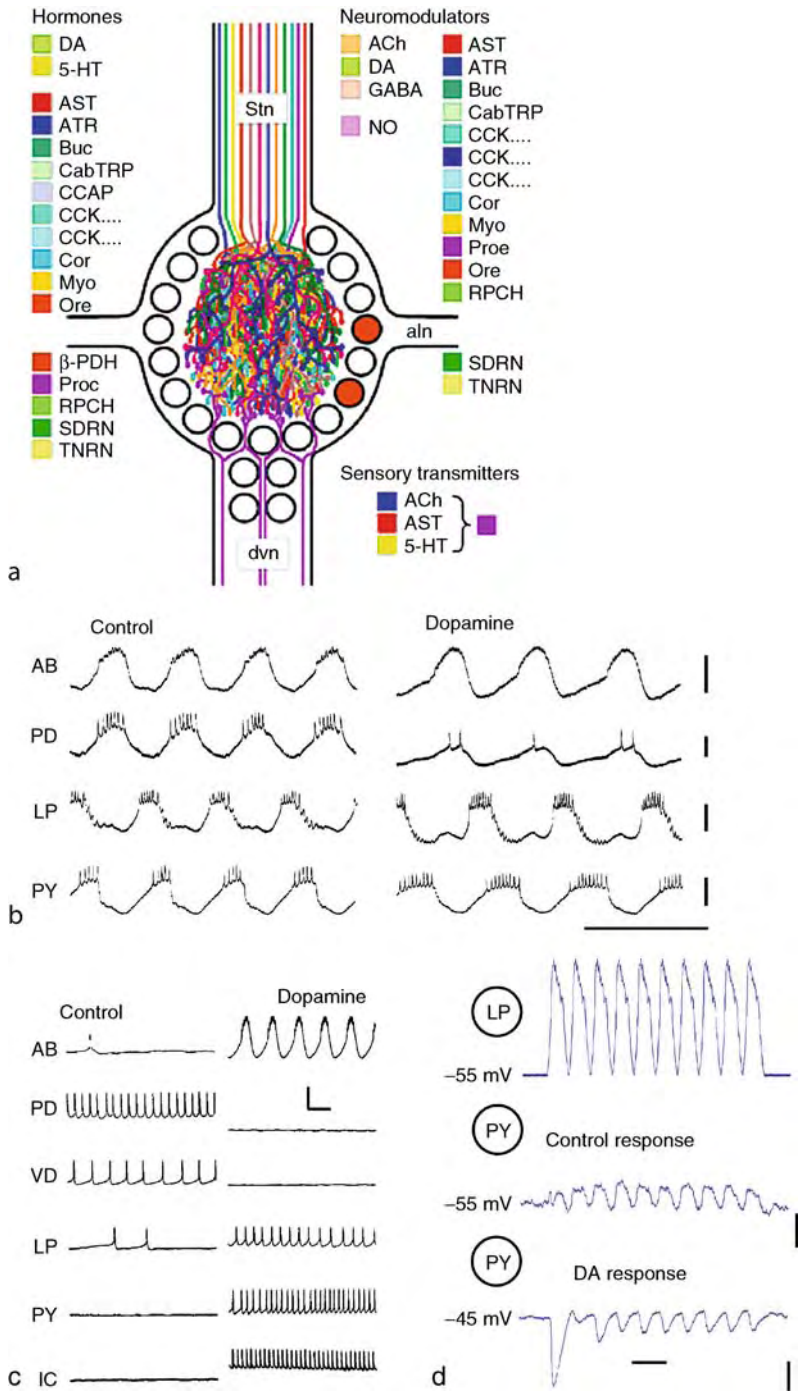
1. Alter the intrinsic firing properties of neurons. Modulators can shape the conditional oscillations, plateau properties, post-inhibitory rebound and delayed excitation of the different pyloric neurons. For example, DA enhances bursting in the AB neuron, enhances post-inhibitory rebound and plateau properties in the LP, IC and many of the PY neurons, and inhibits the PD and VD neurons [6]. As a result, the PD and VD neurons are phase-delayed or fall silent, while the other followers are phase-advanced and fire vigorous bursts of action potentials (Figs. 3b, c).
2. Change which neurons are active in the motor pattern. Modulators can excite some neurons while inhibiting others, changing the active components in the network (Fig. 3c). However, silent neurons can still affect the motor pattern when they are electrically coupled to active neurons, by exerting a functionally inhibitory electrotonic drag.
3. Alter the strengths of synapses in the network (Figs. 3d, 4) [6,7]. A single neuromodulator can strengthen some synapses while weakening others. These changes occur by both pre-synaptic increases or decreases in transmitter release, which is in part due to modulation of calcium currents in nerve terminals, and in part to post-synaptic alterations in transmitter responsiveness. Amines also modify electrical coupling, either directly or indirectly via changes in input resistance. At several synapses, which combine electrical and chemical inhibitory components, dopamine can invert the net sign of the synaptic interaction via opposite effects on the electrical and chemical components (Figs. 3d, 4). Not all of the observed synaptic modulation may have functional consequences for pyloric network function. The magnitude of synaptic strength changes that are sufficient to evoke changes in network activity is still not clear.

The complexity of these effects on the pyloric neurons' ionic currents and synaptic strength is illustrated for one neuromodulator, dopamine, in Fig. 4. In many cases, DA exerts conflicting effects on a target [6]. At several synapses it enhances pre-synaptic release while weakening post-synaptic responsiveness. In some neurons, DA alters complementary sets of ionic currents that by themselves would lead to either increases or decreases in a neuron's excitability. These opposing effects could act as brakes to constrain the neuronal activity within a certain window, and to prevent the neurons from being "over-modulated" and dysfunctional. Alternatively, opposing modulatory effects could themselves be subject to differential metamodulation by other transmitters, which could change the net sign of the DA effect.

DA is an example of a neuromodulator with widespread and divergent actions on the different synapses and neurons in a neural network. In contrast, a number of peptides act through independent receptors but converge on a single ionic current to activate multiple pyloric neurons by a common mechanism [2]. The different peptides target distinct populations of neurons (due to differential expression of their receptors), leading to different motor patterns despite their common ionic targets.

## Involved Structures

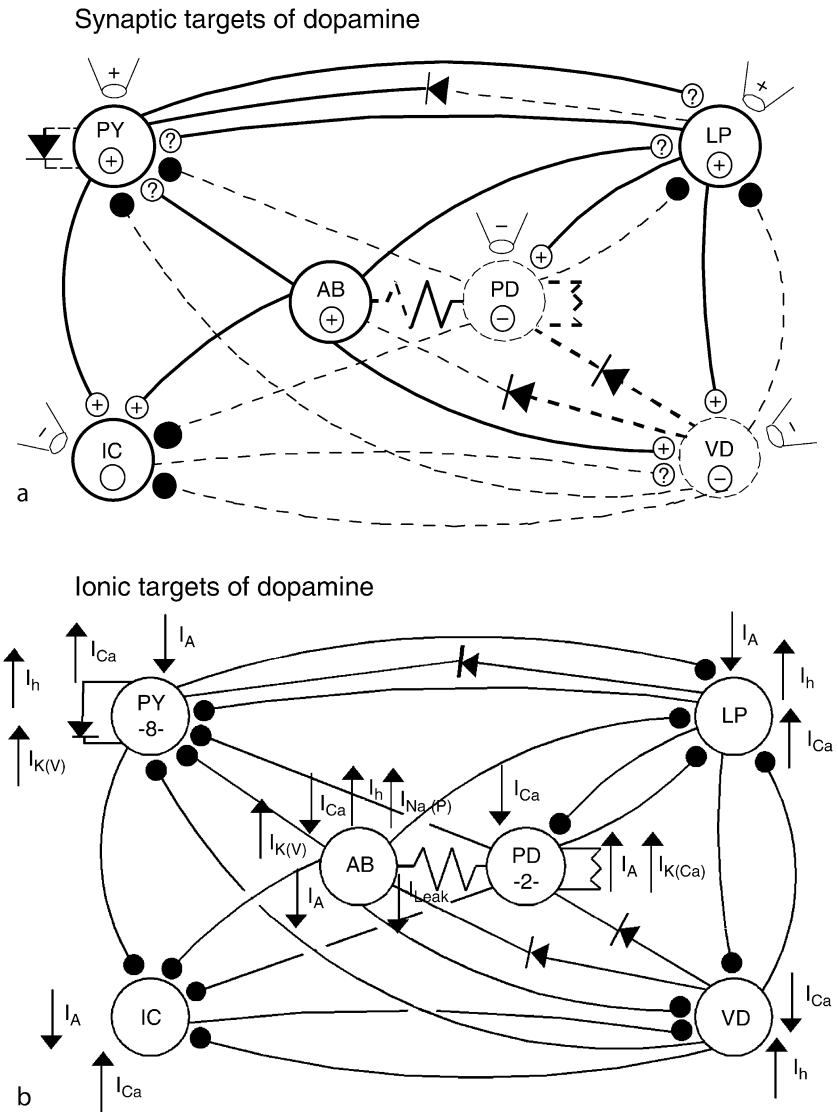
The variability in STG neuron firing properties arises from neuron-specific patterns of expression of genes that encode ion channels, receptors and enzymes. Currents that have been studied in detail include the typical inward currents such as the voltage-sensitive sodium ($I_{Na(V)}$), calcium ($I_{Ca}$), hyperpolarization-activated inward ($I_h$) and persistent sodium ($I_{Na(P)}$) currents, and the non-selective cation current ($I_{CAN}$). In addition, these neurons express outward currents including the transient potassium ($I_A$), delayed rectifier ($I_{K(V)}$), and calcium-activated ($I_{K(Ca)}$) currents. As described above,



**Stomatogastric Ganglion. Figure 3** ►Neuromodulation of STG networks. (a) Diagrammatic summary of known neuromodulatory inputs into the STG (Figure from Eve Marder). (b) Pyloric activity recorded intracellularly from four pyloric neurons under control and dopamine conditions. Calibrations: 1 s and 10 mV (From Kloppenburg et al. (1999) J Neurophysiol. 81:29–38) (c) Dopamine effects on the excitability of synaptically isolated pyloric neurons. Calibrations: 1 s and 5 mV IC; 10 mV AB, PD, VD, LP, PY. (From Flamm and Harris-Warrick (1986) J Neurophysiol 55:866–881) (d) Dopamine reversal of synaptic sign at a mixed electrical/chemical inhibitory synapse. Realistic waveforms (30 mV) were used as voltage clamp stimuli in the presynaptic LP neuron while recording the responses in the post-synaptic PY neuron. Under control conditions, the PY neuron depolarizes in phase with the LP depolarizations. During application of dopamine, the PY neuron hyperpolarizes in phase with the LP depolarizations. Calibrations: 1 s and 1 mV Control, 10 mV DA response. (From Johnson et al. (2005) J Neurophysiol 94:3101–3111).

these currents are major targets of neuromodulators which alter the firing properties of neurons and the strengths of their synapses. Within a single neuron, modulators such as dopamine affect multiple ionic currents to alter its intrinsic firing properties (Fig. 4).

Interestingly, experimental and modeling studies have shown that many different combinations of ionic currents can generate the same basic firing pattern. For example, in different Inferior Cardiac neurons, the amounts of three outward currents varied over a wide range even though the neurons had very similar firing properties; modeling studies support this result, showing that many different combinations of ionic currents could generate the same bursting firing pattern. Similarly, when model pyloric



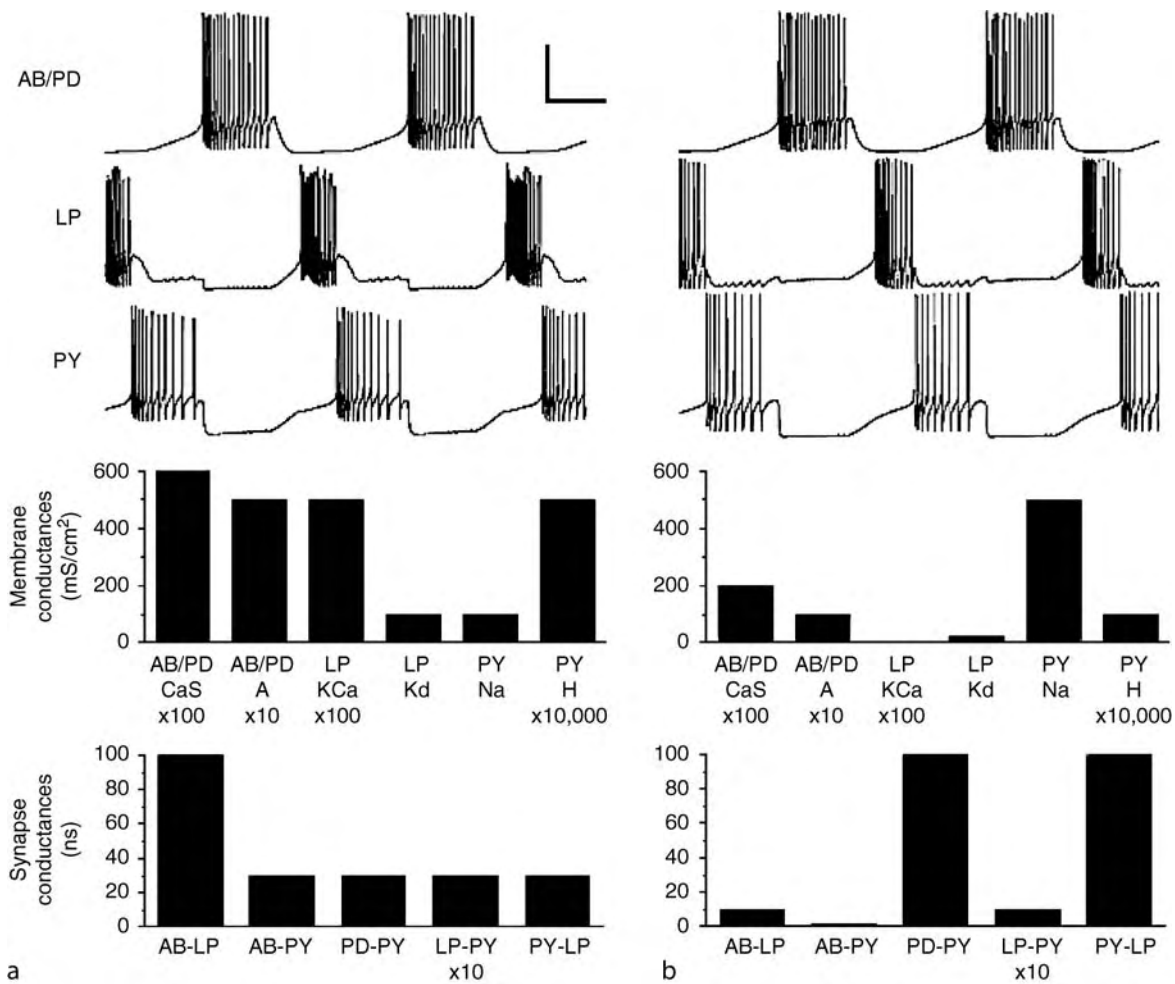
**Stomatogastric Ganglion. Figure 4** Summary of dopamine (DA) effects on the intrinsic and synaptic properties of pyloric neurons in the STG. (a) Synaptic targets of DA. Dopamine alters the strength of every chemical and electrical synapse in the pyloric network. Bold lines indicate synapse strengthening and dashed lines indicate weakening. Electrode tips with (−) and (+) signs indicate reduced and enhanced responses to applied glutamate during dopamine application; (+) signs inside nerve terminals indicate DA enhancement of transmitter release; (+) and (−) signs inside neuron cell bodies indicate effects of DA on cell input resisyance. (b) Ionic targets of DA. Currents affected: $I_{Na(P)}$: Persistent sodium current; $I_{Ca}$: Voltage-sensitive calcium current; $I_A$: transient potassium current; $I_{K(V)}$: delayed rectifier potassium current; $I_{K(Ca)}$: calcium-activated potassium current; $I_h$: hyperpolarization-activated inward current; $I_{Leak}$: voltage-insensitive leak current. Upward and downward pointed arrows indicate DA's effects on different ionic current magnitudes in each neuron.

S

neurons were coupled via variable strength synapses to form more than 20 million versions of a simple three-neuron network, the same motor pattern could be generated by many different combinations of ionic and synaptic parameters [8] (Fig. 5).

Additional evidence for multiple ionic solutions to a neuron's firing properties comes from studies of ►homeostatic regulation, the slow compensatory changes the neurons make when their normal activity pattern is altered. The CPG motor patterns are normally completely dependent on modulatory inputs from other ganglia; when these are blocked the neurons lose their conditional bursting properties. However, if an isolated ►ganglion or neuron is maintained for several days in culture, the neurons restore their bursting properties which are now not dependent on modulatory inputs, and the pyloric rhythm is reactivated. The underlying mechanisms for this include a transcription-dependent increase in sodium and calcium currents and a decrease in potassium currents [9]. In other studies, artificial up-regulation of the transient potassium current, $I_A$, by RNA injection in single pyloric neurons leads to a proportional up-regulation of $I_h$ [10]. Since the increased $I_h$ counteracts the effects of the increased $I_A$, the firing properties of the neurons were essentially unchanged.

This work has led to the general conclusion that the firing properties of a neuron are not rigidly determined by the expression of a fixed ratio of ionic currents, but that there are multiple and redundant solutions for each neuron. It will be a challenge to identify the developmental mechanisms that allow this flexibility while reliably generating neurons with appropriate firing properties.



**Stomatogastric Ganglion. Figure 5** Different synaptic and ionic current magnitudes can create similar pyloric activity patterns. (a) *Top*: Model network activity in three cells created by the specific model membrane and synaptic conductances shown in bottom. (b) *Top*: Similar model network activity created by very different ionic and synaptic conductances shown in bottom. Calibrations: 0.5 s, 50 mV. (From ref. [8]).

### Methods to Measure This System

Studies of the STG have benefited from the convergence of a number of different but complementary experimental approaches:

1. Electrophysiology: Combined intracellular and extracellular recordings allow the complete pyloric or gastric mill motor pattern to be monitored simultaneously. The properties of single neurons can be studied in isolation after removing all synaptic input by fluorescent dye-induced killing of connected neurons and pharmacological blockade of synaptic inputs. Voltage clamp studies allow analysis of individual currents underlying neuronal firing properties.
2. Anatomy: Each identified neuron can be dye-injected, allowing its structure to be carefully mapped, and combined with immunocytochemical mapping of neuromodulator inputs.
3. Imaging studies: intracellular calcium levels can be monitored in single nerve terminals using calcium-sensitive dyes such as calcium green. Intracellular second messenger systems can also be monitored optically using fluorescence resonance energy transfer (FRET) signaling molecules.
4. Molecular biology: A number of ion channel genes have been cloned from lobster and their distribution in the STG mapped by immunocytochemistry. Some have been over-expressed in identified neurons and their effects on neuronal activity determined. Recently, a set of monoamine receptor genes has been identified, and a single cell microarray analysis of multiple genes is being developed.
5. Modeling: Models are a critical adjunct to all the work in the STG. These models have allowed a quantitative analysis of the roles of different synapses and ionic currents in shaping network function, and have demonstrated redundancy in ionic solutions to the firing properties of neurons.

## Stop Codon

### Definition

A trinucleotide sequence within the mRNA that halts RNA translation. The three most common stop codons are UAG, UAA, and UGA.

## Strain

### Definition

A generic name for a variety of measures of the "change of shape and size" of a "small neighborhood" of a body point. In essence, all measures of strain are related to the positive-definite symmetric part in the polar decomposition of the deformation gradient.

►Mechanics
►Measurement Techniques

## Strain-hardening

### Definition

Most soft tissues become stiffer as the stretch or strain is increased – often associated with increasing recruitment

of previously slack collagen fibers. This material behavior is called "strain-hardening."

►Cardiovascular Mechanics

## Streptavidin

### Definition

Streptavidin is a 60 kDa tetrameric protein purified from the bacterium *Streptomyces avidini*. A recombinant 53 kDa form is also commercially available. Like the avidin protein found in eukaryotic sources, streptavidin has a very high affinity for biotin ($K_d$=$10^{-13}$ to $10^{-15}$) but lacks the extensive glycosylation found in avidin. The lack of extensive glycosylation means that strepavidin has the advantage of much lower non-specific binding than avidin and; is therefore, more useful in laboratory applications.

►Serial Analysis of Gene Expression

## Stress

### Definition

Is defined as a constellation of events, comprised of a stimulus (stressor), that precipitates a reaction in the brain (stress perception), which subsequently activates physiological fight or fight systems in the body (stress response). The stress response results in the release of neurotransmitters and hormones that serve as the brain's messengers to the body. An important distinguishing characteristic of stress is its duration. Acute stress is defined as stress that lasts for a period of minutes to hours, and chronic stress as stress that persists for several hours a day or weeks or months. An important marker for deleterious amounts of chronic stress may be a breakdown in the rhythmicity of the circadian cortisol cycle. Stress has long been suspected to play a role in the etiology of many diseases, and numerous studies have shown that stress can be immunosuppressive and hence may be detrimental to health.

## Stress Effects During Intense Training on Cellular Immunity, Hormones and Respiratory Infections

Gomez-Merino Danielle
Department of Physiology, Institut de Médecine Aérospatiale du Service de Santé des Armées, BP 73, Brétigny-sur-Orge, France

### Synonyms

Heavy Exertion; Physical Exercise

### Definition

In this essay on the influence of combined ►stress during intense training on ►cellular immunity, hormones and respiratory infections, we have argued that athletes and soldiers who engaged in intense and repeated ►exercise training programs and experienced combined stressors such as energy and/or sleep deprivation, and/or psychological restraint, are at risk of respiratory tract infections.

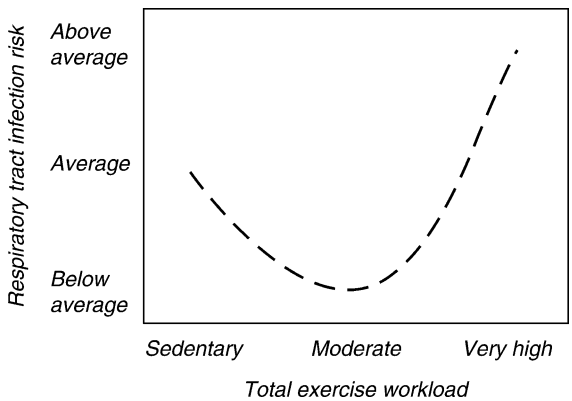
The two parts are distinguished as: (i) intense exercise and alteration of immune responses focusing on cellular immunity and the role played by cytokines. The relationship to the risk of ►upper respiratory tract infections (URTIs) is overviewed [1–4], and (ii) The ►Overtraining Syndrome (OTS) and ►neuroimmunomodulation [5,6]. OTS has been diagnosed in athletes and is characterized by a sports-specific decrease in performance despite periods of recovery together with disturbances in mood state. Signs/symptoms have been categorized according to physiological performance, psychological/information processing, immunological, and biochemical parameters. It is also probable that other signs/symptoms typically associated with overtraining, excluding organic diseases, are evident before deterioration in performance. These might include generalized fatigue, depression, loss of appetite, muscle and joint pain, and an increased incidence of illness. Thus, the relevance of implication of cytokines and the neurotransmitter serotonin in OTS are presented because they play a role in the regulation of immunity.

### Characteristics

Hans Selye first popularized the concept of ►stress in the 1950s. Selye theorized that all individuals respond to all types of threatening situations in the same manner, and he called this the General Adaptation Syndrome (GAS). He claimed that, in addition to the sympathetic nervous system (SNS) arousal, other bodily systems such as the adrenal cortex and pituitary gland may be

involved in the response to threat. As the threat wanes, Selye suggested, body functions return to normal, thereby allowing the body to focus on healing and growth again. But if the threat is prolonged and sustained (chronic), the SNS arousal never gets "turned off," and health can be impaired. With a continuously suppressed immune system, for example, a person would be more vulnerable than usual to infection – which is one explanation of why some individuals get sick so often.

Soldiers or athletes are two populations that experience combined stressors during repeated military field operations or intense training such as intense physical exercise, sleep and energy deficiency, environmental conditions (cold, heat), and psychological pressure. The effects of these various stressors on the health are complex, but could be deleterious as it has been shown that chronic stress leads to immunosuppression. Several exercise researchers have elaborated on the "open window" model, proposing that the athlete who trains excessively, without sufficient recovery time, shows a cumulative effect of the vulnerable "open window" period lasting between 3 and 72 h, and thus may encounter the risk of developing transient immunosuppression and an increased risk of infections, particularly ►upper respiratory tract infections (URTIs) (Fig. 1) [3]. Other infections may occur via the eye, ear or skin. There have also been reports of intestinal upsets such as diarrhea, slow wound healing, and increased susceptibility to environmental and food allergens.



**Stress Effects During Intense Training on Cellular Immunity, Hormones and Respiratory Infections.**
**Figure 1** Exercise and risk of upper respiratory tract infections (URTIs) (from Nieman 2000 [3], with permission of The American College of Sports Medicine). "J"-shaped model of relationship between varying amounts of exercise and risk of upper respiratory tract infections. This model suggests that moderate exercise may lower risk of URTI while excessive amounts may increase the risk.

## Exercise, Alteration of Immune Responses and Risk of Upper Respiratory Tract Infections (URTIs): the Role of Cytokines

The notion has emerged that tissue damage associated with physical exercise, such as muscle and/or connective tissue and/or bone, may alter immune function [6]. Mild tissue damage, followed by recovery, is an integral part of adaptation associated with exercise, but if an athlete increases training loads with additional stress factors, it is possible that a more chronic form of tissue trauma appears. The inflammatory response to injury is characterized by an initial phase of acute neutrophil accumulation, and a later phase of mononuclear cell accumulation. Then, there is a cessation of inflammatory cell influx, and processes of injured tissue repair occur. An important aspect of an inflammation/immune response is the upregulation of cytokines produced by, and mediating communication between and within, immune and non-immune cells, organs and organ systems throughout the body including the central nervous system (CNS). ►Cytokines coordinate infiltration of white blood cells into injured tissue. During the course of inflammation, cells intrinsic to the injured tissue as well as immune cells recruited to the area release chemical attractants (chemokines) that cause leucocyte adhesion to vascular endothelium and migration into the tissue spaces. Chemokines are divided into two families, the CC and the CXC (conserved cysteine residues are separated by no other residue, CC, or by one other residue, CXC), and, like cytokines, display synergy, antagonism, redundancy and pleiotropy in chemotaxis.

When produced in large quantities, there is a spillover of cytokines into the circulation rendering possible the CNS assessment through several mechanisms. They represent a powerful mediator of the stress response in the CNS because they link the CNS, the neuroendocrine and the immune systems [7]. Cytokines are either pro-inflammatory (TNF-α, IFNγ, IL-2) and stimulate both the hypothalamo-pituitary adrenal axis (HPA) and neurotransmitters synthesis (serotonin and norepinephrine) or anti-inflammatory (IL-10, IL-4). Other cytokines such as IL-6 function as pro- and anti-inflammatory. Another anti-inflammatory mediator is the IL-1 receptor antagonist (IL-1ra) that blocks the IL-1 action. There is cytokine synthesis in the CNS, by the glia, microglia, astrocytes and neurons. Also, several tissues at the periphery are able to synthesize cytokines such as skeletal muscles, adipose tissue, epithelial tissue, and adrenals. Cytokine receptors are present in the CNS (to IL-1 in hypothalamus and hippocampus, to IL-6 in hippocampus) and in the periphery (to IL-6 in skeletal muscles, adipose tissue, and adrenals). They represent neuromodulators as they are involved in memory and sleep processes.

Numerous studies are related to the role of cytokines on immune response, particularly the specific and acquired immunity. This specific aspect is triggered by T and B lymphocytes that are respectively involved in the intracellular pathogens destruction (virus, bacteria) and production of specific antibodies to antigens. T lymphocytes are divided into two distinct subsets, named as Th1 and Th2 cells, which are respectively associated with cell-mediated immunity and humoral immunity. Although the two subsets play a role in homeostasis defense of the body, it appears that in response to trauma or infection the balance is in favor of one or the other. The Th1 response induces cell-mediated immunity (monocytes/macrophages) and is present in autoimmune diseases, while the Th2 response induces humoral immunity (differentiation of B cells in antibody-secreting plasma cells, synthesis of antibodies such as IgE, grow and activation of mast cells and eosinophils) and is present in allergy diseases. Regulation of the balance lies on their respective associated cytokines: Th1 includes IL-2, IL-12, IFNγ, while Th2 includes IL-4, IL-6, IL-10, IL-13, and TNF-α. It has been shown that acute and chronic stress can decrease the Th1 response and increase the Th2 response under influence of stress hormones, glucocorticoides (GC) and catecholamines [7]. Acting through their receptors, GCs decrease the cytokine production associated to Th1. Catecholamines triggered similar effects particularly via β-adrenergic receptors.

During strenuous exertion, the relationship between the defined parameters of immunosuppression in the "open window theory" and the incidence of URTIs is a matter of current debate. Many alterations have been noted on ►cellular and humoral immunity. These include suppressed neutrophil function, suppressed lymphocyte count and proliferation, suppressed natural killer (NK) cell count and activity, changes in polymorphonuclear cell priming potential, and decreased serum, nasal and salivary immunoglobulins (Igs) (Table 1) [2,3]. Several studies have explored the relationship between URTIs and two main immune parameters that are decreased during heavy exertion, salivary immunoglobulin A (sIgA) and blood NK cell counts and/or NK activity. At present it is mainly the fall in blood NK cell count and/or activity that have been shown to be associated with an increased risk of URTIs during intense training for soldiers or athletes [2]. Changes in other immune-related factors suggestive of immunosuppression have also been noted after heavy exertion. These include changes in hormones and cytokines favoring a shift from the Th1 to the Th2 cytokine pattern. During intense military training, a relationship between URTIs and NK cell counts concomitantly to hormonal and cytokine responses has been shown, suggesting induction of a Th2 immune response (i.e., decreases in immunostimulatory hormones such as leptin and prolactin and increase in IL-6) [2].

It is well documented that exercise affects local and systemic cytokine production, with similarities to the cytokine response to infection. In sepsis, the cytokine cascades are TNF-α, IL-1β, IL-6, IL-1ra, sTNF-R (soluble receptor to TNF), and IL-10. The cytokine response to prolonged endurance exercise differs from that of infection in the fact that TNF-α and IL-1β were not reportedly increased. Typically, IL-6 is the first cytokine present in the circulation after exercise followed by IL-1ra (IL-1 receptor antagonist), IL-10, and the chemokine IL-8 [4]. The Pedersen group has demonstrated that (i) the major source of circulating IL-6 during prolonged exercise is skeletal muscle, but there is also adipose tissue production, (ii) the muscle production is sensitive to muscle glycogen content, and (iii) during prolonged exercise IL-6 plays a role in glucose homeostasis and lipid metabolism [8].

## The Overtraining Syndrome (OTS) and Neuroimmunomodulation

For the athlete, the increased susceptibility to infectious illness has been associated with the condition of overtraining syndrome (OTS), also referred to as "staleness" or burnout' syndrome. It is often suggested that OTS is the result of an accumulation of stressors that exceed an athlete's finite resistance capacity, similar to that which Selye observed. It is characterized by a sports-specific decrease in performance despite periods of recovery together with disturbances in mood state. Fry and colleagues [9] have categorized signs/symptoms of OTS according to physiological performance, psychological/information processing, immunological, and biochemical parameters. It is also probable that other signs/symptoms typically associated with overtraining, excluding organic diseases, are evident before deterioration in performance. These might include generalized fatigue, depression, muscle and joint pain, and loss of appetite (Table 2). At present, the definitive diagnostic criteria and the biochemical/metabolic mechanism for OTS are unknown. However, exercise scientists have suggested considering the endocrine, immune and nervous systems as a large system serving integrated functions. Thus, the "cytokine" and "IL-6" hypotheses of the OTS have been proposed.

Cytokines play a function as neuromodulators and immune mediators, and represent the systemic aspect of an immune/inflammatory response, which coordinates the whole body response by simultaneously acting on different organ systems including the central nervous system (CNS). Smith [6] hypothesizes that exercise-related immunosuppression is due to tissue trauma sustained during intense exercise, producing cytokines, which drive the development of a Th2 lymphocyte profile. A Th2 cell response results in simultaneous suppression of cell-mediated immunity, rendering the athlete susceptible to infection. Robson [5] explores the cytokine hypothesis of OTS with a direct focus on IL-6 and thus hypothesizes that the principal abnormal factors in OTS are an increased production of and/or intolerance to IL-6 during exercise.

The cytokine hypothesis of OTS relies on the fact that they can access the CNS and may induce brain-mediated signs of illness by acting at central, rather than peripheral, sites. They may directly access brain structures, either using a transport system to cross the blood brain-barrier (BBB), or acting at the level of circumventricular organs (CVO), where this barrier does not exist [6,7]. They may also inform the CNS indirectly via activation of afferent neurons of the vagus nerve; neural afferents may activate transcription and translation of cytokines within the CNS. In the brain, there are specific receptors for IL-1, IL-6, and TNF that have a discrete distribution. Blocking IL-1 receptors in the brain can prevent some of the sickness responses to peripheral administration of cytokines. Furthermore, administration of certain cytokines directly into the brain produces many or all of the sickness responses. IL-1 and IL-6 receptors in the brain are abundant in the area of the hypothalamus. The binding of cytokines in the hypothalamus results in activation of the hypothalamic-pituitary-adrenal axis (HPA-axis) and sympathetic nuclei, resulting in increased levels of circulating catecholamines, and cortisol, the traditional stress hormones. Robson [5] focuses on the IL-6 hypothesis of OTS because it has been shown that intracerebroventricular administration of IL-6 to rats stimulates the HPA axis, increases tryptophan and serotonin metabolism, induces fever, and decreases appetite and

locomotor activity. In addition, the exercise endurance is reduced in IL-6-deficient mice. For the athlete, several risk factors considered either individually or in combination but experienced chronically can weaken the BBB and permit the cytokine access to the CNS: the exercise workload, exposition to infectious agents, hyperthermia, hypoglycemia, and depression. The Nybo researcher group [10] has particularly evidenced the link between prolonged exercise-induced hyperthermia or hypoglycemia and central fatigue.

Examination of neuroendocrine and immune responses that exist during depression has offered insights into the mechanism and treatment of OTS. Similarly, the relevance of implication of neurotransmitters such as ►serotonin (5-HT: 5-hydroxytryptamine) and noradrenaline has been introduced. The 5-HT system is the largest brain system playing a role in the regulation of mood state, sleep, appetite, cognitive function, memory, circadian rhythms, motor function and sexual activity, neuroendocrine and immune responses. A recent study reports in one case of a severe OTS state a decrease in serotonin transmission in certain parts of the brain, using single-photon emission computed tomography (SPECT). Moreover, serotonergic neurotransmission is thought to be a neuromodulatory system exerting its activity in the CNS and in the periphery. Serotonin can affect immune functions and several findings suggest that modulation of the immune system by serotonin occurs at the lymphocytes level. Presence of 5-$HT_{1B}$ receptors has been evidenced in rodent lymphocytes and splenocytes and a human T lymphoblastoid cell line. While there is no report on OTS and change in 5-HT in the immune system, it has been shown that 5-$HT_{1B}$ receptors in lymphocytes are desensitized after intense military training [1].

### Conclusion

In conclusion, populations such as soldiers or athletes submitted to combined stress exceeding stress tolerance [i.e., prolonged and repeated exercises, lack of sleep and energy intake, psychological stress, environmental conditions (heat, cold)] are at risk of immunosuppression and exposed to infections, particularly those of the upper respiratory tract.

## Stress in Mechanics

### Definition

A generic name for a variety of measures of "the forces per unit area" at a point of a body. In essence, all measures of stress are related to the flux tensor associated with the flux of linear momentum. Specific examples are the first Piola-Kirchhoff stress and the Cauchy stress.

►Mechanics

## Stress-induced Analgesia (SIA)

### Definition

Pain reduction occurring in response to a physically taxing or stressful event, such as a forced cold-water swim. Presumed to involve both opioid and non-opioid systems.

►Descending Modulation of Nociception
►Gender/sex Differences in Pain

## Stress/Pressure

### Definition

The force per unit area exerted on a material. The SI unit for stress/pressure is newtons per meter squared (N/m2) which is given the name pascal (Pa).

►Measurement Techniques (Pressure)

## Stress Response

William E. Cullinan
Department of Biomedical Sciences and Integrative Neuroscience Research Center, Marquette University, Milwaukee, WI, USA
Department of Neurosurgery, Medical College of Wisconsin, Milwaukee, WI, USA

### Definition

The stress response is a complex set of coordinated changes involving neuroendocrine, autonomic, and behavioral components. At the neuroendocrine level, a complex cascade of events is initiated in the brain and pituitary, culminating in the ACTH-induced synthesis and release of glucocorticoids from the adrenal glands. Autonomic activation is simultaneously induced, involving widespread and divergent outflow through the sympathetic nervous system and secretion of adrenal catecholamines, resulting in increases in heart rate, respiration, and blood pressure, as well as mobilization of energy resources. Behavioral changes are induced that promote increased attention and arousal, while inhibiting other non-essential activities (e.g. feeding, gastric motility, sexual behavior). The term *stress*, initially coined by in 1936 by Selye [1], described a pathophysiological state induced by physical or psychological stimuli, the persistence of which may lead to disease or death. Such challenges may be real or interpreted threats to homeostatic balance, and can result in an array of responses that may be adaptive or maladaptive.

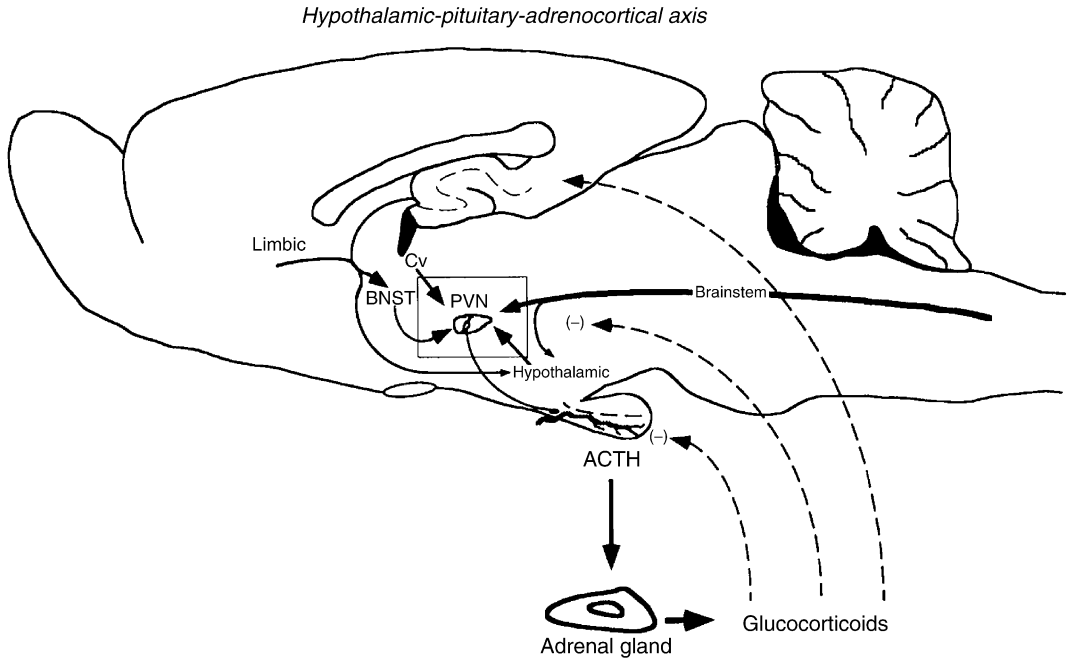
### Characteristics

#### Stress Classes and Consequences

Numerous attempts have been made to subdivide stressors according to class. Most authors have delineated stressors of a psychological or psychogenic origin versus those of a physical nature. Stressors within the former category (e.g. novelty, social defeat) have more recently been termed *processive* or *anticipatory* to emphasize extensive neural processing occurring largely within limbic brain structures prior to transmission to the PVN. Stressors in the latter category (e.g. cardiovascular) have been termed "systemic" or "direct" to underscore a more immediate challenge to homeostasis, as well as an uninterrupted access to the PVN from key afferent sites, particularly in the brainstem. It is the case, however, that overlap exists among both stress classes and the neuronal circuits that mediate them. Remarkably, these circuitries are organized in a hierarchical fashion that enables an appropriate assessment or weighing of the significance of an internal or external threat, with subsequent translation into neuroendocrine, autonomic, and behavioral responses [2]. It also evident that exposure to stress can produce long-term changes in neuronal function through mechanisms at multiple levels, including synaptic neurotransmission, intracellular signaling, gene regulation, and even morphological changes within key structures. Many of these changes may be considered normal adaptations, even in cases of prolonged or chronic stress. However, when the capacity of the brain's stress circuitry to maintain normal responsiveness is exceeded in the face of ongoing challenge, stress may be considered maladaptive, and ultimately deleterious to health.

#### The Hypothalamic-Pituitary-Adrenocortical (HPA) Axis

The origin of the final common pathway of a major neuroendocrine response to stress is the hypothalamic paraventricular nucleus (PVN); neurons in the medial parvocellular division of this nucleus synthesize and release corticotropin–releasing hormone (CRH) and project to the median eminence, where CRH is released into the portal vasculature. CRH stimulates anterior pituitary cells to secrete adrenocorticotropic hormone (ACTH, and additional products cleaved from a common precursor, pro-opiomelanocortin; POMC). ACTH is (Fig. 1) carried through the systemic circulation to the adrenal cortex, where it induces the synthesis and release of glucocorticoids (primarily cortisol in humans, corticosterone in rodents) from the zona fasciculata of the adrenal glands. The hypophysiotropic CRH neurons of the PVN are therefore the primary integrators of the HPA axis, processing stress-related information carried over multiple afferent pathways that differ according to the nature or class of the stressor. The PVN also contains populations of neurons with projections to the brainstem and spinal cord. These neurons, together with cells from adjacent hypothalamic nuclei, regulate outflow to the preganglionic neurons of the autonomic nervous system, including those governing the sympatho-adrenal-medullary response. In addition, arginine vasopressin (AVP), a neuropeptide highly expressed in neurons of the adjacent magnocellular division of the PVN and principally involved in osmotic regulation, is



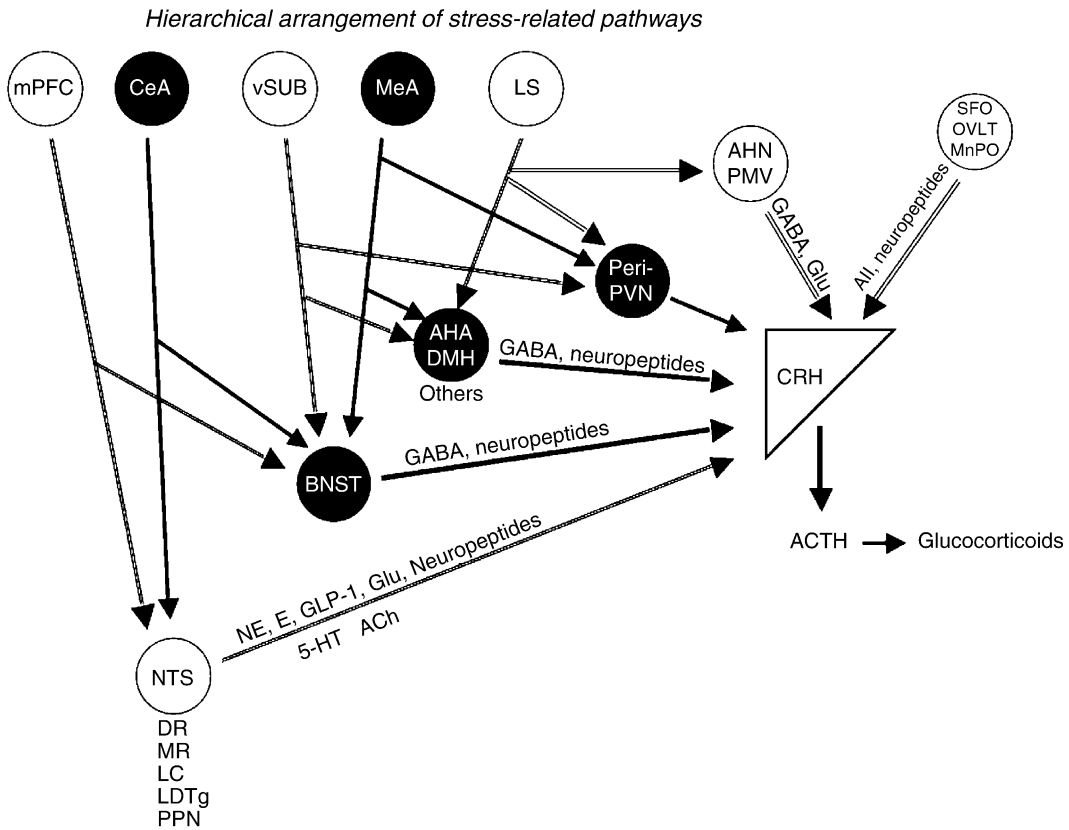
**Stress Response. Figure 1** Diagram illustrating the major components of the Hypothalamic-Pituitary-Adrenocortical (HPA) Axis. Solid arrows indicate sources of regulatory afferents from the brainstem, limbic forebrain, hypothalamus, and circumventricular organs. Dashed lines denote major sites of glucocorticoid negative feedback. Abbreviations: *ACTH* adrenocorticotropic hormone; *BNST* bed nucleus of the stria terminalis; *Cv* circumventricular organs; *PVN* hypothalamic paraventricular nucleus.

co-expressed within hypophysiotropic CRH neurons. AVP is capable of potentiating the effects of CRH on pituitary ACTH release. While CRH is clearly the most potent ACTH secretagogue, hypophysiotropic CRH neurons are also capable of co-expressing a number of peptides in addition to AVP. Recruitment of these transmitters appears to be condition- dependent, affording a wide range of responsivity to the glucocorticoid stress response.

Glucocorticoids have powerful actions throughout the body, targeting a diverse array of tissues including muscle, fat, skin, bone, kidney and liver. These steroid hormones also have direct effects on immune cells, on the production of inflammatory cytokines, as well as within the CNS itself. Dysregulation of glucocorticoid secretion contributes to numerous disease states including cardiovascular, autoimmune, metabolic, and neuropsychiatric disorders. For example, oversecretion of glucocorticoids can suppress immune function, increasing susceptibility to infection [3], and HPA axis overactivity is a common feature in many patients with depressive illness [4]. Conversely, under-activity of the HPA axis increases susceptibility to autoimmune and inflammatory conditions. Regulation of glucocorticoid levels within a normal range is therefore critical to health. Glucocorticoids also play an important role in cognitive processes such as learning, memory and attention, all of which are affected by dysregulation of the glucocorticoid stress response as well as stress-induced changes in levels of circulating catecholamines.

## Afferent Regulation of the PVN

CRH neurons of the PVN are under complex afferent regulation from numerous brain areas. These inputs can be divided into several major classes: brainstem nuclei, local hypothalamic regions, limbic-associated forebrain structures, and circumventricular organs [5] Major sources of stimulatory input to the PVN emanate from caudal brainstem regions containing the neurotransmitters norepinephrine and epinephrine. Most prominent among them are the A2 region of the nucleus of the tractus solitarus (NTS) and the A1/C1 area of the ventrolateral medulla, which have direct lines of input to the medial parvocellular PVN rich in CRH neurons. The noradrenergic input to CRH neurons is particularly dense, and pharmacological effects here are mediated via α-1 adrenergic receptors. These brainstem regions receive visceral afferent information carried (Fig. 2) via the ninth and tenth cranial nerves, and relay information to the HPA axis concerning the state of the internal milieu. They are also interconnected with brainstem cardiovascular and respiratory centers. More recent data have indicated that ascending projections from the NTS also include non-catecholaminergic elements. Moreover, numerous additional brainstem regions send projections to the PVN either directly, or via



**Stress Response. Figure 2** Schematic diagram illustrating complex, hierarchically organized afferent regulation of hypophysiotropic CRH neurons of the HPA axis. forebrain relays. Included are serotoninergic fibers emanating from the dorsal and median raphe nuclei, cholinergic fibers from the pedunculopontine and lateral dorsal tegmental nuclei, noradrengeric projections from the locus coeruleus, as well as inputs from the lateral parabrachial nucleus and periaqueductal gray regions. The majority of these inputs are stimulatory in nature, and many transmit somatic and special sensory information to the PVN. In contrast, a series of local forebrain (including intrahypothalamic) regions are known to distribute GABA-mediated inhibitory projections to the PVN. These include the medial preoptic area, bed nucleus of the stria terminalis, dorsomedial hypothalamic nucleus, and anterior hypothalamic area immediately surrounding the PVN. Interestingly, limbic system associated inputs to the HPA axis (medial prefrontal cortex, hippocampus, amygdala) lack direct projections to the PVN, and influence CRH neurons via relays with neurons located within these local territories [6]. Beyond the aforementioned pathways, research over the past decade has focused on extrahypothalamic CRH and the urocortins-centrally expressed neuropeptides sharing a family resemblance to CRH and acting at its receptors [7]. In addition to these strictly neuronally mediated inputs, blood-borne chemosensory signals reach the PVN either directly via the intrinsic vasculature, or by circumventricular organs (subfornical organ, organum vasculosum of the lamina terminalis) that send neuronal relays to the PVN.

## Glucocorticoid Regulation

Termination of glucocorticoid secretion following stressful episodes is accomplished by negative feedback occurring within different time domains and at multiple

levels of the HPA axis [8]. For example, glucocorticoids inhibit POMC expression and ACTH release at the level of the anterior pituitary, and inhibit hypophysiotropic CRH neurons at the level of the PVN through both genomic and non-genomic mechanisms. Glucocorticoids also act centrally at higher centers; glucocorticoid receptors are found at multiple central sites including the cerebral cortex, hippocampus, septum, amygdala, cerebellum, and brainstem. Two types of the receptor exist. The type II or GR (glucocorticoid receptor) has a widespread distribution in the CNS. The type I, or MR (mineralocorticoid receptor) receptor is more limited in expression, but has a 10-fold higher affinity for glucocorticoids than GR. Both are members of the steroid hormone superfamily, existing in an unbound state within the cytoplasm, but when bound by ligand are translocated to the nucleus where they bind to the promoter regions of responsive genes. Several lines of evidence have suggested that MR may be primarily important in maintaining basal expression of ACTH secretagogues (particularly at the circadian nadir), whereas GR may function principally at the circadian peak and following stressful stimuli. In addition, evidence suggests that glucocorticoid-independent neuronal inhibitory mechanisms are in operation during stressful conditions. For example, inhibition of ACTH release can occur in the absence of glucocorticoid negative feedback [9], implicating additional inhibitory mechanisms involved in restraining HPA-axis activation.

### Limbic Control of Stress Responsiveness

A number of constituent elements of the limbic system have been heavily implicated in the responsiveness of the HPA axis. These regions share the common feature that they lack direct PVN projections. The hippocampus plays a prominent role in inhibition of the glucocorticoid stress response, consistent with its high levels of expression of glucocorticoid receptors (see above). Moreover, functional studies have demonstrated a deficit in negative feedback following lesions of this structure, as well as with receptor inactivation or with gene deletion. Anatomical data are consistent with this picture: the ventral subiculum, the major output structure of the hippocampus, sends an impressive excitatory (glutamatergic) projection to the basal forebrain, but does not contact PVN neurons directly. These signals are converted to an inhibitory signal at the PVN by way of relays among populations of GABAergic neurons in the hypothalamus and BNST.

The amygdala, in contrast to the hippocampus, appears to stimulate the PVN. A major distinction lies in the class of stressors in which these limbic nuclei play a vital role. The medial amygdaloid nucleus stimulates the HPA axis in response to anticipatory but not systemic stressors, whereas the reverse is the case for the central amygdaloid nucleus. Interestingly, projection neurons from both the medial and central amygdaloid nuclei are GABAergic, and like hippocampal projections, do not directly innervate the PVN. Rather, both medial and central amygdaloid regions are also thought to target local inhibitory relay neurons, and thereby function through a disinhibitory mechanism.

Numerous studies have implicated the medial prefrontal cortex in HPA axis regulation. An increasing body of literature has indicated that dorsal components of this region are inhibitory to the PVN, whereas more ventral territories appear to stimulate HPA output [10]. In both cases this limbic cortical output is mediated via multiple relays in forebrain (e.g. BNST), or in the case of ventral prefrontal areas (infralimbic cortex), brainstem regions such as the NTS.

Several additional forebrain regions considered part of the limbic system are known to affect HPA activity. These include the lateral septal nucleus, which inhibits the stress response, as well as limbic components of the thalamus (e.g. paraventricular nucleus of the thalamus) that mediate habituation of the stress response. Finally, several loci within the hypothalamus intersect with classical limbic circuitries, and relays through these regions permit limbic information to be processed with regard to ongoing physiological status. The net effect is that stressor salience is fine-tuned within these local circuits to account for caloric requirements, thermoregulatory status, osmotic balance, and diurnal rhythmicity prior to being translated to the PVN.

## Stress Response (Heat Shock) Protein

### Definition

Protein that is synthesized in response to mechanical, chemical or thermal (heat shock) injury (stress), and which usually promotes survival of the cell.

## Stretch-inactivated Cation Channel (SIC)

### Definition

Stretch-inactivated cation channels underlie the hyperosmotic depolarization which is associated with an increase in membrane conductance. This response is due to the bi-directional, cell-volume-dependent modulation of a non-selective cation conductance. Cells shrinking in the presence of hypertonic solution disinhibit channel activity, which leads to depolarization.

Conversely, cell swelling induced by a hypoosmotic solution inhibits basal channel activity and leads to hyperpolarization.

►Blood Volume Regulation

## Stretch Receptor

### Definition

In many animals, muscles contain specialized sensory end organs that are activated when the muscle in which they are contained is lengthened or stretched. These sensory receptors signal the length of the muscle to the central nervous system (CNS) and can also signal the velocity of a change in length. In the lamprey, these receptors are located in the spinal cord itself and respond when the cord bends during body undulations.

►Intersegmental Coordination
►Sensory Systems

## Stretch Reflex

### Definition

The stretch reflex is a reflex that causes a muscle to contract and shorten after it is stretched. The elongation of a muscle, usually by an external perturbation is encoded by the firing of muscle spindle receptors within the muscle. The Ia muscle spindle afferents synapse on motoneurons of the same muscle, causing the muscle to contract in response to muscle stretch.

# Striate Cortex

## Definition

The striate cortex (also called Brodmann's area 17, V1, and primary visual cortex) is the first cortical visual area. It lies in the calcarine sulcus of the occipital lobe and receives signals relayed from the retina via the lateral geniculate nucleus of the thalamus.

►Striate Cortex Functions
►Geniculo-striate Pathway

# Striate Cortex Functions

Daniel L. Adams, Jonathan C. Horton
Koret Vision Research Laboratory, Department of Ophthalmology, UCSF, San Francisco, CA, USA

## Synonyms

Area V1; Primary visual cortex; Brodmann area 17

## Definition

Striate cortex is the primary sensory cortical area for vision. Damage to striate cortex causes blind regions, called scotomas, in the field of vision. Striate cortex derives its name from the stria of ►Gennari, a prominent band of ►myelin in layer 4, visible to the naked eye. In histological sections, striate cortex has a characteristic laminar cell structure (Fig. 1). Striate cortex is located within the calcarine sulcus on the medial face of each ►occipital lobe. It occupies about 10% of the whole cerebral cortex. Each neuron in striate cortex responds to visual stimuli presented within a small portion of the visual field, known as the ►receptive field (►Visual cortical and subcortical receptive fields). The properties of a visual cell can be ascertained by analyzing the response to different types of visual stimuli falling within the receptive field. Thus, the functions of striate cortex can be defined by identifying the cardinal properties of its constituent cells, such as selectivity for stimulus orientation, direction of motion and stereoscopic depth (►Binocular Vision). These properties must be synthesized within striate cortex, because they are not present in the cells that provide ascending input. Another way to define the functions of striate cortex is to examine how the properties of single cells are related to anatomical structures, commonly revealed by the presence of functional maps. Neurons with similar properties tend to be grouped together, and there is a continuous and gradual change in physiological characteristics across the cortical sheet. Numerous superimposed maps are present within area V1 that together provide full coverage of the visual field for multiple visual modalities.

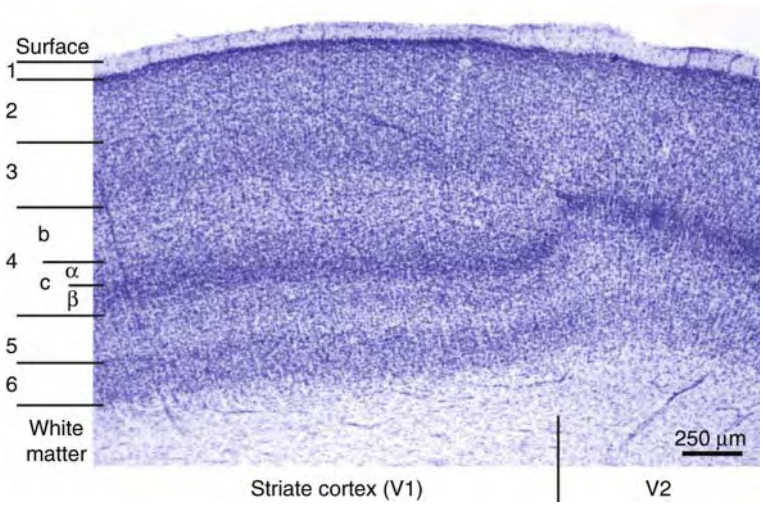
## Characteristics

### Overview

The neural processing of visual signals begins with the capture of light images by photoreceptor cells (►photoreceptors). After some internal retinal processing, visual information exits the eye in the form of action potentials propagated along the axons of ganglion cells (►retinal ganglion cells). These axons are grouped into bundles that form the ►optic nerves. The two optic nerves meet and decussate partially at the ►optic chiasm, to form the ►optic tracts. In the optic tracts, crossed fibers from the nasal half of each retina run alongside uncrossed fibers from the temporal half of each retina. The axons synapse on cells in the ►lateral geniculate nucleus (LGN) of the ►thalamus. The LGN provides the major ascending input to striate cortex, via the ►optic radiations, to layer 4. The main cortical output is derived from layers 2, 3, 5, and 6. Between the input and output layers, intracortical circuitry combines and elaborates visual signals to generate novel receptive field properties. The visual system includes a network of multiple cortical areas, each receiving input from and sending connections to other areas. Each area in the network acts as a specialized processing module, extracting specific types of visual information. Striate cortex can be thought of as the foundation of this network. It distributes and receives information from many different interconnected areas. Striate cortex also sends a major feedback projection to the LGN. The function of this pathway is contentious; it may modulate the flow of information into striate cortex.

### Input

Cells within each layer of striate cortex have characteristic morphologies and patterns of connectivity (►Visual cortex – neurons and local circuits). The input from



**Striate Cortex Functions. Figure 1** Cross section through striate cortex stained with cresyl violet to show neuronal cell bodies. The multi-layered structure of the cortical sheet is evident, as well as the transition between striate cortex and the second visual area, V2. Layer 4 is a conspicuous feature of striate cortex, containing two cell-dense input sublayers (4cβ and 4cα), as well as a cell sparse sublayer (4b) containing the stria of Gennari.

the LGN to striate cortex abides by a laminar organization, such that three categories of LGN cells project to three separate laminar divisions (Fig. 2), also see ►geniculo-striate pathways). Thus, the functional division in the LGN is maintained in the input layers of striate cortex. To generate more specialized functional properties, the signals from multiple LGN inputs converge onto single cortical cells. This convergent processing of visual information in striate cortex is achieved by complex circuits that operate between the input and the output cells.

### *Intracortical Circuitry*

Intracortical circuitry forms the anatomical basis of neural processing of visual information (►Visual cortex – neurons and local circuits). Intracortical projections connect cells that are separated horizontally in the same layer or vertically in separate layers. These connections allow visual signals from many cells to combine and influence each other. In the case of striate cortex (Fig. 3). the dense internal circuitry provides ample opportunity for the integration of functional properties that remain segregated at the level of the LGN. The intracortical circuitry of striate cortex is responsible for the elaboration of the elementary properties of LGN cells into novel, more specialized attributes, such as orientation, direction and binocular disparity tuning.

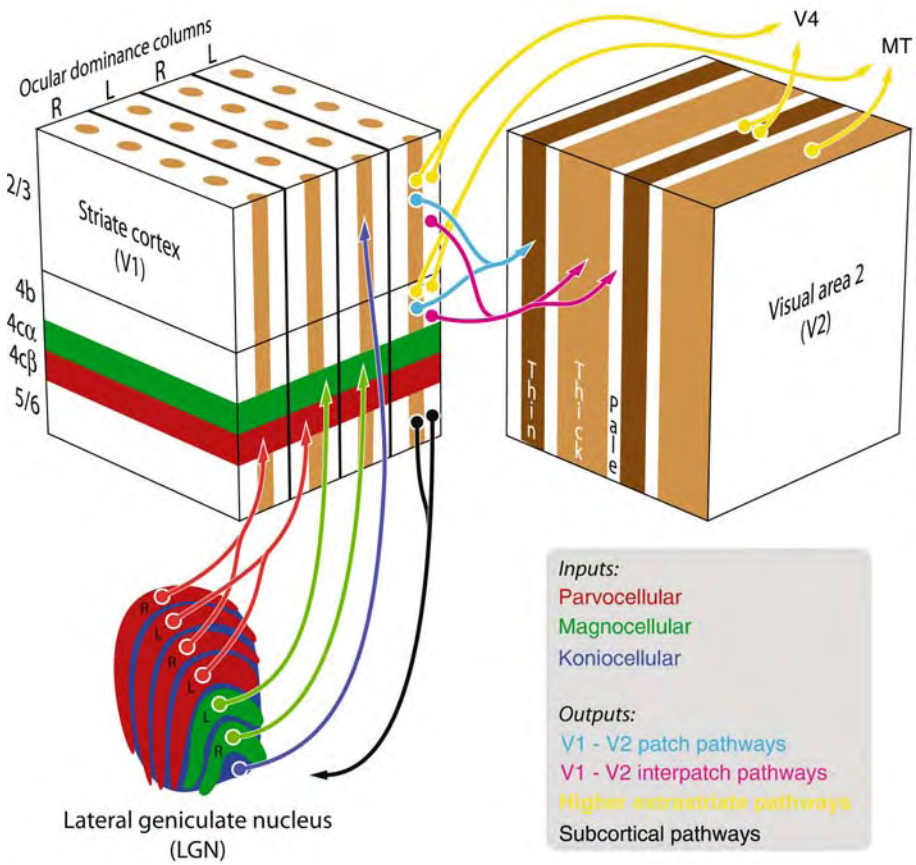
### *Retinotopy*

Neighboring cells in striate cortex represent adjacent points in the visual field. This organizing principle is called ►retinotopy (Fig. 4). A consequence of retinotopic organization is the formation of a map of the visual scene on the cortex. The fovea in each retina corresponds to the ►fixation point. The fovea represented posteriorly near the occipital pole. A vertical line running through the fixation point divides the visual scene into left and right hemifields. Each hemifield is represented in striate cortex of the contralateral hemisphere. Thus if striate cortex on one side is destroyed, vision is lost from the visual field on the opposite (contralateral) side. In this case, the damage is said to have caused a ►homonymous hemianopia – loss of vision from both eyes resulting in complete blindness on one full side of the visual field.

When we examine something closely, like the printed words on a page, we move our eyes so that light reflected from the point of interest is focused onto the fovea of each retina. The ►eye movements (►Saccades) that control this behavior allow us to take full advantage of the fovea by placing it serially on regions of interest. Numerous specializations in the retina (including a high density of ones) endow the fovea with maximum resolution. As a result, more information emanates from the fovea than from the peripheral retina. To serve the fovea, a far greater amount of cortical tissue is allotted to central versus peripheral retina. In fact, the surface area of striate cortex devoted to 1° is about 10,000 times greater at the fovea than in the periphery. This results in distortion of the visual scene by the retinotopic map in striate cortex (Fig. 5).

### *Ocular Dominance*

Cells in the LGN are monocular; they respond to stimuli presented to one eye but not to the other. Likewise, the

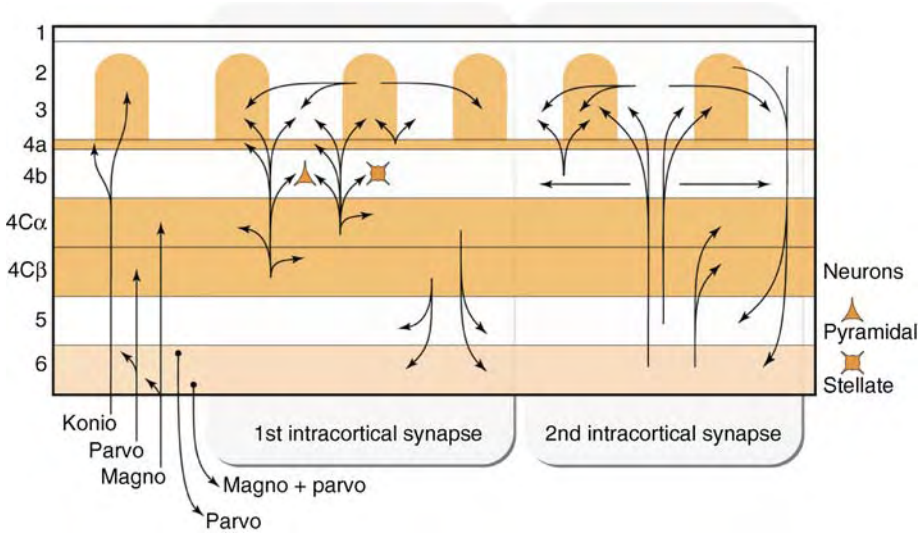


**Striate Cortex Functions. Figure 2** Inputs and outputs of striate cortex. Cells in the LGN provide the major ascending input to striate cortex. Their axon terminals segregate both by eye (R, L) and by layer. Recipient cells in layer 4cβ (parvo), 4cα (magno) and 2,3 (konio) make extensive intracortical connections, partially merging inputs from the three functional LGN channels. The output from striate cortex to area V2 is organized by cytochrome oxidase compartment. The patches (vertical brown cylinders) project to thin stripes, and the interpatches project to thick and pale stripes. The output of V2 also respects cytochrome oxidase divisions: thick stripes project to the middle temporal area (MT), while thin and pale stripes supply area V4.

cells in layer 4c of striate cortex are monocular, because they are targeted selectively by LGN inputs. Layer 4c is segregated into regions dominated by the left eye or the right eye. These two domains interdigitate to form a labyrinthine pattern tangential to the cortical sheet-called "►ocular dominance columns". The pattern formed by ocular dominance columns is distinctive and robust [2]. It is best appreciated when the cortex has been removed from the rest of the brain, unfolded and flattened before histological sections are cut tangential to the surface [3] (Fig. 4b). Rather like a fingerprint, the ocular dominance pattern is unique and highly variable between individuals and species. Columns are found in most carnivores and primates, including humans. In animals that lack columns, monocular cells persist, but they are mixed homogenously in layer 4c. Ocular dominance columns are intriguing, but their function is unknown.

### *Disparity Selectivity*

Most cortical cells in layer 4c are monocular, i.e. they respond to stimulation of only one eye. Binocular integration (►Binocular vision) occurs by the convergence of intrinsic projections from monocular cells in layer 4c onto single cells in the upper and lower layers of the cortex. Most binocular cells are sensitive to small differences in the spatial location of images falling on each retina. This endows them with the capacity to extract information about the depth of stimuli relative to the fixation point: a property known as ►disparity selectivity. Some binocular cells are tuned to respond maximally to stimuli placed on the fixation plane, whereas others prefer stimuli in front of or behind it. As a population, disparity-tuned neurons encode accurate information about depth, and therefore provide the cellular basis for the perceptual phenomenon of ►stereopsis. They also provide signals to the



**Striate Cortex Functions. Figure 3** Intracortical circuitry within striate cortex. (*Left*) V1 is innervated by parvocellular, magnocellular, and koniocellular laminae of the LGN, which segregate in layers 4cβ, 4cα, and 4a 2/3 respectively. Even by the first intracortical synapse, these functional streams intermingle extensively. At the second intracortical synapse, increasing emphasis on horizontal projections further blends V1 signals. The relative strength of projections is not shown in this schematic diagram, nor is the diversity of cell types and classes comprising the intracortical wiring (Figure from [1]).

►brainstem for the ►oculomotor system to drive reflexive, ►disparity dependent► vergence movements that bring both foveas onto a common target in depth.

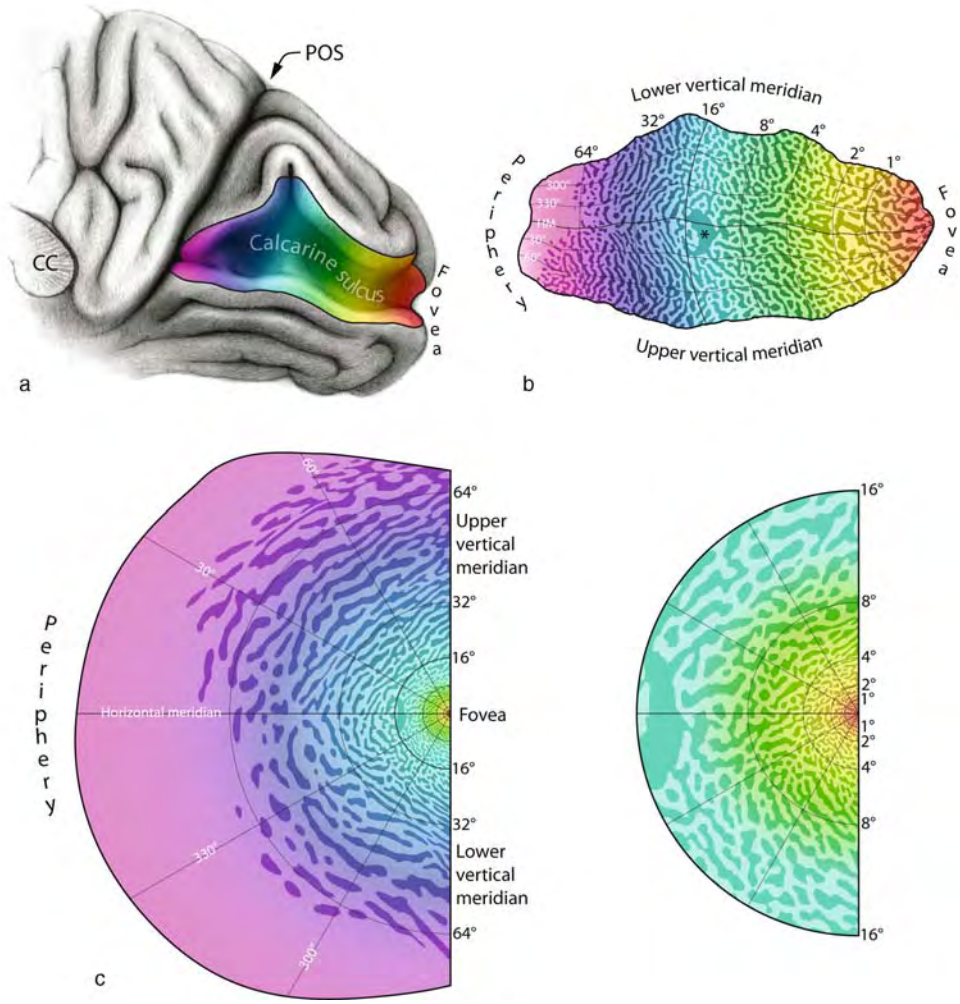
Specialized stimuli called random dot stereograms are often used to study stereopsis because they contain no depth cues except disparity. Random dot stereograms whose elements have opposite contrast in the two eyes (anticorrelated) do not give rise to a sensation of depth. However, cells in striate cortex are selective for the disparity in anticorrelated random dot stereograms. The difference between the responses of a striate cortex cell to correlated versus anticorrelated stereograms is an inversion of the disparity tuning curve. Thus, cells in striate cortex can exhibit disparity-tuned responses that do not lead to a perception of depth [4]. That the activity of cells in striate cortex does not necessarily correlate with perception is an interesting insight into striate cortex function. It is likely that networks of neurons from striate cortex to ►extrastriate areas (►extrastriate visual cortex) must also be activated to produce a conscious visual experience of depth.

### *Orientation Selectivity*

Unlike cells in the LGN, which fire best to small spots of light, most cortical cells outside of layer 4cβ display ►orientation selectivity (Fig. 6). These cells respond optimally when the stimulus is presented at a specific orientation within the ►receptive field [5] (►Geniculostriate pathway; ►Visual cortical and subcortical receptive fields). Since they respond to ►contours, orientation-tuned cells comprise the elementary units necessary for form vision (►form perception). In striate cortex, orientation-tuned cells have a distinct functional organization: orientation tuning rotates gradually as the cortical sheet is traversed in a tangential direction. Optical imaging produces a strikingly ordered ►orientation map, containing singularities (as referred to as pin-wheeles) where neurons with different orientation preferences converge and saddle zones where transitions are more gradual (Fig. 7) [6]. Recent experiments have shown that neuronal maps can be described more accurately by invoking Fourier energy models, rather than simply orientation tuning [7].

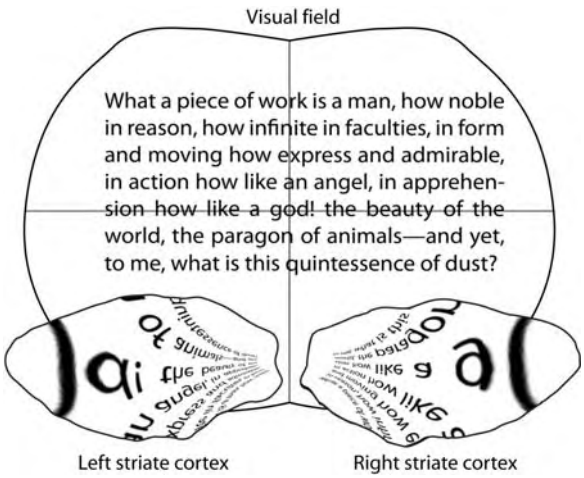
### *Direction selectivity*

The detection of movement is a fundamental function of the visual system. Even animals with rudimentary vision are able to sense motion. In primates, motion vision is thought to be mediated by populations of cells whose responses are tuned to particular directions of stimulus movement. Such cells are less concerned with the orientation, form or color of the stimulus, but are often tuned to its speed. In some cases, the responses of direction selective cells are inhibited when the stimulus moves 180° opposite to the preferred direction. Since LGN cells do not exhibit direction selectivity, it must be generated within striate cortex by projections between multiple non-directional cells in specialized circuits. Direction selective cells are most prominent in layers 4b and 5/6 of striate cortex.

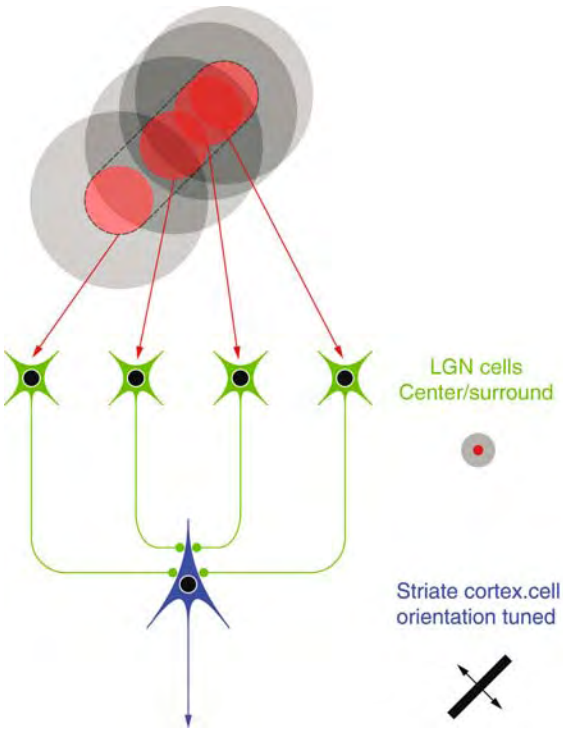


**Striate Cortex Functions. Figure 4** The retinotopic map and ocular dominance column pattern in human striate cortex. (a) Medial face of the right hemisphere with the calcarine sulcus opened to expose striate cortex. Visual eccentricity is color-coded: the representation of the fovea is red and the far periphery is violet. cc = corpus callosum. (b) Unfolded striate cortex, showing retinotopic coordinates. The left eye's columns correspond to the pale regions. The blind spot appears as a solid oval (*). The representation of the monocular crescent also lacks columns, because the extreme temporal visual field is supplied by the contralateral eye alone. (c) Projection of striate cortex back onto the visual hemifield, demonstrating the magnification of central vision in the cortex. The central 16° are shown at higher magnification on the right. Since ocular dominance columns are relatively constant in size, their projection onto the visual field is greatly distorted by cortical magnification.

The direction-selective cells of striate cortex form the building blocks for motion vision (►Visual processing of motion). However, taken in isolation, their responses are not sufficient to describe completely the direction of motion of an object in the visual world. The receptive fields of direction-selective cells in striate cortex are small. Consequently, each cell can respond only to individual components of a moving object. Since the global direction of movement of an object is a sum of all of its component vectors, the responses of many striate cortex cells must be considered to gain an accurate measure of the object's direction; single cells in striate cortex are not equipped to provide this information. This is known as the ►aperture problem, because it arises when one observes the motion of an oriented contour through a small aperture that blocks the view of the ends of the line (Fig. 8). Direction-selective cells in layer 4b of striate cortex project directly to an extrastriate visual area, the medial temporal area (MT), also known as V5. MT cells are also direction-selective, but their receptive fields are larger than those of striate cortical neurons. Single MT cells receive input from multiple



**Striate Cortex Functions. Figure 5** Projection of a visual image onto striate cortex. A greater amount of tissue is allocated to the representation of the central portion of the visual field in striate cortex, resulting in distertion of the text. The crosshair represents the center of gaze, which corresponds to the fovea in each eye. The left side of the visual field is reflected about a horizontal axis and projected onto the right hemisphere (and *visa-versa*). The increase in magnification from peripheral to central visual field in the cortical transformation of the image is logarithmic.



**Striate Cortex Functions. Figure 6** The generation of orientation selectivity in striate cortex. The receptive fields of LGN cells have a center-surround structure. They each respond best to spots of light appearing at the center of the receptive field (*red*). Stimulation of the surround region (*grey*) inhibits the response of each cell. Here a population of center-surround cells (*green*) is shown, forming excitatory synapses onto a single cortical cell (*blue*). If a light impinges on the centers of the LGN cells simultaneously, the cortical cell will be activated maximally. The property of orientation selectivity may be derived from selective connections between such geniculate cells and cortical cells.

direction-selective cells in striate cortex, enabling them to be selective for the global direction of motion of an object in the visual world [8].

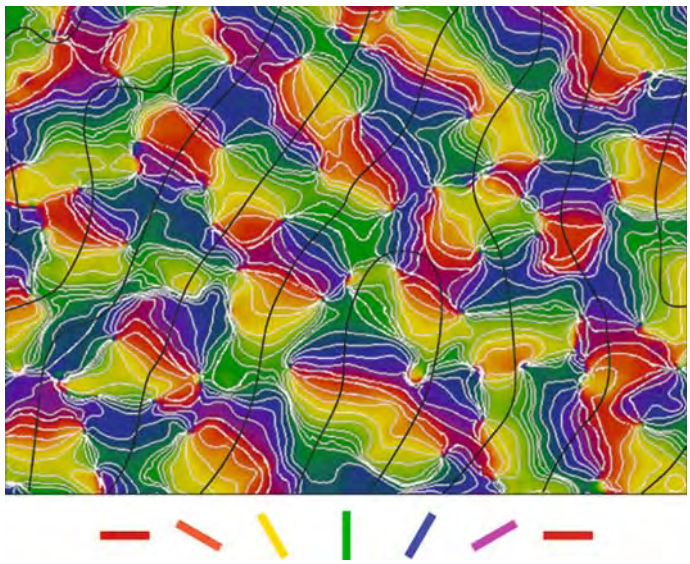
### Color Selectivity

Cells influenced by the wavelength composition of stimuli are said to be color-selective, and provide information necessary for ►color perception (►Color processing). Many cells in striate cortex have a color-opponent, center-surround structure to their receptive fields. This organization reflects an imbalance in the spatial composition of inputs from different ►cone photoreceptors (►Photoreceptors) in the retina. Other cells display the property of double ►color opponency, i.e. their center and surround are maximally inhibited or excited by pairs of different wavelengths. Such cells are ideal for detecting chromatic borders. Some cortical cells are tuned to both the color and the orientation of stimuli.

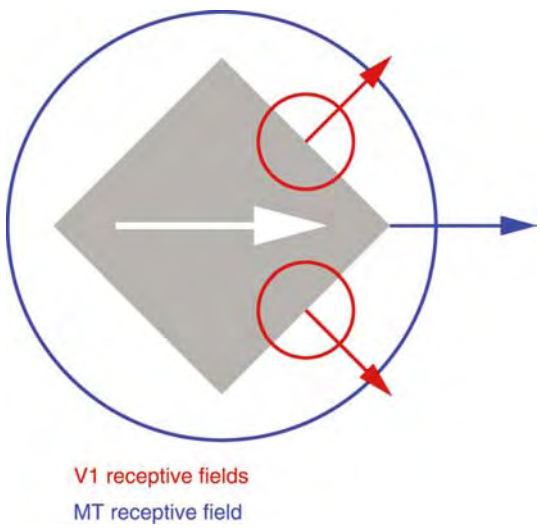
There is a diverse range of wavelength combinations present in natural illumination. The visual system must take into account the wavelength composition of the illuminating light to perceive accurately the color of objects. The process of discounting the influence of the illuminant is called ►color constancy. Cells in striate cortex respond only to the wavelength composition of reflected light rather than the perceived color of the surface [9], i.e. they do not exhibit color constancy. Consequently, "color" cells in striate cortex are more accurately referred to as wavelength-selective. The calculations necessary to provide color constancy must therefore be made in a higher visual area, such as V4. Just as for disparity and direction selective cells in striate cortex, wavelength selective cells encode a physical property of the world that does not necessarily correlate with perception.

### Cytochrome Oxidase Architecture

Cytochrome oxidase is a metabolic enzyme present in mitochondria. The level of cytochrome oxidase is regulated by cell activity over a time scale of hours. In cortical tissue, the density of cytochrome oxidase is heterogeneous. In striate cortex, the input layers stain most richly, indicating that they have the highest rate of



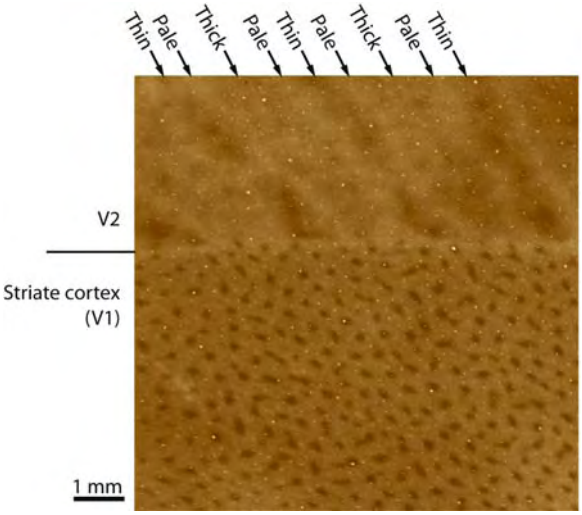
**Striate Cortex Functions. Figure 7** Map of orientation preference in macaque striate cortex. Orientation selectivity is measured by optically imaging the cortical surface in the presence of a voltage-sensitive dye. Physiological response is color coded according to the orientation of the bar stimulus that generates the strongest signal. White lines are iso-orientation contours. Black lines represent the borders of ocular dominance columns. The iso-orientation lines converge at pinwheel centers which tend to be centered within ocular dominance columns (Data from [5]).



**Striate Cortex Functions. Figure 8** The aperture problem. The direction of motion of an object (*the gray square*) cannot be determined by observing the direction of motion of individual local components. The global direction of motion of the object can be determined only from the sum of all the component vectors. Cells in striate cortex are able to signal the direction only of local contours because their receptive fields (*red*) are too small to sum vectors from the whole object. Cells in MT, however, have large receptive fields (*blue*) that are formed by combining the output from many cells in striate cortex. They are better equipped to solve the aperture problem and to encode the true direction of motion (*white arrow*) of the object.

physiological activity. In the tangential plane, cytochrome oxidase histochemistry reveals a regular array of patches, most prominently in layers 2 and 3 (Fig. 9). Also known as puffs or ►blobs, these patches span the full thickness of the cortex, except for layers 1, 4a and 4c. Patches are thought to constitute functional units within striate cortex, because their anatomical connections are distinct. In layers 2 and 3 they receive a direct projection from konio cells in the LGN (Fig. 2) (►Geniculo-striate pathway). Because this projection is monocular, and patches are located within the middle of ocular dominance columns, their cells usually show a strong response bias for one eye. Other physiological properties may correlate with cytochrome oxidase patches in striate cortex. For example, there is weak evidence that unoriented, color-selective cells are clustered within patches. Patches may also be aligned with pinwheel centers in the orientation map [6].

Visual area 2 (►area V2) also has a characteristic cytochrome oxidase architecture (Fig. 9), consisting of parallel stripes (see also ►Extrastriate visual cortex). Three distinct types of cytochrome oxidase stripes are present in the monkey, forming an alternating pattern orthogonal to the area V2 border. There are two classes of dark stripes – thick and thin – separated by pale stripes. The stripes in area V2 extend through the full thickness of the cortex. Each stripe class in area V2 has distinct functional properties, as shown by physiological recording. Moreover, the input and output connections of area V2 are organized by stripe type (Fig. 2).



**Striate Cortex Functions. Figure 9** Functional compartments in V1 and V2 are interconnected. This tangential section was stained for cytochrome oxidase, revealing a regular array of patches in striate cortex and repeating cycles of thick-pale-thin-pale stripes in V2. Patches connect to thin stripes; interpatches supply thick and pale stripes.

### *Output*

The main cortical projection target of striate cortex is V2. V1 cells in patches project to V2 cells in thin stripes (Fig. 2). This projection may be specialized for ►color processing, through a pathway that combines LGN ►parvocellular and ►koniocellular inputs in patches, and then proceeds via area V2 thin stripes to area V4. Cells located in the area V1 interpatch regions project to thick or pale stripes. A substantial proportion of interpatch cells have axons that bifurcate to terminate in both a thick and a pale stripe [1].

Cells in striate cortex also give rise to axons that project to extrastriate areas beyond area V2. Some ►direction-selective cells in layer 4b project directly to MT. Patch and interpatch cells in layers 2 and 3 project directly to area V4, an area thought to process color and form information that also receives input from V2's thin stripes and pale stripes. Thus, the outputs of striate cortex provide the origin for multiple cortical ►visual processing streams, each dividing further to become more specialized for specific visual modalities. Ultimately, these pathways result in a division of labor among multiple, functionally specialized regions of the brain.

## Summary

Striate cortex contains cells that encode basic information about many visual modalities. However, the responses of these cells do not correlate directly with perception. Information must be passed from striate cortex to higher visual areas, where the activity of single cells provides a precise readout of sensory experience. Because signals pass through striate cortex *en-route* to these higher areas, lesions of striate cortex block the flow of information to the whole cortical visual system. Thus, while it may not signal perception *per se*, an intact striate cortex is necessary for conscious vision. Humans with lesions of striate cortex are capable of making only coarse visual discriminations in their blind fields. This preserved visual ability sometimes goes unnoticed by the subject until explicitly tested under laboratory conditions, prompting some investigators to call it "blindsight" (►Blindsight). The existence of such residual vision means that there must be an alternate route to higher cortical visual areas that bypasses striate cortex. Recently a neural pathway that could fulfill such a role was found in the macaque [10]. Small numbers of cells in the LGN were found to project directly to the extrastriate motion processing area MT. This pathway may be responsible for the rudimentary visual capacity to sense motion that persists in the absence of striate cortex.

Compared to more specialized extrastriate visual areas like MT, the functions of striate cortex are manifold. Perhaps it is best thought of as a refinery and distribution station, first extracting and purifying components of visual information, then routing them to appropriate specialized areas of the extrastriate visual system for more detailed analysis.

# Striatopallidum

Daniel S. Zahm
Department of Pharmacological and Physiological Science, Saint Louis University School of Medicine, Grand Blvd., Saint Louis, MO, USA

## Synonyms

Basal ganglia; Cortico-subcortical reentrant circuit; Cortico-basal ganglia-thalamocortical circuit; Forebrain functional-anatomical system; Forebrain macrosystem

## Definition

Striatopallidum refers to a general pattern of neural connectivity, originally limited to the basal ganglia (see essay on ►Basal Ganglia), relating the cerebral cortex to certain ►deep telencephalic nuclei, such as the ►caudate nucleus and ►putamen, which receive massive cortical ►projections and the ►globus pallidus, to which the caudate nucleus and putamen project. The globus pallidus in turn gives rise to outputs that (1) return to motor planning related parts of the cortex via relays traversing the thalamus (see essay on ►Thalamus) or (2) descend into the brainstem to terminate largely in the vicinity of motor related structures associated with the reticular formation of the brain (see essay on ►Reticular Formation). During the past 30 years the meaning of the term striatopallidum has broadened, as cortico-subcortical relationships resembling those of basal ganglia have been described in association with a number of structures classically grouped with the ►limbic system (see also ►Limbic System), including the ►nucleus accumbens, ►olfactory tubercle, ►amygdala and ►bed nucleus of the stria terminalis and some additional territories in the ►basal forebrain.

## Characteristics

The prototypic pattern of neural connections in the striatopallidum, as alluded to in the definition given above, is classically associated with the ►corpus striatum, as in e.g., Nauta and Mehler's classic description of the connections of the ►lentiform nucleus in the monkey [1]. The term striatum refers to visible striations caused by axon fascicles fanning through the corpus striatum, which comprises the caudate and lentiform nuclei. The lentiform nucleus in turn consists of the putamen and globus pallidus. The cerebral cortex of projects massively to the caudate nucleus and putamen, which both comprise mostly medium size, densely spiny, inhibitory neurons, are structurally and physiologically similar and project massively to the globus pallidus. The globus pallidus differs from the caudate nucleus and putamen structurally and functionally and gives rise to the trans-thalamic and descending outputs from the complex. For unknown reasons, the term striatum came to be reserved for the caudate and putamen, distinguishing them from the globus pallidus, or pallidum. Although the deep telencephalic nuclei or basal ganglia, correctly also include the amygdala (also called the amygdaloid complex) and septal nuclei, common usage of the term basal ganglia became limited to the corpus striatum. Hence, the meaning of the term striatopallidum came to approximate that of the term basal ganglia.

A number of more or less epic conceptual developments during the past 30 years have served to broaden the definition of the basal ganglia, resulting in a gradually increasing usage of the term striatopallidum and generalization of its meaning. The first of these occurred during the early 1970's with the discovery that the olfactory tubercle in the rodent is occupied by neural tissue that, in terms of intrinsic character and extrinsic connections, is striatal [2]. The striatum in the olfactory tubercle, which came to be called ►ventral striatum, was observed to interdigitate with another distinct district in the tubercle containing neural tissue of pallidal character representing a rostroventral extension of the globus pallidus protruding into the basal forebrain and deep parts of the tubercle. Cortical inputs to the striatal district of the tubercle, which occupies its superficial and intermediate parts, arise in the primary olfactory (piriform) cortex. The striatal district of the tubercle projects to the overlying so-called ►ventral pallidum, which in turn projects to the ►mediodorsal nucleus of the thalamus [3]. These relationships, combined with the observation that the nucleus accumbens gives rise to a striatopallidal projection to an adjacent part of the ventral pallidum [4], served to confirm the longstanding, tentative characterization of the nucleus accumbens as part of basal ganglia [5].

These findings broadened the concept of basal ganglia. Now the entire cerebral cortex, including the olfactory cortex and hippocampus would be regarded as utilizing mechanisms provided by basal ganglia circuitry. The previously held concept that the cortico-subcortical relationships in brain can be split into distinct limbic (see also synopsis on ►Limbic System) and ►extrapyramidal (basal ganglia) sectors was no longer tenable. On the contrary, the parallel disposition of the newly discovered cortico-basal ganglia-thalamocortical circuit traversing ventral striatum, ventral pallidum and the ►thalamic mediodorsal nucleus and the "classical" basal ganglia circuit involving, e.g., the caudate nucleus and putamen, globus pallidus and anterior ►ventral tier thalamic nuclei (VA-VL), eventually led to a more refined appreciation of parallel, segregated basal ganglia-thalamocortical circuits ([6], see also essays on ►Basal Ganglia and ►Cortico-Subcortical Reentrant Circuits), an appreciation laden with implications for the

diagnosis and treatment of neuropsychiatric illness [7]. Furthermore, the continuity across dorsal and ventral striatopallidum of the massive terminations of the ventral mesencephalic dopaminergic projections energized fields of inquiry concerned with dopamine and its receptors, including neuropsychiatry (in particular as related to schizophrenia) and drug abuse research.

A second major conceptual "advance" was described in a paper that became quite influential essentially by reasserting the validity of some neglected concepts from the classical literature ([8] and references therein). These authors recapitulated the venerable, but largely forgotten, concept that the amygdaloid complex comprises two distinct sectors (see essay on Amygdala). One is a cortical-laterobasal part of the amygdala that is cortex-like in terms of its intrinsic cellular and neurochemical composition and extrinsic connections. The second is a centromedial part that includes the ►central (CeA) and ►medial nuclei (MeA) of the amygdala. Some additional structures exhibiting strikingly similar tissue composition and continuity with the CeA and MeA include the bed nucleus of the stria terminalis (BST), similarly differentiated and organized neuronal groups dispersed within the ►stria terminalis and certain basal forebrain territories extending between the centromedial amygdala and BST, all of which together came to be called ►extended amygdala. A central division of the extended amygdala gets its major descending inputs largely from the cortical-like laterobasal complex of the amygdala and gives rise to outputs to the ►lateral hypothalamus and brainstem somatic and autonomic motor effectors. A medial division of the extended amygdala gets descending inputs largely from the cortical nucleus of the amygdala and projects mostly to neuroendocrine effectors in the medial hypothalamus (see essay on ►Hypothalamus). While acknowledging that the extended amygdala exhibits features that strikingly resemble the intrinsic organization and extrinsic connections of striatopallidum, Alheid and Heimer [8] opted to emphasize those aspects of tissue composition and function that distinguish extended amygdala from striatopallidum and conceived of the two as distinct ►basal forebrain functional-anatomical systems. They also mentioned that additional evaluation would probably reveal the ►lateral septum to be an input (striatal) structure of yet another distinct striatopallidal-like basal forebrain functional-anatomical system receiving massive hippocampal inputs.

A couple of investigators subsequently adopted the fundamental tenets articulated by Heimer and Alheid so completely as to vigorously advocate that the cortico-subcortical relationships of the extended amygdala be regarded without qualification as striatopallidal [9,10]. One effect of these papers has been to further increase the currency of the term striatopallidum in contemporary neuroscience intercourse.

# Striatum

S

## Definition

The striatal components of the striatopallidal complexes. In mammalian terminology, the dorsal striatum is also known as the caudate nucleus and putamen. It receives glutamatergic cortical inputs and dopaminergic inputs from the substantia nigra, and it projects to the globus pallidus. The ventral striatum consists of the nucleus accumbens and the olfactory tubercle. It projects to the ventral pallidum. The striatopallidal complexes are involved in circuits that control the suppression and/or initiation of movements.

# Striatum, Dorsal

## Definition

Caudate nucleus and putamen as part of the basal ganglia.

►Basal Ganglia
►Striatopallidum

# Striatum, Ventral

## Definition

Part of the striatal complex comprising the ventral parts of the caudate nucleus and putamen, the accumbens and striatal districts in the olfactory tubercle, i.e. containing a dense accumulation of medium-sized, densely spiny GABAergic neurons.

►Basal Ganglia
►Striatopallidum

# Striola

## Definition

A central specialized region of otoconia and receptor cells that lies centrally in the otolith maculae.Within the striola lies the imaginary reversal line, where hair cells of opposing polarity reside.

►Peripheral Vestibular Apparatus

# Stroke

Claire Creutzfeld, David Tirschwell
Harborview Neurology - Comprehensive Stroke Center University of Washington School of Medicine, Seattle, WA, USA

## Synonyms

Cerebrovascular disease; Cerebrovascular accident; CVA, Brain attack

## Definition

Stroke is defined as rapidly developed clinical signs of focal (or global[1]) disturbance of cerebral function lasting more than 24 h (unless interrupted by surgery or death), with no apparent cause other than a vascular origin: it includes patients presenting with clinical signs and symptoms suggestive of subarachnoid haemorrhage, intracerebral haemorrhage or cerebral ischaemic necrosis [1].

## Characteristics

### Epidemiology

Stroke is the second leading cause of lost disability-adjusted life years in high-income countries and of death worldwide, after ischemic heart disease; in 2001, an estimated 5.4 million people died from stroke worldwide [2]. In the USA, there are approximately 700,000 strokes each year, killing over 150,000 people; almost a third of stroke victims are younger than 65 years of age [3]. In Western societies, 80% of strokes are ischemic, and the remaining 20% are caused by hemorrhages. One-month case fatality rate for stroke ranges between 8 and 40%, with mortality highest for hemorrhagic strokes and in developing countries [3].

### Etiology/Subtypes

A stroke is caused by disruption of blood supply to a part of the brain. Brain tissue that no longer receives its blood supply can die within a few hours unless something is done to stop the damage. Blockage of an artery leads to *ischemic stroke*. If this blockage lasts less than 24 h, with complete resolution of symptoms, it is called a transient ischemic attack (►TIA). Strokes due to bursting of an artery are called hemorrhagic strokes. In *intracerebral (or intraparenchymal) hemorrhages*, the blood clot forms in the brain itself, while *subarachnoid hemorrhages* are due to bleeding within the membranes surrounding the brain, usually around the base of the brain. Another, rarer form of stroke can occur when a vein (that drains blood out of the brain) is blocked. This is called a *venous stroke*. ►Hypertension is probably the most important modifiable risk factor for stroke: continuous high pressure in vessels results in atherosclerotic plaque formation and endothelial damage.

- *Ischemic Stroke (IS)* represents about 80% of all strokes and is caused by occlusion of an artery supplying the brain. This can be one of the large arteries in the neck or the base of the brain or in small arteries inside the brain itself. The artery occludes either locally or by a blood clot that formed elsewhere in the body and traveled to the brain

[1] Global: this applies to patients with subarachnoid haemmorrhage or deep coma but excluding coma of systemic vascular origin such as shock, Stokes-dams syndrome or hypertensive encephalopathy.

through the artery (►embolic infarct, see ►ischemic stroke). The main modifiable risk factors for ischemic stroke include arterial hypertension, ►atrial fibrillation, cigarette smoking, ►hyperlipidemia, ►diabetes mellitus, and a previous stroke or transient ischemic attack (TIA).

- *Intracerebral hemorrhage (ICH)* is caused by bleeding of a blood vessel inside the brain parenchyma and accounts for approximately 15% of strokes. Damage is caused both by the impaired blood supply and by the pressure on the brain from the hematoma. The most common cause of intracerebral hemorrhage is high blood pressure. Abnormally formed blood vessels in the brain can be another cause, especially in younger people.
- *Subarachnoid hemorrhage (SAH)* results from bleeding of an artery into the membranes surrounding the brain, usually around the base of the brain. Less than 5% of all strokes are SAH. The most frequent cause of subarachnoid hemorrhage is bleeding from an aneurysm. An aneurysm is a bulge of an artery caused by weakening and ballooning of a short portion of the vessel wall. High blood pressure, smoking, excessive alcohol-intake and a family history of burst aneurysms can increase a person's risk of subarachnoid hemorrhage [4].
- *Venous stroke* is caused by a blockage of the veins that allow blood to drain out of the brain (cerebral vein or venous sinus thrombosis). This causes a backpressure that can result in either ►ischemia or hemorrhage. Venous stroke most commonly occurs in the setting of a medical or genetic condition that increases a person's tendency to form blood clots (►hypercoagulable state). Severe dehydration or infection of the sinuses of the head can also predispose to venous stroke. Less than 1% of strokes are venous.

## Signs and Symptoms

The symptoms of stroke depend on the type of stroke and the area of the brain affected. They are usually unilateral, occurring on the side of the body opposite to the affected side of the brain. As is implied in the word "stroke," symptoms typically develop suddenly and rapidly.

Common symptoms include weakness or numbness; confusion, trouble speaking or understanding; loss of vision in all or part of the visual field; loss of balance or coordination, trouble walking or dizziness. Loss of consciousness, headache, and vomiting at the onset occur more often in hemorrhagic stroke and venous stroke because of increased intracranial pressure (ICP).

Seizures may occur in up to 20% of ischemic, 30% of hemorrhagic, and in 40% of patients with venous stroke [5,6,7].

A combination of symptoms caused by impairment of one arterial territory is termed *vascular syndrome*, for example a posterior cerebral artery (PCA) syndrome includes visual problems, as the PCA supplies the visual ►cortex (see "ischemic stroke, vascular syndromes").

## Differential Diagnosis

See: Table 1

## Diagnosis

- Deficits are identified by a careful ►neurological examination, and the severity assessed using one of the standardized stroke scales, i.e., the National Institute of Health Stroke Scale (http://www.ninds.nih.gov/doctors/NIH_Stroke_Scale_Booklet.pdf).
- ►Laboratory workup should include basic metabolic panel with glucose, complete blood count, coagulation parameters and an EKG to identify arrhythmias and/or signs of acute or previous myocardial infarction. If this is abnormal, markers of cardiac ischemia should be checked. In the appropriate setting, hypercoagulable workup and vasculitis testing may be indicated, as well as hepatic function tests, toxicology screen, blood alcohol level, pregnancy test, arterial blood gas. If subarachnoid hemorrhage is suspected and CT scan shows no blood, a lumbar puncture is required.

**Stroke. Table 1** Differential diagnosis of acute stroke presentation

| | |

| • Complicated migraine | • Toxic States |
| • Transient confusion in the elderly and/or demented | • Hypertensive Encephalopathy |
| • Vertigo of peripheral origin | • Conversion disorder |

- ►Imaging: Non-contrast head CT remains the most commonly used imaging modality in the acute setting, because it is fast, easy, widely available and less expensive than MRI. MRI is more sensitive for detection of acute ischemic stroke and is better at identifying acute, small cortical, small deep, and posterior fossa infarcts, and at distinguishing acute from chronic stroke [5]. CT- or MR-Angiography is a helpful noninvasive method to identify any cervical or intracranial stenoses and can detect aneurysms in 95% of the cases [4]. Venous sinus thrombosis can usually be detected on MRI, but if there is clinical suspicion for it, CT- or MR-Venogram should be obtained.
- ►Ancillary tests
  - Cardiac monitoring for at least 24h after the event, to identify arrhythmias.
  - Echocardiogram is an ultrasound study of the heart that can look for any source of cardioembolism, for example wall motion, valvular abnormalities, or a clot inside the heart. "Bubble studies" can identify a ►cardiac shunt as a cause of ►paradoxical embolism.
  - Ultrasound of the arteries in the neck and brain (carotid ultrasound, transcranial ultrasound) evaluates the presence and degree of vessel narrowing and may identify clots traveling through that vessel.
  - With conventional angiography, the arteries and veins of the brain are best visualized and most vascular abnormalities can be detected. At the same time, it can be used for interventions such as closure of an aneurysm or opening of a blocked artery. Being an interventional procedure, it does have it's own risks, which should be weighed against the potential benefit.

## Acute Management

The sooner a stroke is treated, the better the chance of recovery. Patients treated in hospitals with a dedicated Stroke Team or Stroke Unit and a specialized care program for stroke patients have improved odds of recovery. Thus, if a stroke is suspected, emergency medical services should be activated immediately [5]. The treatment of stroke is a rapidly evolving discipline and there are a number of modalities both proven and experimental that are effective in minimizing the damage and improving the outcome from stroke. The details of the treatment of stroke are outside of the intended scope of this encyclopedia.

## Stroke Prevention

Almost a third of all strokes are recurrent attacks [3]. Thus, careful attention needs to be paid to all vascular risk factors. The ways to reduce the risk of a recurrent stroke are very similar to those that can prevent a stroke in the first place.

- Life style/diet: people with any vascular risk factors or a history of a stroke or a heart attack should limit their daily alcohol use, try to maintain their ideal body weight, exercise daily and stop smoking [8].
- Blood pressure (BP): hypertension, defined as a BP of 140/90mmHg or higher for an extended period of time, is the most important modifiable risk factor for stroke, and reduction of BP reduces this risk. Choice of BP-lowering agent is still uncertain but diuretics and/or ACE-inhibitors are recommended [8].
- ►Diabetes mellitus: The risk for stroke (especially ischemic stroke) in people with diabetes can be substantially reduced with tight control of blood glucose. People with diabetes should also be particularly weary of other risk factors, such as hypertension and hyperlipidemia.
- ►Hyperlipidemia: In patients with vascular disease or a history of an ischemic stroke, life style modification, diet and medications are recommended to lower cholesterol levels. Statins have been shown to reduce the risk of ischemic stroke but slightly increase that for hemorrhagic stroke [9].
- Antiplatelet therapy: Patients, who have had a non-►cardioembolic ischemic stroke, should take ASA to prevent stroke recurrence or any other vascular event. The use of other antiplatelet agents (dipyridamole, clopidogrel) may be considered as additional or alternative therapy.
- Anticoagulation is indicated in patients with atrial fibrillation (usually indefinitely), in those where a clear tendency for forming blood clots was found (indefinitely), and in patients with venous thrombosis (for six months, or longer if a presdisposing factor has been identified) [7]. Anticoagulation is relatively contra-indicated after intracerebral hemorrhage.
- After a hemorrhagic stroke, the use of blood thinning medication of any kind (antiplatelet or anticoagulation agents) is associated with a risk of another hemorrhage, but needs to be weighed against the risk of a thrombotic event on an individual basis.

## Prognosis

Prognosis depends on the patient's age, type of stroke and how severe the stroke is at the onset. 20% of victims die within one month of having an ischemic stroke, 40% after an intracerebral hemorrhage and 30% after subarachnoid hemorrhage. The majority of survivors have some long-term disability; 50–70% of stroke survivors do become independent, 15–30% are permanently disabled and 20% live in a nursing home at three months after onset [3].

## Stroke Rehabilitation

Early stroke rehabilitation services are very effective in reducing long-term disability and improving quality of life as well as reducing overall health care costs [10].

Rehabilitation doctors, Speech and Language therapists, Physical and Occupational therapists should be involved early on in the care of a stroke patient.

# Stroma

## Definition

The connective tissue network (of endomysium, perimysium and epimysium) within a muscle. The word of Greek origin actually refers to a supporting function.

►Intramuscular Myofascial Force Transmission

# Structure-from-Motion

## Definition

The perception of three-dimensional structure from motion occurs when, for example, a two-dimensional pattern of dots moves in such a way that the dot trajectories are consistent with the retinal image projected by rotation of a three-dimensional object.

►Visual Motion Processing

# Stumbling-corrective Reaction

## Definition

A reflex initiated in walking mammals to lift the leg over an obstacle when the leg contacts the obstacle.

►Locomotor Reflexes

# Stupor

## Definition

Stupor denotes a state, from which the patient can be aroused by very strong stimuli, but he/she tries to avoid uncomfortable stimuli, and the verbal responses are absent or slow.

# Subacute Sclerosing Panencephalitis (SSP)

## Definition

SSP is a progressive, debilitating, and fatal brain disorder caused by infection with a mutant measles (rubeola) virus. A mutant virus is one that has undergone genetic changes (mutations).

## Subcortical Infarction

### Definition

Subcortical infarcts are located in the basal ganglia, internal capsule, or corona radiata and are thought more commonly to be caused by hypertension and diabetes and less commonly by cardiac or artery-to-artery embolism.

►Ischemic Stroke
►Stroke

## Subcortical Visual Shell

### Definition

Twelve contiguous retinorecipient nuclei of the thalamus and midbrain, not including the terminal nuclei of the accessory optic system. In order from ventrolateral to dorsomedial they are the ventral lateral geniculate n., intergeniculate leaflet, dorsal lateral geniculate n., lateral posterior n., posterior limitans n., nucleus of the optic tract, anterior pretectal n., posterior pretectal n., medial pretectal n., commissural pretectal n. and, positioned dorsocaudally, the superior colliculus.

►Intergeniculate Leaflet

## Subgranular Layer of Hippocampus

### Definition

The subgranular layer of the hippocampus is the region of the dentate gyrus between the granular cell layer and the hilus. Neural stem or progenitor cells (NSPCs) reside in this region. Neuronal progeny of these NSPCs migrate varying distances into the granular cell layer, extending their dendrites and axons into the molecular layer and CA3, respectively.

## Subiculum

### Definition

The subiculum is a band of cells that deep in the hippocampal sulcus continues the CA1 cell layer of Ammon 's horn and, for its part, joins the cell band of the presubkulum. It thus marks the transition from hippocampus to the area surrounding hippocampus. In the subiculum most efferents arise from the hippocampus (-> fornix), afferents come from the entorhinal area primarily.

►Telencephalon

## Subjective Contour

### Definition

►Illusory Contour

►Perceptual Filling-In

## Subjective Day/Night

### Definition

Used in circadian biology when a test subject is housed in constant conditions where circadian rhythms adopt their endogenous, free-running period. Subjective day defines the portion of the endogenous circadian rhythm that would normally be associated with the light phase (daytime). Subjective night defines the portion of the endogenous circadian rhythm normally associated with the dark phase (nighttime). The behaviorally active phase of diurnal organisms occurs during the subjective day whereas it occurs during the subjective night for nocturnal organisms.

►Chronobiology
►Circadian Rhythm

## Subjectivity

### Definition

Subjectivity may be attributed to (i) a particular mental event, because it is experienced by just one person, who has a priviledged access to it; (ii) types of [→] phenomenal consciousness (qualia), because only if one has had such experiences does one know what it is

like to have them; (iii) the entity (subject) that is in mental states, esp. if one takes it to differ in kind from physical objects; (iv) [→] self-consciousness because it is the awareness a person has of herself as herself.

►Argument
►Logic

## Sub-Modality (also Quality)

### Definition

Sub-modalities (qualities) refer to subclasses of modalities, such as, in the visual system, perception of shades of grey from black to white and of different colors, or in the tactile domain, differentiation of pressure, touch and vibration sensations.

►Sensory Systems

## Submusosal Plexus

### Definition

The submucosal plexus is a division of the enteric nervous system, a plexus of small ganglia and connecting nerve fiber bundles that lies within the submucosal layer, between the external musculature and the mucosa of the small and large intestines, forming a continuous network from the duodenum to the internal anal sphincter.

►Autonomic/Enteric Reflexes
►Enteric Nervous System

## Subpallial Amygdala

### Definition

Part of the amygdala that derives from the subpallium, i.e, the ventral part of the telencephalon. It is composed by nuclei of striatal and pallidal origin in all tetrapods.

►Evolution of the Amygdala: Tetrapods

## Subparaventricular Zone

### Definition

A loosely defined population of neurons that resides directly ventral to the paraventricular nucleus (PVN) in the anterior hypothalamus. Neurons in this region receive dense projections from the suprachiasmatic nucleus, the brain's circadian pacemaker, as well as projections from other hypothalamic nuclei. It is hypothesized that these neurons integrate circadian and metabolic information.

►Circadian Pacemaker
►Paraventricular Nucleus (PVN)
►Suprachiasmatic Nucleus
►Ventrolateral Preoptic Nucleus (VLPO)

## Substance P

### Definition

Substance P is a member of a group of polypeptides known as neurokinins or tachykinins. Substance P as well as neurokinin NK1 receptors have been detected in vagal afferent neurons in the area postrema, nucleus tractus solitarii and dorsal motor nucleus of the vagus. Substance P has been shown to increase the firing rate of neurons in the area postrema and nucleus tractus solitarii and to produce retching when applied directly to these areas in animal studies. Substance P is also a co-transmitter in nociceptive group C afferent fibers and is crucially involved in central sensitization.

►Area Postrema (AP)
►Hyperalgesia and Allodynia
►Nucleus of the Solitary Tract

## Substantia Gelatinosa (of Roland)

### Synonyms

►Gelatinous substance

### Definition

A small-celled area in the posterior horn of the spinal cord. Pain fibers synapse here.

►Medulla Spinalis

## Substantia Gelatinosa of the Spinal Nucleus of the Trigeminal Nerve, Caudal Part

### Definition

Substantia gelatinosa (of Roland) at the level of the spinal nucleus of the trigeminal nerve, caudal part. Pain fibers synapse here.

►Medulla Spinalis

## Substantia Innominata

### Definition

The broad expanse of ventral forebrain territory situated beneath the globus pallidus (sublenticular substantia innominata) and anterior commissure (sublenticular substantia innominata) lateral to the lateral preoptic and lateral hypothalamic areas. Rostrally, it tapers into the deep layers of the olfactory tubercle and caudally it merges into the anterior amygdaloid area, ending where the internal capsule reaches the ventral surface of the brain to form the cerebral peduncle. The term, which implies an indeterminate neural organization, has lost some currency with the descriptions of the ventral striatopallidum, extended amygdala and magnocellular basal forebrain system, which occupy territory within the so-called substantia innominata.

►Striatopallidum
►Ventral

## Substantia Nigra

### Definition

The substantia nigra is the largest nucleus of the ►Mesencephalon. A distinction is made between:

- Substantia nigra, pars compacta
- Substantia nigra, pars reticulata

There is a very close, possibly even reciprocal point-to-point, connection between corpus striatum and substantia nigra. The substantia nigra, pars compacta, plays an important role in Parkinson's disease.

►Mesencephalon

## Substantia Nigra, Pars Compacta

### Definition

The dorsal, large-celled segments of the substantia nigra are globally known as pars compacta. The large, polygonal and dopamine-producing cells lie close together. Their very fine dopaminergic efferents form direct synaptic contacts with striatonigral projection neurons. This projection plays an important role in the initiation of voluntary, motor programs.

Parkinson's disease is characterized by progressive loss of neurons in the substantia nigra, pars compacta, degeneration of their ascending projections and reduction of the dopamine content in the corpus striatum. Symptoms include rigor, tremor, akinesia.

►Mesencephalon

## Substantia Nigra, Pars Reticulata

### Definition

The ventral, small-celled sections of the substantia nigra are called the pars reticulata. The cells (cell group A9) are less densely packed, and have a structure similar to that of the inner segment of the globus pallidus. They receive topically organized afferents from the caudate nucleus and globus pallidus (GABA, substance P, dynorphin, enkephalin). Efferents pass to the substantia nigra, globus pallidus, caudate nucleus, and putamen.

►Mesencephalon

## Substantia Nigra: Role in Eye Movements

Okihide Hikosaka
Laboratory of Sensorimotor Research, National Eye Institute, National Institute of Health, Bethesda, MD, USA

### Definition

The substantia nigra (SN), which is located in the ventral part of the midbrain, is either a part of the basal ganglia or closely associated with the basal ganglia.

Its contribution to eye movements is mentioned in the section "►Basal ganglia – Role in eye movements".

## Characteristics

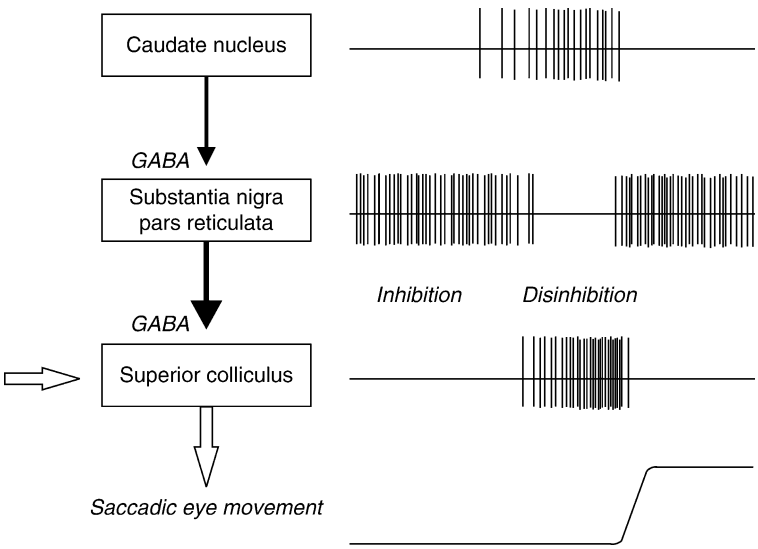
### Lower Level Components

The substantia nigra (SN) is composed of two parts: pars reticulata (SNr), which contains GABAergic neurons, and pars compacta (SNc), which contains dopaminergic (DA) neurons. The relation of the SN to eye movements was first suggested by anatomical studies showing that some neurons in the SNr project to the ►intermediate layer of the superior colliculus (SC) [1] (Fig. 1). The SC in mammals is known to be crucial for orienting of the eyes and head toward an object of interest. An equivalent structure, which is called the optic tectum, is universally present in other vertebrates and is under the control of the homologue of the basal ganglia [2]. Thus, the role of the SN (or the basal ganglia) in eye movements should be considered in a larger framework of animal behavior in which orienting is crucial for survival.

### Higher Level Processes

Neurons in the SNr are characterized by their rapid and tonic firing. Their firing frequency is usually between 40 and 100 spikes/sec in monkeys [3]. Neurons in the internal segment of the ►globus pallidus, many of which are related to skeletal movements, also fire rapidly and tonically. Thus, the high background activity is common to virtually all output neurons of the basal ganglia. Furthermore, virtually all of them are GABAergic. These facts indicate that neurons that receive outputs of the basal ganglia should be kept inhibited by them. The functional importance of the basal ganglia-induced inhibition can be demonstrated experimentally [3]. The inhibition can be reduced or eliminated by injecting a small amount of a GABA agonist (muscimol) into the SNr, because SNr neurons have a high density of GABA receptors and therefore muscimol would inhibit their firing. After muscimol injection in the SNr, animals can no longer maintain stable eye position and make saccades continually and probably involuntarily. This happens to all animals tested: monkeys, cats, and rats. Rats, compared with monkeys, exhibit a wider range of involuntary movements in addition to eye movements. A similar phenomenon occurs for skeletal movements when muscimol is injected in the globus pallidus internal segment. These findings may be relevant to the fact that patients with basal ganglia dysfunction usually exhibit some type of involuntary movements, such as tremor, dyskinesia, dystonia, ballism, and chorea. These involuntary movements may be caused by a reduction of the basal ganglia-induced inhibition. The reduction of inhibition could be sustained or phasic (possibly with rhythms).

However, the sustained inhibition alone can hardly be a motor control mechanism. Neurons in the SNr actually change (usually decrease) their firing rates in preparation for ►saccadic eye movement [3]. Many SNr neurons stop firing in response to a visual stimulus



**Substantia Nigra: Role in Eye Movements. Figure 1** Tonic inhibition and disinhibition of superior colliculus neurons by the basal ganglia. The tonic inhibition of the superior colliculus (SC) by the substantia nigra pars reticulata (SNr) can be reduced by another inhibition from the caudate nucleus (CD) to the SNr. Both CD-SNr and SNr-SC connections are GABAergic. The level of the SNr-SC inhibition determines the likelihood of the occurrence of saccade which is triggered by excitatory inputs from saccade-related areas in the cerebral cortex (not shown).

if the animal is ready to make a saccade to it (Fig. 1). Other neurons do so just before the saccade. Many of these SNr neurons project to the intermediate layer of the SC [3] and have inhibitory synaptic contacts with saccadic burst neurons [4]. This means that the SNr-induced tonic inhibition on SC neurons is removed or reduced before saccade. Note that saccadic neurons in the SC receive excitatory inputs from many brain areas, especially saccade-related cortical areas: the ►frontal eye field (FEF), ►supplementary eye field (SEF), and ►lateral intra-parietal area (LIP). These excitatory cortical inputs, together with the SNr-induced disinhibition, would make SC neurons fire in a burst and the signal is sent to the ►brainstem saccade generators. Note, however, SNr neurons may increase their activity before saccade. In such a case, the SC would be less likely to generate a signal to induce saccades.

In short, the SNr-induced inhibition on SC neurons acts as a gate for saccade generation (Fig. 1). SC neurons are constantly bombarded by excitatory inputs from many brain areas because there are so many objects that can attract our attention and gaze. However, these inputs are often incapable of inducing a burst of spikes in SC neurons due to the SNr-induced tonic inhibition. Only when the SNr-induced inhibition is reduced, SC neurons would exhibit a burst of spikes reliably. This is probably a very efficient mechanism to select an appropriate action in a particular context.

Selection of action is meaningful only if the criteria of selection are identified. There are at least three criteria for the selection of information by the SNr. First, SNr neurons select the spatial vector of saccade by reducing their activity only before saccades that have a certain range of direction and amplitude. However, this selection is common to the excitatory inputs from cortical eye fields, and is unlikely to add a new feature to the signals carried by SC neurons. Second, SNr neurons may select saccades directed to the remembered location of a visual stimulus (►memory-guided saccades) rather than saccades directed to a visual stimulus (►visually guided saccades). This is based on the experimental observation, indicating that some SNr neurons reduce their activity selectively before memory-guided saccades [5]. Third, SNr neurons may select saccades that are directed to a spatial location where a larger ►reward is expected [6]. This is shown by the experiment in which the amount of reward is associated unequally among possible target positions. Many SNr neurons reduce their activity more strongly before a saccade to the location where a larger reward is associated. It is unknown how unique the second and third criteria are to the SNr, compared with other areas that provide the SC with inputs. This is a very important question on the function of the SNr and consequently the basal ganglia in general.

## Lower Level Processes

How is the activity of SNr neurons generated? First, the rapid and tonic firing is thought to be caused by two factors: the intrinsic membrane properties of SNr neurons and the excitatory input from the ►subthalamic nucleus (STN). Second, the decrease in firing rate of SNr neurons is caused by GABAergic inhibitory inputs from the caudate nucleus (CD) [7] (Fig. 1). While the CD-SNr inhibitory connection is known anatomically, its function is confirmed physiologically by the presence of neurons in the CD that increase in firing rate before saccade, and the inhibition of SNr neurons in response to electrical stimulation of the saccade-related region in the CD (see section ►Caudate – Role in eye movements). Third, the cause of the increase in firing of SNr neurons is less certain. Two likely causes, based on anatomy, are the excitatory input from the STN and the reduction of the inhibition from the external segment of the globus pallidus.

As mentioned at the beginning, another part of the substantia nigra (SN) is pars compacta (SNc). While neurons in the SNr are GABAergic, neurons in the SNc are dopaminergic [8]. Neurons in the SNc are a significant constituent of midbrain dopaminergic neurons; others include the ventral tegmental area and the area dorsal to the SNc. A majority of SNc neurons project to the striatum, CD and putamen, and make synapses on projection neurons and interneurons. The importance of midbrain dopaminergic neurons in motor control is highlighted by Parkinson's disease, in which most of these dopaminergic neurons degenerate. Eye movements are also impaired in human Parkinson's disease and its animal models [3]. This seems largely due to a lack of dopaminergic effects on CD projection neurons because local degeneration of dopaminergic axons in the CD leads to severe deficits in saccadic eye movements.

## Process Regulation

How then do dopaminergic neurons in the SNc contribute to saccadic motor control? Unlike SNr or CD neurons, SNc dopaminergic neurons neither fire before or after saccades, nor respond to a visual stimulus that guides saccades. Instead, they respond to reward if it is given unexpectedly [9]. Further, if different visual stimuli are presented to induce different saccades, and if one of the visual stimuli is consistently followed by a larger reward, then SNc dopaminergic neurons respond to it with a short burst of spikes and respond to the other stimuli with suppression of firing [10]. This dependency on expected reward value is common to SNr neurons, although the polarity of response is opposite (i.e., stronger inhibition in SNr neurons). It has been hypothesized that SNr neurons acquire the reward dependency from SNc dopaminergic neurons through

their connections to CD projection neurons. However, unlike SNr neurons, SNc neurons have no spatial selectivity: the reward value associated with the stimulus, but not its spatial location, matters. SNr neurons should then acquire spatial selectivity from non-dopaminergic mechanism, which presumably originates from cerebral cortical areas (including FEF, SEF, and LIP) and is mediated by the CD. To summarize, the CD is an important area where spatial information originates from the cerebral cortex and reward-related information originated from SNc dopaminergic neurons are integrated.

## Substantia Reticularis

►Reticular Formation

## Substrate Adhesion Molecules

### Definition

SAMs Molecules of the extracellular matrix with which cells can interact through membrane receptors. Collagen, laminin and fibronectin are examples of such molecules.

## Subtetanic Contraction

### Definition

Subtetanic contraction is the most common working mode of skeletal muscles: the muscle fibers are activated at a "sufficiently high" frequency such that the single twitch responses merge together, i.e. giving rise to temporal summation. The developed muscle force increases with increasing frequency of activation, due to the increasing temporal summation of single twitches, up to a maximum. The maximal force is achieved with the tetanic contraction, i.e. the condition in which maximal summation (fusion) of twitch responses is reached. Increasing the frequency of stimulation of muscle fibers beyond the tetanic stimulation frequency will not produce further increase in force.

►Force-frequency Relation of Skeletal Muscle
►Tetanus in Muscle Contraction
►Twitch (Muscle)

## Subthalamic Nucleus (Luys)

### Synonyms

►Nucl. subthalamicus (Luys)

### Definition

A well-circumscribed, large-celled nucleus in the caudalmost region of the diencephalon. It belongs with the globus pallidus, inter alia, to the subthalamus.

The lateral globus pallidus projects strictly topographically to the subthalamic nucleus, which in turn projects with inhibitory effects to all parts of the globus pallidus. Efferents also to the caudate nucleus, putamen and substantia nigra. GABA is the transmitter for both projections.

►Basal Ganglia
►Diencephalon

## Subventricular Zone (SVZ)

### Definition

The subventricular zone (SVZ) is the region adjacent to the ventricular zone (VZ), which constitutes the wall of the lateral ventricle. It is most prominent in the medial and lateral ganglionic eminences of the embryonic brain. It is one of the few germinal zones in the adult brain and new neurons are continuously generated in the SVZ. In this region, there are at least four types of cells with distinct functions: Ependymal cells (Type E cells) line the wall of the ventricle. Type B cells are a special form of astrocytes that act as neural stem cells, and are slowly dividing. Type B cells most rapidly generate proliferating Type C transit amplifying precursors. Type C cells then differentiate into Type A cells, migrating neuroblasts. Type A cells migrate anteriorly and then enter the rostral migratory stream (RMS) leading to the olfactory bulb, where they differentiate into interneurons.

## Succinylcholine (Suxamethonium)

### Definition

Depolarizing blocker of the neuromuscular junction; like acetylcholine, it binds to acetylcholine receptors but longer, thereby preventing acetylcholine from docking onto its receptors; since it has the intrinsic capacity of acetylcholine of opening the receptor-related ion channels, it depolarizes the muscle membrane over a prolonged period and causes a depolarization block.

►Neuromuscular Junction

## Sudden Infant Death Syndrome (SIDS)

### Definition

Sudden death of an infant under 1 year of age that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history. Leading cause of postneonatal infant mortality in the United States, Canada and European Countries.

Affected children typically die during the night and early morning hours. One of the leading hypotheses is that SIDS is caused by defects in brainstem neuronal networks that control respiration and/or cardiac stability during sleep. These defects result in a failure of protective responses to life-threatening stressors (e.g. hypoxia) during a critical period in the postnatal development of the child.

►Laryngeal Chemoreflexes

## Sufficiently Exciting

### Definition

Sufficiently Exciting refers to actions taken on (inputs to) a physical system. It is used in conjunction with a model estimator – one would like to "excite" the physical system with the purpose of creating data that reflects the behavior of this system as much as possible.

►Adaptive Control

## Sulcus Lateralis (Sylvii)

### Definition

Major fissure on the lateral side of the hemisphere between temporal and parietal lobes.

## Sulcus Limitans

### Definition

The sulcus limitans appears in the developing neural tube. The central canal of the tube forms a small sulcus at its midlateral point on each side. This sulcus defines the boundary between the dorsally developing sensory and the ventrally developing motor regions.

## Summation by Retinal Ganglion Cells

### Definition

Although retinal ganglion cells are the retinal sampling element, each ganglion cell may sum input from numerous photoreceptors. More numerous ganglion cells (e.g. midget cells) summate from fewer receptors than sparser cell types such as P giant cells. Also, all ganglion cell types summate over larger groups of photoreceptors in peripheral than in central (foveal) retina.

►Photoreceptors
►Retinal Ganglion Cells
►Visual Processing Streams in Primates

## Summation Tones

### Definition

Tonal components at the output of a nonlinear system with frequencies equal to the sum of the frequencies of the input tonal components.

►Acoustics

## Sumo

### Definition

Small Ubiquitin-related Modifier (SUMO) proteins are a family of 4 proteins that are similar to ubiquitin in that they can be covalently attached (sumoylation) to other proteins though a process analogous to ubiquitination.

Unlike ubiquitination, sumoylation is a post-translational modification that is not used primarily to tag proteins for degradation but rather is utilized in other cellular processes, such as nuclear-cytosolic transport, transcriptional regulation, apoptosis, protein stability, response to stress, and progression through the cell cycle.

►Receptor Trafficking

## Sumoylation

### Definition

SUMO conjugation to its target is analogous to that of ubiquitination in that it involves an enzymatic cascade. In the first step, an ATP dependent protease (the SENP proteases) cleaves a C-terminal peptide (the last four amino acids). SUMO then becomes bound to an E1 enzyme (SUMO Activating Enzyme (SAE)) and then passed to an E2 conjugating enzyme (Ubc9). Sumoylation then occurs on a protein with a consensus SUMO attachment sequence, with the help of an E3 ligase. The SUMO attachment sequence is the B-K-x-D/E motif. In the absence of this consensus sequence, the E3 ligase facilitates attachment. Several Sumo-E3 ligases exist and themost common are the PIAS proteins, which belong to the zinc-RING finger superfamily of proteins. Sumoylation, like ubiquitination, is reversible and SUMO can be removed by a protease (e.g. Ulp2) in an ATP dependent manner. SUMO, like ubiquitin, can form chains, but unlike ubiquitin, SUMO chains are likely to be preassembled prior to conjugation onto the target protein.

►Receptor Trafficking

## SUNA

### Definition

Short-lasting Unilateral Neuralgiform Headache Attacks with Cranial Autonomic Symptoms.

►Trigeminal Autonomic Cephalalgias
►Headache

## SUNCT

### Definition

Short-lasting Unilateral Neuralgiform Headache Attacks with Conjunctival Injection and Tearing.

►Trigeminal Autonomic Cephalalgias
►Headache

## Superior Cerebellar Peduncle

### Synonyms
►Pedunculus cerebellaris sup.

### Definition
The major cerebellar efferents pass through this peduncle: cerebellothalamic tract and cerebellorubral tract. Since they cannot be easily distinguished from each other they are collectively known as the "superior cerebellar peduncle."

The only afferent tract is the anterior spinocerebellar tract, conducting proprioceptive information from the spinal cord to the spinocerebellum.

►Cerebellum

## Superior Cervical Ganglion

### Synonyms
►Ganglion cervicale sup.

### Definition
Sympathetic ganglion. The associated neurons are situated in the upper thoracic cord (the cervical cord has no sympathetic neurons).

## Superior Colliculus

### Synonyms
►Colliculus sup.

### Definition
Upper hill of the quadrigeminal lamina. Involved in fast eye movements, synaptic center for optokinetic reflexes (saccades). Afferents from the retina and visual cortex (opticofacial winking reflex), inferior colliculus and auditory cortex (reflex movement in direction of source of noise). Involved in accommodation reflex. Efferents to oculomotor cranial nerve nuclei and spinal cord.

Damage to the superior colliculi results in interruption of reflex eye movements, but not in impairment of cognitive perceptivity (e.g. image recognition).

►Mesencephalon

## Superior Colliculus and Hearing

Andrew J. King
Department of Physiology, Anatomy and Genetics, Sherrington Building, University of Oxford, Oxford, UK

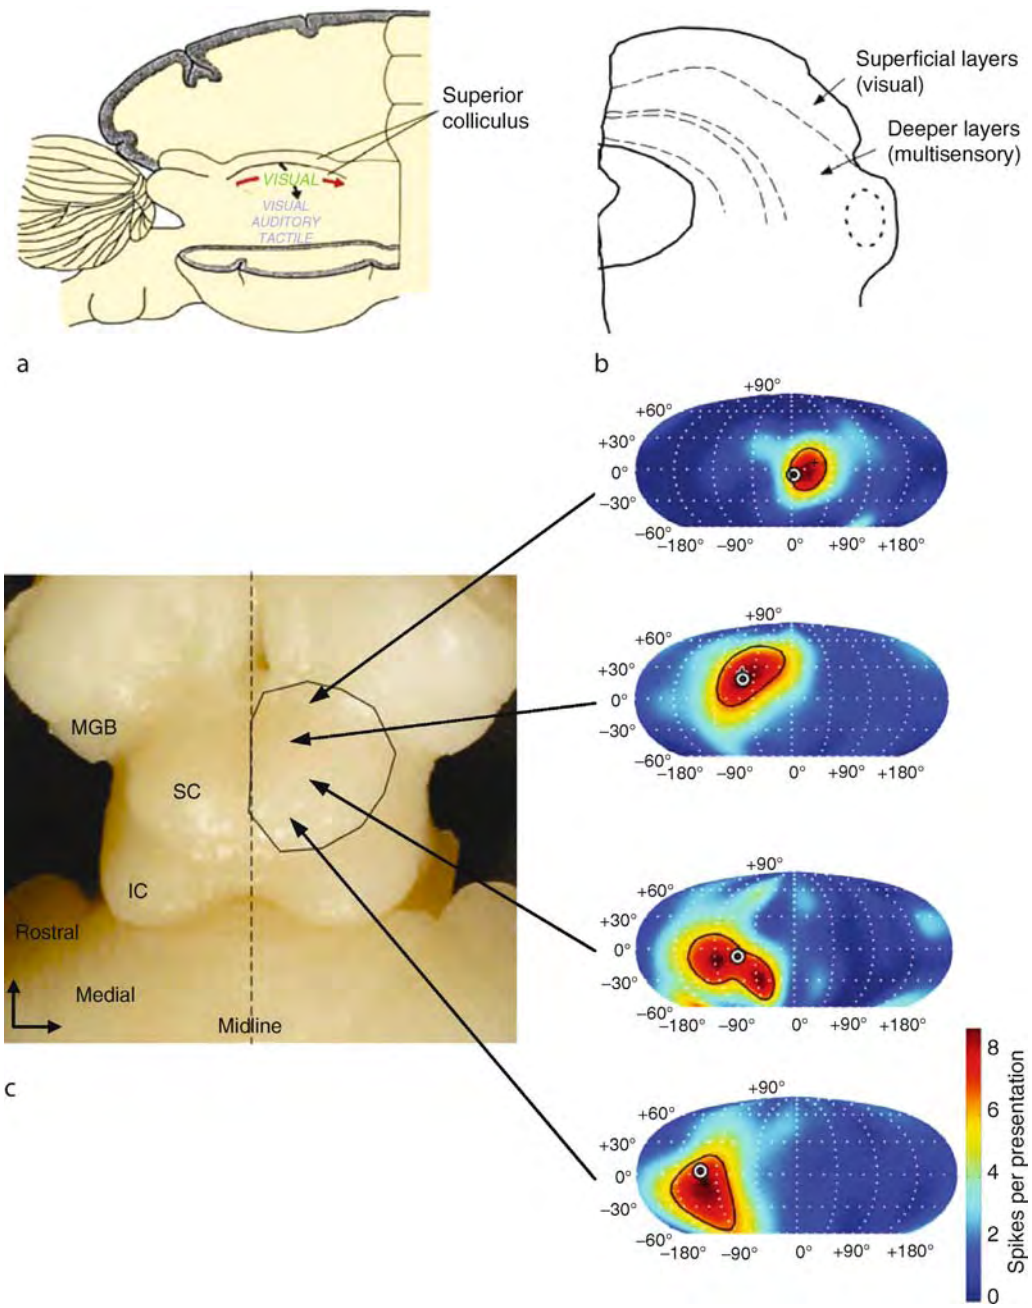
### Synonyms
Auditory space map

### Definition
The map of auditory space in the ►superior colliculus, which is superimposed upon and integrated with the representations of other sensory modalities, thereby allowing different sensory cues to guide orienting movements of the eyes, head and body.

### Characteristics
One of the key functions of the central nervous system is to obtain information about the external environment and to control movement of the body within it. Critical to this is an ability to determine the whereabouts of specific events, such as potential prey or predators, so that they can be attended to, approached or avoided as the need arises. In order that they can trigger movement, sensory signals must be integrated with motor-related activity. This is actually a common feature of neurons in both cortical and subcortical areas that contribute to the control of movement. One brain region involved in sensorimotor processing that has received particular attention is the superior colliculus, which forms part of the roof of the ►midbrain (Fig. 1a).

This nucleus contains overlapping sensory and motor maps, which provides an efficient means by which activation by a stimulus from a particular location in space can be transformed into motor commands that specify the movements required to orient toward that stimulus [1].

#### Sensory Maps in the Superior Colliculus
While a role for the superior colliculus in the visual control of ►saccadic eye movements – rapid changes in eye position that redirect gaze toward objects of interest so that they can be seen with better resolution – has long been recognized, it is now known that this nucleus plays a more general function in mediating sensory-evoked orienting movements as well as certain other behaviors. The dorsally located superficial layers of the superior colliculus receive almost exclusively visual inputs that arise directly from the ►retina and indirectly from the visual cortex, whereas the more ventral intermediate and deep layers are innervated by auditory and somatosensory as well as visual structures. Consequently, these layers should be viewed as a



**Superior Colliculus and Hearing. Figure 1** Representation of auditory space in the superior colliculus. (a) This schematic depicts the brain of a ferret, which is representative of other mammals, in which the posterior part of the cortex has been removed so that the left and right superior colliculi can be visualized. The sensory inputs to different regions of this midbrain nucleus are indicated. (b) Outline of a coronal section of the superior colliculus. The location of different layers is depicted by the dashed lines. The most dorsal superficial layers are exclusively visual, whereas the deeper layers contain neurons that are responsive to visual, auditory and/or somatosensory stimuli. Many neurons in the deeper collicular layers also discharge prior to eye and head movements toward these sensory targets. (c) Auditory spatial receptive fields of four deeper layer neurons recorded in the right superior colliculus at the positions shown on a dorsal view of the midbrain. Color scale indicates the mean number of action potentials evoked per stimulus presentation, with the maximum response indicated by the red regions. The black cross shows the direction of the centroid vector, which indicates the preferred sound direction for each neuron, while the white circle represents the location of a visual stimulus that evoked the strongest response from neurons recorded in the overlying superficial layers. Note that the visual and auditory receptive fields covary within the superior colliculus.

multisensory region, in which many of the neurons receive converging inputs from different sensory modalities (Fig. 1b).

Each of these sensory representations is organized into a map of space. This is based on individual neurons responding to the appropriate stimulus when it falls within a restricted region of space known as the ►receptive field. The locations of these receptive fields vary systematically with the locations of the neurons within the superior colliculus (Fig. 1c). Moreover, the visual, auditory and somatosensory maps are topographically aligned with each other. Thus, visual and auditory stimuli located in front of the animal or objects touching the face are represented in the most anterior or rostral part of the nucleus, whereas stimuli located behind the animal will activate the most posterior or caudal part. Similarly, neurons in the medial part of the superior colliculus respond most strongly to visual or auditory targets above the animal or to stimulation of the upper part of the body, while neurons on the lateral side respond best to stimuli coming from below.

The registration of the sensory maps across the different layers of the superior colliculus is also observed at the level of individual multisensory neurons, which have overlapping spatial receptive fields in each of the sensory modalities to which they respond. When different types of stimuli are presented together at approximately the same time and from the same region of space, these neurons typically respond more strongly than they do to each individual stimulus [2]. Indeed, the responses to multisensory stimulation sometimes exceed the sum of the responses to the individual stimuli. By contrast, if the different stimuli to which the neurons respond are widely separated in space or time, inhibitory interactions tend to be observed, resulting in weaker responses to multisensory stimulation.

In addition to having sensory responses, deeper layer superior colliculus neurons can exhibit premotor activity. In other words, they discharge prior to and during orienting movements of the eyes, head and, in species where they are mobile, the ears [3]. This motor-related activity is also organized into a map, which can be demonstrated by observing the amplitude and direction of the orienting movements produced by focal electrical stimulation of different regions of the colliculus. Because the sensory and motor maps are in register, neurons responsive to stimuli from a particular direction in space may also be active prior to movements that shift the direction of gaze to that location in space.

Direct evidence for a role for the individual sensory representations in the control of orienting movements has come from studies in which different regions of the superior colliculus have been inactivated. Cooling of the superficial layers of the colliculus on one side only degrades the accuracy of orienting responses to visual stimuli presented in the opposite hemifield, whereas additional inactivation of the intermediate layers results in auditory orienting deficits too [4]. Partial unilateral lesions of the deeper layers have also been shown to eliminate the improvement in the accuracy of localization responses that is normally observed when visual and auditory stimuli are paired at the same location in space [5], further establishing a link between the sensory response properties of superior colliculus neurons and orientation behavior.

## Representing Auditory Space in the Brain

Maps of visual space and of the body surface in the brain have their origin in the way in which these sensory signals are represented at the receptor surface. The optical properties of the eye allow each part of the retina to sample a different region of the visual world, collectively giving rise to a neural map of visual space. Similarly, each region of the body surface is represented by the activity of ►mechanoreceptors in that part of the skin. The visual and somatosensory maps found in the superior colliculus and elsewhere in the brain therefore arise from spatially ordered projections that begin with the output from their respective sense organs.

The formation of a map of the auditory world in the brain presents a different challenge, however, as the auditory receptor cells in the ►cochlea are tuned to different sound frequencies rather than positions in space. The direction of a sound source is determined by comparing the amplitude level and timing of the sounds reaching the two ears. In addition to these "►binaural" cues, the external ear – the visible part of the ear – filters the incoming sound, changing its spectral composition in ways that depend on the direction of sound incidence. In humans and other mammals, binaural cues provide the principal basis by which sound sources in the horizontal plane are localized, whereas spectral cues are utilized for distinguishing between sounds in front of and behind the head and for localization in the vertical plane.

Neuronal sensitivity to each of these localization cues is first established in a different region of the ►brainstem. These pathways converge in the ►inferior colliculus, where a topographic representation of space first emerges, which is then transmitted to the deeper layers of the superior colliculus. The steps leading to the synthesis of the auditory space map have been studied in most detail in barn owls, a species with particularly good directional hearing [6]. Because of an unusual asymmetry in its ears, barn owls actually use one of the binaural cues – interaural level differences – to determine the vertical angle of their prey, such as a mouse on the ground, whereas interaural time differences are used for pinpointing its horizontal location. Although interaural time differences are the primary

cues for localizing low frequency sounds in mammals, they do not contribute to the spatial selectivity of superior colliculus neurons, which tend to be broadly tuned to high frequency sounds. Instead, the map of auditory space is based on a combination of interaural level differences and spectral cues [7].

Most studies have focused on how the direction of a sound source is represented in the superior colliculus. In echolocating bats, some neurons can specify target distance, as a result of being tuned to the delay between the animals' ultrasonic vocal signals and the returning echoes produced by reflections from objects in the flight path. The importance of the superior colliculus in acoustic orienting of echolocating bats in three-dimensional space is further highlighted by the finding that neurons in this nucleus discharge just before the animals produce biosonar pulses but not when they emit communication calls [8].

### What Happens When the Eyes (or Ears) Move?

An important consequence of the differences in the way in which the visual, auditory and somatosensory maps in the superior colliculus are constructed is that independent movements of the sense organs – such as the eyes or the ears – should result in the sensory representations becoming misaligned. This is not a problem for the barn owl because its eyes and external ear structures are effectively immobile. But in mammals, changes in the direction of gaze are accompanied by shifts in the location of auditory and somatosensory receptive fields, indicating that these sensory signals are transformed into coordinates that take into account the current position of the eyes [3]. This presumably allows accurate orienting movements to be maintained irrespective of initial eye position.

### Sensory Experience and the Development of the Auditory Space Map

In addition to being continually updated by eye-position signals, the auditory space map is shaped by sensory experience as it emerges during development [9]. This is necessary because the values of the auditory localization cues corresponding to a particular sound direction depend on the size and shape of the head and external ears, which can vary markedly between and within individuals. In particular, vision plays a key role in aligning the different sensory maps, as revealed by the dramatic changes produced in the auditory responses when visual inputs are altered. This has been demonstrated most clearly by mounting prisms in front of the eyes of young barn owls in order to shift their visual world to one side. The resulting misalignment between the visual and auditory maps is overcome by a corresponding shift in auditory spatial tuning. Similar findings have also been obtained in mammals [9], suggesting that establishing and maintaining the registration of the maps is critical for synthesizing the different sensory cues associated with targets that can be both seen and heard. As a result these cues can be used to specify the orienting movements that bring about a change in the direction of gaze.

### The Superior Colliculus and Auditory Localization

Although a close relationship between the sensory representations in the superior colliculus and reflexive orienting behaviors has been established in a range of species, it is important to appreciate that a map of auditory space is not a prerequisite for localizing sound. In higher mammals (carnivores and primates), lesions of the auditory cortex result in deficits in sound localization, yet there is no evidence for a space map in the cortex. Instead, cortical neurons seem to carry information about sound source location in both the number and timing of their action potentials [10]. Nevertheless, it is likely that interactions between the cortex and midbrain, possibly mediated by descending ►corticofugal projections, contribute to behaviors that require sound localization.

# Superior Colliculus-Fixation Neurons

## Definition

Neurons that have a steady discharge when a subject is attentively fixating a spot of light, even when the spot disappears and the subject fixates the same, though invisible, location in the dark. These cells are located in a restricted zone of the rostral superior colliculus encompassing the foveal representation of the visual field.

►Fixation System

# Superior Colliculus – Quasi-Visual Neurons

Mark M. G. Walton, David L. Sparks, Xintian Hu
Division of Neuroscience, Baylor College of Medicine, Houston, TX, USA

## Definitions

Quasi-visual neurons – ►Superior colliculus neurons that exhibit a tonic discharge that begins ~70 ms after the onset of a visual target and continues until saccade onset, but that have response fields that are predictive of the vector of the saccade, rather than the retinotopic location of the visual target.

## Characteristics

### Higher Order Structures

Quasi-visual (QV) neurons are found in the intermediate gray layer of the superior colliculus (SC). The SC is a seven layered structure in the midbrain involved in ►sensorimotor integration and orienting behavior.

### Parts of This Structure

Currently, very little is known about the morphological characteristics of QV neurons or their afferent and efferent projections. It seems likely, however, that these neurons receive direct projections from FEF. Neurons with similar properties have been described in frontal eye fields [1], and saccade related neurons in SC are known to receive direct projections from FEF. However, it should be pointed out that these authors believe that QV neurons in FEF are best thought of as visual neurons that would send signals to SC only indirectly.

### Functions of This Structure

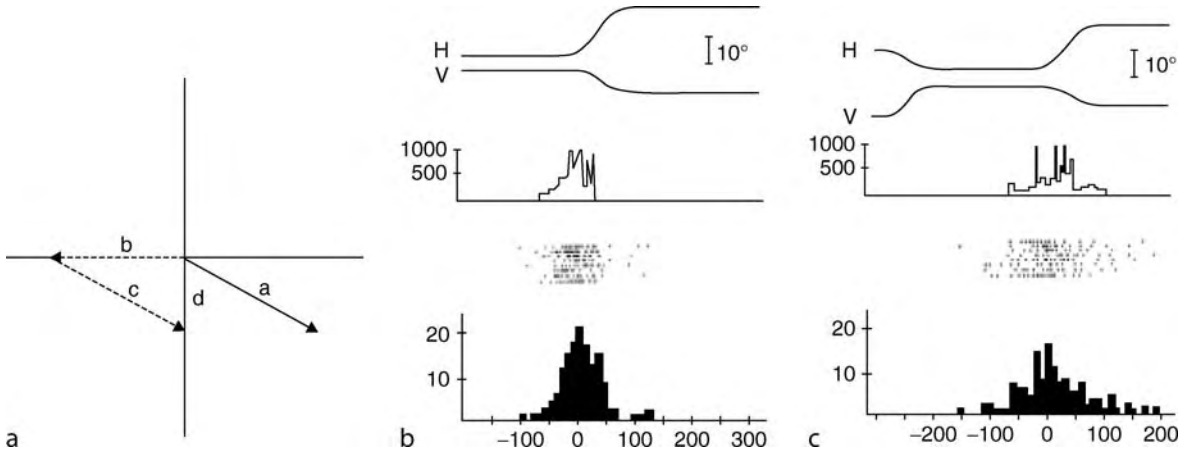
Quasi-visual neurons are one of several functional classes of neuron in primate superior colliculus originally described by Mays and Sparks [2]. On a simple, target-step saccade task, QV neurons resembled visual cells, with no alteration of firing rate associated with saccade onset. On these trials, they exhibited a sustained discharge that began ~70 ms after target onset and continued until the saccade occurred. Sustained responses occurred even if the target was flashed for only 20–80 ms.

The unique characteristics of these neurons could be seen using a ►double saccade task. On these trials, the vector of the saccade associated with the most vigorous discharge was found to be the same as that associated with the most vigorous discharge in the target step task (Fig. 1). This was true even though, for the double saccade task, no visual target ever appeared at the retinotopic location corresponding to the endpoint of the second saccade. That is, when a dissociation exists between the retinotopic location of the visual target and the saccade vector, the response fields of QV neurons appear to be associated with the latter. The timing of neuronal discharge was not tightly linked to either visual target onset or saccade onset.

On ►visual probe trials, a peripheral visual target was briefly flashed while the monkeys fixated a central fixation target. On these trials, QV cells exhibited a sustained discharge that persisted until ~200 ms after target offset. These authors also tried a variant of the double saccade task in which the second target was within the classical receptive field of the neuron. In this case, QV neurons discharged 110–120 ms after the onset of the second target, despite the fact that the first saccade was directed to a different location. Thus, these neurons are visually responsive, and can respond vigorously even when the saccade being planned is to a location outside their response fields. These results show that quasi-visual cells are neither completely visual nor completely motor, at least not in the usual sense. Instead, they seem to have elements of both visual and motor responses. These authors suggested that these cells might encode static eye position error (the difference between current and desired eye position).

Since Mays and Sparks first described QV neurons, several studies have suggested potential roles for these cells. Amador et al. [4] suggested that QV neurons might play an important role in the generation of anti-saccades. On ►anti-saccade tasks, these authors observed that monkeys occasionally made erroneous saccades to the target followed by extremely short latency "turnaround saccades" to the correct location. It was suggested that QV neurons may play a role in generating these very short latency turnaround saccades.

Very short ►intersaccadic intervals are sometimes observed when the task calls for a sequence of saccades [5]. These short intersaccadic intervals seem to require that the brain begin some of the computations



**Superior Colliculus – Quasi-Visual Neurons. Figure 1** (a) The initial eye position is at the origin. The vector labeled *a* indicates a saccade in the ►target step saccade task, to the location marked with the arrow. In the double saccade task, the first saccade is labeled *b* and the second is labeled *c*. Note that the vector of the second saccade of the double saccade task matches the vector of the saccade in the target step task. (b) Response of a quasivisual neuron associated with the saccade labeled *a* in panel (a). (c) Response of the same neuron during the double saccade task. Note that the cell responds vigorously for saccade *c* even though no visual target ever appears at that retinotopic location. On visual probe trials, the cell would respond to the appearance of a visual target at the location indicated by *a,* even if the animal is not required to make a saccade to this location (data not shown) (Adapted from [3]).

necessary for the second saccade even before the first saccade is executed. Tian et al. [2] described neurons (also referred to as QV neurons) with very similar properties in monkey frontal eye fields. These authors reported evidence that these neurons form a map of the spatial locations of potential saccade targets. Such a map would allow sequences of saccades to be programmed, and spatially accurate saccades executed, even if the visual targets are all extinguished prior to the first saccade. Thus, it may be that QV neurons in SC play an important role in the generation of sequences of saccades by helping the brain to maintain a spatially invariant representation of possible saccade target locations, even though each saccade alters the retinotopic location of those potential targets.

However, it must be pointed out that, to date, no subsequent studies have used the double saccade task while recording from QV neurons in SC. Therefore, the original Mays and Sparks paper remains the only study to provide data regarding cells that can be confidently classified as QV neurons in SC.

### Higher Order Function

QV neurons seem to be part of a spatial memory system that also encompasses the Frontal Eye Fields, and possibly the Lateral Intraparietal area and area 46.

### Quantitative Measure for This Structure

Currently, the only quantitative measurements available for QV neurons are those related to the discharge properties of these neurons, discussed above.

# Superior Colliculus – Role in Eye Movements

Mark M. G. Walton, David L. Sparks, Xintian Hu
Division of Neuroscience, Baylor College of Medicine, Houston, TX, USA

## Definitions

►Gaze – The direction of the line of sight with respect to external space.

Oculocentric reference frame – A coordinate system specifying the location of a target with respect to the current direction of fixation.

►Superior colliculus – A seven layered structure in the midbrain, involved in ►sensorimotor integration and the control of orienting behaviors.

## Characteristics

### Higher Order Structures

The superior colliculus occupies an important central role in the circuitry controlling orienting movements (►Orienting responses) and sensorimotor integration. Consistent with these functions, this structure receives both sensory and motor inputs from a large number of cortical and subcortical areas.

### Parts of this Structure

The superior colliculus is a seven-layered structure in the midbrain involved in orienting behavior and sensorimotor integration. The most dorsal of the three cellular layers and the surrounding two fibrous layers are generally referred to as the superficial layers [1]. The four ventralmost layers (two cellular and two fibrous) are typically referred to as the deep layers (or, alternatively, the intermediate and deep layers).

### Functions of this Structure

The role of the superior colliculus in the control of eye movements is part of its more general role in the control of gaze, including combined movements of the eyes and head [1]. In the intermediate and deep layers, several classes of neuron modulate activity in association with saccades. Saccade related burst neurons (SRBN) are characterized by a high frequency burst of spikes, beginning ~20 ms before the onset of saccades of a particular vector [2]. The movement fields of these neurons are arranged in a topographic map that lies approximately in register with the receptive fields of visual neurons in the superficial layers. Thus, the vector of the saccade is encoded by the location of activity within the collicular map. Some burst neurons (referred to as visuomotor burst neurons) also exhibit a visually evoked burst of spikes that begins ~70 ms after target onset. These cells are sometimes regarded as a separate class, although a continuum exists between exclusively motor bursters and those with strong bursts for both target onset and saccade onset. Saccade-related activity is also, to varying degrees, often dependent on the presence of a visual target [3]. Some cells respond equally vigorously regardless of whether or not the visual target is extinguished before the saccade, while others do not respond at all if the saccade is directed to the remembered location of a target that has been extinguished. Again a continuum exists, with most cells responding more vigorously if the visual target is still present at the time of the saccade. On ►delayed saccade tasks, some neurons, usually referred to as prelude or buildup cells, display tonic activity during the interval, beginning roughly 70 ms after target onset and ending at saccade onset, often culminating in a burst of spikes that is time-locked to saccade onset. These cells have been described as having open movement fields, meaning that they respond to any saccade that is in the optimal direction and that is equal to, or larger than, a particular value [4]. Quasivisual neurons are another class of cell described by Mays and Sparks [2]. These cells appear to be encoding ►motor error, and are best thought of as being neither completely visual nor completely motor. Fixation neurons are found near the rostral end of SC. These cells fire tonically during periods of steady fixation and pause for most saccades in all directions. Injection of muscimol into the rostral SC interferes with the monkey's ability to suppress unwanted saccades to peripheral visual targets [5]. On the basis of these observations, it was proposed that fixation cells are involved in the maintenance of active fixation. As shown by Krauzlis et al. [6]; however, many of these cells also burst for small contraversive saccades. These authors concluded that these cells encode motor error. Thus, the exact role of fixation cells in the control of saccades remains controversial.

In most current models of the saccadic system, a corollary discharge of the premotor burst is fed back to a comparator, which compares actual eye displacement to desired eye displacement. When this value reaches zero, the saccade ends. According to one view, SC is kept up to date about the progress of the ongoing saccade through feedback signals from the brainstem saccade generator. Evidence to support this notion has come from studies in which saccades were interrupted mid-flight by stimulating the omnipause (OPN) region. Keller, Gandhi, and Vijay Sekaran [7], for example, reported that the saccade resumes after the end of the stimulation and reaches the target correctly. These authors found that the same region of SC that was active before the saccade becomes re-activated for the resumed movement, which seems to indicate that the SC must have received feedback regarding the interruption.

On the other hand, the SC might be upstream from the local feedback loop. According to this idea, the SC generates a saccadic command that is sent to the brainstem saccade generator, but receives no feedback related to the progress of the saccade. These models, however, have difficulty explaining results such as those described above [7].

Lefevre et al. [8] proposed a model of saccadic control in which the superior colliculus is seen as less important than the cerebellum. More specifically, these authors proposed that the superior colliculus determines the timing of saccade onset and provides a general drive

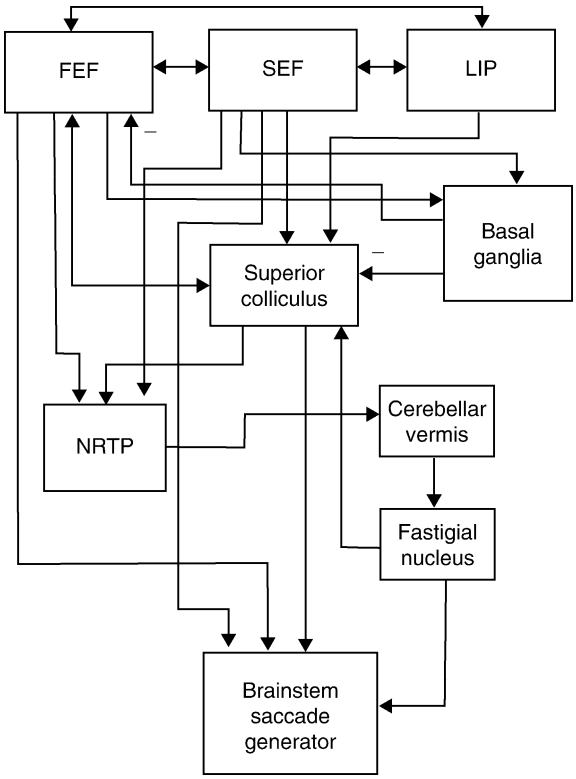
**Superior Colliculus – Quasi-Visual Neurons.**
**Figure 1** Coronal section showing the superior colliculus. Layers are labeled with roman numerals (Adapted from [10]).

that moves the eyes approximately in the right direction. According to this view, activation of the superior colliculus is neither necessary nor sufficient for saccades to occur. In support of this idea, the authors pointed out that lesions of the cerebellum severely impair saccadic eye movements. In contrast, primates still make reasonably accurate saccades even when the superior colliculus is ablated. As post-lesion plastic changes in alternative saccadic pathways can potentially mitigate the effects of permanent lesions, several studies have examined saccade metrics and accuracy following reversible inactivation of SC (for example, see [9]). While these studies reported a noticeable tendency for the post-injection saccades to be slower, of longer duration, and hypometric, reversible inactivation of SC does not prevent monkeys from making saccades to visual targets.

## Higher Order Function

As can be seen from the above discussion of cell types, there is good evidence that the SC is involved in the transformation of sensory signals into eye movement commands. The intermediate layers of SC receive visual, somatosensory, and auditory input from a large number of brain areas, as well as input from other saccade-related structures such as frontal eye fields, supplementary eye fields, and the lateral intraparietal area. As discussed above, a number of studies have described neurons in SC that are difficult to classify as clearly sensory or clearly motor [2].

In many species, the superior colliculus is involved in generating movements that orient the eyes and ears to visual and auditory stimuli of interest. In mammals, for example, the intermediate and deep layers carry signals related to movements of the eyes, head, and pinnae.



**Superior Colliculus – Quasi-Visual Neurons.**
**Figure 2** Simplified wiring diagram of the saccadic system. The superior colliculus occupies a central role in the saccadic system circuitry.

## Quantitative Measure for this Structure

Studies investigating the role of the SC in eye movement control typically attempt to quantify neuronal behavior by measuring the firing rate of individual neurons in the deeper layers. Most commonly, this involves measures such as firing rate, the number of spikes in the burst, and the timing of the burst with respect to visual target onset and/or saccade onset. For example, peak spike frequency is correlated with peak saccade velocity.

## Superior Frontal Gyrus

### Synonyms

►Gyrus front. sup.

### Definition

In the area of the frontal gyrus close to the precentral gyrus is situated the premotor cortex, which plays an important role in planning effector voluntary movements and has close interaction with the cerebellum, thalamic nuclei and basal ganglia.

At the level of the superior frontal gyrus is situated the frontal eye field, which is involved in planning voluntary eye movements. Hyperactivity of these neurons due to hemorrhage or tumors causes conjugate movements of both eyeballs (deviation conjugee). Conversely, destruction of tissue causes ipsilateral deviation conjugee, since now the activity of the contralateral eye field no longer has an antagonist.

►Telencephalon

## Superior Longitudinal Fasciculus

### Synonyms

►Fasciculus longitudinalis sup.

### Definition

With its two branches (anterior brachium and posterior brachium), the superior longitudinal fasciculus establishes connections between virtually all cortical areas. The part of the fasciculus connecting the motor (Broca's) speech center with the sensory (Wernicke's) speech center is called the arcuate fasciclulus.

►Pathways

## Superior Oblique Muscle

### Definition

Superior oblique is one of the six eye muscles.

►Eye Orbital Mechanics

## Superior Olivary Nuclei

Tom C. T. Yin
Department of Physiology and Neuroscience Training Program, University of Wisconsin-Madison, Madison, WI, USA

### Synonyms

Nuclei of the superior olive; Superior olivary complex; SOC

### Definition

The superior olivary nuclei are a group of nuclei located in the brainstem near the junction of the pons and medulla. It is the first auditory relay after the cochlear nucleus on the way to the auditory cortex and is the major point at which information from the two ears is integrated.

### Characteristics

#### Introduction

The superior olivary nuclei or complex (SOC), as they are more commonly called, occupy an important and unique position in the ascending auditory pathway. The SOC lies at the ponto-medullary border. Acoustic information is conducted from the outer ear into the inner ear where the cochlea transduces the mechanical energy into neural impulses that are conveyed by the auditory nerve fibers, which compose one component of the VIII cranial nerve, into the central nervous system. The other component of cranial nerve VIII is the vestibular nerve which originates from the vestibular apparatus of the inner ear. All auditory nerve fibers

synapse in the cochlear nuclei where there is some initial processing of the afferent information. Cells in the cochlear nuclei then project to the SOC of both sides so that the SOC represents the first major point at which cells combine the inputs from the two ears. Therefore the SOC is a critical point for processing of binaural information which is essential for accurate sound localization. To understand the neural processing, we must first consider what cues are needed for sound localization.

Imagine walking down the street of a town late at night and suddenly hearing a strange sound. In this situation, there are two important tasks that our auditory system must do. It has to identify the sound (a cat meowing or the footsteps of a possible mugger) and it has to tell us where the sound comes from. We understand very little about how the auditory system can identify sounds but considerably more about the neural processes that underlie the ability to establish where a sound originates.

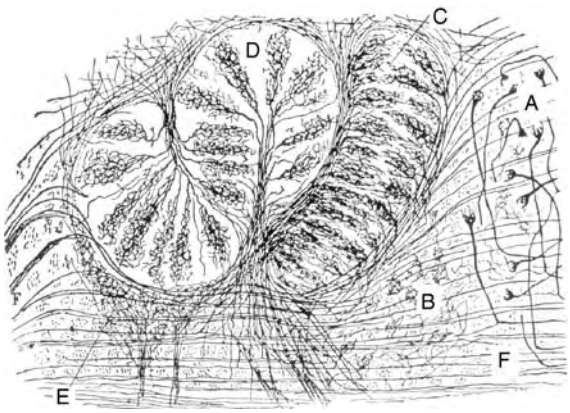
Note that the problem of localizing a stimulus is quite different for the auditory system than it is for the other two major sensory systems, vision and somatosensation. In both of the latter systems the location of a stimulus is naturally encoded in the location of the sensory receptor since there is a map of the space in the sensory epithelium, in the retina for the visual system and on the body surface for the somatosensory system. By contrast, the inner ear contains a map of the frequency, not location, of the sound. The location of the sound must then be computed by the nervous system by analyzing the small differences between the sounds at the two ears, ►interaural time differences (ITDs) and ►interaural level differences (ILDs, also called interaural intensity differences, IIDs). A remarkable feature of the auditory system is its sensitivity to these interaural disparities: the maximum ITD for the human head when a sound is opposite one ear is about 800 μs while human subjects can detect ITDs as small as 10 μs.

The maximum ILD is heavily dependent upon the frequency of the sound since the head acts as an effective acoustic shadow only for sounds with wavelengths that are shorter than the dimensions of the head, i.e. for high frequency sounds. Thus maximal ILDs are on the order of 20–30 dB at 15–20 kHz at the upper end of human hearing and only a few dB at the lower end of human hearing. Therefore, we would expect ILDs to be an effective cue only at high frequencies. The width of an average human head is around 15 cm which corresponds to the wavelength of a 2,000 Hz tone. Therefore ILDs should be effective for frequencies above 2 kHz and ineffective for lower frequencies. On the other hand the phase-locking that encodes temporal patterns in the cochlea is also frequency dependent: in mammals auditory nerve fibers will only phase-lock to tones below about 2–3 kHz. Therefore timing information about the fine structure of sounds is only preserved at low frequencies and ITDs would only be effective at those frequencies. The frequency dependence of ITDs and ILDs is the basis for the classical duplex theory of sound localization [1].

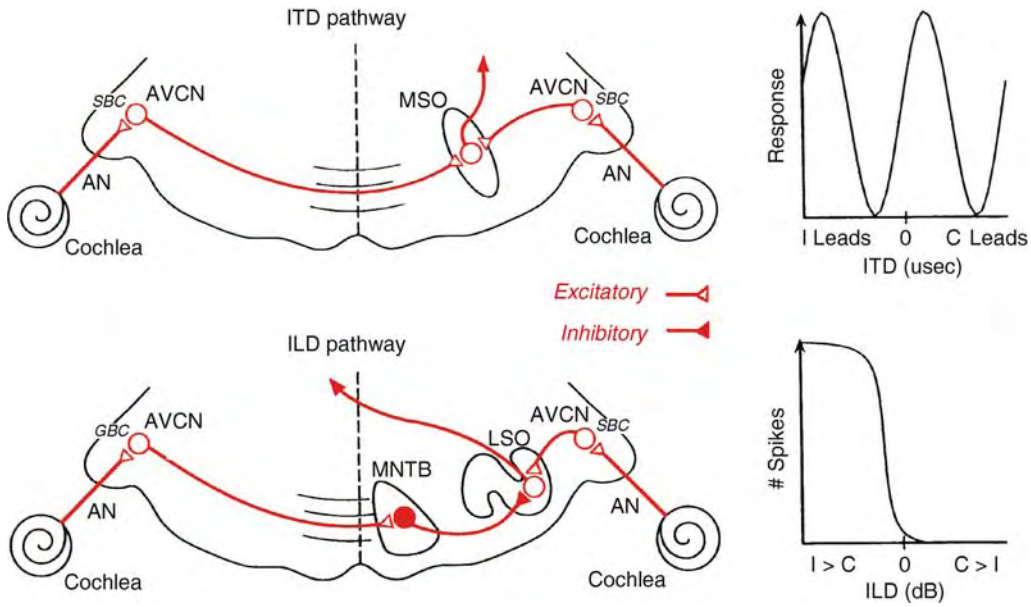
Where in the nervous system are these cues encoded? The most likely candidates are the nuclei in the superior olivary complex (SOC) which occupy a unique position in the ascending auditory pathway: they represent the first major point at which cells in the auditory system combine the inputs from the two ears. These inputs arrive from the anteroventral cochlear nucleus of both sides and they are shown in Fig 1 from a classical drawing of the left SOC [2] from Golgi stained sections of the neonatal cat. In Fig. 1 the midline is to the right and the three major nuclei can be discerned from lateral (left) to medial (right): ►lateral superior olive the (LSO), ►medial superior olive (MSO) and the ►medial nucleus of the trapezoid body (MNTB). In the cat in coronal sections the LSO takes the appearance of a prominent S-shape while the MSO is a narrow nucleus. The LSO and MSO are the key players in the encoding of the two interaural cues of ITDs and ILDs.

## Processing of Interaural Time Differences

Fig. 2 shows simplified versions of the circuits that are believed to be important for encoding the interaural cues of ITDs and ILDs. ITDs are believed to be encoded by cells in the medial superior olive (MSO). Anatomically, cells in the MSO receive excitatory inputs from the spherical bushy cells of the anteroventral cochlear



**Superior Olivary Nuclei. Figure 1** Drawings of the terminal arborizations from Golgi stains of afferents to the superior olivary nuclei of the neonatal cat. The three major nuclei are labeled: (A) medial nucleus of the trapezoid body, (C) medial superior olive, and (D) lateral superior olive. In addition two periolivary nuclei are also shown: (B) ventromedial periolivary nucleus and (E) lateral periolivary nucleus. The fibers of the trapezoid body (F) are also labeled.



**Superior Olivary Nuclei. Figure 2** Schematic drawings of the two circuits in the superior olivary complex that encode interaural time differences (ITDs) (*above*) and interaural level differences (ILDs) (*below*). Abbreviations: *AN*, auditory nerve fibers; *AVCN*, anteroventral cochlear nucleus; *MSO*, medial superior olive; *LSO*, lateral superior olive; *MNTB*, medial nucleus of the trapezoid body; *SBC*, spherical bushy cell; *GBC* globular bushy cell. To the right are drawings of typical responses of a cell in the MSO (*top right*) to variations in ITDs of pure tones and responses of a cell in the LSO (*bottom right*) as a function of the ILD in dB. The response to ITDs is periodic at the period of the stimulus tone and reflects the fact that the cells in the MSO are sensitive to interaural phase differences.

nucleus of each side. MSO cells are unusual cytoarchitecturally in having prominent dendrites that extend to the lateral and medial side where they meet the afferents from the left and right side (Fig. 1). The afferents from the ipsilateral cochlear nucleus synapse on the lateral dendrites while those from the contralateral side synapse on the medial dendrites. Physiologically, the cells in the MSO have been shown to be binaurally excited and exquisitely sensitive to the time of arrival of sounds to the two ears [3,4]. MSO cells behave like coincidence detectors with very sharp temporal windows so that they respond only when the inputs from the two sides arrive coincidentally or nearly so. A widely accepted model of this circuit was first proposed by Jeffress [5] who hypothesized that the timing of the arrival of inputs from each side is governed by the delays associated with differences in axonal length and that there is a systematic change in axonal delays from one end of the MSO to the other, which would result in a map of ITDs across one axis of the MSO. Since the pathlength to the MSO is naturally longer from the contralateral ear, then a natural consequence of the coincidence mechanism is that MSO cells respond best when the sound source is in the contralateral sound field where the sound can reach the contralateral ear before the ipsilateral ear and thus compensate for the longer axonal path from the contralateral side.

Recent studies of the anatomy [6] and physiology [7] of the MSO have shown the existence of inhibitory inputs which originate from the medial nucleus of the ►trapezoid body (MNTB) and ►lateral nucleus of the trapezoid body (LNTB). The MNTB receives input from the spherical bushy cells of the anteroventral cochlear nucleus of the contralateral side while the LNTB receives input from the same cells on the ipsilateral side. The function of these inhibitory circuits is still controversial [8].

## Processing of Interaural Level Differences

A parallel circuit in the superior olivary complex is believed to be responsible for encoding interaural level differences (ILDs) (Fig. 2, bottom). Cells in the ►lateral superior olive (LSO) receive excitatory input from the spherical bushy cells of the ipsilateral side and inhibitory input from the contralateral side that is relayed via an inhibitory interneuron in the medial nucleus of the trapezoid body (MNTB) [9]. The MNTB cells received input from the globular bushy cells of the contralateral side by way of a very specialized synaptic ending, the calyx of Held. In accordance with this circuit, cells in the LSO are excited by stimulation of the ipsilateral ear and inhibited by stimulation of the contralateral ear.

For binaural stimuli, LSO cells respond to the difference in intensity (ipsilateral intensity – contralateral

intensity) of the sounds to the two ears. Thus for free-field sounds, LSO cells respond well to stimuli presented in the ipsilateral sound field where the level of the sound is greater in the ipsilateral than the contralateral ear and poorly when the sound is in the contralateral sound field.

The large calyceal synapses between the globular bushy axons and the MNTB cells are very unusual one and can be seen prominently in Fig. 1. It is often said to be the largest synapse in the brain. The presynaptic element is so large that recordings can be made from both the pre- and post-synaptic neurons so that this synapse has become a model for biophysical studies of synaptic transmission.

It is well-known that there is a systematic crossed relationship between the representation in the cerebral cortex and body part or sensory field in all sensory and motor systems. The right motor cortex controls muscles on the left side of the body, cells in the left visual cortex have receptive fields in the right visual field, and cells in the left somatosensory cortex respond to touch or pain to the right side of the body. Note that cells in the MSO respond preferentially to sounds in the contralateral sound field whereas cells in the LSO respond to sounds in the ipsilateral sound field. This apparent paradox is resolved by having MSO project to the ipsilateral inferior colliculus while most LSO cells project to the contralateral inferior colliculus (Fig. 2). The subsequent projections of the inferior colliculus to the medial geniculate and then onto the cortex are all predominantly uncrossed which then makes cells in the auditory cortex respond to sounds in the contralateral sound field, as with the other sensory systems.

All of the nuclei in the superior olivary complex, like those of other ascending auditory nuclei are tonotopically organized, i.e. there is a systematic map of frequency along one axis of the nucleus. In accordance with the expectations of the classical duplex theory, both the MNTB and LSO have a disproportionate representation of high frequencies, which are associated with ILDs, while the MSO is biased toward low frequencies, which are useful for encoding ITDs. In animals with different head sizes, the ability to localize low frequency tones appears to be correlated to the size of the MSO. Interestingly, humans have a very prominent MSO, which is correlated with the importance of ITDs for sound localization but a very small LSO, even though we are clearly able to encode ILDs.

### The Periolivary Nuclei

In addition to the major nuclei of the SOC, the MSO, LSO and MNTB, there are also some smaller nuclei that collectively are usually referred to as the periolivary nuclei. The size and prominence of the periolivary nuclei vary somewhat from one species to another and the identification of individual nuclei vary from one investigator to another. An interesting aspect of these nuclei is that in some animals they are the source of the olivo-cochlear efferents [10]. These efferent fibers project from to the cochlea and innervate primarily the outer hair cells, though there are also fibers that end on the inner hair cells. Since 90% of the auditory nerve fibers innervate a single inner hair cells, the action of the olivo-cochlear efferents must be indirect. Current theories center on the fact that the outer hair cells are motile and can contract which could affect the micromechanics of the basilar membrane motion and consequently modulate the inner hair cell response. In rodents the olivo-cochlear efferents originate from cells that are located within the lateral superior olive.

# Superior Olive

## Synonyms

►Nucl. olivaris sup.; ►Superior olivary nucleus

## Definition

The superior olivary complex comprises the nuclei:

- Nucleus of the trapezoid body
- Nucleus of the superior lateral olive

- Medial nucleus of the superior olive

and is thus a vital synaptic center in the auditory tract, playing an important role in acoustic reflexes (reflex eye movements towards the source of noise, fright movements).

►Mesencephalon

## Superior Parietal Lobule

### Synonyms

►Lobulus parietalis sup.

### Definition

In the direction of the occipital pole, the inferior and superior lobules unite at the postcentral gyrus.

Analogous to the secondary motor cortex there is also a secondary sensory cortex for the somatosensory control; this is believed to stretch across both lobules and to be responsible for analysis, recognition and assessment of tactile information.

►Telencephalon
►Visual Space Representation for Reaching

## Superior Prefrontal Gyrus

### Definition

Part of the frontal lobe; involved in orchestrating executive function.

## Superior Rectus Muscle

### Definition

Superior rectus is one of the six eye muscles.

►Eye Orbital Mechanics

## Superior Semicircular Canal Dehiscence Syndrome

### Definition

Disorder of the labyrinth caused by a dehiscence (opening) in the bone that covers the superior canal. Patients can develop vestibular and/or auditory symptoms and signs. The effect of the dehiscence is to create a third mobile window into the inner ear.

►Disorders of the Vestibular Periphery

## Superior Temporal Gyrus

### Definition

The superior temporal gyrus is the cerebral cortical fold immediately ventral to the lateral fissure. Its posterior portion is part of the language cortex.

## Superior Vestibular Nucleus

### Synonyms

►Nucl vestibularis sup.

►Vestibular Nuclei
►Pons

## Supernormal Stimulus

### Definition

Stimulus with a releasing value that is higher than the releasing value of the natural key stimulus.

## SuperSAGE

►Serial Analysis of Gene Expression

## Supersensitivity of Blood Vessels

### Definition

Increased response (constriction) of blood vessels to circulating or neurally released noradrenaline (and other vasoactive agents) following partial or complete denervation, decentralization or decrease of activity in postganglionic vasoconstrictor neurons. The increased response to noradrenaline is primary due to a decrease of neural uptake of noradrenaline by the postganglionic terminals.

## Supervenience

John Symons
Department of Philosophy, The University of Texas at El Paso, El Paso, TX, USA

### Definition

Supervenience is a philosophical term of art that refers to the determination relation between lower and higher-level ontological phenomena. For example, physicalists believe that psychological facts supervene on neural facts.

### Description of the Theory

In the 1970's and 1980's the concept of supervenience figured in philosophical debates as a promising way to shed light on the mind-body problem. According to the standard view in metaphysics and philosophy of mind, supervenience is a relation between two sets of properties such that:

1. They vary together in a regular way.
2. One set somehow determines the other.
3. That the two sets are different in kind.

For example, mental properties can be said to supervene on physical properties if they are covariant and if physical properties are more basic than mental properties. Likewise, baldness supervenes on the distribution of hair, computer operating systems supervene on computer hardware, ethical actions supervene on the movements of bodies, etc.

Supervenience is not an exotic or purely philosophical notion. The basic idea arises quite naturally out of our belief that some features of reality depend on others. In the philosophy of mind, the supervenience thesis rests on the belief that mental life depends on the activity of the brain (or on the brain plus some aspects of the environment). If one believes that any change at the psychological level can only happen by virtue of a change at the neural level then one holds a version of the supervenience thesis for mental life. While supervenience has some intuitively appealing features, the challenge is to get clear on the notions of fundamentality and determination that are central to the supervenience thesis.

The precise nature of the determination involved in the supervenience thesis depends, among other things on modal considerations; on what is meant by necessity and possibility. For instance, when one says that no higher-level change in the properties of an object is possible without a change in its lower-level properties, a variety of things can be meant depending on the force of "is possible." If one believes that the determination relation holds across all possible worlds then one is arguing for a stronger version of supervenience than if one contends that the determination relation holds only for our world, as it actually is, with its physical laws as they happen to be. Additionally, the supervenience thesis will have different implications depending on what one means by the object in question. Global, regional and local supervenience relations can be distinguished, depending on where one sets the parameters of the object in question. Global supervenience takes as its object, the entire universe, for regional and local supervenience the object is some subset of the universe.

### Metaphysical Assumptions

Discussions of the notion of supervenience begin with some familiar and widely shared metaphysical assumptions. It is assumed, for example that facts about the natural world can be understood as falling into distinct levels. Chemical, biological, psychological and economic facts fall into distinct levels, hierarchically arranged from the more basic and general, or "lower," to the more specific and "higher." In this picture, physics is the most fundamental science and physical facts and laws have maximal generality, insofar as they apply to all of nature. With this stratified picture of nature comes the notion that each of the higher-levels depends on the lower levels in some sense. In this spirit, contemporary neuroscientists and philosophers of mind generally assume that psychological facts are determined by neuroscientific facts which are, in turn, determined by bio-chemical facts.

While supervenience is completely compatible with reductionism, supervenience theorists generally assume that the relationship between levels is non-reductive. Many philosophers who accepted non-reductive physicalism were drawn to supervenience as a way of embracing a respectable physicalist metaphysic while at

the same time maintaining a form of irreducibility for mental level facts.

Having a belief, a feeling or a desire is not simply a matter of possessing one or more of a defined set of physical properties. For instance, the dog, the octopus and the Martian might all be in pain while possessing differently structured brains, or even – at least in the case of the Martian – no brain at all. One can imagine different structures realizing precisely the kinds of behaviors or functions that we associate with any mental term. Considerations of this kind, so-called multiple realizability arguments, encouraged most contemporary philosophers of mind to abandon classical reductionism for some version of non-reductive physicalism. This means that they reject claims that the mind simply is the brain (the identity theory) as well as claims that the micro-physical description of reality is the only description we need (strong reductionism).

While multiple realizability arguments led many philosophers to reject straightforward reductionism, it seems unscientific to deny that mental life is dependent on the physical stuff in which mental life is realized. If one wishes to maintain a commitment to physicalism while rejecting reductionism one faces the problem of understanding the nature of the dependence between higher and lower-level facts about organisms. The mind-body problem in its contemporary form is the problem of reconciling physicalism and anti-reductionism. This is quite different from the mind-body problem we inherited from Descartes, which involved accounting for the interaction between spatial and non-spatial substances.

Philosophers noticed that this modern version of the mind-body problem could be understood in terms of the relationship between properties. For example, an object can have properties related to its shape, velocity, mass, position, color and the like without the problem of their compatibility or causal relations ever arising. Some of an object's properties clearly determine others. For instance, the characteristics of an object's surface will determine its colors. In other cases, properties may have no obvious connection or determinative relationship. Consider the relationship between the mass of a vase and its distance from Paris. The analysis of notions like mentality in terms of properties opened the possibility that an object can have both physical and psychological properties without encountering Cartesian-style problems about the relationship between spatial and non-spatial substances. Properties-based metaphysical analyses were attractive to non-reductive physicalists precisely because they permit us to talk about objects, events and states of affairs as having both physical and psychological properties.

Donald Davidson's anomalous monism is an example of this kind of properties- based metaphysics. Davidson accepted a physicalistic metaphysics while denying that science will generate a straightforward reduction of mental types to physical types. And yet, Davidson did not believe that mental life somehow floated free of the physical world. Rather, as a scientifically inclined philosopher, he was committed to the idea that there are no events that have only mental properties [1]. However, saying that an object that has mental properties must also have physical properties is not necessarily any comfort to the reductionist. After all, as Jaegwon Kim points out, while it is true that if an object has a color, it must have a shape, there is no necessary relationship between for example, the squareness of an object and its redness [2].

Anomolous monism, by itself, does not offer much of a theory of the relationship between mental and physical properties. And yet there seems to be more of a connection between minds and bodies than exists between shapes and colors. In his classic paper "Mental Events" Davidson attempts to reconcile his commitment to physicalism with his anti-reductionism using the concept of supervenience. Davidson is widely credited as introducing the term "supervenience" in its contemporary form in that paper. In a frequently cited passage he defines supervenience as meaning "that there cannot be two events alike in all physical respects but differing in some mental respect, or that an object cannot alter in some mental respect without altering in some physical respect" [1,3]. According to advocates of supervenience in the philosophy of mind, this definition has far more substance than something like the mere necessary dependence of color properties on shape properties. To say that minds supervene on brain states for example, is to suggest that one can only have a mental property by virtue of having some neural property, and that understanding this dependence relation will allow us to understand the nature of the relationship between mental life and embodiment. The implicit claim is that supervenience will give us more than the simple acknowledgement *that* there is some relationship between the two.

## Kinds of Supervenience

In addition to assuming that facts about more fundamental levels of reality must determine facts at higher ontological levels, there are two additional assumptions that are related to the first:

1. Changes at the higher level depend on changes at the lower level.
2. Identical states of affairs at the lower level necessitate identical states of affairs at the higher level.

In the case of the relationship between mental and physical phenomena these two assumptions are exemplified in the following way:

1a. Changes at the psychological or mental level are only possible via changes at the neural level.

2a. It is impossible for organisms to be in identical brain states without also sharing the same psychological states.

For neuroscientists, these are fundamental assumptions. After all, neuroscience would of little general interest if psychological differences were not determined in some law-like way by neural differences. Of these two assumptions, 2 can be understood as the minimal requirement for a physicalist metaphysics. Of course 2a is debatable and might be made compatible with physicalism given some fancy philosophical footwork. We can rephrase 2 so as to bring out its modal character:

2m. It is not possible for two things to be identical at the lowest level and not identical at higher-levels.

In this form we can see that the strength of the modal component is very important to the meaning of the overall claim. If it is merely a claim about the way things happen to be in this world, then one is only committed to "weak supervenience." If it is a claim about the relationship between the two levels in all worlds that we can properly describe, then it is an example of a "strong supervenience" claim.

Debates over the nature of the determination relation itself have also distinguished between conceptual, metaphysical and nomological supervenience. To say that *m* nomologically supervenes on *p* is simply to say that there happens to be a lawlike connection between the two. For example *m* might supervene on *p* because of the ways that the laws of physics happen to stand in some world. This, of course, would be to claim that *m* weakly supervened on *p*.

Metaphysical supervenience involves the assertion that a determination relation holds across all possible worlds. If *m* metaphysically supervenes on *p* then in all possible worlds *m* will appear every time *p* appears. Finally, to claim that *m* conceptually supervenes on *p* is to suggest that anyone who understands the concepts *p* and *m* will recognize that they are related. Certain conceptual truths, for instance, that unmarried males are bachelors, or that 2 + 2 = 4 hold across all possible worlds. Conceptual truths of this kind sometimes entail supervenience relations. For example, as discussed previously, baldness, supervenes on hair distribution. Or, to put it another way, one's hair distribution properties determine whether one has the property of being bald. Since being bald, is, by definition connected to having an unacceptably meager distribution of hair, one can see hair distribution as determining baldness across all possible states of affairs. Both metaphysical and conceptual supervenience are cases of strong supervenience.

While it is illuminating to examine the consequences of altering the modal strength of claims about determination relations, such analyses do not provide significant insight into the nature of determination itself. Supervenience claims entail the existence of a determination relation, are governed in large part by one's modal commitments, however, bracketing the modal component of the claim, it seems that the supervenience claim itself does not do very much more than point to precisely the phenomenon we had hoped to understand, namely the covariation of mental and biological properties.

By saying that mental facts supervene on neuroscientific facts, philosophers promised some understanding of how higher-level facts about mental life are determined by lower-level facts about neuroscience. After three decades of debate, supervenience has not lived up to the hopes of its advocates. As Jaegwon Kim, one of the most important proponents of supervenience, puts it: "We must conclude then that mind-body supervenience is not an explanatory theory; it merely states a pattern of property covariation between the mental and the physical and points to the existence of a dependency relation between the two." (1998, 14) Property covariation is the problem to be explained, and can be accounted for in a variety of ways. Unfortunately, supervenience is not one of them. Perhaps one reason for increased interest in emergence and reduction in recent philosophy of mind may be the realization that these approaches hold out the possibility of the kind of explanatory account of the relationship between mind and body that supervenience failed to provide.

While even its most ardent advocates concede that supervenience did not live up to their expectations, it is nonetheless clear that analyses of the nature of supervenience have helped us to understand what counts as an acceptable explanation of the mind's place in nature given our basic commitments to physicalist metaphysics.

# Supervised Learning

## Definition

Supervised learning is a form of learning in computational models such as artificial neural networks. The network is trained by computing the difference between its output and a teaching signal, which has to be

provided externally. This difference, the net error, is used in order to estimate by how much, and in which direction, to adjust connection weights in the network.

A disadvantage of supervised learning is that in many cases the existence of a teaching signal is not justified by the context of the application. It has been proposed that supervised learning occurs in the cerebellum.

# Supplementary Eye Field

Jeffrey D. Schall
Center for Integrative and Cognitive Neuroscience, Vanderbilt Vision Research Center, Department of Psychology, Vanderbilt University, Nashville, TN, USA

## Definition

The supplementary eye field (SEF) is an area in the dorsal medial frontal lobe of the cerebral cortex that contributes indirectly to the control of movements of the eyes.

## Characteristics

### Higher Level Structures

SEF is located at the rostral end of the supplementary motor area, contiguous with the representation of orofacial, pinna and forelimb movements. SEF is located in Brodman's area 6 and corresponds to area F7 [1]. The human SEF is located on the medial surface of the superior frontal gyrus in the upper part of the paracentral sulcus (Fig. 1).

### Lower Level Components

The connectivity of SEF is distinct from that of the skeletal motor cortex surrounding it, and SEF shares many but not all efferent targets and afferent sources with the frontal eye field (FEF) [2,3]. The major thalamic inputs to SEF arise mainly from the medial ventroanterior nucleus and the lateral segment of the mediodorsal nucleus as well as the intralaminar thalamic nuclei. These thalamic inputs convey signals mainly from the visuomotor zone of the substantia nigra pars reticulata, the intermediate layers of the superior colliculus and the face representation of the deep cerebellar nuclei. SEF projects to the caudate nucleus in a zone largely but not completely overlapping afferents from FEF, to the superior colliculus in a more diffuse pattern than the FEF counterpart, to specific brainstem oculomotor regions such as the nucleus raphe interpositus, the nucleus reticularis tegmenti pontis, the nucleus prepositus hypoglossi, the mesencephalic reticular formation, the interstitial nucleus of Cajal and the pontine reticular formation as well as the dorsomedial pontine nuclei.

SEF is reciprocally connected with several cortical areas, although fewer visual areas than is FEF. SEF interacts directly with area MST, the superior temporal polysensory area, area LIP, with anterior and posterior cingulate cortex and with the postarcuate premotor areas as well as the supplementary motor area and with prefrontal cortex in areas 12 and 46. SEF is also heavily connected with FEF in a spatial pattern that departs from the typical topography observed between other cortical areas.

### Higher Level Processes and Lower Level Processes

#### *Sensory Processes*

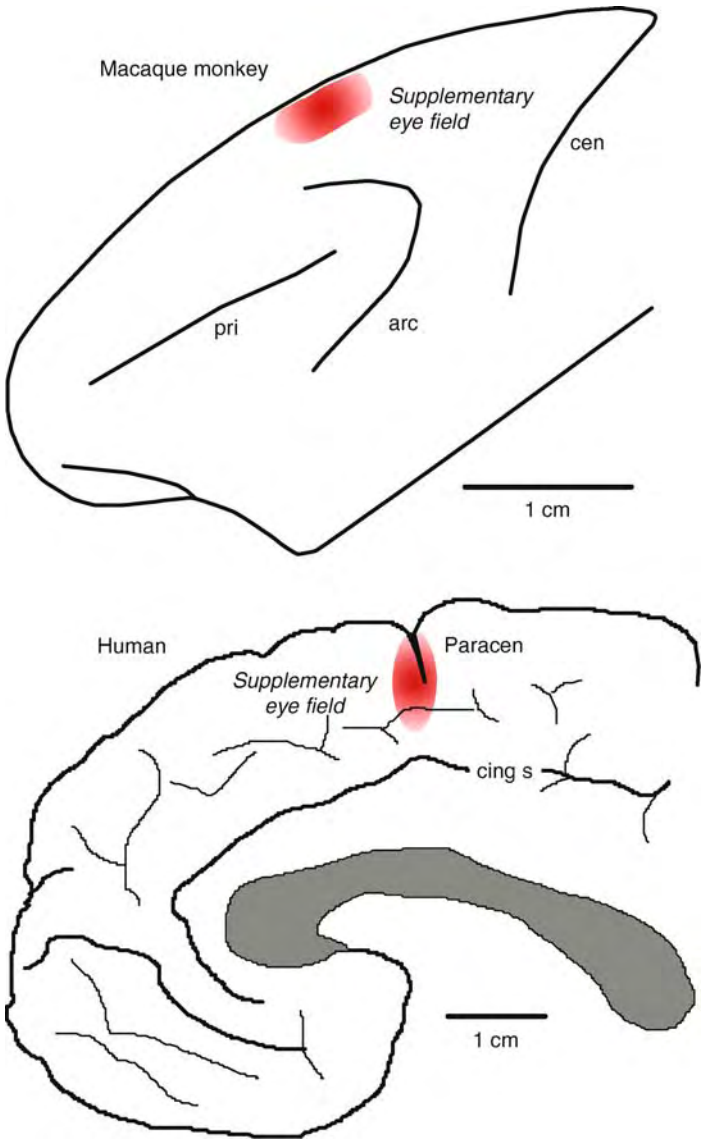
Neurons in SEF respond to visual and auditory stimuli [2,3]. However, visual responses are later and less vigorous than those observed in FEF. SEF neurons exhibit various kinds of extraretinal modulation including anticipatory activity and responses conditional on stimulus-response mapping rules [4]. Thus, SEF visual responses reflect less about the properties of the image and more about the stimulus in the context of the ongoing behavior.

#### *Gaze Control*

A great deal of evidence demonstrates that the SEF plays some role in the production of movements of the eyes [2,3]. In his pioneering electrical stimulation studies in humans, Penfield noted gaze shifts evoked by stimulation of the rostral part of the supplementary motor area (SMA). This finding has been confirmed using subdural electrode arrays to stimulate and record in humans. Schlag and Schlag-Rey first identified SEF as an area in which low intensity microstimulation evokes saccades and neurons discharge in relation to saccade production [5]. SEF neurons are also active in relation to the production of pursuit eye movements [6].

Numerous functional brain imaging studies using PET and fMRI have described activation in and around SEF of humans producing saccades [7]. Common findings include greater activation in SEF associated with antisaccades or memory-guided saccades relative to simple visually guided saccades.

Several other characteristics of SEF distinguish it from FEF. Electrical stimulation of many sites in SEF evokes saccades with dimension and direction dependent on the position of the eyes in the orbit, unlike what is observed in FEF or superior colliculus. Also, the saccade-related activity of many SEF neurons is contingent on the context in which the saccade is produced.

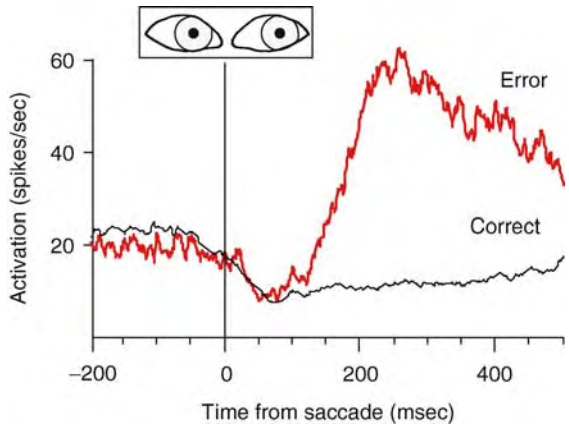


**Supplementary Eye Field. Figure 1** Location of supplementary eye field in lateral view of frontal lobe of macaque monkey (*top*) and medial view of frontal lobe of human (*bottom*). In macaque monkeys, SEF is located on the dorsomedial convexity, medial to the upper limb of the arcuate sulcus. In humans, SEF is located dorsally on the medial surface around the paracentral sulcus. Abbreviations: *arc*, arcuate sulcus; *cen*, central sulcus; *cing s*, cingulate sulcus; *pri*, principal sulcus.

Finally, despite the apparent relation of SEF to saccade production, when tested in a task requiring control of saccade initiation, few neurons in SEF generate signals that are sufficient to control gaze. Thus, although anatomically and physiologically SEF seems to parallel FEF in many respects, SEF seems to play a less essential or potent role in saccade production.

### Supervisory Control

Diverse more complex functional properties of SEF neurons have been described including conditional motor learning, object-centered representation, production of anti-saccades and sequences of saccades and eye-hand coordination. Theories of executive control cite five types of behavior that require supervisory control – planning or decision making, error correction, producing responses that are not well-learned, dealing with difficult or risky conditions and overcoming habitual responses. These categories include the conditions under which various investigators have reported neural activity in supplementary eye field. Therefore, these diverse findings can be organized under the hypothesis that SEF is part of a supervisory control network that is called into action when alternative



**Supplementary Eye Field. Figure 2** Activity of a representative SEF neuron aligned on the initiation of a saccade that was correct (black) and an error (red). This neuron signaled the production of errors.

responses are difficult to distinguish, habitual responses must be overcome, consequences are uncertain, and deliberation is necessary [8,9]. The supervisory system exerts control over the processes that produce sensory-guided movements. Physiological evidence for a supervisory system in humans includes a scalp potential referred to as the error-related negativity that occurs when subjects produce errors. In macaque monkey SEF, certain neurons exhibit modulation specifically following a saccade that is an error (Fig. 2). Other neurons in SEF signal the anticipation and receipt of reinforcement. Still other neurons in SEF seem to signal the amount of mutually incompatible co-activation occurring. Error, reward and conflict signals form the basis of current models of executive control. Therefore, the most plausible current hypothesis about the function of SEF proposes that it provides executive control when saccades are produced under complex conditions.

### Function

SEF contributes to the executive control of eye movements.

### Pathology

Damage to SEF in humans or monkeys results in symptoms that are relatively mild and difficult to discern. Experimental ablation or inactivation of the SEF in macaque monkeys does not impair accurate fixation of eccentric visual targets or execution of saccadic eye movements to single visible or to remembered target locations. Modest impairment in production of sequences of saccades is observed. Transcranial magnetic stimulation that transiently inactivates SEF in humans also impairs production of a memorized sequence of eye movements. It should be noted that combined ablation of the FEF and the superior colliculus, leaving the SEF intact, produces effective gaze paralysis. These observations reinforce the conclusion that SEF plays an indirect role in gaze control. A recent report of one patient with a lesion restricted to SEF in one hemisphere described impaired self-control but intact error monitoring during a saccade task.

## Supplementary Motor Area (SMA, F3)

### Definition

A secondary motor area located on the medial wall of the frontal lobe anterior to the hindlimb representation of primary motor cortex. This area has projections to primary motor cortex and is also contains large numbers of corticospinal neurons. SMA is important for producing bilateral movements and sequences of movements.

## Synonyms

SCN

## Definition

A hypothalamic nucleus lying above the optic chiasm and functioning as a master clock by setting the phase of activity of responses throughout the body.

## Characteristics

**There is a clock in the brain**. If one were placed in an environment such as a cave, where there are no time cues at all, then cycles of sleep and wake would persist with a period of approximately 24 h. It was once considered possible that this ~24 h periodicity was the result of the earth's rotation around the sun. It is now well established however, that this rhythm is the achievement of a brain clock, located in the suprachiasmatic nucleus (SCN) of the hypothalamus. The experimental evidence that the SCN is the locus of a master clock in the brain that organizes the daily activities of the body is very robust, as it comes from many types of studies in many different labs, all of which converge on this conclusion. Thus, lesions of the SCN abolish all daily rhythms, transplants of the nucleus restore rhythmicity to an SCN-lesioned host animal, with the period of the donor, and ►rhythmicity of the SCN is sustained *in vitro and in vivo*, in the absence of input from the rest of the brain. In summary, the SCN is the locus of a brain clock that signals time of day to the body, findings that have been amply reviewed[1–4]. The SCN is necessary for these functions, and they can not be taken over by any other brain region.

**The SCN is made up of individual cells that are themselves circadian clocks**. The SCN contains ~10,000–20,000 neurons and about a third as many astroglia. For many years, it was unclear whether circadian rhythmicity was an emergent property of a network of ►oscillators working together, or a property of individual cells. The cellular basis of circadian rhythmicity was first seen in daily changes in spontaneous electrical activity of neurons. This discovery made it logical to seek the intracellular mechanism of rhythmicity. One of the most important discoveries of the past decade has been the identification of clock genes. These clock genes occur in a wide variety of organisms, ranging from prokaryotic bacteria, to plants, flies and mammals. Importantly, there is striking homology between clock genes among animals, enabling rapid discovery in research.

Within individual cells, the clock mechanism involves multiple core ►feedback loops consisting of positive and negative regulatory elements of transcription/translation which mediate the expression of a large number of genes at distinct circadian phases [4,5]. Briefly, the elements of the feedback loop include the transcriptional activators ►BMAL1 and ►CLOCK and the negative regulators PER and CRY which act on circadian ►E-box promoter elements. Post-translational modifications involving protein phosphorylation and ubiquitination temporally separate the turnover of the key positive and negative components of the clock, thereby producing a period length for the entire cycle of changes of approximately 24 h. Additional interlocking loops are produced by E-box–mediated regulation involving the ROR/►REV-ERB binding element (RORE) and the DBP/E4BP4 binding element (D-box). By assessing the expression level of key-clock genes and or their protein products, we can assess the time of day encoded in the cell.

**Coordination of bodily rhythms and function of timing information**. In orchestrating the timing of daily rhythms in physiology and behavior, the SCN prepares the body for the transitions between day and night. Daily rhythms can be seen not only in the salient behaviors of sleep and wake, but in virtually all behavioral and physiological responses that can be measured. For example, there are rhythmic oscillations in speed of responding in timed tasks, in the secretion of hormones, in concentrations of urinary metabolites, and in hunger and eating. Many of these responses enable the anticipation of changes that will soon occur. The optimal timing of each of these functions ensures their occurrence in the appropriate temporal niche: correct timing is a form of resource partitioning.

**Light provides the most salient and reliable synchronizing or entraining signal from the environment**, and functions to set the phase of SCN oscillators. The ►retina is the only light sensitive tissue in mammals, and the SCN receives direct input from the retina via the ►retinohypothalamic tract. (In contrast, non-mammalian vertebrates have a photosensitive ►pineal gland and/or ►photoreceptors within the brain itself and many organisms have light sensitive cells in various parts of the body). The SCN gets photic information from both rod/cone photoreceptors and from ►intrinsically photosensitive retinal ganglion cells (RCGs) [6]. The ►rods and ►cones, containing the photopigments rhodopsin

and iodopsin, are the classical photoreceptors in the outer retina of the eye. Rods and cones send their signals to neurons in the inner retina, the RGCs. Most RGCs project their axons via the optic nerve to brain areas involved in (conscious) vision. On the other hand, a small proportion (~1%) of RGCs expresses the photopigment ►melanopsin, is intrinsically photosensitive and project via the retinohypothalamic tract to the SCN among other brain regions. Projections of these intrinsically photosensitive RCG's make up about 80% of the retinal input to the SCN and regulate (not conscious) detection of light and dark, or nonvisual photoreception.

**Intercellular communication in the SCN**. One might imagine that SCN oscillators acts as a coherent unit, producing one synchronized rhythm throughout the nucleus. This is not at all the case. SCN neurons have a topographically and functionally structured arrangement, with distinct populations of neurons that are heterogeneous in morphology, physiology and neurotransmitter content [2]. Some neurons receive information about light via the retina, others mediate intercellular communication within the nucleus. Each of these functional cell types transfers photic or circadian signals to other brain regions. Synchronization of neurons within the SCN is achieved via multiple mechanisms including synaptic transmission, gap junctions, and possibly by diffusible signals, ensuring robust responses in the face of genetic or environmental perturbations. An orderly sequence of activation of cells occurs, and this has been studied by exploring the circuitry of the SCN.

**The SCN has two main communicating compartments: ventral core and dorsal shell**. Within the nucleus, the neurons located in a ventral "►core" subdivision receive light input from the retina and communicate that information to neurons of the dorsal "►shell." Core neurons express the neuropeptides, ►vasoactive intestinal peptide (VIP) and ►gastrin-releasing peptide (GRP). Core neurons are not detectably rhythmic or show very low levels of rhythmicity, measured by either electrical activity or clock gene expression. In a sense, core SCN neurons behave as "gates," sometimes open and sometimes closed to environmental input, and they function to narrow the phase dispersion of individual oscillating cells in the shell SCN [3]. Core cells express immediate early genes such as cfos and the core clock genes ►*Period1 (Per1)* and *Period2 (Per2)*, during the night or subjective night, but not during the day or subjective day. Furthermore, the expression of immediate early genes and proteins is highly correlated with the behavioral ►phase shifting effects of light. In contrast to the core, neurons of the dorsal shell contain ►vasopressin (►VP) and rhythmically express *Per1* and *Per2* [2] and have daily electrical activity rhythms, with higher firing rates during the day than at night. That rhythmic electrical activity is important in producing synchrony among SCN neurons has been shown in studies using tetrodotoxin, which prevents action potentials by blocking voltage-dependent Na+ channels. Application of tetrodotoxin to SCN slices, results in the loss of synchrony among SCN neurons.

The orderly expression of circadian rhythmicity dependent on networks of cells between core and shell and within shell networks has been confirmed by work both *in vivo* and *in vitro*. Lesions of the core SCN result in loss of behavioral and physiological rhythmicity, even when cells of the shell SCN survive ablation. If the dorsal and ventral SCN in a brain slice are separated by a cut, neurons in the dorsal shell become desynchronized, while those in the ventral core remain synchronized. In a slice preparation that lacks an ►SCN core, ►rhythmicity is unstable and of low amplitude, measured by bioluminescence of luciferase reporter for *Per2* [3]. In contrast, if a slice contains both core and shell neurons, a high amplitude, stereotyped spatiotemporal pattern of changes in gene expression occurs, with a complex wave of activation in a series of steps, beginning at the dorsomedial SCN, spreading ventrally in the outer shell and then centrally to the inner shell and a simpler pattern of deactivation involving a contraction of expression towards the central inner shell. A similar slow spread of signal is seen in SCN from animals sampled at different times. Taken together, these findings consistently indicate that core neurons are necessary for rhythmicity in SCN tissue and in the behavior and physiology of the animal, and that a temporally organized sequence of activation occurs on a daily basis in the SCN.

The major **neurotransmitters and chemical synapses in the SCN that comprise its circuits include** GABA, VIP and GRP. GABA and its receptors are expressed throughout the SCN. GABAergic transmission shows a circadian rhythm, and GABA treatment both phase shifts and synchronizes firing rate rhythms among SCN neurons [7]. In the SCN, both VIP and GRP occur in the core retinorecipient region and these peptides have daily rhythms, with GRP peaking in the day and VIP peaking in the night. VIP- and GRP-containing neurons have extensive intra- and extra-SCN projections and their respective targets, $VPAC_2$ receptor (encoded by the *Vipr2* gene) and the GRP receptor ($BB_2$) are both more heavily expressed in dorsal SCN. Mice lacking BB2 receptor expression maintain molecular and behavioral rhythmicity albeit with subtle alterations, indicating that GRP-BB2 signaling functions to amplify endogenous circadian rhythmicity. By contrast, mice deficient in VIP(*Vip*−/−) and mice lacking $VPAC_2$ expression ($Vipr^{2-/-}$) *are both incapable of sustaining normal circadian locomotor rhythms suggesting that this signaling system is necessary for sustaining circadian clock function. Indeed, molecular rhythms of clock genes and c-Fos are severely attenuated in the SCN of* $Vipr^{2-/-}$ *mice while the firing rate rhythms of* $VIP^{-/-}$ *and* $Vipr^{2-/-}$ *SCN cells are blunted or absent and show disrupted synchronization.*

*GRP administration leads to induction of Per1 and Per2 mRNA as well as c-Fos protein in the dorsal SCN, and produces phase shifts in firing rate rhythms in SCN slices and in locomotor behavior. GRP administration restores neuronal rhythms in Vipr$^{2-/-}$ SCN slices.*

**Output signals of the SCN**. Information from the SCN is transmitted directly, by neuronal projections to other brain regions and indirectly, via intermediate neurons to peripheral organs such as the pineal gland and liver via intermediate neurons [8]. Hypothalamic intermediate neurons in the ►subparaventricular zone and the paraventricular nucleus are important in this process. In addition, diffusible signals from the SCN are also sufficient to restore and sustain circadian behavioral rhythms in SCN-ablated animals. Consistent with this finding, transplanted fibroblasts assume the rhythmic phenotype of their host animal. Several prohormones and peptides are rhythmically produced in the SCN, and are candidate signaling molecules. Several diffusible signals have also been identified as output factors of the SCN, including ►transforming growth factor-alpha, ►prokineticin-2 and cardiotropin-like cytokine. Neural targets of SCN efferents such as the subparaventricular zone and ►paraventricular nucleus of the thalamus, express receptors for many of these molecules.

**The brain clock is one part of the circadian system in the body**. In regulating rhythmicity throughout the body, the SCN is part of a circadian system that involves a body-wide, hierarchically organized network of oscillators. The output from the SCN synchronizes the activity of ►peripheral oscillators, found in most tissues. These peripheral oscillators express autonomous rhythms, independent of the brain clock, but the SCN is required to synchronize the phase of peripheral oscillators within and between tissues.

The molecular oscillations of clock cells occur in virtually all tissues including the eyes, liver, kidneys, skin and muscles in mammals [9]. These oscillators in peripheral tissues can not maintain rhythmicity for a prolonged time, and dampen rapidly if they do not receive time cues from the SCN or the environment. The master clock in the SCN controls the peripheral oscillators by means of neuronal and/or humoral signals. When the SCN is lesioned, the circadian gene expression dampens in the peripheral tissues, probably because peripheral oscillators are desynchronized from each other. Understanding the actions of factors downstream of the SCN is will be a key to understanding how coordinated circadian rhythmicity is achieved in the brain and the rest of the body. Disruption of normal circadian patterns occurs in diverse disease symptoms including metabolism, cancer, and sleep [10], and the development of therapeutic interventions to treat circadian-related disorders depends on understanding the basic biology of rhythmicity and clocks.

# Suprachiasmatic Nucleus Core

## Definition

One of two major anatomical and functional compartments of the suprachiasmatic nucleus (SCN). The core is more densely innervated by retina, visual thalamus, and brainstem than the other compartment , but contains fewer intrinsically rhythmic neurons or "clock" cells. Neurochemically, the core is typically demarcated by vasoactive intestinal polypeptide-containing neurons that densely innervate cells of the shell SCN. It is thought that the core SCN acts to integrate internal physiological and neural states with extrinsic environmental time cues and conveys these to the main oscillator in shell SCN. Reciprocally, circadian phase information from the shell SCN is relayed to the core SCN neurons via inhibitory synaptic transmission to ensure that core SCN neurons responses to extrinsic signals are appropriately phased.

►Suprachiasmatic Nucleus Shell

## Suprachiasmatic Nucleus Gating

### Definition

The notion of gating alludes to the function served by a "gate" in ordinary English usage. Thus, gating is the process in which a signal passes through when the gate is open, and fails to pass through when the gate is closed. The suprachiasmatic nucleus response to light is gated, in that a light pulse during the nocturnal animal's subjective night produces a change in gene expression in the nucleus along with a resetting of rhythmic behavior, while a light pulse during the animal's day produces no response. This is true even when the organism is housed in complete darkness, and the physical conditions at the time of exposure to light is identical at both times points.

►Clock Genes
►Suprachiasmatic Nucleus

## Suprachiasmatic Nucleus Shell

### Definition

One of two major anatomical and functional compartments of the suprachiasmatic nucleus (SCN). The shell is less densely innervated by retina, visual thalamus, and brainstem than the other compartment , but contains more intrinsically rhythmic neurons or "clock" cells. Neurochemically, the shell is typically demarcated by arginine vasopressin-containing and somatostatin-containing neurons. The precise distribution of these varies across the rostrocaudal axis of the SCN as well as between species. However, dense innervation of the shell SCN cells with fibers and terminals from neurons in core SCN is relatively invariant across most rodent species.

Currently, the shell is believed to function as the main oscillator of the SCN and regulates via inhibitory neurotransmission neural activity in the core SCN. Potential resetting information is in turn relayed to the shell SCN by core SCN neurons.

## Supramarginal Gyrus

### Definition

The supramarginal gyrus is the convolution of the inferior parietal lobule that arches around the terminal part of the ascending ramus of the lateral fissure. It is a part of the association cortex, which when damaged, can result in an agnosia, a failure to recognize. For example, in tactile agnosia there is a failure to recognize an object by tactile and kinesthetic sense (stereognosis) even though the sensory pathways and primary somatosensory cortex are intact.

## Supramodal

►Multimodal Integration

## Supraoptic Nucleus

### Synonyms

►Nucl. Supraopticus; ►Supra-optic nucleus

### Definition

Situated directly above the optic nerve, this nucleus together with the paraventricular nucleus forms the neuroendocrine system of the posterior lobe of the hypophysis. Efferents go to the neurohypophysis where they release into the blood ADH (vasopressin) and oxytocin. ADH (antidiuretic hormone) inhibits the permeability of renal epithelia to water. Oxytocin effects contraction of the uterus when giving birth and controls the release of milk during the lactation phase.

Dysfunction of this nuclear region induces the clinical manifestations of diabetes insipidus with severe polyuria (more than 20 l per day), since the lack of ADH results in a more or less unimpeded efflux of water from the renal epithelium.

## Sweat Gland Control

Toshio Ohhashi, Yoshiko Kawai
Department of Physiology, Shinshu University School of Medicine, Matsumoto, Japan

### Definition
Thermal sweating plays an important role in keeping the body temperature constant. It appears over the whole body surface. In contrast, mental or emotional sweating is usually produced by emotion, mental stress and sensory stimulation. The active sweating appears on the palms and soles.

### Characteristics
#### Quantitative Description
Human perspiration is classified into two types: insensible perspiration and active sweating. Insensible perspiration usually means the insensible loss of body weight. Water loss from the respiratory passages, the skin, and gaseous exchanges in the lungs contribute to the insensible loss of body weight. In the skin, the epidermis may be supplied with water originating from blood in the skin microcirculation and interstitial spaces so that water can evaporate from its dry surface. Thus, the evaporation of water from the skin seems to depend on several environmental factors such as ambient temperature and ambient humidity.

Heat, mental stimuli, muscular exercise and carbon dioxide are well known to induce active sweating in human beings. From the physiological point of view, such active sweating may be classified into two types: thermal and mental or emotional. Thermal sweating plays an important role in keeping the body temperature constant. It appears over the whole body surface. Emotion, mental stress and sensory stimulation are the other causal agents of active sweating. Mental or emotional sweating usually appears on the palms and soles. The physiological

features of mental sweating differ considerably from those of thermal sweating. Mental sweating has a shorter latent period for its onset. It immediately attains a certain rate of secretion that corresponds to the intensity of stimulation, remains as long as the stimulation lasts and subsides quickly after it ends.

Eccrine glands contribute to both types of sweating. The eccrine gland is tubular, the secretory part forming a closed coil. The duct begins in this coil and is partly embraced by it. It opens on the skin surface through a corkscrew-like channel that pierces the epidermis. The active sweat glands are present most densely on the sole, forehead and palm, somewhat less on the back of the hand, still less on the lumber region, and the lateral and extensor surfaces of the extremities, and least on the trunk and the flexor and medial surfaces of the extremities [1]. The secretory nerve fibers innervated in human sweat glands are sympathetic, which seem to be cholinergic in character as sweating is produced by pilocarpine and stopped by atropine [2]. Recently vasoactive intestinal peptide (VIP) coexisting in the cholinergic nerve fibers has been suggested as a candidate neurotransmitter that may control the blood circulation of the sweat glands [3]. The sudorific nervous system is also separated into parts for thermal and emotional sweating, each being controlled by its own regulatory centre in the brain that is associated with the sweat glands in its respective region of the skin.

Kuno (1956) [1] postulates that sweat glands of the general body surface are under the control of the center for thermal sweating which is a part of, or is closely associated with, the hypothalamic temperature regulation center. Whereas the center for mental sweating is located in the cerebral cortex and not only controls directly the sweat glands of the confined areas, such as palms and soles, but also affects sweating of the general body surface through exciting the center of thermal sweating. The presence of a cortical sweat-inhibitory center has also been suggested. Thus, sweat response to mental stimulation may appear body surface only when close to or above the threshold of thermal sweating. Even in a temperature environment, however, neural impulses for thermal sweating still reach the sweat glands and mental effects can be visualized on a focal area where local sweating has been provoked by a suforific agent [4]. Thus, the findings imply that the differences in nature between palmar and non-palmar sweating may possibly be relative ones, especially in the periphery, as suggested by Nakayama (1969) [5]. On the other hand, the other studies suggest that the palmar and non-palmar sweatings are under the control of essentially different central mechanisms as mentioned by Kuno (1956) [1]. It has been demonstrated that a single stimulus can cause inhibition of non-palmar sweating simultaneously with facilitation of palmar sweating [6]. Thus, various non-thermal stimuli appear to exert two ways of effects on non-palmar sweating, excitation and inhibition, while they equally bring about facilitation of palmar sweating. The stimuli that provoke emotional excitation or protopathic sensation are considered to produce facilitation of non-palmar sweating. Consequently, there appears to be a higher central mechanism that is closely associated with such mental functions and exerts an excitatory effect on the center for thermal sweating. The limbic cortex that is considered to be the structure closely related to emotion, protopathic sensation and also to autonomic functions may likely be involved in this mechanism. The sweat-suppressive response on the general body surface appears to be provoked by stimuli that act as mental stress involving thought and memory, and by efforts for physical tasks. It is assumed therefore that the activity of regions in the neocortex may be concerned with this sweat-suppressive mechanism, possibly by exerting an inhibitory effect on the center for thermal sweating. In contrast, palmar sweating responds to any non-thermal sweating [6].

Regarding central mechanisms of active palmar sweating responses, a very impressive paper by using the newly developed ratemeter [7] was reported that the average electroencephalographs (EEGs) contained slow wave fluctuations, which occurred 5 s prior to the onset of mental calculation-mediated palmar sweating response (MSR). The central source locations of the MSR-related potentials were analyzed by the EEG dipole tracing method. In conclusion, the mental stimulation activated the medial part of the amygdala 5 s prior to the MSR in one subject or the lateral part of the hippocampus 5 s prior to the MSR in another subject. Thus, it seems reliable to assume that the mental stimulation such as arithmetic calculations elicits electrical activity in the limbic system including the amygdala and hippocampus. This activation of limbic system was confirmed to increase the sympathetic sudomotor activity 3 s prior to the onset of MSR [7].

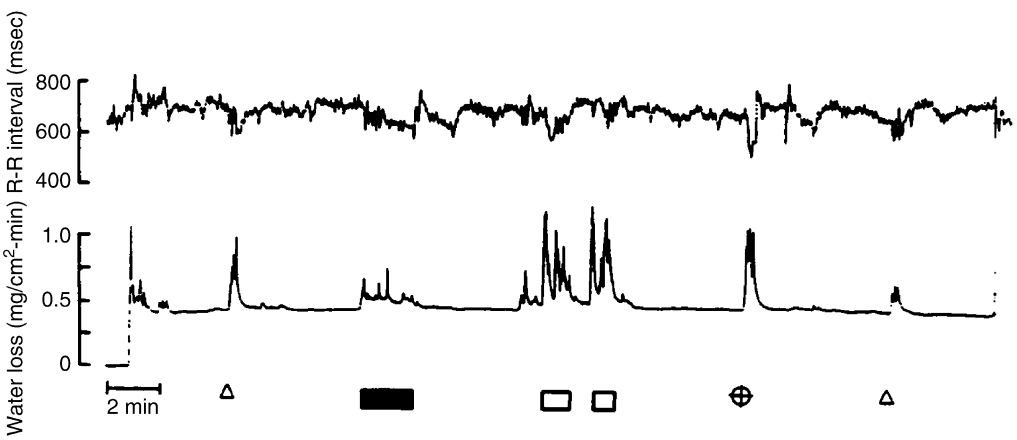
The amygdala has long been thought to be involved in emotional behavior, and its role in anxiety and conditioned fear has been highlighted [8]. Thus, emotional expression may be mediated by neural connections from the lateral to the central nucleus of the amygdala, which, through its projections to hypothalamus and brainstem areas, is thereby able to coordinate the behavioral, endocrine and autonomic responses that form an integrated emotional response [9]. In a clinical case, a complete reduction of active palmar sweating responses was reported in a young female patient with viral encephalitis that elicited inflammatory damage to the bilateral amygdala. The damage was confirmed through functional neuroimaging techniques such as functional magnetic resonance imaging (fMRI) (Asahina M (2001) Personal communication). On the other hand, no functional change in noradrenergic sympathetic nerve fibers

innervated in microcirculation of the palmar skin was, however, observed in the same patient.

### Measurements for Palmar Active Sweating

We measured the responses of active sweating by using the newly developed ratemeter (SKD-2000, Skinos, Nagoya, Japan) attached to the palmar side of the left thumb (attached area 1 $cm^2$). In brief, the ratemeter consists of three parts: (i) a specialized chamber equipped with a capacitance-typed humidity sensor and an electrical circuit to compensate changes in ambient temperature, (ii) a supply element for dehumidified air, and (iii) an electrical signal processing circuit. The ventilated chamber has two compartments. The first compartment is formed for mixing both the water perspired from skin and the dehumidified air supplied from the air supply unit. The second compartment is formed on top of the first one and connected with the first compartment through a communicating hole. The humidity sensor and a small thermistor are set on the roof of the second compartment. The dehumidified air passed through a tube filled with silica gel for drying was circulated through the two compartments (flow rate 300 ml/min). Thus, the ratemeter is handy and suitable to use clinically at the bed-side because of no usage of huge cylinder system. The absolute amount of palmar perspiration including active sweating responses is calculated electrically through three parameters: (i) relative humidity recorded with the capacitance-typed thin-film humidity sensor, (ii) temperature of air circulated through the ventilated chamber, and (iii) the saturated vapor pressure calculated theoretically with the air-temperature. These parameters are subjected to calculation in analogue of the absolute amount of the palmar perspiration, and then, after A/D conversion, to microcomputation. Ultimately, the absolute amount of the loss of water per a constant area of the palmar skin and a constant time is recorded on a chart recorder and stored into a personal computer. The data stored were analyzed with a commercial software program (Hyper Wave, Kissei Komtec, Matsumoto, Japan).

Figure 1 demonstrates representative recordings of mental and physical stimuli such as performance of mental arithmetic, talking with a friend, deep respiratory movement and hand grasping on palmar perspiration and on the R-R intervals determined by continuous recordings of a surface electrocardiogram. Palmar perspiration including active sweating was recorded by the home-made ratemeter with the capacitive humidity sensor. The insensible perspiration and active sweating were evaluated on the thumb of the left hand of a healthy man aged 48. Three cycles of deep inspiration with deep respiratory movement caused a marked decrease in the R-R interval followed by three spikes of the active sweating with a short time lag. Performance of mental arithmetic, such as repetitive subtraction of 7 from 1,000, also produced a significant increase in active sweating on the palm. The stimulation simultaneously produced a decrease in the R-R intervals with phasic oscillations, which returned to the control level with an overshoot after the stimulation. When a friend entered the examination room, a marked increase in the active sweating with many oscillations was observed without a significant change in the R-R intervals. When the subject started to talk with his friend a significant increase in the active sweating was found with a tentative decrease of the R-R intervals. Grasping of a 25 kg weight with the right hand for 20 s caused a cessation of respiratory movement followed by a marked increase in active sweating with oscillations and a sustained decrease in R-R intervals. These findings suggest that the new home-made ratemeter is



**Sweat Gland Control. Figure 1** Representative recordings of palmar active sweating. The effects of mental and physical stimuli such as deep respiratory movement (Δ), performance of mental arithmetic (■), talking with a friend (□), and hand grasping (⊕) on palmar perspiration recorded by the ratemeter (lower panel) and on changes in the R-R intervals (upper panel) in a healthy male subject aged 48. [10].

suitable for detecting phasic changes in active sweating on the palmar skin and that the changes in sweating do not always agree with oscillatory changes in the R-R intervals in humans. In addition, grasping of the hand is confirmed to be one of best stimuli to selectively activate eccrine sweat glands in human palms.

## Sweating Disorders

### Definition

The sweating disorders are classified into anhidrosis and hyperhidrosis. An anhidrosis disorder is defined as the inability of the body to produce and/or deliver sweat onto the skin surface. Hyperhidrosis over the whole body surface may be seen as a component of various diseases, e.g. night sweat, inphthisis. More marked hyperhidrosis appears restricted to certain parts of the body surface, and the following patterns seem to appear frequently, (i) Hyperhidrosis on the palms and soles, (ii) Hyperhidrosis of the axillae, (iii) Hyperhidrosis on the face, and (iv) other varied patterns of hyperhidrosis.

## Sympathetic Ganglia

►Autonomic Ganglia

## Sympathetic Ganglion Block

### Definition

Normally in the paravertebral chain, the discharge of only one preganglionic axon is responsible for transmission to each postganglionic cell, as the only effective inputs are suprathreshold with a very high safety factor, as at the neuromuscular junction. Acetylcholine (ACh) released from preganglionic terminals activates subsynaptic nicotinic receptor-channels (nAChRs). Ganglionic nAChRs in sympathetic ganglia differ from nicotinic receptors elsewhere, with the α3/β4 subunit predominating.

The effects of specific antagonists depend on subunit composition, but will also depend on the size of the underlying synaptic current.

## Sympathetic Nervous System

### Definition

Division of the autonomic nervous system that is concerned with catabolic activity by such actions as augmenting cardiac output, promoting blood supply to skeletal muscles and inhibiting the digestive system. This system arises from the thoracolumbar segments of the spinal cord in mammals. This system innervates the vasculature throughout the body as well as specific targets such as the dilator pupillae, the cardiac pacemaker, lymphoid tissues, the male internal reproductive organs, etc. It is excitatory to sphincters in the gastrointestinal tract and inhibitory to the rest of the gut.

►Ageing of Autonomic/Enteric Function
►Autonomic Ganglia
►Sympathetic Pathways

## Sympathetic Pathways

### Definition

The sympathetic pathways form one of the major subdivisions of the autonomic nervous system (there are also parasympathetic pathways and enteric pathways, and an afferent or sensory component). They extend from the thoraco-lumbar spinal cord to the peripheral organs, including the adrenal gland, heart and all the blood vessels of the body, and represent the autonomic thoraco-lumbar outflow.

The axons of the preganglionic neurons of the sympathetic pathways (preganglionic fibers) reach the corresponding ventral roots, they emerge as separate nerve (called white rami communicantes) which in turn reach the paravertebral sympathetic chain (or trunk).

The chain, a symmetrical structure on each side of the body, is made of ganglia and connecting nerve strands, and extends from the base of the skull to the sacral region; within the chain the preganglionic fibers spread out cranially and caudally and reach all ganglia. The

largest ganglia are the superior cervical ganglion, which provides sympathetic innervation to organs of the head, including cerebral blood vessels and skin, and the stellate ganglion, the main target of which is the heart.

Some preganglionic fibers reach the adrenal gland; others travel further away from the spinal cord, form the splanchnic nerves and reach sympathetic ganglia located in front of the abdominal aorta, the prevertebral ganglia. The preganglionic sympathetic neurons are cholinergic while the ganglion neurons and their postganglionic fibers are in the great majority adrenergic.

These secrete noradrenaline that stimulate the heart to beat faster and more strongly and blood vessels to constrict and to increase blood pressure (but to dilate pulmonary and coronary vessels).

## Sympathetically Maintained Pain (SMP)

### Definition

Sympathetically-Maintained Pain (SMP) is a pain that is maintained by sympathetic afferent innervation or by circulating catecholamines. It may occur in several conditions, such as Complex Regional Pain Syndromes (CRPS I and II), inflammatory pains, phantom pain, metabolic neuropathies, neuralgias. Blockade of the sympathetic outflow to the affected extremity by a local anesthetic injected close to the appropriate paravertebral ganglion/ganglia (stellate ganglion for forearm, lumbar ganglia L4/L5 for the hindlimb) significantly reduces the for ≥6 hours.

## Synapse

Masami Takahashi
Department of Biochemistry, Kitasato University School of Medicine, Sagamihara-shi, Kanagawa, Japan

### Synapse

There are more than 100 billion neurons and many more glial cells in the human brain. Neurons extend long

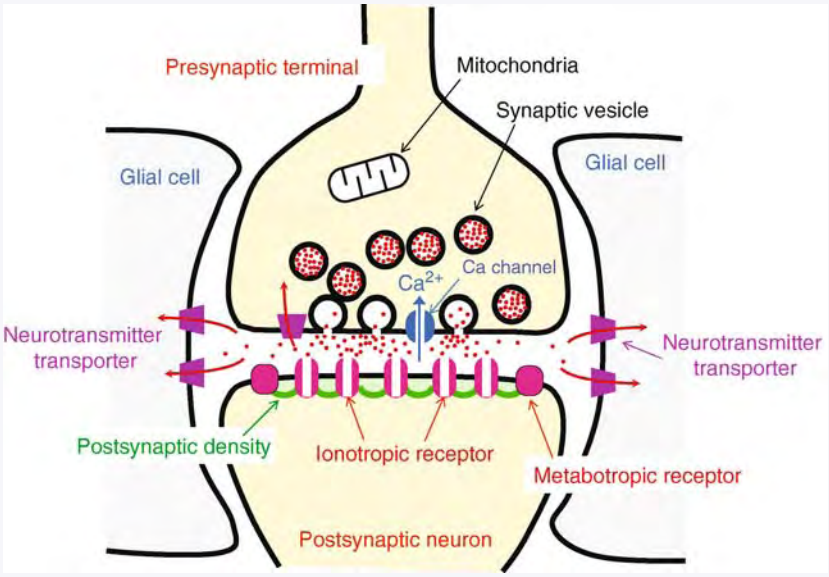
neurites and form neuronal networks whilst having functional contact through a specialized structure called the synapse, and various brain functions are conducted by this neuronal network. Neurons have two types of neurite, one is dendrite and another is axon. Neurons receive signals through many synapses formed on dendrite and cell soma. These signals are processed by summation or integration (►synaptic integration), and finally generate action potentials at the hillock of axon. Action potential propagates along the long axon and communicates a message to other neurons through synapses made along axons and/or axonal terminals.

There is a special gap between two neurons at the synapse, thus the electrical signal, the action potential, cannot propagate beyond the synapse. In many cases, synaptic transmission is mediated by a chemical substance called ►neurotransmitter. Since the electrical signal cannot spread over synapses without restriction, and signals propagate after conversion to chemical signals, it becomes possible for data processing to occur for the expression of higher brain functions. It may be possible to say that there are numerous numbers of biological switches, they are synapses, in the neuronal network, and multiple brain functions are achieved by controlling the neuronal network with these switches. More importantly, the properties of synapses are changing in the short-term as well as in the long-term in a neuronal activity-dependent manner, and sometimes, formation and disappearance of synapses occurs in some cases. This characteristic property of synapses called synaptic plasticity enables us to survive after a struggle for existence by acquiring and storing information from the environment, and using this information to properly modify the property of the neuronal network to make proper responses. More importantly, memories stored in the neuronal network are absolutely essential for human personality, and it has now become a very important problem to overcome memory disorders in an aging society.

## Basic Structure and Functions of Chemical Synapse

### Structure of Chemical Synapse

Usually, synaptic transmission is conducted unidirectionally from a presynaptic neuron to a postsynaptic neuron. As a consequence, a synaptic structure is composed of presynaptic and postsynaptic elements separated by a 20–50 nm space called the synaptic cleft (Fig. 1). In the presynaptic nerve terminal, many small clear vesicles called synaptic vesicles, which have a diameter of around 40–50 nm, are accumulated. There are also some large dense-cored synaptic vesicles that have a diameter of 70–200 nm. Presynaptic cytoplasm also contains mitochondria that are usually positioned some distance away from the synaptic vesicles. Mitochondria provide ATP, necessary for the accumulation of chemical neurotransmitters into the synaptic vesicles by active transport, and perhaps, are involved in the regulation of intracellular $Ca^{2+}$ homeostasis. In the presynaptic plasma membrane face to postsynaptic membrane, there is a specialized region called the active zone, where neurotransmitter release occurs (►active



**Synapse. Figure 1** Basic structure of chemical synapse. Neurotransmitters are stored in synaptic vesicles and are released from presynaptic nerve terminals by a $Ca^{2+}$ -dependent exocytosis. Neurotransmitters activate both ionotropic and metabotropic receptors in the postsynaptic plasmamembrane. Neurotransmitters in the synaptic cleft are recovered for reuse to neurons and glial cells by membrane neurotransmitter transporters.

zone). The synaptic cleft is filled with extracellular matrix, which contains a number of extracellular proteins thought to be important in synapse formation and stabilization, such as laminin and cell adhesion molecules (►synaptic adhesion molecule). Many ►ionotropic and (►G protein-coupled receptor (Metabotropic receptor)) metabotropic receptors are accumulated at the portion of postsynaptic membrane directly opposed to the presynaptic terminal. The region just beneath the receptor-laden postsynaptic membrane often has a characteristic protein-rich structure called postsynaptic density (PSD). In addition to the receptors, many proteins for signal transduction are functionally organized into a huge multi protein complex in PSD through bindings to several ►scaffold proteins. Some receptors also exist in the presynaptic plasma membrane, which are important for feedback regulation of neurotransmitter release. Except for the synaptic contact between the pre and post synaptic membrane, the synaptic structure is entirely covered with astroglial cells. Recent studies revealed that several neurotransmitter receptors are also expressed in glial membrane, and the glial cells may play active roles in the regulation of synaptic function.

## Mechanisms of Chemical Synaptic Transmission

By an invasion of action potential into presynaptic nerve terminals, a voltage-dependent Ca channel is activated and $Ca^{2+}$ ions are introduced into the nerve terminal, which triggers neurotransmitter release into the synaptic cleft by an ►exocytosis of synaptic vesicles involving docking and fusion of the synaptic vesicle membrane with the presynaptic plasma membrane. Neurotransmitters spread in the synaptic cleft by diffusion and bind to receptors in postsynaptic membranes for activation. ►Ionotropic receptors activation causes a rapid change in membrane potential and the probability of action potential generation. Activation of metabotropic receptors ►(G protein-coupled receptor (Metabotropic receptor)) slowly induces the generation of second messengers and/or a change in membrane potential through a modulation of ion channel function. All of these changes cause a change in responsibility to other synaptic input. After activation of these receptors, neurotransmitters in the synaptic cleft are removed by membrane transporters and/or neurotransmitter degradation enzymes in the neuronal and glial plasma membranes or the extracellular matrix to terminate synaptic transmission.

# Presynaptic Mechanisms

## Neurotransmitters

Two groups of substances are used as chemical ►neurotransmitters. One is a group of relatively small molecular size, which are some amino acids, monoamines, acetylcholine, and ATP, and another is a group of neuropeptides. Many nonpeptidic neurotransmitters are stored in small clear synaptic vesicles, whereas the peptidic neurotransmitters are stored in the large dense-core vesicles.

It is not so easy to classify a substance as a neurotransmitter, and even for glutamate, which is established as a major neurotransmitter in the vertebrate brain, it took a long time to be approved as a neurotransmitter. At least the following five conditions should be satisfied for classification as a neurotransmitter: (i) The substance is synthesized in neurons. (ii) The substance is stored in presynaptic terminals. (iii) The substance is released after stimulation of neurons. (iv) An equivalent effect is observed by the substance exogenously applied. (v) A removing mechanism exists.

### Properties of Neurotransmitters

#### *Dale's Low*

Usually, every neuron has only one kind of small neurotransmitter (Dale's low). Thus, neurons can be characterized by the neurotransmitter that they have. For example, neurons having glutamate, γ-aminobutyric acid (GABA), adrenalin (epinephrine), and acetylcholine as neurotransmitters are called glutamatergic, GABAergic, adrenergic, and cholinergic neurons, respectively. However, ATP coexists with acetylcholine and catecholamine in some synaptic vesicles and in secretory vesicles. There is also a report showing that GABA and glycine are used as neurotransmitters in one neuron. Thus, it is not clear how Dale's low is strictly approvable. It is obvious that most of the neurons have both small clear synaptic vesicles and large dense-cored vesicles, and thus, most of the neurons have at least two types of neurotransmitter, one is nonpeptidic and another is peptidic.

#### *Glutamate and Aspartate*

In vertebrate brain, glutamatergic neurons are distributed throughout the central nervous system and glutamate is used as a major excitatory neurotransmitter in the brain. Glutamate is synthesized from 2-oxoglutarate, an intermediate product of tricarboxylic acid cycle, by transaminase. Glutamate binds and activates both ionotropic receptors such as NMDA receptors and non-NMDA receptors, as well as various metabotropic glutamate receptors. Glutamate is recovered from synaptic cleft by membrane glutamate transporters present in neuronal and glial plasma membranes. Aspartate is also used as a neurotransmitter in some kinds of neurons.

#### *Gamma-Aminobutyric Acid (GABA) and Glycine*

GABA and glycine are used as major inhibitory neurotransmitters in the mammalian central nervous system (CNS). GABA is synthesized from glutamic acid by glutamic acid decarboxylase (GAD). GABA activates ionotropic $GABA_A$ receptor and metabotropic

$GABA_B$ receptor. Glycine is mainly used in the spinal cord. Only the ionotropic receptor is known as a glycine receptor.

### Monoamines

Non-amino acid compounds that have an amino residue such as catecholamine and indoleamine are generally known as monoamines. In the nervous system, dopamine, noradrenalin (norepinephrine), and adrenalin (epinephrine) are used as neurotransmitters, and are synthesized from tyrosine by tyrosine hydroxylase and following several other enzymes. As for indoleamine, serotonin is used as a neurotransmitter, which is synthesized from tryptophan by enzymes including tryptophan hydroxylase.

Most of the cell bodies of monoaminergic neurons are accumulated in the brain stem and their neurites are innervate to a broad range of brain regions. The axons of these neurons are highly branched and often have varicosities, and the monoamines are released from these structures diffusely around the releasing site. All of the receptors for monoamine neurotransmitters are metabotropic, and no ionotropic receptor is known so far. Thus, the major roles of monoamine neurotransmitters are not regular synaptic transmission conducted by glutamate and GABA, but are regulatory roles to alter the responsibility of postsynaptic neurons to other synaptic input.

Cell bodies of dopaminergic neurons are enriched in the substantia nigra and ventral tegmental areas in the mid brain, and participate in emotional control and complex motor activities. Seretonergic neurons are mainly located in the laphe nucleus in pons, and are related to mode and anxiety. Noradrenergic neurons are enriched in locus ceruleus in pons, and have responsibility for emotional excitement, judging for a decision, sleep and mood. In the mammalian peripheral nervous system noradrenalin is used as a neurotransmitter of postganglionic neurons.

### Acetylcholine

Acetylcholine is a neurotransmitter of motor neurons in vertebrate neuromuscular junctions and induces very fast contraction of skeletal muscles. In mammalian CSN, cholinergic neurons are enriched in basal ganglia, such as nucleus basalis Meynert and septal nucleus, and pons, and these cholinergic neurons send their neurites to a broad range of brain areas. In the peripheral nervous system, acetylcholine is a neurotransmitter of preganglionic neurons and postganglionic neurons of the parasympathetic nervous system. Acetylcholine is synthesized in nerve terminals from acetyl-coenzyme A and choline by choline acetyltransferase. Acetylcholine activates the nicotinic acetylcholine receptor, an ionotropic receptor, and muscarinic acetylcholine receptor, a metabotropic receptor. Acetylcholine is released in the synaptic cleft and is hydrolyzed by acetylcholinesterase located in cell membranes as well as in the extracellular matrix. The resulting choline is used for acetylcholine synthesis after reuptake by membrane choline transporter.

### ATP

ATP is a universal energy currency, but is also used as a neurotransmitter in neurons. ATP is shown to be stored in synaptic vesicles of *Torpedo* electric organs and secretory vesicles of adrenal chromaffin cells, however, the transport mechanism into synaptic vesicles is not yet known. ATP activates ionotropic P2X receptors and metabotropic P2Y receptors. ATP also activates metabotropic adenosine receptors after conversion to adenosine.

### Peptidic Neurotransmitters

More than 50 neuropeptides are found in the mammalian brain and many of these peptides are likely to be used as neurotransmitters. After being synthesized in endoplasmic reticulum in neuronal cell soma, neuropepitdes are packed in vesicles and transported along long axons to presynaptic terminals. All of the neuropeptide receptors are metabotropic, and induce slowly activated and prolonged responses in their target neurons. Neuropeptides released into the synaptic cleft is degraded by extracellular peptidases without reuse. Conventional neuronal excitation does not induce exocytosis of large dense-cored vesicles, and neuropeptides are released only after high frequency stimulation. Thus, neurons change a property of synaptic transmission in a frequency-dependent manner.

Neurotrophins, such as nerve growth factor and brain-derived neurotrophic factor, are polypeptides essential for the survival and maturation of neurons in the developing stage. These neurotrophins are also expressed in adult brain and participate in the regulation of neuronal and synaptic activities [1]. At least some portion of neurotrophins are released from neurons by exocytosis in an activity-dependent manner. Neurotrophins exert their action through the activation of Trk receptors, which are members of the receptor tyrosine kinase super family.

## Storage of Neurotransmitter into Synaptic Vesicles

Various ►vesicular neurotransmitter transporters for nonpeptidic neurotransmitters are expressed in small synaptic vesicles and specifically accumulate neurotransmitters in a type-dependent manner. $H^+$ -ATPase is also expressed in synaptic vesicle membranes, and creates a proton gradient across the membrane by the hydrolysis of ATP. All of the vesicular neurotransmitter transporters used this proton gradient to actively transport neurotransmitters into vesicles. Glutamate and glycine are very common amino acids, and thus the

expression of vesicular transporters of glutamate and glycine characterize glutamatergic and glycinergic neurons.

## Exocytotic Release of Neurotransmitters

### *Exocytosis*

Neurotransmitters stored in synaptic vesicles are released into the synaptic cleft by ►exocytosis, which involves the docking and fusion of the synaptic vesicle membrane with the presynaptic plasma membrane. The idea that neurotransmitters are released not by simple diffusion but by a package of elementary unit (►quantal transmission) was initially postulated by Kats and Miledi from a quantal analysis of synaptic transmission of frog neuromuscular junctions. This hypothesis is further supported by the discovery of synaptic vesicles using electron microscopy. Although it has been hypothesized that neurotransmitters are released by an exocytosis of synaptic vesicles, it is only recently that direct experimental evidence supporting this idea was obtained. Early experiments of freeze-fracture electron microscopic techniques revealed that small holes appeared along ►active zones and possible synaptic vesicle proteins appeared in the presynaptic membrane after electric stimulation of presynaptic fibers. The appearance of synaptic vesicle proteins in plasma membranes after stimulation was also observed in cultured neurons by immunocytochemistry, using antibodies that recognize epitopes located in the luminal site of synaptic vesicles. However, all of these results were obtained by using fixed preparations, and real-time process of exocytosis was not observed in these experiments.

The area of cell surface membrane is expected to be increased after the fusion of synaptic vesicle membrane, and cell surface area can be measured by observing membrane capacitance by an electrophysiological technique (►Capacitance measurement). Increment of cell surface area after stimulation is successfully observed in real time with good time resolution using adrenal chromaffin cells and Calyx of Held, a neuronal preparation having a giant presynaptic terminal. Furthermore, the process of exocytosis was visually observed in real-time in adrenal chromaffin cells and hair cells of the inner ear by using video-enhanced microscopy and total-reflection fluorescence microscopy (►evanescent field fluorescence microscopy). The exocytotic process was also monitored in various neuronal preparations, including neuromuscular junction, brain slice, and cultured neurons by using a fluorescence die, ►FM1-43, and pH-sensitive fluorescence proteins.

### *Merit of Exocytosis*

Neurotransmitters released into the synaptic cleft bind reversibly to their receptors in the postsynaptic membrane, and the binding speed is dependent on their concentration. Thus, to achieve rapid activation of the receptor, it is necessary to increase neurotransmitter concentration very rapidly after action potential propagation to the nerve terminals. Various problems will arise for cellular metabolisms and function if any particular substance accumulates in the cytoplasm at a very high concentration. By using vesicles that have a lipid bilayer membrane, it becomes possible to accumulate neurotransmitters of very high concentration without any effect on cellular metabolism. The extracellular concentration can be increased very rapidly by releasing all of the content in a single process. It is also possible to regulate the efficiency of neurotransmitter release by changing the distribution and location of synaptic vesicles in presynaptic terminals.

### *SNARE Proteins*

Both the plasma membrane and the synaptic vesicle membrane is composed of phospholipid bilayers, and it is necessary to fuse these two membranes for exocytosis. However, the hydrophilic head group of phospholipids are hydrated, and as two lipid membranes are difficult to bring close to each other within 2 nm, the assistance of proteins is necessary to promote membrane fusion. So called SNARE proteins play an essential role in bringing membranes close enough to induce membrane fusion (►Presynaptic proteins).

In neurons, three SNARE proteins, VAMP-2/synaptobrevin2 in synaptic vesicle membranes, and syntaxin and SNAP-25 in plasma membranes, are involved in the exocytosis of synaptic vesicles. It is now believed that membrane fusion is induced by a complex formation of these SNARE proteins. It is possible to regulate exocytosis and ►synaptic vesicle recycling by modifying the formation or dissociation of the SNARE complex. Many SNARE binding proteins are expressed in presynaptic terminals and are likely to be involved in the regulation of presynaptic functions.

### *$Ca^{2+}$-Sensitivity*

Exocytotic secretion is a cellular function generally observed in eukaryotic cells. There are two pathways for secretion, one is an unregulated constitutive pathway and another is a regulated pathway. Neurotransmitter release is one of the regulated pathways and is triggered by $Ca^{2+}$. Various ►calcium binding proteins that have different affinities to $Ca^{2+}$ are expressed in the brain, and it is widely accepted that the $Ca^{2+}$-binding protein which regulates neurotransmitter release is a synaptotagmin, a synaptic vesicle protein that has C2 domains. The affinity of $Ca^{2+}$ to C2 domain is not very high, but this property is quite important for the $Ca^{2+}$ binding of neurotransmitter release. Action potential invasion to presynaptic terminals activates a voltage-dependent Cachannel near the ►active zone, and $Ca^{2+}$ influx into

the terminal triggers exocytosis. Intracellular $Ca^{2+}$ will return to the basal level by $Ca^{2+}$ excretion mechanisms, but it takes some time to return to the basal level. If the $Ca^{2+}$ binding protein has a high $Ca^{2+}$ sensitivity, neurotransmitter release will continue by this residual $Ca^{2+}$. Since neurons send different kinds of messages along axons by changing the pattern and frequency of action potentials, the resolution of signal will decrease if the neurotransmitter release is not terminated quickly after invasion of action potential. Many $Ca^{2+}$ binding proteins of high $Ca^{2+}$ affinity are also expressed, but their functional roles are not well defined.

#### *Elementary Steps of Exocytosis*

Prior to $Ca^{2+}$-induced membrane fusion, there are several elementary steps necessary for exocytosis, which are tethering, docking and ►priming of synaptic vesicles. Several ►presynaptic proteins are involved in each step, and neurotransmitter release is regulated by modifying the functions and properties of these regulatory proteins.

There are several different synaptic vesicle pools that have different exocytotic properties, such as readily releasable pools, releasable pools, and storage pools. In *Drosophila* neuro-muscular junction, these pools are specially refined by an imaging analysis (►synaptic vesicle recycling). Some synaptic vesicles are anchored to the actin cytoskeleton in presynaptic terminals through a phosphoprotein, synapsin, and their association is regulated by protein kinases. Some synaptic vesicles are believed to be preset in the vicinity of a Ca channel in the active zone to achieve very fast release of neurotransmitter within 0.2 ms after activation of Ca channel. The efficiency of neurotransmitter release could be regulated by changing the size of vesicle pools and location of the vesicles.

#### *Synaptic Vesicle Recycling*

After their synthesis in the cell body, synaptic proteins are transported to the presynaptic nerve terminals along axons by an axonal flow, and it takes time to reach the nerve terminals. Normal synaptic transmission is conducted by an exocytosis of small synaptic vesicles. If all of these vesicles are used only once without recycling, the synaptic vesicle is easily depleted after high frequency stimulation. To avoid such a situation, synaptic vesicles are locally recycled and reused (►synaptic vesicle recycling). After exocytosis, synaptic vesicle proteins are selectively recovered from the plasma membrane by clathrin-mediated endocytosis. The synaptic vesicles are reformed either directly or after being incorporated into an endosome-like structure. In some cases, neurotransmitters are released from synaptic vesicles by a kiss and run mechanism without full fusion. Neurotransmitters are released through a fusion pore, which is formed transiently by the docked vesicles and the plasma membrane. After detaching, the neurotransmitter is refilled and reused for the next stimulation.

### Postsynaptic Mechanisms

Neurotransmitters bind to receptors in the postsynaptic membrane. Two types of receptors, the ►ionotropic receptor and the metabotropic receptor (►G protein-coupled receptor), are used for synaptic transmission and they induce postsynaptic responses in different mechanisms. Many different subtypes of receptors are usually expressed in the brain, and thus each neurotransmitter is able to induce different kinds of responses in different neurons and brain regions.

### Ionotropic Receptors

#### *Structure of Ionotropic Receptors*

►Ionotropic receptors are ligand-gated ion channels, and their opening and closing is regulated by neurotransmitter binding. Ionotropic receptors are composed of several subunits, and an ion channel pore is formed in the center of the complex. The structure and numbers of subunits are varied among different receptors. Nicotinic acetylcholine receptor, $GABA_A$ receptor, glycine receptor and serotonin 5-$HT_3$ receptor have five subunits, and each subunit has four transmembrane segments with extracellular orientation of both amino- and carboxy-terminals. Glutamate receptors are composed of four subunits, and each subunit has two fully transmembrane segments and one loop structure arriving ion channel pore. The amino- and carboxy-terminal of each subunit are exposed to extracellular and cytoplasmic face, respectively. Glutamate receptors are further classified into NMDA receptor and nonNMDA receptor (AMPA-type and kainate-type) according to their pharmacological properties. The ATP receptor is composed of three subunits that have two transmembrane segments. Both amino- and carboxy-terminals are located in the cytoplasm.

#### *Roles of Various Ionotropic Receptors*

Ionotropic receptors can be classified into two types depending on the difference in ion permeabilities. Excitatory receptors permeate monovalent cations, such as $Na^+$ and $K^+$, and the activation of the excitatory receptor induced membrane depolarization called excitatory ►postsynaptic potential (epsp), which increases the probability to generate action potential in postsynaptic neurons. Some excitatory receptors, including NMDA receptors, also permeate $Ca^{2+}$ that plays important roles for regulation of synaptic function and for synaptic plasticity. Glutamate, serotonin, acetylcholine, and ATP are neurotransmitters acting on excitatory receptors.

In contrast, inhibitory receptors have permeability to anions, typically chloride in many cells. Hyperpolarization of membrane potential called inhibitory

►postsynaptic potential (ipsp) is generated by the activation, which reduces the probability of action potential generation in postsynaptic neurons. The neurotransmitters of these receptors are GABA and glycine. It is noteworthy that GABA and glycine receptors do not always behave as inhibitory receptors. In immature neurons, the intracellular $Cl^-$ concentration is higher than that in matured neurons, and thus activation of $GABA_A$ and glycine receptors induce an efflux of $Cl^-$, and depolarize membrane potential sometimes leading to action potentials.

### *Signal Processing by Ionotropic Receptors*

In the neuromuscular junction, an action potential invaded in the endplate generates an action potential in skeletal muscles without failure, to assure rapid and smooth contraction of the skeletal muscle. In a marked contrast, the size of epsp in most of the central synapses is much smaller than that generate action potential, and single synaptic input will never generate action potentials. Every neuron has multiple innervations and an action potential is generated after the summation of individual epsps. There are two types of summation, special summation and temporal summation. Spatial summation is a way of achieving an action potential in a neuron which involves input from multiple cells. Because the potential produced by a brief synaptic current falls off relatively slowly, it is possible to get summation of the effects by repeated stimulation of a single ending if the frequency of firing of the presynaptic fiber is high enough. This type of summation is called temporal summation. Neurons receive both excitatory and inhibitory input, and a summation of epsps and ipsps, which is called integration (►synaptic integration), determines the probability of action potential firing.

## Metabotropic Receptor

### *Roles of Metabotropic Receptors*

Synaptic transmission mediated by ionotropic receptors induces a rapid change in membrane potential of postsynaptic neurons and is called an ordinary transmission. On the other hand, synaptic transmission mediated by metabotropic receptors (►G protein-coupled receptor (metabotropic receptor) is characterized as a slow and prolonged response to alter the responsibility to the following synaptic input, and is called a neuromodulatory transmission. Sometimes neurotransmitters for metabotropic receptors are called neuromodulators. Membrane potentials may change after activation of a metabotropic receptor, however, the change is small and slow compared to that caused by an ionotropic receptor.

The importance of neuromodulatory transmission is a long-lasting effect raging from several hundred milli seconds to several hours. These sustained effects are essential for various long-lasting brain functions such as learning, memory, and adaptation. Gene expression may be changed after activation of a metabotropic receptor, which induces very stable and sustained changes in neuronal properties.

Many more kinds of metabotropic receptors are expressed in brain compared to ionotropic receptors. Glycine is an exceptional neurotransmitter having no metabotropic receptor. All of the receptors for monoamines and neuropeptides are metabotropic, and only one type is ionotropic among six serotonin receptors.

### *Structure of Metabotropic Receptors*

Metabotropic receptors are members of the ►G protein-coupled receptors (metabotropic receptors) (GPCR) and have seven transmembrane segments with an extracellular amino-terminal domain and an intracellular carboxy-terminal domain. The ligand binding site is varied among different types of receptors. Glutamate binds to the amino-terminal domain and catecholamine binds to a site in the transmembrane domain. Metabotropic receptors bind to tertrameric G proteins through the cytoplasmic region. The functional role of the metabotropic receptor is to activate G proteins. Tetrameric G protein is composed of three subunits, α, β, and γ, and 20, 5, and 7 different kinds of isoforms are expressed, respectively. The cellular response is varied depending on which type of G protein is coupled to the receptor. Activation of the receptors coupled to the Gs subfamily elevates intracellular cAMP concentration by activating adenylate cyclase, whereas that coupled to the Gi/o subfamily suppresses cAMP production. The receptors coupled to the Gq subfamily activate phospholipase Cβ and induce production of second messengers, diacylglycerol and $IP_3$. These second messengers can activate various protein kinases, and in turn phosphorylate various synaptic proteins to modulate synaptic functions. Gene expression is also induced by the receptor activation. Activated α and βγ subunits of G protein also bind to ion channels, and sometimes generate epsp and ipsp in postsynaptic neurons.

## Receptor Ion Channel Complex Formation

►Scaffold proteins are proteins which have various protein binding domains in their structure, such as PDZ domain, SH3 domain GK domain. Many kinds of proteins including receptors, ion channels, and proteins for signal transduction, bind to the scaffold protein through specific binding motifs. Several scaffold proteins can be cross-linked with adaptor proteins. Thus, a fudge multiprotein complex is formed in the synaptic site. Presynaptic and postsynaptic protein complexes are cross-linked through cell ►adhesion proteins bound to the scaffold proteins, and these multi protein complexes play very important roles to properly arrange the many synaptic proteins at the synaptic site.

The binding of membrane proteins to the scaffold proteins could be regulated by protein phosphorylation, and these regulations may be important for the regulation of the synaptic function. Scaffold proteins are also important for the axonal transport of neurotransmitter receptors to the synaptic site. Cargo vesicles having a glutamate receptor are linked to microtubule-dependent motor proteins via scaffold protein complexes.

## Removal of Neurotransmitter from Synaptic Site

Neurotransmitters must be removed quickly after activation of the neurotransmitter receptor. A prolonged exposure of neurotransmitters to their receptors results in various unfavorable phenomenon. Receptors will be desensitized, and the resolution of signals made by repetitive action potentials will be weakened. In addition to simple diffusion, membrane transporter and degradation enzymes mediate the removal of neurotransmitters from the synaptic cleft. The importance of the clearing system could dreadfully be visualized by a terrible criminal event by Japanese terrorists, who spread salin, an inhibitor of acetylcholine degradation enzyme, in the subway station and killed many people in Japan. It is also noteworthy, that huge numbers of people take a blocker of serotonin transporter to reduce anxiety.

### Neurotransmitter Transporter

Most small neurotransmitters are recovered to presynaptic nerve terminals by membrane transporters (►neurotransmitter transporter) and further accumulated into synaptic vesicles by ►vesicular neurotransmitter transporters for reuse. So far, transporters specific for glutamate, GABA, glycine, dopamine, noradrenalin, serotonin, and choline have been identified. Membrane transporters actively transport neurotransmitters by using $Na^+$ gradients across plasma membranes, which are generated by $Na^+/K^+$-ATPase using hydrolyzing energy of ATP. Membrane transporters are also present in glial membranes. Glutamate incorporated into glial cells is converted into glutamine and sent to the neuron. Glutamine is again converted into glutamate in neurons and used again as a neurotransmitter.

### Degradation Enzymes

Acetylcholine is hydrolyzed by acetylcholinesterase into choline and acetic acid. Acetylcholineesterase is localized in the plasma membranes of the CNS, but it also exists in the extracellular matrix in the neuromuscular junction. After hydrolysis, the resulting choline is reuptaken by membrane choline transporters and is used for acetylcholine synthesis. A part of the monoamines released into the synaptic cleft is metabolized by catechol-*O*-methyl transferase (COMT) and monoamine oxidase (MAO). Peptidic neurotransmitters are degraded by peptidase.

## Retrograde Messenger

Most neurotransmitters send information from presynaptic neurons to postsynaptic neurons, however, some information transmits in a retrograde manner. All ►retrograde messengers are labile and membrane permeable, and thus not stored in vesicles. They are generated by synaptic activation and act on presynaptic cells instantly by diffusion.

Nitric oxide (NO) is a messenger molecule of gas generated from arginine by nitric-oxide synthase (NOS). The life time of NO is only a few seconds. $Ca^{2+}$ influx into postsynaptic cells via NMDA receptor and Ca channels activate $Ca^{2+}$ -dependent NOS [2]. NO is diffused through plasma membranes and activates guanylate cyclase in the presynaptic terminal, resulting in a generation of cGMP, which in turn activates cGMP-dependent protein kinase. The presynaptic function could be regulated through the phosphorylation of some presynaptic proteins.

Cannabinoid is a chemical giving euphoria and found in hashish. It induces a neuronal action through the binding to cannabinoid receptors. Endogenous cannabinoid is generated in postsynaptic cells after synaptic activation, and the generated cannabinoid modulates presynaptic function through binding to a presynaptic cannabinoid receptor.

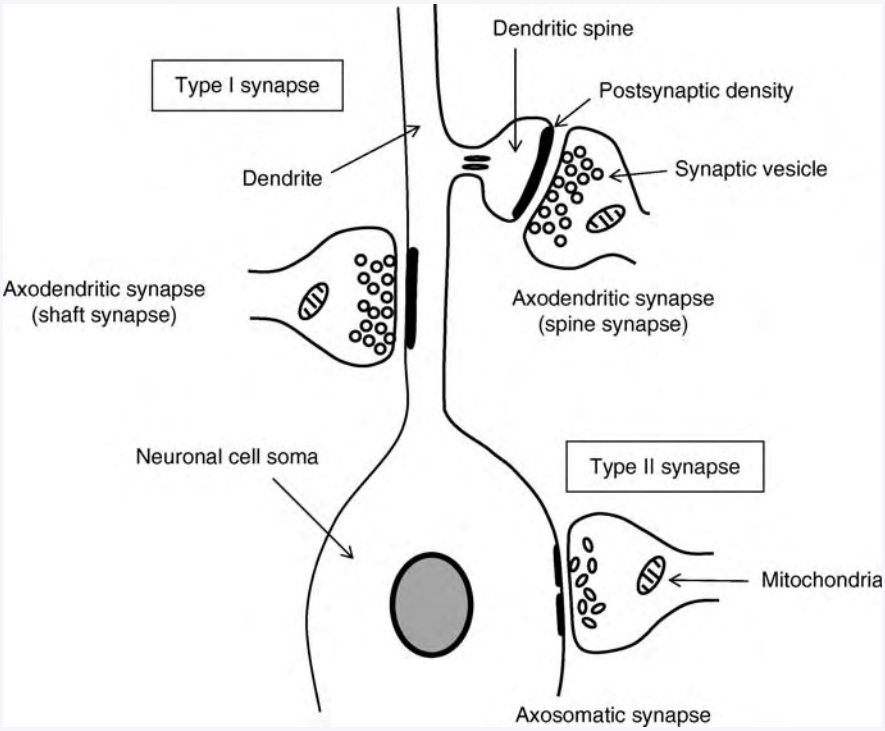
## Variation of Synapse

Basic mechanisms of synaptic transmission are common among many chemical synapses, however, there are many variations in the structure of chemical synapses. In addition, there are also electrical synapses in the brain (Fig. 2).

### Morphological Variations

There are two common morphological types of synaptic connections in the brain, Gray type I and type II. Type I synapses are often glutamatergic and therefore excitatory, whereas type II synapses are often GABAergic and therefore inhibitory. In type I synapses the synaptic cleft is slightly widened to approximately 30 nm, and the active zone is larger. The synaptic vesicles have a characteristic round shape in electronmicroscopy. The PSD is very thick, and amorphous dense basement-membrane material appears in the synaptic cleft. In type II synapses, the synaptic cleft is 20 nm across and the active zone is smaller. PSD is less obvious and there is little or no basement membrane in the synaptic cleft. The synaptic vesicles tend to be oval or flattened.

Ribbon synapses are found in certain primary sensory cells, such as photoreceptors and mechanoreceptors. These synapses are identified by the presence of proteinaceous ribbon within their presynaptic terminals. Spine synapses are a synapses formed on the dendritic spine. The spine is connected to the dendritic shaft by a thin neck which restricts the rise in



**Synapse. Figure 2** Variations of chemical synapses in the central nervous system. Chemical synapses are classified by their mode of innervations and by the structure of postsynaptic density.

$Ca^{2+}$ concentration in the spine. Thus, each spine represents a distinct biochemical component. The morphology and properties of spine synapses change dramatically in a synaptic activity-dependent manner, which is quite important for synaptic plasticity and possibly in memory storage.

## Variation in Mode of Innervation

Neurons of the CNS have several thousand synaptic inputs on average, and synapses are formed in various regions of the neuron. The synapse made on dendrite and cell soma is called axodendritic synapse and axosomatic synapse, respectively. Many axodendritic synapses are excitatory, and axosomatic synapses are inhibitory. Dendrodendritic synapses are synapses formed between dendrites, and are characteristic for their bidirectional transmission. An axoaxonal synapse is a synapse formed at presynaptic terminals, and is responsible for presynaptic regulation.

## Synapses in Peripheral Tissues

Synapses can also be found in peripheral tissues. The basic structure is the same as those of central synapses, however, there are marked variations in their structure to optimize their functional roles [3].

### *Neuromuscular Junction*

The neuromuscular junction is a synapse formed between motor neurons and skeletal muscle cells. This synapse is specialized to provide transient, fail-safe excitation of the postsynaptic muscle cells, ensuring muscle contraction whenever the motor neuron is active. The speed of transmission is quite fast to induce rapid contraction of skeletal muscle. To achieve these characteristic properties, the neuromuscular synapse is optimized for releasing large quantities of acetylcholine very rapidly. The synaptic structure shows a characteristic structure called end plate. Thus, the epsp (►postsynaptic potential) of the neuromuscular junction is often referred to as endplate potential. A neuromuscular synapse consists of a highly branched presynaptic termination of the motor neuron that innervates long, cylindrical muscle cells. A single synapse has several hundred active zones, where a large cluster of synaptic vesicles is accumulated. The postsynaptic component apposed to the presynaptic active zone is characterized by a postjunctional fold, a tremendous number of nicotinic acetylcholine receptors are clustered at the peak of this fold. This arrangement allows the receptor to detect the release of acetylcholine quickly and efficiently. Acetylcholinesterase is found in the extracellular matrix of the synaptic cleft and postjunctional fold.

### *Autonomic Neuronal Synapse*

Autonomic neurons regulate smooth muscle contraction and secretion from various endocrine and exocrine cells. The synapses of autonomic neurons act over a

slower time scale, and thus the synaptic structure is quite different from that of fast-acting synapses. Presynaptic terminals at these synapses are varicose in structure and filled with dense-core vesicles containing various neurotransmitters, including acetylcholine, catecholamines, ATP, and peptides. These vesicles are dispersed throughout the presynaptic cytoplasm, and there are no indications of the active zones. The synaptic cleft is larger than the one of other types of synapses and can be as great as 2 μm. The postsynaptic cell also lacks a postsynaptic density and receptor clustering.

### Electrical Synapse

Although they are a distinct minority, electrical synapses are found in all nervous systems [4]. The extracellular space between pre- and postsynaptic neurons at an electrical synapse is 3–3.5 nm, which is much smaller than the synaptic cleft of general chemical synapses (about 20–50 nm). The narrow space between these neurons is bridged by a gap junction channel, and the intracellular current flow is through the gap junction. In the mammalian nervous system, most electrical synapses are bidirectional and the current can flow in either direction across the gap junction. These channels are formed by two hemichannels, one in the presynaptic neuron and the other in the postsynaptic neuron. Each hemichannel is called connexon, which is composed of six subunits of an identical protein called connexin, arranged in a hexagonal pattern with a 2 nm diameter central hole. At electrical synapses, the current generated by voltage-gated channels at the presynaptic neuron flows directly into the postsynaptic neuron, and thus, the transmission at such a synapse is very rapid (<0.1 msec) compared to a chemical synapse. Electrical synapses are present where the activity of neighboring neurons are to be highly synchronized. On the other hand, plastic regulation of transmission is difficult in electrical synapses.

## Preparation for the Study of Synaptic Functions

Since a synapse is a very small fine structure containing a large number of proteins, it is not easy to study the synapse functions in the brain. Many unique preparations have been used for the study of synaptic functions.

### *Giant Synapse Preparation*

In electrophysiological experiments, the synaptic current is recorded only from postsynaptic neurons, since the size of the presynaptic nerve terminal is too small to insert a microelectrode. To measure the membrane potential and capacitance, preparations having large presynaptic terminals, such as neuromuscular junctions and giant synapse of squid have been used. In the mammalian central nervous system, the Calyx of Held, a particularly large synapse in the auditory central nervous system, is used.

### *Slice Preparation*

It is possible to keep brain thin slice (200–500 μm thickness) in artificial cerebro-spinal fluid saturated with 95% $O_2$/5% $CO_2$, pH 7.4 for several hours to several days, and the electric response can be monitored without disturbance of aspiratory and cardiac vibrations. Since neuronal networks are retained in the ►slice preparation, it is possible to study the properties of the neuronal network. It is also easy to change extracellular conditions, and many imaging techniques using various dyes sensitive to membrane potential, $Ca^{2+}$, and pH, as well as FM dye such as ►FM1-43 are applicable.

It is also possible to keep brain slices on membranes for longer periods in a cell culture media, preserving the neural network in these preparations. However, most of the synaptic contacts may be lost after preparation and are regenerated after cultivation. Proliferation of nonneuronal cells is also remarkable in this preparation, and the structural differences between the culture and the brain become larger with time.

### Dissociation Culture of Neurons

Enzymatically dissociated neurons from embryonic and neonatal rodent brain are able to be kept in culture for long periods. Synaptic formation and neuronal maturation advances in culture. Many experimental techniques including electrophysiology, imaging, and biochemical measurement are easily applicable. Activity of the postsynaptic cell body could be monitored by electrophysiological methods as well as imaging techniques using voltage-sensitive dyes and $Ca^{2+}$-sensitive dyes. Presynaptic activity is monitored using FM dye (►FM1-43). Some caution should be kept in mind, that is, neuronal maturation may be advanced in culture, however, it is not certain how the maturation is completed. Except for cerebellar granule cells in culture, where >90% cells are glutamatergic neurons, it is also a problem that many kinds of neurons coexist in culture. Since many neurons extend many neurites and form numerous synapses randomly, it is difficult to get a record from pre- and postsynaptic neurons at the same time. To overcome this difficulty, an elegant method of culture called ►autapse has been developed. In this method, a single neuron is cultured on a small glial island of 200–700 μm diameter. The neuron makes synaptic contact on its cell body. It is possible to stimulate and record postsynaptic responses with the same single electrode. It is also possible to inject various substances and antibodies into the cell body to see the effect on both pre- and postsynaptic functions, since these substances easily diffuse to presynaptic terminals.

### Adrenal Chromaffin Cell

Since the presynaptic terminal is a very small structure, it is difficult to quantically measure the process of neurotransmitter release in real time. Adrenal medullary chromaffin cells are derived from the same precursor cells as those of autonomic neurons and share many common properties with neurons. In fact, chromaffin cells from neonatal rat adrenal are still able to differentiate into neurons in the presence of nerve growth factor. It is easy to prepare a fairly homogeneous cell preparation, enough even for biochemical studies from bovine adrenal medulla. Chromaffin cells have about 30,000 dense-core vesicles containing either noradrenalin or adrenalin of around 280 nm in diameter, and release these catecholamines by a $Ca^{2+}$ -dependent exocytosis. It is easy to keep in culture for a long period, enough to do multiple types of experiment including a transient gene expression using virus vector. The exocytotic process of the dense-cored vesicles is monitored by a membrane ►capacitance measurement, electrophysiological measurement with carbon fiber electrode, video-enhanced microscopy, and total reflection fluorescence microscopy (►evanescent field fluorescence microscopy). For biochemical analysis, membrane permeabilized model cells are used successfully. Clonal PC12 cells derived from rat adrenal tumor have also been used extensively.

### Synaptosome

When brain is homogenized in an isotonic sucrose solution, nerve terminals are pinched-off and resealed to a round structure called a ►synaptosome of 0.5–1 μm in diameter. Synaptosomes are enriched in postmitochondrial P2 fraction of brain homogenate and further purified by a density gradient ultracentrifugation. Synaptosomes contain one to several mitochondria and regenerate membrane potential by the action of $Na^{+}/K^{+}$-ATPase when they are incubated in the presence of glucose and oxygen. They can be kept alive for several hours. PSD structures are tightly attached to most synaptosomes. Synaptosomes have been used for the biochemical assay of neurotransmitter synthesis, release and reuptake. By modifying the preparation, synaptoneurosomes and synaptodendrosomes in which both presynaptic terminal and dendritic spine are resealed, have been obtained.

A recent study revealed that glial cells release glutamate and various peptides by a $Ca^{2+}$-dependent exocytotic mechanism. A resealed cellular fragment of glial cells called gliosome is prepared from brain homogenate by a Percoll gradient ultracentrifugation. Gliosomes are different from synaptosomes in density and ultrastructural morphology. Glutamate is released from gliosomes in a $Ca^{2+}$-dependent manner.

### Mutant Mouse

Many knock-out mice of synaptic proteins have been generated and successfully used for the study of these proteins in synaptic function.

## Synapse Formation and Plasticity in Development

### Synaptogenesis

During development, neurons extend neurites and make synaptic contacts after finding a proper target neuron. The tip of a growing neurite represents a characteristic structure called a growth cone, which is completely different from the presynaptic terminal in structure. A growth cone is enriched in actin and is a very active structure with extending and retracting filopodia to find a proper target cell. The extension of a neurite is controlled by various guidance molecules and growth factors.

The process of ►synaptogenesis was extensively studied in the neuromuscular junction [5]. On attaching to a target cell, the growth cone stops moving and shows morphological changes. The nerve terminal is bloated and synaptic vesicles appear inside. CAZ (cytomatrix assembled at active zone) becomes visible with maturation to form an active zone. In response to the presynaptic differentiation, postsynaptic differentiation also proceeds. Postsynaptic density and synaptic folding are formed beneath the active zone. Nicotinic acetylcholine receptor clusters are formed on the edge of synaptic folding, and acetylcholine esterase is enriched in the extracellular matrix in the synaptic folding. Several soluble factors including agrin play crucial roles in this coordinated differentiation. Morphological changes in synaptic structure during maturation are also observed in neurons of CSN.

### Synaptic Plasticity in Development

A basic design of the neuronal network is genetically determined, however, activity-dependent fine tuning is necessary to complete the formation of the neural network. Most of the neurite extensions occur in an activity-independent manner, plasticity of the neuronal network is obvious in the stage of synaptogenesis. Synaptogenesis starts in the brain from late embryonic to early postnatal stages. In many brain regions, extra synapses are transiently formed during the early postnatal period, and are then decreased to adult level in an activity-dependent manner. In other words, multiple innervation occur first, followed by a selective ►synaptic elimination of extra synapses, with synaptic activity playing a crucial role in the selection.

Synaptic plasticity in development has been extensively studied in sensory systems. Retinal ganglion neurons send a projection to the visual cortex in the brain via monosynaptic transmission. In the adult brain, the projections from the left eye are spatially separated

from those from the right eye. In contrast, most neurons of the visual cortex have dual innervations from both the right and left eye at birth. In a particular period called the critical period during the early postnatal period, selective elimination of extra synapses occur to shift to a unitary innervation. Multiple innervated neurons compete with each other to occupy the synaptic site, and neuronal activity during the critical period has a definite effect on the competition. If one eye is closed during the critical period, synaptic connection from the closed eye fails in the competition and the modified innervation map is fixed through the whole of life. A similar phenomenon is also observed in the sensory cortex for face fungus in rat, and in the phenomena called ►imprinting in birds. Activity-dependent synaptic elimination (►synapse formation and elimination: competition and the role of activity) is also observed in climbing fiber synapse in cerebellum, and in neuromuscular junctions.

The critical period is different among different species. In the human cerebral cortex, the number of synapses increases markedly after birth and attains a maximal level around four months after birth. It declines thereafter to adult level in early childhood. The visual projection area is smaller and the auditory projection area is larger in a patient with a congenital visual defect than those of a normal person. If one eye is temporally closed with an eye bandage to cure cockeye during the critical period, the patient will have a visual defect throughout the whole of his life. On the other hand, if a person starts practicing the violin in the critical period, the person will have a more exhaustive movement of fingers since his motor area for fingers increased throughout life.

### Synaptogenesis in Adult Brain

If new synaptic formation is an event in development, we can say that the brain continues to develop throughout the whole of life. Many synapses are forming, loosing and change their property to change the function of the neuronal network, and these characteristic features are an origin of many remarkable functions, including, learning, memory, thinking and creativity, those that are not determined by genetic information.

Neurogenesis still occurs in some regions of the adult brain including the dentate gyrous of hippocampal formation [6]. Newly formed neurites of granular cells forms many new synapses in the dendrite of CA3 pyramidal cells. There is good evidence to show that synaptogenesis also occurs in the adult bran. The number of dendrites, branching point of dendrites, and synapses increase in a rat brain cortex which is kept in a complex environment. A partial rearrangement of sensory cortex has been observed in some adult animals after inhibiting sensory neurons from the finger in prosimian and bat.

## Synaptic Plasticity

### Importance of Synaptic Plasticity

Signal processing by inonotropic receptor-mediated summation and integration (►synaptic integration) determine the output without changing the individual synaptic response. If a neuronal network only has such a system for signal processing, it is not possible to store information acquired by external inputs, or to use this information to change the property and function of the neuronal network in response to environmental change in the battle for survival.

A characteristic feature of synapses is to change the size of epsp dynamically in response to previous activity. In other words, the strength of synaptic transmission is continuously changing in an activity-dependent manner whilst retaining a history of prior activity. What kind of information is stored in the neuronal network as a memory is not determined by genetic information. Synaptic plasticity is believed to be a molecular and cellular basis of learning and memory. Identity is one of the most important properties for human beings, and is established on memories. Memorial defect by aging is now becoming a serious problem for the aged society, since the identity of the aged person disappears with the loss of their memory. It is also necessary to rearrange neuronal networks to change the response for adaptation to environmental change. These properties are also dependent on the characteristic property of the neuronal network. There are multiple mechanisms of variety of time scale in synaptic plasticity. In some cases, reconstruction of neuronal networks by loosing or forming synaptic contact occurs.

### Plasticity of Various Time Constant

#### *Facilitation*

At most synapses, repetitive high-frequency stimulation (called a tetanus) is initially dominated by a growth in successive epsp amplitude, called synaptic facilitation. This process builds to a steady state within about 1 s and decays equally rapidly when stimulation stops. When a pair of stimuli is given to some synapses with several ten second intervals, the amplitude of the second response either increases, called paired-pulse facilitation, or decreases, called paired-pulse depression, compared to the first response. These properties are often used as a parameter of presynaptic activity.

#### *Potentiation*

Some synapses display a growth in epsp amplitude that lasts minutes and is called potentiation. The potentiation that appears after moderate (50–100 per sec) tetanic

stimulation is called posttetanic potentiation (PPT), which is observed in many synapses including the neuromuscular junction.

### Long-Term Potentiation

In some synapses, a brief high-frequency titanic stimulation induces a long-lasting increase in the amplitude of epsp, called ►long-term potentiation (LTP). Whereas PTP decays within a few minutes, LTP decays over the course of several hours or, under certain conditions, up to a month or more. Low-frequency stimulation sometimes results in long-lasting depression of epsp, called long-term depression (LTD). It is also possible to cancel LTP and LTD by applying proper stimulation after a while, and these phenomenon are called depotentiation and dedepression, respectively. The expression and maintenance of LTP and LTD are not derived from a single mechanism, but are generated by multiple mechanisms, from short-time mechanisms without new gene expression to long-term mechanisms involving gene expression and protein synthesis.

## Typical Studies of Synaptic Plasticity

Synaptic plasticity is quite an important phenomenon in brain functions, and extensive studies have been successfully conducted in invertebrate and vertebrate nervous system.

### Aplysia Neuron

*Aplysia* is a marine mollusk and has a relatively simple nervous system. Eric Kandel and his colleagues found that *Aplysia* showed activities of primitive learning and memory, and extensively studied the mechanisms in cellular and molecular levels [7].

Some neurons have very large cell bodies and are easy to identify in ganglion. Major neurons are numbered and characterized. The identified neurons reconstruct a neuronal circuit in culture and show synaptic plasticity that is observed in the neuronal network of living animals. Thus, it is easy to study synaptic function for a long period (several hours to several days) with multiple techniques.

*Aplysia* uses gills for respiration that show a withdraw reflex when some stimuli is applied on their bodies to protect them. When animals were repeatedly stimulated with water puffing every three minutes for four hours, the withdrawal response decreased with time and finally showed no response. This phenomenon is called habituation, and is also popular in our life. This habituation originates from a change in synaptic property between the sensory neuron and the motor neuron. Inactivation of Ca channel responsible for neurotransmitter release, as well as a decrement of releasable synaptic vesicles is a major mechanism of this phenomenon.

When noxious stimuli are applied to a habituated *Aplysia*, the animal again shows a withdrawal response even to a weak stimulus that does not induce any response under normal conditions. This phenomenon, called sensitization, results from the stimulation of neurotransmitter release from the sensory neurons. A noxious stimulus activates interneuron innervated at the presynaptic nerve terminal of the sensory neuron. Serotonin released from the interneuron activates a presynaptic serotonin receptor of the sensory neuron. Activation of presynaptic serotonin receptor coupled with Gs results in an elevation of intracellular cAMP level, which in turn activates PKA. PKA suppresses K channel activity by phosphorylation, which in turn prolongs $Ca^{2+}$ influx through Cachannels. The stimulation of neurotransmitter release from the sensory neuron is also induced by increasing the size of the releasable pool of synaptic vesicles in PKA- and PKC-dependent mechanisms.

Sensitization is usually retained for less than a day, however, when the noxious stimuli are repeatedly applied everyday for several days, the effect of sensitization sustains over one week. The important finding is that mechanisms are quite different between the short-term sensitization and the long-term sensitization, and new gene expression and protein synthesis are essential for the expression of the long-term sensitization. Prolonged and repeated activation of serotonin receptors results in continuous activation of PKA, and the catalytic subunit of PKA translocates to the nucleus and activates cAMP-dependent gene expression by activating CREB by phosphorylation.

### LTP and LTD in Hippocampus

Memory formation and special learning are impaired when the hippocampus is injured in humans and rat, indicating that the hippocampus plays a critical role in memory. A lot of attention has focused on the hippocampus since LTP was found there. There are three synapses in the major neuronal circuit in the hippocampus, and LTP is observed in all of these synapses. The mechanisms of LTP induction are different among these three synapses, and the mechanism of the CA1 synapse has been most extensively studied. In brief, LTP is induced in a CA1 synapse according to the following mechanism. Synaptic transmission of the CA1 synapse is mediated by glutamate and two types of glutamate receptors, NMDA and AMPA, both being expressed at the post synaptic site. Under normal conditions, the NMDA receptor is blocked by $Mg^{2+}$ ions, and the AMPA receptor plays a predominant role in synaptic transmission. High frequency stimulation activates many AMPA receptors and a resulting large depolarization of postsynaptic membrane cancels the $Mg^{2+}$ block of NMDA receptors. In addition to $Na^{+}$, $Ca^{2+}$ ions influxes into the

postsynaptic site, and induce a $Ca^{2+}$ -dependent process that leads to LTP. CaMKII plays a critical role in the $Ca^{2+}$ -dependent induction of LTP.

Several important ideas have been obtained from studies of hippocampal LTP, one of the most important ones being gene-expression-dependency. Just like short-term sensitization in *Aplysia*, expression of short-term LTP is not dependent on new gene expression and protein synthesis, and posttranslational modification including protein phosphorylation of preexisting proteins play major roles. On the other hand, gene expression and new protein synthesis are indispensable for the expression of LTP. Many genes changing expression patterns in the induction of LTP have been identified, however, the precise consequences of these gene expressions and LTP induction has not yet been clarified.

LTP in CA1 is associative (►associative long-term potentiation (LTP)) and both pre- and postsynaptic activities are necessary for their induction. In contrast, CA3 synapse shows no association, and it occurs by a presynaptic mechanisms. Cyclic AMP-dependent protein phosphorylation may play a critical role in the induction of CA3 LTP.

## Cellular and Molecular Mechanisms of Synaptic Plasticity

There are many possible mechanisms for inducing a long-lasting change in synaptic properties and function.

### *Protein Phosphorylation*

Gene expression is not required for the expression of short-term synaptic plasticity, and posttranslational modification of preexisting protein plays a crucial role in this mechanism. Activation of metabotropic receptors and $Ca^{2+}$ mobilization activate various kinds of protein kinases and phosphatase, which in turn change the state of phosphorylation of many synaptic proteins. These mechanisms are present in both presynapse and postsynapse. In presynaptic terminals, protein phosphorylation modifies the presynaptic function by phospohorylating neurotransmitter synthesizing enzymes, such as cAMP-dependent phosphorylation of tyrosine hydroxylase, various proteins involved in neurotransmitter release (►regulation of neurotransmitter release by protein phosphorylation), and ►vesicular neurotransmitter transporter. In the postsynapse, phosphorylation of neurotransmitter receptors are predominant in its regulation [8].

### *Translocation of Receptors*

In developing neurons, there appear many ►silent synapses in which are devoid of AMPA receptors and only NMDA receptors are expressed in the synaptic membrane. Since the NMDA receptor is blocked by $Mg^{2+}$ at normal membrane potential, no synaptic current is induced by glutamate. With maturation of the brain, these silent synapses become activated, and the number of silent synapses decreases with maturation. However, some silent synapses are still present in the adult brain, and participate in the synaptic plasticity such as LTP.

In early studies, phosphorylation of the AMPA receptor was believed to be primarily important for the activation, however, recent studies revealed that translocation of the AMPA receptor from the intracellular store site to the plasma membrane is predominant in its activation. The expression of the AMPA receptor in the synaptic plasma membrane is likely to occur by an ►exocytosis of intracellular vesicles carrying AMPA receptors. $Ca^{2+}$ is necessary to induce LTP in CA1 synapses. CaMKII is likely to be involved in triggering exocytosis.

### *Adhesion Molecules*

Synaptic connection is retained by cell adhesion molecules in the presynaptic and postsynaptic membrane (►synaptic adhesion molecule). To alter the synaptic connection, the regulation of adhesion molecules is important. Cadherin-mediated regulation is important for the change in spine structure. Degradation of adhesion molecules is necessary for the rearrangement of synaptic connections. Many ►extracellular proteases are expressed in the synaptic area and play important roles in LTP formation.

### *Spine, Morphological Change*

Actin cytoskeleton is abundant in the dendritic spine, and the spine changes their morphology dynamically in a synaptic activity-dependent manner (►spine, morphological change). There is a dramatic change in spine morphology several tens of minutes after induction of LTP. The dynamics of the actin cytoskeleton is regulated by $Ca^{2+}$ and by multiple signal transduction mechanisms downstream of the metabotropic receptor and neurotrophin receptors. There are at least two types of spines. One is filopodia-like and has no AMPA receptor. Another is mushroom-like in shape and expresses AMPA receptor. After induction of LTP in the filopodia-like spine, it changes to the mushroom-like spine and acquires AMPA receptor.

In electronmicroscopic observations, two types of spine synapse are also observed, one is a nonperforated and another is a ►perforated synapse, in which PSD is discontinuous. The number of perforated synapses increases after LTP induction, and attains a maximal level 15–60 min after induction. Since some nonperforated synapses have no AMPA receptor, these morphological changes may be accompanied by the activation of ►silent synapses.

Many synaptic terminals are formed in the cell soma. Since the postsynaptic compartments are not separated

from each other, the effect of synaptic input spreads over the entire cell surface, no input specificity is achieved. On the contrary, the postsynaptic components of spine synapse are separated one by one, and the diffusion of various substances is restricted by the narrow spine neck. Thus, most changes in the postsynaptic site are restricted to the synapse, and input-specificity of plasticity appears.

In the memory circuit of an electrical computer, there are fudge numbers of condensers that are used for memory storage and calculation by changing the condenser into two states, charged and uncharged. In addition, each condenser is accompanied by a transistor switch to charge or discharge condensers. In the brain, there are numerous numbers of spines, which can change their state and shape reversibly. Each spine has an input of glutamatergic neurons, and the glutamate released from each presynaptic site can induce a change of spine structure and state. This analogy suggests a possibility that the spine might be an element for memory storage. There are fudge numbers of spines in the brain, enough to store fudge numbers of memories. Furthermore, since the structure of large spines is very stable, long-term storage of memory could be stored in the spine. In future, we might be able to read memory stored in the brain by analyzing spine structure.

#### *Gene Expression and Protein Synthesis*

New gene expression and protein synthesis is essential for the expression of long-term plasticity. Many genes whose expressions are changed in LTP have been identified and characterized. It is not so clear how these gene products participate in the changes of synaptic structure and functions in the brain.

Synaptic signals should be delivered to the nucleus where gene expression takes place. In CA1 synapses, synaptic activity is thought to be delivered by $Ca^{2+}$ and/or $Ca^{2+}$-dependent protein kinases. In *Aplysia* neurons, it has been shown that MAP kinase and PKA translocate to the nucleus after stimulation and activate gene expression by phosphorylating CREB. The importance of CREB in long-term memory is also shown in the mammalian brain [9,10].

One of the characteristic features of synaptic plasticity is input specificity. Since proteins are usually synthesized in the cell body, the synthesized proteins should be transported selectively to synapses, where the synaptic activity for plasticity occurs. There are at least two possibilities to achieve this input specificity. One is a hypothetical idea of a synaptic tag [11,12]. Synaptic activity results a trace in synapse, and the newly synthesized protein accumulates at the specific synapse according to the tag.

The second idea is a local protein synthesis at the synaptic site [13,14]. It has now been established that some mRNAs are present in the dendrite, and a noncoding region of mRNA is essential for dendritic delivery of the mRNA. Several mRNA binding proteins have been identified. Many membrane proteins are glycosylated in the Golgi complex in the cell body, but the mechanisms of glycosylation of locally synthesized protein is not yet known.

## Neuronal Defect Related to Synaptic Functions

### Neuronal Defects in Development

Since synaptogenesis starts in the late stage of pregnancy, deficiency of synaptic function is not assumed to make severe effects on brain development during embryonic age. In fact, many knock-out mice of synaptic proteins died after birth. The severe effects are derived by disorders that occur during the critical period as described above.

### Plasticity-Related Neuronal Defects

Plasticity of the dendritic spine structure and functions are quite important for the expression of various brain functions including learning and memory. Abnormal spine shape, or spine dysgenesis, is associated with various forms of mental retardation [15]. Reduction of hippocampal volume is observed in patients with major depression, possibly due to a retraction of dendrites and a reduction of neuronal connectivity. Antidepressant treatments appear to protect against hippocampal volume loss and also increases adult neurogenesis in hippocampus [16].

The secretion of glucocorticoids from the adrenal cortex is one of the major responses to stress. Strong and prolonged stress makes various severe effects on the structure and functions of the hippocampus, since its expression level of the glucocorticoid receptor is quite high. Repeated stress causes atrophy of dendrites in the CA3 region, and both acute and chronic stress suppresses neurogenesis of dentate gyrus granule neurons [17]. Maternal behavior in the rat permanently alters the development of stress response by altering glucocorticoid receptor expression in the hippocampus by an epigenetic mechanism. Pups which do not have enough maternal care during the first 10 days of life, showed stress vulnerability and increased anxiety throughout their whole life [18].

### Psychoactive Drugs

Defects in synaptic function result in various problems in the brain, and many compounds that act on synaptic proteins are widely used for clinical use as physiological drugs. Tricyclic antidepressive agents like imipramine, and a selective serotonin reuptake inhibitor (SSRI) like fluoxetine, are widely used for the treatment of depression, bipolar disorder, and anxiety disorder by inhibiting serotonin transporter. Barbiturate and benzodiazepine are used as an antianxiety drug, which binds to the $GABA_A$ receptor and enhances GABA action by

increasing affinity of GABA to the receptor. Benzodiazepines are also used as a sedative and anticonvulsant drug. Positive and negative symptoms appeared in patient with schizophrenia, and antagonists of the dopamine receptor like haloperidol and that of the NMDA receptor are used for the treatment, respectively.

## Drug Dependence

In many countries, street drugs are illegal since most of these compounds induce drug dependence. Many of these drugs exert their action by acting on synaptic proteins. Amphetamine and cocaine are stimulant drugs. They induce releases of dopamine and noradrenalin and suppress reuptakes of these neurotransmitters. On the other hand, morphine acts as an agonist of the opiate receptor. Marijuana is a psychoactive drug and an agonist of the metabotropic cannabinoid receptor.

## Toxins

Many toxins exert their action by blocking the functions of synaptic proteins [19]. Tetanus toxin and botulinum neurotoxin are protein neurotoxins produced by an anaerobic bacterium, *Clostridium tetani* and *Clostridium botulinu*, respectively [20,21]. Several immunologically distinguishable forms of botulinum neurotoxin, designated as types A, B, C, D, E, F, and G, are produced by different strains of *Clostridium botulinum*. All of these neurotoxins act primarily on neurons and inhibit neurotransmitter release from presynaptic nerve terminals. These neurotoxins are composed of a heavy chain and a light chain held together by a disulfide bond. The heavy chain is responsible for the specific binding to their neuronal receptors in axonal terminals. As for type A and type B botulinum neurotoxins, neuronal receptors are identified as synaptic vesicle proteins SV2 and synaptotagmin, respectively. Following the attachment on the surface of axon terminals, the toxin can be taken into neurons by endocytosis, and then the light chain enters into the cytoplasm. The light chain is a $Zn^{2+}$ -dependent protease and exclusively hydrolyzes peptide bonds within SNARE proteins in a type-specific manner, and inhibits neurotransmitter release by disturbing SNARE complex formation. Botulinum toxins are successfully used for the treatment of crossed eyes, migraine headaches, dystonia, and many other defects [22].

Tubocurarine chloride is a toxin obtained from the arrow poison curare. It binds to nicotinic acetylcholine receptor and blocks its function. Both α-bungarotoxin obtained in snake venom, and α-conotoxin obtained from the venom of the marine cone snail also inhibit the nicotinic acetylcholine receptor. Omega-conotoxins from the cone snail and ω-agatoxin isolated from the venom of spider inhibit neuronal Ca channels and suppress neurotransmitter release from presynaptic terminals.

Sarin (O-Isopropyl methylphosphonofluoridate) is an extremely toxic substance used as a chemical weapon. It is a very potent inhibitor of acetylcholinesterase. Acetylcholine is one of the most important neurotransmitters of the respiratory center in the brain stem, and disturbance of the cholinergic system in the center results in a blockage of the diaphragm. In the peripheral nervous system, the nicotinic acetylcholine receptor is desensitized, and thus sarin induces a paralysis of the muscles. Interestingly, donepezil, another inhibitor of acetylcholinesterase marketed under the trade name Aricept, is used in the treatment of Alzheimer's disease, where it is applied to increase cortical acetylcholine.

## Autoimmundiseases

Some patients of autoimmune diseases have autoantibodies to synaptic proteins. ►Myasthenia gravis is a neuromuscular disease leading to fluctuating muscle weakness and fatiguability. The weakness is caused by circulating antibodies that block acetylcholine receptors at the post-synaptic neuromuscular junction. ►Lambert-Eaton myasthenic syndrome is also an autoimmune disease accompanied by progressed muscle weakness. The autoantibodies to Ca- channels and synaptotagmin, a synaptic vesicle protein, are generated in the blood of patients.

### Definition

Synaptic ►competition is a cellular process by which the presence of one synapse affects the stability or survival of other synapses on the same postsynaptic cell. Synapse elimination refers to synapse loss due to either a low "intrinsic merit" of the synapse for survival or to its failure in winning synaptic competition with other synapses on the same cell [1]. Such competition and elimination can be driven by either neuronal/synaptic activity or other activity-independent processes [2]. We here summarize the evidence of activity-dependent synaptic competition and elimination in various brain regions, together with potential underlying cellular mechanisms.

### Characteristics

#### Introduction

Synaptic competition is a cellular process by which the presence of one synapse affects the stability or survival of other synapses on the same postsynaptic cell. Synapse elimination refers to synapse loss due to either a low "intrinsic merit" of the synapse for survival or to its failure in winning synaptic competition with other synapses on the same cell. Such competition and elimination can be driven by either neuronal/synaptic activity or other activity-independent processes. The idea that the strength of synaptic connections between neurons may be modified can be traced back to Ramon y Cajal, who proposed that such modification serves as a cellular mechanism for learning and memory. That memory formation involves making and breaking

existing synaptic connections has been a popular idea over the past century, but solid experimental evidence in support of this idea has been elusive. Recent morphological studies of synapse stability in the adult rodent brain have revealed rather limited synaptic remodeling under normal conditions. In contrast, initial synaptic connections established early in the developing nervous system undergo substantial remodeling, with some connections stabilized and others eliminated, as a result of experience. This developmental remodeling of connectivity often involves cooperative and competitive interactions between converging synapses on the postsynaptic cell and in many cases depends on the pattern of electrical activity. We here summarize the evidence of activity-dependent synaptic competition and elimination in various brain regions, together with potential underlying cellular mechanisms.

## Visual System

Activity-dependent synaptic competition and elimination in the central nervous system was first indicated by work of Hubel and Wiesel on the development of ocular dominance columns (ODCs) in the visual cortex. Cortical neurons preferentially responding to one eye or the other are normally found to be segregated into alternating columns in the primary visual cortex, representing sorting of geniculocortical projections serving two eyes during postnatal development. The sorting process occurs prior to eye opening and is highly sensitive to visual experience. Depriving visual input to one eye of a newborn cat or monkey by suturing the eyelid during a critical period after birth leads to retraction of geniculocortical projections serving that eye. Interestingly, the consequences of visual deprivation during early postnatal period are much more severe in cats subjected to monocular deprivation than binocular deprivation, suggesting that competition driven by activity between two eyes, rather than the reduced activity in one eye, is responsible for sorting geniculocoritical projections. The ODCs develop by a progressive segregation of initially overlapping geniculocortical projections serving two eyes. While the initial alternating pattern of projections is established by mechanisms independent of the retina activity, pruning of extensive overlapping projections is likely to be driven by activity, including spontaneous or visually evoked retinal activity, because blocking the firing of retinal ganglion cells (RGCs) in both eyes prevents complete ODC formation.

Early in development there is also substantial overlap of retinogeniculate projections from the two eyes in the lateral geniculate nucleus (LGN). Segregation of these projections into eye-specific layers occurs before the onset of vision, but at a time when ►spontaneous activity waves are prominent in the retina. Blocking all activity in both eyes prevents segregation of retinogeniculate projections and can desegregate already existing eye-specific projections later in development, although it is unclear whether the specific pattern of the waves is required for eye-specific segregation. When the activity is altered in one eye, the more active eye acquires more synaptic territory than the less active eye, suggesting activity-mediated competition. Furthermore, even after eye-specific segregation is completed, activity in one eye can further prune retinogeniculate projections by reducing the convergence of RGC inputs onto a single LGN neuron from 12 to 20 to one. This within-eye pruning based on activity-dependent competition among RGCs facilitates sharpening of the receptive field of LGN neurons. Such activity-dependent competition may be attributed to the competition in the growth or stability of RGC axonal arbors. In the developing optic tectum of zebrafish, reducing neuronal and synaptic activity in a subset of RGCs leads to suppression of their axon growth and branching and this suppression is relieved by blocking the activity of nearby RGC axons as well [3].

The successive levels of the mammalian visual system are organized into retinotopic maps that preserve an orderly representation of visual inputs at the retina, through topographically precise retinogeniculate, retinocollicular and geniculocoritical projections. Formation of these maps requires specific patterns of spontaneous activity in the retina because disrupting these waves affects map formation at all levels. While the initial projections may establish a crude retinotopic map via axon guidance based on ►molecular cues, interfering with both axon guidance cues and spontaneous wave activity in the same animal results in a dramatic cumulative effect in disrupting the map in the superior colliculus. Finally, the development of retina circuitry itself also depends on activity. Depriving the retinal activity by blocking spontaneous activity or dark rearing blocks both the normal maturational loss of ON-OFF responsive RGCs and the pruning of dendrites at the stratified ON and OFF layers of the inner plexiform layer, although it is unclear whether dendritic pruning in this layer results from competitive interaction among bipolar inputs.

## Somatosensory System

Somatosensory projections in the brain exhibit a ►somatotopic map, with axons of peripheral receptor sheets projecting in an orderly manner onto central brain structures. The most intensively studied system is the rodent trigeminal pathway where the patterned array of the whisker is replicated in the patchy distribution of afferents and the modular organization of their postsynaptic counterparts along the pathway from the periphery to the primary somatosensory cortex. The whisker-related patterns are first established in the brainstem nuclei, then in the ventro posteromedial

nucleus of the thalamus, and finally in the somatosensory cortex ("barrels"), where neurons respond best or exclusively to deflection of the corresponding facial whisker. These somatotopic maps emerge during early development in ascending order along the neuroaxis, with a sequence that includes afferent fibers segregation before rearrangement of their target neurons in discrete zones along the pathway. It is generally believed that the initial crude topographic projection of the afferent fibers is independent of sensory experience, but the presence of segregated afferent fibers and postsynaptic glutamate receptor activities are required for the subsequent parcellation of their postsynaptic targets [4].

That cortical map formation depends on a competitive process is suggested by the finding that damage of the branch of the trigeminal nerve supplying the whisker pad prior to birth results in a reduction of the cortical representation of the whiskers and a concomitant increase in the representation of other peripheral receptor surfaces. Whether and how such competition occurs through synaptic competition and elimination are unknown. ►Synapse elimination has been observed in the ventral posteromedial thalamic nucleus of young animals, where multiple afferents on each neuron are reduced to one or two afferents as the animal matures. However, this synapse elimination and remodeling occurs even in animals deprived of sensory experience from birth, indicating that the process is independent of sensory experience, although spontaneous neuronal activity may still be required.

Morphological organization of somatosensory cortical neurons into barrels during development depends on signals conveyed by invading thalamic axons and sensory activity. Indeed, primordial visual cortex transplanted into the neonatal somatosensory cortex form barrels when invaded by axons from somatosensory thalamic nuclei, and genetic manipulations that interfere with the appropriate segregation of these axons disrupt barrel formation. Moreover, that sensory peripheral sensory signals may be instructive in sculpting the somatosensory cortical map is also evidenced by lesion or genetic studies showing that altering the number of functioning whiskers leads to shrinkage, expansion or addition of barrels. However, such aberrant barrel formation may result from sprouting and retraction of afferents and dendrites due to neuronal degeneration and alteration in the number of afferents, involving competitive ►synapse formation, rather than activity-dependent synaptic competition. Notably, changes in whisker use drive functional changes in the barrel neurons without affect anatomical appearance of barrels, suggesting no gross reorganization of synaptic connections. Nevertheless, sensory deprivation results in a specific loss of GABAergic synapses and impairment of secondary dendritic branches in the barrel cortex. Thus, activity may lead to synapse elimination of at least a subset of synapses in the somatosensory cortex, presumably through a competitive process.

## Auditory System

Sound entering the ear stimulates cochlea hair cells, which make synaptic connection with spiral ganglion cells that give rise to the primary auditory nerve for carrying auditory information into the brainstem. From there the signals converge in the inferior colliculus that sends projections to the thalamus, which further relays auditory signals to the auditory cortex. In these relay areas neurons are arranged in a topographic manner according to the sound frequencies to which they are most sensitive. Although the topography of these connections is apparent early in development, the precision of the map is refined later in development through an activity-dependent process [5]. Developmental pruning of both axonal arbors and dendritic branches has been widely observed in the auditory system. Cochlear nerve axons and their target neurons in nucleus magnocellularis (NM) undergo extensive parallel structural transformations involving pruning of cochlear axonal arbor, massive reduction of dendrites in NM neurons, and elimination of poly-neuronal innervation. Since otocyst removal has no effect on the extent, timing, and pattern of dendritic loss, this extensive synapse elimination is independent of the sensory activity. Interestingly, after this early massive remodeling, NM neurons undergo further dendritic growth before maturation in a sensory activity-dependent manner.

In contrast to that in the NM, developmental remodeling of axons and dendrites in the nucleus laminaris and superior olivary nucleus (SON) after the onset of hearing appears to be activity-dependent. Cochlea removal or blockade of glycinergic transmission impairs remodeling of axonal and dendritic morphology in SON. Since most of the remodeling occurs after the onset of hearing, acoustically evoked activity is likely to be involved, although spontaneous activity may also contribute. Indeed, correlated spontaneous activity is present in the embryonic brainstem and auditory nerve. The spatiotemporal pattern of spontaneous firing could provide developmental cues for the spatial ordering of auditory projections, as suggested by the presence of a systematic relationship between the rate of rhythmic bursting and the tonotopic location in the chick. Such activity-dependent remodeling of connectivity may contribute to the tonotopic map refinement at many different levels in the auditory system.

After the onset of hearing, the auditory cortex undergoes a transition from a tonotopic map dominated by broadly tuned, high frequency-selective neurons to the adult tonotopic map consisting of neurons that represent the full spectrum of acoustic inputs. ►Sensory-evoked activity is responsible for this transition. Early

acoustic environment is critical for the maturation of tonotopic maps, because exposing rat pups to pulsed white noise or rearing them in continuous moderate-level noise impairs the emergence of adult-like tonotopic map, whereas exposure to pulsed tones of specific frequencies results in accelerated emergence and expansion of auditory cortex representations of those frequencies. This activity-dependent remodeling of cortical maps are likely to involve synaptic competition and elimination, although whether functional refinement of the map directly reflects structural reorganization of synaptic connectivity remains to be determined.

### Olfactory System

The olfactory sensory neurons in mammals express only one of about 1000 odorant receptor genes and neurons expressing a given receptor are randomly dispersed within one of four broad zones in the olfactory epithelium. The axons of these sensory neurons converge upon spatially conserved glomerulus within the olfactory bulb. The topographic mapping between sensory neurons and specific glomeruli may depend on the expression of specific molecules along their projection pathways or in themselves. There is evidence, however, that activity in these olfactory neurons may also play a role. Although the patterns of axon convergence in the bulb is largely intact in mice lacking functional olfactory cyclic nucleotide-gated channels, hence no odorant-evoked activity occurs in these neurons, non-correlated spontaneous activity may still be required for the correct mapping process. Indeed, sensory map is not affected when conditional expression of tetanus toxin light chain inhibits synaptic transmission in the majority of olfactory sensory neurons. However, inhibition of synaptic release in a small subpopulation of neurons expressing the P2 receptor results in correct targeting of the sensory axons initially, but the P2 glomerulus is not maintained and P2 neurons ultimately diminish. Preventing excitation of the neuron has a similar effect on the formation of the olfactory map. Thus, spontaneous neuronal activity may play a role in pruning or stabilization of axon terminals of olfactory neurons on their glomerular target cells, but there is little evidence that synaptic competition is involved in olfactory map formation.

### Cerebellum

The two main afferent systems in the cerebellar cortex are the climbing fibers (CF) originated from the inferior olivary nucleus and the mossy fibers (MF) from various nuclei in the spinal cord, brain stem, and deep cerebellar nuclei. Each CF directly contacts the proximal dendritic compartment of a single Purkinje cell, whereas the MFs influence Purkinje cells indirectly through granule cells, whose axons form the parallel fibers (PFs) that synapse onto the dendrites of many PCs. There is evidence for a complex ►topographic map of these afferents fibers. For example, cutaneous inputs carried by CFs are topographically organized to form a map of peripheral body, with CF axonal arbors in register with cortical parasagittal bands of chemically heterogeneous PCs. The formation of these precise topographic maps involves both activity independent and dependent steps. First, positional information shared between CFs and PCs during embryonic development provides the molecular code for the formation of coarse-grained maps independent of neuronal activity. Activity-dependent mechanisms are later required for the transition to a fine-grained map, by pruning CF terminal arbors on each PC from multiple to single CF innervation [6]. This pruning involves strengthening one CF while weakening all other CFs during the first postnatal week, leading to the elimination of the latter. Moreover, alteration of the temporal pattern of CF activities specifically during development impairs such CF elimination in vivo, suggesting an activity pattern-dependent synaptic competition.

In addition to potential competition among homologous CFs, there is also heterologous competition between CFs and PFs that results in their segregation into different dendritic domains of each PC. Weakening of the CF input leads to the reduction of its dendritic territory and concomitant strengthening and expansion of the PF input, and vice versa. Furthermore, elimination of CFs depends on the activity of developing PF-PC synapses, because CF elimination is affected by reducing PF inputs, through granule cell degeneration, impairment of granule cell function, or genetic manipulation of PF-PC synapse formation or efficacy. The similarity in the consequence of reducing CF and PF activities in CF elimination suggests that similar mechanisms may underlie synaptic competition/elimination among homologous vs. heterologous inputs.

### Autonomic Ganglia

Ganglionic cells in the autonomic nervous system are innervated by preganglionic neurons of the spinal cord or brainstem and send projections to target tissues via spinal nerves to control involuntary functions of the body. In mammals, characteristic patterns of sympathetic and organ responses elicited by the activity of individual spinal axons are due to mapping between specific spinal segments and peripheral targets. This mapping requires a stereotyped and selective innervation of ganglion cells by preganglionic axons, with each ganglion cell innervated by one or few axons from specific contiguous spinal cord segments. During development there is a transition from initially exuberant innervation of each ganglion cell by many preganglionic axons to innervation by only one or a few axons. Since the spinal segment responsible for activating the mature and neonatal ganglion cell is the

same, developmental synapse elimination involves reduction of preganglionic axons from the same spinal segment, suggesting competition occurs among axons of nearby spinal neurons. Furthermore, transection of a portion of preganglionic nerve innervating a developing ganglion leads to sprouting of residual preganglionic axons and partial restoration of original multiplicity of innervation. These results are all consistent with the idea that synaptic elimination is not simply due to the intrinsic merit of the input, but involves competition among inputs, presumably for a postsynaptic factor of limited supply, e.g., locally secreted trophic factor (see Mechanisms).

The competitive interaction that determines the final number of preganglionic axons converging upon a single ganglion cell depends on the proximity of competing synapses, with each surviving synaptic terminal claiming a certain territory on the dendritic or somatic surface and neurons with more extensive dendritic arbors receiving more axons. This distance-dependent synapse competition can be explained by a limited amount of available postsynaptic factors. This synapse competition appears to be activity-dependent, because among converging inputs to a single ganglion neuron, strong synapses become further strengthened and weak synapses further weakened during synapse elimination. Moreover, the synaptic strength for each synaptic input of a multiply innervated cell is, on average, weaker than that of a singly innervated cell, suggesting that the total synaptic strength of a postsynaptic ganglion cell is conserved, due to a limited amount of a synapse-related factor.

## Neuromuscular Junction

Each muscle fiber in the neonatal animal is multiply-innervated by axon collaterals of several motoneurons, but becomes singly-innervated during early postnatal life [7]. This process depends on synapse elimination involving withdrawal of a subset of nerve terminals of each motoneuron innervating a given muscle (i.e., reduction of the size of motor units) rather than reduction in the number of motoneurons innervating a muscle. Partial denervation of the muscle at birth results in the retention of the large motor unit size without substantial collateral motor axon sprouting. Synapse elimination is competitive rather than a random process of withdrawal, since muscle fiber without a single axon is never observed. The elimination is also activity-dependent. Blocking motoneuronal activity prevents elimination, while elevating activity accelerates it. Importantly, when the relative synaptic efficacy of two competing axons at a single neuromuscular junction is impaired by genetic deletion of acetylcholine in one axon, the latter loses the competition, suggesting that the strength of the synapse is predictive of the outcome of the competition [8].

## Mechanisms of Activity-Driven Synapse Competition

### *The Hebb's Rule for Synapse Competition*

Hebb postulated that strengthening of a synapse might be achieved by repetitive presynaptic activation that leads to postsynaptic firing. This postulate was later transformed into a simple rule – coincident pre- and postsynaptic activity leads to synapse strengthening and stabilization. To account for the finding of Hubel and Wiesel on activity-dependent remodeling of connectivity in the developing visual system, Stent further extended the ►Hebb's rule by assuming that noncoincident pre- and postsynaptic activity leads to synapse weakening and elimination. Modeling studies showed that such correlation-based Hebb's rule could explain activity-dependent refinement of developing visual circuits. In the past decade, a temporally specific form of Hebb's rule has been proposed, based on findings of spike timing dependent synaptic plasticity in a variety of systems [9]. The temporal order in the spiking of pre- and postsynaptic neurons was shown to be critical for synaptic modification, in addition to the extent of coincidence in spiking: "Pre-before-post" results in strengthening and "post-before-pre" leads to weakening of the synapse. This spike-timing dependent plasticity offers an element of causality in the activity-induced synaptic competition: Inputs that contribute to (and cause) the postsynaptic spiking are advantageous in synaptic competition over those inputs arriving after postsynaptic spiking has just occurred. Importantly, experimental evidence for the validity of various forms of the Hebb's rule mainly came from studies of activity-induced functional changes of synaptic efficacy, e.g., long-term potentiation (LTP) or long-term depression (►LTD), rather than changes in the morphological connectivity.

### *Importance of Temporal Pattern of Activity*

The importance of the pattern of activity in synapse competition has been demonstrated mainly in the development of ocular dominance and orientation selectivity of the primary visual cortex. Rearing kittens with induced squint (strabismus), which alters the pattern but not the absolute level of activity, results in striking changes in the binocular property of cortical cells, reflecting altered synapse competition of geniculocortical inputs. Artificially imposing synchronous activity on optic nerves from the two eyes prevents segregation of thalamocortical projections into ocular dominance columns, whereas asynchronous activity allows segregation. Similarly, synchronous activation of optic nerves blocks the development of topographic maps in the optic tectum and reduces orientation selectivity in the cortex. Spike-timing-dependent synaptic modification provides a natural basis for such pattern dependent competition. In the developing *Xenopus* visual system, spike timing-dependent induction of ►LTP and LTD has been demonstrated, but whether such persistent changes in

functional efficacy of synapse is causally related to structural changes in connectivity remains unknown.

### Contribution by GABAergic Inhibition

Activity in the brain depends on a proper balance of excitation and inhibition. It is thus not surprising that GABAergic activity plays a regulatory role in the refinement of developing circuits. In mice lacking one form of the enzyme (GAD65) responsible for GABA synthesis, the ocular dominance plasticity resulting from monocular deprivation is absent, and increasing GABA inhibition in diazepam-treated mutant mice allows the appearance of ocular dominance plasticity. In the developing retinotectal system, a proper level of GABAergic inhibition is required for normal refinement of the retinotopic map in the tectum, both the \increase and decrease of inhibition impede ►map refinement. Interestingly, the role of GABAergic inhibition appears not only to reduce the overall neuronal excitation, but also to sharpen the temporal pattern of the neuronal activity by shortening stimulus-evoked discharges, potentially facilitating spike timing-dependent refinement of neural circuits. Shunting of specific excitatory inputs may also be achieved by selective distribution of inhibitory synapses on the dendrite. Finally, inhibitory synapses may also undergo competition and refinement as well, because they are integral part of the neural circuit. At present, it is unknown how nascent inhibitory connections, while playing important regulatory roles in refining excitatory connections, can themselves undergo activity-driven refinement and be properly consolidated into the mature circuit.

### Causal Link Between LTP/LTD and Synapse Competition

At some synapses repetitive co-activation of the pre- and postsynaptic cell leads to not only homosynaptic LTP, but also heterosynaptic LTD of non-coactive converging synapses onto the postsynaptic cell, thus providing a potential competitive mechanism for synaptic elimination. The hypothesis that synapse stabilization and elimination are mechanistically linked to or even result from activity-induced LTP and LTD, respectively, remains to be fully tested. Many lines of correlative evidence support this hypothesis. Blocking NMDA receptor activation, which abolishes many forms of LTP/LTD, impedes refinement of developmental circuits. Repetitive visual stimuli that modify developing visual circuits can induce NMDA receptor-dependent LTP/LTD of retinotectal synapses. During the postnatal critical period, the composition of ►NMDA receptors undergoes experience-dependent developmental regulation in the visual system, and there is a correlation between the susceptibility for LTP/LTD induction and for circuit refinement. However, whether LTP/LTD is relevant or a prelude to structural refinement in the visual system remains unknown. Synapse elimination (structurally) will certainly eliminate the synaptic function, but whether LTD will lead to synapse elimination is unclear. Recent studies in hippocampal slices has provided evidence that LTP/LTD induction is followed by a swelling/shrinkage of dendritic spines, supporting the linkage between synaptic efficacy and synaptic structure.

### The Trophic Factor Hypothesis

Purves and Lichtman have proposed that synaptic competition involves the competition between co-innervating presynaptic terminals for a limited amount of "trophic factors" derived from the postsynaptic cell. This hypothesis can be extended to factors in the postsynaptic cytoplasm or plasmalemma, together with a localized retrograde signaling to the presynaptic nerve terminal. Competition for the trophic factor can be regulated by activity. The activity can serve a permissive role for synapse competition by regulating the synthesis and release of trophic factors/retrograde signals, whereas other activity-independent mechanisms determine the competitive advantage of a synapse. For activity to serve an instructive role, the pattern of activity in the co-innervating nerve terminals may determine the outcome of competition by controlling the uptake or the efficacy of the trophic factor at the nerve terminal. The local release of trophic factors may also depend on local synaptic activation, which is in turn driven by the pattern of activity, including the timing of pre- and postsynaptic spiking. The ►neurotrophin family of proteins, which are known to regulate synaptic function and axon/dendrite morphology, are attractive candidates for the trophic factor in synapse competition [10]. The expression and secretion of neurotrophins, and their potentiating actions on the synapse, are all activity-dependent. Neurotrophins are required for the development of ocular dominance column and for the induction of activity-induce LTP in several systems. Furthermore, neurotrophin secretion is activity-pattern dependent, and the secreted neurotrophins are likely to act locally by its binding to cell surfaces at the synapse, allowing them to serve as local synaptic modulators. Activity-dependent depletion of available neurotrophins in the local environment of the synapse may lead to the functional and structural modification underlying synapse elimination.

## Concluding Remarks

Studies of synapse competition and elimination in the near future are likely to be facilitated greatly by the availability of many new technologies for selective neuronal labeling and optical imaging in the living animal. Transgenic animals with selective populations of fluorescence-tagged neurons, together with in vivo multi-photon imaging, will allow us to directly monitor changes in the morphology of axons and dendrites during the process of synapse competition and refinement over

prolonged period in the intact brain. Fluorescent $Ca^{2+}$ or membrane-voltage sensors will allow us to monitor neuronal activities, and photo-activated probes expressed in selective neuronal populations will allow us to directly manipulate neuronal activity and to examine how activity drives synapse competition and elimination.

# Synapse Formation: Neuromuscular Junction Versus Central Nervous System

Pamela Arstikaitis, Alaa El-Husseini
Department of Psychiatry and the Brain Research Centre, University of British Columbia, Vancouver, BC, Canada

## Synonyms

Synaptogenesis; Establishing stable neuronal contacts; Neuron-to-neuron communication

## Definition

Synapses are the structural basis of communication between neurons in the ►central nervous system (CNS) and between neurons and muscle cells in the ►peripheral nervous system (PNS). Synapse development involves the formation of a contact between axon terminals and specific sites on the appropriate target. This is followed by contact stabilization and maturation which involves the recruitment of the appropriate protein machinery at pre- and postsynaptic sites.

## Characteristics

### Formation of the Vertebrate Neuromuscular Junction (NMJ)

Formation of a NMJ synapse involves the establishment of a connection between a presynaptic terminal of a ►motoneuron and a postsynaptic skeletal muscle cell. The NMJ is a large and accessible structure that develops in a stereotypical manner as each muscle fiber receives input from a single motoneuron axon. As a result, the molecular, cellular and physiological properties of this synapse have been well characterized. In the stereotypical NMJ, numerous presynaptic ►active zones are directly aligned with a postsynaptic specialization called a junctional fold.

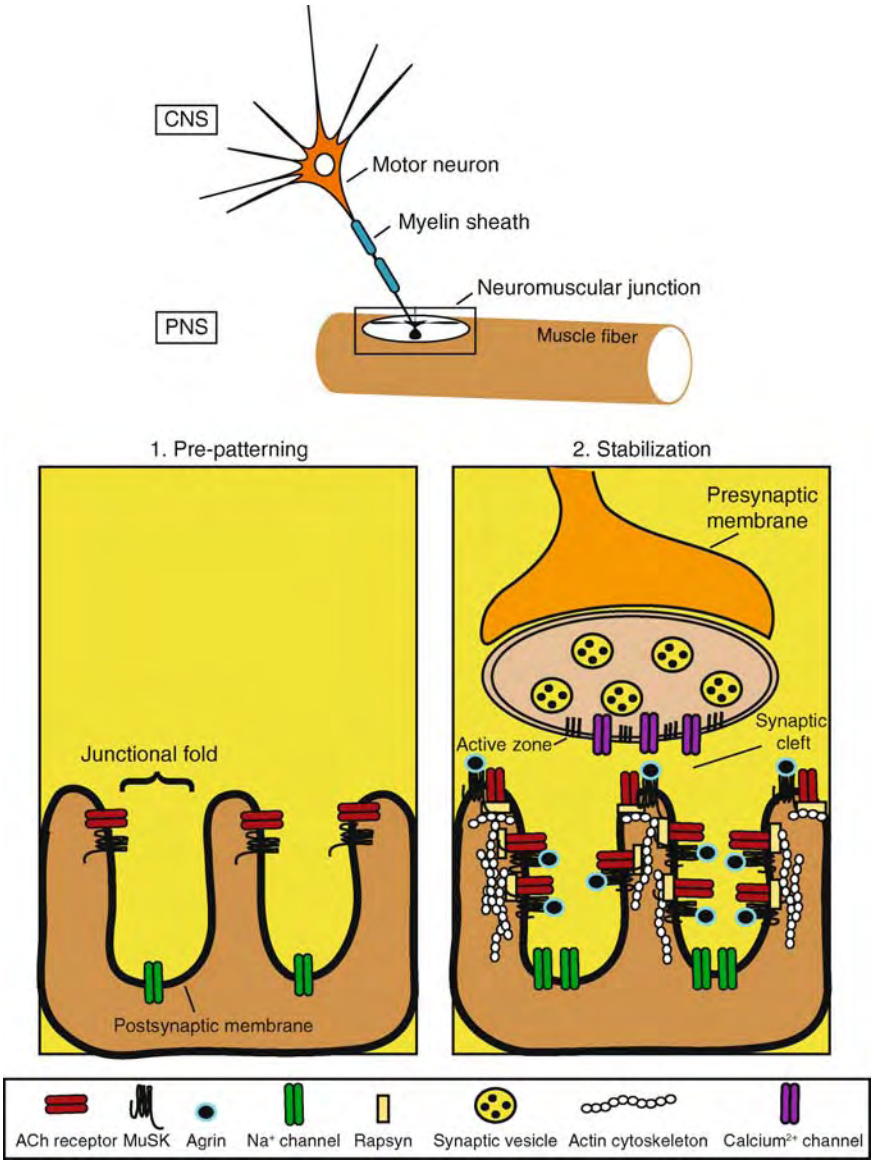
The folds are introversions into the muscle plasma membrane, with cationic ligand-gated ►acetylcholine receptors localized to the top and voltage gated sodium channels deeper within these folds [1]. In response to an action potential, the multiple release sites of the presynaptic terminal have a high probability of vesicular release and the amount of ►acetylcholine released saturates the ►postsynaptic receptors. To control the efficacy of transmission, an enzyme called acetylcholinesterase (AChE) present at the synaptic cleft, acts to degrade the released transmitter, terminating the signal. Another important structural component of the NMJ is the thick basal lamina of the ►extracellular matrix (ECM) that runs through the cleft. During formation and maturation of the synapse, components of the ECM at the NMJ serve critical signaling and structural roles as a diffusion barrier for AChE.

NMJ formation is directed by reciprocal interactions between motor neurons and muscle fibers. ►Laminins, a component of the NMJ basal lamina, have come forward as a muscle derived signal involved in the development of the presynaptic terminal [1]. Specifically, ►laminin β2 has been shown to act as a stop signal for incoming axons *in vitro*. Mice lacking laminin β2 form few active zones and fail to align vesicles apposed to receptors on the muscle fiber [1]. These results highlight the importance of muscle-derived signals in proper NMJ development.

At the postsynaptic side, high concentrations of acetylcholine receptors (AChRs) are clustered at central regions of the myofibers following muscle production. This occurs before the arrival of the motoneuron axonal ►growth cone, and is termed pre-patterning [2].

Recent in vivo studies demonstrate that AChRs are preferentially formed at the endplate band where

innervation occurs, suggesting that the site where the motoneuron contacts the muscle may not be the only factor determining synapse location. As the motoneuron axon approaches the muscle fiber, secreted factors such as ►agrin and ►neuregulin, are released from the axon that results in further clustering of AChR and maturation of postsynaptic specializations [1] (Fig. 1). Agrin is secreted by motor neurons and by muscle, which binds



**Synapse Formation: Neuromuscular Junction Versus Central Nervous System. Figure 1** Sequence of events that underlie synapse formation at the neuromuscular junction. Motor neurons from the motor cortex located in the CNS send axons ensheathed in myelin to target muscle cells. A contact between a motoneuron axon and muscle fiber constitutes the neuromuscular junction (NMJ; left panel). At NMJ, acetylcholine receptors (AchRs) are positioned at the postsynaptic membrane opposite to the presynaptic nerve terminal ►active zone containing the neurotransmitter acetylcholine (Ach). An early step of NMJ synapse formation is pre-patterning of AChRs in the endplate region. This is thought to be a muscle-specific program as initial clustering of AChRs occurs in the absence of input from the motor neuron. It is thought that MuSK activation occurs independently of agrin to induce AChR clustering during pre-patterning. Synapse stabilization and maturation involves enhanced clustering of AChRs and this process is thought to require agrin and MuSK. Furthermore, rapsyn, a scaffolding molecule bound to the actin cytoskeleton, also modulates anchoring of AchRs. Based on findings reviewed in [1].

to ►muscle-specific receptor tyrosine kinase (MuSK). Activation of ►MuSK causes enhanced AChR clustering and the production of more AChRs [3] (Fig. 1).

In mice lacking agrin, AChRs are reduced in number with a wider distribution and show incomplete motoneuron terminal differentiation, suggesting that postsynaptic differentiation is necessary for additional presynaptic development [1]. AChR-inducing activity (ARIA) or ►neuregulin-1 increases AChR expression through activation of its receptor, membrane associated tyrosine kinases related to EGF receptors (►erbB receptors) [1]. Unlike agrin, neuregulin/erbB signaling is dispensable to NMJ function, and thus may play a modulatory role in NMJ development [1]. Another protein important for pre-patterning of AChR clustering is the scaffolding molecule ►rapsyn, which directly binds to and stabilizes AChRs on the surface of the developing muscle. Interestingly, since rapsyn-deficient mice lack receptor clusters [2] (Fig. 1). Studies on mice deficient in the enzyme required for neurotransmitter synthesis, ChAT [1] revealed that motoneuron activity is important for the refinement and maintenance of NMJs [1]. In summary, recent studies revealed several signals from both the pre- and postsynaptic sites are needed to establish stable contacts between ►motoneurons and muscle cells and to induce receptor clustering and maturation of the NMJ.

## Formation of Central Nervous System (CNS) Synapses

### *Synapse Heterogeneity*

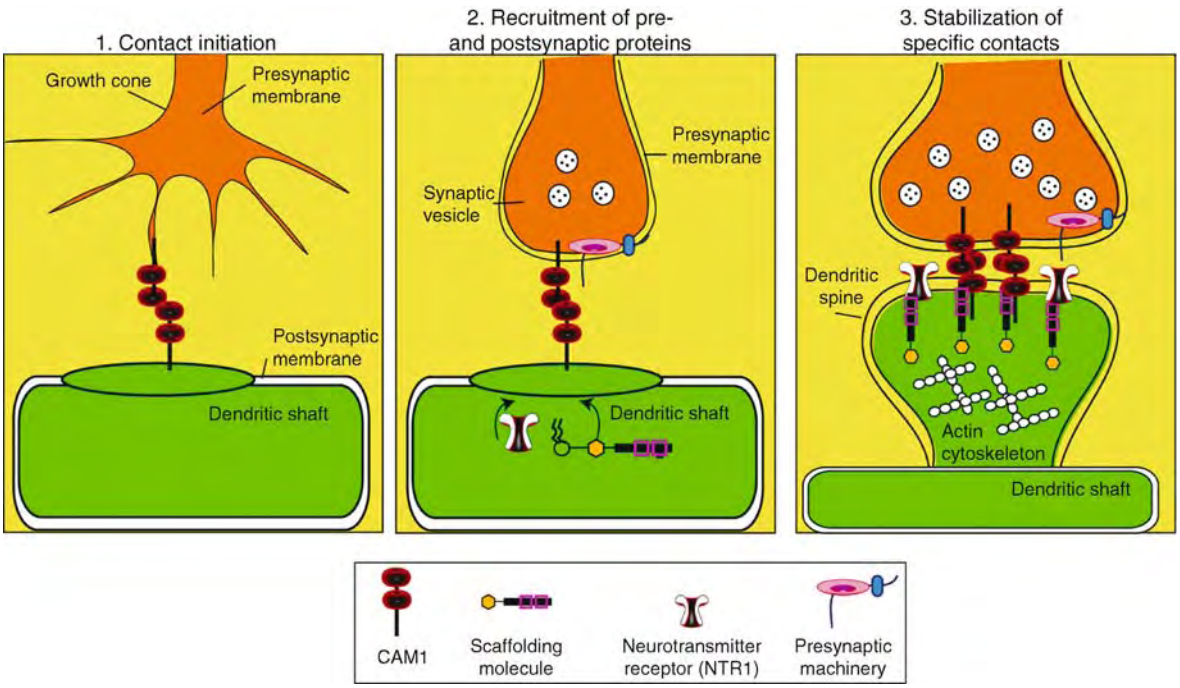
Mechanisms involved in central nervous system (►CNS) synapse development are far less understood due to multifarious neuronal types and the neurotransmitter they release. In addition, there are differences in their temporal development [2]. Neurotransmitter released from pre►synaptic vesicles bind to postsynaptic receptors eliciting a specific effect that depends on the (i) type and number of postsynaptic receptors, (ii) developmental stage of the neuron, (iii) type of neurotransmitter released, and (iv) neuronal activity [2]. Despite the complexity of CNS synapses, the basic principles of NMJ formation still hold true, such as the cooperation of axonal and target-derived signals and modulation by activity. Several classes of molecules including ►cell adhesion molecules, secreted factors, and scaffolding proteins have emerged as important proponents for the formation and maintenance of CNS synapses (Fig. 2).

### *Overview of Synaptogenesis: Carefully Choreographed Steps*

The formation of a CNS synapse involves several key steps, which include: neuronal contact establishment, recruitment of pre- and postsynaptic proteins, contact stabilization and maturation [2] (Fig. 2). Each of the steps of ►synaptogenesis outlined above requires crosstalk between two neurons. Developmental regulation of protein expression, as well as mechanisms that govern localization of neurotransmitter receptors and associated proteins to particular contact sites, are key processes that control synaptic contact maturation and function.

Correct connectivity is essential for a functional neuronal network thus, target regulation must be specific [2]. To achieve this, axons often travel long paths before reaching the appropriate target cell (Fig. 2). This has been described in terms of axonal ►growth cones that extend ►filopodia searching for the proper target. Dendrites also extend growth cones and are decorated with filopodia which are thought to be important for contact initiation [2] (Fig. 2). Axon guidance is aided by cues in their environment that act as attractive and repulsive cues. Secreted factors, for example, Wnt and fibroblast growth factor (FGF) function as retrograde signals to regulate axon arborization and synaptic differentiation. Specifically, Wnt is released from postsynaptic neurons, resulting in a decrease in axon extension and an increase in growth cone size. This effectively "slows" down the axon once it reaches the appropriate target and enhances the possibility of contact initiation.

A successful contact formation requires cross-talk between the axon and target cell to recruit the appropriate neurotransmitter release machinery and their receptors at contact sites [3]. Cell adhesion complexes are also attractive candidates for the regulation of synaptogenesis as they can function to bi-directionally regulate molecular and morphological changes in ►synapse formation [3]. Due to the large number and diversity of neuronal contacts formed during synaptogenesis, multiple adhesion systems must exist to offer sufficient possible combinations to ensure formation and stabilization of proper contacts between neurons. A prime example includes ►cadherins, homomeric adhesion molecules, thought to regulate target recognition in the CNS. The cadherin superfamily is comprised of more than 100 members, including classical cadherins, cadherin-related proteins and ►protocadherins, many of which are expressed in the brain [3]. Thus, matching cadherins in axons and dendrites is believed to promote selective adhesion between appropriate partners in a "lock and key" fashion. Because of their adhesive properties, adhesion molecules are thought to serve four major functions: (i) Synaptic contact initiation, (ii) contact stabilization and recruitment of other molecules that regulate synapse maturation, specificity and function, (iii) maintenance of mature synapses, and (iv) trans-synaptic signaling which allows communication between the pre- and postsynaptic compartments to synchronize neurotransmitter release and postsynaptic neurotransmitter activity and signaling [3]. Importantly, recent studies revealed that many

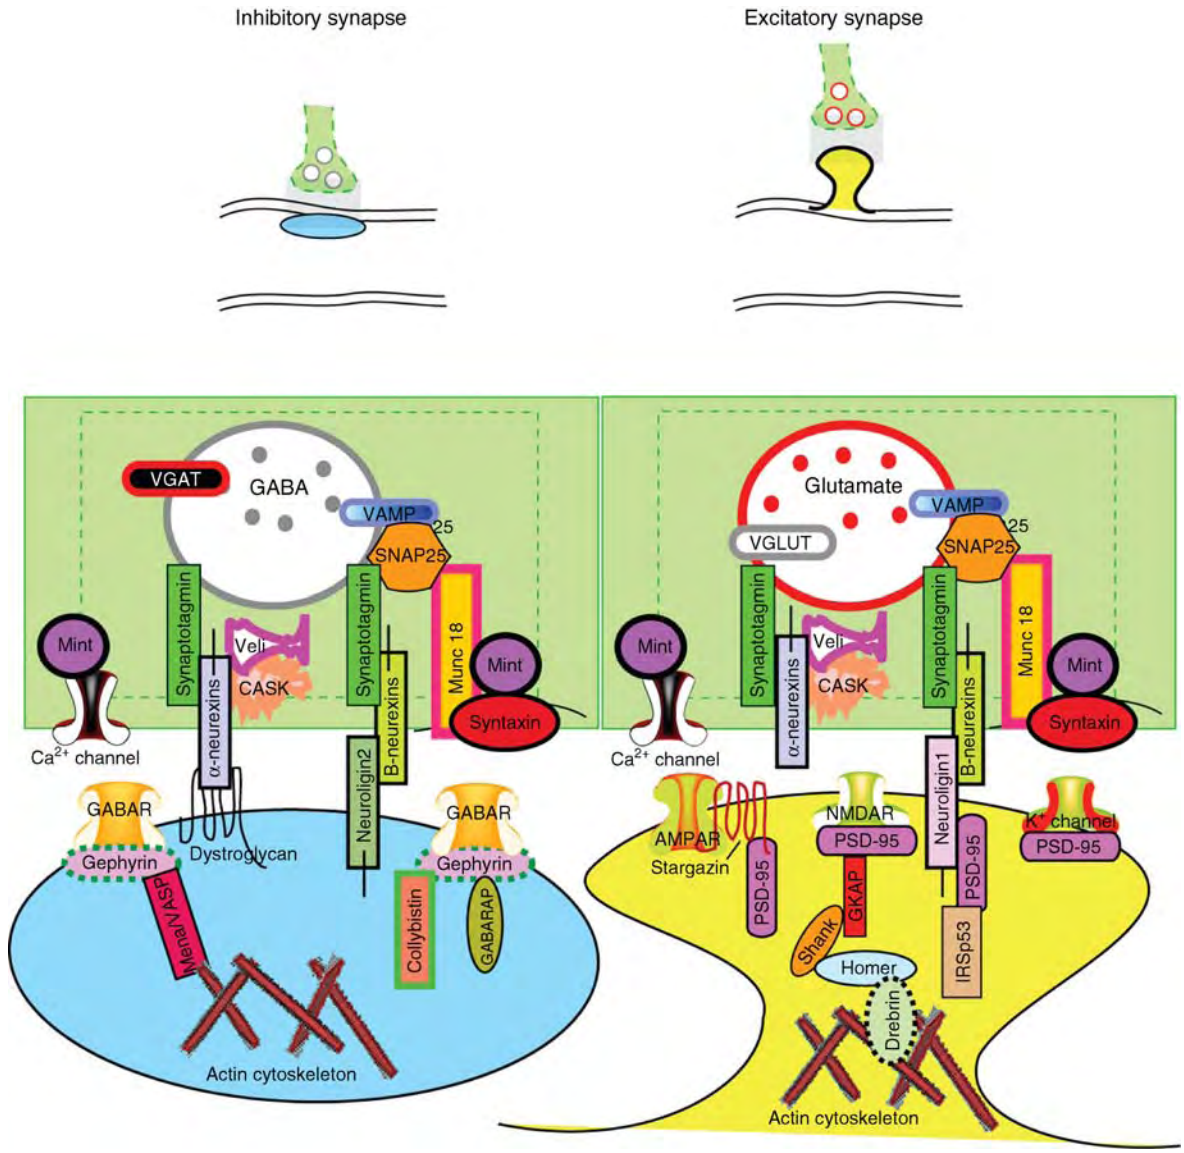


**Synapse Formation: Neuromuscular Junction Versus Central Nervous System. Figure 2** Proposed role of cell adhesion and scaffolding molecules in the formation and stabilization of glutamatergic CNS synapses. (left panel) Specific cell adhesion molecules (CAMs) are thought to control contact specificity. At this early stage, axonal growth cones are thought to contact the dendritic shaft of postsynaptic cells to establish a contact. Dendritic filopodia are also thought to participate in initial contact initiation and formation of bulbous protrusions known as dendritic spines. Initial contact can also occur by axons contacting dendrites in passing. Another key step in synapse formation is contact maturation at which recruitment of pre- and postsynaptic proteins takes place. (middle panel) During synapse maturation, presynaptic neurotransmitter synthesis and release machinery are recruited to the presynaptic terminal (referred to as presynaptic machinery in legend). At the postsynaptic side, cell adhesion molecules, scaffolding proteins and neurotransmitter receptors are recruited. (right panel) Some of the key neurotransmitter receptors and associated adhesion and scaffolding proteins recruited to mature glutamatergic excitatory synapses are indicated. The recruitment of these proteins is thought to regulate both contact stabilization and neurotransmitter receptor clustering, as well as changes in synapse morphology such as spine formation. The dynamic addition and removal of these molecules at mature synapses controls synaptic strength and plasticity.

aspects of memory formation and animal behavior can be affected when adhesion molecules are disrupted or eliminated. Thus, delineating the role of the various adhesion systems in synapse formation will help not only understanding the intricate mechanisms involved in neuronal contact formation and maturation, but also in establishing the specific neuronal circuits that regulate neuronal communication and ultimately brain function. However, numerous adhesive complexes have been discovered and this makes them both interesting and difficult to study.

A family of cell adhesion molecules that are emerging as critical modulators of synapse induction and maturation are postsynaptic ►neuroligins and their presynaptic binding partners, ►neurexins [3,4] (Figs. 2 and 3).

One thousand isoforms of neurexins potentially can be generated by alternative splicing and this suggested a role for these molecules in controlling synapse type and specificity. The intracellular domains of both neuroligin and neurexin are short and terminate in PDZ (PSD-95, discs large and zona occludens1)-domain binding sites, which aid in connecting them to other synaptic proteins [3,4]. For instance, association of ►neuroligin-1 with scaffolding molecules such as PSD-95 can modulate synapse size and number (Fig. 2). Surprisingly, recent studies illustrate that neuroligins and neurexins can regulate formation of glutamatergic (excitatory) synapses and GABAergic (inhibitory) contacts, where neuroligin-1 is localized primarily to ►excitatory synapses and ►neuroligin-2 is localized to ►inhibitory synapses [3,4] (Fig. 3). Manipulation of the levels of these proteins can influence the excitatory/inhibitory synaptic ratio, leading to the proposal that neuroligins may play a role in maintaining the balance of synaptic input. Other adhesion molecules including SynCAMS, ephrins, and SALMs also play a role in synapse induction and maturation (Fig. 2). This highlights the



**Synapse Formation: Neuromuscular Junction Versus Central Nervous System. Figure 3** Differential recruitment of adhesion and scaffolding molecules to excitatory and inhibitory synapses. Excitatory and inhibitory synapses are distinguished based on their morphology and molecular composition. (left panel) The majority of inhibitory transmission in the mammalian CNS is mediated by GABA and these inhibitory synapses are mainly formed on dendritic shafts. (right panel) In contrast, glutamatergic synapses are the major excitatory synapses in the CNS, which are mainly formed on dendritic protrusions known as spines. Inhibitory and excitatory synapses share the majority of proteins involved in presynaptic release however, their terminals contain specific enzymes that synthesize and transport neurotransmitters into presynaptic vesicles. At the postsynaptic membrane, distinct neurotransmitter receptors, adhesion and scaffolding proteins are localized. Excitatory synapses also contain an electron dense organelle called the postsynaptic density (PSD). The differential sorting of adhesion and scaffolding molecules to particular neuronal contacts is thought to modulate synaptic signaling. For instance, the adhesion molecule neuroligin1 is enriched at excitatory sites where it regulates recruitment of PSD-95, a major scaffolding molecule localized to excitatory synapses. In contrast neuroligin2, is enriched at inhibitory synapses and induces recruitment of gephyrin. This differential recruitment of proteins at particular synaptic sites is thought to gauge retrograde signaling at the synapse as well as clustering of neurotransmitter receptors and associated proteins. Coupling of adhesion and scaffolding molecules also provides an anchor to the cytoskeleton and controls synapse morphology. Based on findings reviewed in [4].

redundancy of signals present in the CNS for contact initiation and synapse maturation.

### Morphological and Structural Changes Associated with Synapse Maturation

During the recruitment of pre- and postsynaptic proteins to initial sites of contact, the content and morphology of pre- and postsynaptic membranes develop in a coordinated manner. Maturation of glutamatergic synaptic contacts, the most characterized synapses in the brain, involves the formation of spines, ►actin rich dendritic protrusions with a bulbous head [4]. Spines are thought to emerge from dendritic filopodia, long and thin protrusions which have been proposed to initiate contacts by actively seeking nearby axons [5]. Mature spines contain an electron dense organelle called the ►postsynaptic density (PSD) which contains receptors and associated scaffolding and signaling molecules which are thought to regulate ►glutamate receptor clustering and function at the synapse [5]. Several adhesion and scaffolding molecules that regulate spine morphology have been identified (Fig. 2). Adhesion complexes affecting spine morphology include: neuroligins, cadherins, integrin ligands (laminin and reelin), Eph receptors and syndecans as well as members of the immunoglobulin superfamily [6]. Scaffolding proteins affecting spine morphology include PSD-95, shank/homer complex and IRSp53. Overexpression studies in cultured neurons of PSD-95, neuroligin and IRSp53, two proteins that bind to PSD-95, increases the density of ►dendritic spines [6]. Another key molecule involved in spine morphogenesis is drebrin A as it promotes actin assembly and the synaptic clustering of PSD-95 in the ►PSD [7]. Interestingly, overexpression of drebrin A, shank/homer complex or syndecan can accelerate the maturation of filopodia-like protrusions into mature spines [6]. Furthermore, blocking N-cadherin function results in loss of spines and appearance of filopodia-like protrusions. Finally, integrin ligands have been shown to affect dendritic spines: laminin increases spine density whereas reelin promotes spine stability [2].

Clustering of neurotransmitter receptors and associated proteins at newly formed contact sites is critical for synapse maturation. Most of our knowledge of the importance of molecules in the control of receptor clustering and function has emerged from the discovery of scaffolding proteins associated with ►glutamate receptors. These studies revealed that scaffold proteins function to bind and recruit other proteins that regulate actin cytoskeleton remodeling and signal transduction. This links neurotransmitter receptor activation to intracellular cytoskeletal and signaling modification. An important family of molecules that participates in this process is the scaffolding proteins that regulate clustering and assembly of neurotransmitter receptors as well as proteins that regulate actin cytoskeleton remodeling and signal transduction [6]. The membrane-associated guanylate kinase (MAGUK) family of scaffolding proteins is of central importance in regulation of protein clustering at the synapse. Many MAGUKS contain PDZ domains which function in protein-protein interactions. The prototypical MAGUK is PSD-95 which binds directly to N-methyl-D-aspartate-type (►NMDA) glutamate receptor subunits and voltage-gated potassium channels and indirectly to α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (►AMPA) type glutamate receptors [8] (Figs. 2 and 3). Overexpression of PSD-95 enhances maturation of presynaptic terminals and increases spine size. Consistent with this, knockdown of PSD-95 results in reduced clustering of AMPA receptors (AMPARs), GKAP and Shank and an overall decrease in the number of excitatory contacts [9]. Despite the striking effects of PSD-95 on synapse maturation of cultured neurons, the majority of excitatory synapses in PSD-95 knockout animals display normal synapse number and size [9]. This result could be explained by a redundancy in the function of the numerous PDZ proteins located at the synapse. AMPARs are directly linked to two other scaffolding proteins glutamate-receptor-interacting protein/AMPAR-binding protein (►GRIP/ABP) and protein interacting with C kinase 1 (PICK1) and these interactions may regulate synaptic targeting and trafficking of AMPARs [8] (Fig. 2). GRIP is localized to both axons and dendrites in neurons and functions to stabilize AMPARs and other interacting proteins at synaptic sites. PICK1 is present at synaptic and non-synaptic sites in neurons and may function to direct AMPARs to endocytic or exocytic buds through BAR domain binding, which is a sensor for lipid membrane curvature (Fig. 2). Phosphorylation of the C terminus of GluR2 alters its binding specificity for GRIP and PICK1, and contributes to synaptic plasticity by altering AMPAR trafficking [8].

In contrast, the majority of inhibitory transmission in the mammalian CNS is mediated by ►GABA, a neurotransmitter responsible for modulation of neuronal excitability and function [2]. GABAergic synapses are not associated with a clear PSD and are usually found on the dendritic shaft [4,5]. Thus, excitatory and inhibitory synapses can be distinguished based on morphology and molecular composition of the postsynaptic component [2] (Fig. 3).

The last step in synapse development involves fine-tuning of neuronal circuits such that the formed synapses may be stabilized or lost [2]. Recent studies suggest that neuronal activity plays a role in fine-tuning the number of contacts formed, ultimately leading to

stabilization of a particular subset of contacts which persists in the adult nervous system [3]. In the adult brain, changes in synaptic content, shape and their adhesive properties are thought to be the key mechanisms that control synaptic strength and plasticity, processes implicated in the regulation of information storage and transfer between neuronal cells. Thus, the continual formation and remodeling of synaptic contacts in early development and adulthood, respectively, play a key role in refining neuronal circuitry and communication between neuronal cells.

### Abnormalities in Synapse Development Associated with Neurodevelopmental Disorders

Recent studies indicate that improper synapse formation may be a leading cause of neurodevelopmental disorders such as ►autism, mental retardation, and schizophrenia [10]. Autism is the most genetically determined disorder manifested at early stages of postnatal development [10]. Thus, the behavioral and cognitive deficits exhibited in autistic patients are thought to result from improper development of neuronal circuitry implicated in sensory, mnemonic, social and emotional information processing [10]. Interestingly, neuroimaging studies of aberrant circuitry in autistic patients has lead to a model whereby altered excitation (E)/inhibition (I) ratio involved in information processing may underlie the dysfunctions in patients with autism [3]. During brain development, alteration in the E/I ratio can lead to abnormal synaptic connectivity and function, resulting in severe neurological impairments. As mentioned earlier, neuroligins are important proteins for controlling the function of excitatory and inhibitory synapses, making them good candidate genes affected in autism. Indeed, rearrangement of chromosomal regions of neuroligins and PSD-95 genes and mutations in neuroligins and neurexins have been associated with autism [10]. In addition, mutations in the adhesion molecule NrCam and the scaffolding protein Shank3 have been linked to autism, however, the underlying biological mechanism(s) associated with altered expression of these proteins remains unclear [6]. Many forms of mental retardation and memory impairment also have been also linked to defects in spine maturation [5]. Thus, emerging evidence indicates that defects in synapse formation/maturation may be a common defect associated with several neurodevelopmental disorders.

### Acknowledgments

The author, Pamela Arstikaitis, would like to dedicate this article to the memory of the supervisor, Dr. Alaa El-Husseini who recently passed away. Alaa was a brilliant scientist whose love and passion for science was contagious as he touched numerous people with his energy and aspirations.

### Definition

Synaptic adhesion molecules are a diverse family of cell adhesion molecules involved in the development and maintenance of synapses [1–4].

Synaptic adhesion molecules are localized transiently or permanently at mature synapses and/or developing precursors, and in most cases, they are highly enriched in the synaptic membranes. They may directly participate in adhesion by connecting pre- and postsynaptic membranes together, or adhesion may not be their primary function, but the specific ligand-receptor recognitions transmit signals to the cytoplasm. They may be involved in one or multiple steps in synapse development and maintenance: specific target recognition, synaptic differentiation, and stabilization and modulation of synaptic structure (see Function). As brain function relies on specificity of synaptic connectivity among different classes of neurons as well as regulation of synaptic connections, these molecules must play pivotal roles in the development and maintenance of lower and higher brain functions. Impairment of synaptic adhesion molecules is likely to affect brain functions (see Pathology).

### Characteristics

#### Higher Level Structures

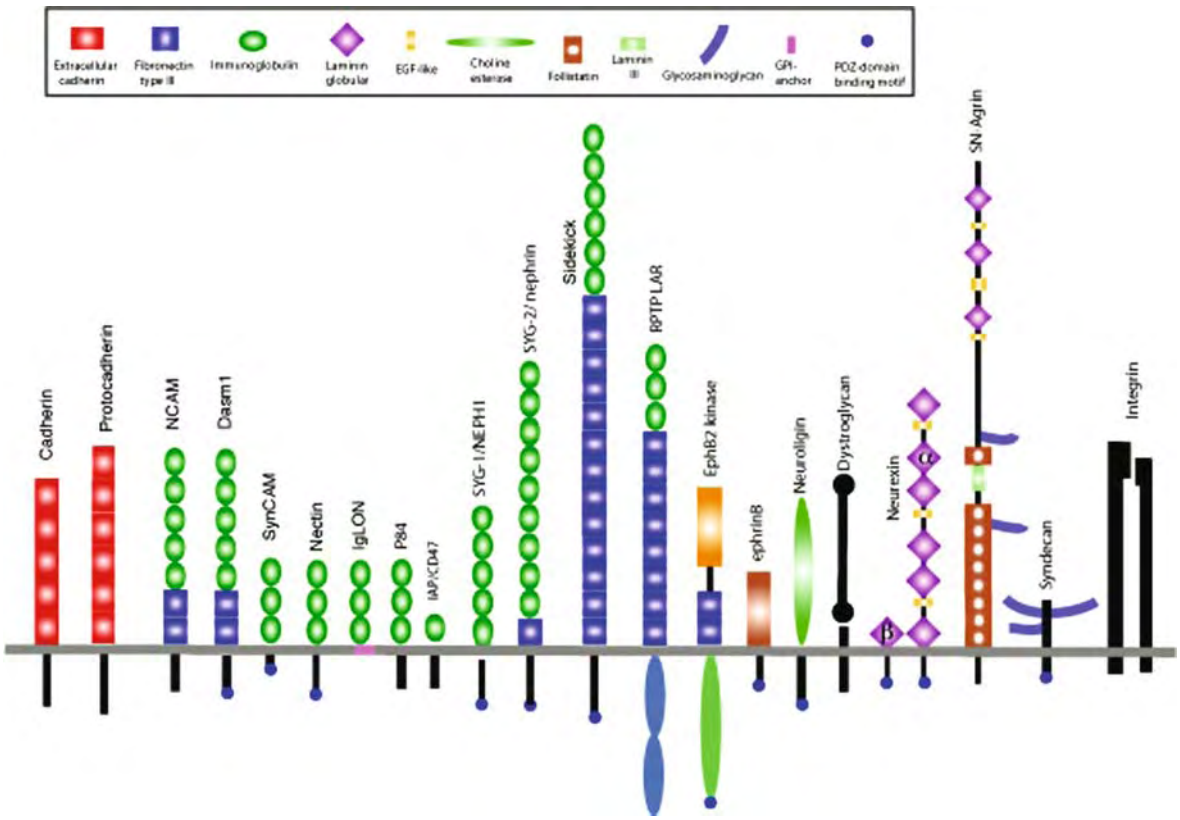
The term "synapse (synaptein)," first coined in 1897 by Charles Sherrington, comes from the Greek: "syn" meaning "together," and "haptein" meaning "to fasten or bind." As this etymology indicates, two neuronal membranes at synapses close together with a narrow space (~20 nm) between them: synapses are specialized forms of cell-cell junctions. A principal difference between synapses and other junctions is that synapses are asymmetric between presynaptic and postsynaptic structures. The presynaptic specialization, usually on the axon, has an apparatus for neurotransmitter storage and release (the synaptic vesicle and active zone). The postsynaptic specialization, usually on dendrites, has neurotransmitter receptors, and associated scaffolding and signaling proteins (the postsynaptic density).

There are two types of adhesive structures at synapses: puncta adherentia and synaptic junctions [5]. Synaptic junctions are the sites of neurotransmission, whereas puncta adherentia are formed at the surrounding area outside of the active zone. The puncta adherentia are a neuronal form of ►adherence junctions that are maintained by cadherins. The occurrence of these adhesive structures and synaptic adhesion molecules varies depending on which synapse or stage of development is observed.

#### Lower Level Components

Many of the synaptic adhesion molecules are members of the cadherin and immunoglobulin superfamilies [2,3] (Fig. 1).

Another major family of adhesion molecules, the integrins, is also present at synapses, together with members of families that are adhesive but are not generally considered as adhesion molecules- e.g. the Eph receptor



**Synaptic Adhesion Molecule. Figure 1** Synaptic adhesion molecules.

kinases and their ephrin ligands, and neurexins and their partners, the neuroligins.

Classic cadherins are $Ca^{2+}$-dependent, single-pass transmembrane molecules with five extracellular cadherin (EC) repeats, which mediate primarily homophilic (more rarely heterophilic) adhesion. N-cadherin was one of the first adhesion molecules shown to be localized at the synaptic cleft. Cadherins directly couple to cytoskeletons via intracellular proteins called catenins, and generate puncta adherentia at synapses.

The protocadherins bear varying numbers of EC repeats in their ectodomains. The vertebrate protocadherin genes have a genomic organization that is similar to that of the immunoglobulin gene, and which consists of "variable" and "constant" exons orientated in a tandem array on a single chromosome. This striking genomic organization led to (as yet unproven) postulation that protocadherin diversity underlies synaptic specificity. Indeed, some members are concentrated at synapses, albeit not confined to them.

The immunoglobulin (Ig) superfamily represents a highly diversified group of cell surface molecules responsible for a wide range of molecular and cellular recognition functions. They contain varying numbers of extracellular cysteine-looped domains that are characteristic of antibody molecules. Many have one or more fibronectin type III (FNIII) repeats between the Ig domains and the membrane. This superfamily can be further classified according to occurrence of other domains. Synaptic adhesion molecules belonging to this superfamily are N-CAM, Dasm1, nectins, SynCAMs, IgLONs, Syg-1, Syg-2, sidekicks, and LAR. A striking feature of most, if not all, synaptic adhesion molecules of this family is that they possess a C-terminus motif for binding PDZ scaffolding proteins that likely contribute to their synaptic localization.

Integrins are heterodimers of α and β subunits, and mediate adhesion of cells to the extracellular matrix and to other cells. Integrins are present at the vertebrate neuromuscular junction, where they presumably interact with the basal lamina. Several integrins have also been observed at vertebrate central nervous system synapses.

Eph receptor tyrosine kinases and their ephrin ligands can be grouped into two families: ephrinA ligands are attached to the membrane by a glycosylphosphatidylinositol-anchor and bind to EphA receptors, while ephrinB ligands are transmembrane proteins that bind to EphB receptors. EphB receptors have been localized to the synapse.

Neuroligins constitute of a family of neuronal cell-surface proteins with a cholinesterase domain that lacks enzymatic activity. Neuroligins bind to β-neurexins,

another class of neuronal cell-surface proteins that contain laminin globular domains. There are three neurexins, which undergo extensive alternative splicing to potentially express a bewildering number of isoforms. Both neurexins and neuroligins have a motif for binding to PDZ scaffolding proteins, and are enriched at the synapse.

In addition to these adhesion molecules, several transmembrane molecules have been reported to be localized at synapses. These include syndecans, dystroglycan, and membrane-tethered agrin. Leucine-rich repeats-containing transmembrane molecules including the *capricious* protein were accumulated at some Drosophila neuromuscular junctions.

## Function

### Specific Target Recognition

Specific connectivity among a myriad of neurons is the hallmark of the nervous system. Following differentiation and migration, a developing neuron reaches its final destination in the nervous system. To establish neuronal connections with its target, a neuron must extend axonal and dendritic processes towards the proximity of targets located significant distances away, and finally select the choice of proper partner neurons with which to form specific synapses in a jungle of neuronal processes. Presynaptic inputs from defined neurons are not only connected to specific types of postsynaptic neurons, but are often synapsed to restricted subcellular compartments such as spines vs. shafts or dendrites vs. soma. To explain the mechanism that underlies synaptic specificity in neural circuit formation, Roger Sperry formulated the "chemoaffinity theory," in which adhesion molecules determine wiring specificity of the "lock and key" sort. Many examples of receptor-ligand partners are known that guide growth of axons towards their approximate target areas. However, there must also be molecular and cellular mechanisms that mediate the interaction between direct synaptic partners and initiate synapse formation.

Recent studies on an array of Ig superfamily molecules have shown that this group of adhesion molecules is important for the synaptic specificity. For example, SYG-1 and SYG-2 were isolated in a genetic screen for *C. elegans* mutants with altered synaptic positions. SYG-1 and SYG-2 belong to a subgroup of the Ig protein family that is conserved from *C. elegans* to human [6]. Sidekicks have been implicated in selective synapse formation in the chick retina. A shared feature of SYG-1, SYG-2, and sidekicks is a motif for binding to PDZ-scaffolding proteins, suggesting a model in which adhesion-triggered recruiting of key PDZ proteins is a first step in precise synaptic wiring. Neurofascin is an L1-related Ig superfamily molecule, and its ankyrin-dependent subcellular localization determines subcellular localization of GABAergic synapses in the cerebellum.

### Synaptic Differentiation

Synapse formation involves stabilization of initial sites of weak adhesion between axons and targets, followed by recruitment of specific protein complexes to newly formed presynaptic and postsynaptic structures [4,7,8]. Axons can usually release small amounts of neurotransmitter even before they contact a postsynaptic partner, and many postsynaptic cells express neurotransmitter receptors before they are innervated. Once pre- and postsynaptic processes establish contact, the machineries for release of and response to neurotransmitter are concentrated at sites of contact, and placed in precise apposition to each other. Important features of presynaptic differentiation include aggregation of appropriate synaptic vesicles and association with active zones; critical features of postsynaptic differentiation include clustering of specific postsynaptic receptors and association with signaling and scaffolding proteins. There is also a high degree of variation in synaptic neurochemistry and morphology- e.g. excitatory, inhibitory, asymmetric, symmetric, ribbon, en passant, and terminal. The fact that these specializations develop specifically at contact sites, and that they develop in exact apposition, demonstrate that adhesion-mediated local signaling must provide the coordination between the target neuron and the innervating axon.

The synaptic adhesion molecule neuroligin-1 was the first target-derived signal shown to induce presynaptic differentiation of excitatory synapses in hippocampal axons [2]. This differentiation is mediated by neuroligin interaction with β-neurexin. More recently, it has been revealed that this interaction mediates both glutamatergic and GABAergic synapse formation in hippocampal neurons, and differences in neuroligin isoform and binding specificity may control the formation and functional balance of excitatory and inhibitory synapses. SynCAM1 is the other membrane protein shown to provide a target-derived signal during synaptic differentiation [8]. SynCAM1 belongs to a family of proteins characterized by three extracellular immunoglobulin-like domains and a cytosolic tail with a PDZ-binding motif. SynCAM and neuroligin-1-induced artificial synapses were essentially identical, but it appears that neuroligin-1 contributes to more morphological aspect of synapse induction.

A panoply of synaptic adhesion molecules were also shown to control localization and function of postsynaptic neurotransmitter receptors. The EphB receptor tyrosine kinases and their ligands, the ephrinsB regulate function of a NMDA type glutamate receptor. The receptor-type protein tyrosine phosphatase LAR is an Ig superfamily that is important for the surface expression and clustering of AMPA-type glutamate receptors at synaptic sites. In the developing brain, excitatory synapses initially contain only NMDA receptor and therefore are "silent" at the resting membrane potential.

However, later, synapses acquire AMPA receptors. Dendrite arborization and synapse maturation 1 (Dasm1), the Ig superfamily member, appears to control this excitatory synapse maturation [9].

### *Stabilization and Regulation of Synaptic Structure*

At all the intracellular junctions, adhesion molecules connect two membranes, and stabilize the architecture of the junction. Likewise, synaptic adhesion molecules protect synapses by adhering pre- and postsynaptic membranes. Stability of interneuronal synaptic membranes from mechanical force is obvious from the ability to isolate intact synaptosomes. The fact that synaptic adhesion molecules stabilize synaptic structure indicates that strengthening and weakening of adhesion could regulate synaptic structure. Such a function would be of importance to synaptic plasticity, which is believed to involve changes in synaptic density and size, to synapse maturation, which requires the organized enlargement of presynaptic boutons and postsynaptic structures, and to synapse elimination, which is de-adhesion of two synaptic membranes. These synaptic remodeling events are likely to contribute to one of the mechanisms that underlie learning and memory.

The majority of excitatory synapses in the brain are made onto dendritic spines, knobby protrusions of the dendritic shaft. Dendritic spines are highly dynamic, and undergo a variety of actin cytoskeleton-based morphological changes both during synapse formation, and in response to activity changes. It is believed that changes in dendritic spine number and morphology reflect synaptic plasticity, particularly changes in synaptic connections between neurons. Several studies have shown that a cadherin-catenin adhesion system controls spine structure in cultured hippocampal neurons [10]. N-cadherin localization and adhesive strength change in response to neural activity. These observations suggest that synaptic activity dynamically regulates both the strength and the localization of cadherin-based adhesions, changes that may be important for regulating synaptic plasticity.

## Pathology

As synaptic adhesion molecules regulate synaptic development and maintenance, their dysfunction may cause synaptic deficits that ultimately underlie disorders ranging from neurodevelopmental syndromes to neurodegenerative disorders. Autism is a neurodevelopmental syndrome that affects an estimated 2–6 per 1,000 individuals. It has been hypothesized that changes in neuronal circuitry and synaptic signaling are responsible for the behavioral and cognitive aberrations in autistic patients. Point mutations in neuroligins have been linked to a small subset of patients with autism-spectrum disorders. Cognitive decline characterizes mental retardation syndromes such as Cri-du-Chat and neurodegenerative disorders, such as Alzheimer's disease. Involvement of cadherin-mediated adhesion in cognitive decline has been suggested by cognitive dysfunction in δ-catenin-deficient mice, and cleavage of N-cadherin by presenilin 1-dependent γ-secretase protease. Mutations in the nectin-1 gene cause cleft lip/palate ectodermal dysplasia, frequently associated with mental retardation.

Impaired development and plasticity of synapses could also underlie the synaptic pathology of schizophrenia. However, more research is needed on which and how synaptic adhesion molecules contribute to etiology of this psychiatric disease.

# Synaptic Competition

## Definition

A mechanism for synaptic refinement, in which less heavily used synapses are eliminated.

►Activity-Dependent Synaptic Plasticity

## Synaptic Convergence

### Definition

The projection of multiple neurons onto a single target neuron. Synaptic convergence makes it possible for the target neuron to integrate across many synaptic inputs.

## Synaptic Depression

### Definition

The reduction in postsynaptic response to presynaptic release of neurotransmitter that occurs during trains of stimuli. At the neuromuscular junction, the cause of synaptic depression is thought to be a reduction in release of acetylcholine following each stimulus. At other synapses, there may also be a postsynaptic contribution.

►Acetylcholine
►Neuromuscular Junction

## Synaptic Elimination

Yoshio Hata
Division of Integrative Bioscience, Tottori University Graduate School of Medical Sciences, Yonago, Japan

### Synonyms

Synapse loss

### Definition

Synaptic elimination is a process of brain development that reduces the number of synaptic contacts. The process is important for the formation of precise neural circuitry, which is necessary for proper brain functions. Synaptic contacts are generated in excess during the early phase of development. In subsequent stages, the redundant synapses are eliminated while the proper ones are strengthened to construct specific neural connections. Synapse elimination takes place in various neural tissues including cerebral cortex, cerebellum and ►neuromuscular junctions, and is supposed to be a general mechanism of the development of neural circuitry. The process of elimination is often regulated by neural activity so that active synapses are strengthened, whereas the inactive ones are weakened and ultimately eliminated.

### Characteristics

#### Quantitative Description

The brain is not mature at birth and significant developmental events take place postnatally. During postnatal development, there is a period (►critical period) of exuberant synapse formation followed by a period of synaptic "pruning" in the brain. The developmental profile of synapse number and density (number of synapses per unit volume) has been examined in various mammalian species including human.

In the primary visual cortex of monkey, synapse density increases rapidly around birth [1]. This period of ►synaptogenesis begins two months before birth, and the synaptic density reaches approximately the same level as that in adults. The rapid synaptogenesis continues for another two to three months after birth when the synaptic density reaches its maximum (about 90 synapses/100 $\mu m^3$). The synapse density is maintained at this high level during the next two years. At puberty, however, synapse elimination begins and the synapse density rapidly decreases to the adult level (40–50 synapses/100 $\mu m^3$) by five postnatal years. The postnatal development of synapse density reveals a similar profile, high synapse density during adolescence and lower density in maturity, in other cortical areas such as somatosensory, motor and limbic areas [2]. While the rapid synaptogenesis takes place concurrently in different cortical areas, the synapse elimination appears to begin earlier in the visual and somatosensory cortex than in the prefrontal cortex. However, the period of synapse elimination largely overlap with each other among cortical areas, and reach the adult level at the time of sexual maturity.

The development of cortical synapses follows a similar time course in the human brain. In human visual cortex, the synapse density shows a rapid increase at around two months of age and reaches the maximum at 8–10 months [3]. The synapse density then declines to the adult level at around ten years of age. In the frontal cortex, however, the beginning of synapse formation is delayed, and the synapse density gets to the maximum value at around two years of age. The high synapse density remains until eight years of age, and then slowly declines to the adult level at around 16 years. Thus, the rapid synaptogenesis and the following synapse elimination might take place at different times in different cortical areas in human [4].

The synapse elimination is regulated by experience-dependent mechanisms. If monkeys are raised without visual inputs by removing both eyes in utero, the

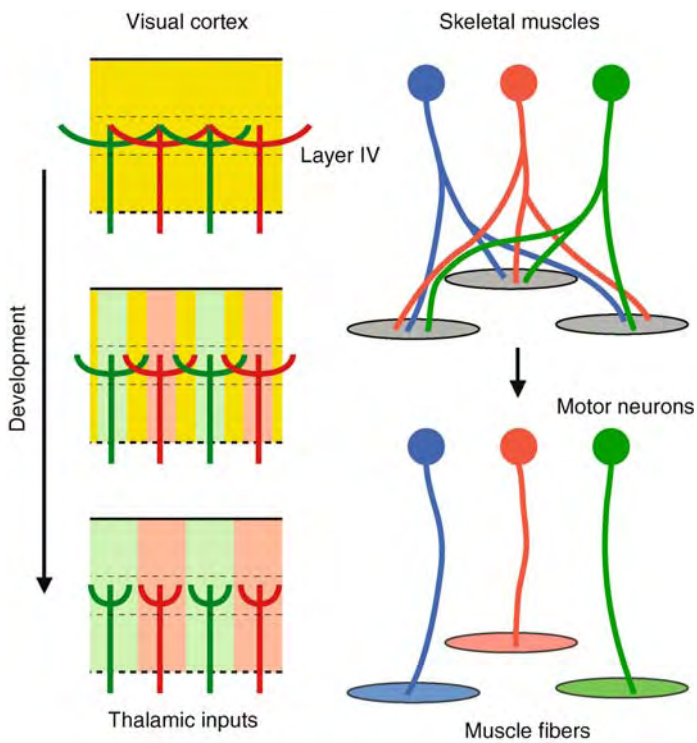
decrease of a class of synapses in the visual cortex does not take place [5]. Furthermore, visual deprivation in one eye of developing animals leads to a strong suppression of cortical response to the deprived eye, and ultimately to the selective pruning of the input axons carrying information from the deprived eye [6].

## Higher Level Processes

The elimination of redundant synapses is an important step for the construction of specific neural circuitry in the mature brain. Early formed neural connections tend to include aberrant projections. During development, the synapses made by such aberrant axons should be eliminated and the axon should finally retract. For example, refinement of neural connections by elimination of redundant synapses is well documented in skeletal muscles and autonomic ganglia [7]. Early in development, each muscle fiber and ganglionic neuron is innervated by multiple input axons from motor neurons and preganglionic neurons, respectively (Fig. 1, right).

Thereafter, all but one input axon innervating the same target lose their synaptic contacts and retract, so that each muscle fiber and ganglionic neuron is innervated by a single axon in the adult. Although the synapses made with the inappropriate axons would disappear, the appropriate axons that will innervate the target in maturity grow in size and complexity to make more synaptic contacts. Thus, the development of neural networks is not a simple formation or elimination of synapses, but the redistribution of synapses so that each axon can focus its contacts to the appropriate targets.

A similar process also operates in the central nervous system. Input axons carrying information from each eye distribute separately in the primary visual cortex of higher mammals including cats, monkeys and humans [8] (Fig. 1, left). In young animals, however, the input axons from two eyes widely spread over the visual cortex and overlap with each other. The input axons gradually retract from inappropriate cortical territory and obtain the adult-like segregated distribution. In the cerebellum of newborn animals, the Purkinje cells are innervated by multiple climbing fibers that originate in the inferior olive [9]. During development, redundant climbing fibers are eliminated and single fibers innervate each Purkinje cell.



**Synaptic Elimination. Figure 1** Schematic representation of the rearrangement of neural connections during postnatal development. In the primary visual cortex (*left*), the ascending axons from the lateral geniculate nucleus provide inputs to cortical layer IV. The axons from two eyes (red and green, respectively) initially overlap and gradually segregate to occupy different cortical regions. The muscle fibers are innervated by multiple motor neurons at birth (*right*). The input axons lose their synaptic contacts to the inappropriate targets and project to single muscle fibers in the adult.

## Process Regulation

The synapse elimination is largely regulated by mechanisms depending on neural activity. The developmental refinements of neural circuitry in various brain areas show that the competition between inputs plays an important role in determining which synapse should be eliminated (►activity-dependent synaptic competition).

The direct observation of the process of synapse elimination in neuromuscular junctions offers a great deal of insight into the mechanisms of the process [7]. In the mouse neck, each muscle fiber receives axonal innervations from several motor neurons at birth. The number of innervations reduces in the following two weeks and each muscle fiber begins to receive single input. Before the withdrawal of redundant axon terminals, synapses on them reveal a functional weakening. Synaptic potentials recorded in the developing muscle fibers show that each of the multiple inputs has strong synaptic effects, enough to cause muscle contraction at birth, and the strength of each synaptic input is often indistinguishable from each other. Therefore, it is difficult to predict which input would subsequently monopolize the fiber. The input that is going to be eliminated ultimately becomes gradually weaker before any sign of retraction could be observed in the presynaptic terminals. The weakening of synaptic potentials is caused by a reduction in neurotransmitter release and by a reduction in postsynaptic receptor density. The physiological synapse elimination is followed by axonal withdrawal of weak inputs.

Synaptic interactions play a key role in determining which input should be eliminated. If neural activity of motor neuron axons is blocked pharmacologically, redundant axons do not retract and ►multiple innervations persist. Suppression of synaptic interactions at the neuromuscular junctions by blocking acetylcholine (ACh) receptors also prevents the input elimination. Thus, neural activity and the following synaptic interactions are necessary for the synapse rearrangements (►activity-dependent synaptic rearrangement). In addition, if a small part of a single neuromuscular junction, which is innervated by one axon, is functionally blocked by applying an irreversible blocker of the postsynaptic ACh receptors, the ACh receptors gradually disappear only in the blocked region. Subsequently, the axon terminals innervating the blocked region withdraw as observed in natural development. On the other hand, blocking ACh receptors in the entire area of a single neuromuscular junction does not induce synapse elimination. Thus, synapse inactivation can lead to elimination of the synapse only when the other synapses are active, suggesting that local imbalance of input strength is an important factor to initiate synapse elimination. The synaptic interactions at active synapses might generate suppressive signals in the postsynaptic cells that can destabilize inactive synapses in the surrounding region, together with supportive signals that maintain the activated synapse. Although the molecular machinery of such intercellular signaling is yet to be characterized, several protein kinases and phosphatases might be involved in the process. For example, in mutant mice in which protein kinase C (PKC)-gamma is genetically inactivated, the elimination of multiple innervations of cerebellar Purkinje cells by climbing fibers, as mentioned above, is markedly prevented [10]. Thus, the activity of PKC is essential for normal elimination of redundant climbing fibers.

The relative strength of inputs also guides the rearrangement of input axons in the visual system [8]. Blocking visual inputs from one eye induces a strong suppression of the cortical responses to the eye, followed by a significant retraction of input axons serving the eye. If the visual inputs from both eyes are blocked, however, the suppression of cortical responses is limited and the input axons are maintained.

## Pathology

Abnormal synapse elimination prevents the construction of normal neural circuitry and is supposed to underlie various psychiatric disorders, such as fragile X syndrome and schizophrenia.

# Synaptic Excitability

## Definition

Related to the responsiveness of a neuron to excitatory input.

# Synaptic Inputs

## Definition

The contacts between neurons are called synapses. Any given neuron can receive input from just a few to over 100,000 other neurons. The synaptic inputs can be excitatory, meaning that they are likely to make the cell produce action potentials, or they can be inhibitory, meaning that they are likely to stop the cell from producing action potentials. Synaptic inputs interact with the electrical excitability of neurons to process neural information and generate output action potentials.

## Synonyms

Dendritic integration; Single neuron computation

## Definition

Neurons in the central nervous system receive many thousands of synaptic inputs, integrate them, and give off outputs in the form of nerve impulses. The process of determining outputs from the inputs is called ►synaptic integration. Since most of the synaptic contacts are made on the dendritic arborization, and the nerve impulses are generated at the initial segment of the axon near the cell body, the most important part of the integration takes place at the dendrites, and hence is referred to as ►dendritic integration [1]. Some of the integration takes place at ►presynaptic terminals where transmitter release is regulated by inputs from other sources. In addition to synaptic interactions, neurons and glial cells interact with each other via non-synaptic mechanisms such as ►volume transmission [2] or ►ephaptic interaction. All of these processes and mechanisms are involved in the integration of information in the neural cell assembly. Further, the process of synaptic integration is not stereotypical but, over various lengths of time, undergoes plastic changes that are referred to as ►synaptic plasticity. Some forms of synaptic plasticity, the short-term plasticity, such as ►paired pulse facilitation, take place while incoming information is being processed, and thus can be regarded as part of the integration processes.

## Characteristics

### Dendritic Integration

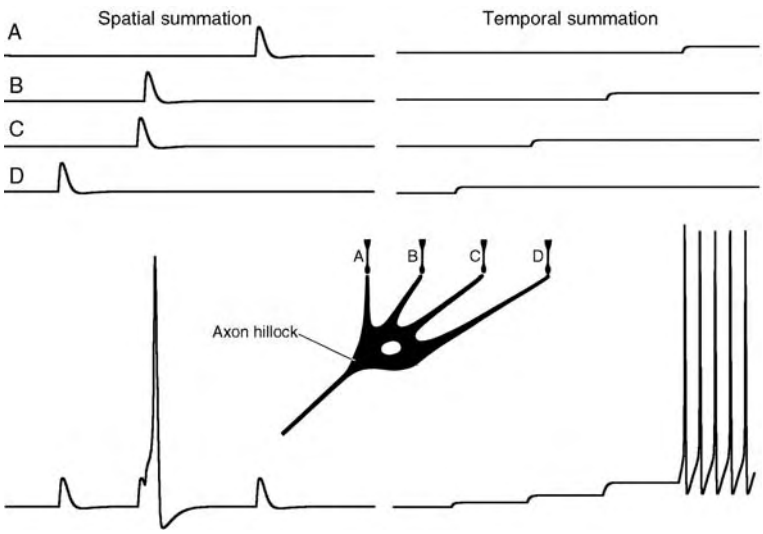
Most of the synaptic contacts are made on dendritic processes, where there are special structures called postsynaptic density apposing presynaptic terminals. Binding of transmitters released from the presynaptic terminals to the receptors located at the postsynaptic density generates postsynaptic potentials. The postsynaptic potentials spread along the dendrites to the cell body and to the initial segment of the axon. In the course of the spread, the potentials are distorted depending upon the electrical properties of the dendrites. If the ►summation of the distorted postsynaptic potentials provides sufficient depolarization, nerve impulses are generated at spike initiation zones somewhere along the dendrite-soma-axon axis, most probably near the initial segment, and will be sent out as outputs.

#### *Synaptic Summation: Spatial and Temporal Summation*

There are two basic modes of summation, ►temporal summation and ►spatial summation. Summation of postsynaptic potentials with a fast decay time can be significant only when the inputs coincide in time. This kind of summation happens when synaptic inputs arrive at spatially separate synaptic sites, and is called spatial summation. Neurons that summate inputs with this manner are called coincidence-detectors. Postsynaptic potentials with a slow decay time can summate over time, even when inputs arrive with some delay. This kind of summation is called temporal summation, and the neurons that show temporal summation are called integrate-and-fire units (Fig. 1).

#### *Synaptic Summation: Non-linear Summation*

Summation of postsynaptic potential is generally non-linear for several reasons. One reason is that a large change in membrane potential induced by one input can reduce the driving force for the synaptic current for the second input. Another reason is that an increase of membrane conductance induced by one input can shunt the postsynaptic current of the second input. For instance, GABA mediated transmissions usually result



**Synaptic Integration. Figure 1** Spatial summation and temporal summation. Two modes of synaptic summation, when four synaptic inputs (A–D) arrive at four separate locations of a neuron with brief intervals. Spatial summation (left): Summation of postsynaptic potentials with a fast decay time can be significant only when they coincide in time. Temporal summation (right): Postsynaptic potentials with a slow decay time can be summated overtime.

in a small change in membrane potential, usually hyperpolarizing, but can inhibit the response for the second input because the postsynaptic current due to the second input flow through the GABA receptor channel without charging the membrane. This type of inhibition is called ►shunting inhibition.

### *Spread of Postsynaptic Potential in Passive Dendrites*

One of the characteristic features of neurons is that they have rich dendritic arborizations. Due to this, the neurons are not isopotential, and postsynaptic potentials will be distorted as they spread from the input location to other locations along the dendrites. The conceptual basis of our understanding, concerning the manner by which postsynaptic potential spreads along the dendrite, was established by W. Rall and his colleagues through theoretical and modeling studies [3]. According to their pioneering works, in which cable theory was applied by assuming that the dendrites can be lumped to a simple cable, the important factors that determine the spread of potential are the passive properties of the dendrites, such as the diameter, membrane resistivity and cytoplasmic resistivity. They predicted that the amplitude of postsynaptic potentials decay significantly as they spread from the input site towards the cell body or the initial segment. The longer the dendrites, the greater the decay. They also predicted that the dendrites behave as frequency filters that curtail fast component. These predictions have been shown to be the case experimentally by performing multiple electrical recordings from single neurons [4] (Fig. 2).

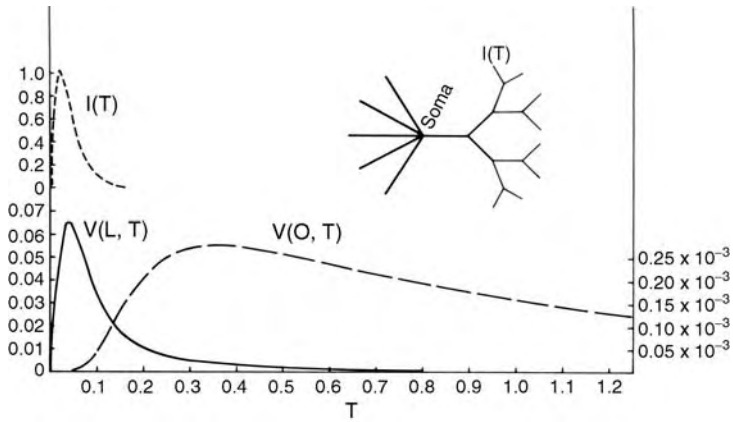
The extent of shunting inhibition depends on the locations of synaptic contacts. For instance, a GABA mediated inhibitory input made on the distal end of a dendrite would not strongly inhibit a glutamate mediated excitatory input made near the cell body, whereas a GABA mediated input made on the cell body or on the initial segment can prevent the cell from generating an outgoing impulse, no matter how many excitatory inputs the cell receives (Fig. 3).

### *Roles of Active Membrane Properties on Dendritic Integration*

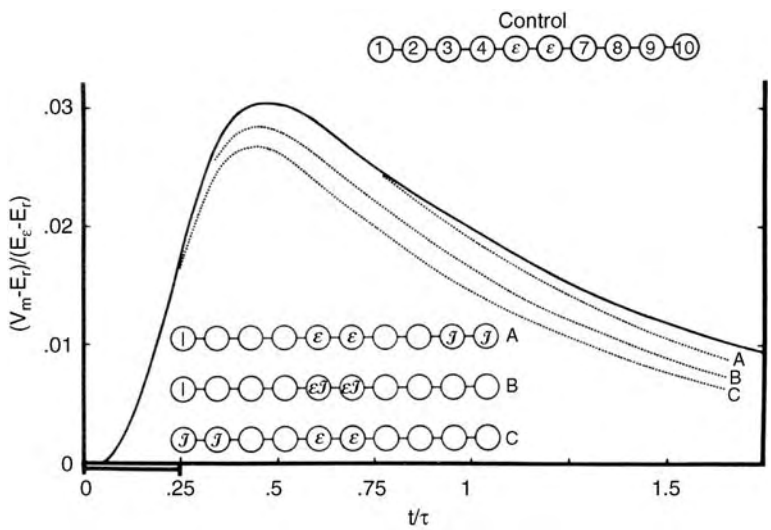
Despite early studies showing active properties of dendrites, it has long been the common understanding that the dendrites are electrically passive structures providing nothing but an area for synaptic contacts. Recently, however, it has become well recognized that various types of voltage-gated ion channels with different ion selectivities, voltage sensitivities, kinetics and density distributions are distributed along the dendritic membrane [5]. These channels endow the dendritic membrane with complex characteristic features that may have strong impacts on dendritic integration.

#### *Low Voltage-Activated Ion Channels*

Some types of ion channels distributed along the dendrites, such as A-type K channels and T-type Ca channels are low-voltage activated, show rapid inactivation, and can be activated or inactivated by small changes in membrane potential near the resting potential. There are some other types of ion channels, such as Ih channels, that can be activated by hyperpolarizing the membrane potential below resting potential. These low voltage activated channels may



**Synaptic Integration. Figure 2** Distortion of postsynaptic potentials computed voltage time course at the input receiving branch terminal (solid curve) and at the soma (lower dashed curve) for an injected current $I(T)$ (upper dashed curve) are shown. The soma response $V(0,T)$ (scale at left) is much smaller and slower than the response at the input site $V(L,T)$ (scale at the right). The neuron model is shown on the upper right (adapted from Rall W, Rinzel J (1973) Biophys J 13:648–688).

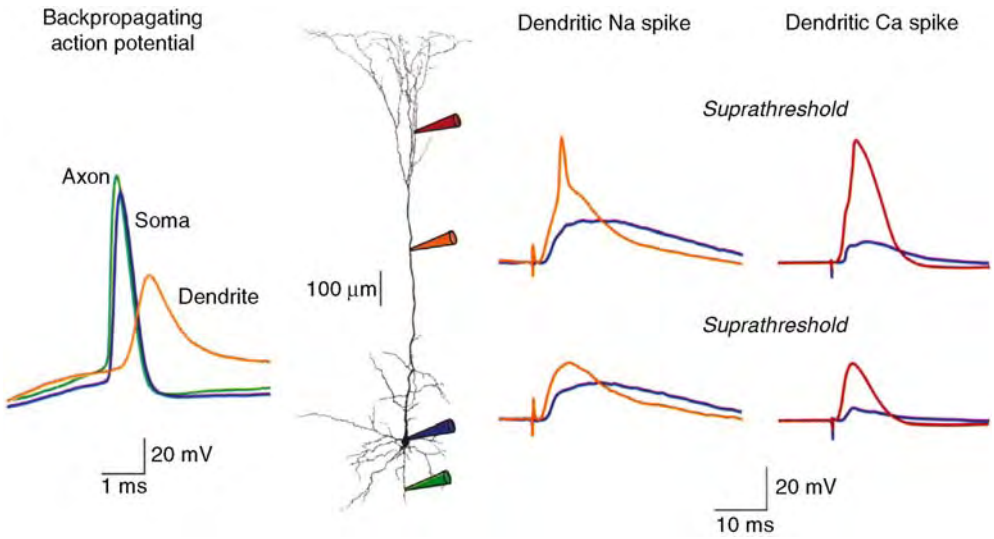


**Synaptic Integration. Figure 3** Effect of inhibitory-conductance location upon transient soma-membrane depolarization. The continuous curve represents the uninhibited "control" transient in compartment 1 for an excitatory input ($\mathcal{E}$) at compartments 5 and 6. The dotted curves show the inhibitory effect of having $\mathcal{J}$ in compartments throughout the time (adapted from Rall W (1964) In: Reiss RF (ed) Neural theory and modeling. Stanford University Press, Stanford, CA).

distort postsynaptic potential by boosting or dampening membrane potential changes.

### *Dendritic Action Potentials*

Dendritic membranes of many types of neurons in the central nervous system are excitable. Cortical and hippocampal pyramidal neurons generate Na dependent fast action potential, which can propagate along the dendrites. The direction could be either forward (from the dendrites toward the cell body) or backward (from the some toward dendrites) depending on the situations [6]. Pyramidal neurons and cerebellar Purkinje neurons generate Ca dependent slow action potential in their dendrites. Although it has been shown that these dendritic action potentials can be triggered by synaptic inputs, their functional roles are not yet well understood. One possible role is that these potentials may be important in determining the pattern of the output in the form of axonal impulses. Postsynaptic potentials generated by local synaptic inputs, which are not large enough to initiate action potentials at the initial segment, might trigger dendritic action potentials that



**Synaptic Integration. Figure 4** Dendritic Excitability. Recordings are from neocortical layer 5 pyramidal neurons. Left: An action potential evoked by distal synaptic input recorded simultaneously from the axon, soma, and the apical dendrite 300 µm from the soma. Right: Generation of dendritic Na and Ca spikes. Recordings are made simultaneously from the soma and the dendrite (adapted from Hausser M, Spruston N, Stuart GJ (2000) Diversity and dynamics of dendritic signaling. Science 290:739–744).

convey information to the initial segment and initiate impulses that can travel down the axon. Another possibility is that the dendritic action potential may be important in inducing a transient increase of intracellular Ca concentration (Fig. 4).

### *Transient Increase of Intracellular Ca and Dendritic Integration*

Transient increase of intracellular Ca accompanies various neuronal activities [7]. There are several sources for the Ca. Firstly, activation of Ca-permeating ligand gated channels, such as NMDA-type glutamate receptor or nicotinic acetylcholine receptors α7 subunits, allow Ca to enter from the extracellular space. Secondly, Ca enters through voltage gated Ca channels, activated during Ca-dependent action potentials or during depolarization due to any mechanism. Thirdly, activation of intracellular signaling pathways induces Ca release from intracellular stores.

Elevated Ca modulates synaptic integration by various mechanisms. Some of these mechanisms are by directly gating ion channels such as Ca-dependent K channels, by modulating ion channels through Ca-dependent phosphorylation, or by triggering synthesis of proteins involved in synaptic responses such as transmitter receptors.

## Synaptic Integration at Presynaptic Sites

The presynaptic terminals are also postsynaptic sites at many synapses, in that various types of receptors on the membrane receive ligands from various sources. Firstly, axons of some neurons, such as GABAergic interneurons, make synaptic contacts on presynaptic terminals and inhibit transmitter release [8]. This type of inhibition is called ►presynaptic inhibition. Secondly, transmitters released from the terminal can diffuse in the synaptic cleft to bind to receptors on the synaptic terminals and inhibit transmitter release. This type of action is called ►autoreception. The transmitter can also diffuse at longer distances (►spill over), and act on the presynaptic terminals of nearby neurons as well as on the postsynaptic neurons. Interaction by these mechanisms is called volume transmission.

In addition, molecules that can diffuse across membrane, such as nitric oxide, carbon mono-oxide, arachidonic acids, and endocannabinoids that are generated in the postsynaptic neurons, diffuse back to the presynaptic terminals and modulate synaptic transmission. This type of mechanism provides additional pathway of volume transmission, and is called ►retrograde transmission [9].

At the presynaptic terminals, the probability of transmitter release can vary from time to time as nerve impulses arrive at the terminals. This phenomenon can be demonstrated by activating the presynaptic fibers at short intervals, typically few tens of milliseconds. The release probability for the second impulse may be either higher or lower compared to that for the first impulse. These types of short-term plasticities are called paired pulse facilitation or ►paired pulse depression, respectively.

The details of integration in presynaptic terminals are not well understood. Since transmitter release is a rather complex phenomenon involving large varieties of molecules and mechanisms, the mechanisms for the integration in the presynaptic terminals are likely to be diverse.

### Higher Level Processes

Integration of information is the most important task the brain or nervous system performs. To execute this task, assembly of neurons and neuroglias form networks at local and global levels. Synaptic integration is an cellular-level elementary process for this task. At the local and global network level, information is integrated by processes that have principles of their own.

### Lower Level Processes

The following is a list of the important lower level processes involved in synaptic integration:

1. Gating of ion channels
2. Synaptic activation of intracellular signaling pathways
3. Dynamics of Ca ion
4. Diffusion of molecules in and out of the cells
5. Release of transmitters

### Process Regulation

Process of synaptic integration is regulated both extrinsically and intrinsically. Depending on mental or physical situations, various neuromodulators such as catecholamines or peptides, activate receptors on neurons, modulate functional proteins and lipids, control gene expressions, and regulate synaptic integration. Activities of neurons give rise to activation of similar intracellular mechanisms that can be activated by neuromodulators, and regulate synaptic integration.

### Function

Synaptic integration is the basis for any kind of information processing taking place in the central nervous system.

JÜRGEN SANDKÜHLER
Department of Neurophysiology, Center for Brain Research, Medical University of Vienna, Vienna, Austria

## Synonyms

LTP

## Definition

►LTP is an intensively studied model of synaptic plasticity. LTP is defined as a long-lasting (but not necessarily irreversible) increase in synaptic strength. Early phase LTP is independent of *de-novo* protein synthesis and lasts for up to three hours. Late phase LTP involves protein synthesis and lasts longer than three hours. Synaptic strength is the magnitude of the post-synaptic response (i.e., the post-synaptic potential or the post-synaptic current, but not action potential firing, see below) in response to a pre-synaptic action potential. LTP can be expressed pre- and/or post-synaptically. Synaptic strength can increase if the release of neurotransmitter(s) is enhanced and/or if the postsynaptic effects of the neurotransmitter(s) become stronger. LTP at synapses in hippocampus is the prime model for learning and memory formation. Recent studies have shown that LTP can also be induced in pain pathways and likely contribute to hyperalgesia caused by inflammation, trauma or neuropathy.

## Characteristics

### How to (and how not to) Measure LTP

When studying LTP it is essential to measure the changes of mono-synaptically-evoked post-synaptic

currents or potentials in response to a single pre-synaptic action potential. Whole-cell patch-clamp recording is now the most often used technique. To evaluate LTP at the first synapses in nociceptive pathways, transverse slices from lumbar spinal cord of rats or mice with long dorsal roots attached can be prepared to study mono-synaptic, Aδ-fiber or C-fiber evoked excitatory postsynaptic potentials or currents in identified dorsal horn neurons [1].

Some aspects of LTP can only be studied in the entire animal. *In vivo* C-fiber -evoked field potentials can be measured in superficial spinal dorsal horn, for example in response to high intensity electrical stimulation of the sciatic nerve for up to 24 h [2]. These extracellulary recorded field potentials reflect summation of post-synaptic, mainly mono-synaptically-evoked currents but not action potential firing [2].

LTP can not be directly investigated by recording action potential discharges of post-synaptic neurons because action potential firing not only depends upon synaptic strength, but also on membrane excitability and the balance between excitatory and inhibitory input to the neuron. For the same reasons poly-synaptically-evoked responses can generally not be used to study synaptic strength and changes thereof.

## Induction Protocols

### *High Frequency Electrical Nerve Stimulation*

LTP at spinal synapses of small diameter primary afferents has most often been induced by high intensity, high frequency burst-like stimulation (typically 100 Hz bursts given several times for 1 s at C-fiber strength) both, *in vitro* and *in vivo*. In spinal cord slice preparations, both, Aδ-fiber and C-fiber [2,4]-evoked responses are potentiated by high frequency stimulation (HFS) when post-synaptic neurons are mildly depolarized to −70 to −50 mV. The same HFS induces, however, long-term depression (LTD) of Aδ-fiber-evoked responses if cells are hyperpolarized to −85 mV, suggesting that the polarity of synaptic plasticity is voltage-dependent.

The role of most spinal dorsal horn neurons in nociception is uncertain with one notable exception. Lamina I neurons that express the NK1 receptor play a pivotal role in development of hyperalgesia in behaving animals. Interestingly, HFS induces LTP selectively at C-fiber synapses with lamina I neurons that express the NK1 receptor and send a projection to the parabrachial area (Fig. 1). In contrast, HFS fails to induce LTP at synapses with neurons that express the NK1 receptor and send a projection to the periaqueductal grey or at synapses with neurons which do not express the NK1 receptor and have no identified supraspinal projection (Fig. 1) [1,3].

Conditioning HFS at C-fiber intensity of sciatic nerve afferents induces LTP of C-fiber, but not Aβ-fiber -evoked field potentials in superficial spinal dorsal horn of deeply anaesthetized rats [2,4]. In contrast, conditioning HFS at A-fiber intensity fails to induce LTP of either A- or C-fiber -evoked field potentials in intact animals. In spinalized animals, conditioning HFS at Aδ-fiber intensity induces, however, LTP of C-fiber-evoked field potentials.

### *Low Frequency Electrical Nerve Stimulation*

Some C-fibers may discharge at rates as high as 100 imp $s^{-1}$ for short periods of time (e.g., at the beginning of a noxious mechanical stimulus). Most C-fibers discharge, however, at considerably lower rates, around 1–10 imp. $s^{-1}$ (e.g., in response to an inflammation or an injury). Conditioning stimulation within this lower frequency range is also successfully used to induce LTP at C-fiber synapses. In a spinal cord-dorsal root slice preparation, conditioning electrical low frequency stimulation (LFS 2 Hz for 2–3 min, C- fiber strength) of dorsal root afferents induces LTP selectively at C-fiber synapses with lamina I neurons that express the NK1 receptor and project to the periaqueductal grey (Fig. 1) [3]. C-fiber synapses with lamina I neurons that express the NK1 receptor and project to the parabrachial area or with no identified supraspinal projection are, in contrast, not potentiated by LFS (Fig. 1) [3]. Thus, the pattern and the frequency of discharges in C- fibers determine which synapses at the origin of different ascending pain pathways are potentiated.

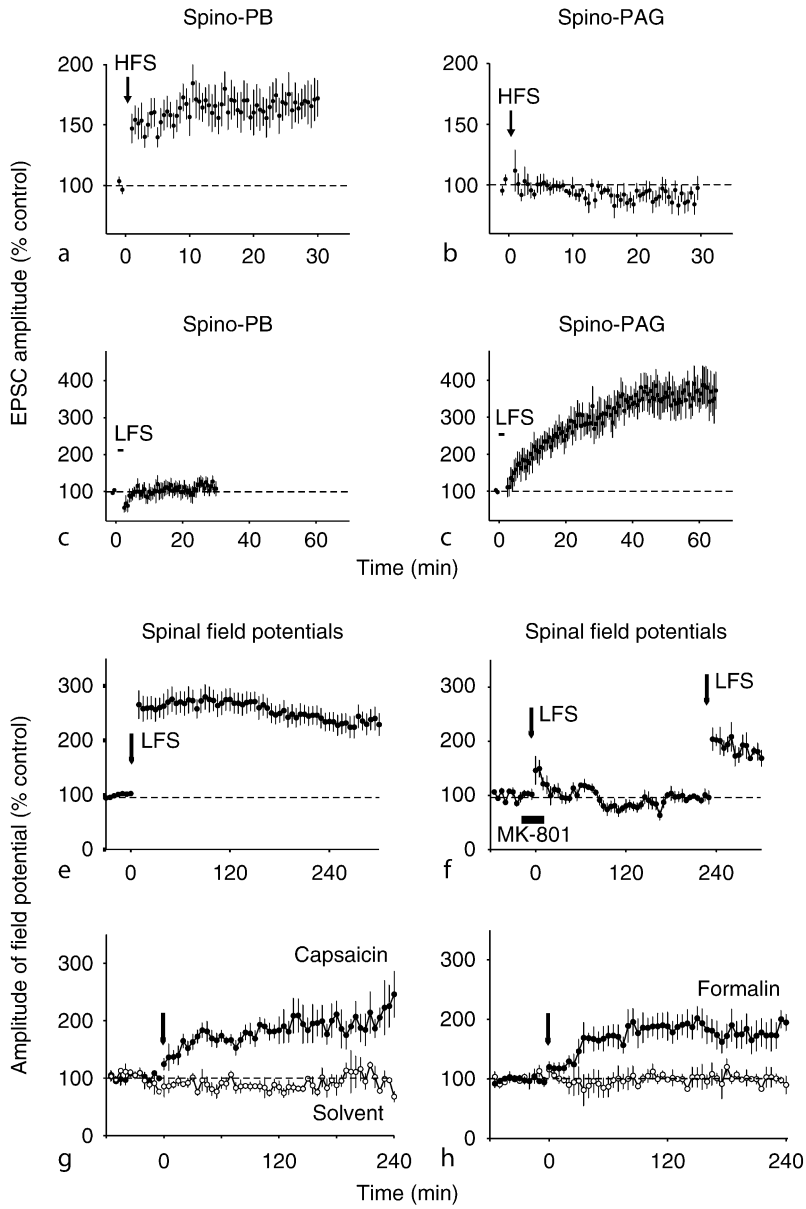
In spinal cord slices from neonatal rats, field potentials evoked by electrical stimulation in the tract of Lissauer are potentiated by repetitive burst-like stimulation at 10 Hz.

In deeply anaesthetized adult rats with their spinal cords intact, LFS (at 2 Hz for 2–3 min) of sciatic nerve at C-fiber intensity but not at Aδ-fiber intensity also triggers LTP of C-fiber-evoked potentials (Fig. 1) [3].

In conclusion, HFS and LFS have divergent effects on the strength of different C-fiber synapses. This finding is in line with previous reports illustrating that the frequency of the afferent barrage in C-fiber may have qualitatively different effects in spinal cord. For example, brain-derived neurotrophic factor is released from primary afferents in spinal cord slices in an activity-dependent manner by HFS at 100 Hz, but not by 1 Hz LFS of primary afferent nerve fibers. Furthermore, in spinal cord slices from mice, HFS (100 Hz) of primary afferent nerves at C-, fiber intensity, but not LFS (900 pulses at 1 Hz) selectively induces phosphorylation of extracellular receptor-activated MAP Kinases (ERK1/2) in spinal dorsal horn lamina I.

### *Natural Noxious Stimulation*

In the brain, LTP induction requires synchronous, high-frequency pre-synaptic activity or pairing of low-level



**Synaptic Long-Term Potentiation in Pain Pathways. Figure 1** A-D show contrasting forms of LTP expressed in distinct groups of spinal lamina I projection neurons *in vitro*. A, B Time courses of mean amplitudes (±SEM) of C-fiber-evoked EPSCs in lamina I neurons with a projection to the parabrachial area (PB, n = 8) or the periaqueductal grey (PAG, n = 7). Conditioning HFS induced LTP in all spino-PB neurons tested but was ineffective in spino-PAG neurons. C, D Conditioning LFS induced LTP in all 18 spino-PAG neurons tested but was never effective in seven spino-PB neurons. E–H LTP can be induced by natural, low frequency afferent barrage evoked by inflammation of peripheral tissue *in vivo*. Mean time courses of C-fiber-evoked field potentials recorded extracellulary in superficial spinal dorsal horn in response to electrical stimulation of left sciatic nerve of deeply anaesthetized adult rats with spinal cords and afferent nerves intact. Conditioning electrical LFS (2 Hz, 2 min at C-fiber intensity) of sciatic nerve at time zero (arrow) induced LTP (n = 28, E) which was prevented by NMDA receptor antagonist MK-801 (3 mg $kg^{-1}$, i.v.-infusion over 30 min: horizontal bar, n = 5, F). A second conditioning LFS four hours later (arrow) was partially effective in inducing LTP. Subcutaneous injections of transient receptor potential vanilloid 1 channel agonist capsaicin (1%, 100 µl, n = 5, G) or formalin (5%, 100 µl, n = 6, H) into the glabrous skin at the ipsilateral hind paw, within the innervation territory of the sciatic nerve at time zero (arrows) induced LTP (closed circles), while injections of the respective solvents (open circles) had no effects (n = 3 in each group). Modified from [4].

pre-synaptic activity with strong post-synaptic depolarization. At least some of the C-fiber synapses in superficial spinal dorsal horn are apparently unique in that LTP can be induced by LFS and by natural, low or high frequency, asynchronous and irregular discharge patterns in sensory nerve fibers. In animals with spinal cord and descending pathways intact, intraplantar subcutaneous injections of capsaicin (100 µl, 1%) or formalin (100 µl, 5%) induce slowly rising LTP (Fig. 1) [3].

Some forms of low level afferent input lead to LTP only if descending, presumably inhibitory pathways are interrupted or weakened. Noxious radiant heating of hindpaw skin induces LTP in spinalized animals but not in animals with spinal cord intact. Likewise, repetitive, noxious squeezing of the skin or the sciatic nerve induces LTP of C-fiber-evoked field potentials only in spinalized rats. These findings demonstrate that endogenous antinociceptive systems not only raise thresholds for nociception, but also those for the induction of LTP.

### *Pharmacological Induction*

LTP can also be induced at C-fiber synapses in the absence of any pre-synaptic activity. Spinal application of a dopamine 1/dopamine 5 receptor agonist in *vivo* induces a slowly developing LTP of C-fiber-evoked field potentials that lasts for at least 10 h and which is blocked by a dopamine 1/dopamine 5 receptor antagonist. In spinalized, deeply anaesthetized, adult rats, superfusions of spinal cord segments with NMDA (10 µM), substance P (10 µM) or neurokinin A (1 µM) are all sufficient to induce LTP of C-fiber-evoked field potentials. With spinal cord and descending (inhibitory) pathways intact, spinal applications of NMDA (1–100 µM), substance P (1–100 µM) or neurokinin A (1 or 10 µM) fail, however, to induce LTP of C-fiber-evoked field potentials.

## LTP of A-Fiber-Evoked Responses

Spinal field potentials evoked by excitation of primary afferent A-fibers are depressed by conditioning 50 Hz stimulation of the sciatic nerve. After systemic application of the $GABA_A$ receptor antagonist bicuculline, the same conditioning stimulus now produces LTP rather than LTD [5]. Similarly, 50 Hz conditioning stimulation produces short lasting potentiation followed by LTD in control animals, but LTP in animals with a chronic constriction injury (CCI) of the sciatic nerve. Topical application of muscimol (10 µg), a $GABA_A$ receptor agonist, to spinal cord prevents tetanus-induced LTP of A-fiber-evoked field potentials in animals with a CCI. This also suggests that the polarity of synaptic plasticity is context-sensitive and not solely dominated by the type of afferent input.

## Signal Transduction Pathways of LTP Induction and Maintenance

LTP can, in principle, be induced and expressed by pre-synaptic or by post-synaptic mechanisms or by any combination thereof. At present, there is clear evidence for a post-synaptic, $Ca^{2+}$-dependent form of LTP induction in spinal cord lamina I neurons. Induction of LTP at C-fiber synapses requires co-activation of NK1 and NK2 receptors, opening of ionotropic glutamate receptors of the NMDA type, opening of T-type voltage-gated calcium channels, and activation of group I but not group II or III metabotropic glutamate receptors. Activation of NK1 receptors by substance P may directly enhance single NMDA channel opening and NMDA receptor-mediated currents in lamina I neurons. All this may lead to a substantial rise in post-synaptic $[Ca^{2+}]_i$.

A rise in post-synaptic $[Ca^{2+}]_i$ is essential for LTP induction, and the magnitude in $[Ca^{2+}]_i$ rise is linearly correlated with the magnitude of LTP *in vitro* [1]. Recent data demonstrate that LTP-inducing stimuli cause a substantial rise in $[Ca^{2+}]_i$ in lamina I neurons not only in slice preparations, but also in intact animals [3]. Not surprisingly therefore, signal transduction involves $Ca^{2+}$-dependent pathways including activation of protein kinase C, calcium-calmodulin-dependent protein kinase II (CaMKII), protein kinase A (PKA) phospholipase C (PLC), inositoltriphosphate-3 ($IP_3$) receptors, mitogen-activated protein kinase (MAPK) and nitric oxide synthase (NOS).

Inhibition of protein synthesis in spinal cord by either cycloheximide or anisomycin selectively inhibits the maintenance of the late-phase of spinal LTP, but does not affect either LTP induction or baseline responses of C-fiber-evoked field potentials [6].

Importantly, the very same signal transduction pathways are required for full expression of hyperalgesia in animal models of inflammatory and neuropathic pain.

## LTP Induction can be Prevented

In mature rats, a deep (surgical) level of anesthesia with either urethane, isoflurane or sevoflurane is insufficient to pre-empt LTP induction of C-fiber-evoked field potentials [7]. LTP is, however, prevented by low dose intravenous infusion of the µ-opioid receptor agonist fentanyl [7]. Similarly, LTP of spinal field potentials elicited by stimulation in the tract of Lissauer in spinal cord slices is blocked by DAMGO, a more specific agonist at the µ-opioid receptor. Activation of spinal $\alpha_2$-adrenoreceptors by clonidine or spinal application of the benzodiazepine diazepam also prevents LTP induction *in vivo*.

Functional blockade of glial cells by intrathecal administration of fluorocitrate changes the polarity of HFS-induced synaptic plasticity. When HFS is given

1 hr, but not 3 hr after fluorocitrate, LTD but not LTP of C-fiber-evoked field potentials is induced.

## Reversal of LTP

After LTP induction of C-fiber-evoked field potentials, synaptic strength can be normalized by brief, high frequency conditioning electrical stimulation of sciatic nerve fibers at Aδ-fiber intensity. Reversal of LTP by Aδ-fiber stimulation is time-dependent and effective only when applied 15 or 60 min but not 3 h after LTP induction.

Spinal application of either NK1 or NK2 receptor antagonists one to three hours after HFS (i.e., after LTP is established) does not affect maintenance of LTP [2], suggesting that activation of these receptors, which are required for the induction of LTP, are not essential for its maintenance.

## Functional Consequences of LTP in Pain Pathways

Changes of synaptic strength may have a powerful impact on signal flow in selected pathways. A typical consequence of LTP at excitatory synapses would be an increase in action potential firing of the same and perhaps also downstream neurons in response to a given stimulus. Indeed, LTP-inducing conditioning stimuli have been found to facilitate action potential firing of multireceptive neurons in deep dorsal horn [8]. This is likely due to LTP at the first synapse in the nociceptive pathway, but other mechanisms of facilitation should not be excluded. Action potential firing would also be enhanced if membrane excitability is increased (i.e., the threshold for action potential firing is lowered), if inhibition is less effective or if inhibition is even reversed and becomes excitatory (e.g., due to a reversal of the anion gradient in the post-synaptic neuron).

Conditioning HFS of the sciatic nerve fibers that induces LTP at synapses of C-fibers in spinal cord has behavioral consequences in rats and causes thermal hyperalgesia of the ipsilateral hind paw for six days. This suggests that LTP at C-fiber synapses has an impact on nociceptive behavior.

## Perceptual Correlates of LTP in Pain Pathways

In human subjects, conditioning HFS of cutaneous peptidergic afferents causes increased pain perception in response to electrical test stimuli applied through the same stimulation electrode [9]. Noxious stimulation with punctate mechanical probes in skin adjacent to the site of HFS conditioning uncovers a marked (2–3 fold) increase in pain sensitivity (i.e., secondary hyperalgesia [9]). Touching the skin around the conditioning stimulation electrode with a soft cotton wisp evokes pain only after HFS. Thus, HFS also induces secondary mechanical allodynia. Hyperalgesia at the conditioning site but not secondary hyperalgesia or allodynia at adjacent skin areas is prevented by pre-treatment with ketamine, a clinically used drug which, among other effects, also blocks NMDA receptors.

All thermal modalities comprising cold and warm detection thresholds, cold and heat pain thresholds as well as pain summation (perceptual "wind-up") remain unaltered after conditioning HFS of peptidergic skin nerve fibers.

When verbal pain descriptors are used to evaluate pain in addition to its perceived intensity after HFS, a significant long-term increase in scores for sensory but not for affective descriptors of pain is detected [10]. Within the list of sensory descriptors, those describing superficial pain, those for heat pain and those for sharp mechanical pain are all potentiated. The authors conclude that brief painful stimuli rarely have a strong affective component and that perceived pain after HFS exhibits predominantly a potentiation of the C-fiber-mediated percepts hot and burning [10].

In humans subjects, conditioning LFS also causes increased pain sensitivity in the area around the LFS conditioning skin site, but a depression of pain evoked by stimulation through the same electrode [9].

## Conclusions

LTP at synapses between primary afferent C-fibers and a group of nociceptive neurons in spinal cord lamina I that express the NK1 receptor for substance P is a potential mechanism underlying some forms of pain amplification in behaving animals and perhaps human subjects. Both LTP and hyperalgesia involve the same essential elements (i.e., primary afferent C-fibers and lamina I neurons that express the NK1 receptor). Further, the induction protocols, pharmacological profile and signal transduction pathways are virtually identical.

## Synaptic Modification

►Synaptic Plasticity

## Synaptic Plasticity

Minoru Tsukada
Brain Science Institute, Tamagawa University, Tamagawa-gakuen, Machida, Tokyo, Japan

### Synonyms

Synaptic modification; Long term potentiation; Hebb-like learning rules; Spatiotemporal learning rule LTP STLR

### Definition

#### Long term Potentiation (LTP) and Hebb-like Learning Rules

Long term potentiation (LTP) is a long-lasting increase in the amplitude of a synaptic response following brief, high-frequency activity of a synapse and is loosely defined as an enduring, activity-dependent increase in synaptic efficacy.

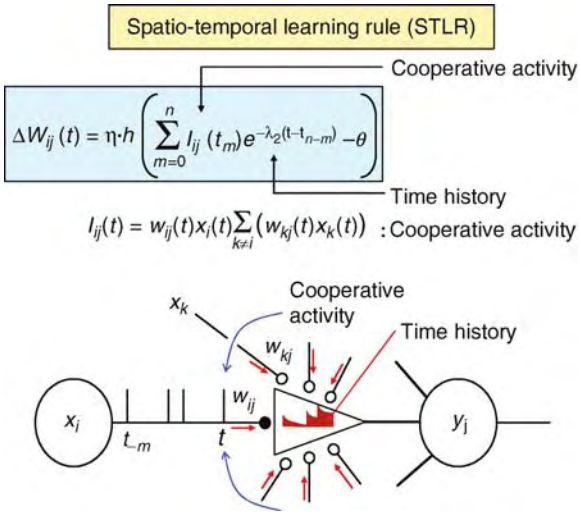
Hebb-like synaptic plasticity is the assumption that synaptic modification is strengthened only if the pre- and post-synaptic elements are activated simultaneously.

LTP that requires coincident pre- and post-synaptic activity is a plausibly biological correlate for the Hebbian synaptic modification.

### Characteristics

#### Hebb and the Spatiotemporal Learning Rule (non-Hebb)

Synaptic plasticity is considered to be a fundamental mechanism of learning and memory. Hebb [1] proposed the idea that synaptic modification is strengthened only if the pre- and post-synaptic elements are activated simultaneously. Experimentally, long term potentiation (LTP) and long term depression (LTD) are generally considered to be the cellular basis of learning and memory. Recently, a series of experiments provided direct empirical evidence of Hebb's proposal. These reports indicated that synaptic modification can be induced by repetitive pairing of EPSP and back-propagating action potentials (BAPs) [2]. Pre-synaptic spiking within tens of milliseconds [ms] before post-synaptic spiking induced LTP whereas the reverse order resulted in LTD. This spike timing dependent LTP/LTD has been confirmed by using pyramidal cell pairs in hippocampal cultures, in which they found an asymmetric profile of LTP and LTD in relation to the relative timing between EPSPs and BAPs [3]. On the other hand, the spatiotemporal learning rule (STLR), proposed as a non-Hebb type by Tsukada et al. [4,5] (Fig. 1), consists of two distinctive factors; "cooperative plasticity without a cell spike," and "its temporal summation."



**Synaptic Plasticity. Figure 1** The spatiotemporal learning rule (STLR).Where $w_{ij}(t)$; the value of a weight from neuron *j* to neuron *i* prior to adjustment, $\Delta w_{ij}(t) = w_{ij}(t+1) - w_{ij}(t)$, η; the learning rate coefficient, $x_j(t)$; the level of excitation of input to neuron *j*, $y_i(t)$; the output of neuron *I*, $I_{ij}(t)$; the value of cooperative activity from neuron *j* to neuron *i*, $h(u)$; a sigmoid function of the potentiation force, θ is the thresholds, and $\lambda_2$ is the decay constant of temporal summation which is a slow dynamic process ($\lambda_2$ = 223ms) (Aihara, et. al. 2000).

### Experimental Support for STLR (non-Hebb)

The STLR consisted of two defining factors: (i) cooperative plasticity without a post-synaptic spike and (ii) temporal summation. We have obtained evidence for temporal summation from neurophysiological experiments by applying temporal stimuli to Schaffer collaterals of CA3 [4,6]. The coincidence of spike timing of Schaffer collateral paired stimuli of CA3 played a crucial role in inducing associative LTP [7]. The ►homosynaptic and ►heterosynaptic associative LTP could be induced under conditions which inhibited the activation of dendritic Na + channels. Our results show that LTP can indeed occur at dendritic synapses of hippocampal CA1 pyramidal neurons even in the absence of a post-synaptic somatic spike. These results suggest that if the two inputs synchronize at the dendritic synapse of CA1 pyramidal cells then the synapse is strengthened and the functional connection is organized on the dendrite. If the two inputs are asynchronous then the connection is weakened. The functional connection/disconnection depends on the input-input timing dependent LTP (Fig. 2).

This differs from the Hebbian learning rule that requires coactivity of pre-synaptic and post-synaptic neurons. The STLR incorporated two dynamic processes: fast (10–30 ms) and slow (150–250 ms) processes. The fast process works as a time window to detect a spatial coincidence among various inputs projected to a weight space of the dendrites of hippocampal CA1 pyramidal neurons, while the slow process works as a temporal integrator of a sequence of events. By fitting parameters to the physiological data of the LTP time scale, we determined the decay constant of fast dynamics to be 17 ms, which corresponds to the period of hippocampal ►gamma oscillations [8]. In contrast, the decay constant of the slow dynamics is 169 ms, which corresponds to a ►theta rhythm. In combination, these findings suggest that cell assemblies are synchronized at two time scales in the hippocampal-cortical memory system. This phenomenon appears to correlate with the memory formation in the spatio-temporal context.

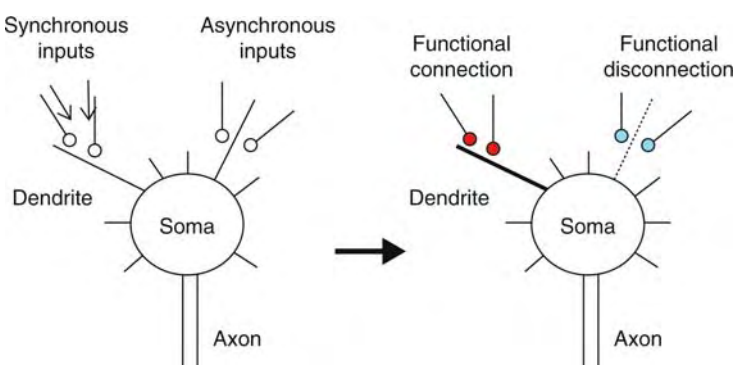
### The Functional Differences Between STLR and Hebb

We applied two rules to a single-layered artificial neural network and compared its ability to separate spatiotemporal patterns with that of other rules, including the Hebbian learning rule and its extended rules. The simulation results [5] showed that the STLR rather than the Hebbian learning rule or its extensions had the highest efficiency in discriminating spatiotemporal pattern sequences. The novel features of this learning rule were induction of cooperative plasticity without a post-synaptic spike and the time history of its input sequences.

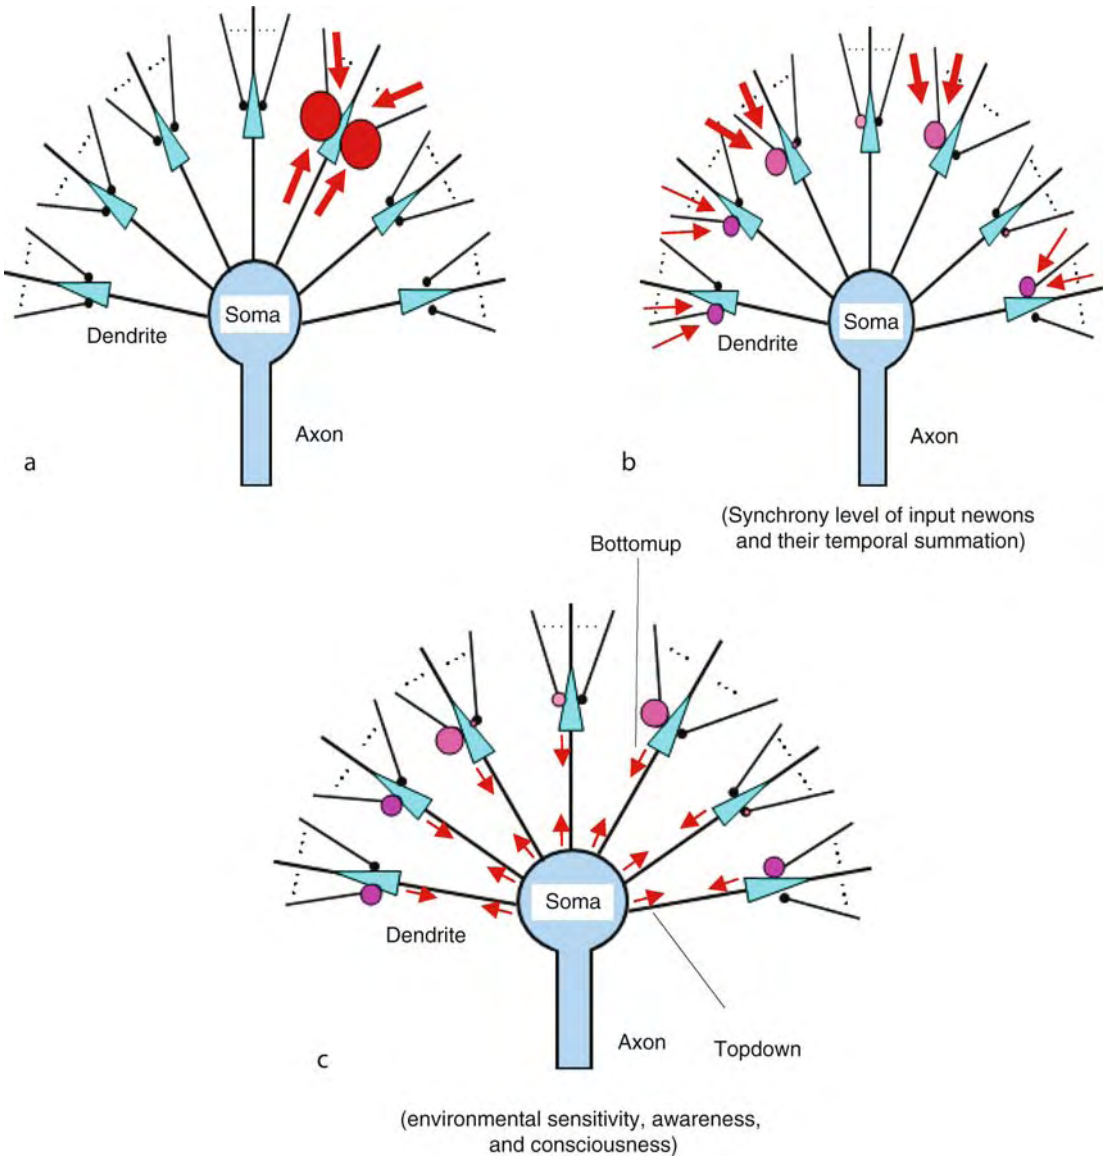
According to the Hebbian rule, connections strengthen only if the pre- and post-synaptic elements are activated simultaneously, and thus, the Hebbian rule tends to map all of the spatio-temporal input patterns with identical firing rates into one output pattern. Hebbian rule has a natural tendency to attract analogous firing patterns into a representative one, so called "pattern completion." In contrast, the STLR produces different output patterns depending on individual input patterns. Thus, the STLR has a high ability in pattern separation, while the Hebbian rule has a high ability in pattern completion.

The extension of the theoretical simulation results imply that this phenomenon occurs in a dendrites-soma system of a single pyramidal cell. This system includes a spine structure, ►NMDA receptors, and Na + and Ca + channels. The pyramidal cell integrates all of these local dendrite functions. Our previous research revealed that the STLR and the Hebbian rule coexist in single pyramidal neurons of the hippocampal CA1 area. The Hebbian rule leads to the pattern completion (Fig. 3a) and the STLR leads to the pattern separation (Fig. 3b).

In the STLR, synaptic weight changes are determined by the "synchrony" level of input neurons (bottom-up), whereas in the Hebbian rule, the soma



**Synaptic Plasticity. Figure 2** A schematic representation of functional connection/disconnection by cooperative activity dependent LTP/LTD.



**Synaptic Plasticity. Figure 3** Functional differences between Hebb (a), and STLR (b), and their interaction (c) in a dendrite(local)-soma(global) system of single pyramidal cells of the CA1.

fires by integrating dendritic local potentials or by top-down information such as environmental sensitivity, awareness, and consciousness (top-down) (see Fig. 3c and its legend). The coexistence of the STLR (local information) and the Hebbian rule (global information) on the neuronal level may support this dynamic process that repeats itself until the internal model fits the external environment. The dendrite-soma interaction in pyramidal neurons of the hippocampal CA1 area can play an important role in the context formation of policy, reward, and value in ►reinforcement learning.

The role of soma spiking as top-down information raise a number of interesting computational predictions. Fist, hippocampal theta is one of candidates of top-down information which is driven by the medial septum [9]. The theta stimulation in the adult rat hippocampas can induce LTP [10]. Second, extrinsic modulators, such as acetylcholine, serotonin, norepinephrine and dopamine, can alter neuronal throughput and BAPs (so-called "meta-plasticity") in such way that these transmitters diffuse broadly.

When you are confronted by certain situations, you naturally compare it to your previous experiences and attempt to predict what may happen and plan your actions in respect to predicted outcomes that we found favorable. In this way, your past, present, and pre-future memory work together and determine your actions. If these actions do not fit, then a new hypothesis is

formulated, new data is reasoned, and the previous model is amended. The coexistence of the STLR and the Hebbian rule may support this dynamic process, which repeats itself until the internal model fits the outer environment. In reinforcement learning, the dendritic-soma interaction in single pyramidal neurons of the hippocampal CA1 area can play an important role in the context formation of policy, reward, and value.

## Synaptic Plasticity, Selectivity

### Definition

When high-frequency stimulation is applied to one of the two independent pathways innervating the same postsynaptic cells, LTP is usually induced selectively in the tetanized pathway and is not induced in the other independent pathway. This characteristic of LTP is called "selectivity" or "specificity."

## Synaptic Properties

### Definition

The strength of synaptic connections and whether they are inhibitory or excitatory are all properties which affect the network behavior. Synaptic transmission can be modulated in diverse ways both pre and postsynaptically. Also critical is temporal summation of postsynaptic potentials, which can lead to short term potentiation of synaptic properties.

## Synaptic Proteins and Regulated Exocytosis

### Synonyms

Exocytotic cycle; Synaptic release mechanism; Machinery of the neuronal secretory pathway

### Definition

As one of the most highly differentiated and thus specialized secretory cells, neuronal functions are in many ways directly or indirectly defined by the specificity, efficiency, and speed of the synaptic release process. From the instant that a depolarizing waveform invades the terminal of a chemical synapse to detection of a post-synaptic response can be as fast as ~150 μs; the lag between calcium influx and fusion is estimated to be as little as 60 μs. Despite hundreds of synaptic vesicles (SV) in a given neuron, the supply is not inexhaustible, necessitating that neurons also have fast

and efficient mechanisms to retrieve, refill and recycle SV, in particular to compensate for high frequency release under strong (e.g. highly repetitive) stimulus conditions. This dynamic cyclic pathway, coupling the release and retrieval processes, together with preceding steps that efficiently direct and move nascent SV from the trans-Golgi toward the synapse and then onto specialized sites on the plasma membrane (PM), is generally referred to as the regulated exocytotic pathway. Localized transient increases in cytoplasmic free calcium concentrations ($[Ca^{2+}]_{free}$) in the vicinity of open voltage-gated ►$Ca^{2+}$ channels act as focal sources of $[Ca^{2+}]_{free}$ that may reach 10–100 μM (relative to ~200–300 nM resting $[Ca^{2+}]_{free}$). These transient ►$Ca^{2+}$ microdomains are the primary trigger (e.g. "regulator") for the defining step of exocytosis: fusion of the SV and PM. This regulated membrane fusion (e.g. merger of the apposed bilayer membranes) results in an opening (the fusion pore) that enables release of the SV luminal content into the synaptic cleft; the released neurotransmitters then interact with receptors on the post-synaptic membrane, resulting in the depolarization of that cell and thus propagation of the original electrical signal to the next component(s) of the neural circuit.

The regulated exocytotic pathway thus consists of a series of concomitant and inter-connected stages that overlap temporally and also at the molecular level. Being highly conserved across eukaryotes, much has been learned over the last three decades using other secretory cell types and even cell fractions as model systems; despite access even to synaptosomes, the extremely small size and accessibility issues inherent to most synapses, and the fast kinetics of the release process, severely limited or obviated the coupled functional–molecular analyses necessary to effectively dissect underlying molecular mechanisms. The inability to "cleanly" separate certain functions still limits our understanding of specific molecular mechanisms. This is slowly changing, with many research groups bringing different combinations of refined and advanced techniques to bear on questions of the specific roles that particular proteins, or protein interactions, play at defined stages of the exocytotic pathway. The integrated work from a tremendous range of research teams – combining electrophysiological (e.g. patch clamp), imaging (e.g. ►Total internal reflection microscopy and confocal microscopy), ultrastructural (e.g. ►Electron microscopic tomography and rapid freeze), molecular biological, proteomic, and other research techniques, in a range of fast secretory cell types (albeit perhaps not all as fast as the "fastest" of neurons, e.g. neuroendocrine cells, oocytes, paramecium, and so forth) – makes this area one of the most fruitful inter- and multi-disciplinary junctions in modern Cell Physiology. In the last 15 years alone the field has gone from having virtually no known key proteins, to having identified dozens or more proteins critical to the exocytotic pathway, with some even known to function at reasonably well-defined stages and with certain partners. There is little doubt that the interdisciplinary and cooperative interactions that have fuelled this area of research will continue to drive a fuller and more thorough molecular understanding of the different stages in the exocytotic pathway, their transition points, and what specific adaptations and mechanisms may (or may not) be neuron-specific.

## Characteristics

Based originally on the convergence of results from a range of different functional assays in a variety of different cellular model systems, the exocytotic pathway is now generally thought of as constituting a series of stages [1]. The actual proteins functioning at a specific stage, or indeed the specific molecular function of a given protein (or its interactions) in one or more stages, is often not yet so well understood. This is however rapidly changing with the continued growth and application of cutting-edge technologies in Neuroscience research. The exocytotic pathway (or more specifically the path of an SV in this cycle) is thus generally said to proceed via the following stages: trafficking, targeting, tethering, docking, priming, triggering, fusion, and retrieval. To specifically delineate it from the release portion of the exocytotic pathway, the retrieval stage is commonly referred to as endocytosis. Short descriptions of each stage follow and include mention of at least some of the proteins that are more commonly agreed to (likely) function in the associated molecular mechanisms. It is important to note that despite often being cartooned as specific steps, there are no clear-cut delineations between many of the stages, and indeed molecular mechanisms contributing to a given stage may already initiate their functions in preceding stages. For example, while some representations suggest that priming occurs after docking, considering the myriad of molecular alterations that may underlie this stage it is possible that some occur before, during, or after tethering and docking. Potential confusion is further compounded by the aforementioned speed of exocytosis in neurons, in many instances making the timing of specific molecular events difficult to clearly define.

### Trafficking

Newly synthesized SV leave the soma and undergo anterograde transport to the synapses via well-characterized mechanisms. This energy-dependent axonal transport utilizes microtubules as cytoskeletal tracks and is mediated by the motor protein kinesin (an ATPase with a microtubule binding domain). At the synaptic terminal, other transport or translocation machinery appears to take over, not only for further SV trafficking

but, importantly, to aid in segregating SV into functionally-defined sub-populations or pools. Defined largely based on the results of secretion assays and time-resolved electrophysiological measurements (e.g. membrane capacitance changes assessed by patch clamp recording) these pools are defined not only physically but in most cases also molecularly, generally corresponding to the different stages of exocytosis [1]. Moving from the axon-terminal interface toward the release sites of the synaptic terminal, three sequentially arranged pools of SV are broadly described as:

1. Unprimed (UPP) – a large population of SV mostly located deeper within the terminal that, upon passing through preparatory steps, can refill the Reserve pool. Also known as the resting or depot pool, these SV can be recruited during periods of massive stimulation and/or disruption of SV retrieval and recycling.
2. Reserve (RP; a.k.a. slowly releasable) – a population of SV that are not fully release-ready but can be rapidly recruited to that terminal pool.
3. Readily releasable (the RRP) – those SV fully docked at the PM and competent for fast, $Ca^{2+}$-triggered release; a sub-population of only a few vesicles has been identified as an Immediately releasable pool (IRP).

In the terminals it appears that the myosin motor proteins mediate translocation between these pools, utilizing actin clusters as tracks; myosin is known to interact with the SV proteins synaptobrevin (a.k.a. VAMP) and synaptophysin. Actin clusters also likely serve in some capacity to delimit SV movement between pools.

## Targeting

The next stage or process is intimately linked with trafficking and tethering (see below) as there must be a control mechanism to ensure that SV are targeted to appropriate synapses and subsequently, within the terminal, to proper/effective release sites. Concerning the latter, there is little direct evidence for specific protein functions although small G-proteins of the rab family have been suggested to have a role, as has the ►exocyst complex.

## Tethering

Those SV destined to fuse with the PM must of course be positioned at it. The localization near and initial loose or reversible attachment of SV to the PM is termed tethering and may in part involve cytoskeletal elements and rab proteins. At the ultrastructural level, tethering generally refers to those SV-PM attachments at distances that are greater than half an SV diameter (e.g., >25 nm). Due to their roles in linking the SV and cytoskeletal elements, and in promoting SV clustering at active zones (see below), the synapsins have also been implicated as tethering elements.

## Docking

Proceeding from the tethered state, a more stable and intimate contact of the SV and PM is required to ensure the efficiency of triggered fusion and reduce the associated energy barriers. This likely represents a continuum of molecular states, from tethering through to the loose formation of inter-membrane SNARE complexes. Physically, a fully docked SV is generally regarded as being held within ~5–10 nm of the PM.

In nerve terminals, tethering, docking, and in particular fusion, are restricted to a specialized area of the presynaptic PM known as the active zone (AZ). This is a region of clustering of voltage-gated calcium channels that are close to, or constitute part of, SV docking sites. In electron micrographs, the AZ appears as an electron dense region of the PM, with an associated cytomatrix complex, and these are located directly across the synaptic cleft from the postsynaptic density; his tight alignment ensures the speed and fidelity of synaptic transmission [2]. Thus, proteins enriched in the AZ and its cytomatrix have been implicated in tethering and docking [1–3]. These include the rab-interacting RIM, as well as Piccolo, Bassoon, Munc13, ►Liprin-α, and ►ELKS that have been shown to interact with each other as well as with other accessory proteins including synaptotagmin, ►spectrin, calmodulin, ►DOC2, ►14-3-3, Munc18, and elements of the cytoskeleton, as well as with the voltage-gated calcium channels (that bind syntaxin, SNAP-25, synaptotagmin, and ►CSP via a specific protein interaction, or ►synprint, domain). Scaffold/►adaptor proteins including ►CASK, ►Mint, and ►Velis have also be identified as binding partners of some of these potential docking elements. In addition, syntaxin, that binds Munc13, is recognized to be required in docking. It seems likely that this is due to its role in the so-called inter-membrane SNARE complex that bridges the SV and PM. Specifically, syntaxin and SNAP-25 form dimers at the AZ, and these then bind with synaptobrevin on the vesicle membrane; together, these form extended coil-coil structures that are said to "zipper-up" from their N-terminal ends toward the C-terminal ends (containing the membrane anchoring regions) and thus bring the membranes into close apposition. This complex (likely in multiple copies at a docking site) is also thought to ensure the specificity of SV targeting. As the initial complex is in only a loose interaction, this and intermediate states (preceding the final tightly coiled complex), may represent increasingly stabilized interactions involved in tethering and docking.

## Priming

At the different stages described, and upon docking to the membrane, SV also undergo a series of molecular alterations that imbue them with full $Ca^{2+}$ sensitivity and fusion competence. Simply, the SV become part of the RRP (or even IRP) and are capable of fast, $Ca^{2+}$-triggered release. Priming is thus another broad term, describing all functional molecular modifications, specifically including any ATP-dependent processes that facilitate and enable subsequent fast SV fusion. A number of proteins have been identified as critical to priming, including phosphatidylinositol kinases and the phosphatidylinositol transfer protein. As priming is sensitive to the levels of $[Ca^{2+}]_{free}$, and requires ATP, protein kinase activities have also been found to be critical. Specifically, the activities of the cAMP-dependent protein kinase and of protein kinase C have been linked to the replenishment or maintenance of the RRP; this could in part be due to stabilization of the inter-membrane SNARE complex [1]. Although it may occur rapidly and exist only transiently, many now consider the fully zippered SNARE complex to be the final step of priming; at this point the SV and PM are in close apposition as required to efficient fusion, the tight coiling of the SNARE complex likely having reduced part of the high energy barrier to subsequent membrane merger [4 and references therein].

## Triggering

After priming, the ensuing molecular steps, up to and including fusion, do not require ATP. This has been interpreted to indicate that the localized fusion site has been set-up (e.g. much like a "loaded-spring") to respond with virtually unfailing efficiency. As the trigger, $Ca^{2+}$ is thus thought to release the mechanism. The best evidence for this is the fact that the lipidic steps of membrane merger can be blocked with certain molecules (e.g. lysophosphatidylcholine) despite triggering of the associated upstream machinery by $Ca^{2+}$; washout of the LPC then results in the rapid completion of fusion despite the absence of the trigger. Currently, the best candidate for a $Ca^{2+}$ "sensor" is the protein synaptotagmin that is associated with the SNARE complex and also with specific membrane lipids. It is thought that $Ca^{2+}$-triggered interactions of specific domains in the synaptotagmin molecule with lipids may promote some of the membrane rearrangements that then initiate membrane fusion [5]. Certainly this would explain the association of synaptotagmin with the synchronous SV release that occurs with the opening of voltage-gated $Ca^{2+}$ channels. The existence of additional sensors is also postulated based on the estimated numbers of $Ca^{2+}$ ions that are thought to effect the release reaction; these estimates currently remain somewhat model-dependent.

## Fusion

The triggered fusion of the SV and the PM is the defining step of regulated exocytosis. Specifically, this requires the triggered focal merger of the SV bilayer membrane with that of the PM, at a highly restricted and specialized domain within the AZ. Without this, there is no release of neurotransmitters, no signaling between neurons, and thus no effective neural circuitry. The actual molecular mechanism mediating bilayer merger has been studied for decades and has relied heavily on biophysical analyses of membrane properties and associated mathematical modeling to reach our current understanding of the process. It is now reasonably clear that the inter-membrane SNARE complex itself does not drive membrane fusion [4,6], nor does it seem do other protein components, despite their contributions to delimiting the site, controlling the timing, and facilitating the outcome. It is currently most widely accepted that the fusion pore itself is likely to be lipidic. The stalk-pore hypothesis describes a series of transient, high curvature membrane intermediates that yield the lowest energy molecular pathway to fusion pore opening and full expansion [7,8]. At this stage of terminal fusion (e.g. full vesicle collapse), the vesicle and plasma membranes are continuous and only an active retrieval mechanism can reform the vesicle and recycle it for another round of exocytosis (see below).

Yet there is accumulating evidence to suggest another form of tightly coupled fusion and recycling that does not utilize full fusion [9]. "Kiss & Run" has been identified as a transient fusion event that results in only a partial release of vesicle content prior to the reversal or resealing of the fusion pore (sometimes referred to as a "flickering" pore). This is perhaps best thought of as a tight, focal interface between fusion and retrieval in which the SV never loses its identity. Variations on this theme suggest the continued docking or the undocking of the SV following the transient fusion event. There is evidence indicating that kiss & run is a specific response to certain modes of synaptic stimulation. If this is the case, a single synapse is even more versatile and complex in its responses than had been previously imagined, and modulation of the fusion pore may be a key step in signal integration.

## Endocytosis

The classical pathway of SV recycling involves the formation of clathrin-coated vesicles near previous release sites, with a ▶fission reaction mediated by dynamin and associated proteins actually severing the new vesicle from the PM [10]. These vesicles are processed through endosomal intermediates before being refilled with transmitter (via specific transporters) and re-entering the RP or RRP as new SV. Recycling of the SNARE complex components, in part through the

concerted actions of NSF and α-SNAP, is particularly important in this process. Another, faster, non-clathrin based mechanism of SV retrieval is also recognized that does not require subsequent passage through intermediate compartments; SV are quickly refilled and thus rapidly re-enter the RRP. Kiss & Run may be a highly specialized form of this latter recycling mechanism.

## Synonyms

Target specificity

## Definition

Specificity of synaptic connections between neurons and their target cells. In a narrower definition, it refers to the formation of synaptic structures between neurons and their specific cellular or subcellular targets.

## Characteristics

### Description of the Process

The proper functioning of the nervous system depends on precise interconnections between distinct types of neurons. Therefore, understanding the molecular mechanisms of synaptic specificity – the specificity with which connections form between neurons – is a central issue in modern neuroscience. The magnitude of the complexity involved in this process is daunting. In the human brain, each of the roughly $10^{11}$ neurons establishes connections with, on average, over a thousand target cells in a highly characteristic manner. Remarkably, much

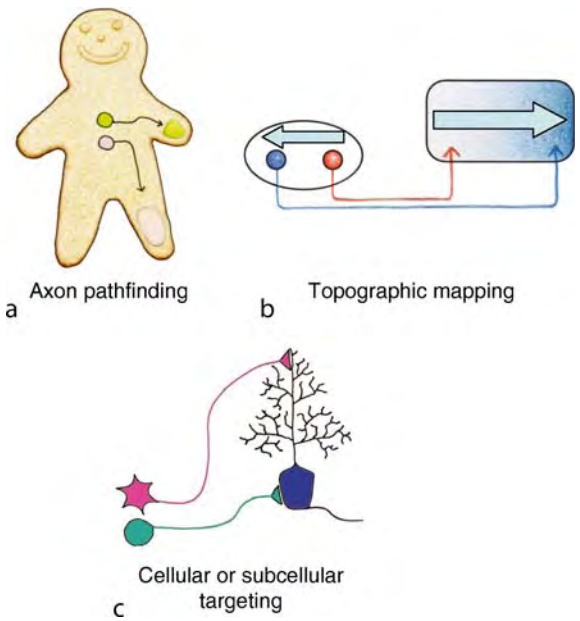
of the intricate patterning of these synaptic connections can be generated in the absence of activity or experience; thus the information necessary for this precise wiring must be largely encoded by the genetic program. It was Roger Sperry who first showed that synaptic specificity could be generated in a predetermined manner, independent of the experience of the animal [1]. After a series of experiments on the retinotectal projection in frogs, he proposed the highly influential "►chemoaffinity hypothesis" [see Glossary]. The theory posits that individual target cells and their innervating nerves must carry matching sets of molecular markers or have "chemoaffinity" to establish specific connections between them. This idea motivated subsequent studies on the molecular mechanisms of synaptic specificity.

Synaptic specificity is generated in a stepwise fashion through three major stages of neuronal recognition (Fig. 1) [2,3].

Neurons first extend axons over long distances along stereotyped pathways toward their target region (axon pathfinding). Some neurons then search for a specific location or position within a field of target cells that represents a map of sensory information (topographic mapping).

Finally, neurons select individual target cells with which to make synaptic connections (cellular targeting). In many cases, presynaptic axons not only distinguish potential target cells but also recognize the appropriate subcellular region of the target cell (for example, the cell body versus dendrites; subcellular targeting).

The focus of this essay is mainly on the third step–cellular and subcellular targeting – addressing the topic of synaptic specificity in its narrower sense. Please refer to other essays for detailed accounts of the first two steps of the generation of synaptic specificity. Also see the essay on "target selection".



**Synaptic Specificity. Figure 1** Generation of synaptic specificity. Synaptic specificity is generated in a stepwise fashion through three major stages: axon pathfinding (a), topographic mapping (b) and cellular and subcellular targeting (c).

## Regulation of the Process

Axons extend toward their targets by attractive and repulsive guidance cues expressed along the pathway, as well as by cues from the target cells themselves [2]. Axons recognize and respond to these cues with a specialized terminal structure, the growth cone. The growth cone bears receptors that bind to the guidance cues and elicit signal transduction cascades that regulate growth cone steering. The guidance cues expressed by target cells, together with their receptors on the presynaptic cells, determine target specificity and are collectively called target recognition molecules. Compared to the wealth of information on the molecules and signaling that regulate axon pathfinding and topographic mapping, relatively little is known about molecules involved in selection of discrete target cells. However, functional analysis of several candidate molecules begins to illuminate the molecular mechanisms of target recognition (as described below in more detail). As initially postulated by Sperry, target specificity indeed appears to be regulated by the action of the molecular labels on the target (or nearby) cells and their receptors on specific presynaptic cells. Some of such labels are cell adhesion molecules that promote interaction between specific pre- and postsynaptic cells.

How the tremendous diversity of synaptic connections is coded by such cellular labels on neurons and targets is an important but unsolved problem. Is it coded by differential and/or combinatorial use of a relatively small number of molecules? Or are there diverse sets of complementary molecules expressed on individual cells? Several large families of cell surface proteins have been implicated in synaptic specificity, including the cadherin-related neuronal receptors (CNRs), neurexins/neuroligins, odorant receptors and *Drosophila* Dscams. For example, alternative splicing of the *Drosophila* cell adhesion molecule Dscam potentially generates 38,016 isoforms [4]. However, whether these large gene families indeed mediate synaptic specificity remains to be determined. On the other hand, there is evidence that molecules without such immense diversity can function as target recognition molecules (as described below in more detail).

## Higher-Level Processes

For proper neural wiring to occur, the guidance cues expressed along axon pathways and targets and their

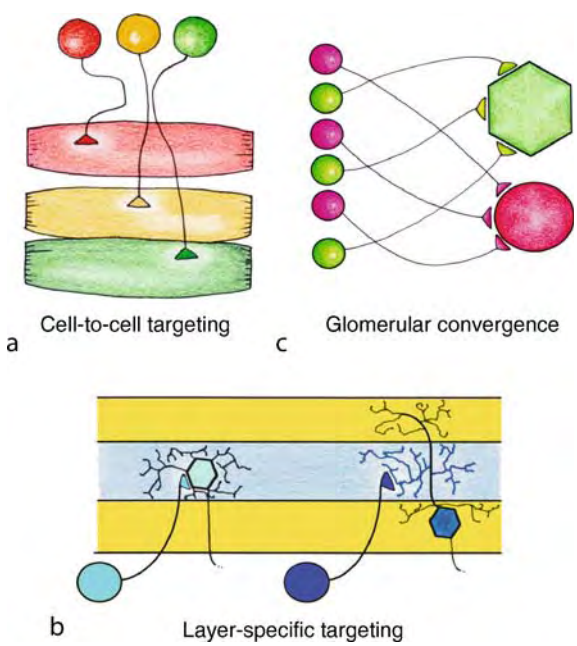
receptors in the presynaptic cells, have to be expressed at the right place at the right time. This process is regulated in part by the action of transcription factors as they specify the fate of individual neurons. For example, combinatorial expression of LIM-homeodomain transcription factors, the LIM code, determines the axon pathways of motor neurons toward their distinct muscle targets in vertebrates as well as in *Drosophila*. However, the specific downstream axon-guidance molecules that are regulated by these transcription factors are not yet defined.

## Examples of Synaptic Specificity: Selecting Discrete Targets

### *Cell-to-Cell Targeting*

Upon reaching the target region, neurons must choose specific synaptic partners from among a number of potential targets in the vicinity. In the cerebral cortex, for example, chandelier cell interneurons form synapses only with pyramidal neurons and in the cerebellum, ascending fibers connect only with Purkinje cells. The molecular mechanisms of cell-to-cell targeting are currently best characterized in the *Drosophila* neuromuscular system (Fig. 2a) [5].

In each segment of *Drosophila* larvae, ~40 motor neurons specifically innervate 30 muscle cells. Each motor neuron contacts many different muscles in the target region before forming synapses with only one or a few targets, suggesting the presence of specific cues present on individual target cells. Molecular and genetic studies have indeed identified several cell-surface or secreted proteins that are expressed in different subsets of muscles and can either attract or repel specific motor neurons. These include cell adhesion molecules with leucine-rich repeats (LRR), connectin, toll and capricious, a cell adhesion molecule of the immunoglobulin superfamily fasciclin3 (Fas3) and the attractive and/or repulsive secreted guidance molecules known as netrins and semaphorins. Connectin, Fas3 and capricious are also expressed on the presynaptic axons that innervate the muscles that express the same molecule and appear to mediate homophilic and attractive interaction between the synaptic partners. On the other hand, netrins, semaphorins and toll are expressed only on the target cells; they promote or inhibit synapse formation by binding to heterophilic receptors on the growth cone. These candidate target recognition molecules appear to function in a partially redundant manner to determine synaptic specificity; although gain-of-function mutations or ectopic expression of these molecules dramatically affects target specificity, loss-of-function mutations generally lead to only minor defects. Consistent with this idea, presynaptic motor neurons are able to integrate the information provided by multiple attractive and repulsive muscle cues.



**Synaptic Specificity. Figure 2** Examples of discrete targeting. Synaptic specificity can be generated by different forms of neuronal targeting. (a) Cell-to-cell targeting as in the case of a *Drosophila* neuromuscular connection. (b) Layer-specific targeting as found in the tectum and the cerebral cortex. (c) Glomerular convergence in the olfactory system.

### *Layer-Specific Targeting*

Layer-specific (also called lamina-specific) innervation is a common form of neuronal targeting, since many targets in the central nervous system, such as the tectum and the cerebral cortex are divided into multiple layers [6]. Arriving axons thus form specific synaptic connections by selecting the right layer(s). In some cases, the postsynaptic cells and their dendrites are themselves confined to a particular layer (Fig. 2b, left). In other cases, postsynaptic cells have dendritic branches that extend through multiple layers (Fig. 2b, right). In the latter case, presynaptic cells must recognize not only the specific target cell but also its correct dendritic segments for synapse formation (subcellular specificity). Several candidate target recognition molecules that are expressed in a layer-specific manner in vertebrates have been reported, including N-cadherin, sidekicks (Sdks) and ephrins. Of these, the best characterized are Sdk1 and Sdk2, which are homologous immunoglobulin superfamily cell adhesion molecules that are expressed in different subsets of retinal cells [7]. Sidekick proteins are concentrated at synapses that form between Sdk-expressing pre- and post-synaptic cells. Ectopic expression of Sdks in normally Sdk-negative presynaptic cells redirects their terminals to Sdk-positive layers.

A good model system for layer-specific targeting is photoreceptor targeting in the *Drosophila* visual system [4]. Eight photoreceptors (R cells; R1–8) that comprise the simple eye project to distinct layers of the optic lobe; R1–R6 project to the first optic ganglion (the lamina) and R7 and R8 project to distinct layers in the second optic ganglion (the medulla). Large-scale genetic screening has been used to identify several receptors and cell adhesion molecules that are involved in this targeting process, including the cadherins N-cadherin and flamingo and the receptor protein tyrosine phosphatases LAR and PTP69D [4]. Although the expression of these molecules is not restricted to particular R cells or target layers, the mutant phenotypes indicate that they function in specific aspects of R cell targeting. On the other hand, the LRR cell adhesion molecule capricious, which was originally identified for its role in neuromuscular specificity (as described above), is specifically expressed in R8 cells and their target cells in the medulla [8]. Both loss-of-function and gain-of-function analyses suggest that capricious regulates layer-specific targeting by mediating specific axon-target interaction.

### *Glomerular Convergence: Targeting in the Olfactory System*

The odorant receptors constitute a large receptor family (~1,000 in mammals). Olfactory neurons that express a particular receptor are scattered in a large area of the nasal epithelium. Yet, their axons converge onto specific target glomeruli in the olfactory bulb (Fig. 2c). The odorant receptor itself has been implicated in this targeting process [9]. When a single odorant receptor is deleted, the neurons that normally express it fail to converge on their target glomerulus. On the other hand, replacing a normal olfactory receptor with an ectopic one causes olfactory neurons to target neither the normal glomerulus nor the one expected for the new receptor. Instead, they map to an ectopic glomerulus located in between. These results suggest that while odorant receptors are important in glomerulus targeting, they are not the sole determinants.

### *Targeting Mediated by "Guidepost Cells"*

In some cases, synaptic specificity between two neurons is determined by the function of a third cell. The HSNL motor neurons in *C. elegans* form synaptic connections with VC4 and VC5 neurons and the vulval muscle vm2, in the vicinity of the vulval epithelial cells [10]. The vulval epithelial cells, but not the target cells themselves, are important in synaptic positioning. Thus, the epithelial cells serve as guidepost cells that induce the formation of specific synaptic sites. SYG-1 and SYG-2, a pair of transmembrane proteins of the immunoglobulin superfamily that heterophilically bind to each other, have been implicated in this process. SYG-1 is expressed in presynaptic HSNL motor neurons and SYG-2 in the guidepost epithelial cells. Both are necessary for normal synapse formation by the HSNL neurons. Ectopic expression of SYG-2 induces the accumulation of SYG-1 and presynaptic markers in HSNL adjacent to that region.

# Synaptic Transmission: Model Systems

Zhong-Ping Feng
Department of Physiology, University of Toronto, Toronto, ON, Canada

## Synonyms

Model presynaptic release sites

## Definition

Model systems are being used to define the structural and functional attributes of synapses, which are specialized points of physical and functional contact between two communicating neuronal elements.

## Characteristics

Cell-cell communication is essential to all nervous system functions. Synapses allow signals to be transmitted from neurons to their targets, providing the minimal building blocks necessary for neural integration. ►Chemical synapses, which consist of presynaptic and postsynaptic compartments separated by a synaptic cleft, are highly specialized structures that mediate the transmission of signals from presynaptic termini to postsynaptic targets via chemicals known as ►neurotransmitters. The structural and functional features of synapses are conserved in vertebrates and invertebrates.

At most chemical synapses, an action potential that invades a presynaptic terminal leads to a depolarization that causes voltage-activated calcium channels to open. A calcium influx increases the intracellular calcium concentration, resulting in the generation of calcium microdomains or nanodomains, which facilitate the fusion of transmitter-containing synaptic vesicles to the presynaptic membrane. After fusing to the membrane, the synaptic vesicles release their contents (neurotransmitters) into the synaptic cleft via exocytosis. The transmitters released by exocytosis diffuse to the postsynaptic membrane where they bind to ►postsynaptic receptors; thus, directly or indirectly, alters the excitability of the postsynaptic cells. At ►excitatory synapses, transmitter binding to postsynaptic receptors allows a net inward current, which depolarizes the membrane toward the action potential threshold (►Excitatory postsynaptic potential (EPSP)); whereas at ►inhibitory synapses, transmitter binding to postsynaptic receptors allows a net outward current, which drives the membrane potential away from threshold and maintains a membrane potential that is negative relative to the threshold value (►Inhibitory postsynaptic potential (IPSP)). Thus, the synapse mediates communication between the presynaptic and postsynaptic cells.

A variety of forms of the synapse have been identified. Depending on the nature of the postsynaptic cell, the synapse can be divided into two major categories: the ►neuro-muscular synapse (Neuromuscular junction, NMJ), which refers to a synapse formed between a presynaptic neuron and a postsynaptic muscle cell, and the ►neuronal synapse (►Central synapse), which refers to a synapse formed between two neurons.

Much of our understanding of the basic properties of synaptic transmission is the result of a large body of work done on neuromuscular junctions, largely due to its anatomical simplicity and accessibility. Using these models, the principle structures of presynaptic features, release mechanisms of acytelcholine, and synaptic efficacy of transmission have been determined. For instance, studies on frog neuromuscular junctions demonstrated the quantal release of synaptic vesicles by Del Castillo and Katz in 1954, vesicle fusion to cytoplasma membrane by Heuser and Reese in 1973, acetylcholine-dependent single-channel activity by Neher and Sakmann in 1976, the calcium requirement for release by Katz and Miledi in 1967, and the collocalization between the presynaptic calcium channels and postsynaptic acetylcholine receptors by Robitaile and colleagues in 1990. In addition to principle studies of neurotransmission, NMJs with specific features have also been used to investigate modulatory mechanism of synaptic transmission. For instance, Atwood and colleagues in 1967 showed that crustacean phasic and tonic glutamatergic motor neurons are innervated to a common muscle cell, but evoke different postsynaptic excitatory responses. The phasic EPSPs are large and often exhibit synaptic facilitation, whereas the tonic EPSPs are small and usually exhibit synaptic depression. These distinct properties have made crustacean NMJ models useful to study synaptic specialization. A number of genetic models of invertebrates have been used to identify molecules that are involved in regulating and mediating neurotransmission at neuromuscular junctions. For instance, the role of synaptotagmin in the NMJ transmission were investigated in *Drosophila* by Littleton and Colleagues in 1993, and Schwarz's group in 1994, and in *C. elegans* by Nonet and colleagues in 1993 and Jorgensen and colleagues in 1995.

Many of the principle properties that have been established for synaptic transmission at neuromuscular junctions are shared by central synapses. However, recent studies have shown that certain features of central synapses are distinct from those of neuromuscular junctions. For instance, Ceccarelli and colleagues in 1973 showed that presynaptic vesicles in neuromuscular junctions are locally reused at the synapse at which they are recycled. Work by Krueger and colleagues in 2003 indicated that functional synaptic vesicles in hippocampal neurons exhibit considerable mobility and can transit from the stable ►synaptic release sites along axons to other sites. Presynaptic proteins associated with neurotransmission are also shared amongst the neighboring terminals. Another example is the size of the quantal response, an elementary unit of synaptic transmission. The variability of the quantal size in the NMJs is low (the coefficient of variation is ~0.3), whereas that in the central synapses is ranged widely (the coefficients of variation are from 0.23 to 0.6), dependent on the preparation used. In addition, certain molecules that are critical to synapse formation in neuromuscular junctions play different roles in central synapses. For instance, agrin is essential to neuromuscular junction formation as showed by McMahan in 1990. Serpinskaya and colleagues in 1999 reported that central synapses, however, form in the absence of agrin.

Our limited understanding of the presynaptic mechanisms of neuronal (central) synapses can be

attributed to the complex anatomical structures and small size of most of neuronal synapses, which makes the synapses less accessible to electrophysiological recordings. Unlike the situation in neuromuscular junctions, in neuronal synapses the structures of both the presynaptic and postsynaptic neurons are highly variable. A stereotypical presynaptic element is the nerve terminal of axon, which forms synapse with a postsynaptic dendrite (axonal-dendrite synapse), a postsynaptic soma (►Axonal-soma synapse), or a postsynaptic axon (►Axo-axonal synapse). However, atypical synapses can form between a presynaptic dendrite and a postsynaptic axon (►Dendro-axonal synapse), or between cell somata (►Soma-soma synapse). Although afferent axons are only rarely postsynaptic to dendrites, the ultrastructures of dendro-axonal synapse have been described in dorsal horn of cats and monkeys by Ralton III's group in 1984, and of rats by Cruz and colleagues in early 1990s. *In vivo* axo-axonal synapses have been described in both invertebrates and vertebrates. For instance, ultrastructures of synaptic vesicle clustering in crayfish and in spider crabs have been shown at both axonal sites by Atwood's group in 1970s. Depolarization of an inhibitory efferent axon projection to the excitatory terminals results in modulation of excitatory transmitter release. Ralton III's group detailed the axo-axonal structures in rats, monkeys, and cats. The same group in early 1980s also reported multiple forms of synaptic connections in the macaque spinal cord, including axo-dendritic, axo-axonal, axo-somatic, and dendro-axonal synapses. One of the short-comes of these native synapse preparations in higher animals is to determine the presynaptic release properties due to the small size of the synapses and the complex anatomy, which does not permit direct access to the synaptic sites for functional analysis.

Our understanding of synaptic transmission in neuronal synapses largely relies on the availability of synapse models in which functional properties of synaptic transmission can be detected by direct electrophysiological recordings at the presynaptic release sites. This entry will focus on the major neuronal synapse models used to study the mechanisms and control of transmitter release in the neuronal synapse.

## Native Neuronal Synapse Models

### *Squid Giant Synapse*

The squid giant synapse forms between a presynaptic second-order giant fiber and a postsynaptic third-order giant nerve. These synapses are particularly large (100s μm). Synaptic transmission in the squid giant synapse was first recorded by Bullock and Hagiwara in 1957. Later studies using this synapse model demonstrated the correlation between the presynaptic depolarization, presynaptic calcium concentration and postsynaptic potential. For example, Llinas' group in early 1980s showed that calcium entry is directly related to the release of transmitter and confirmed the power relationship between calcium concentration and transmitter release by Katz and Miledi in 1970.

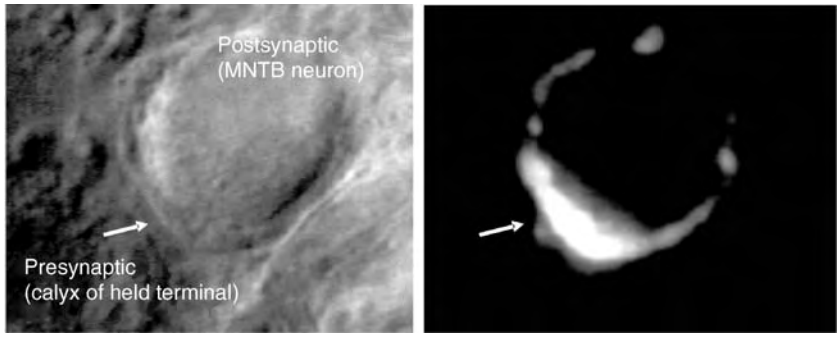
### *Calyceal Synapses*

Giant calyceal synapses were first described in the nucleus magnocellularis of the avian auditory system. A classical example is the chick ciliary synapse as described by Marin and Pilar in 1964 and by Stanley and Goping in 1991. In this giant chick synapse, the presynaptic element envelops the postsynaptic ciliary neuron and contains a typical fast-transmitting cholinergic nerve terminal. Glutamatergic synapses are also observed in neurons of the chick nucleus magnocellularis (nMAG), one of the avian cochlear nuclei that receives somatic, calyceal innervation from the auditory nerve fibers as reported by Zhang and Trussell in 1994.

Hans Held (1894) first described calyceal synapses in the mammalian auditory brainstem, and these giant synapses were further characterized by Lorente de No in 1980, and Spirou and colleagues in 1990. The "endbulb of Held" synapses form between auditory fibers (presynaptic) from the spiral ganglion in the inner ear and the bushy cell soma (postsynaptic) of the ventral cochlear nucleus, and ►calyx of Held synapses form between a projection of globular bushy cells (presynaptic) in the anterior ventral cochlear nucleus and the cell soma of a principal neuron (postsynaptic) in the medial nucleus of the trapezoid body (MNTB) (Fig. 1).

The calyx of Held is a typical example of an axonal-soma synapse, from which Forsythe (1994) pioneered the first patch clamp recordings from nerve terminals. The globular bushy nerve terminals in this synapse release glutamate, resulting in fast AMPA and slow NMDA excitatory postsynaptic currents.

One of the major advantages of the calyx of Held as a model for the study of synaptic transmission is the accessibility of its large presynaptic terminal (10–15 μm), which permits patch-clamp recordings, capacitance measurements of exocytosis in combined with calcium imaging, and uncaging studies. These features have made the calyx of Held a popular synapse model of central synaptic transmission in the last decade. For instance, this model system has been used to study the quantal properties of transmission by Schneggenburger and colleagues in 1999, the calcium sensitivity of transmitter release by Bollmann and colleagues in 2000, the regulation of presynaptic calcium level and vesicle release by Takahashi's group in 1996, and the presynaptic mechanisms of short-term synaptic plasticity by a number of groups including Barnes-Davies and Forsythe in 1995, Turecek and Trussell in 2001, and Xu and Wu in 2005. The calyx of Held has also been used to study the developmental and



**Synaptic Transmission: Model Systems. Figure 1** The calyx of Held synapses in the auditory brainstem slice. maturational changes that occur in presynaptic function as reported by Taschenberger and von Gersdorff in 2000, and Joshi and Wang in 2002. Manipulation of the presynaptic release mechanism at the molecular level is the major challenge in using this model system.

### *Retinal Bipolar Cells*

The retinal bipolar cells of goldfish have a single, large and bulbous synaptic terminal, 8–12 μm in diameter, allowing patch-clamp recordings to be made on either dissociated bipolar cells or detached terminals as reported by Matthews' group in 1994. The ribbon-type terminals of the retinal bipolar cells, which secrete glutamate via the fusion of small, clear-core vesicles to the presynaptic membrane, have been used to study the mechanisms of calcium-dependent exocytosis and synaptic vesicle recycling.

### *Neurohypophysial Nerve Terminals*

The nerve terminals of neurohypophysis (the posterior pituitary gland) extending from supraoptic and paraventricular nuclei release peptide neurohormones into the capillaries of the hypophyseal circulation. Arginine-vasopressin and oxytocin are the two major peptides found in neurohypophysial secretory granules. Some neurohypophysial nerve terminals have endings as large as 8–10 μm in diameter. Neurohypophysial synapse preparations have been used to study the calcium-dependent release mechanisms of peptide hormones in the work by Lemos and Nordmann in 1986 and Jackson and colleagues in 1991.

### *Hippocampal Brain Slices*

Hippocampal brain slices have been used to study the presynaptic mechanisms involved in synaptic plasticity in the CA1 region since the work by Creager and colleagues in 1980. Direct patch-clamp recordings have been achieved on the mossy fiber terminal in the hippocampal CA3 region by Geiger and Jonas in 2000. This study demonstrated that slow recovery from inactivation of presynaptic $K^+$ channels regulates presynaptic strength by enhancing presynaptic calcium influx. The major limitation of this model is again the small presynaptic site.

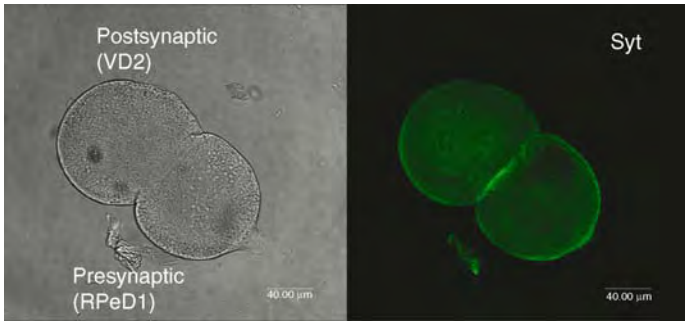
## Synapse Models in Primary Cell Culture

### *Neurite-Neurite Synapses*

Synaptic connectivity has been extensively studied in synapses formed in primary dissociated neuronal cell culture. Rotten hippocampal neuronal cultures are commonly used to study synapse function and structure *in vitro*. Unfortunately, the identities of the synapses in these cultures are usually unknown until the recording is completed. In addition, glial cells are required to establish these cell cultures, and functional synapses take up to weeks to form, increasing the variation and complexity found in these preparations. Simpler invertebrate neuronal cell culture models, such as those derived from mollusks, are also used to study synaptic function and synapse formation. Invertebrate *in vitro* systems offer some major advantages, including neurons that are usually individually identifiable, synapses that form in the absence of glial cells, and neurites that proceed with large growth cones. However, even in simple mollusk model systems, the neurite-neurite synapses are small, and electrophysiological recordings are often performed at cell somata that lie some distance from the synapse. The number of synapses in these cultures and the time it takes for the synapses to form between neurites varies between preparations. The formation of synapses depends primarily on neurite outgrowth. The temporal and spatial sequences of synaptic dynamics are difficult to observe directly. Thus, in an ideal model, the synapse would form between the cell bodies of identified neurons in the absence of neurites, namely a soma-soma synapse.

### *Soma-Soma Synapses*

In culture, synapses form between neuronal somata in the absence of neurites. The major advantage of



**Synaptic Transmission: Model Systems. Figure 2** A soma-soma synapse between identified *Lymnaea stagnalis* neurons in culture. Left: light image; Right: confocal image showing synaptotagmin clustering at the presynaptic site. Scale bar: 40 mm (Courtesy of Peter Gardzinski and Zhong-Ping Feng).

this model is that the synapses are large and relatively easily accessible for electrophysiological recordings and calcium imaging. The soma-soma synapse model, which most often employs neurons derived from molluscs, was pioneered in leech [1] and subsequently refined in the snails *Helisoma* [2] and *Aplysia* [3]. Feng et al. [4] adapted the soma-soma synapse approach to *Lymnaea stagnalis*. Functionally well-defined presynaptic and postsynaptic neurons can be individually isolated and paired in a soma-soma configuration in cell culture (Fig. 2).

Simultaneous electrophysiological recordings can be directly performed on the pre- and postsynaptic sites. Specific synaptic connections, similar to those observed *in vivo* and *in vitro* between neurites reported by Syed's group in early 1990s, have been detected between the identified neurons. In addition, voltage-induced calcium hotspots [5] and synaptic vesicle aggregation, labeled by FM1-43 signaling [6] or synaptotagmin [7], have been observed at the presynaptic sites. Formation of inhibitory and excitatory synapses has been showed to require distinct trophic factors [4,8]. The synaptic efficacy of *Lymnaea* soma-soma synapses is regulated by the cAMP-PKA signal transduction pathway [9] and glial cells [10]. Our recent study showed that the C2A and C2B calcium binding loops of synaptotagmin play different roles in synapse formation and synaptic transmission between soma-soma synapses [7]. The *Lymnaea* soma-soma synapse provides an unrivaled functional model for investigating the molecular mechanisms underlying synapse function.

## Isolated Synapse Preparation

### *Synaptosome*

Synaptosomal preparations are made from isolated nerve terminals and axonal varicosities *in vitro*. The well-sealed synaptosomes contain 70–100% of presynaptic boutons and terminals, and closely resemble the nerve terminal or varicosity from which they were derived. This model system has been used to identify proteins and mechanisms involved in exocytosis since the work of Whittaker's group in 1964. Direct patch clamp recording was first made by Nicholls and Sihra in 1986. Synaptosomes are derived from non-uniform sources of nerve terminals and varicosities and contain a mixture of multiple-types of synapses and transmitters; these features limit its usefulness in studies on the specificity of synaptic release mechanisms.

In summary, every model has its own particular strengths and limitations. The major advantage of the *in vitro* soma-soma synapse model between *Lymnaea* neurons is that the giant synapse forms between individually identifiable cells. In contrast to native giant synapses, the soma-soma synapse model allows direct assessment of the timing of synapse development, thus offering an ideal model not only for studying the cellular and molecular mechanisms of synaptic function, but also allowing investigations of the maturation of synapses formed between adult neurons.

# Synaptic Vesicle

## Definition

Synaptic vesicles are membrane-bound organelles found in presynaptic terminals. They accumulate neurotransmitters and neuromodulators, and release these substances into synaptic cleft by a $Ca^{2+}$-dependent exocytosis.

►Synaptic Vesicle Recycling

# Synaptic Vesicle Recycling

Hiroshi Kuromi
Institute for Behavioral Sciences, Gunma University Graduate School of Medicine, Maebashi, Japan

## Definition

Proteins of Synaptic Vesicle (SV) component are synthesized in the neuronal cell body and transported to the terminal by axonal transport. In addition, SVs are reformed by recycling of SVs after exocytosis at the nerve terminal. The recycling process includes endocytosis of SVs, refilling with neurotransmitter, translocation to release sites, and reformation of pools of SVs.

## Characteristics

### Quantitative Description

#### *Time Course of SV Recycling*

The time course of SV recycling varies depending on the type of synapses, or on the intensity and duration of the stimulus. In optical measurements by using fluorescence dye, the time required for a SV to be endocytosed, transported, and prepared for a new round of release was estimated to be shorter than 40 s at the frog neuromuscular junction, and in cultured rat hippocampal neurons [1], rapid recycling (few sec) was also detected in cultured hippocampal neurons. The time for recycling becomes much longer at prolonged stimulation. The first step of SV recycling is the endocytosis at the plasma membrane of nerve terminals. The half time of endocytosis after a brief burst of exocytosis is approximately 20 s or a few seconds [2]. With capacitance measurement at the giant terminal of goldfish bipolar neurons and at saccular hair cells, the time constant of the endocytosis following exocytosis was estimated as brief as 2 s. For SV attachment to the plasma membrane and pre-fusion may be required approximately 10–20 ms and for $Ca^{2+}$-triggered fusion less than 1 ms, most of SV recycling consists of reformation of release-ready SVs and neurotransmitter uptake.

#### *SV Pools*

The active zones of nerve terminals are considered as release sites for neurotransmitter. Few SVs (5–10) are attached to the active zone and considered as release-ready SVs. There are clusters of some 200–500 SVs that are situated next to the active zone. The majority of SVs are located in the cytosol of the nerve terminals. From functional determinations, SVs are divided into three groups (pools), the Immediately Releasable (a few percent of the total), the Readily Releasable (10–20%), and the Reserve pools (all the rest) in nerve terminals of fly and frog neuromuscular junctions, goldfish retina, and mammalian hippocampal and calyx of Held synapses [3].

### Higher Level Structures

Neurons release neurotransmitters only at nerve endings, which are situated far from the cell body. The supply of SVs by transportation from the cell body to nerve endings is not enough to maintain continuous release of neurotransmitters for a long time. How can nerve endings sustain a high rate of release of transmitters for a prolonged period without exhausting their supply of SVs? Some forms of local recycling of SVs must occur at the nerve ending.

### Lower Level Components

According to the vesicle hypothesis, neurotransmitter is contained in SVs and transmitter release occurs by exocytosis of SVs. After exocytosis, SVs are slowly retrieved from the plasma membrane, mainly by formation of clathrin-coated pits. The retrieved SVs are processed in the terminal to generate new SVs, either by direct uncoating of clathrin-coated SVs or via intermediate ►endosomes (cistemae) that later give rise

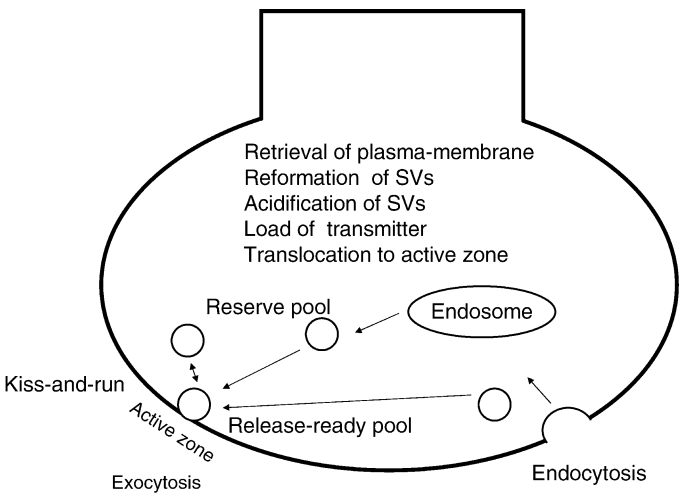
to new SVs [4]. In addition, a faster clathrin-independent retrieval mechanism, including "►kiss-and-run," where SVs fuse only temporarily with the presynaptic membrane before retrieval has also been suggested [5] (Fig. 1). The frequency of stimulation may determine vesicle endocytosis through two different recycling routes. Ceccarelli et al. [5] used low frequency stimulation, and found no requirement for endocytic intermediates. Heuser and Reese [4] used high frequency stimulation, and found that vesicle reformation was required for endocytic intermediates. Electron microscopic observations revealed that two endocytic pathways exist in single presynaptic boutons of *Drosophila*. During recovery, after blockade of endocytosis in a temperature-sensitive dynamin mutant, *shibire*, one pathway of endocytosis was found to be fast, did not rely on endosomal intermediates, and refilled a pool of vesicles near the active zone. A slower pathway refilled a vesicle pool distal to the active zones, through cisterna-like intermediates [6]. The pool recovered via the fast pathway supplied SVs for evoked release (at low frequency, and may constitute a ►readily releasable pool). The second pool may constitute the ►reserve pool of SVs for transmitter release at a high frequency.

## Higher Level Processes

The recycling of SVs in presynaptic terminals is regulated by retrograde signals from postsynaptic cells. Fluorescence imaging and pharmacological analysis showed that a nitric oxide (NO) signal generated postsynaptically regulates endocytosis, and at least one later step in SV recycling in rat hippocampal neurons in culture. In goldfish retinal slices, fast endocytosis of SVs in presynaptic terminals is inhibited by postsynaptically released GABA-mediated chloride influx.

## Lower Level Processes

In the kiss-and-run cycling of SVs [5], no endocytic process is necessary. During kiss-and-run cycling, SVs transiently release transmitter through a narrow pore, and the empty vesicle either detaches from the active zone or remains in place and is refilled with transmitter. Recently recycled SVs occupy a privileged location near the active zone, which would neatly explain their preferential reuse. The importance of clathrin-mediated endocytosis in recycling of SVs is well established. Assembly of endocytotic machinery proteins including clathrin, adaptor proteins (AP-2), endophilins and formation of clathrin-coated pits are necessary for retrieval of SVs from the plasma membrane by dynamin. For further steps of recycling of SVs after retrieval of clathrin-coated SVs, the clathrin-coated SVs are processed for uncoating. An interaction between Hsc70 and auxilin are suggested to be required for uncoating. Genetically induced disruption of genes encoding these proteins in *Drosophila* resulted in severe impairment of SV recycling. In either case of clathrin-mediated or kiss-and-run cycled retrieval of SVs, after fission of SVs by dynamin, empty SVs acidify via proton pump activity (vacuolar ATPase) to generate an electrochemical gradient across the SV membrane. SVs are then filled



**Synaptic Vesicle Recycling. Figure 1** Synaptic Vesicle Recycling. There are alternative pathways for SV recycling; kiss-and-run cycling and full fusion followed by endocytosis. During kiss-and-run cycling, SVs transiently release transmitter through a narrow pore, and the empty vesicle either detaches from the active zone or it remains in place and refills with transmitter. Kiss-and-run cycling occurs at the active zone, is dependent on dynamin, but does not require clathrin assembly. After exocytosis, SVs are slowly retrieved from plasma membrane, mainly by formation of clathrin-coated pits. The retrieved SVs are processed in the terminals to generate new SVs, either by direct uncoating of clathrin-coated SVs or via intermediate endosomes (cistemae) that later give rise to new SVs.

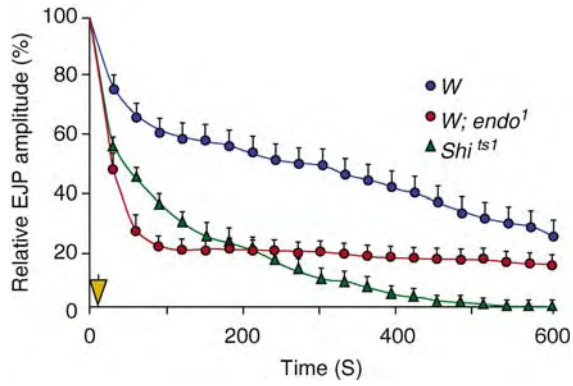
with neurotransmitters by active transport, which is mediated by transporters specialized for individual transmitter, utilizing energy of $H^+$ gradient. There are specific transporters for glutamate (GLUT 1, 2 and 3), ATP, and acetylcholine, a common transporter for glycine and GABA, and one for all catecholamines. SVs filled with neurotransmitters are translocated to the area near to active zones. Although participation of cytoskeleton and motor proteins in this active transport process has been suggested, direct evidence has not yet been obtained.

## Process Regulation

Following incorporation of the SV membrane into the plasma membrane by exocytosis, the endocytic process could be blocked by removing extracellular $Ca^{2+}$. The block could then be released by re-adding low concentrations of extracellular $Ca^{2+}$ [7]. One of the roles of $Ca^{2+}$ influx in endocytosis of SVs is in assembly of endocytotic machinery proteins at the plasma membrane. When $Ca^{2+}$ influx linked to endocytosis was selectively blocked at the *Drosophila* neuromuscular junction, components of SV were incorporated into the plasma membrane but no clathrin clusters were formed [8]. $Ca^{2+}$ influx accelerates endocytosis at rat cultured hippocampal neurons. However, elevation of the intracellular $Ca^{2+}$ level to a few hundred nM inhibits endocytosis in goldfish bipolar terminals.

## Function

The most striking demonstration of the importance of recycling of SVs in animal behaviors came from the phenotypic characterization of temperature-sensitive *Drosophila shibire* mutants ($shi^{ts}$) [9]. $Shi^{ts}$ flies are normal at a permissive temperature of 19°C, but become rapidly paralyzed at the non-permissive temperature of 29°C. Exocytosis occurs normally at 29°C, but endocytosis is impaired, leading to a rapid depletion of SVs. The roles of clathrin-mediated endocytosis of SVs and kiss-and-run cycling of SVs in synaptic transmission are clearly demonstrated in *endophilin* mutants. Endophilin is a key molecule for clathrin-mediated-endocytosis. Electrophysiological recordings at the neuromuscular junction in *endophilin* mutants demonstrated that a lack of clathrin-mediated endocytosis does not affect neurotransmitter release at low levels of synaptic activity. However, when stimulated at a high frequency, *endophilin*-null neuromuscular junctions undergo a strong synaptic depression, highlighting the importance of clathrin-mediated recycling. However, neurotransmitter-release is not completely abolished (►neurotransmitter release, elementary step). Neurotransmission remained at the 15–20% level throughout the stimulus. In contrast, at restricted temperatures in *shibire*, neurotransmission is completely abolished after intense-stimulation [10] (Fig. 2).



**Synaptic Vesicle Recycling. Figure 2** Roles of Endocytosis of SVs, Kiss-and-Run Cycling and Clathrin-Mediated Endocytosis, in Synaptic Transmission. Amplitude of the excitatory junctional potential (EJP) evoked by nerve stimulation at 10 Hz. Values are relative to the EJP amplitude measured at 1 Hz before applying the tetanus. Blue circles, w; red circles, $endo^1$; green triangles, $shit^{s1}$, recorded at the non-permissive temperature. The yellow arrow indicates the approximate time at which full depletion of the total vesicle pool in $endo^1$ mutant terminals would occur at 10 Hz stimulation in the absence of vesicle retrieval by using $shit^{s1}$; endo1 animals [10].

## Synaptodendrosome

►Synaptosome

## Synaptogenesis

Masumi Ichikawa
Tokyo Metropolitan Institute for Neuroscience, Tokyo, Japan

### Synonyms

Synapse formation

### Definition

Formation and maturation of synaptic contacts during development in the central and peripheral nervous system.

Synapse is the specialized contact between neurons through which they communicate. Synaptogenesis is a process in which synaptic contacts form and mature. The formation of synaptic contact is a complex process requiring the coordinated assembly of components on either side of the ►synaptic cleft. Synapse assembly begins when the immature presynaptic process contacts the postsynaptic neurons, leading to formation of an active zone where ►neurotransmitters are released into the synaptic cleft. During the postsynaptic process, receptors and signaling molecules are induced and localized, conferring the capacity to transduce the given signal into a postsynaptic response. The morphological rearrangements take place once synaptic targets establish their initial contact. During these maturational changes, functional molecules are also rearranged in synapses.

### Characteristics

Following proliferation, migration and differentiation, a developing neuron reaches its final destination in the nervous system. To establish contact with its synaptic partners, a neuron must extend axonal (presynaptic) and dendritic (postsynaptic) processes towards targets located significant distances away. Extending axons and ►dendrites are guided towards their targets. The journey of both ►axons and dendrites towards its synaptic partner is regulated by a series of intermediate targets by cell–cell interaction and gradients of diffusible chemotrophic factors, which can be attractive or repulsive in nature [1–3]. Synaptogenesis involves a series of vary gradual structural, functional, and molecular changes in differentiation and maturational processes.

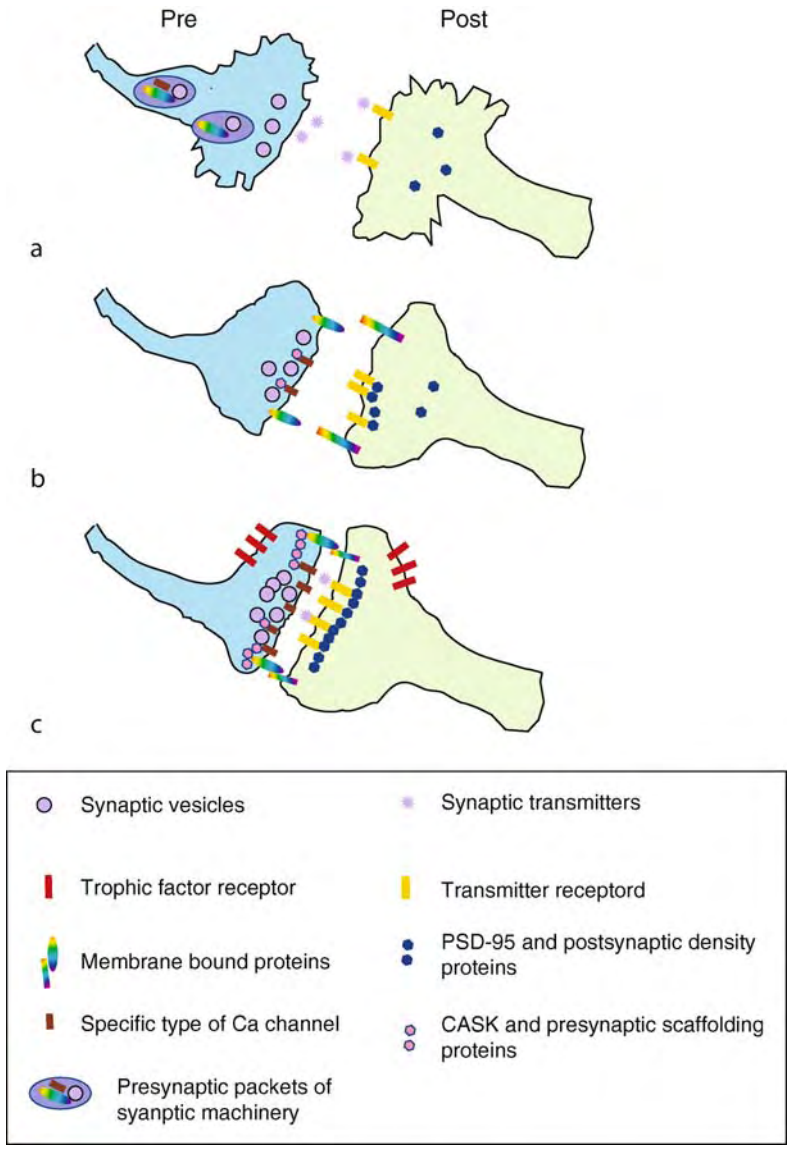
### Cell-Cell Interaction during Synapse Formation

The formation of synapses involves an interaction between the presynaptic and the postsynaptic elements. Postsynaptic densities without presynaptic processes, and free presynaptic processes with associated ►synaptic vesicles, have been observed ultrastructurally in the developing brain. Prior to synaptic contact, receptor molecules of neurotransmitter are present on the surface of postsynaptic processes, and synaptic vesicles in the isolated presynaptic processes release synaptic transmitters before synapse formation. Transmitter-receptor interaction attracts appropriate target processes by binding to and stimulating postsynaptic processes. These two pre- and postsynaptic elements must first come into close proximity. Both pre- and postsynaptic processes play active roles in identifying and attracting their potential synaptic partners through a series of cell-cell interactions, either diffusible (neurotransmitter, ►neurotrophic factor) or ►cell adhesion molecules (N-CAM, cadherin, SyCAM, neurexin, neuroligin) [1] (Fig. 1). Whilst making contact, these molecules stabilize pre- and postsynaptic scaffolding proteins such as CASK and PSD-95M. Subsequent formations of synaptic contacts and interactions between neurotrophic factors and receptors leads to clustering of specific (non-L type) ►Ca channels and synaptic vesicles in presynaptic processes and transmitter receptors in postsynaptic processes [4]. Other molecules localize in pre and postsynaptic elements during cell–cell interactions (Fig. 1).

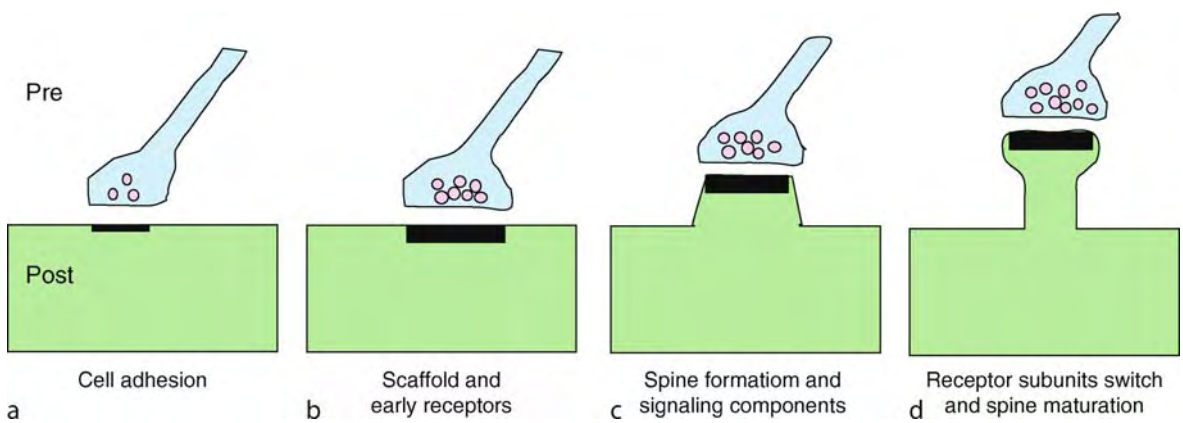
1. Pre- and postsynaptic growth processes approach each other. Transmitter-receptor interaction attracts appropriate target processes by binding and stimulating postsynaptic processes. Various components of pre- and postsynaptic specialization, including presynaptic packets containing synaptic machinery and channels, and postsynaptic proteins are mobile prior to contact.
2. As extending growth processes contact, the processes smooth, and asymmetric interactions between cell adhesion molecules mark the synaptic sites and stabilize pre- and postsynaptic scaffolding proteins.
3. Subsequent formation of synaptic contacts and interactions between neurotrophic factors and receptors lead to clustering of specific (non L type) Ca channels and synaptic vesicles in presynaptic processes and transmitter receptors at the postsynaptic processes.

### Differentiation and Maturation of Synapse

There is no general rule about the order of maturation of the pre- and postsynaptic structures, but in each case, the order is apparently invariant. A number of factors may have to act in combination to result in the functional maturation of the synapses (Fig. 2).



**Synaptogenesis. Figure 1** Steps of synaptic contact formation.



**Synaptogenesis. Figure 2** Maturation of spine synapses.

An approximate sequence of assembly of postsynaptic components is related to maturational changes in synaptic structure. (i) Pre- and postsynaptic processes form morphologically unspecialized but functioned contact. The earliest synapses recognized ultrastructurally contain only few synaptic vesicles. (ii) Putative scaffolding proteins such as PSD-95, GKAP/SAPAP, and Shank families localize to synapse early with an increase of size of PSD. Synaptic vesicles begin to accumulate at presynaptic processes. (iii) Many spine associated components such as actinin, drebrin, and CaMKII cluster at synapses late in development, concurrent with the outgrowth of spines. (iv) Rapid neurotransmitter receptor accumulation occurs in the spines. NMDA type glutamate receptors undergo a subunit switch from NR2B to NR2A associated with maturation of spines.

Functional activity may be necessary to ensure full maturation and permanent stability of the synapses.

### *Morphological Maturation*

1. The number of synaptic vesicles increases in development and differentiation.

   The earliest synapses recognized ultrastructurally contain only a few synaptic vesicles. The number of synaptic vesicles increases with development. In the rat cerebral cortex, a fourfold increase in the number of vesicles per terminal has been observed [5,6].
2. The size of pre- and ►postsynaptic density increases in maturation [6].
3. The outgrowth of ►dendritic spines occurs in the late stage of development.

   Dendritic spines develop gradually following initial synapse formation. Quantitative electron microscopic studies show that spine synapses develop from shaft synapses by outgrowth through a stage of stubby spine [7].
4. The shape of spine changes dependent on the activity of stimulation.

   Activity can regulate the pre- and postsynaptic structure and synapse formation. However, there is not yet a consensus on how activity influences synaptic constituents. The variation may reflect differences in cell type, developmental state, experimental preparation, time course, and mode of activity manipulation [8,9].

### *Molecular Differentiation*

1. Changes in cell adhesion molecules occur. The actions of cell adhesion molecules is not limited to initial contact formation, but is also involved in specific target recognition and regulation of synaptic size and strength [5].
2. Maturational changes in structural proteins occur. Scaffolding protein (PSD-95, GKAP/SAPAP, Shank families) localize to synapses early, functional protein (CaMKIIa and syndecan-2) cluster at synapses late in development, concurrent with maturation of dendritic spines [1].
3. Receptor subunits switch in association with the changes of the presynaptic terminal. Many spine associated components such as actinin, drebrin, and CaMKII cluster at synapses late in development, concurrent with the outgrowth or maturation of dendritic spines. NMDA type glutamate receptors also undergo a subunit switch from NR2B to NR2A [2].
4. Neurotrophins (NGF, BDNF, NT3, 4/5) have been implicated in multiple aspects of synaptic development. BDNF induces axonal and dendritic branching and remodeling, increases the efficacy of synaptic transmission, and modulates the functional maturation of synapses [10].

## Critical Period of Synaptogenesis in Developing Brain

The onset of synaptogenesis occurs according to a remarkably invariant timetable. In each region of the mammalian brain, there is usually a difference of less than a few days between individuals of the same species in the appearance of the first synapses on any particular type of neurons. Synapses appear suddenly and increase rapidly in numbers. Excessive production of synapses, followed by elimination of redundant synapses, occurs in many regions.

Dramatic increases in synaptogenesis of mammalian cerebral cortex occur during the early postnatal period of development. The critical period of synaptogenesis is postnatal 2 weeks in rodent cerebral cortex and the first year after birth in human visual cortex [11,12].

## Activity-Dependent Synaptogenesis in Adult Brain

Recent developments in real time imaging techniques have revealed not only that synaptic structures are motile, but also that a fraction of synapses undergo a continuous elimination and formation process in adult CNS. Activation of neuronal networks enhances dynamic mechanisms at both the presynaptic (remodeling of axonal branching) and postsynaptic (turnover of dendritic spines) level. Structural changes of synapses can occur rapidly within 24 h of sensory stimulation [8,12]. Activity dependent synaptogenesis takes place in adult CNS.

## Synonyms

Synaptoneurosome; Synaptodendrosome; Neurosecretosome

## Definition

The ►synaptosome is a subcellular particle deriving from the interruption of the axonal termini (see ►Axon) after the brain tissue has been homogenized in a buffer isoosmotic with the plasma. It represents mainly the presynaptic compartment or presynaptic spine but often retains part of the postsynaptic components according to the experimental condition used.

The ►synaptoneurosome is a composite particle containing one or more presynaptic compartments (synaptosome) attached to a postsynaptic element (neurosome) [1]. In the ►synaptodendrosome, the axon terminal adheres to a larger portion of the postsynaptic compartment (dendrite) (see ►Dendrite) [2]. Finally, the ►neurosecretosomes are a subtype of synaptosomes isolated from neurosecretory neurons such as neurons from the neurohypophysis [3].

## Characteristics

### Quantitative Description

The synaptosomal particles have a variable size according to their composition. The simplest synaptosomes are small bodies with a mean diameter of 0.6 μm or up to 1 μm for the neurosecretosomes [1,3]. As the neurosome vesicle measures around 1 μm, the complete synaptoneurosome has a mean diameter of 1.6 μm [1].

### Pre and Postsynaptic Compartment Purification

The quality and composition of the synaptosomal fraction depends on the purification method used. The use of one or multiple step gradients as well as the homogenization of the brain, performed manually or mechanically, leads to a different population of synaptosomes with variable intact postsynaptic compartments.

The traditional procedure utilizes the separation of particles deriving from brain tissue homogenate, through an isoosmotic density gradient [4]. The homogenate is loaded on a sucrose gradient that is then centrifuged at high speed. During the centrifugation, each particle sediments at a specific location along the gradient according to the size and weight leading to the separation of four major subcellular fractions. The bottom fraction (P1) contains mainly nuclei and cell debris, whereas the middle fraction (P2) is a heterogeneous population including myelin fragments, synaptosomes and free mitochondria. At the top, the microsomes, ribosomes and smaller entities form two distinct fractions (P3 and P4). The further separation of the middle fraction (P2) leads to the isolation of synaptosomes.

To improve the quality of synaptoneurosomes fractions, recently, a second density gradient has been employed that makes use of chemicals based on the iodixanol [5]. While the purity of the preparation is very high, the synaptoneurosome recovery is quite low. An alternative method, frequently used for the isolation of synaptoneurosomes, makes use of subsequent filtration steps in isoosmotic buffer. The brain homogenate is passed first through a 100 μm nylon mesh filter and then through a 5 μm filter [1].

## Higher Level Structures

The synaptosomes appear as spherical or elongated particles containing the nerve terminal often joined to a partial or complete postsynaptic compartment [4,5]. The particle is coated by a membrane, which seals off at the point where the axon is fractured. This continuous envelope preserves the integrity of synaptoneurosome and thus both the presynaptic and postsynaptic compartments retain their main structural features [4].

The presynaptic element (see ►Chemical synapse, ►presynaptic structure) contains a pool of synaptic vesicles (see ►Synaptic vesicle) that are organized in the active zone (see ►Active zone) close to the presynaptic membrane [1,4].

As mentioned, although in the synaptosome preparation the postsynapse is often not well preserved, the sealed presynaptic compartment is frequently attached to a residual of postsynaptic membrane. In the intact synaptoneurosomes the postsynaptic element is well conserved as shown by a sealed membrane containing a dense structure beneath the membrane, known as postsynaptic density (PSD) (see ►Postsynaptic density) [1]. Figure 1 shows: (i) a drawing of a synaptic contact (pre and postsynaptic compartments) that is piched off during the isolation of synaptoneurosomes, (ii) an image, acquired at the electron microscope, of a synaptoneurosome obtained with a protocol previously described [5] and (iii) a colored drawing of the same electron microscopy image.

## Lower Level Components

At the ultrastructural level, the synaptosomal particles retain the cytoplasm components and organelles.

*In vivo*, the presynaptic element presents an active zone (see ►Active zone) containing numerous synaptic vesicles 40–250 nm in diameter: a storage of releasable neurotransmitters (see ►Neurotransmitter). Generally, the synaptosomes contain small vesicles (40–60 nm in diameter), both clear-core vesicles with acetylcholine or amino acid transmitters, and dense-core vesicles (see ►Dense core vesicles) with catecholamines [6,7]. Sometimes larger dense-core vesicles (see ►Large dense core vesicles) have been observed containing neuropeptides (up to 250 nm in diameter) or biogenic amines [6,7]. In the neurosecretosomes the hormones are packaged in large neurosecretory granules (around 150 nm in diameter), with a dense core surrounded by a clear zone [3].

The presynaptic element preserves also the molecular machinery for exocytosis of synaptic vesicles (see ►Presynaptic exocytosis) [7] and the synaptophysin fractions are highly enriched in proteins, involved in neurotransmitter release, such as synaptophysin (see ►Synaptophysin) [5]. In intact synaptophysin, the exocytosis apparatus can maintain its functionality (see below). Within the presynaptic compartment one or more mitochondria are found and supply the energy for the local metabolism [4,7].

The pre and postsynaptic elements in the synaptoneurosome are joined together, as expected in a chemical synapse (see ►Chemical synapse). As mentioned, the Postsynaptic membrane shows a local thickening, the postsynaptic density (PSD), which links the neurotransmitters receptors to signaling protein and cytoskeleton. In fact, the key component of this machinery, known as postsynaptic density protein 95 (PSD-95), (see ►PSD-95) is highly enriched in synaptosomal fractions [5].

In polarized cells, the mRNAs are delivered to specific subcellular compartments to be locally translated. In neurons, mRNAs as well as the translational machinery have been found in dendrites and in axons, especially in growth cone (see ►Dendritic protein synthesis) [8 and references therein]. In synaptoneurosomes, ►dendritic mRNAs, polyribosomes [8 and references therein] and translational factors [9] have been detected and messenger RNAs can be locally

translated upon synaptic stimulation (see below) [5,8 and references therein]. Lately, small non-coding RNAs such as microRNAs and the Brain Cytoplasmic RNA 1, *BC1*, have also been detected at synapses [2,10].

## Higher Level Processes

The synaptosomes maintain their viability and metabolic activity, in media isotonic to plasma, for some hours after isolation [6]. The high membrane potential and the low intracellular calcium concentration indicate the integrity of synaptosomal particles [7].

Importantly, the synaptosomes include mitochondria that supply the energy needed for the metabolic activities of presynaptic terminals. In fact the synaptosomal mitochondria possess a stable membrane potential which sustains the ATP production for the bioenergetic metabolism [7]. As the synaptosomal particles are vulnerable to osmotic shock, the suspension in hypo-osmotic media leads to bursting of synaptosomes and release of intact synaptic vesicles and mitochondria [6].

In conclusion, the viable synaptosome behaves similarly to the synaptic compartment *in vivo* and can react to physiological and not physiological stimulations modulating its own functions (see below).

## Lower Level Processes

The synaptosomes retain the ability to release the neurotransmitters by calcium-dependent exocytosis (see ►Exocytosis) as it occurs at synapses [7]. After stimulation, the synaptic vesicles move toward the active zone and, occasionally, the fusion of the vesicles with the membrane can also be observed. The endocytotic recycling of membranes provides the replenishment of vesicles pool (see ►Synaptic vesicle recycling). The synaptosomes release different class of neurotransmitters – cathecolamines, neuropeptides and amino acid transmitters, mainly glutamate [7 and references therein].

As previously mentioned, the synaptoneurosomes retain the majority of cytoplasmic components, including the synaptic mRNAs and the protein synthesis apparatus. Active translation in these particles has been shown by the incorporation of radiolabeled amido acids into proteins [5,8 and references therein]. Interestingly, protein synthesis within synaptoneurosomes is activity-regulated. After stimulation, the translation of subset of synaptic mRNAs encoding for key synaptic proteins increases. Last, but not least, the intact synaptoneurosomes possess functional neurotransmitter receptors and relative signalling complex. As a consequence, they retain the ability to trigger events and processes occurring in the intact neuronal cell (see below).

## Process Regulation

Although the synaptosome maintains the metabolic machinery of synaptic terminals, it has lost the axonal input and thus it cannot receive physiological stimuli. Nevertheless, the intact synaptosome possesses functional neurotransmitters receptors that are up to respond to pharmacological drugs. In fact, the synaptosomal membrane has a negative membrane potential whose polarity changes after receptors activation as it happens in the whole neuron [7].

The stimulation can be obtained by alteration of ionic environment increasing potassium ion, by pharmacological inhibition of ion channels such as potassium channel [7] or by administration of physiological or pharmacological receptors agonists. In particular, treatment of synaptoneurosomes with metabotropic glutamate receptor (mGluR) agonists increases the amount of ribosomes associated with mRNAs, i.e. increases general local protein synthesis [8 and references therein]. Moreover, the administration of glutamate activates the translation of specific synaptic mRNAs [5]. At last, synaptoneurosomes maintain also the ability to respond to neurotrophic factors such as brain-derived neurotrophic factor (BDNF) which activates the protein synthesis machinery [9] enhancing the translation of specific mRNAs [10].

## Function (Purpose)

The synaptosomes provide a versatile model to study the ultrastructure and the physiological features of the synapses.

The synaptosomal preparations can be used as starting material to isolate synaptic elements such as synaptic vesicles, synaptic mitochondria, purified postsynaptic density and synaptic mRNAs.

The synaptosomes have been used as a model to study synaptic processes. First, the synaptosomes have been extensively exploited to investigate neurotransmitter release, especially the glutamate release, and the regulation of this process [7]. In this context, the synaptosomes also enabled the study of the molecular basis of both endocytosis and exocytosis as the synaptosome is the simplest compartment containing the endocytotic and exocytotic apparatus [7]. Second, the synaptoneurosomes and the synaptodendrosomes have been exploited to identify the synaptically localized mRNAs and to study the regulated local protein synthesis [2,5,8 and references therein]. As the neurotransmitters receptors and the membrane maintain their functionality, the synaptosomal preparations have also been used to investigate the physiological regulation of above-mentioned processes after receptors stimulation or ion channel blockade.

## Syncope

### Definition

Acute, brief and transient loss of consciousness and postural tone (general muscle weakness and inability to stand upright) with spontaneous and complete recovery. A syncope is often preceded by faintness which denotes a lack of strength with a feeling of giddiness, swaying ground or surrounding objects, and impending loss of consciousness (presyncope). There are many possible causes of syncope, in particular cardiovascular changes and changes in blood state (e.g., hypoxia, anemia etc.) with a reduced supply of oxygen to the brain. Syncopes may thus be classified as vasodepressor (vasovagal) or neurocardiogenic syncope, postural hypotension with a defect in vasomotor reflexes, cardiac syncope, carotid sinus syncope, and others.

## Syndactyly

### Definition

Syndactyly describes the congenital or artificial webbing of adjacent fingers. As a consequence, webbed fingers cannot be used independently resulting in temporal coincidence of tactile inputs to these fingers.

►Somatosensory Reorganization

## Syndrome of Inappropriate ADH Secretion (SIADH)

### Definition

SIADH is characterized by plasma antidiuretic hormone (ADH) levels that are elevated above those

expected on the basis of body fluid osmolality and blood volume or arterial pressure.

►Blood Volume Regulation
►Vasopressin (VP) or Antidiuretic Hormone (ADH)

## Synergist Muscles

### Definition

Muscles acting to produce the same motion or torque at a joint.

►Impedance Control

## Synergy

►Coordination

## Synesthesia

### Definition

Synesthesia is a condition, in which otherwise normal persons experience sensations in a non-stimulated sensory modality when stimulated by stimuli in another sensory modality or sub-modality. It runs in families, prevails among women and non-right-handers. These synesthetes may see letters or numbers colored (e.g. 5 as green and 6 as red: grapheme-color synesthesia or lexical synesthesia; blind people may have colored impressions of Braille signs), "see" tones as colors (e.g. C-sharp as blue: color-hearing), "hear" colors, "taste" shapes, "smell" the color red, describe music as movements of colored forms in visual space. The most common synesthetic experiences are color-hearing (with clear associations of particular colors with particular sounds) and grapheme-color synesthesia. In synesthetes who clearly associate specific graphemes with specific colors (e.g. "R" is blue), display of the grapheme in another color (e.g. red) may evoke affective reactions (e.g. uneasiness). Evidence is accumulating to indicate that these synesthetic sensations are real perceptions and may be due to hyperactivity of color-sensitive cortical areas or "cross-activation" of brain areas concerned with the associated percepts, thus extending normal processes in multisensory integration by hyperconnectivity between different cerebro-cortical areas. Many well-known artists are known to have been synesthetes, e.g. Alexander Scriabin, Olivier Messiaen, Arthur Rimbaud, Charles Baudelaire, Vladimir Nabokov, Vasily Kandinsky, David Hockney.

►Synesthesia

## Synkinesias

### Definition

Co-contractions of normally independently controlled muscles. For example, in *jaw winking*, voluntary movements of the lower face coincide with, e.g., eye closure.

## Synovial Fluid

### Definition

Synovial fluid is the fluid found on the articulating surface of joints. It is closely associated with the

cartilage fluid and is essential for the virtually frictionless movement of joints.

►Articular Cartilage

## Synovium

### Definition

Thin membranous layer lining synovial joints that secretes synovial fluid and contains nerves and vessels (both blood and lymphatics).

►Joints

## Synprint

### Definition

A synaptic protein interaction site localized to the large intracellular loop between domains II and III of the α1 subunits of N- and P/Q-type $Ca^{2+}$ channels. Enables binding of syntaxin, SNAP-25 and synaptotagmin to the $Ca^{2+}$ channels, affecting the efficiency of $Ca^{2+}$ entry vesicle release coupling.

►Calcium Channels – an Overview
►Synaptic Proteins and Regulated Exocytosis

## Synprint Motif

### Definition

Acronym of synaptic protein interaction region: an approximately 225 amino acid stretch in the intracellular domain II-III linker region of the α1-subunit of mammalian Cav2.1 and Cav2.2 channels which binds SNARE proteins. The site is considered unique to vertebrate N-type $Ca^{2+}$ channels and P/Q-type $Ca^{2+}$ channels and seems to be at the origin or the tight coupling between these channels and presynaptic vesicles.

## Synthetic Quality in Olfaction

### Definition

In odor-mixture psychophysics, a synthetic quality occurs when a mixture of odorants smells like something different than the component odorants.

►Olfactory Information

## Syphilitic Meningitis

### Definition

Syphilitic meningitis mostly occurs within two years of the primary infection and is characterized by nocturnal headache, malaise, fever, stiff neck, and cranial nerve palsies.

## Syringomyelia

### Definition

An abnormal cystic structure within the center of the spinal cord resulting from the cerebro-spinal fluid (CSF) build-up. It most commonly occurs in the cervical spine. It can be primary or secondary (develops as a result of blockage of the CSF flow). The most common causes include birth defects, tumors and trauma. This condition is associated with Chiari I and II malformations. Typical symptoms include segmental muscular weakness and atrophy with associated specific sensory loss (loss of pain and temperature sensation with preservation of the sense of touch).

Surgical intervention may be needed to alleviate the symptoms and the indications usually depend on the primary cause.

►Gliomas

## Syrinx

### Definition

A special secondary vocal organ of birds, a modification of the lower part of the trachea, a “lower larynx.”

## Tabes Dorsalis

### Definition

Late consequence (5 to 15 years after the primary infection) of the chronic inflammation initiated by Treponema pallidus (syphilis or lues), leading to degenerative and sclerotic changes in posterior spinal nerve roots, large-diameter neurons in the dorsal-root ganglia, long thick myelinated fibers in the dorsal columns, optic nerves and oculomotor nuclei. Tabetic patients suffer from lightning root pains, severe deficits in touch and position sense without serious impairment of temperature and pain sensation, spastic gait, failing vision, small and irregular pupils, gastric crisis, urinary and sexual disturbances.

## Tachycardia

### Definition

Tachycardia refers to an abnormally rapid heart rate, and in clinical practice this is often taken to be a resting heart rate in excess of 100 beats per minute. Tachycardia may be seen with fever and sympatho-excitation. It also results from specific disorders affecting the generation and transmission of impulses in the electrical conduction system of the heart. With extreme tachycardia cardiac output declines because the high rate of ventricular contraction does not permit adequate flow of blood into the ventricles. Hence, rates in the range of 250–300 beats per minute are unsustainable and carry a high risk of ventricular fibrillation followed by cardiac arrest.

## Tachykinins

### Definition

Tachykinins are a group of related endogenous peptides, substance P, neurokinin A and neurokinin B, which are widely distributed within the nervous system. Substance P and neurokinin A are formed by cleavage of a larger protein precursor, pre-pro-tachykinin.

Nociceptive sensory neurons express substance P and neurokinin A and release these mediators in the periphery as well as in the dorsal horn of the spinal cord. Inflammation increases substance P expression. Activation of nociceptors results in the release of substance P in the periphery, which contributes to neurogenic inflammation. Substance P release in the dorsal horn contributes to the development of chronic pain. The effects of tachykinins are mediated by a group of G-protein coupled receptors called NK1, NK2 and NK3, which bind substance P, neurokinin A and neurokinin B, respectively.

## Tactile Attention

Christine Elaine Chapman
Group de recherchezurle système nerveux central, Département de Physiologie & École de Réadaptation, Faculté de Médecine, Université de Montréal, Montréal, QC, Canada

### Definition

Attention allows one to focus awareness and the processing capacities of the brain on objects and events relevant to one's immediate, behavioural goals, and this within the context of a central nervous system (CNS) that is constantly bombarded by a steady stream of sensory inputs. Tactile attention specifically refers to attention to somatic sensory stimuli. While this term can encompass all of the submodalities that contribute to somatic sensation (touch/pressure, position/movement, temperature, pain), most experimental studies have concentrated on characterizing sensory responsiveness to touch during manipulations of attention, and this is the focus of this essay.

### Characteristics

#### Quantitative Description

Attention can be directed either voluntarily (top-down, endogenous) or involuntarily (bottom-up, exogenous) towards a specific stimulus. Typical examples would be, respectively, searching through a hand bag to find a pen versus the attention-grabbing elicited by the onset of vibration from a cell phone in one's pocket. Attention can be focused on any number of attributes of the stimulus, including its spatial location, features (texture, shape, size, consistency etc) and/or modality. Attention can be directed to a single stimulus (selective attention), or can be shared across multiple stimuli (divided attention). Finally, attention can be directed towards a stimulus either covertly or overtly (respectively, with or without orienting the receptors towards the stimulus). Overt orientation can include orienting the head and eyes towards an object of interest, so as to facilitate interactions. For example, an insect might land on one's arm, but the eventual motor response would depend on whether the insect might potentially bite (wasp) or not (housefly). For touch, the hand is appropriately shaped and positioned during the transport phase of a reach-to-grasp movement, thereby ensuring that the object will be secured in an efficient manner. Vision of the object is not essential for orienting to occur. Examples include the coordinated tongue and jaw movements that accompany chewing of a food morsel, or the adjustments in hand and finger posture that occur when grasping an object in the dark. Finally, orienting behaviour can be aversive, in the case of, for example, a painful tactile stimulus.

## Description of the Process

In comparison with the visual system, there is much less information available about the effects of attention on the perception of tactile stimuli. For all modalities, attentional effects are inferred by measuring the time taken to evaluate the stimulus (reaction time), response accuracy and also measures of sensory sensitivity (detection or discrimination thresholds). Faster reaction times are presumed to reflect speeded up processing and decision making, although the measures can also reflect increased readiness to move. Improved accuracy and reductions in sensory thresholds are likewise considered to reflect enhanced processing of sensory inputs. Some caution is necessary, however, because such changes can also reflect a change in response criterion or bias (willingness to report the presence of a stimulus when measuring detection threshold, for example).

### *Spatial Attention*

When attention is directed with spatial cues to different fingers of the hands, then the ability to discriminate surface texture and also vibrotactile stimulation shows a modest improvement with cueing (attention towards or away from the location of the stimulus). The effects are, however, dependent on the task design only being obvious when the task is more difficult, detecting the absence rather than the presence of a change in stimulus intensity [1]. Using reaction time measures, more robust attentional enhancements are seen in simpler tasks in which subjects discriminate the spatial location of vibrotactile stimuli applied to the fingers of each hand (thumb and index finger), in this case within the context of a cross-modal manipulation of attention (tactile and visual). Reaction times to vibrotactile stimuli are faster when attention is correctly directed to the general location of the stimulation (right or left hand) as compared to when attention is misdirected to the unstimulated side [2]. Interestingly, an asymmetry is observed for targets located on the left as compared to the right, with cueing having larger effects for the former, potentially reflecting a default rightward attentional bias.

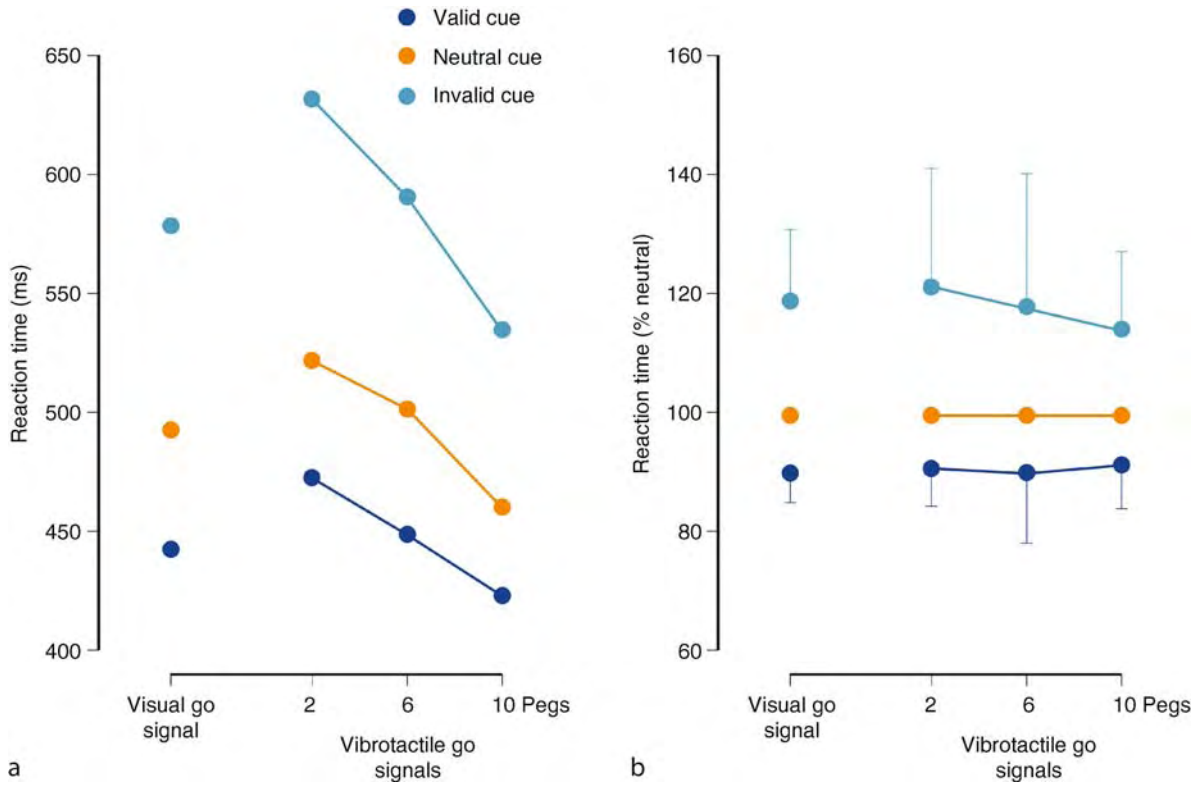
### *Cross-Modal Attention*

To what extent are attentional controls similar across different modalities? This question can be approached by measuring the ability of subjects to perform similar sensory tasks under different attentional states: attention directed towards or away from each modality, or divided across modalities. Figure 1a shows typical results obtained in a cross-modal manipulation of attention across touch (vibrotactile stimuli to the fingertip) and vision (illumination of a central light), based on simple reaction time measures [3].

Subject attention was redirected on a trial-by-trial basis with instruction lights: directed attention (valid cue) versus divided attention (neutral cue). The subject's task was to respond as quickly as possible to the presentation of the stimulus (tactile or visual). The design included a small number of invalid cues (attention misdirected). Typically, reaction times are shortest with directed attention, intermediate for divided attention, and longest when attention is misdirected. Interestingly, attention has proportionally similar effects on the detection of weak and stronger vibrotactile stimuli, as well as on detection of the visual stimulus (Fig. 1b), suggesting that attention may exert a generalized effect on perceptual abilities across touch and vision. Although the experimental design could be criticized since the visual and tactile stimuli did not come from the same spatial location, an advantage for directed attention over divided attention is also seen when the spatial confound is controlled, in this case in the context of experiments contrasting attentional influences across three modalities, touch, vision and audition [2]. In a task involving spatial discrimination, attention has proportionally larger effects on tactile than visual or auditory stimuli. While this observation might reflect different mechanisms when attention is divided across multiple modalities (versus two modalities), it should be stressed that touch requires physical contact between the surround and the receptors, and that this contact may serve as a reference point for interpreting incoming inputs. In contrast, audition and vision have no such reference.

### *Orienting*

An involuntary or reflexive shift of attention to a tactile cue is referred to as orienting. There is evidence that a preceding vibration can shorten reaction times to vibrotactile stimuli, even though the subjects had been instructed that the vibration had no relation to the target location (right or left hand) and that it should be ignored. Whether such effects are reflexive in nature is, however, not clear: for example, shortened reaction times have been shown using relatively long delays between the alerting cue and the stimulus to discriminate (200–400 ms), but such delays fall well within the time required for voluntary movement in response to a stimulus. Another approach, somewhat akin to studies of cross-modal attention, has been to show that vision of the stimulated body part (non informative since the subjects can not see the actual stimulus application), accompanied or not by orienting the head and eyes, improves the ability of subjects to perform tactile discrimination tasks. These results have been challenged since changes in response bias (willingness to report stimuli as being present) might have occurred, and contributed to the apparent enhancement of tactile sensitivity [4]. The underlying mechanisms are likely complex since performance on other somatic sensory tasks, specifically haptic shape and orientation, are



**Tactile Attention. Figure 1** (a) Mean reaction times for detecting visual and vibrotactile stimuli as a function of the cue condition (n = 12): valid (attention directed to the correct modality); neutral (attention divided); and invalid (attention misdirected). Attention was directed on a trial-by-trial basis. The vibrotactile stimulus intensity was systematically varied by increasing the number of active pins in the vibrotactile array presented to the right index finger. (b) Normalized mean reaction times, taking the mean reaction time in the neutrally cued trials as 100%. Adapted from [3].

modified simply by providing non informative visual feedback or orienting the head (and eyes) towards the stimuli. Moreover, the nature of the interaction (performance enhanced or degraded) is critically dependent on the task itself, specifically whether the task calls upon an intrinsic (body-centred) or extrinsic (centred on external coordinates) reference frame.

## Higher Level Processes

### *Single Unit Recordings in Monkeys*

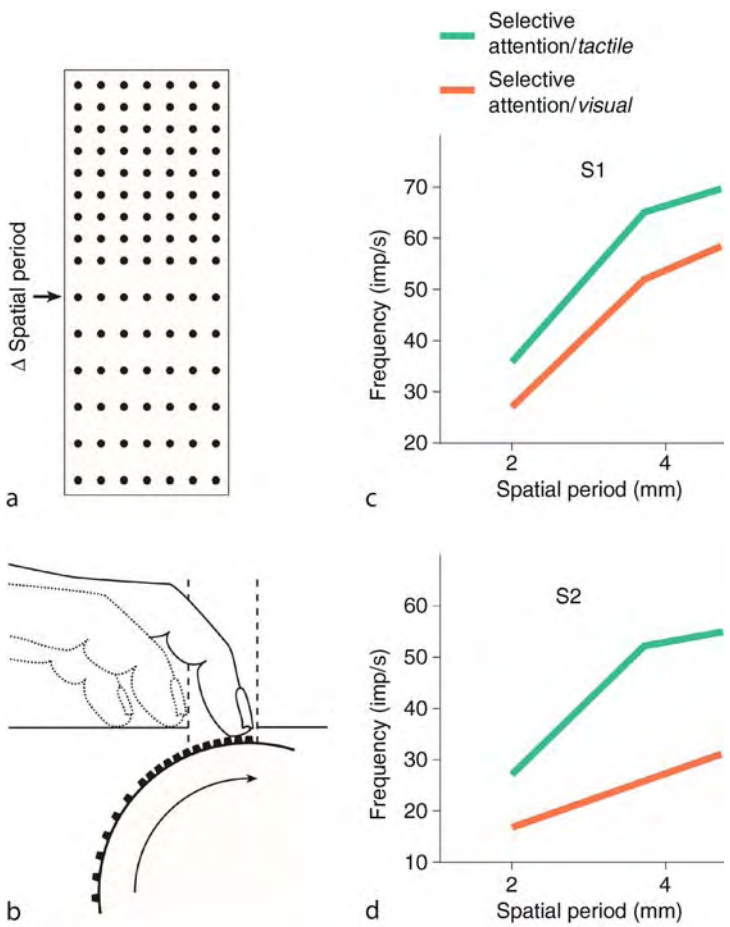
In general terms, studies of visual attention indicate that selective attention can modulate the firing rate elicited by sensory stimuli and the times at which spikes fire. Behaviourally relevant, or salient, inputs may be selected and/or amplified, so improving the signal-to-noise ratio; irrelevant signals may be filtered or gated. The extent to which such mechanisms contribute to tactile attention is only now being explored.

Tactile information from the periphery is conveyed to the parietal receiving areas (▶primary and secondary somatosensory cortex, S1 and S2) through the dorsal column – medial lemniscal pathway. There is limited evidence for attentional modulation of neuronal responses at the thalamic relay site for lemniscal inputs, the ventrobasal nucleus, corresponding to the second major relay for peripheral afferent information after the dorsal column nuclei. In contrast, related factors, in particular the level of arousal, can produce large changes in neuronal responses to tactile inputs at the level of the thalamus with neurones being more responsive as arousal increases.

The results of recordings from awake primates trained in tactile discrimination tasks (vibration, tactile roughness, tactile letter recognition) along with diversionary tasks (visual or auditory) indicate that selective attention to tactile stimuli can influence neuronal responses in S1 cortex, but the effects can be up to three times larger in S2 cortex and more than twice as frequent [1,5,6]. As in studies of human psychophysics, sensory stimuli are presented under different conditions of attention. Neuronal responses evoked by attended tactile stimuli are compared with those evoked by the same stimulus while attention is shifted either to another modality and/or to another spatial location.

Sustained selective attention towards tactile stimuli enhances neuronal responses to tactile stimuli, both in S1 and S2 cortex [5,6]. Within the S1 cutaneous hand representation, selective attention particularly modulates discharge during the portion of the trial in which the attended feature, a change in surface texture, might occur. By examining stimulus-response functions under different attentional conditions (relevant versus irrelevant), it has been possible to show that S1 neurones show *an additive increase* in neuronal responsiveness to tactile stimuli with directed attention, i.e., the entire stimulus-response curve is shifted upwards (Fig. 2c) [6].

In the S2 hand representation, the effects are much more generalized, sometimes spanning multiple epochs within the trials [5,6]. Moreover, some cells show attention-related changes in activity even prior to the start of tactile stimulation, i.e., a shift in baseline activity accompanies the shift in attention towards tactile stimuli. Concentrating on the epoch containing the salient feature (a change in surface texture), examination of the stimulus-response curves indicates that response gain is increased with directed attention, i.e., there is a *multiplicative increase* in S2 responsiveness to tactile inputs [6]. As shown in Fig. 2d, the slope of the stimulus-response curve is increased. These effects are, moreover, selective in that only cells responsive to changes in surface texture, the salient feature, show an increase in response gain. Together, it appears that tactile attention, at least within the context



**Tactile Attention. Figure 2** Neuronal mechanisms underlying attentional enhancement of cortical responsiveness to tactile stimuli (cross-modal manipulation of attention, tactile/green or visual/red). Recordings were made from monkeys trained to discriminate either a change in surface texture (a, b) or a change in light intensity (not shown). Textured surfaces (a) were mounted on a drum and scanned under the fingertips (b). (c) When attention is directed to the tactile modality (green), then the stimulus-response curve for texture-sensitive neurones in S1 shows an upward shift (additive mechanism), in comparison to when the animal attended and discriminated visual stimuli. (d) S2 texture-sensitive neurones show evidence for an increase in response gain, as shown by the increased steepness of the slope of the stimulus-response curve (multiplicative mechanism). Adapted from [6].

of a tactile-visual cross-modal manipulation of attention, both selects and amplifies salient inputs in S2. There is likely a second and independent attentional mechanism, operational in both S1 and S2, which produces an additive increase in neuronal responsiveness, evident in the population of cutaneous neurones activated by the tactile stimulation.

Two other mechanisms likely contribute to attentional tuning in S2 cortex. There is evidence for increased synchrony with directed attention to tactile stimuli, and work in the visual system suggests that this can produce a multiplicative increase in stimulus-sensitivity. In addition, many S2 cells show a marked post-reward suppression (in the context of a task requiring the monkey to attend and discriminate changes in tactile roughness), with some cells losing their stimulus-sensitivity. Such a response pattern is not found in S1 [6]. This inhibition may allow neuronal resources to actively disengage from attended inputs, ensuring that attention can be shifted elsewhere. The suppressed discharge may provide a neuronal correlate for the psychophysical phenomenon of "inhibition of return" whereby sensory processing at recently attended locations may be slowed when the stimulus – visual, auditory or tactile – is repeated with a short inter-stimulus interval.

This description of attentional influences is, however, very much dependent on the experimental paradigm used to study attention. There is good evidence that a more complex design, combining spatial and cross-modal attention, elicits an initial suppression of neuronal responses to tactile stimuli [1] in both S1 and S2. Moreover, S2 cells show evidence of subsequent enhancement during a later interval, corresponding to that which contained the salient tactile feature, specifically the presence or absence of an amplitude pulse. Together this pattern of modulation likely enhances the signal-to-noise ratio for the relevant input.

### Recordings in Humans (Imaging and Evoked Potentials)

While single unit recordings can provide detailed information about the cellular mechanisms related to attention, the "view" is limited to the regions sampled with a microelectrode. One of the advantages of whole brain imaging (►PET, positron-emitting tomography; ►fMRI, functional magnetic resonance imaging) is that an overview of the entire neuronal network involved in controlling attention can be obtained, although with much less temporal resolution than possible with single unit recordings. The latter is, in part, overcome with more recent methods for recording event-related potentials triggered by tactile stimuli (e.g., ►MEG, magnetoencephalographic recordings).

Regional cerebral blood flow (►rCBF) elicited by tactile stimulation is increased with attention. Even simple anticipation of light tactile stimulation can increase S1 rCBF. In both S1 and S2, the area of activation (seen using fMRI) is larger with directed attention, but this only reaches significance for S2. Consistent with single unit recordings, rCBF shows larger increases in S2 than S1 when attention is directed to tactile stimuli. In addition, sustained attention to tactile or visual stimuli results in the activation of a cortical network that includes the right dorsolateral frontal cortex and bilateral inferior parietal lobule (possibly corresponding to primate area 7b), and this independent of the laterality of the stimulus. This network may underlie the well known right hemispheric dominance of human attention (see Pathology, below) [7]. Multimodal alerting stimuli – capturing attention involuntarily – also activate preferentially right hemisphere structures, including the temporo-parietal junction and the inferior frontal cortex [8] along with other structures (insula, left anterior cingulate and supplementary motor area).

Evoked potential studies confirm that, as seen in non human primates, attention can enhance responsiveness to tactile inputs, with the effects being significant in S2 but not S1. The latter result may, however, reflect technical limitations with MEG recordings since this only "sees" regions located perpendicular to the surface, picking up responses from area 3b in the central sulcus, but not areas 1 and 2 on the crown of the postcentral gyrus. Somatosensory cortical evoked responses are modulated by cross-modal (tactile/auditory) and spatial manipulations of attention. Attentional effects are evident for relatively short-latency components (70–100 ms post-stimulus). The need to average together many responses, however, means that these experiments are often based on sustained attention to, for example, a single modality during a block of trials (often with short inter-trial intervals). Subject reports may not be made until after the block of trials (e.g., count the number of rare or oddball stimuli perceived). Thus, the link to the attentional processes that likely accompany selective attention to features or spatial locations is not obvious.

### Lower Level Processes

Unexpected stimuli can draw attention involuntarily towards the stimulus. As discussed above, both voluntary and involuntary attention activate preferentially, but not exclusively, right hemisphere structures. The extent to which these activations overlap is not known at present. Attentional systems are, moreover, constrained to act in concert with other systems, including controls over sleep and wakefulness. For example, there exists a diffuse and widespread cholinergic innervation of cortex arising from basal forebrain structures which modulates neuronal responsiveness to sensory stimuli, including tactile [9]. The norepinephrine system may also play an important role.

### Function

Attention, as indicated by its definition, acts so as to focus awareness and the processing capacities of the brain on objects and events relevant to one's immediate, behavioural goals.

### Pathology

Unilateral parietal lesions in humans, frequently involving the right posterior parietal regions, often result in spatial neglect (failure to attend to the contralateral side of space) and perceptual extinction (patients are unaware of stimuli applied to the contralesional side of the body when stimuli are presented simultaneously to the ipsi- and contralesional sides) in the absence of major sensory deficits. Perceptual extinction can be seen for tactile stimuli, as well as visual and auditory stimuli, but is not necessarily associated with neglect. When one simultaneously touches two mirror sites on the body, patients with ►tactile extinction do not perceive the contralesional (left) touch, although single contralesional touches can be detected. This phenomenon is thought to involve a disorder in spatial attention. Left tactile extinction may appear or be enhanced when patients look to the right; conversely, looking to the left can improve the perception of contralesional stimuli. In addition, tactile extinction is modulated by the position of the affected hand: extinction can improve when the affected hand is placed in the right rather than the left hemispace [10].

# Tactile C Fibers

VAUGHAN G MACEFIELD
School of Medicine, University of Western Sydney, Sydney, NSW, Australia
Prince of Wales Medical Research Institute, Sydney, NSW, Australia

### Synonyms

Low-threshold C fiber mechanoreceptors; CT afferents; CT fibers

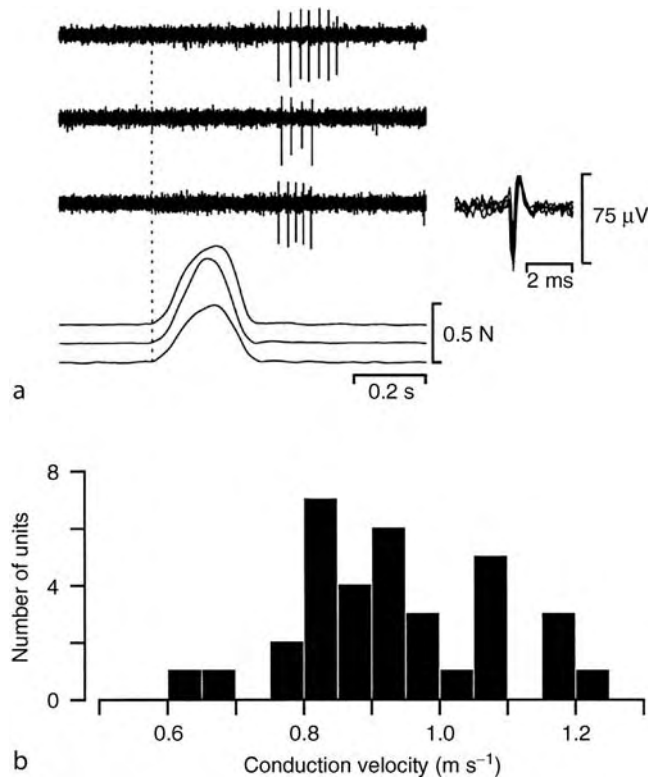
### Definition

Tactile C fibers are a class of slowly-conducting (unmyelinated) sensory axon in the skin. Like other unmyelinated afferents, it is believed that the sensory terminals of these fibers are free nerve endings, though there are specializations in their sensory specificity. Whereas the majority of afferent C-fibers in the skin serve nociceptive, thermoceptive or chemoceptive functions, tactile C fibers (CT afferents) are unusual in possessing low mechanical thresholds – they respond to stimuli that are typically in the "light touch" range and hence in the province of the classic ►cutaneous mechanoreceptors – the myelinated tactile afferents. First described in the hairy skin of the cat [1], the first human tactile C fibers were found in the skin of the face, during percutaneous microelectrode recordings (►microneurography) of the infraorbital [2] and supraorbital [3] nerves. More detailed studies documented the properties of these fibers in the hairy skin of the forearm [4–6]. Given that this region is typical of the skin of much of the body, it is reasonable to conclude that tactile C-fibers are distributed widely over the body, though they have not been found in the hand. That they have been found in the hairy skin of the thigh [7] and foot would certainly suggest that they are ubiquitous.

### Characteristics

#### Quantitative Description

Typical of C-fibers recorded by microneurography, tactile C-fibers generate negative-going, triphasic action potentials (Fig. 1). The receptive fields of CT

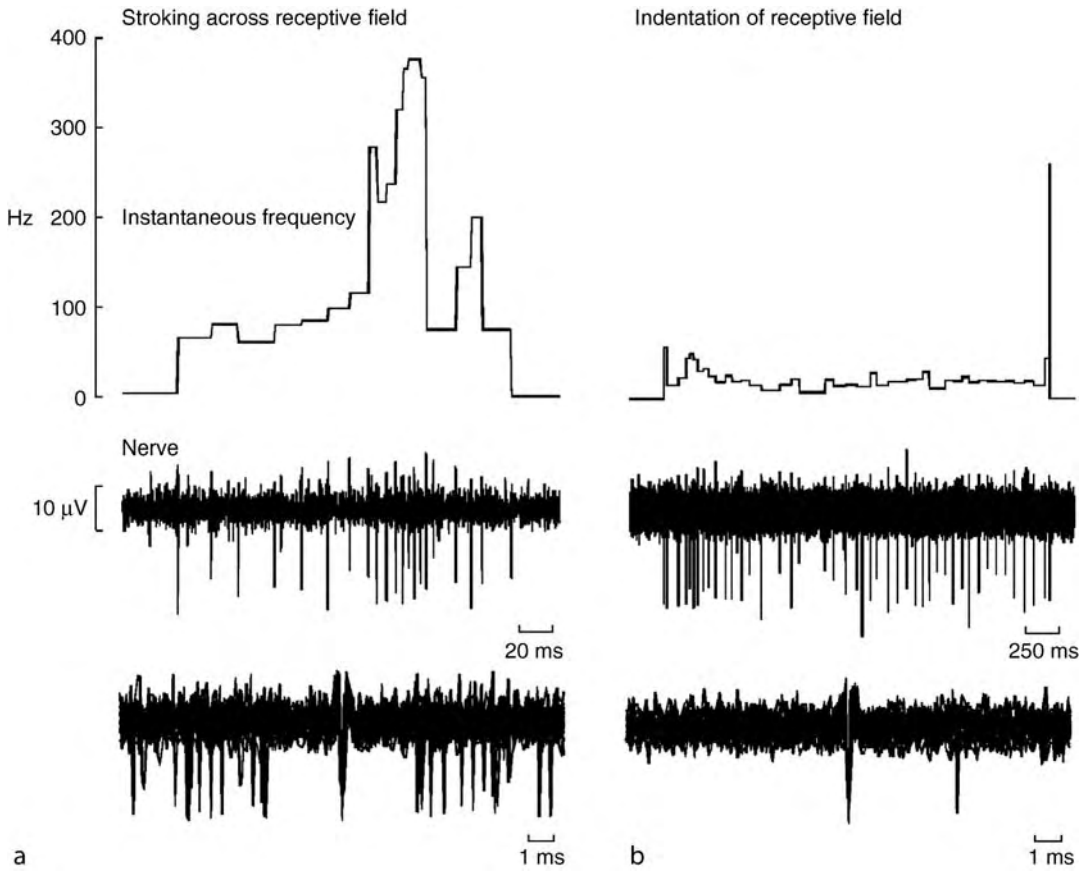


**Tactile C Fibers. Figure 1** Microelectrode recording from a low-threshold mechanosensitive C-fiber afferent in the forearm skin. The mechanoreceptor responded at long latency to brisk taps over its receptive field (a); superimposed spikes in the inset show the typical morphology of an extracellualr recording from an unmyelinated axon. Conduction velocities, measured from the onset of the mechanical stimulus, are show for 34 CT afferents in (b). Figure reproduced from [5].

afferents are similar in shape and size to those of the myelinated tactile afferents with small receptive fields – the ►rapidly-adapting type I mechanoreceptors (FA I) and ►slowly-adapting type I mechanoreceptors (SA I). Indeed, they also share the feature of possessing several (1–9) "hot spots" within the receptive field, as assessed by scanning the area with a 5 mN probe; these zones of maximal sensitivity presumably correspond to the locations of the sensory terminals of the axons [6]. Figure 1 shows the responses of a CT afferent to percussive stimulation of the skin.

Estimation of conduction velocities from the latency to a mechanical or electrical stimulus reveals a mean conduction velocity of ~0.9 m/s, i.e., within the range of conduction for unmyelinated axons [4]. CT afferents possess some unusual features: they respond in a slowly-adapting fashion to forces applied normal to the skin but, unlike the slowly-adapting (myelinated) cutaneous afferents, typically generate a sustained "off-discharge" following a brisk percussive stimulus. One can speculate that this after-discharge may contribute to stimulus localization; indeed, there is evidence that – in the absence of large-fiber cutaneous input – CT afferents can provide information on the location of a punctate stimulus [8]. And while they have a poor capacity to follow high-frequency vibration, stroking the skin is a particularly effective stimulus: peak firing rates of ~100 Hz can be achieved by light stroking, the slower the stimulus the greater the response [3]. Peak firing rates of 400 Hz – approaching the absolute refractory period for C fibers – have also been observed. An example, from a CT afferent located on the hairy skin of the foot, is illustrated in Fig. 2. Interestingly, the response to light stroking exceeds the response to indentation; the myelinated ►fast-adapting type I mechanoreceptors (FAI) likewise respond preferentially to stroking.

As stroking with cotton wool can activate CT endings their mechanical thresholds must be very low. Indeed, the indentation (von Frey) thresholds of CT fibers in the face are similar to the those of the slowly-adapting type I mechanoreceptors supplying the hand (0.6–2.3 mN; [3]); CT afferents of the forearm have thresholds ranging from 0.3–2.5 mN; [4]. Interestingly, CT afferents demonstrate "fatigue" with repeated stroking stimuli, and with sustained indentation exhibit a biphasic response: an initial excitation that adapts, followed by a slow acceleration in the discharge [5]. The mechanism for the latter is unknown.



**Tactile C Fibers. Figure 2** Microelectrode recording from a low-threshold mechanosensitive C-fiber afferent located on the dorsum of the foot. The mechanoreceptor responded vigorously to stroking over its receptive field with cotton gauze (a); instantaneous frequencies were higher then those generated by indentation of its receptive field (b). Unpublished data from Macefield.

## Higher Order Processes

Given that CT fibers are sensitive to light stroking of the skin it has been suggested that they subserve an affective component of touch, engaging areas of the brain involved in the processing of emotion – the limbic system – rather than those comprising the discriminative somatosensory system. Studies in patients lacking large-fiber sensory axons yet preserved small-fiber function reveal that their capacity to feel this light touch remains. Moreover, the stroking stimuli feel "pleasant." Furthermore, brain imaging studies have shown that light stroking of the hairy skin in these patients activates the insular cortex but not the primary somatosensory cortex [9]; the insula is also engaged in feelings of warmth [10].

## Process Regulation

There is no evidence that the sensitivity of CT afferents can be modified by efferent control mechanisms.

## Function

As noted above, the sensitivity of CT afferents to caress-like touch, and their projection to the insular cortex, suggests that their primary role is in the affective aspects of touch.

## Pathology

It is not known whether the loss of CT afferent input is associated with any specific pathology, though one would expect these afferents to be involved in the small-fiber neuropathies that compromise conduction along unmylinated axons (e.g., diabetes). However, as noted above, these afferents may provide some significant tactile information in large-fiber sensory neuropathies, in which tactile (and proprioceptive) information provided by myelinated axons is lost.

## Tactile Detection Threshold

### Definition

For any particular stimulus parameter (see "detection of tactile stimuli"), the absolute threshold is the lowest magnitude that the subject is able to detect on more than 50% of trials. Measuring thresholds is complicated by interaction of different stimulus parameters. For example, a commonly used measure is the threshold force (or pressure) of a Von Frey hair applied to the skin. But this depends on the temporal profile of the contact, including contact velocity and acceleration. Thresholds are measured using a range of approaches including the method of limits (ascending or descending), the staircase method, and forced choice paradigms.

►Processing of Tactile Stimuli

## Tactile Discrimination Threshold

### Definition

A difference threshold, (or difference limen) for a particular parameter of a tactile stimulus is the smallest difference in magnitude of the parameter between two stimuli that a subject is able to detect on more than 75% of trials. Like detection thresholds, difference or discrimination thresholds are quantified using a number of different methods. Forced choice methods are commonly used to minimize subjects' biases.

►Processing of Tactile Stimuli

## Tactile Extinction

### Definition

When one simultaneously touches two mirror sites on the body, patients with tactile neglect do not perceive the contralesional touch, although single contralesional touches can be detected. Patients can also show extinction in other modalities (vision, audition, olfaction).

►Tactile Attention

## Tactile Form Discrimination

### Definition

The complexity and spectrum of forms which characterize the objects that we encounter in everyday life are many and varied. They range from the simple curve of an apple to the complex shapes encountered during common tasks, for example using eating utensils or operating computer devices such as a keyboard, mouse or track ball. Information about these characteristics is essential for successful task manipulation or identification. For the most part, when manipulating objects, form identification is done at the unconscious level with the success of the task dependent on the ability of the tactile system to extract the precise three-dimensional form of encountered objects. Most of these complex object characteristics can be reduced to a smaller number of elemental components and these have been studied extensively in psychophysics experiments and complementary neural experiments. Experimental stimuli range from bars, gratings and curvatures to complex patterns such as embossed letters and Braille-type characters. These are either scanned across or indented into the skin surface and either human ability is quantified or neural responses are characterized for the specific parameter being studied. Ultimately

these studies of tactile form discrimination address key questions concerned with the spatial resolution within neural populations, i.e., how precise information is represented within neural population responses.

## Tactile Sensation in Oral Region

Greg K. Essick[1], Mats Trulsson[2]
[1]Department of Prosthodontics and Center for Neurosensory Disorders, School of Dentistry, University of North Carolina, Chapel Hill, NC, USA
[2]Department of Prosthetic Dentistry, Institute of Odontology, Karolinska Institutet, Sweden

### Synonyms

Touch sensation, or mechanosensation, in the mouth and on the lips

### Definition

Oral ►tactile sensation is the conscious sensation, or perceptual experience, evoked by physical contact between an oral tissue (e.g., tip of the tongue) innervated by tactile receptors (►low-threshold mechanoreceptors) and some other entity such as a food particle, a tooth or the lip [1]. The sensation can occur passively when an object moves into contact with innervated tissue, or actively when the tissue moves into contact with an object.

The ►oral region refers to the oral cavity, bound anteriorally by the oral port, the ►vermilion of the lips, and posteriorally by the anterior pillar of the fauces, the palatoglossal arches [2]. It is bound superiorly by the palate and inferiorally by the floor of the mouth, under the tongue. When the upper and lower teeth are occluded, the oral cavity is subdivided further into a vestibular region external to the teeth (internal portions of lips and cheeks) and oral cavity proper internal to the teeth (tongue and palate).

Oral tissues innervated by tactile receptors include epithelium and teeth [1]. The epithelium is subdivided into the transitional epithelium of the lips (the vermilion); the delicate lining mucosa of the lips, cheeks, alveolus, ventrum of the tongue, soft palate, and floor of the mouth; and the tougher masticatory mucosa of the hard palate, gingiva (gum tissue surrounding the teeth), and ►tongue dorsum less the specialized chemosensory epithelium in the taste buds located therein [2]. The tactile sensory ►innervation of the teeth is located in the ►periodontal ligaments, which attach the roots of the teeth to the surrounding alveolar bone. The oral tissues differ in their roles and the mechanical demands placed on them during function, in their sensory innervations, and thus in their sensitivity to touch.

### Characteristics

#### Psychophysical Approaches

Attributes of oral tactile sensations are assessed using ►psychophysical approaches. The simplest attribute, that of ►tactile detection, is often characterized by the lowest force (e.g., in mN, or more commonly in grams) or the lowest pressure against the innervated tissue, or the smallest vertical skin displacement (e.g., in μM) required for detecting touch on a pre-specified percentage (e.g., 50%) of applications [1,3]. Nylon filaments that buckle to deliver calibrated forces are often used to measure static detection ►thresholds. Mechanical probes that move sinusoidally in and out of the tissue at controlled ►frequencies and displacements are sometimes used to measure dynamic, ►vibrotactile detection thresholds. In both cases, sensitivity is expressed by the inverse of the threshold value.

►Two-point thresholds are measured in the oral region to assess suprathreshold tactile sensation [1,4]. These thresholds are the minimum separations (e.g., in mm) at which two points of physical contact feel like two distinct points (the two-point perception threshold) or can be discriminated from one point of contact (the ►two-point discrimination threshold). These ►differential thresholds depend not only on spatial attributes of tactile sensation (►spatial acuity), but ►intensive and ►temporal attributes as well.

Threshold measures assess tactile sensation indirectly. For example, after injury and ►regeneration of peripheral nerves that supply the oral tissues, the thresholds may be totally normal yet tactile sensations feel qualitatively different than before the injury.

The most complex attributes of suprathreshold tactile sensations are assessed by methods that require subjects to actively manipulate standardized textured stimuli or miniature three-dimensional forms (such as embossed letters of the alphabet) with the tip of the tongue. Psychophysical responses are obtained to quantify how well the subject identifies the stimuli (e.g., a square object or the letter "E"; ►tactile form discrimination) or to characterize evaluative judgments of the stimuli, e.g., in terms of perceived grittiness, oiliness, dryness, or tactile pleasantness. Appreciation of textural attributes is an important component of the enjoyment of food and drink.

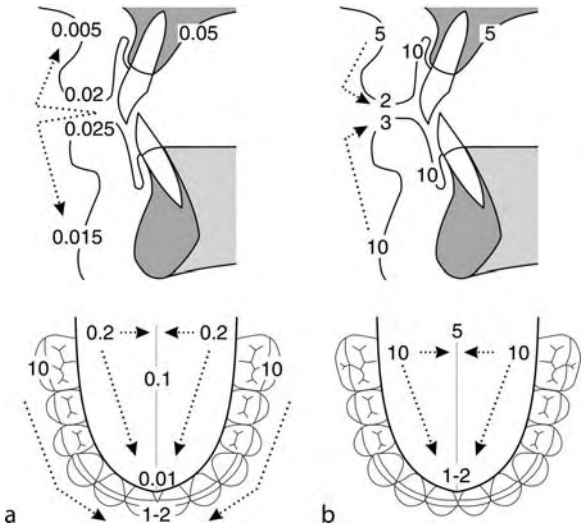
### *Behavioral Approaches*

During eating, forces exerted by the teeth must be regulated to effectively cleave boluses of food while oral soft tissues are kept clear of the ►occlusal table. The same low-threshold mechanoreceptors that underlie tactile sensation underlie the exacting ►motor control required for ►biting, chewing and speaking [1,5,6]. The consequences of loss of ►information from the mechanoreceptors can be evaluated by studying behavior before and after anesthetizing sensory nerves to the tissues under investigation. A second approach is to study patients who have lost sensory innervation as a result of injury to peripheral branches of the ►trigeminal nerve.

## Description of the Condition

### *Regional Variations in Tactile Detection Sensitivity (Fig. 1a)*

Within the mouth the contact detection threshold is lowest on the tip of the tongue (about 10 mg) [1,7]. Among other oral and facial structures, thresholds are only lower on the perinasal skin (5 mg). Slightly less sensitive than the tongue tip is the vermilion of the upper and lower lips (20 mg), followed by the anterior hard palate (50 mg). Thresholds do not remain constant across individual structures [3]. For example, across the vermilion, sensitivity is highest at the border with the ►hairy perioral ►skin, and lowest at the mucocutaneous junction with the oral labial and ►buccal mucosa. On the tongue dorsum, sensitivity falls at least ten fold antero-posteriorally over the anterior two thirds of the tongue along the midline, and decreases further by a factor of about 2 from the midline to the lateral edges of the tongue. There is no consensus description as to how sensitivity varies over the extent of the hard and soft palates or of threshold values at sites that have been studied. Tactile detection thresholds on the gingiva (100s of mg) are substantially higher than those observed on the lips, tongue dorsum, or central portion of the palate. On average, detection sensitivity does not differ on the two sides, right vs. left, of the oral region.



**Tactile Sensation in Oral Region.**
**Figure 1** Approximate values of touch detection thresholds in grams (a) and of two-point thresholds in millimeters (b) on perioral (*top*) and lingual/dental tissues (*bottom*). Dotted arrows denote directions over which sensitivity increases (see text). Collectively, the tip of the tongue and vermilion of the lips are rivaled only by the fingertips in tactile sensitivity and tactile discrimination acuity. Note that the sensitivity of the teeth to static touch is orders of magnitude less than that of the oral soft tissues.

### *Dental Tactile Detection Sensitivity*

Subjects with natural teeth are able to detect foils only 20 μm in thickness when they are placed between the teeth, demonstrating an extraordinary level of sensitivity. The contact detection threshold is lowest for the anterior teeth, 1–2 g, and increases distally along the arch to about 10 g for the molars. Infiltration of local anaesthesia close to the tooth dramatically increases the threshold value, confirming the role of low-threshold ►periodontal mechanoreceptors in dental tactile sensitivity [8].

### *Regional Variations in Tactile Discrimination Capacity (Fig. 1b)*

With some noted exceptions, tactile discriminative capacity varies similarly among orofacial structures to tactile detection sensitivity [1,4,7]. The two-point thresholds are lower on the tip of the tongue than any other body location, approximating 1 mm. Slightly less sensitive than the tongue tip is the vermilion of the

upper (2 mm) and lower (3 mm) lips, and the anterior hard palate (5 mm). Notably, values for these diverse structures are all within the normal range for the fingers, attesting to their high acuity. On the tongue dorsum, sensitivity falls 4–5-fold antero-posteriorally over the anterior two thirds of the tongue along the midline, and decreases by a factor of 2–3 from the midline to the lateral edges of the tongue. Positionally matched sites on the ventral side of the tongue are reported to be less discriminative, as well as sites located sublingually. From the upper and lower vermilion of the lips, the two-point thresholds decrease oro-fugally, approximating 8–10 mm on the vestibular mucosa intraorally, as well as on the inferior border of the chin and on the cheeks extraorally. On average, tactile discriminative capacity does not differ on the two sides of the oral region, although right vs. left sided differences have been reported on the tongues of individual subjects.

### Anatomical Variation in the Innervation of the Oral Tissues

Stimulus-evoked activity in the low-threshold mechanoreceptors that innervate the oral region is the peripheral basis for oral tactile sensation. Overall, the density of innervation is highest anteriorally, declines both posteriorally and laterally, and is higher on the pinnacle surfaces of the tissues, e.g., dorsal vs. ventral surface of tongue, vermilion vs. cutaneous or mucosal surfaces of lips, ►interdental papillae versus other areas of the alveolar ridge, and gyri versus sulci of palatal rugae (horizontal corrugations of tissue behind the upper front teeth) [9]. To a first approximation, tactile discrimination capacity varies in parallel with these variations in innervation density (see sections above). Tactile detection sensitivity depends additionally on the compliance of the tissue, affected by the state of hydration and degree of keratinization [3].

The density of the oral sensory innervation has not been quantitatively estimated, but is thought to be rivaled only by that of the hand [10]. This is evidenced by the relatively large diameters of the terminal branches of the trigeminal nerve in relation to the relatively small surface areas of tissue supplied, the high ►tactile acuity of the tongue and lips, and the relatively large volume of somatosensory cortical and thalamic grey matter devoted to the oral region.

Compared to the skin of the hand, the corpuscular endings of myelinated afferents terminating in oral tissues are less clearly defined, more variable in morphology, and less numerous. Certain morphologically identifiable receptor endings found ubiquitously in the hand are limited in the oral region. For example, the ►Pacinian corpuscle is notably absent with perhaps the exception of the ventrum of the tongue; ►Merkel's disk receptors found in most oral tissues are notably absent from the dorsum of the tongue [10].

### Low-Threshold Mechanoreceptors in the Lips and Oral Mucosa

The low-threshold mechanoreceptors found in the lips and ►oral mucosa have functional properties similar to three of the four types of ►cutaneous mechanoreceptors described in the glabrous skin of the human hand (FA I, SA I and SA II afferents; See essays entitled "Cutaneous mechanoreceptors, anatomical characteristics" and "Cutaneous mechanoreceptors, functional behavior") [1,6]. Slowly-adapting mechanoreceptors with a high dynamic sensitivity (i.e., they respond vigorously to the onset of the mechanical stimulus) and an irregular discharge during maintained tissue deformation resemble the SA I afferents (Fig. 2a).

Another group of slowly adapting mechanoreceptors characterized by a regular discharge rate, exquisite sensitivity to lateral skin stretch, and ►spontaneous activity is similar to SA II afferents (Fig. 2b). Rapidly-adapting mechanoreceptors in the lips and oral mucosa resemble those of the ►FA I afferents (Fig. 2c). Importantly, no mechanoreceptors encountered in human recording experiments have showed response properties similar to those of ►FA II afferents (Pacinian corpuscles). As such, the oral region, unlike the hand, is notably insensitive to high frequency vibrations and mechanical transients, the stimuli to which FA II mechanoreceptors are most sensitive.

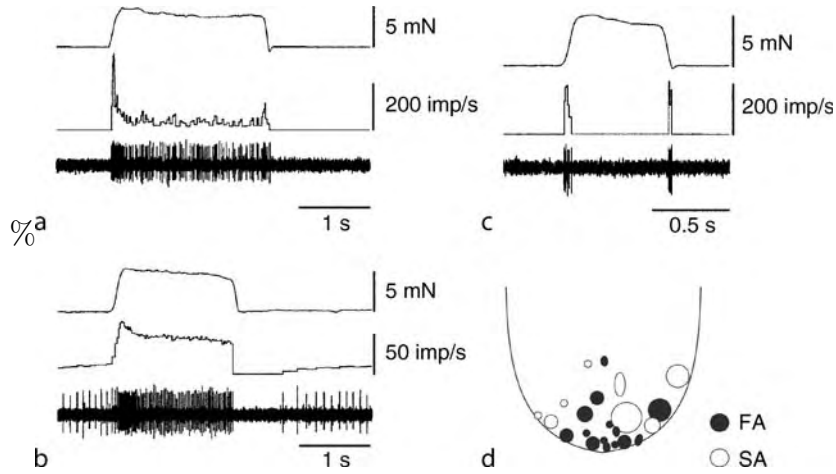
The ►receptive fields of oral mechanoreceptors are generally small and well defined, with the smallest fields observed at the tip of the tongue (ca. 1 mm in diameter; Fig. 2d). The majority (ca. two thirds) of the mechanoreceptors terminating superficially in the tongue adapt rapidly to maintained tissue deformation [10]. In contrast, most (ca. two thirds) mechanoreceptors in the facial skin, lips and buccal mucosa are slowly adapting [1,6].

### Low-Threshold Mechanoreceptors in the Periodontal Ligaments

The periodontal ligaments are richly innervated with ►Ruffini-like nerve ►endings, which signal information about intensive, temporal, and spatial aspects of tooth loads [1,5,8]. These receptors show slowly adapting response properties and possess the capacity to discharge continuously during sustained tooth loads, provided that the force is strong enough and applied in an appropriate direction (Fig. 3a).

The resemblance in response properties to those of SA II mechanoreceptors (Ruffini endings) in the skin is striking: The presence of spontaneous activity, a steady discharge response to steady loads, relatively weak responses to the onset of stimuli, and directional selectivity in the effectiveness of loads.

Recordings from human subjects reveal that the receptive fields of about half of the periodontal mechanoreceptors involve more than one tooth, typically two to



**Tactile Sensation in Oral Region. Figure 2** Recordings from the three different types of low-threshold mechanoreceptors found in the lips and oral mucosa. Response properties are similar to those of tactile receptors in the human hand: SAI (a), SAII (b), and FAI (c). For each panel, the upper trace is the force in mN applied to the receptive field, the middle trace is the instantaneous frequency response in impulses per second, and the lower trace is the electrical afferent nerve recording. (d) Receptive fields of single mechanoreceptive afferents from human lingual nerves. (Modified from [10]).

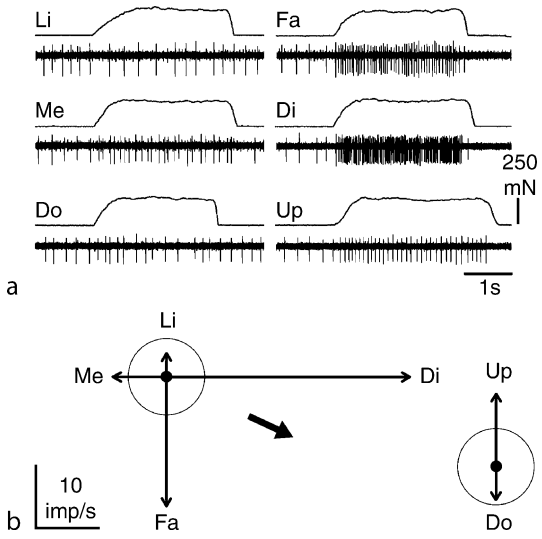
four teeth [1,5]. Each afferent always exhibits the highest response rates to stimulation of one particular tooth, the receptor-bearing tooth, with a gradual and rather sharp decline in responsiveness to loads applied to the adjacent teeth. Mechanical coupling between neighbouring teeth likely causes the multi-tooth receptive fields.

Human periodontal mechanoreceptors are normally broadly tuned to the direction of tooth loading (Fig. 3). As such, an individual periodontal mechanoreceptor provides ambiguous information about the direction of a force applied to the tooth. However, information about the precise direction of force is represented reliably in the activity from small populations of receptors, which possess preferred directions at which forces evoke the greatest neural responses [1]. The preferred directions of the mechanoreceptors supplying the mandibular anterior teeth and the premolars are quite evenly distributed around the circumference of the tooth, as viewed in the horizontal plane. In contrast, the receptors supplying the molars have a clear preference for the distal-lingual direction, i.e., toward the back of the mouth and toward the tongue. There is also a preference for downward-directed forces, but with fewer receptors responding preferentially in this direction because the number of receptors decreases from front to back along the dental arch [5].

Based on the relationship between the magnitude of tooth load and the steady-state discharge rate of the receptor, human periodontal receptors can be classified into two groups, saturating receptors and non-saturating receptors [5,6]. The saturating receptors constitute about 80% of the population and show a marked curved relationship between the steady state discharge rate and the amplitude of the tooth load. The receptors at the anterior teeth feature their highest sensitivity to changes in static force at force levels below some 1 N. The corresponding value for the posterior teeth is slightly higher, about 3–4 N. At higher forces, the sensitivity gradually decreases and the receptor discharge attains approximately its highest rate for all force levels above the limit. Moreover, for the saturating receptors the sensitivity to changes in force (dynamic sensitivity) decreases in parallel with the static sensitivity as the force increases. The non-saturating receptors, on the other hand, exhibit nearly linear stimulus-response relationships implying that these receptors efficiently encode force and force changes also at high forces levels.

## Higher Level Structures and Processes

Neural pathways and structures within the central nervous system for the ▶somatosensory processing of information signaled by low-threshold mechanoreceptors in the trigeminal nerve are mostly similar to those associated with the spinal nerves (see essay entitled "Central somatosensory projections"). A noted exception is the mesencephalic nucleus, which consists, in part, of cell bodies of periodontal mechanoreceptors that distribute to the apex of the tooth [1]. In the somatosensory (ventrobasal) thalamus, the orofacial region is represented medial to subcorporal regions; however, in primary somatosensory cortex (postcentral gyrus), it is represented laterally (see essay entitled "Somatosensory cortex I (SI)").



**Tactile Sensation in Oral Region.**
**Figure 3a** Recordings from a single periodontal mechanoreceptor to forces applied in six directions to the lower central incisor (the receptor-bearing tooth). For each panel, the upper trace is the force in mN applied to the tooth in the stated direction: lingual (Li), facial (Fa), mesial (Me), distal (Di), downward (Do), and upward (Up). The lower trace is the electrical afferent nerve recording. (b) Vectoral representation of the responses to sustained force application in the horizontal (left) and axial (right) directions. The length of each vector is proportional to the mean discharge rate evoked in each direction. The spontaneous discharge rate is represented by the circle with the radius indicating its intensity. The thick arrow represents an estimate of the most efficient excitatory stimulus direction in the horizontal plane, i.e., the calculated preferred direction. (Modified from Trulsson et al.: J Physiol 447:373–389, 1992).

## Regulation of the Process

As similar for the upper and lower limbs, mechanoreceptive information from the orofacial region is selectively ►gated during voluntary movements. As a result, certain aspects of tactile sensation are altered during functional activity.

## Function

### *Low-Threshold Mechanoreceptors in the Face and Oral Mucosa*

The exceptionally high innervation densities of the tips of the tongue and digits of the hand support their unique role in manipulation and exploration of objects. In contrast, low-threshold mechanoreceptors supplying the buccal mucosa and face discharge vigorously not only when the tissue is touched (Fig. 2), but also in response to deformations of the tissue that occur during voluntary lip and jaw movements (e.g., during generation of air pressures for speech sounds or during chewing; Fig. 4) [1,6].

The precise nature of the responses indicates that these mechanoreceptors, most often viewed as exteroceptors mediating tactile sensations, also serve a role in ►proprioception, signalling detailed information about the consequences of muscle activation on the soft tissues (see essay entitled "Proprioception: Role of cutaneous receptors"). This function is particularly important for the control of the facial muscles, since these muscles lack receptors that are traditionally considered proprioceptors, i.e., they have no muscle spindles, Golgi tendon organs, or joint receptors.

### *Low-Threshold Periodontal Mechanoreceptors*

Dental tactile sensations are secondary to the important role played by periodontal mechanoreceptors in the motor control of the jaw. The anterior teeth are most highly innervated and are involved in the initial stages of food intake, before food is transferred to posterior segments of the dentition. Sometimes the anterior teeth are even used as a "third hand" in manipulative tasks, or as a precision cutting tool. Proper execution of these tasks relies heavily on sensory information as does the execution of comparably exacting manipulative tasks performed by the densely innervated finger tips of the hand. The shift from a high sensitivity of the receptors to most directions at the anterior teeth to the distal-lingual direction at the molars meets the functional demands of the anterior versus posterior teeth. During chewing, the anterior teeth experience forces in all directions, whereas the forces that normally act on the molars are limited more distal-lingually.

Model simulations reveal that periodontal mechanoreceptors possess the capacity to signal information about the mechanical events that occur when humans use their teeth to manipulate, bite and chew food [1,5]. For example, the saturating receptors respond distinctly to small forces similar to those produced by the initial contact with food, and effectively signal small changes in low force levels as occur when subjects manipulate, position and hold food between the teeth. Consistent with model simulations, behavioural experiments have shown that subjects use signals from periodontal receptors in the fine motor control of the jaw for these tasks (Fig. 5).

Human subjects with anesthesia applied to the teeth demonstrate a marked disturbance in the control of precisely directed, low biting forces, but not in generating the higher forces required to bite through food substances.

## Pathology

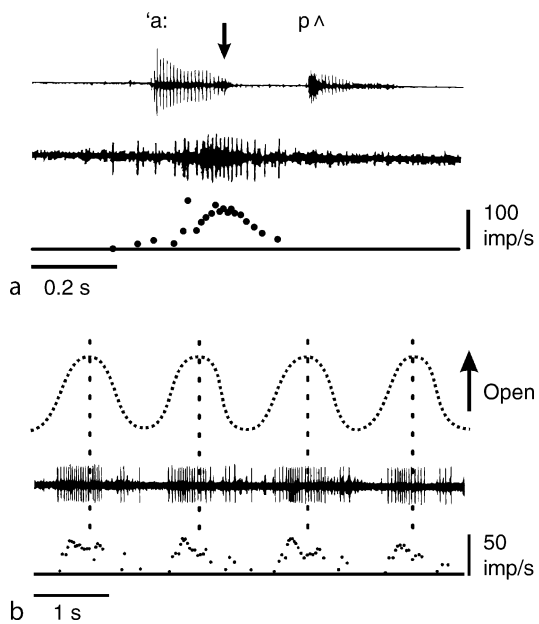
### *Effects of Loss of Mechanoreceptive Input*

Temporary loss of tactile sensory function is common after accidental injuries or injuries to the trigeminal nerve as a result of oral surgical procedures. Patients often report bothersome altered sensations, drooling,

biting the lip, tongue or cheek, and difficulty with speech or kissing. Altered sensation in the lips and tongue can substantially impair the patient's quality of life, particularly if it remains long term. Lack of coordination in chewing has been observed following denervation of intraoral receptors including periodontal receptors.

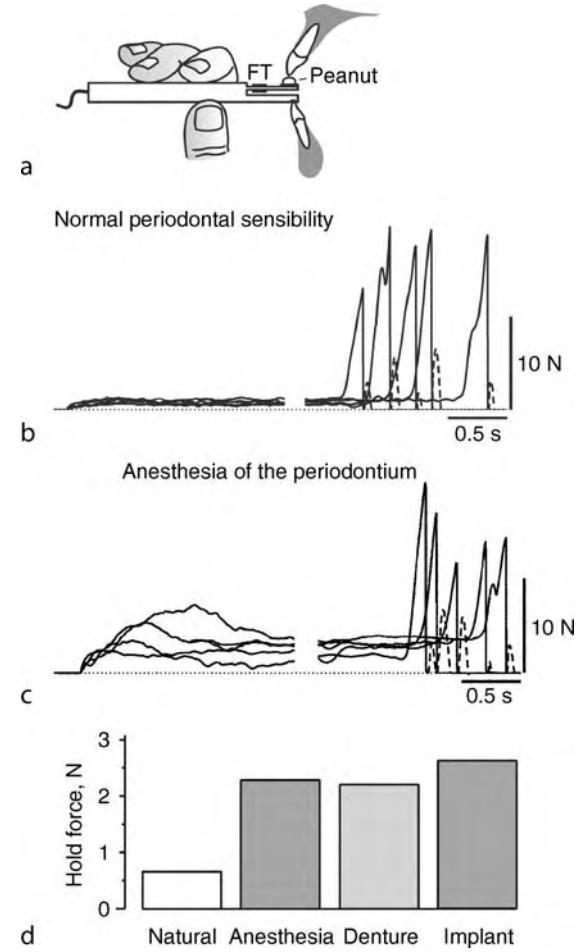
### *Dental Implants and Osseoperception*

Unlike natural teeth, ►dental implants are in direct contact with the jawbone without an intervening periodontal ligament. Despite the lack of periodontal mechanoreceptors, tactile-like sensations, via a process called ►osseoperception, are evoked by mechanical stimulation of an implant. These sensations are mediated by mechanoreceptors located in the surrounding tissues (e.g., ►periost, mucosa, muscle or joint). The dynamic, vibrotactile detection threshold tends to be relatively similar for implants and natural teeth. However, the static detection threshold of implants has been reported to be 10–50 times higher than that of natural teeth.



**Tactile Sensation in Oral Region.**
**Figure 4** Recordings from an oral mechanoreceptor in the infraorbital nerve during speech gestures and chewing movements. The afferent was slowly adapting with receptive field located in the buccal mucosa about 1 cm lateral to the corner of the mouth. (a) Activity evoked when the subject said ['a:pA]. Audio signal, microelectrode record, and instantaneous discharge frequency represented in top, middle and bottom traces, respectively. Arrowhead indicates a moment of rapid lip movements resulting in "pop-puff" sounds in the audio record. (b) Activity evoked by chewing movements. Top trace is of chewing movement; middle trace and bottom trace as in (a). (Modified from Johansson et al.: Exp Brain Res 72:209–214, 1988).

Moreover, similar to subjects with anesthetized teeth, patients with dental implants show a disturbed fine motor control of jaw actions associated with biting and intraoral manipulation of food (Fig. 5d).



**Tactile Sensation in Oral Region.**
**Figure 5** Importance of periodontal mechanoreceptor feedback to fine motor control of the jaw. (a) Subjects were instructed to position the apparatus so that a peanut half, resting on a duraluminum plate equipped with force transducers (FT), could be held and split by a pair of opposing central incisors. b and c, Examples of force profiles (five superimposed trials) obtained during normal periodontal sensibility (b) and during anaesthesia (c) of the periodontium. Note the considerably higher and more variable hold forces produced by the subjects during the anaesthesia. (d), Bars represent the mean hold force of (i) subjects with natural teeth, (ii) subjects with anesthetized natural teeth, (iii) subjects with full removable dentures supported only by the mucosa, and (iv) subjects with dental prostheses (in both jaws) supported only by osseointegrated implants. (Modified from Trulsson and Johansson: Exp Brain Res 107:486–496, 1996 and Trulsson and Gunne: J Dent Res 77:574–582, 1998).

# Tactile Senses – Touch

Yoshiaki Iwamura
Department of Sensory Science, Kawasaki University of Medical Welfare, Okayama, Japan

## Introduction

Touch is the sensation arising from our own body. We identify our own body parts as well as objects coming into contact with our body through somatosensory receptors on the skin and deep tissues. The definition of touch has been changed in western science history. In ancient Greece, Aristotle defined touch as the sensation through the flesh. It included everything but vision, audition, olfaction, and gustation. Thus, it included even visceral sensation in the current knowledge. The origin of touch sense: where the receptors for touch sense existed was not known. In the end of nineteenth century, touch was defined as the sense evoked by the stimulus imposed on the passive skin surface. The definition made investigation of the touch sensation more prosperous, and several receptor types for touch were identified morphologically in the skin. The research of touch in the passive sense has dominated the modern psychological and physiological research field since then. In the middle of twentieth century, D. Katz and J. J. Gibson opposed the general attitude of investigators to limit touch to the passive world and stressed the importance of active touch, that is, the only touch sensation in daily life to perceive objects by manipulation. Active touch is a complex sensation based on signals from receptors of both skin and deep tissue, and on unique central mechanisms. The issue is currently one of major subjects of somatosensory research. This chapter deals with the somatosensory system – from the peripheral receptors to the neocortex, which engages in touch sensation in both the passive and active sense.

## Cutaneous Mechanoreceptors, their Anatomical Characteristics

Light mechanical stimulation to the skin causes a tactile, pressure or vibration sensation. Such stimulation activates cutaneous mechanoreceptors. They are located in the epidermis, dermis, or sometimes at subcutaneous tissue, and are innervated by myelinated nerve fibers with a large to medium caliber. Electron-microscopically identified receptors are Merkel cell-neurite complex, Ruffini endorgan, Meissner's corpuscle, hair follicle receptors (lanceolate receptors), sinus hair follicles, and encapsulated corpuscles, such as, Krause ending, Pacinian corpuscle, and others. Details of the morphology of these cutaneous mechanoreceptors have been described (►Cutaneous mechanoreceptors, anatomical characteristics).

## Mechanosensory Transduction

Mechanoreceptors work as sensory transducers to transform mechanical energy into electrical energy. Receptor potential is generated and then converted into a series of impulses at a spike-generating site, the first Ranvier node of sensory nerve fibers innervating receptors. Different structures of cutaneous mechanoreceptors may be suitable to receive different forms of mechanical energy. Lamella of corpuscles works as mechanical filter. There is still controversy over the functional role of Merkel cells in the Merkel cell-neurite complex.

The application of mechanical forces to mechanoreceptors open mechanosensitive ion channels, increase membrane conductance, and generate receptor potentials. By using techniques of both electrophysiology and molecular biology, mechanosensitive ion channels have been extensively studied in nematode (*Caenorhabditis elegans*) and arthropod (*Drosophila*). However, ion channels gated by low mechanical stimulation have not yet been identified in mammals (►Mechanosensory transduction).

## Processing of Tactile Stimuli

Low-threshold cutaneous mechanoreceptors are activated by the tactile stimuli, stresses and strains arising from the interaction between the skin and objects when we touch or manipulate objects by hand. Four classes of mechano-sensitive units were recorded in the peripheral nerves, first in cats and then in humans. They are called fast adapting afferent I (FAI), fast adapting afferent II (FAII), slowly adapting afferent I (SAI), and slowly adapting afferent II (SAII). These four receptor types have different response characteristics because of differences in their structure and in their location in the skin. During manipulation, the receptor responses are determined by different features of the manipulated object and by hand movements. Such features include contact or grip force, the presence of shear forces, the area and shape of the contact region, the surface texture, the shape and compliance of the object, and the presence of slip between the object and the skin. A population of mechano-receptive afferents is able to simultaneously encode multiple stimulus parameters because each parameter has a different representation in the spatial and temporal patterns of activity across the afferent population. An overview is presented on how these tactile sensors of the glabrous or hairy skin represent object and task parameters such as simple stimuli, pattern and form, texture, shape, and manipulation. A brief note is also presented on the central mechanisms (►Processing of tactile stimuli).

## Cutaneous Mechanoreceptors, Functional Behavior

Responses of cutaneous mechanoreceptors to the controlled skin indentation have been assessed in the human skin by the technique of microneurography. Receptive field properties of these receptor units were described in detail. Differences exist in the population of common receptors between the glabrous and hairy skin. There are unique receptor types in the hairy skin, the field units and tactile C units that will be described in a separate essay. There are four types of mechanoreceptors in the human grabrous skin, FAI, FAII, SAI and SAII, and their analogue in the hairy skin. The mode of activation of the glabrous skin mechanoreceptors by the manipulation of objects such as lifting or holding is described in detail. The results of microstimulation of single afferents are also noted (►Cutaneous mechanoreceptors, functional behavior).

## Tactile C Fibers

These are a class of slowly conducting unmyelinated sensory nerves, found in the hairy skin, and are called as tactile C fibers. Whereas the majority of afferent C fibers in the skin are noticeptive, thermosensitive, or chemosensitive, tactile C fibers are unusual in that they are mechano-sensitive, have a low and respond better to slowly moving mechanical stimuli. Unlike myelinated low threshold mechanoreceptors, tactile C fibers are limited to the hairy skin. They were found first in the cat hairy skin and then in human forearm skin. They convey information of innocuous touch sense from the hairy skin to the brain not to the primary somatosensory cortex, but possibly to the insular cortex. Their functional role is thus thought to be in the affective aspects of touch (►Tactile C fibers).

## Vibration Sense

The viberation sense, a subset of the sense of touch, is transducted by the Pacinian receptor channel. It corresponds to Fast adapting type II afferents (FAII). The Pacinian corpuscle is sensitive to sinusoidal vibrations of between 0.4 and 700 Hz. It is able to follow at a 1:1 ratio the individual periodic displacements in a U-shaped sensitivity function with a maximal sensitivity at between 250 and 300 Hz. Exquisitely sensitive, it can be activated by a displacement as small as 0.1 μm (peak) at 250 Hz. Vibration sense is thought to be a highly sensitive "alerting" system to indicate that something is present, on or near the surface of the skin (►vibration sense).

## Aging of Tactile Sense

The tactile sense (touch) is not exempt from the effects of advancing age. These effects go largely unnoticed by most people because interaction with the environment is much more salient in vision and hearing. Although these effects have been studied for about 80 years, for the most part the early studies used poorly controlled stimulators such as cotton swabs, hairs and primitive electronic devices. Controlled laboratory experiments using modern technologies for measurement have been used to investigate aging of the vibratory sense. Studies of the tactile sense usually fall into two broad categories, namely measurements made at threshold and at suprathreshold levels of stimulation. Research on the effects of aging on the tactile sense has focused on measuring both threshold and suprathreshold responses (►Aging of tactile sense).

## Tactile Sensation in Oral Region

Oral tactile sensation is a conscious perceptual experience. It is evoked by physical contact between oral tissue innervated by tactile receptors (low-threshold mechanoreceptors) and some other entity such as a food particle, a tooth or the lip. The sensation can occur passively when an object moves into contact with innervated tissue, or actively when the tissue moves into contact with an object. The oral region refers to the oral cavity. When the upper and lower teeth are occluded, the oral cavity is subdivided further into a vestibular region external to the teeth (internal portions of lips and cheeks) and oral cavity proper internal to the teeth (tongue and palate). The oral tissues differ in their roles and the mechanical demands placed on them during function, in their sensory innervations, and thus in their sensitivity to touch.

Attributes of oral tactile sensations are assessed using psychophysical or behavioral approaches. There are regional variations in tactile discrimination capacity, and in the innervation of the oral tissues. The exceptionally high innervation densities of the tips of the tongue support its unique role in manipulation and exploration of objects. Low-threshold mechanoreceptors supplying the buccal mucosa and face discharge vigorously not only when the tissue is touched, but also in response to deformations of the tissue that occur during voluntary lip and jaw movements.

Neural pathways and structures within the central nervous system for the somatosensory processing of information signaled by low-threshold mechanoreceptors in the trigeminal nerve are mostly similar to those associated with the spinal nerves (►Tactile sensation in oral region).

## Somatosensory Projections to the Central Nervous System

Somatosensory projections arise from sensory receptors and nerve fibers distributed throughout the body. They are concerned with the sensory modalities of touch, pain and thermal sensation, and the kinesthetic sense, the sense of body position and movement. The different modalities of somatic sensation are derived from sensory receptors or nerve endings in the skin or from receptors in muscles and joints.

Somatosensory information is carried from all parts of the body to the central nervous system via vast numbers of nerves that finally enter either the spinal cord or the brainstem. Upon entering the central nervous system, somatosensory nerve fibers may project, as a result of branching in their axons, into more than one target site at which they make synaptic connections with neurons of the central nervous system. Within the spinal cord there are at least three major pathways for conveying somatosensory information to higher centers of the brain for somatic sensation and perception, the dorsal column (DC) system, the spinothalamic tract (STT) system and the spinocervical tract (SCT) system.

Somatosensory information may also be conveyed to higher centers of the brain over less direct pathways, in particular, involving spino-reticular pathways whose functions are not entirely clear, but are probably not of major importance for the signaling of detailed discriminative information for sensory experience (►Somatosensory projections to the central nervous system).

## The Somatosensory Cortex I (SI)

The cortical area involved in the somatosensory processing in the rostralmost parietal lobe, the postcentral gyrus. The somatosensory cortex was defined earlier as the cortical regions where the cortical stimulation provoked either localized bodily movements in monkeys or subjective somatosensory experiences in humans. Later, cortical evoked potentials were recorded by electrical stimulation of the body surface in various animals to determine the extent of the somatosensory cortex. At least three areas, the somatosensory cortex I (SI), II (SII), and the supplementary somatosensory cortex have been identified in primates including humans.

Over the surface of the somatosensory cortex I (SI) in the human postcentral gyrus, the somatotopic map of the body representation was drawn, based on evoked subjective somatic sensation. In animals, cortical evoked potentials are recorded with the shortest latency after stimulation of the periphery, and analogous somatotopic maps of the body representation were drawn.

The following subjects were discussed in the light of current knowledge. Anatomical structures of SI, cytoarchitectonic subdivisions of Brodman, thalamic inputs, cortico-cortical association connections, callosal connections, corticofugal connections, somatotopic representation of the body surface, plastic alteration of the somatotopy, representation of pain in SI, columnar structures, diversity of the neuronal receptive field along a perpendicular array, hierarchical processing in the hand region, vertical neuronal arrays representing active touch, bilateral representation of the body in SI, attributes of tactile perception represented in the cortical activity (►The somatosensory cortex I (SI)).

## The Somatosensory Cortex II (SII)

SII is the cortical area involved in the somatosensory processing in the frontoparietal operculumin in primates and in the lateral cortical region in the cat. It is defined as a separate cortical region from SI.

The anatomical position of SII and the results of single neuronal recording studies revealed that SII is a higher stage of somatosensory information processing, downstream to SI. SII receives cortico-cortical projections from SI in addition to the thalamic inputs. SII projects to the frontal lobe and insular cortex. In SII the bilateral representation of the body, especially that of hands and feet is more common. The functional role of SII in somatic sensation is not yet clear, but its possible and specific role in tactile object recognition, tactile memory, tactile attention processes, and process of decision making have been discussed in the light of its anatomical connections to other cortical areas, experimental evidence in both animals and humans and clinical observations of human patients (►The somatosensory cortex II (SII)).

## Somatosensory Cortex, Plasticity

The somatosensory cortex is characterized with a somatotopic representation of the contralateral body. Areas depend on inputs from the somatosensory thalamus and other somatosensory areas for activation. The loss of a source of activation, such as afferents from the hand, is followed by neurons developing responsiveness to remaining inputs, such as those from the face or arm.

Sensory experiences can also alter the response properties of neurons, often in ways that they become more selective for the experienced stimuli. These plastic changes in somatosensory cortex are mediated by the growth of axons and the formation of new synapses in the somatosensory system, as well as by cellular changes that influence the sensitivities of neurons to neurotransmitters.

A major loss of sensory inputs results in an extensive reactivation of deactivated portions of the somatosensory cortex by remaining somatosensory inputs in ways that result in misperceptions, such as feeling touch or pain in a missing (phantom) limb. Researchers are trying to understand the mechanisms of neural plasticity so that useful forms of plasticity can be promoted, and harmful types of plasticity can be prevented (►Somatosensory cortex, plasticity).

## Barrel Cortex

The layer IV of mouse and rat SI cortex is characterized with a unique structure called barrels. When viewed in sections cut parallel to the cortical surface and stained with the cytochrome oxidase (CO) stain, they appear as oval dense zones: one for each of the digits and pads on the feet, and one for each of the large and many of the small whiskers on the face around the nose and mouth.

Rodents have specialized the whiskers on their face into exquisitely sensitive tactile organs with which they explore their environment, by moving the whiskers back and forth (whisking). Each whisker in these species is a complex sensorimotor organ that can move the whiskers precisely to gather the most salient information.

Each whisker follicle is innervated by over 200 sensory fibers that render it extremely sensitive to the direction, magnitude, duration, frequency and velocity of any stimulus that can perturb the whiskers. In the rat's vibrissa (whisker) system, neurons representing whiskers at each level in the pathway are topographically organized into functional "whisker maps". These maps correlate well with the anatomically discrete cell aggregates at each level: "barrelettes" in the brainstem, "barreloids" in the thalamus and "barrels" in layer IV of the primary somatosensory cortex (SI). Each map replicates the spatial arrangement of whiskers on the face (►Barrel cortex).

## Haptics

Haptics is defined as sensing objects by manipulation or palpation. Haptic sensing is focused on perceiving the physical properties of external objects rather than internal tactile sensations, and the hand is the primary organ through which the external world is explored tactually.

Haptic sensing involves both the tactile and proprioceptive sensory modalities. The tactile inputs come from cutaneous mechanoreceptors in the hand that encode the surface features and shapes of objects as they are explored, whereas the proprioceptive signals provide information about joint angles, the rate of joint movement and the forces generated on contact, all of which can assist in perceiving the properties of objects held in the hand. It is this active process of manual exploration in which there is a close interplay between finger movements and tactile perception that distinguishes haptics from passive touch.

For some properties, such as the perception of roughness of a surface or the detection of minute surface irregularities, it appears to matter little whether the hand moves over a stationary surface (haptic sensing) or the surface is moved across a stationary hand (tactile sensing), all that is important is that there is relative motion between the skin and the surface.

For other properties, such as the perception of weight, hand movements greatly facilitate perception, as reflected in the increased sensitivity to changes in weight when an object is lifted as compared to when it rests on the passive hand. Peripheral proprioceptive feedback resulting from the active movement provides an additional source of information about the object. A further source of information about force comes from the cortically generated motor command transmitted to the muscles involved in supporting the weight. Copies of these commands, known as corollary discharges, are sent to a number of the sensory areas in the cortex and are involved in the perception of force.

Impairments in haptic object recognition can occur in the absence of primary sensory loss. They are usually associated with lesions in the posterior parietal lobe, sensory thresholds on the hand are normal or only mildly impaired, but there is a profound deficit in recognizing objects haptically. A number of terms are used to describe these impairments in haptic object recognition consequent to cortical damage, including astereognosis, tactile apraxia and tactile paralysis. The deficits appear to result from difficulties in tactile shape perception and inefficient manual exploration strategies. Lesions in the posterior parietal lobe therefore affect the capacity to make precise controlled finger movements and to plan these movements efficiently, both of which are essential to haptic object recognition (►Haptics).

## Active Touch

Active touch refers to the act of touching, and implies voluntary, self-generated movements. With active touch, the environment is explored using specialized touch organs in order to gather information about the properties of surfaces (texture, hardness, temperature) and/or objects (size, shape, weight, location) located in the nearby peri-personal space. In contrast, passive touch, or the act of being touched, implies that the sensory input is generated by an external agent, and this type of touch is not generally exploratory in nature and experienced only occasionally in daily life.

In humans and other primates, the hand is generally used for active tactile exploration of the surround. The

hand is characterized with a high density of peripheral sensory receptors, a correspondingly large cortical representation and thus high sensory acuity. The hand is not only a touch organ, but also has a highly developed ability to make independent finger movements. The manipulation provokes rich sensory signals of both a cutaneous and proprioceptive nature to be sent to the brain.

Since D. Katz (1925) and J. J. Gibson (1962) emphasized the importance of investigating active touch, there have been many studies to compare various aspects of the two modes of touch experimentally, and whether the perception is equivalent with active and passive touch has been studied. A number of studies have compared perceptual performance using active and passive touch, but these have concentrated almost exclusively on tasks dependent on cutaneous feedback. Their results have shown that perceptual performance with active and passive touch is similar when exploratory conditions are suitably matched. Equivalence for active and passive touch has been shown for a variety of cutaneous tasks, including the detection of minute surface irregularities, texture discrimination, scaling the roughness of various surfaces, and recognition of raised tactile patterns (letters, Braille characters). Occasionally, investigators have shown an advantage for active touch over passive touch, e.g. recognition of Braille characters, but the findings have not been confirmed in other studies using similar types of pattern recognition tasks.

There has been a long-standing debate about the perceptual equivalence of active touch and passive touch. Current evidence indicates that there is perceptual equivalence for active and passive touch in a range of tasks, mostly dependent only on cutaneous inputs. Active touch, on the other hand, likely enjoys an advantage over passive touch in being more efficient: the relevant sensory information is collected, and analyzed, more rapidly. The underlying neuronal mechanisms differ, because only active touch involves voluntary movements. Thus it is conceivable that the motor commands associated with active touch may trigger central mechanisms such as attention that contribute to enhance neuronal responses to salient inputs during active touch. Finally, active touch enjoys a number of advantages over passive touch: digits can be oriented so that the most sensitive skin areas contact the object and; movement speed can decline at critical times during exploration, so minimizing suppressive gating influences (themselves speed-dependent). It thus seems unwise to generalize from results obtained using one form of touch to the other (►Active touch).

## Tactile Attention

Attention allows one to focus awareness and the processing capacities of the brain on objects and events relevant to one's immediate behavioral goals. Tactile attention specifically refers to attention to somatic sensory stimuli. While this term can encompass all of the submodalities that contribute to somatic sensation (touch/pressure, position/movement, temperature, pain), most experimental studies have concentrated on characterizing sensory responsiveness to touch during manipulations of attention.

In comparison with the visual system, there is much less information available about the effects of attention on the perception of tactile stimuli. Attentional effects are inferred by measurement of reaction time, response accuracy and also measures of sensory sensitivity (detection or discrimination thresholds). Faster reaction times are presumed to reflect speeded up processing and decision-making. Improved accuracy and reductions in sensory thresholds are likewise considered to reflect enhanced processing of sensory inputs.

Psychophysical studies in humans on (i) spatial attention, (ii) cross-modal attention and (iii) orienting, and the results of experimental studies to examine the neuronal correlate of human psychophysics, single unit recordings from SI and SII in monkeys were described. The neuronal responsiveness to tactile stimuli was enhanced by a vibratory cue. The enhancement was more pronounced in SII than in SI. Possible mechanisms of the attentional tuning in SII were discussed in detail.

There are studies to investigate the effects of attention in humans. Regional cerebral blood flow (rCBF) elicited by tactile stimulation is increased with attention. Even simple anticipation of light tactile stimulation can increase SI rCBF. In both SI and SII, the area of activation (seen using fMRI) is larger with directed attention, but this only reaches significance for SII. Consistent with single unit recordings, rCBF shows larger increases in SII than SI when attention is directed to tactile stimuli. In addition, sustained attention to tactile or visual stimuli results in the activation of a cortical network that includes the right dorsolateral frontal cortex and bilateral inferior parietal lobule (possibly corresponding to primate area 7b), and this is independent of the laterality of the stimulus. This network may underlie the well-known right hemispheric dominance of human attention. Evoked potential studies confirm that, as seen in non human primates, attention can enhance responsiveness to tactile inputs, with the effects being significant in SII but not SI (►Tactile attention).

# Tactile (Touch) Receptors

►Cutaneous Mechanoreceptors, Anatomical Characteristics

## Tactile Vocoder

### Definition

Devices designed for use by the deaf and hard-ofhearing in order to display the sounds and patterns of speech upon the surface of the skin by vibrations.

►Aging of Tactile Sense

## Tail Currents

### Definition

Membrane currents measured during ion channel closing. Tail currents are associated to channel de-activation and are typically measured during a voltage-clamp pulse on return to resting membrane potentials. The pulse is preceded by a step depolarization able to open a significant fraction of available ion channels.

## Tailor's Cramp

### Definition

George Vivian Poore (1890) described a case of Tailor's Cramp and other troubles affecting the function of the hand. He described two forms: (i) the spasmodic form, which was like a focal ►dystonia, and a neuritic type, a diffuse form, which had a neuromuscular cause.

## Tangential Migration

### Definition

Interneurons are produced in subpallium and migrate into the telencephalon parallel to the pial surface.

## Tangle

### Definition

A characteristic feature of the brains of Alzheimer's patients, the intracellular aggregates of paired helical filaments, composed of the protein tau.

►Alzheimer's Disease
►Neuroinflammation: Chronic Neuroinflammation and Memory Impairments

## Tanycyte

### Definition

A specialized cell type located in the ventricular ependymal wall. Developmentally related to radial glia, these cells are found in select regions along the third ventricle, the floor of the cerebral aqueduct, and the caudal floor of the fourth ventricle. They express a variety of neuroendocrine marker molecules, and take up various protein tracers from the cerebrospinal fluid. The function of tanycytes remains incompletely understood, but their likely functions include forming diffusion barriers and mediating neuroendocrine communication between the cerebrospinal fluid, portal capillary networks, and neuronal groups in adjacent brain parenchyma. They have been proposed to be involved in providing T3 to the central nervous system (CNS) following T4 uptake from the cerebrospinal fluid (CSF).

►Hypothalamus-Pituitary-Thyroid Axis

## Tanycytes

### Definition

Tanycytes are cells lining the third ventricle establishing contacts with blood vessels of the ME.

## Tardive Dyskinesia

### Definition

Refers to dyskinetic movements secondary to longterm use of neuroleptic (antipsychotic) or anti-emetic medications, which have dopamine antagonist activity. Tardive dyskinesia is typical choreatic, dystonic, or a combination of the two. It is best to prevent tardive syndromes by using the lowest dose of an atypical antipsychotic for the shortest possible duration. Once present, treatment of tardive dyskinesia can be challenging. The data supporting the use of Vitamin E and benzodiazepines are weak, although the sedative/ anxiolytic effects of the latter may suppress abnormal movements. There are no large scale head-to-head studies comparing atypical neuroleptics among themselves. Clozapine and quetiapine have the lowest reported cases of tardive dyskinesia. Dopamine depleting agents may also be used in intractable cases of tardive dyskinesia.

►Chorea
►Drugs for Motor Disorders

## Target Organ (Autonomic)

### Definition

Target organs are organs innervated by autonomic nerves, and are also called effector organs. Examples include the pupil, heart, blood vessels, sweat glands, gastrointestinal tract, hormone secretory organs, and urogenital organs.

►Parasympathetic Nervous System
►Sympathetic Nervous System

## Target Selection in Axon Growth

### Definition

The phenomenon by which axons enter and recognize specific zones comprised of their target cells.

►Axon Pathfinding

## Target Specificity

►Synaptic Specificity

## Target Step Saccade Task

### Definition

At the beginning of a trial, a visual target is presented, and the subject (human or monkey) is required to fixate it. At the end of the fixation period, this target is extinguished at the same time that a second target comes on. The subject must then make a gaze shift to fixate the new target. This standard task allows for precise experimental control of the direction and amplitude of gaze shifts.

## Targeting Endothelial Dysfunction Through Treatment of Erectile Dysfunction: Current Pharmacological Treatment and Mechanism of Action

Bobby D. Nossaman[1,3], Subramanyam N. Murthy[1], Serap Gur[2], Wayne G. Hellstrom, Philip J. Kadowitz[1]
[1]Department of Pharmacology, Tulane University Medical Center, New Orleans, LA, USA
[2]Department of Urology, Tulane University Medical Center, New Orleans, LA, USA
[3]Department of Anesthesiology, Ochsner Health System, New Orleans, LA, USA

### Definition

►Erectile dysfunction is defined as a persistent medical and/or psychological disorder that refers to the inability to obtain an adequate penile erection for satisfactory sexual activity.

### Characteristics

Erectile dysfunction is a neurovascular disorder modulated by hormonal, local, biochemical and structural

changes of the penis [1]. The incidence of erectile dysfunction increases with age and affects approximately 30 million men with a tripling of the prevalence of complete impotence in men from 40 to 70 years of age [2,3]. Erectile dysfunction, as well as diverse diseases such as hypertension, atherosclerosis, hyperlipidemia, obesity, congestive heart failure, renal failure, and diabetes, is associated with functional and structural changes of the ►vascular endothelium (endothelial dysfunction) with additional aberrations in vessel wall contractility leading to vascular wall remodeling [2,4]. The penile vascular endothelium plays an important role in erection and when dysfunctional, it is involved in the pathogenesis of this medical condition. The vascular endothelium responds to a variety of insults and changes from a healthy functional state to an unhealthy endothelium that promotes vasoconstriction, hypercoagulation, and inflammation. This ability of the vascular endothelial to promote parendymal dysfunction makes this tissue an important target for medial intervention [3,4].

Three important vasodilators produced by the endothelium, nitric oxide (NO), prostacyclin, and endothelium-derived hyperpolarizing factor, act to maintain normal endothelial function (►endothelial nitric oxide). However, the endothelium primarily controls local vascular function through the release of NO, which protects the vessel wall against the development of excess wall stiffness, inflammation, thrombosis, and the development of atherosclerosis [3]. There is now emerging evidence to suggest that malfunction of this major pathway plays an important role in the endothelial dysfunction found in erectile dysfunction and in cardiovascular diseases [3]. Current pharmacological therapies that are beneficial in the management of erectile dysfunction, their mechanism of action, and potential side effects are the focus of this chapter.

## Pathogenesis

Endothelial dysfunction is involved in the pathogenesis of erectile dysfunction and may be an early sign of cardiovascular disease as the risk factors for cardiovascular disease; diabetes, hyperlipidemia, hypertension, obesity, and smoking have also been shown to be involved in the development of erectile dysfunction. Moreover, erectile dysfunction could be considered an early manifestation of cardiovascular disease [2,4].

Although cardiovascular disease and erectile dysfunction were thought to be the end result of atherosclerosis, recent studies suggest that erectile dysfunction can develop prior to the development of overt manifestations of vascular damage from atherosclerosis as studies suggest symptoms of erectile dysfunction in patients can precede the onset of symptoms from other cardiovascular diseases, due to the observations that the inflow penile blood vessels are smaller than found elsewhere in the body [1,3]. Early development of impaired penile blood flow and organ dysfunction, suggest this disease could be used as a barometer of the status of overall cardiovascular health, even if patients have no other cardiovascular symptoms [3]. Earlier detection would facilitate earlier intervention and could offer the potential of providing effective treatment for erectile dysfunction and as well as to improve outcomes from other cardiovascular diseases [3].

## Current Pharmacological Therapy

### *Life Style Changes*

Current therapy for erectile dysfunction includes counseling to change life-style. Patients are advised to decrease excessive alcohol use, stop smoking, increase exercise, correct hyperlipidemia, and control all co-morbid medical diseases such as hypertension, obesity, and diabetes [3,5].

## Androgen Replacement Therapy

Hypoandrogenism may be an important factor in the induction of erectile dysfunction. Androgen replacement therapy is a therapeutic option for erectile dysfunction following clinical investigation that androgen levels are low. Androgen replacement therapy offers additional benefits including increased muscle mass, decreased lethargy, and decreased development of osteoporosis [3,5].

### *Mechanism of Action*

Testosterone stimulates endothelial and neuronal production of NO and can improve endothelial repair mechanisms by increasing bone marrow-derived endothelial progenitor cells number in the peripheral circulation [6]. Furthermore, androgens may stimulate the differentiation of progenitor cells into smooth muscle cells and inhibit their differentiation into adipocytes. Androgens also have a direct effect on penile tissue to maintain erectile function and help reverse the metabolic and structural changes in the corpus cavernosum that cause venous leakage [7].

### *Side Effects*

The risk of prostate disease should be discussed before implementing hormonal replacement therapy. Although testosterone replacement therapy does not induce the development of prostate cancer, testosterone supplementation can exacerbate existing prostate cancers, and a diagnosis of prostate cancer remains a contraindication [3].

## Selective Type 5 Phosphodiesterase Inhibitors

Currently, the most effective pharmacological therapy for erectile dysfunction is the selective type 5 phosphodiesterase (PDE5) inhibitor class of drugs

(►selective type 5 phosphodiesterase inhibitors) [3]. Sildenafil, tadalafil, and vardenafil are effective, safe and reliable oral agents. All three drugs in this class have similar pharmacology and each is effective in patients with erectile dysfunction of all ages, severity and etiology. While there are clear pharmacokinetic and pharmacodynamic differences between these agents, clinical differences are difficult to identify [8].

Testosterone, plus PDE5 inhibitor therapy, may also be beneficial in improving erectile function in hypogonadal men (►male hypogonadism) who are unresponsive to PDE5 inhibitor therapy [3].

### *Mechanism of Action*

NO mediates penile erection under normal conditions, with PDE5 the major cGMP-hydrolyzing enzyme in the penis. When this enzyme is blocked with use of the PDE5 inhibitor class of drugs, released NO is sustained couses a greater increase in cGMP with resultant enhancement of corpora cavernosal inflow and improved erection [3].

### *Side Effects*

There have been concerns about the effects of these agents on the heart and their safety profile in patients with coronary artery disease. The concerns focused on the reported effects of PDE5 inhibitors on blood pressure and heart rate, cardiac electrophysiology, and cardiovascular adverse events in clinical trials. Since there are currently three PDE5 inhibitors, attention has been given to class effects as well as unique individual safety and adverse events. These drugs lower blood pressure as they are mild vasodilators, but these effects are usually mild and produce few symptoms. However, when combined with nitroglycerin, blood pressure drops can be profound and life threatening [3].

There are reports of changes of the QT interval although none of the three agents are dangerously associated with QTc prolongation; although vardenafil has a drug-insen a warning for patients at risk for QTc prolongation [3].

There do not appear to be significant cardiovascular safety issues in men with satisfactory cardiac and performance status [3]. It is interesting to note that sildenafil has been shown to have a protective effect in an experimental model of ischemia reperfusion in the heart [9]. Indeed, with the observed vasodilator effect from these drugs, studies point to the improved exercise tolerance and coronary dilation in patients taking PDE5 inhibitors [3].

Patients presenting to the emergency room with a chief complaint of chest pain suggestive of a heart attack need to inform emergency personnel if they are taking a PDE5 inhibitor. Similarly, before administration of, emergency personnel need to ask patients if they have used PDE5 inhibitors. Nitrates should not be given for at least 24 h after a patient uses sildenafil or vardenafil and at least 48 h after a patient uses tadalafil [3].

Additionally, rare reports of the development of non-arteritic anterior ischemic optic neuropathy in diabetic men using PDE5 inhibitors may reduce the use of these agents [3].

## Conclusion

Erectile dysfunction was once viewed primarily as a psychological issue, but is now understood to represent predominantly organic etiologies and is a highly manageable disorder in most patients. Goal directed assessment and management implies a focus on patient (and partner) preferences regarding various treatment options. Psychosocial interventions also may serve as useful therapeutic adjuncts. Sexual dysfunction is more likely to occur among men in poor physical and emotional health but is also highly associated with negative experiences in sexual relationships and overall mental well-being [10]. Treatment options range from oral pharmacological agents to surgery and may be pursued in a stepwise management approach. In conclusion, Erectile dysfunction has a significant association with cardiovascular disease and this disease could serve as a harbinger of subsequent cardiovascular events [5].

# Tastant

Patricia M. Di Lorenzo, Jen-Yung Chen, Andrew M. Rosen, Andre T. Roussin
Dept. of Psychology, Binghamton University, Binghamton, NY, USA

## Synonyms

Taste stimulus; Sapid Saporous, Saporific stimulus

## Definition

A tastant is a water-soluble chemical that produces a taste sensation by activating ►taste receptor cells (TRCs) and producing activity in taste-related pathways (see ►Taste) in the nervous system.

## Characteristics

### Taste Qualities

Taste stimuli encompass a variety of chemical structures, but, some would argue, evoke only a handful of different sensations. A taste quality may therefore encompass a group of ligands that produce a similar sensation in a particular species. In humans and most mammals, there are four commonly known "primary" or "basic" taste qualities: salty, sour, bitter (►taste-bitter) and sweet. A preponderance of recent evidence points to umami, described as "savory," as a fifth basic taste quality. Another group of chemicals that have been put forward as potential tastants are fatty acids. Though not exhaustive, Table 1 is a list of tastants and the taste qualities that they evoke in humans. For more detailed information about the chemistry of tastants, see [1].

Taste receptor proteins are embedded in the membranes of ►taste receptor cells (TRCs). TRCs use a variety of mechanisms, including second-messenger cascades utilizing the ►G-protein gustducin or direct mediation of ion-channel flux, to transduce tastants into biological reactivity. The mechanisms of ►transduction are specific to the taste receptor.

In mammals, ►taste information is conveyed by nerves innervating the ►taste buds of the oral cavity. Most species have evolved a homologous group of taste-specific fiber paths. The activation of these paths by various ligands defines these chemicals as tastants, as opposed to odorants (see ►olfactory perception). Some sensations that are often labeled as "taste," such as metallic or alkaline, actually arise from the concurrent stimulation of trigeminal or ►olfactory pathways. "Tastes" or "flavors" in the colloquial sense are actually combinations of taste, olfactory, tactile and thermal sensations; there are very few purely taste sensations. In part, that accounts for the observation that people can lose a large part of their sense of taste and not be aware of any deficit [2].

#### *Saltiness*

Salt intake is essential to maintain osmotic balance in the body and to support nervous transmission. The deletion of salt from the diet, or the removal of the adrenal gland, lead to salt cravings, also known as a "salt appetite." In mammals this is expressed as an increase in the amount of the highest concentrations of NaCl that is ingested. Salt deprivation early in life can also lead to permanent changes in the development of the gustatory system in rodents.

The sensation of saltiness in its purest form is produced by NaCl. Other salts produce taste qualities e.g. bitter or sour, in addition to saltiness. Some salts (e.g. NaCl or KCl, see below under Sweetness) at low concentrations can be perceived as sweet.

In rodents, the transduction of NaCl is thought to involve the entry of $Na^+$ ions directly into the TRC through two separate pathways. The first is through epithelial sodium channels (ENaCs) that are reversibly blocked by the diuretic amiloride. These amiloride-sensitive channels are located on the apical portion of the TRC. $Na^+$ is thought to enter the TRC through these channels, depolarize the TRC membrane, thereby opening $Na^+$, $K^+$ and $Ca^{++}$ channels and promoting transmitter release. The second, amiloride-insensitive transduction pathway for NaCl is by $Na^+$ entry through $Na^+$ channels located on the basolateral TRC membrane below the tight junctions within the ►taste bud. The degree to which these transduction pathways are utilized in human salt perception is unknown.

There is also a role for the anion in the transduction and subsequent perception of saltiness. Small anions such as $Cl^-$ act through a paracellular shunt by diffusing past the tight junctions. This produces a negative region at the basal portion of the TRC which further promotes the influx of positive ions. The tight junctions control this diffusion and current flow; they pass small cations more freely than larger ones. This accounts for the observation that salts with larger anions, e.g. Na-gluconate, do not taste as salty as those with smaller ones, e.g. NaCl.

**Tastant. Table 1** Examples of tastants and the taste qualities that they evoke

| Salty salts | Notes |
|---|---|
| NaCl | prototypical salty stimulus, found in table salt; tastes sweet at low concentrations |
| LiCl | Tastes sweet and sour at low concentrations |
| $Na_2SO_4$ | can evoke sweet, sour, bitter and salty taste |
| $NaNO_3$ | a.k.a. saltpeter; found in leafy green vegetables, fertilizer; used as a food preservative in hot dogs |
| Na-gluconate | product of fermentation of glucose; chelating agent used to clean metal and glass |
| **Bitter Salts** | |
| KCl | Tastes sweet-bitter at low concentrations |
| $CaCl_2$ | used to melt ice on roads, in cement and to add saltiness to foods such as pickles |
| $NH_4Cl$ | tastes salty-sour; found in volcanic rock; used to slow melting on ski slopes and to flavor vodka |
| $NH_4Br$ | used as a flame retardant and in manufacture of photographic chemicals |
| $MgCl_2$ | found in seawater; called “nigari” in Japanese; used as a coagulant in making tofu from soy milk |
| **Sour** | |
| HCl | prototypical sour stimulus; inorganic acid |
| acetic acid | main ingredient of vinegar |
| citric acid | found in citrus fruits, strawberries and kiwis; part of cellular citric acid cycle |
| lactic acid | produced by bacteria in fermented foods |
| malic acid | found in most fruits and some vegetables; also present in wine |
| $HNO_3$ | highly caustic; used in explosives and fertilizer |
| NaOH | a.k.a. lye; used in drain cleaner and food preparation; highly caustic |
| tartaric acid | Found in fruits, especially grapes; main acid in wine |
| **Sweet** | |
| *sugars* | |
| sucrose | prototypical sweet stimulus; main ingredient in table sugar; disaccharide consisting of glucose and fructose |
| fructose | monsaccharide; found in honey, tree fruits, berries, melons, beets, onions; used in corn syrup |
| glucose | monsaccharide; main product of photosynthesis; main source of energy in cells |
| lactose | disaccharide consisting of glucose and galactose; makes up 2–8% of milk solids |
| maltose | disaccharide consisting of two units of glucose; metabolized by yeast in the fermentation process |
| *amino acids* | |
| *dl*-alanine | a nonessential amino acid; found in meat, poultry, fish and dairy foods |
| *d*-histidine | unlike the *d*- isomer, it is not a part of mammalian protein |
| *d*-tryptophan | unlike the *d*- isomer, it is not a part of mammalian protein |
| glycine | a nonessential amino acid; an inhibitory neurotransmitter; required along with glutamate to activate NMDA receptors |
| threonene | an essential amino acid; found in cottage cheese, lentils, sesame seeds, meat, poultry, fish |
| *proteins* | taste sweet to humans but not rodents |
| brazzein | 500–1000X sweeter than sugar; heat stable; derived from the fruit of West African ballion plant |
| monellin | 1000X sweeter than sugar; degrades with heat; found in fruits of West African serendipity shrub |
| thaumatin | 2000X sweeter than sugar; heat stable; found in seed coating of katemfe fruit of West Africa; taste builds slowly and leaves a licorice-like aftertaste |
| **Intense (artificial) Sweeteners** | |
| Na-saccharin | 300X sweeter than sugar; bitter aftertaste; tastes bitter at high concentrations |
| Acesulfame-K | bitter aftertaste; tastes bitter at high concentrations; 180–200X sweeter than sugar |
| Aspartame | 180X sweeter than sugar; degrades with heat; |
| cylclamate | 30–50X sweeter than sugar; heat stable |
| dulcin | 250X sweeter than sugar; removed from market in 1954 over carcinogenic concerns |
| neotame | 8,000–13,000X sweeter than sugar, structurally related to aspartame, moderately heat stable |

**Tastant. Table 1** Examples of tastants and the taste qualities that they evoke (Continued)

| Salty salts | Notes |
|---|---|
| **Bitter** | |
| quinine HCl | prototypical bitter stimulus; an alkaloid derived from the bark of the South American cinchona tree; used to treat and prevent malaria |
| quinine $SO_4$ | see quinine HCl |
| urea | a.k.a. carbamide; organic compound used in many industrial applications |
| sucrose octaacetate | intensely bitter; used as a bitter additive to prevent poisoning; denatures alcohol |
| cycloheximide | highly toxic; made by bacterium *Streptomyces griseus*; used as fungicide in agriculture |
| denatonium | the most bitter substance known; used as a bitter additive to prevent poisoning; denatures alcohol |
| caffeine | a.k.a. guaraneine, mateine, theine; found in berries and leaves of >60 plants; found in coffee, tea, many soft drinks and chocolate; CNS stimulant |
| nicotine | alkaloid found in nightshade family of plants, e.g. tobacco; neurotoxin used in pesticides, cigarettes; highly addictive |
| salacin | derived from bark of white willow; found in aspirin; antipyretic, anti-inflammatory and analgesic |
| aristolochic acid | derived from Aristolochiaceae family of plants; carcinogenic and nephrotoxic |
| phenythiocarbamide (PTC) | a.k.a. phenylthiourea; coded by dominant gene, is tasteless to part of the population |
| 6-n-propylthiouracil (PROP) | coded by dominant gene, is tasteless to part of the population; less toxic than PTC |
| **Umami** | |
| monosodium glutamate (MSG) | Found in meats, cheese, mushrooms and tomatoes |
| l-aspartate | nonessential amino acid; neurotransmitter and excitotoxin |
| disodium 5′-inosate (IMP) | enhances umami taste when presented with MSG; used as an additive to instant noodles and potato chips |
| disodium 5′-guanolate (GMP) | enhances umami taste when presented with MSG; derived from dried fish and seaweed; used as a food additive |
| **Fatty acids** | |
| linoleic acid | polyunsaturated omega-6 fatty acid; found in sunflower and safflower oil; used in making soap, emulsifiers |
| oleic acid | monounsaturated omega-9 fatty acid; found in olive and grapeseed oil |
| stearic acid | saturated form of oleic acid |
| **Other** | |
| Polycose® | an easily digestible source of calories used as a nutritional supplement in humans; consists primarily of polysaccharides derived from starch, a.k.a. glucose polymers, maltodextrins, maltooligosaccharides; very attractive to rodents but less so to humans |
| ethanol | a.k.a. ethyl alcohol, grain alcohol; contained in alcoholic beverages; produced by fermentation; taste is a mixture of sweet and bitter |

(Abbreviation: a.k.a., “also known as.”)

### Sourness

The sensation of sourness is associated with organic and inorganic acids or other molecules that are acidic in nature. Acids are associated with unripened fruit and are produced by the fermentation process. Bacteria associated with rotting food also produce acids (e.g. lactic acid). Most fruits (e.g. citric acid) and vegetables (e.g. succinic acid) contain acids, as does wine (tartaric and malic acids) and vinegar (acetic acid).

Although it was originally thought that the perception of sourness appears to be directly related to the concentration of the hydrogen ion, more recent studies suggest that this is not so for organic and dilute inorganic acids [3,4]. A variety of transduction mechanisms have been studied for sourness, and it appears that there are large species differences in the mechanisms that are present. Mechanisms that have been proposed include a proton exchange mechanism, a stimulus-gated $Ca^{++}$ channel and the direct entry through a $H^{+}$ channel that has yet to be identified. Recently a polycystic–kidney-disease-like ion channel (PKD2L1) has been identified as a candidate sour taste

sensor in mice. This ion channel is located on a subset of taste receptor cells that are distinct from those responsible for sweet, bitter and umami taste. Mice in which PKD2L1-expressing cells have been experimentally ablated have been shown to be devoid of responsiveness to sour stimuli while responses to all other taste qualities remain intact [5].

### Bitterness

Bitterness is thought to signal toxicity and is therefore of utmost importance to the survival of the organism. Many plants that are poisonous taste bitter.

The perception of bitter is mediated by the ►T2R receptors, a highly divergent group of ►G-protein-coupled Receptors (GPCRs). These receptor types are expressed on a subset of cells that have been shown to be distinct from those expressing sweet and umami. The wide variety of receptor subtypes dedicated to bitter tastants accounts for the diversity of chemicals that evoke bitter taste sensations. These include some plant alkaloids such as quinine, the prototypical bitter substance, brucine, nicotine, strychnine and caffeine, as well as hydrophilic salts of $Ca^{++}$, $Mg^{++}$, $Ba^{++}$, $Cs^{+}$, $K^{+}$ or $NH_4$. Other compounds such as urea, sucrose octaacetate, denatonium chloride and many of the D-isomers of amino acids also taste bitter. Some intense sweeteners such as Na-saccharin and acesulfame-K can taste bitter at high concentrations and have a bitter aftertaste.

Among humans, there is a well-studied genetic variation in the ►GPCR T2R38 that is correlated with the ability to detect the bitterness of a family of structurally related chemicals containing the N–C = S moiety. Two examples of these compounds are phenythiocarbamide (PTC) and 6-n-propylthiouracil (PROP). Sensitivity to PTC and PROP is correlated with the number of fungiform papillae on the anterior tongue and can predict preferences for sweet and fatty foods in humans. An association between sensitivity to PROP and alcohol dependence has also been suggested. PTC and PROP sensitivity are controlled by the PTC loci on human chromosome 5p15 7q31 that codes for a member of the T2R bitter receptor family.

### Sweetness

There are a wide variety of compounds that produce a sweet sensation, including mono-, di-, and polysaccharides, polyalcohols (e.g. glycerol, xylitol, mannitol), along with some amino acids, peptides and proteins. The prototypical exemplar of the sweet taste quality is sucrose, a disaccharide. In addition, some salts, including NaCl, KCl, NaOH, KOH, salts of berrylium and lead acetate and carbonate, taste sweet at low concentrations. The sweetness of weak solutions of lead (a toxic substance when ingested) has particularly troubling implications for public health.

Most sweet and umami tastants are transduced by a group of three ►GPCRs, T1R1, T1R2, and T1R3, collectively termed the ►T1R receptors. In humans, genes for the ►T1R receptors have been localized to chromosome 1. Sweet sensing TRCs express a heterodimer of the T1R2 and T1R3 receptors. The result, a T1R2/T1R3 receptor, mediates sensation of sweet tastants. There remains, however the possibility that other receptors for sweet as well as umami tastants exist [6].

Considerable across species differences in sweet perception are related to variation in the T1R sequence and expression. For example, cats lack any sensitivity to sweet tastes due to the absence of T1R2 receptors. Due to mutations of the T1R2 and T1R3 genes sequence, some compounds that are sweet to humans (e.g. aspartame, cyclamate, neohespiridin dihydrochalcone, neotame and the sweet proteins brazzein, monellin and thalmatin) are tasteless to rodents and New World monkeys.

### Umami

Although still controversial to some, there is good evidence that the taste of umami should be considered a fifth "basic" taste quality. Umami was formally described by Ikeda in 1908. The word "umami" means "deliciousness" or "savory" in Japanese; the word "xianwei" is the equivalent of umami in Chinese. Umami-inducing compounds include monosodium glutamate (MSG) and two 5′-ribonucleotides, disodium 5′-inosate (IMP) and disodium 5′-guanosalte (GMP). IMP and GMP have the ability to enhance the taste of MSG when mixed with it. MSG, IMP and GMP are found in meats, cheeses, mushrooms (e.g. *Lentinus edodes*, shitake), fish (e.g. katsuobushi or bonito, a mackerel-like fish), kelp or sea tangle (*Laminaria japonica*, seaweed or kombu) and tomatoes. Other compounds such as L-aspartate, some higher order peptides and organic acids can also induce an umami sensation.

The receptor for umami is a heterodimer of the T1R1 and T1R3 ►GPCRs. The T1R1/T1R3 receptor is broadly responsive to L-amino acids in rodents and narrowly tuned to umami in humans [6]. The Taste-mGluR4 (also a ►GPCR) has also been implicated in the transduction of umami taste.

### Fats (lipids)

The discovery of a transduction mechanisms sensitive to free fatty acids (the hydrolyzed product of triglycerides) in the membrane of TRCs [7] has led to the speculation that "fattiness" may be an additional taste quality. Two transduction mechanisms have been described: the inhibition of the delayed rectifying $K^{+}$ channels and through the fatty acid CD36 transporter. Behavioral evidence suggests that fatty acids (e.g. linoleic acid, oleic acid and stearic acid) may qualify as tastants in both rats and humans and that the taste of fatty acids is detectable without the aid of input from other sensory cues such as texture, viscosity or smell.

### Water as a Tastant

Because water elicits a response in TRCs and in the taste nerves of some species, it can be considered a tastant. Its action is thought to involve an aquaporin, AQP5, a membrane channel that selectively admits water molecules into the cell. Water entry then activates a volume regulated anion channel.

Water can also elicit a sweet aftertaste when it is used to rinse the mouth after application of a sweet taste blocker.

### Taste Modifiers and Mixture Effects

There are several substances that are known to modify the taste quality evoked by some tastants when they are presented just before or along with that tastant. For example, the $Na^+$ channel blocker amiloride can reduce the saltiness of NaCl when mixed with it. Thaumatin is a sweet-tasting protein found in the West African plant *Thaumatoccus danielli* that can block bitterness, as can adenosine monophosphate. Lactisol (Na-2-(4-methoxy-phenoxy) proprionate, a synthetic compound found in roasted coffee, is a potent suppressor of sweetness, while chlorogenic acid and cynarin, both found in artichokes, are sweetness enhancers.

Many examples of sweet blockers or modifiers are plant-derivatives [8]. For example, treating the tongue with Miraculin, a glycoprotein derived from the berry fruit of the West African bush *Synespalum dulcifica*, can make sour substances taste sweet even though miraculin itself is tasteless. Similarly, circulin, derived from *Circuligo latefolia* can also make sour substances taste sweet. Two substances derived from the leaves of the plant *Gymnema sylvestre*, gymnemic acid and gurmarin (a peptide) suppress sweetness in humans and rats respectively. Ziziphin, purified from the leaves of *Ziziphus jujuba*, and hodulcin, extracted from the leaves of *Hovenia dulcis*, can both block sweet taste.

When chemicals of different taste qualities are mixed there are often changes in the perceptual properties of the components of the mixtures. The most common effect is that of mixture suppression. For example, NaCl, will suppress bitterness when salt is added to a bitter substance. Sucrose and citric acid will suppress each other, as in lemonade, when mixed. Synergy, though rare, can also occur, as in the enhancement of umami taste by the addition of IMP or GMP to MSG. For a detailed review of taste mixture effects in humans, see [9].

## Function

### Taste Perception Across Species

The function of taste perception (►taste – conscious perception of; taste – context dependence) is mainly in the regulation of ingestion of nutrients and avoidance of toxic substances. Through the evolutionary process, the taste system in various species has adapted to its metabolic and/or dietary requirements. For example, the T1R2/T1R3 receptor that is specialized for sweet perception in mammals, may instead be sensitive to amino acids in lower phyla such as fish (see below). In vertebrates, genes that code for T1R receptors are highly conserved across phyla whereas genes that code for T2R receptors are highly divergent [10].

#### Invertebrates

Insects such as drosophila do not have the same complement of T1R and T2R taste receptors as vertebrates have. Instead, a large family of ~60 candidate gustatory receptor genes (*Gr*) provides the receptors for taste. Most research has focused on the perception or sweet and bitter perception, e.g. cells containing GR5a receptors selectively respond to sugars and cells containing GR66a receptors respond to bitter compounds. Perception of sour taste has not been studied in detail in Drosophila. However, detection of salt is thought to be mediated by direct influx of sodium ions into TRCs via DEG/EnaC channels such as PPK11 and PPK19 (Amrein and Thorne, 2005). The lack of homology with mammalian taste receptors has suggested that the taste system in insects and mammals has evolved independently. Even so, taste preferences of drosophila and humans are quite similar.

#### Fish

Fish have highly developed chemosensory systems and are often the subject of taste research. The taste buds of fish are distributed around the lips and oral cavity, as well as across external body surfaces and fins. Interestingly, there is an overlap between taste and olfactory systems in fish; sugar, salt and quinine activate both taste and olfactory receptors. However, T1R and T2R families of receptors have been identified in the taste, but not the olfactory systems of fish. These receptors serve the same behavioral functions of attraction (T1Rs) and aversion (T2Rs) as they do in mammals, but in fish, T1R2 receptors are responsive to amino acids rather than sugars as in mammals.

#### Amphibian (Frog)

Amphibians such as frogs are usually active at night and eat insects and other invertebrates. Early physiological studies found that individual taste cells and fibers can respond to multiple taste stimuli: salts (especially $CaCl_2$), amino acids, sour, and bitter. Interestingly, large water responses have also been noted in frog. These responses may serve in osmotic regulation since amphibians have highly permeable skin.

#### Reptiles (Lizards and Snakes)

Taste buds are present on the tongue and/or oropharyngeal area in most reptiles, though taste buds have been found in only some species of snakes. Most reptiles are

predators and their sensitivity to tastants of various qualities reflects their diet. The lacertid lizard, *Podarcis lilfordi*, for example, can behaviorally discriminate among sucrose, lipids and proteins and the lizard *Anolis carolinensis* can discriminate between untreated crickets and crickets treated with either dextrose/aspartame powder (sweet sensation for humans) or quinine hydrochloride powder (bitter sensation for humans).

#### *Birds*

The taste buds of birds are similar to those in mammals; most of them are distributed on the posterior part of the tongue and floor of the pharynx. Many birds (e.g. chickens) are unresponsive to sweet tastes. Parrots, hummingbirds, and other nectar and fruit feeders are exceptions. Most birds can detect salt, are more tolerant to sour than humans, and most will reject bitter solutions.

#### *Mammals*

In general, mammals have more taste buds than other animals. Among mammals, the dog's sense of taste is poorly developed compared with that of humans, while the pig has a greater sensitivity to taste. It has been shown that cats lack a sweet receptor and are neither attracted to nor avoid the taste of sweet carbohydrates and intense sweeteners. For most rodents and primates, sweet, salty, sour, bitter and umami tastants are easily identified across a wide range of stimulus intensities.

## Synonyms

Gustation

## Definition

Of the five senses, taste, along with olfaction, allow the sensing and discrimination of chemicals. In particular, taste enables the analysis of the chemical content of foods present in the oral cavity. This task is performed through the integration of signals emanating from specialized cells capable of detecting sapid stimuli, and transmitted to the brain via the gustatory branches of cranial nerves with which they are connected. The gustatory information collected in the mouth bears direct consequences on the ingestive behavior and digestive events.

## Characteristics

### Description of the Peripheral Structure

#### *Taste Cells in the Oral Cavity Are the Sensors of Sapid Stimuli*

Foods that enter the oral cavity are subsequently analyzed by chemical sensors. In particular, water-soluble molecules or tastants dissolved in saliva come into contact with specialized chemosensory cells that contain taste receptors. Taste cells are strategically disseminated in the oral cavity on the tongue, the palate, the epiglottis, the pharynx and the larynx. Taste cells are typically found grouped together in a structure called the taste bud. Regions rich in taste buds are often called papillae although ►filiform papillae do not contain taste buds. On the tongue there are three types of papillae containing taste buds, which can be distinguished by their location and their morphology from which their names are derived.

On the dorsal surface in the anterior part of the human tongue there are about 200 mushroom-like pegs called ►fungiform papillae each containing between one and six taste buds. ►Two foliate papillae, each shaped like a leaf are found on the lateral edges towards the back of the tongue, one on each side and each containing between 300 and 3,000 taste buds. Finally, near the back of the tongue between three and 13 ►circumvallate papillae protrude from the dorsal surface of the tongue. Each circumvallate papillae is surrounded by a circular invagination (trench) embedded deep in the epithelium and along which between 700 and 3,000 taste buds are distributed. Circumvallate papillae are arranged in a row forming a chevron

shape located in front of the sulcus terminalis at the boundary with the oropharynx.

The taste bud is a structure shaped like an onion containing 30–100 elongated cells (Fig. 1).

The apical region of the taste bud is designed to sense sapid molecules while the baso-lateral region of the taste bud communicates information to the brain through afferent fibers that form synapses with selected cells within the taste bud. At their apical pole, taste cells are in contact with the saliva in the mouth by means of microvilli protruding through the taste pore. Below the pore, are tight junctions that create a selective intercellular barrier separating the functionally distinct apical and basal region of the elongated cells of the taste bud.

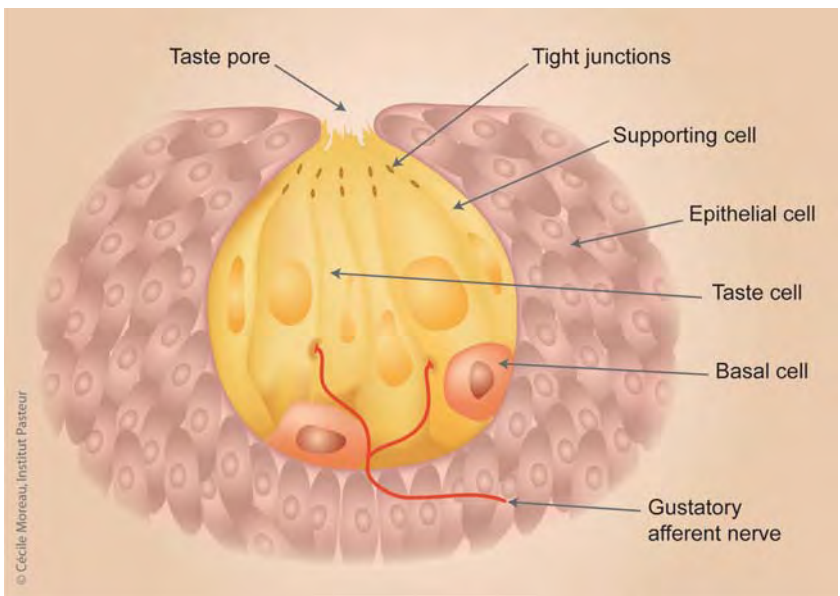
Ultrastructural, cellular and molecular studies have distinguished four types of cells composing the taste bud [1]. Type I cells or "dark cells" which act as supporting cells. Type II cells or "light cells" which extend microvilli at their apical pole where taste receptors for sweet, umami and bitter compounds are thought to reside. Type III cells or "intermediate cells" have the distinctive feature to be in contact with afferent sensory nerve fibers through conventional chemical synapses. Types II and III cells are commonly referred to as "taste cells." Additionally, a population of progenitor cells (type IV) of epithelial origin is found at the base of the taste bud. It is estimated that taste cells are renewed every ten to fifteen days from the progenitor cells. Taste bud innervation is important for taste cell survival in that it provides trophic factors to the taste bud that in fact will degenerate when the sensory nerve is severed.

### *A Variety of Receptors and Transduction Mechanisms Mediate Tastants Detection by Taste Cells*

Some taste cells are equipped at their apical pole with specialized receptors responsible for the detection of sapid molecules. These receptors, also called taste receptors, are involved in the detection of a wide variety of substances with extremely variable chemical structures including but not restricted to: ions, carbohydrates, alkaloids, small proteins and amino acids. The taste sensations evoked by these compounds can be categorized into five basic modalities known as bitter, salty, sour, sweet and umami. Two main types of receptors appear to be involved in the detection of sapid chemicals [2]. Sour and salty stimuli are detected by ion channels, while G protein coupled receptors (GPCRs) are involved in sweet, bitter and umami detection.

In mice, a heteromer composed of two members of the transient receptor potential (TRP) family of ion channels (PKD2L1 and PKD1L3) has emerged recently as one of the main sensors of sour stimuli by taste cells. Salty sensation is thought to be mediated, at least in part by an amiloride sensitive sodium channel (ASSC) which belongs to the epithelial sodium channel (EnaC) family of ion channels.

In humans, two families of GPCRs, namely Tas1Rs and Tas2Rs, are involved in the detection of sweet,

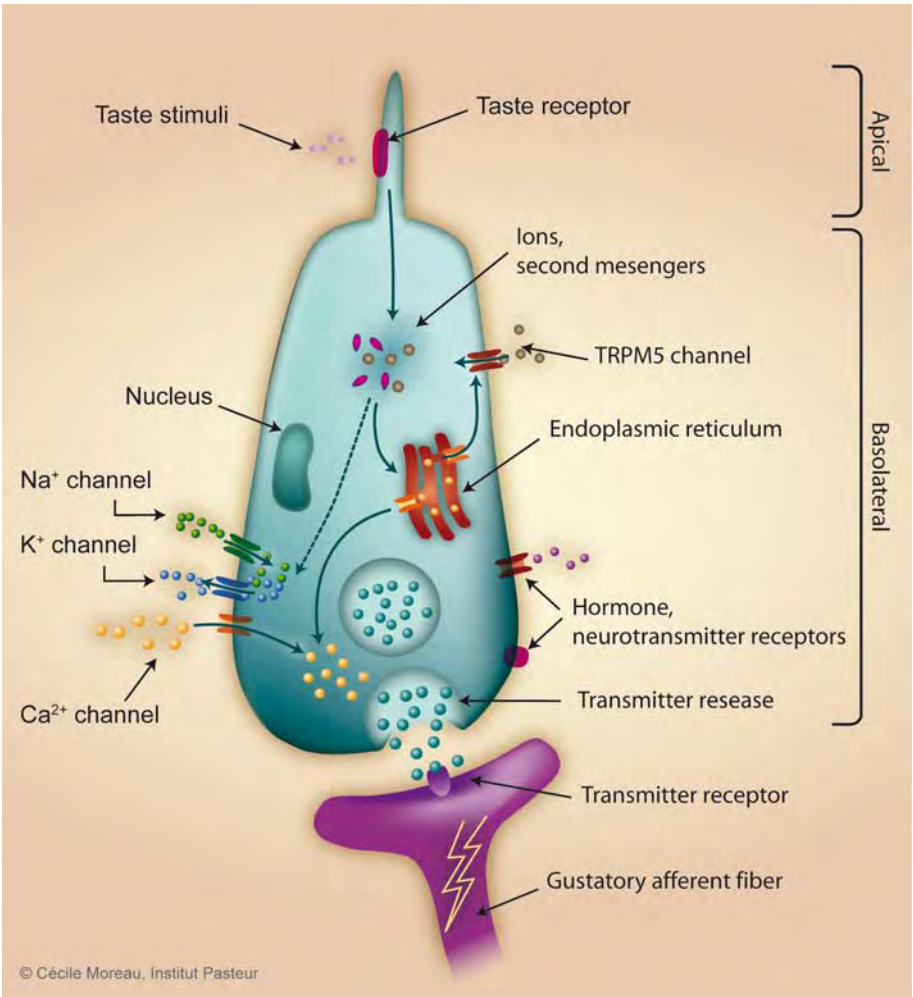


**Taste. Figure 1** Diagram showing the organization and various types of cells composing the taste bud. The taste bud is a structure shaped like an onion composed of elongated as well as rounded basal cells and surrounded by epithelial cells. In the apical region, microvilli from elongated cells (taste cells and supporting cells) protrude through the taste pore (diameter about 20 μm), where they come into contact with the saliva in the mouth. In the baso-lateral region of the taste bud, taste cells communicate the taste information to afferent nerve fibers through synapses.

umami and bitter tasting chemicals. The Tas1R family comprises three members which assemble as pairs to produce functional receptor for sweet (Tas1R2-Tas1R3) or umami (Tas1R1-Tas1R3) tasting substances. The Tas2R family includes 25 members, four of which have been shown to function as receptors for bitter tasting compounds. Slight genetically inherited modifications in the Tas2R38 receptor protein have been shown to be linked to the sensitivity of some individuals to detect the bitter chemical phenylthiocarbamide (PTC).

When activated by tastants dissolved in the saliva, taste receptors modify the physiological properties of the taste cell in which they are expressed, ultimately leading to neurotransmitter release (Fig. 2).

This process can be mediated by ion channels acting as taste receptors through which cations directly enter the cell. Alternatively, in the case of GPCRs a cascade of intracellular events implicating heterotrimeric G-proteins coupled to the receptor as well as effector proteins producing second messengers is involved. For example, the signaling cascade engaged after stimulation of Tas1R or Tas2R receptor is believed to involve the release of the Gβγ subunits from the taste specific G-protein alpha subunit called gustducin which couples to the receptors as an heterotrimeric complex. This leads to the activation of the phospholipase C beta-2 which hydrolyzes phosphatidylinositol-4,5-bisphosphate (PIP2) into inositol 3-phosphate (IP3) and diacylglycerol (DAG). Then, IP3 activates



**Taste. Figure 2** Molecular organization of a taste cell. The taste cell is an elongated cell for which the apical and baso-lateral surfaces which are separated by tight junctions are functionally distinct. Tastants dissolved in saliva are recognized by taste receptors located in microvilli extending from the apical membrane of the cell. Upon activation of the receptor which can be a GPCR or an ion channel, an intracellular signal transduction cascade is initiated involving ion channels such as TRPM5 located on the baso-lateral membrane of the cell. This cascade ultimately leads to an increase in intracellular $Ca^{2+}$ thereby causing synaptic vesicles to release neurotransmitter at the synapse with primary sensory neurons.

receptors causing the release of $Ca^{2+}$ from intracellular stores, which in turn activates TRPM5, a member of the TRP family of ion channels. Gating of TRPM5 by intracellular $Ca^{2+}$ allows entry of monovalent cations into the cell and subsequent depolarization [3]. This is followed by the release of neurotransmitter by the activated cell and transmission of the signal produced to the afferent fibers on their way to the central nervous system.

### *Branches of the Cranial Nerves Carry the Taste Information from the Taste Buds to the Brain*

Primary sensory neurons from three cranial nerves (VIIth, IXth and Xth) make synapses with taste buds. Anatomical studies have shown that single nerve fibers from the taste branches of these cranial nerves contact several taste buds and that each taste bud is in contact with several fibers. The innervation of the taste buds in the oral cavity follows a logic along an antero-posterior axis. Taste buds in the fungiform and anterior part of the ►foliate papillae are innervated by the chorda tympani branch of the facial nerve (VIIth). This nerve also contacts taste buds on the palate through its greater superior petrosal branch.

The circumvallate and caudal taste buds of the foliate papillae are innervated by the lingual branch of the glossopharyngeal nerve (IXth). Taste buds in the larynx are innervated by the superior laryngeal branch of the vagus nerve (Xth). These primary sensory neurons travel through the geniculate, petrosal, and nodose ganglia respectively before entering the solitary tract and synapse with neurons in the rostro-lateral part of the nucleus of the solitary tract (rNST) in an area called the gustatory area [4].

In rodents, electrophysiological studies of the responsiveness of single fibers within these nerves following stimulation of the tongue with tastants have shown that single fibers carry the information from several taste qualities, but that their sensitivities vary according to the taste stimulus. Hence fibers have been classified into four different types [5]. In the rat, fibers of the chorda tympani can be classified into NaCl best, quinine best, sucrose best and HCl best based on their relative sensitivity to four types of taste stimuli. The same is true for the glossopharyngeal taste fibers, although the proportion of the relative fibers vary between the two nerves. Fibers of the glossopharyngeal nerve being predominantly responsive to HCl and quinine while fibers of the chorda tympani nerve are mainly responsive to sucrose and NaCl [6]. In the hamster, the greater superior petrosal branch of the chorda tympani is thought to be predominantly responsive to sucrose and the superior laryngeal branch of the vagus nerve present the particularity to be responsive to water [7].

## Description of the Central Structure

### *The Taste Information Travels via the Brainstem and the Thalamus en Route to the Cortex*

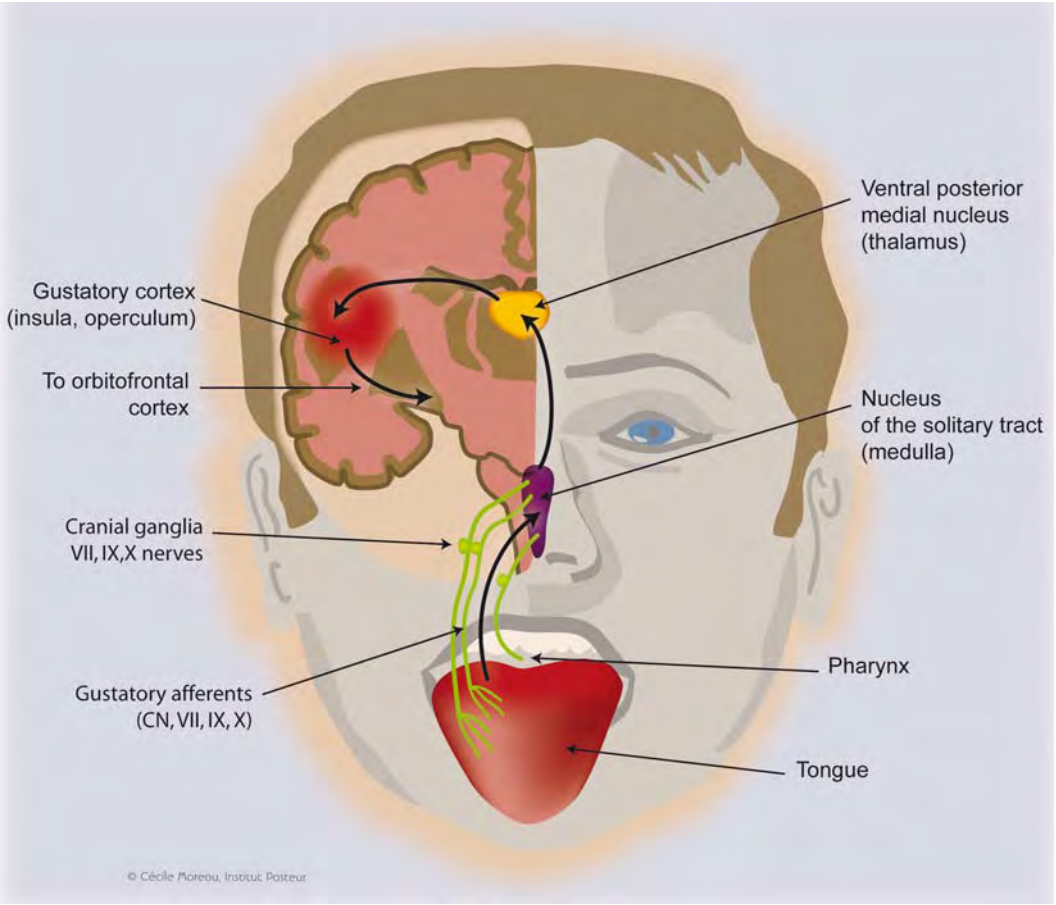
Afferent fibers from the various peripheral nerves innervating taste buds in the oral cavity converge onto second-order neurons in the rNST, which in turn project to the parvocellular region of the ventroposteromedial nucleus of the thalamus. From there the taste information reaches the gustatory cortex traveling via neurons projecting to the anterior insula in the temporal lobe, as well as to the operculum in the frontal lobe before being further processed in the orbitofrontal cortex [8,9] (Fig. 3).

Clinical observations as well as brain imaging technology have shown that the gustatory information travels on the ipsilateral side.

The segregation of first-order neurons emanating from distinct region of the oral cavity contributes to creating a topographical map of taste inputs from the oral cavity in the brainstem. Gustatory neurons become more broadly tuned as they become central such that neurons from the gustatory cortex are broadly tuned to perceptually distinct stimuli, suggesting that ensemble of neurons operate at that level. Furthermore, cortical neurons are able to integrate stimuli from mechanical, visual and olfactory sensors to provide an image of the food placed in the oral cavity.

### *Taste Information Coding*

Over the years, anatomical, electrophysiological, biochemical, cellular and molecular biology studies have allowed tremendous progress in our understanding of the organization of the mammalian gustatory system. The receptors involved in the detection of tastants are being unraveled and it seems pretty clear at this point that taste bud cells specialized in the detection of tastants of the five taste modalities are distinct. Nonetheless, gap junctions and paracrine secretions indicate that cells within the taste bud communicate with each other. Moreover, the nerve fibers contacting a few taste buds and several cells within each taste bud respond to different taste stimuli, suggesting that each fiber receives information from cells with different receptive fields. The implication of such an organization would be that distinct activation patterns in the entire fiber population encode specific taste sensations. This model, also called the "distributed model," is being challenged by findings putting forward the "labeled line" model according to which nerve fibers are connected to populations of taste bud cells specialized in the detection of a specific stimulus [10]. In the labeled line model, fibers would be dedicated to a single taste modality and thus segregated until at least reaching the gustatory area of the NST. One can envision that a straight feed



**Taste. Figure 3** Pathways involved in the processing of the taste information in human. The information generated by taste receptors in the oral cavity travels through cranial nerves VII, IX and X to the nucleus of the solitary tract (brain stem). The second relay is in the thalamus where the information is further processed before reaching the frontal operculum and insula, also called primary gustatory cortex, and then the orbitofrontal cortex. In rodents, the taste information travels through the solitary tract and parabrachial nuclei of the brain stem before reaching the gustatory cortex.

forward system like in the labeled line model would be appropriate for the efficient control of the ingestive behavior after sampling while perception of taste stimuli would require further processing as well as integration of multisensory information. Much remains unknown, therefore a better understanding of the functional organization of the taste system will provide valuable insight into the mechanisms underlying taste detection.

## Taste – Bitter

### Definition

Bitterness is a property of a diverse group of chemicals, many of which are toxic. Quinine, found in tonic water, is the prototypical bitter substance. Many bitter tasting chemicals contain alkaloid structures, indicating that the sense of "bitterness" evolved to enable animals to recognize and avoid poisonous plants. Bitter tastes are transduced by a family of G-protein coupled receptors, the T2R receptors. There is a wide variety in the number of T2R receptors in humans and not all of the ligands that bindwith themhave been identified. There are some bitter substances, e.g. phenythiocarbamide (PTC) and 6-n-propylthiouracil (PROP) and structurally related compounds, that taste bitter to some people but not others. Sensitivity to PTC and PROP is correlated with the number of fungiform papillae on the anterior tongue and can predict preferences for sweet and fatty foods in humans. An association between sensitivity to PROP and alcohol dependence has also been suggested. PTC and PROP sensitivity are controlled by the PTC loci on human chromosome 5p15 7q31 that codes for a member of the T2R bitter receptor family.

►Tastant

## Taste – Conscious Perception of

### Definition

The process by which organisms acquire, select, organize and interpret taste sensations elicited by applying taste stimulus to taste receptor cells. Conscious perception of taste requires the participation of the taste cortex, but our reactivity (swallowing or spitting out) to tastants in the mouth does not.

►Taste

## Taste – Context Dependence

### Definition

Our perception of the flavor of food is a complex combination of taste, olfaction, tactile and thermal senses. So, the context, that is, the simultaneous presence of other types of sensations, in which a taste occurs can affect our perceptions and value judgments of that taste. For example, a fruity odor can enhance and lower the threshold for the perception of a sweet stimulus. Also, in solutions containingmultiple tastants, sensory thresholds for components of the mixture can be raised. Two additional variables also provide context for taste perception: physiological state, e.g. hunger, hormonal state, and experience, e.g. history of conditioned taste aversions.

►Taste

## Taste – Salt

### Definition

Salt taste is one of our basic taste modalities, also called taste qualities or basic tastes. It is thought to be part of a system that maintains adequate body mineral levels. Salt taste is primarily the taste of sodium chloride, which elicits the "purest" salt taste. However, other compounds, including various potassium, calcium, and ammonium ions also elicit salt taste. Salt taste is linked to pleasantness and is thus associated with intake behavior. It is believed but not proven that salts stimulate a dedicated population of taste receptor cells on the tongue and other parts of the oral cavity. Evidence suggests that two signal transduction pathways mediate salt taste. One is specific for sodium, blocked by amiloride in rodents, and possibly involves the epithelial sodium channel ENaC. The other mediates the taste of sodium and other ions as well. It involves an ion channel that is sensitive to cetylpyridinium chloride. Ion fluxes through these membrane channels of specific taste receptor cells likely lead to receptor potentials, i.e., electrical excitation. The stimulus is eventually propagated to the afferent cranial nerves VII, IX, and X and conveyed to the cerebral cortex where neuronal activities reflect the cognitive perception of salty.

►Gustation
►Tastant
►Taste

## Taste – Sour

### Definition

Sour taste is one of our basic taste modalities, also called taste qualities or basic tastes. It appears to be

involved in water and electrolyte balance and in warning against spoiled food or unripe fruits. Sour taste is initiated by protons. Several transduction mechanisms have been described to underlie sour taste including activation of proton-gating of acid-sensing cation channels (ASICs) or of hyperpolarization and cyclic nucleotide-gated channels (HCN). Sour taste is transduced by a dedicated population of taste receptor cells on the tongue and other parts of the oral cavity. These cells express the polycystic kidney disease 2L1 (PKD2L1) gene that could be part of the sour "receptor." Cation fluxes through membrane channels of the specific taste receptor cells likely generate receptor potentials, i.e., electrical excitation. The stimulus is eventually propagated to the afferent cranial nerves VII, IX, and X and conveyed to the cerebral cortex where neuronal activities reflect the cognitive perception of sour.

►Acid-Sensing Ion Channels
►Gustation
►HCN Channels
►Tastant
►Taste

## Taste – Sweet

### Definition

Sweet taste is one of our basic taste modalities, also called taste qualities or basic tastes. It is thought to be a detector of calories, particularly in the form of carbohydrates. It detects mono and disaccharides, but also certain amino acids, sweet tasting proteins of tropical fruits, and artificial sweeteners. Sweet taste is linked to neural networks engaged in attraction, thereby promoting intake behavior. Sweet taste is defined by a specific population of taste receptor cells on the tongue and other parts of the oral cavity that are characterized by the expression of the sweet taste receptor molecule, which is a class C G protein-coupled receptor composed of the two subunits TAS1R2 and TAS1R3. The receptor heteromer is activated in vitro by numerous tested sweet tasting substances that bind to various binding pockets.

Evidence also suggests that homomers of TAS1R3 and TAS1R2 may function as sensors for some sweet tasting compounds. Contacts of sweet tasting molecules with the specific taste receptor cells trigger signal transduction reactions leading to receptor potentials, i.e., electrical excitation. The stimulus is eventually propagated to afferent cranial nerves VII, IX, and X and conveyed to the cerebral cortex where neuronal activities reflect the cognitive perception of sweet.

►Gustation
►Tastant
►Taste

## Taste – Umami

### Definition

Umami taste is considered to be one of our basic taste modalities, also called taste qualities or basic tastes. In humans it is the taste of glutamate, in rodents many amino acids contribute to this sensation. Umami taste is therefore considered to be a detector of calories, in the form of protein. A hallmark of umami taste is that 5′-ribonucleotides enhance the perception of glutamate. Umami taste is linked to neural networks engaged in attraction, thereby promoting intake behavior. It is defined by a specific population of taste receptor cells on the tongue and other parts of the oral cavity that are characterized by the expression of the umami taste receptor, a class C G protein-coupled receptor composed of the two subunits TAS1R1 and TAS1R3.

Activation of the TAS1R1–TAS1R3 heteromer through amino acids is enhanced by 5′-ribonucleotides reflecting the characteristic sensory property of umami taste. Evidence also suggests that metabotropic glutamate receptors or taste specific variants thereof contribute to umami taste. Contacts of umami tasting molecules with the aforementioned specific taste receptor cells trigger signal transduction reactions leading to receptor potentials, i.e., electrical excitation. The stimulus is eventually propagated to the afferent cranial nerves VII, IX, and X and conveyed to the cerebral cortex where neuronal activities reflect the cognitive perception of umami.

# Taste Bud

Makoto Sugita
Department of Oral Physiology, Graduate School of Biomedical Sciences, Hiroshima University, Hiroshima, Japan

## Synonyms

A cluster of gustatory chemosensory cells

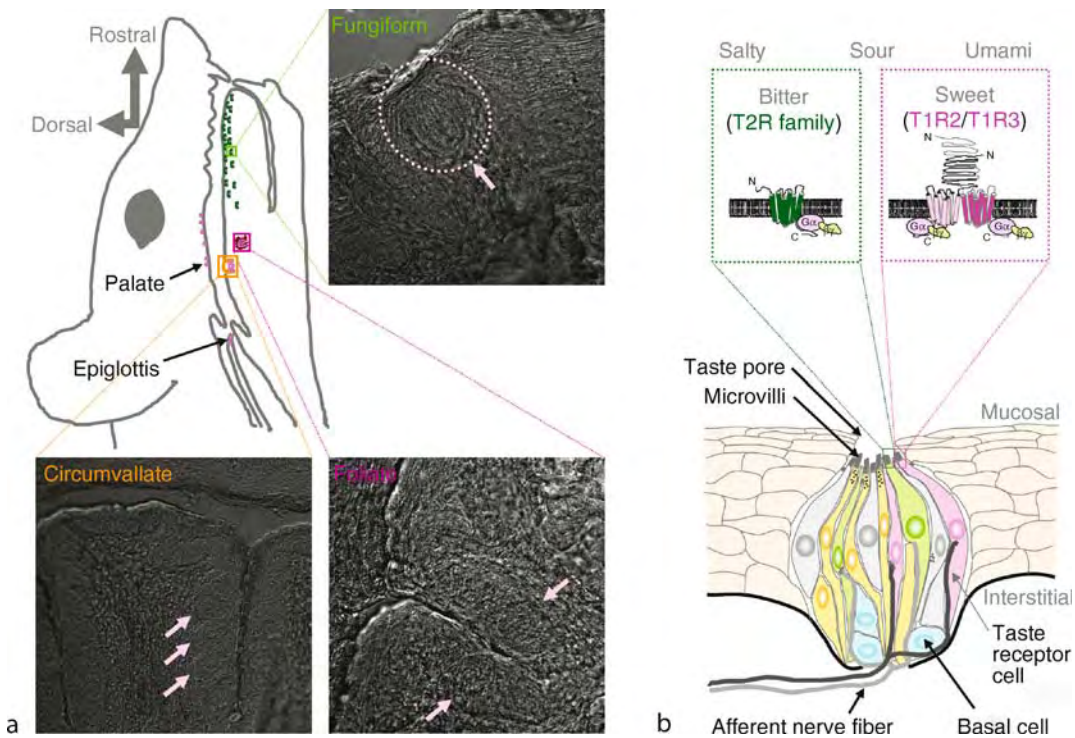
## Definition

Taste buds are onion-shaped aggregates of 50–150 cells embedded in oral and pharyngeal epithelia. They contain proliferative basal cells as well as elongated cells, which span the depth of the epithelium and are oriented perpendicularly to the basal lamina. Taste bud cells arise from local epithelial progenitors. However, they have characteristics of both epithelia and neurons. Taste bud cells are renewed because of a limited life-span, and constantly differentiate from progenitor cells throughout life, generating heterologous cell populations. Among those, a subset of the elongated cells that express taste receptors is responsible for detecting sweet, bitter, salty, sour, and umami stimuli in foods. Sensing of the chemical signals in the taste receptor cells leads to activation of specific populations of neurons in the brain, which enables us to evaluate nutritious diets and to prevent the ingestion of toxic substances.

## Characteristics

### Location of Taste Buds

Lingual taste buds reside within three types of papillae in mammals (Fig. 1). (i) Fungiform papillae containing one or a few taste buds are found in the anterior two-thirds of the tongue. Depending on the species, from approximately 100 to several hundred fungiform papillae form in a stereotypical array on the dorsal lingual surface [1]. (ii) Circumvallate papillae are present at the posterior dorsal border between the oral and pharyngeal tongue. Mouse possesses one circumvallate papilla, whereas human possesses 8–12



**Taste Bud. Figure 1** Locations and morphological characteristics of taste buds. (a) Schematic representation of the regions containing taste buds in the mouse oral cavity. Differential interference contrast images of the coronal sections of taste buds embedded in fungiform, foliate and circumvallate papillae are also shown. Arrow heads indicate locations of taste buds. (b) Schematic representation of a taste bud and associated structures. The taste receptor cells detect sweet, bitter, salty, sour and umami stimuli, and transmit taste information to afferent nerve fibers. The sensations of bitter and sweet taste are initiated by the interaction of sapid molecules with the T2Rs and the T1R2/T1R3 heteromers, respectively, expressed in the taste receptor cells. The bitter and sweet receptors are expressed in non-overlapping populations of taste receptor cells.

circumvallate papillae in a V-shaped formation [1]. (iii) Foliate papillae are found at the posterior lateral sides of the tongue. There is one foliate papilla composed of a series of clefts on each side of the tongue. In the circumvallate and foliate papillae, taste buds lie in the epithelial linings which grow below the surface of the tongue, facing a cleft [1]. Circumvallate and foliate papillae contain hundreds of taste buds each. In addition to residing in lingual papillae, taste buds are also located in the epithelium of the epiglottis, pharynx, and palate (Fig. 1a).

Taste buds in the fungiform papillae and in the palate are innervated by the ganglion neurons in branches of the facial nerve, the chorda tympani and greater superficial petrosal nerve, respectively. Taste buds in the foliate and circumvallate papillae located at the posterior tongue are innervated by the glossopharyngeal nerve. The superior laryngeal nerve, a branch of the vagus nerve, innervates the taste buds in the epiglottis. Each ganglion neuron contacts multiple taste receptor cells within a taste bud, and relays taste information to the neurons in the solitary tract nuclei of the medulla. From the solitary tract nuclei, taste information is transferred to the neurons in the pontine parabrachial nuclei, then to the thalamus, and then to the gustatory cortex.

## Development and Maintenance of Taste Buds

During mouse development, taste papillae appear first as the epithelial thickenings, described as placodes, at embryonic day (E) 12.5 [1,2]. Then, the placode undergoes series of invaginations and evaginations to form a papilla with a distinctive epithelium over a connective tissue core. Taste buds are first morphologically evident within the papillary epithelium at approximately E18. Nerves reach the basement membrane of developing taste papillae at E14, begin to penetrate into the papillary epithelium by E15, and densely innervate it by E16. Importantly, initiation of papillae morphogenesis does not require innervation. Furthermore, the rodent taste papillae structurally form well before taste bud cells fully differentiate within the papillae.

Wnt-β-catenin signaling is activated in developing fungiform placodes and taste bud cells [2]. Enhanced stimulation of Wnt-β-catenin signaling in mutant mice causes massive overproduction of enlarged fungiform papillae and taste buds. Conversely, ablation of Wnt-β-catenin signaling blocks initiation of fungiform papillae morphogenesis [2]. Thus, Wnt-β-catenin signaling confined to the epithelium plays a critical role in initiating fungiform papilla development while regulating expressions of its downstream targets such as Sox2 and Shh and BMP4, and leads to the production of taste buds [2,3]. During the development, taste bud progenitors express brain-derived neurotrophic factor (BDNF) before innervation, although it remains unclear whether BDNF expression is dependent on Wnt-β-catenin signaling and Sox2 at present. BDNF-deficient mice show severely malformed taste-bud bearing papillae and severe reduction of taste buds, a loss of proper innervation of remaining taste buds and a loss of taste discrimination [4]. Ectopic overexpression of BDNF led to the misdirection of gustatory axons into non-gustatory tissue, which resulted in sparsely innervated gustatory papillae with few taste buds [5], although the intrinsic BDNF levels in the gustatory epithelium might not be reduced. On the other hand, afferent nerve transection causes either loss of taste buds or appearance of atrophic taste buds. When denervated taste buds are reinnervated, taste buds are reconstituted. It is controversial whether nerves are necessary to initiate taste bud morphogenesis. However, molecular signals exchanged between afferent nerves and taste buds are important for certain steps of development and maintenance of taste buds.

## Morphologic Characteristics and Molecular Markers of Taste Bud Cells

Based on the ultrastructural features, mammalian taste bud cells have been classified into type I (dark) cells, type II (light) cells, type III (intermediate) cells, and basal cells [6]. Basal cells are likely to be progenitor cells. The type I cell possesses an electron-dense cytoplasm, and is slender with several long microvilli of various lengths extending into the oral cavity. The nucleus of the cell is invaginated. Many electron-dense granules are apically localized in the cell. The type II cell is a more electron-lucent, spindle-shaped cell with a large round nucleus, short thick microvilli, and electron-lucent, swollen cisternae of smooth endoplasmic reticulum. The type III cell is a slender, spindle-shaped cell with intermediate electron-density in the cytoplasm between the type I and type II cells, and with a solitary thick microvillus. The type III cell possesses perinuclear dense-core vesicles, and is characterized by conventional synaptic contacts with nerve processes [6].

The presence of a particular molecular marker is likely to correlate with cell type. Type I cells contain blood group H antigen. Type III cells express neural cell adhesion molecule (NCAM), and synaptic proteins such as SNAP25, syntaxin-1, and synaptobrevin-2 [6]. Subpopulations of type III cells contain either protein gene product 9.5 (PGP 9.5) or serotonin (5-HT). Type II cells express signaling molecules of taste transduction, including G protein-coupled taste receptors, α-gustducin, phospholipase C β2 (PLCβ2), and type III inositol 1,4,5-trisphosphate ($IP_3$) receptor ($IP_3R3$) [6]. Syntaxin-1 and synaptobrevin-2 are present in type II cells. PGP 9.5 is expressed in a subset of type II cells that do not express α-gustducin. NCAM and 5-HT are also reported to be present in a small subset of PLCβ2- and $IP_3R3$-expressing cells. Thus, some proteins are expressed in more than one

morphologic taste cell type, especially in both type II and type III cells. It remains unclear whether different types of taste bud cells represent independent cell lineages, whether one cell type (for example, type III) grades into another (for example, type II) as the taste cell matures or differentiates, or whether asymmetric cell division of basal cells underlies production of the lineage-restricted basal cells or the different types of taste bud cells and receptor cells in a nerve-dependent or -independent manner. Nevertheless, their ultrastructural characteristics in combination with molecular expression patterns suggest that the type II and type III cells differentiate to function as the specialized cells that transduce taste stimuli into neural signals, whereas type I cells play a supportive or glia-like role. Of note, BDNF expression persists in adult taste system. BDNF is localized to the synaptically connected type III cells and type II cells, but is absent from basal cells and type I cells, implying its potential role in maintaining synaptic function [7].

## Functions of Taste Receptor Cells in Taste Buds

The cells expressing taste receptors (taste receptor cells) are responsible for detecting sweet, bitter, salty, sour, and umami taste stimuli (Fig. 1b). The sensations of bitter, sweet and umami tastes are initiated by the interaction of sapid molecules with G protein coupled receptors (GPCRs) in the apical membranes of taste receptor cells. Two families of mammalian taste receptors, T1Rs and T2Rs, have been implicated in sweet, umami and bitter detection [8]. There are 36 intact T2R genes in mice and 25 genes in humans. Some of the T2Rs are reported to be functional bitter receptors both in vivo and in vitro. Most of the members of the T2R receptor family are co-expressed in the same subset of taste cells [8], suggesting that this cell type recognizes a diverse array of structurally distinct bitter compounds without a fine discriminatory power among different bitter compounds. The T1R receptor family (T1R1, T1R2 and T1R3) generates at least two heteromeric receptors. The T1R1/T1R3 and T1R2/T1R3 heteromers function as umami and sweet receptors, respectively [8]. Thus, T1R3 are commonly used as a subunit of both sweet and umami receptors. The human T1R1/T1R3 heteromer selectively senses L-glutamate over other amino acids, whereas the mouse T1R1/T1R3 heteromer appears to act as a sensor for many L-amino acids with similar affinity because of the differences between human and rodent T1R1 subunits. The single T1R2/T1R3 receptor can recognize a large collection of diverse chemical structures of sweeteners such as natural sugars, some amino acids, proteins and synthetic sweeteners, by using different domains of its receptor complex for recognition.

Both T1Rs and T2Rs are partially coexpressed with the α-subunit of the G protein gustducin, a taste-specific signaling molecule. Mice deficient in α-gustducin show markedly reduced behavioral and nerve responses to bitter, sweet and umami compounds [9]. Thus, the gustducin heterotrimer plays substantial roles in bitter, sweet and umami transduction in vivo. Binding of those taste compounds to the G protein-coupled receptors leads to dissociation of the heterotrimeric G protein gustducin. Then, the released Gβγ subunits (Gβ3 and Gγ13) activate PLCβ2, which hydrolyzes phosphatidylinositol-4,5-bisphosphate into diacylglycerol and $IP_3$. Subsequently, $IP_3$ activates $IP_3R3$, which elicits the release of $Ca^{2+}$ from intracellular stores to the cytoplasm. Rapid increases in $[Ca^{2+}]_i$ open basolaterally located TRPM5 channels. Elevation of $[Ca^{2+}]_i$ and TRPM5-mediated membrane depolarization might be required for the neurotransmitter release onto afferent nerve fibers, which relay and process taste information. Importantly, T2Rs and T1Rs are not co-expressed in the same taste receptor cells, although T2R-expressing cells and T1R-expressing cells are localized in the same taste buds [8]. Furthermore, there is no coexpression of T1R1 and T1R2, suggesting that sweet, umami and bitter taste modalities are encoded separately by the activation of distinct cell types.

Salty and sour taste transduction appears to be mediated by ion channels belonging to the transient receptor potential (TRP) family, and the epithelial sodium channel (ENaC)/degenerin (DEG) family. NaCl salt taste is initiated by current flowing into the taste receptor cells through amiloride-sensitive epithelial sodium channels (ENaC) located in the apical membrane. $Na^+$ influx through the cation channels elicits membrane depolarization, leading to the production of action potentials that result in the neurotransmitter release onto an afferent nerve fiber. Therefore, amiloride reduces, but not completely eliminates, the responses to NaCl in taste receptor cells and chorda tympani nerves. The member(s) of the TRP family, such as TRPV1, might be also involved in amiloride-insensitive salt taste transduction. Protons are the primary sour taste stimuli since acid-elicited sour taste is proportional to proton concentration. The proton-gated channels, the proton-conducting channels as well as pH-dependent ion exchangers in taste receptor cells are believed to be involved in sour taste transduction. Generally, upon acid stimulation, the proton-gated channel activities elicit membrane depolarization directly via the current flow through the channel, leading to the production of action potentials and the neurotransmitter release. Genetic ablation of the cells expressing PKD2L1, a member of the TRP family, shows complete unresponsiveness to sour tasting stimuli in peripheral nerve recordings [8]. Therefore, the PKD2L1-expressing cells are likely to be acid-sensing cells. PKD2L1 may substantially function as a component of the sour taste receptor, while interacting with the other member of the TRP family, such as

PKD1L3, and forming a pH-regulated cation channel [8]. Alternatively, the other molecules, selectively expressed in a subset of PKD2L1-expressing cells, may play a role in triggering sour taste transduction. The ▶acid-sensing ion channels (ASICs) of the ENaC/DEG family are also proposed to be involved in sour taste transduction. Importantly, PKD2L1 was found to be expressed in a subset of taste receptor cells distinct from those responsible for bitter, sweet, and umami taste transduction [8].

It is reported that transmitters such as serotonin, glutamate, acetylcholine, norepinephrine, and several neuropeptides are released from taste bud cells. However, the taste receptor cells appear to transmit information to the primary afferent neurons by releasing ATP, which activates the ionotropic purinergic receptors $P2X_2/P2X_3$ on the postsynaptic membrane of the neurons [10]. $P2X_2/P2X_3$ double knock-out mice lost all of the sweet, bitter, salty, sour, and umami responses in the chorda tympani and glossopharyngeal nerve recordings [10], implying that the taste receptor cells on the tongue and their associated afferent neurons may commonly employ ATP as a neurotransmitter and $P2X_2/P2X_3$ as receptors, respectively.

### Taste Coding in Taste Buds

Identification of taste receptors and their downstream signaling molecules revealed ▶taste coding in the periphery. Mice lacking either PLCβ2 or TRPM5 diminish behavioral and nerve responses to sweet, umami and bitter taste stimuli [8]. Thus, the T1R and T2R families converge on a common signaling pathway in the taste receptor cells. Nevertheless, separate populations of taste receptor cells appear to be uniquely tuned to sweet, umami, and bitter taste, since mice engineered to rescue PLCβ2 exclusively in T2R-expressing cells respond normally to multiple bitter compounds, but not to sweet or umami taste [8]. In addition, genetic ablation of either T1R2- or PKD2L1-expressing cells showed specific unresponsiveness to only a single taste quality (sweet and sour, respectively) in the tastant-induced activity of nerves innervating the tongue [8]. Thus, distinct populations of taste receptor cells are uniquely tuned to detect sweet, umami, bitter and sour taste. Furthermore, transgenic mice expressing a RASSL k-opioid receptor in either T1R2-expressing (sweet) or T2R-expressing (bitter) cells display attraction and aversion, respectively, to the synthetic opioid agonist spiradoline, which is a normally tasteless compound [8]. Therefore, activation of a specific type of taste receptor cells and its line of neurons is dedicated to elicit a specific behavior. To constantly maintain the contrastive behavioral responses as taste cells turn over, a newly arising taste cell expressing either T1R2 or T2R might selectively form a synapse with an appropriate afferent nerve carrying specific taste information. Alternatively, the afferent nerve fibers which transmit specific taste information might contact common progenitor cells, induce the expression of the specific receptor, and thus cause the cells to become specific taste receptor cells. Clarification of the molecular and cellular mechanisms underlying the establishment of connectivity between taste receptor cells and their associated afferent neurons is now of critical relevance to understand taste coding in the central nervous system, and to decipher the neuronal activities responsible for eliciting contrastive behavioral responses.

# Taste Coding

## Definition

Insight into how taste information is processed in taste receptor cells and afferent neurons. The two models, "labeled-line" and "across-fiber pattern," have been

proposed. In the labeled-line model, information of each taste quality (salty, sour, sweet, umami or bitter) is processed through activation of non-overlapping populations of taste receptor cells and their associated afferent neurons. In the across-fiber pattern model, the afferent neurons are broadly tuned, and the specification of any one taste quality is embedded in a unique combinatorial pattern of activity distributed across populations of neurons.

## Taste Hedonic Value

### Definition

It refers to palatability. Recordings of orofacial and somatic behavioral patterns are used to measure palatability. As a consequence of conditioned taste aversions, the hedonic value of the conditioned taste becomes aversive, thus, being disliked.

►Conditioned Taste Aversion

## Taste Learning

►Conditioned Taste Aversion

## Taste Neophobia

### Definition

Unconditioned response to novel tastes. It consists in a reduced intake compared with later presentations provided that it was not followed by aversive visceral consequences.

►Conditioned Taste Aversion

## Taste Reactivity Test

### Definition

It refers to a method developed by H.G. Grill and R. Norgren in 1978 for assessing the orofacial and somatic responses induced by a taste stimulus in the rat using videotape recordings. It is applied to the study of the palatability shifts induced by learning. Among other responses, appetitive patterns include paw licking and mouthing while aversive patterns include gaping, chin rubbing, and head shaking.

►Conditioned Taste Aversion

## Taste Stimulus

►Tastant

## Taste-potentiated Odor Aversion

### Definition

The process by which the combined presentation of both an odor and a taste paired with visceral malaise leads to a strong aversion to the odor. Taste-potentiated odor aversion refers to the increase in the strength of odor aversion after odor and taste conditioning, similar to taste aversions induced in one-trial, long-delay conditions.

## TATA-Box

### Definition

The DNA sequence element recognized by the TATA-box binding factor, a critical component of TFIID. The TATA sequence is usually located 35 bp upstream of the TSS and its presence in a promoter helps to position the pre-initiation complex (PIC) so that transcription fires from one major site. Not all genes, however, contain TATA-boxes.

►Promoter

## Tau Mutation

### Definition

A missense mutation of the casein kinase 1ε gene that causes alteration in enzymatic activity of this serine-threonine kinase. Phosphorylation of the PER proteins is altered in mutant animals, leading to early degradation of PER and shortening of circadian periodicity. Originally discovered in a group of hamsters that display a shortened behavioral circadian rhythm, the Tau mutation was the first altered circadian phenotype observed in mammals.

►Circadian Rhythm
►Clock

## Taxis

### Definition

Movement by a freely motile simple organism towards or away from a stimulus (such as a light, temperature or chemical gradient).

## Taxon Navigation

### Definition

Behavior relying on an egocentric reference frame and directed by an association between a cue and a goal to get a goal location. Locomotion based on routes; that is locomotion rules based on making a memorized set of paths and turns at particular distances and landmarks. Taxon locomotion is inflexible in that the subject can only traverse previously learned routes.

►Spatial Learning/Memory
►Spatial Memory

## Tay-Sachs Disease

### Definition

Fatal genetic lysosomal storage disease due to a defect of β-hexosaminidase, which leads to accumulation of the ganglioside $G_{M2}$ in lysosomes. Infants seem to develop normally initially, but after a few months start deteriorating in terms of their physical (developing muscle atrophy and paralysis) and mental abilities (developing blindness, deafness, ►dysphagia, ►dementia, ►seizures and increased startle response to noises). A rarer form involves young adults with unsteady gait, progressive deterioration and cherry-red spots in their eyes.

## Tectobulbar and Tectospinal Tract

### Synonyms

Tractus tectobulbaris + tectospinalis

### Definition

Deep layers of the superior colliculus project to nuclei of the brainstem (often called bulb). The greatest bundle descends close to the midline on the contralateral side, while one much smaller bundle continues on its ipsilateral course. The tectospinal tract runs parallel over a long distance.

►Mesencephalon

## Tectobulbospinal Tract

### Definition

One of the names of the fiber tract which originates in the superior colliculus (anterior part of the "tectum mesencephali"), undergoes decussation in the midbrain, descends near the midline through the pons and medulla and terminates in the upper segments of the spinal cord. Its pontomedullary portion, after the decussation in the midbrain and till the entry in the spinal cord, is called "predorsal bundle."

►SC-Tectoreticulospinal neurons (TRSNs)
►Superior Colliculus
►Tectum

## Tecto-reticulo-spinal Neurons

### Definition

Superior colliculus (SC) efferent neurons whose response properties for orienting movement (synergic eye and head movement) and projections have been extensively documented in the cat. Their axons have been shown to decussate in the midbrain and descend through the contralateral predorsal bundle to project to various preoculomoter structures in the brain stem, including the paramedian pontine reticular formation, where burst neurons are located.

►Burster-Driving Neurons
►Paramedian Pontine Reticular Formation (PPRF)
►Superior Colliculus

## Tectospinal Tract

### Synonyms

►Tractus tectospinalis

### Definition

A large projection from the substantia nigra terminates in a very regular pattern of bands in the superior colliculus, middle gray layer. This layer contains the cells giving rise to the predorsal fasciculus, a major descending bundle, which dispatches a large number of fibers to premotor and motor centers in the brainstem and spinal cord. Runs in the medial longitudinal fasciculus.

►Mesencephalon

## Tectum

### Definition

The dorsal part of the midbrain derived from the alar plate in development.

## Tectum of Mesencephalon

### Synonyms

Tectum mesencephali; Tectum of midbrain

►Quadrigeminal Plate
►Mesencephalon

## Tegmental Area (Forel's Field)

### Synonyms

Nuclei campi perizonalis (Forel-Feld); Nuclei of perizonal fields (Forel's field)

### Definition

Between the thalamus and zona incerta is situated Forel's tegmental field. It belongs to the subthalamus and consists of myelinated axons which belong to the thalamic fasciculus. This is composed of the lenticular fasciculus and ansa lenticularis and is the most important connection between the globus pallidus and ventral lateral thalamic nucleus.

►Diencephalon

## Tegmentum

►Tegmental Area (Forel's Field)

## Tegmentum (Midbrain, Pontobulbar)

### Definition

A term used in macroscopic anatomy of the brainstem. In the midbrain it includes all structures between the cerebral peduncles and substantia nigra ventrally and the borders of the superior and inferior colliculi dorsally. In the pons it comprises all structures overlying the basilar pontine nuclei and, in the medulla, those overlying the medial lemniscus and the pyramidal tract.

►Inferior Colliculus
►Pyramidal Tract
►Superior Colliculus

## Tegmentum of Mesencephalon

### Synonyms

Tegmentum mesencephali; Tegmentum of midbrain

### Definition

Quadrigeminal plate. This deep layer of the Mesencephalon stretches between the tectum of Myelencephalon and the cerebral peduncles, arising to the surface only deep in the interpeduncular fossa.

A number of cranial nerve nuclei are encountered here as well as the reticular formation of Myelencephalon with its nuclei, the substantia nigra and parts of the central gray matter of ►Mesencephalon.

►Mesencephalon

## Tegmentum of Pons

### Synonyms

►Tegmentum pontis

### Definition

The tegmentum of pons comprises the dorsal part of the pons and contains the nuclei of the cranial nerves: trigeminal nerve (V), abducens nerve (VI), facial nerve (VII) and vestibulocochlear nerve (VIII).

►Pons

## Telencephalic

### Definition

Refers to the telencephalon, which is the rostral (front) part of the forebrain and consists of the pallium and subpallium.

►Evolution of the Wulst

## Telencephalon

### Definition

In most vertebrates, bilateral and dorsal evaginations of the rostral forebrain. In ray-finned fishes, the telencephalon is everted. In all vertebrates, it shows two major divisions: pallium and subpallium. The subpallium includes at least part of the preoptic region, which is neither evaginated nor everted.

At a deep level, it is composed of the commissures, the limbic system and the basal ganglia, on the surface of both hemispheres it is composed of the greatly folded cortex (cerebral cortex). All "higher" brain functions are found here, e.g. voluntary motor control, motor and sensory speech, cognition, visual and auditory systems, surface and proprioceptive sensibility. Also memory as well as affective and emotional mechanisms.

## Teleost Fish

### Definition

The taxonomic class of teleost ("bony") fish is the largest and most successful group of fishes, representing approximately 95% of all living fish species, and making up approximately half of all living vertebrates.

## Temperature Regulation

### Definition

Temperature regulation refers to the maintenance of the temperature or temperatures of a body within a restricted range under conditions involving variable internal and/or external heat loads. The regulated body temperature, however, is not rigidly fixed, and may change under certain conditions, such as time (circadian variation) or fever. Temperature regulation is established by behavioral means in poikilothermic animals, and additionally by autonomic means in homeothermic animals including humans. The temperature of only the central part of the body (core) is well maintained, while the temperature of outer layer of the body (shell) fluctuates to a greater degree. The basic mechanism of regulation involves a negative feedback system. Brain areas important for temperature regulation are distributed throughout the neural axis; the most important reside in the preoptic area of the hypothalamus. About one fifth of the neurons in this region change their activities with changes in local brain temperature, and are called thermosensitive neurons. The majority of these neurons increase their activity with increases in local temperature. Certain types of nonspecific cation channels are responsible for the thermosensitivity. The spinal cord is another important thermosensitive site. Additionally, warm and cold receptors in the skin detect external temperatures and provide signals for the feed forward control that allows corrective responses to be initiated before a deviation in core temperature occurs. The preoptic area integrates brain and skin temperature signals, and sends efferent signals to the thermoregulatory effector organs. The sympathetic nerves innervate most effectors including skin blood vessels, sweat glands, and brown adipose tissue.

►Hypothalamus

## Template

### Definition

Manifestation (trace) of memory in the brain that can be use to compare and adapt incoming information.

## Template in Birdsong

## Definition

Temporal coding in the olfactory system refers to the fact that some temporal components of the neuronal activity are used as cues for representation of odor quality and/or intensity.

Animals detect and discriminate a large variety of odor molecules in their environment. These molecules are recognized by odorant receptors (nearly 1,000 types of odorant receptors) located on sensory neurons in the olfactory epithelium. Sensory neurons that express a given odorant receptor are widely distributed within a specific zone of the olfactory epithelium. Each odorant can bind to multiple, but specific, odorant receptors so that the quality of an odorant is determined by the combination of a number of odorant receptors, each recognizing a specific molecular feature of the odorant molecule. Moreover, within the olfactory epithelium, odorant molecules migrate differentially according to their relative sorption properties and this migration can be enhanced or slowed down by inhalation rate or duration. Thus, the physico-chemical properties of odorant molecules determine a spatio-temporal representation of odors at the peripheral level. This representation is transferred to the glomeruli of the olfactory bulb (OB) by the axons of sensory neurons.

Anatomical, genetic and functional mapping studies indicate that each odorant is represented at the bulbar level by a spatial map of activated glomeruli. This glomerular organization is highly conserved across species, indicating that such spatial representation is crucial for information coding. However, while this spatial information is probably sufficient when an animal has to discriminate very different odors, it will need a more precise representation for discrimination between very similar odors. Similarly, separation of odorants in a mixture needs more precision than a purely spatial representation. This precision might be provided by a mechanism that exploits the temporal aspects of neuronal activity. The temporal representation of a stimulus in neuronal structures has been evaluated through the observation of electrophysiological signals, mainly: (i) action potentials of individual cells and (ii) local field potentials (LFPs) of the network, representing the summated activity of a large neuronal population and their interactions.

## Characteristics

What is "time" for olfactory coding? For about two decades, the theory of coding in the olfactory system has evolved according to two main ideas: (i) Information about an odor is carried by patterns of activity across a large population of neurons in the olfactory system, (ii) the absolute time of spikes is not the relevant information in ►odor coding; rather, the time has to be considered as relative to a particular clock or time basis. Olfactory information may be represented at various timescales: a slow timescale, depending on odor sampling processes (>100ms), and a faster one imposed by the network oscillatory activity (on the order of 10ms). Whatever the time basis, the coding principle consists in the transfer of reliable information including both odor intensity and odor quality.

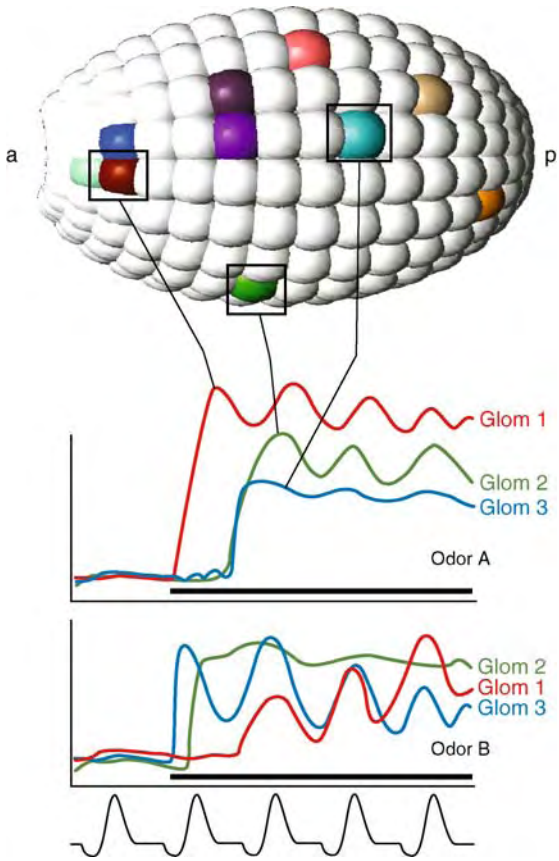
### A Slow Time Scale Related to Odor Sampling

Because breathing results in periodic sampling of the olfactory environment in mammals, the respiratory cycle represents a naturally fitted temporal frame. The respiratory frequency, often named theta frequency, may vary from 1–2 Hz in anaesthetized animal to 8–12 Hz in the sniffing bouts of behaving rats. At the moment, there is no direct evidence that respiratory dynamics has a significant functional role in temporal coding; however, it is highly suggested by the fact that temporal coupling between olfactory and respiratory signals depends on chemical features of the odorants. Such coupling appears at multiple levels: receptor neuron input to the OB, OB network activity, OB output neuron activity and cortical cell activity.

#### *At the Peripheral Level*

Temporal dynamics of receptor neuron input to the OB can be visualized by calcium imaging methods [1]. Such an activity is oscillatory at the glomerular level and locked to the respiratory cycle. These odor-evoked ►glomerular oscillations differ in amplitude, latency and rise time in an odorant-specific manner (see Fig. 1).

Moreover, the odor-evoked response of each glomerulus is differentially modulated by sniffing parameters such as frequency. When odor concentration increases, response latencies are reduced, response amplitudes are increased, new glomeruli are recruited, but the temporal sequence of glomerular activation is maintained. Thus, each odor is represented by a specific glomerular activation sequence, both within a sniff and across consecutive sniffs, which contains a concentration-invariant information. The temporal patterning of glomerular activity is then partly transmitted to relay neurons, the mitral and tufted cells.



**Temporal Coding in Olfactory System. Figure 1**
Temporal patterns of glomerular activation. *Top*: schematic representation of the glomerular layer of the olfactory bulb *a: anterior, p: posterior. Middle*: Representation of glomerular response intensity for three glomeruli: y-axes indicate the level of activation of the glomeruli (in arbitrary unit) in response to two odors A and B (horizontal bars indicate odor stimulation). *Bottom*: respiratory monitoring, negative deflection: inspiration; positive deflection: expiration. The amplitude, latency and rise time of activation vary across glomeruli and across odors. The fluctuation in the level of activation of the glomeruli is closely related to the respiratory phase. The temporal sequence of activated glomeruli differs between odors.

### At the Bulbar Level

Traditionally, the temporal aspects of coding have been mainly investigated by extracellular unitary recording methods. Most works agree with the observation that periodic sampling of odors influences bulbar activity spiking discharges both in the OB and the piriform cortex. Particularly, mitral cells, OB secondary neurons, show a definite temporal pattern of firing with respect to particular phases of the respiratory cycle [2] (see Fig. 2).

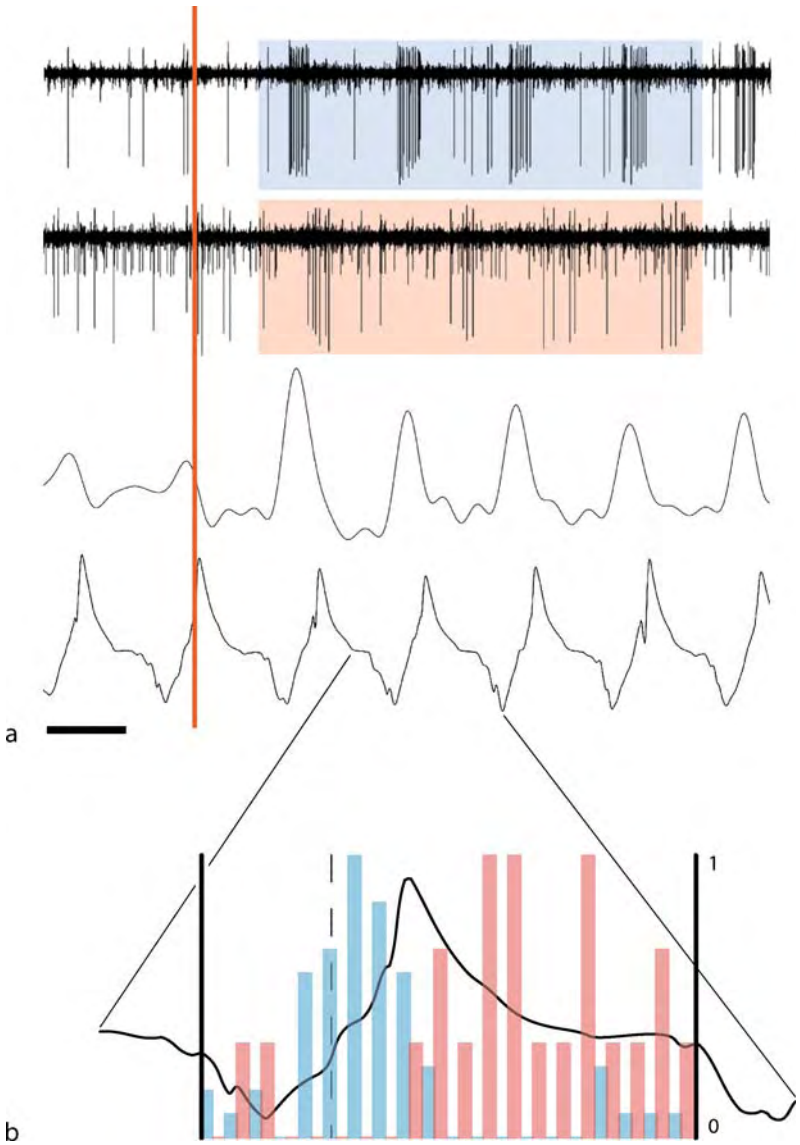
Responses are not static but evolve over the time of a respiratory cycle. An important phase in the respiratory cycle is the transition epoch between inhalation and exhalation: around this point, spike discharges present the maximum of activation or suppression. This point represents also the maximum of recruitment of sensory neurons. These respiratory related oscillations act by enhancing the temporal precision of spike discharge [3]. Odor representation is relevant when the activity is considered over a population of mitral cells. Indeed, no individual unit is able to reliably discriminate between odorant stimuli. On the contrary, a distinct representation of odorants, even as similar as enantiomers, is possible when considering responses from a population of mitral cells integrated over single respiratory cycle.

Respiratory-phase information seems to be concentration-invariant since the profile of mitral cell responses relative to the respiratory phase is relatively unaffected by changes in odor concentration. Concentration coding rather relies on the latency and number of spikes in a burst relative to the respiratory cycle: mitral cells respond to stronger odorant stimulation with more spikes per burst and a shorter latency to the time of the first spike.

Glomerular and mitral dynamics probably contribute to the representation of odorant information. Firstly, the cortex would recognize the temporal sequence of glomerular activity patterns and/or the temporal characteristics of each glomerulus response within the sequence. This sequence is determined by the chemical nature of odor, the sniffing behavior and the sampling-related mechanisms. Then, within this sequence, odor representation would be refined by the dynamic map of mitral cells respiratory-phased activities which is more related to the intrinsic network connectivity.

Behaviorally, ▶odor discrimination can be achieved in a single sniff both in animal (rodent, rabbit) and human, implying that odor can be represented within a single respiratory cycle. In rodents, there is a speed-accuracy trade-off in olfactory discrimination, discrimination being less accurate or longer when odors are very similar. In any case, each sniff can be considered as a complete snapshot of the olfactory environment [4]. Perception can be modified by changes in sniffing frequency. For example, different bulbar maps depending on sniffing frequency can represent the same stimulus. Particularly, rapid sniffing allows the animal to improve detection of a novel odor in the odor landscape [5]. Thus, by regulating its sniffing rate and depth, the behaving animal can influence the representation of odor stimulus and then its perception. This led some authors to the conclusion that the sniff itself is part of the olfactory percept [6].

In non mammalian animals, a slow dynamics exists which also depends on odor sampling process and which could reproduce the slow breathing rhythm: flicking in crustaceans, antenna movements in insects or coughing in fish, all of these sampling mechanisms represent an



**Temporal Coding in Olfactory System. Figure 2** Respiration-related activity of mitral cells.(a) *Top traces*: unitary extracellular activity from two simultaneously recorded mitral cells (raw signal band-pass filtered: 300–3000 Hz). *Lower trace*: bulbar LFP (raw signal band-pass filtered: 0.5–5 Hz). *Bottom trace*: Respiratory monitoring (negative/positive deflection: inspiration/expiration). Time bar: 500 ms. Vertical red bar: odor stimulation onset. Low frequencies in the LFP signal follow the respiratory rhythm with peak activity occurring at the inspiration/expiration transition point. Both mitral cells emit odor evoked spike bursts at different epochs of the respiratory cycle.(b) Respiration-cycle triggered histogram showing the average spike distribution of both cellular activities relative to the respiratory cycle. Vertical axis: normalized firing rate; a value of 1 corresponds to the maximum rate. Blue/red bars indicate the average firing rate of cells 1 and 2 over the four respiratory cycles included in blue/red boxes on top traces.

analogous to sniffing behavior, both in function and frequency. The representation of odors evolves along the time: early representations are a coarse categorization of the odor while the late representations become sharp images of the odor, allowing for fine discrimination.

The slow timescale related to sampling process can thus be considered as a first temporal cue in odor coding.

## A Fast Time Scale Related to Network Dynamics

At the bulbar and cortical levels, additionally to this slow temporal reference, the network produces another signal that may be used as time basis: the fast network oscillations of the LFPs. The oscillatory nature of LFPs may be exploited by the system as a common clock, a temporal reference for different cells or diverse areas. Stimulus-evoked oscillatory synchronization of

neurons results in the forming of a neural assembly in which neurons are bound temporally: neurons from a same assembly fire synchronously and in relation with the LFP oscillation phase. In such a coding principle, the relation between LFP oscillations and unitary activities is the relevant parameter for odor encoding.

In locusts, an individual neuron of the antennal lobe (analogous to the mammalian OB) synchronizes with different neurons at different epochs of the oscillatory response. Each odor is thus represented by a specific sequence of activated neurons that synchronize at different cycles of an oscillatory population response [7]. In fishes, the strength of coupling between LFP oscillations and spikes of relay neurons determines the nature of the information conveyed: spikes tightly coupled with the oscillation convey information about odor category whereas the less synchronized spikes from the same population of neurons convey information about precise odor identity [8]. In mammals, such mechanisms have not been described. Even if mitral cell spikes preferentially occur during the troughs of gamma oscillations, no simple rule has been revealed indicating a relation between odorant quality and pattern of LFP/spikes coupling. Bulbar processing in mammals is probably more complex due to the higher complexity of the network and its entries, and to the existence of several oscillatory regimes. Indeed, oscillatory activity is related to respiratory cycle in freely-breathing animals (see Fig. 3).

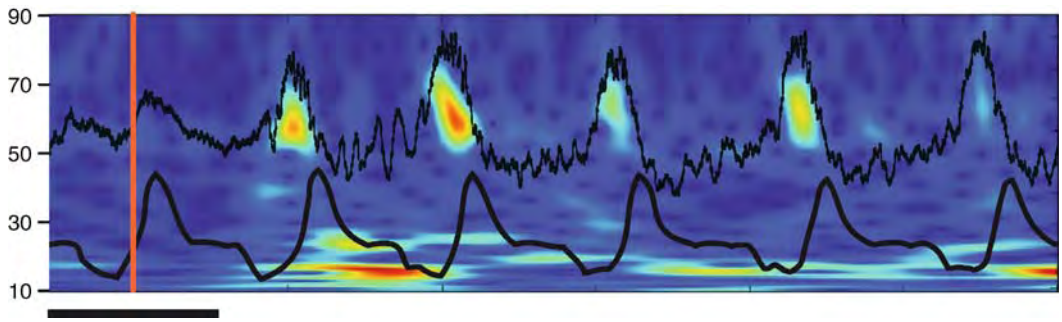
During odorant stimulation, LFP alternatively oscillates in the gamma range (40–80 Hz) around the inspiration-expiration transition epoch and in the beta range (15–35 Hz) during the other respiratory phases [2]. At least in anesthetized animals, the pattern of beta/gamma alternation depends on odorant quality and/or intensity. The hypothesis can be advanced that synchrony on gamma and/or beta oscillations would selectively tag the activity of neurons that code for one odor. The subpopulation of synchronized mitral cells could be recognized as an assembly by coincidence detection mechanisms in the olfactory cortex. During gamma regime, the oscillation synchronized neuronal map would represent the perceptual significance of odour (chemical features, concentration…); during beta regime, the oscillation synchronized neuronal map would represent the contextual significance of odor (ecological significance, significance in a learning task…).

Behaviorally, does the system use the oscillations it produces? The best argument today comes from a work in the honeybee, using a behavioral learning paradigm. It has been shown that altering synchronization of neurons impairs the discrimination of molecularly similar odorants. Thus, oscillatory synchronization of neuronal assemblies is essential for fine sensory discrimination [7].

In the mammal, the functional role of oscillatory synchronizations is still hypothetic. In the olfactory bulb and cortex of the behaving rat, odor presentation induces a power decrease in gamma oscillations and an increase in power of beta oscillations. In the trained rat, odorant stimulation evokes a spatial distribution of oscillatory activity which depends on the chemical nature of the stimulus, but also on its behavioral meaning [9]. Indeed, on the one hand, beta LFPs oscillations spatial map is characteristic of the odor; on the other hand, the emergence of a powerful odor-induced beta oscillatory activity is predictive of behavioral odor recognition.

## Conclusions

In summary, odor information is represented in the bulbo-cortical network by (i) the spatio-temporal sequence of



**Temporal Coding in Olfactory System. Figure 3** Odor-evoked LFP oscillatory activity in the olfactory bulb. *Foreground, top*: LFP recording, raw signal (0–5000 Hz); *bottom*: respiratory monitoring. *Background*: Time frequency representation of the raw LFP signal. x-axis = time, y-axis = frequency (in Hz). Time bar: 500 ms. Energy is color coded: the warmer the color the higher the amplitude of the oscillation in the signal. The oscillatory activity occurs in bursts, alternating between the beta range (10–35 Hz) and the gamma range (40–90 Hz) frequencies. The occurrence of oscillatory bursts is patterned by the respiratory cycle, with gamma bursts occurring around the inspiration/expiration transition and beta bursts occurring during the expiration phase.

activated glomeruli, (ii) the spatial combination of active neurons, (iii) the slow temporal sequence of activity patterns imposed by sampling-related process, (iv) the rapid synchronization of neuronal subpopulations relative to the network oscillatory regime. Therefore coding in the olfactory system is not a static phenomenon but a dynamical process with different temporal components, each of them probably readout by an adapted mechanism. This spatio-temporal representation is moreover dynamically reorganized by experience.

Sampling related process and odor characteristics impose the slow temporal dynamics, while intrinsic network dynamics established the fast LFP oscillatory regimes. Thus both dynamics are generated by system functioning. Dynamical representation of odors can nevertheless stand for a code provided that the neural network uses these temporal clues as a computational variable for coding. Firstly, the slow respiration-related rhythm could subserve a filtering function whereby neuronal responses could be selected on the basis of their respiratory phase. Such a functional phase-coding relative to theta cycle (i.e. related to respiratory frequency) has been evidenced in hippocampus place cells [10]. Secondly, the fast network oscillations probably intervene in a second step by refining the pattern of activated neurons through a synchronization binding process. This coding principle is better understood in other systems [10]. In such conditions, temporal dynamics, although epiphenomenal, are used by the system and thus may be considered as supporting temporal coding. The ultimate evidence would be provided in mammals if behavioral experiments could show changes in behavior in relation with a modification of the bulbocortical dynamics.

## Synonyms

Time coding, electrosensory

## Definition

Confronted with a variable environment, organisms are faced with the task of extracting information to guide their behavior. A massive amount of raw information is encoded by the peripheral nervous system, which is then winnowed down, processed, and analyzed by the central nervous system in order to obtain behaviorally-relevant information. Time is an inherent element of neural coding. The timing of neural activity reflects the timing of stimuli responsible for that activity, and thereby informs the organism of the stimulus time of occurrence. An organism's accuracy in determining when something occurred is thereby limited by the degree of temporal precision achieved by its nervous system.

The nervous system can also use time to encode information beyond the stimulus time of occurrence. For instance, barn owls compare the arrival times of sounds at the two ears to determine the horizontal location of sound sources in space, bats use the delay between their echolocation calls and returning echoes to determine the distance to a target, and many organisms use precise temporal patterns to convey information in their communication signals. Neuroethological studies of the underlying neural mechanisms for such behaviors have revealed a great deal about the specializations that nervous systems have evolved for preserving and representing temporal information. Time plays an especially critical role in electroreception, perhaps more so than for any other sensory system. Weakly electric fish have therefore served as important model systems for studying the neural basis of accurate and precise ►temporal coding.

## Characteristics

### Quantitative Description

Weakly electric fish possess an electromotor system that generates weak ►electric organ discharges, or ►EODs, from a specialized electric organ, as well as an electrosensory system for receiving and analyzing these EODs. Unlike acoustic signals that propagate as traveling pressure waves, electric signals exist as non-propagating electrostatic fields [1]. This is a behaviorally significant, distinguishing feature of electric signals. The temporal structure of acoustic signals is distorted by factors such as reflection, refraction, absorption, dispersion, and reverberation. This has the effect of smearing the fine temporal structure of the signal, limiting the amount of information that may be transmitted using temporal features. By contrast, electric fields are not subject to these sources of distortion. As a result, the fine temporal structure of electric signals is preserved, and information may be encoded at very minute time scales [1]. For this reason, weakly electric fish are exquisitely sensitive to temporal features of electric signals, with sensitivity in some species extending to the submicrosecond range [2].

### Higher Level Structures

Although the available evidence indicates that electrosensory systems have independently evolved multiple times, the electrosensory pathways of weakly electric fish share a common overall design [3]. Electric signals are first received by specialized electroreceptors located in the skin and distributed throughout the body [4]. Primary afferent fibers, located in the lateral line nerves, transmit electroreceptor input to the hindbrain, where they terminate in a derived brain region termed the ►electrosensory lateral line lobe (ELL). The first steps in electrosensory processing occur within the ELL, where primary afferent input, feedback loops from higher electrosensory regions, and descending input from other modalities and motor pathways converge [3]. ELL neurons project primarily to two distinct areas, the preeminential nucleus between the hindbrain and the midbrain, and the ►torus semicircularis in the midbrain [3]. The preeminential nucleus gives rise to a prominent ELL feedback pathway. In the torus semicircularis, additional electrosensory processing occurs. Studies on temporal coding and processing in electrosensory pathways have focused on the preservation of timing by primary afferents and ELL neurons, and on the extraction of information, by comparing differences in timing between different inputs within specialized circuits in the ELL and torus semicircularis.

### Lower Level Components

#### *Electroreceptor Organs*

In weakly electric fish, the encoding of sensory information within the EOD is achieved by tuberous ►electroreceptor organs, which give rise to two distinct types of afferents: amplitude coders and time coders [4]. Amplitude-coding afferents encode the amplitude of EODs in their firing rate, relative latency to the first action potential, or number of action potentials. Time-coding afferents are much more sensitive than amplitude-coding afferents. In response to each outside positive-going voltage step, they fire a single action potential at a short fixed latency, thereby providing a precise marker of the EOD time of occurrence.

#### *Specialized Features of Time-Coding Circuitry*

The electrosensory pathways of weakly electric fish are characterized by several unique anatomical specializations, which have been associated with neural circuits in which action potential timing precision is of the utmost importance [5]. The neurons are relatively large, which increases input resistance, thereby rendering the neurons less sensitive to synaptic noise. These large neurons are typically spherical and adendritic, which minimizes differences in the arrival times of multiple synaptic inputs, and shortens the distance between synapses and the action potential initiation zone of the axon, thereby minimizing the attenuation of synaptic current. The axons are correspondingly large and heavily myelinated, which increases conduction velocity, thereby minimizing the effect of jitter on the timing of spike arrival at the synaptic terminal. These axons give rise to large club endings that engulf a large portion of the postsynaptic soma. This large size ensures sufficient synaptic current for overcoming the high input resistance of the postsynaptic cell. In addition, these synapses are often mixed chemical/electrical, which helps ensure rapid activation of the postsynaptic cell.

### Higher Level Processes

Species Recognition in Pulse-Type Mormyrids

In mormyrid electric fish from Africa, electric communication appears to be mediated exclusively by time-coding electroreceptors called ►knollenorgans [6]. Knollenorgans are much more sensitive than other tuberous electroreceptor organs, making them well-suited to detecting the EODs of distant conspecifics. Perhaps the strongest evidence for their privileged role in communication comes from the fact that every time a fish generates its own EOD, knollenorgan input is blocked by inhibition at the projection site of primary afferents in the nucleus of the electrosensory lateral line lobe (nELL). This inhibitory input comes from an electric organ corollary discharge pathway, which originates in the command center for EOD production, and provides a precise reference of EOD timing. As a result, activity caused by the fish's own EOD production never reaches higher processing centers in the midbrain.

Mormyrids generate a pulse-type EOD, in which the duration of a single EOD pulse is much shorter than

the interval between pulses [7]. The EOD waveform is highly stereotyped and conveys several aspects of the sender's identity, such as its species, sex, dominance, and possibly even its individual identity. The total duration of the EOD is a particularly salient variable across species, ranging from as little as 100 μs to over 10 ms, and it may also exhibit sex- and status-related differences, with dominant males having a longer EOD than females [7]. Early playback studies in the field have demonstrated that this temporal variation plays an important role in electrocommunication [6]. Specifically, the relative timing of positive and negative voltage transients in the EOD plays a critical role in sender recognition.

Knollenorgans are able to faithfully encode the timing of these transients. The EOD of a neighboring fish will cause current to flow into one half of the body surface and out the other, meaning that knollenorgans on these two surfaces will be exposed to opposite stimulus polarities (Fig. 1a).

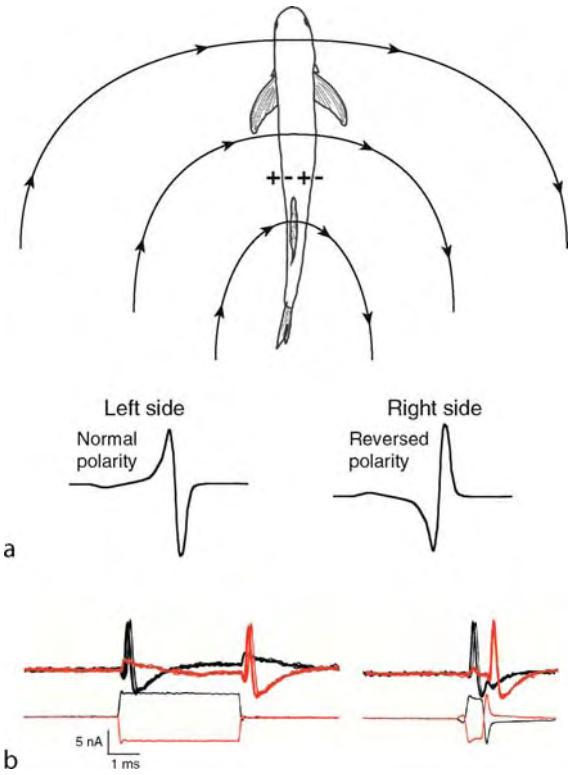
As knollenorgans only respond to positive-going voltage steps, those located where current is entering the skin respond to the EOD onset, while those located where current is exiting the skin respond to the EOD offset (Fig. 1b). Thus, by comparing spike times from opposite sides of the body, a mormyrid can determine the duration of the EOD waveform [6]. A similar mechanism for waveform discrimination in wave-type electric fish has also been proposed [8].

### *The Jamming Avoidance Response in Wave-Type Species*

In contrast to pulse-type electric fish, wave-type species generate an EOD in which the duration of each pulse is approximately equal to the intervals between pulses, resulting in a continuous, quasi-sinusoidal waveform. When an object enters the electric field, it causes modulations in the EOD that are used by the fish to extract information about the object, a process called ►active electrolocation (Fig. 2a).

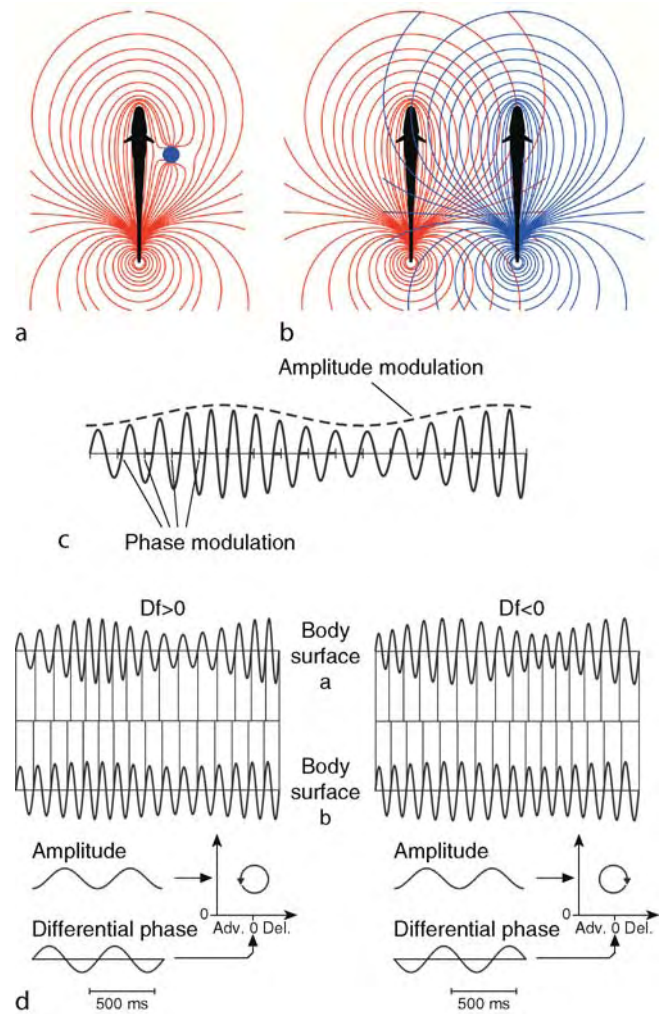
However, when fish encounter another individual with a similar EOD frequency, they experience mutual jamming of their electrolocation systems (Fig. 2b). To avoid this jamming, the fish shift their EOD frequencies away from each other, a behavior termed the ►jamming avoidance response (JAR) [2].

Properly executing the JAR requires that a fish determine whether it has a higher or lower EOD frequency than its neighbor. Extensive studies in a gymnotiform fish, *Eigenmannia*, and a mormyriform fish, *Gymnarchus*, have revealed a common algorithm for making this distinction [2]. The combination of two EODs leads to sinusoidal modulations in amplitude and phase (timing), at a frequency equal to the frequency difference between the two EODs (Fig. 2c). However, the temporal relation between amplitude and phase modulation is reversed, depending on whether the fish has a higher or lower EOD frequency than its neighbor (Fig. 2d). Thus, by comparing these two features, the fish can make the correct decision to either increase or decrease its EOD frequency [2]. However, detecting phase modulation requires that the fish have a timing reference. As the fish's own EOD and its neighbors EOD have different spatial distributions, different portions of the body surface are subject to different depths of modulation (Fig. 2d). Thus, the fish can extract phase information by comparing inputs from time-coding afferents on two different regions of the body surface, one that is strongly modulated with one that is weakly modulated (Fig. 3).



**Temporal Coding in Electroreception.**
**Figure 1** Temporal coding by knollenorgan electroreceptors in mormyrids. (a) Current flow through a fish's body resulting from EOD production by another fish. One side of the body is outside positive/inside negative, while the other half is outside negative/inside positive, meaning that the EODs detected across the two skin surfaces are of opposite polarities. (b) By stimulating a single knollenorgan with both normal and reversed polarity currents, one can emulate the response of knollenorgans located on opposite sides of the body. Action potentials occur on stimulus onset under normal polarity (black), while they occur on stimulus offset under reversed polarity (red). In a natural situation, the difference in action potential times would occur between different knollenorgans, which could then be compared to determine the stimulus duration.

T



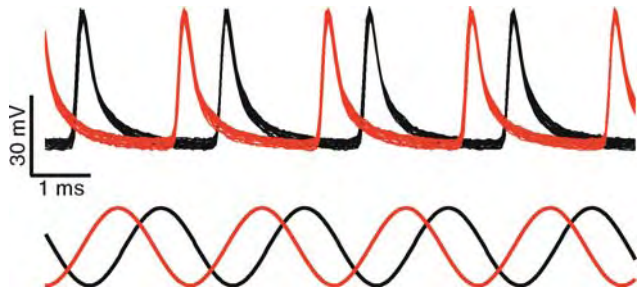
**Temporal Coding in Electroreception. Figure 2** (a) In active electrolocation, the electric field of a weakly electric fish (shown as isopotential lines in *red*) is distorted by the presence of an object (shown in *blue*). (b) The electric field (*red*) may also be distorted by the EOD of another individual (*blue*). (c) To avoid jamming of active electrolocation systems by another individual with a similar EOD frequency, the fish performs the JAR, which relies on comparing modulations in amplitude and phase that result from combining the two EODs. (d) Two different body surfaces are subjected to stronger (a) and weaker (b) interference from a neighbor's EOD, which results in different depths of modulation. The temporal relationship between amplitude and the phase of "body surface a" relative to "body surface b" is reversed when switching the sign of Df, which results in a different sense of rotation in a Lissajous graph.

A different algorithm for the JAR, one which relies on temporal asymmetries in the natural EOD waveform that are encoded exclusively by time-coding afferents, has also been proposed [8].

### *Mechanisms of Temporal ►Feature Extraction*

The previous sections dealt with the problem of neural encoding, or how precise temporal information can be represented by the timing of action potentials in sensory neurons. We now turn to the problem of how these action potential trains may be used to extract information about specific stimulus features; in this case, how precise spike times may be compared to extract information about timing differences. Although similar adaptations are in place for preserving timing information in the early stages of sensory processing, these temporal comparisons are achieved by quite different mechanisms in different species.

In mormyrids, the nELL neurons relay phase-locked knollenorgan input to the torus semicircularis, where their axons terminate in a region called the anterior exterolateral nucleus (ELa). Within ELa, there are two distinct types of neurons, large cells and small cells, both of which receive excitatory input from nELL axons (Fig. 4a). Upon entering ELa, the nELL axons immediately terminate onto one or two large cells, and



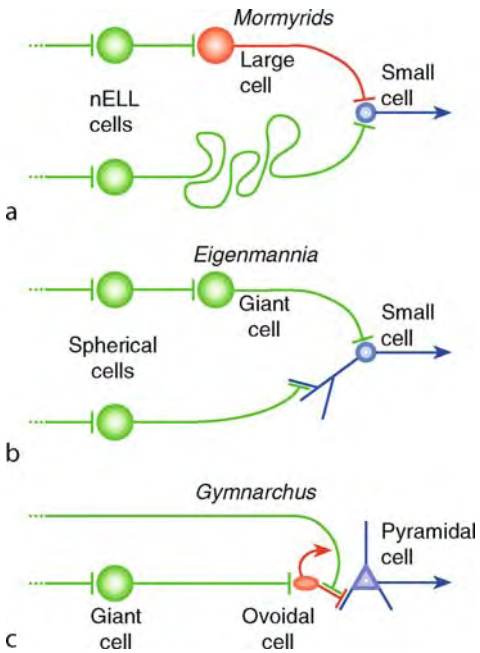
**Temporal Coding in Electroreception. Figure 3** Time-coding afferent activity in the wave-type fish *Gymnarchus*. The *top* traces show action potentials recorded from a single afferent (multiple sweeps are superimposed), while the *bottom* traces show the stimuli that elicited these responses. The *black* traces show the response to an unmodulated sine wave, while the *red* traces show the response to a sine wave advanced in time. The action potential times precisely follow the stimulus cycle. In a natural situation, the difference in action potential times would occur between afferents at different body surfaces that are exposed to different depths of phase modulation. The action potential times could then be compared to extract information about timing differences.

then wind their way throughout the nucleus, twisting and turning over distances of 3–4 mm before branching and terminating onto a large number of small cells [9]. The large cells project exclusively within ELa, terminating on small cells with large inhibitory synapses [9]. Thus, the small cells receive phase-locked input from two different sources: excitatory input from nELL axons responding to EOD onset from one part of the body, and inhibitory input from ELa large cells responding to EOD offset from another part of the body (Fig. 4a).

As the excitatory input is delayed by the time it takes an action potential to propagate down the long, winding path of the nELL axon, a given small cell will only respond to EODs longer than a certain duration, such that the delayed, excitatory response to EOD onset arrives before the inhibitory response to EOD offset [9].

In *Eigenmannia*, temporal comparisons are also made in the torus semicircularis. Large spherical cells within the ELL relay phase-locked afferent input to both giant cells and small cells within the torus in a somatotopic fashion (Fig. 4b). The giant cells then project widely across this somatotopic map onto several small cells, which therefore receive timing information from different portions of the body surface and are sensitive to temporal disparities between those surfaces [2,3]. The giant cells synapse directly onto the soma of the small cells, while the spherical cells synapse on the small cell dendrites, thereby delaying the arrival of the signal at the soma due to the passive propagation of synaptic current along the dendrite (Fig. 4b).

In *Gymnarchus*, temporal comparisons occur within the ELL rather than the torus. Nevertheless, the underlying circuitry for time disparity detection shares several similarities with the circuits in mormyrids and *Eigenmannia* [10]. Time-coding primary afferents synapse onto the dendrites of small ovoidal cells in the ELL and also project to giant cells within the ELL



**Temporal Coding in Electroreception. Figure 4** Circuits for making temporal comparisons in weakly electric fish. Neurons known or thought to be inhibitory are shown in *red*. Based on physiological recordings, neurons that are known to be sensitive to temporal disparities between different body surfaces are shown in blue. The *dashed lines* from the *left* represent incoming primary sensory afferents, while the *arrows* pointing to the *right* represent axonal projections to other regions. (a) Knollenorgan pathway in mormyrids. (b) Time-coding pathway in *Eigenmannia*. (c) Time-coding pathway in *Gymnarchus*.

(Fig. 4c). The giant cells, in turn, project to the soma of ovoidal cells. The ovoidal cells thereby receive convergent timing input from different body surfaces [10]. Although physiological recordings from ovoidal cells have not yet been made, their dendrites make

T

dendro-dendritic connections with nearby pyramidal cells [10], which are remarkably sensitive to temporal disparities between different body surfaces [2]. This sensitivity appears to be due, at least in part, to a complex adaptation mechanism, and preliminary evidence suggests that inhibition may play a role at the ovoidal cell-pyramidal cell synapse.

Despite the differences among these neural circuits, certain generalizations can be made (Fig. 4). In each pathway, there is an obvious shift in size from large, spherical neurons that are involved in preserving and relaying timing information, to small neurons that make the actual timing comparisons between different inputs. Once the temporal comparison is made, spike times do not need to be as precise, because the presence or absence of some stimulus feature (a particular timing difference) may now be represented by the overall level of neural activity (firing rate). Thus, there is no need for the neurons to be so large at the point of comparison. Furthermore, it may be that the small size of the comparator neurons reduces the attenuation of rapid synaptic currents by minimizing membrane capacitance. Although employing different mechanisms, delaying the arrival of spikes from one input to the comparator neuron seems to be another general feature. By adjusting this neural delay, the circuit can determine the stimulus delay that will result in a simultaneous arrival of inputs from different sources. If both inputs are excitatory, this particular delay will elicit the strongest response. If one input is inhibitory, then this particular delay will elicit the weakest response. Either way, the comparator neuron is tuned to differences in the arrival times of different inputs.

### Function

It is clear that knowledge of precise stimulus timing can be used to obtain a wealth of information from the environment. The three examples discussed come from organisms with disparate evolutionary histories that use timing information for different purposes. Nevertheless, there are strong similarities between their temporal coding pathways, suggesting that the unique features of these pathways represent specialized adaptations. Although the examples discussed in this chapter come from an eclectic group of organisms for which time holds special significance, the unique features of their time coding pathways are also found in other temporal coding systems [5]. This finding underscores the fact that basic principles in neuroscience may best be realized through a comparative, neuroethological approach to neural structure and function.

## Temporal Rule of Multisensory Integration

### Definition
The principle that multisensory stimuli from will be integrated depending on their relative temporal parameters. Typically, stimuli presented at the same time will result in enhanced multisensory integration, while stimuli presented at different time result in decreased multisensory integration, or multisensory inhibition. For any given neuron, a "temporal window of multisensory integration" will exist such that stimuli from different sensory modalities will be integrated only if both presented within this window. Different neurons and different brain areas may have different temporal windows for optimal multisensory integration.

►Multimodal Integration

## Temporal Summation in Pain

### Definition
Perceived increase in pain created by repeated administration of brief noxious stimuli. This perceptual phenomenon presumably occurs when high frequency stimulation of group C polymodal nociceptive afferents amplifies second-order neuronal activity in the spinal cord dorsal horn. This series of events has been shown to involve N-methyl-D-aspartate (NMDA) glutamate receptors. Temporal summation is thought to reflect central neural mechanisms similar to those responsible for the hyperalgesia and allodynia that accompany many forms of clinical pain.

# Tendon

Thomas G. Sandercock
Department of Physiology, Northwestern University, Feinberg School of Medicine, Chicago, IL, USA

## Synonyms

Series elasticity; Aponeurosis; External tendon; Muscle-tendon unit

## Definition

A fibrous band of tissue, mainly composed of collagen, that connects the muscle fibers to bone.

## Characteristics

### Introduction

Tendon is a tough band of fibrous connective tissue that links the muscle fibers to the skeleton, allowing efficient force transmission from muscle to skeleton. The function of tendon is analogous to a rope, in that the tendon unit can only pull. Tendons are highly resistant to extension, but they are relatively flexible, and can therefore be angulated around bone surfaces, or deflected beneath retinacula, to change the final direction of pull. Tendon, along with the related aponeurosis, allows complicated muscle architectures, with widely varying muscle shapes, to exert force at the precise location needed for efficient movement. Tendon is very stiff, yet its spring-like properties play an important role in energy storage and hence efficient locomotion and movement.

### Anatomy

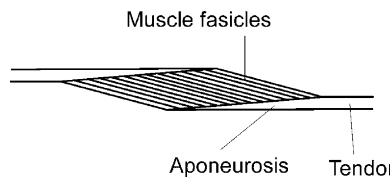
Muscles have amazing diversity, and not surprisingly, so do their tendons. Some muscles attach to bone directly, without any visible tendon, but this is the exception. Some tendons connect muscle to muscle. Tendons come in a wide range of sizes and shapes. They usually take the form of cords or straps. They can be round, oval, or elongate in cross-sectional profile. The total cross-sectional area varies greatly and is generally proportional to muscle strength. The length of the tendon also varies. Length is determined by its location and function in the body, but, as described below, will affect the stiffness of the muscle-tendon unit and therefore its functional properties.

Aponeuroses are broad flat sheets of collagen fibers arising at the muscle fascicle termination and merging into the tendon (see Fig. 1).

The term tendon is sometimes used to describe just the external tendon, but because of their similar composition and continuum of the collagen fibrils, in this essay the term tendon will also include the aponeuroses. However, since the aponeuroses are at the boundary with the muscle fibers, they are subject to different loading conditions. Muscle has a nearly constant volume. Hence, when the fibers shorten they must increase in cross-sectional area. This places additional force on the aponeurosis, compared to the external tendon, which may alter the mechanical properties [1].

Tendon and aponeuroses are composed primarily of the protein collagen. There are numerous types of collagen isoforms, but type I and III predominate in adult tendon. Groups of three collagen molecules polmerize together to form the base unit. These units are then staggered to form a microtendon, and in turn, a fibril. Most of the strength of tendon is due to the parallel densely-packed collagen fibrils. Fibril-associated collagens and proteoglycans are present in small quantities and are critical for tendon structure. Under a light microscope the dominant feature of tendon is the wavy collagen fibers. This wavyness disappears as soon as the tendon is loaded. Tenocytes, a specialized fibroblast, are also visible and are responsible for the maintenance of collagen structure. The low density of vascular networks in tendon leads to their characteristic white appearance.

The muscle fibers terminate in specialized processes producing collagen. At the muscle-tendon junction the sarcolemma exhibits finger-like extensions and invaginations that increases the surface area and helps transmit force. The last actin filaments in the muscle terminate in transmembrane proteins that link to the collagen matrix outside. These collagen fibrils fuse



**Tendon. Figure 1** Muscle-tendon unit. A simplified view of muscle fascicles originating and terminating on the aponeuroses, which in turn becomes the tendon.

together to form microtendons and then in turn the aponeurosis and tendon [2].

The direction of force from a tendon is often altered by specialized structures. Retinacula are fibrous bands which bind down the tendons and alter direction much in the way a pulley can redirect force. An example is the retinaculum redirecting force from the extensor digitorum longus muscle along the surface of the foot. Some tendons have bones inserted in them. An extreme example is the patella. It is inserted in the tendon from the quadraceps, and serves to redirect the force to the lower leg. In situations where tendons and other structure move relative to each other and are in tight apposition, synovial sheaths and bursae provide mechanical isolation. An example are synovial sheaths of the digital flexor tendons. Some tendons have no special isolation and partially slide next to synergist tendons. Example are the tendons from the plantaris and gastrocnemius muscles. Where tendons of synergists run next to each other collagen strands often connect the tendons, linking them together. They must slide together or a shear force develops between the tendons.

## Material Properties

Tendon acts like a very rigid spring. The farther it is stretched – the more force it produces. The simplest model treats it like a linear spring.

$$\Delta F = k\Delta l \tag{1}$$

Where $\Delta F$ is the change in force, k is the stiffness of the spring, and $\Delta l$ is the change in length. In general, the greater the cross-sectional area the stiffer the tendon (larger k), and the longer the tendon the lower the stiffness. For this reason the material properties are expressed as normalized values – stress versus strain (see Zajac for greater detail [3]). Force normalized by the cross-sectional area is stress ($N/m^2$ or Pa).

$$\sigma = F/A \tag{2}$$

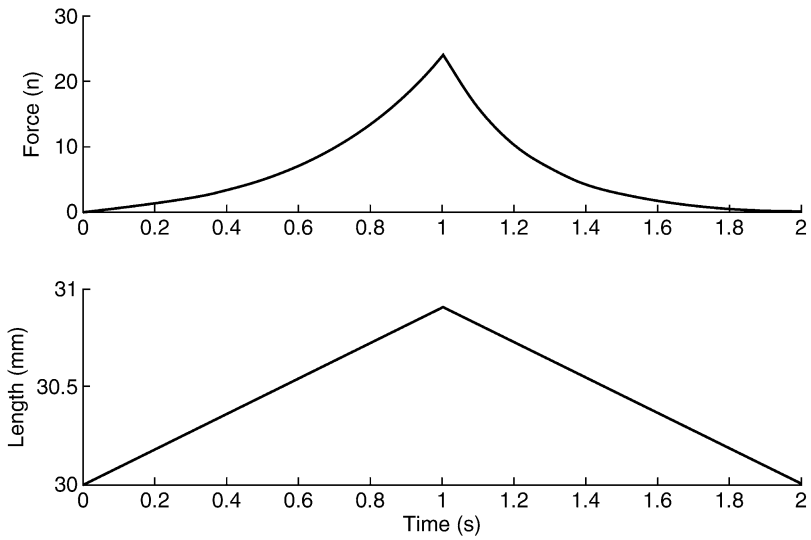
Change in length divided by the original length is strain.

$$\varepsilon = (l - l_0) - l_0 \tag{3}$$

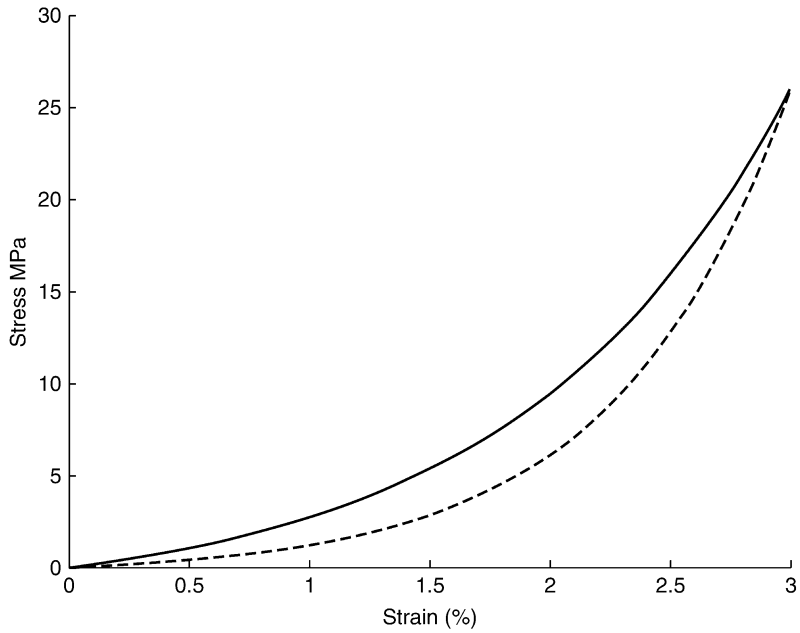
A linear spring is a good first approximation for tendon, but it does not capture its many complexities. Figure 2 shows the behavior of an isolated tendon as it is stretched and shortened. It is immediately apparent that as it is stretched, force increases in a nonlinear fashion. Initially it shows a toe region where force increases slowly with stretch. This has been attributed to the length before the collagen fibrils have straightened out. Next comes a quasi-linear region where force increases more rapidly with stretch. The stretch was stopped when the tendon was stretched to about 3% of its initial length. For most muscles the tendon cross-sectional area is matched to muscle size, so this 3% stretch represents about how far tendon stretches during an isometric contraction when a muscle is fully activated. Next the tendon was shortened. It produced less force than it did on stretch. This is readily apparent in Fig. 3. Here the force-length characteristics from Fig. 2 are normalized and plotted as a stress-strain curve. Substantial hysteresis is seen. The hysteresis is significant because it shows some energy is lost in the stretch shortening cycle.

The slope of the stress-strain curve is the elastic (Young's) modulus, and is a measure of the stiffness of the tendon (see below).

$$E = \sigma/\varepsilon \tag{4}$$



**Tendon. Figure 2** Force from cat soleus external tendon during stretch and shortening. The tendon was about 30 mm in length with a cross-sectional area approximately 1 $mm^2$.



**Tendon. Figure 3** Stress-strain properties for cat external tendon. The *solid line* shows the results during stretch and the *dotted line* during shortening. The difference between them is an example of hysteresis.

At maximal muscle activation, the elastic modulus of tendon is approximately 1.0 GPa. At maximal muscle activation tendon strain is approximately 3%. This will vary if a muscle has a proportionately thicker tendon.

Tendon has many other complex properties. When tendon is stretched, well beyond the 3% strain shown in Fig. 3, it reaches a yield point and the tendon ruptures. The rupture point depends on the tendon history as well as the speed at which the tendon is stretched (strain rate). In general tendon shows many history effects – its material properties change with time. Hence the stress-strain curve, hysteresis, and fatigue all depend on how often and how fast a tendon is loaded. These complex properties generally are generally not considered in musculo-tendon models used for motor control. When a mathematical model is needed to describe tendon it is usually modeled as a linear spring, an exponential spring, or with a piecewise exponential-linear relationship.

Tendon material properties are similar between muscles and between vertebrate animals. The exception is the stiffer ossified tendons of some birds. There is substantial disagreement to what degree the material properties of tendons vary with different muscles, species, and ages [4]. Part of the problem is the experimental error encountered in securing the cut end of excised tendon. Because of this problem the measured stress-strain properties of excised tendon vary by a factor of two. The difference between the material properties of tendon and aponeurosis is also an open question.

Muscle is known to exert force proportional to its cross-sectional area (see physiological-cross-sectional area in muscle). Muscle can exert a maximum of about 200–300 kPa. The cross-sectional area of the tendon will determine how near breaking it is during maximum loads. The length of the tendon and its cross-sectional area will determine how much it will stretch at full loads. A thinner tendon will be more compliant but will have a smaller safety factor for rupture. Different muscles will require tendons with different properties for efficient functioning.

## Stiffness of the Muscle-Tendon Unit

Stiffness is a measure of the ability of a muscle to resist a length change due to a small perturbation. It is defined as the change in force divided by the change in length. Stiffness is one of muscles most important functional characteristics and plays a key role in stabilizing the joints. Because the muscle fibers are in series with the tendon, the stiffness of the muscle-tendon complex depends on both, with the least stiff element dominating. In general, at activation levels near maximal for the muscle, tendon stiffness plays a significant role in the overall muscle-tendon stiffness [5].

## Contractile Properties – The Series Elastic

Tendon can be considered to be in series with the muscle fibers (see Fig. 1). Thus, tendon is part of the series elastic in Hill-type muscle models (see essay on modeling). If a muscle-tendon is held at a fixed length and the muscle is stimulated, the muscle fibers shorten and the tendon is stretched, until steady state is reached where the force from the muscle fibers balance the recoil force from the tendon. This is often referred to as an isometric contraction even though the muscle fibers

have shortened. Griffiths [6] used piezoelectric crystals to measure muscle fiber length during contraction of cat medial gastrocnemius. He demonstrated that even during a stretch of the muscle tendon unit there is often some shortening of the muscle fibers. The difference is made up by stretch of the tendon. Ultrasonography (the imaging of muscle tissue with sound) has shown similar effects in humans [7].

## Energy Storage

Tendon can play a significant role in efficient locomotion. When tendon is stretched it stores potential energy that can be recovered as work as the tendon is released. The characteristics of tendon allow 80–95% of this energy to be recovered. Wallabies use elastic storage in the ankle flexors during hopping [8]. When the foot was on the ground the muscle fascicles contracted nearly isometrically. The tendon stretched and recoiled but the muscle fascicles remained at almost the same length and did little work. Thus, energy was stored in the tendon on landing and then returned as kinetic energy on takeoff. Some animals make extreme use of this behavior. The camel has gastrocnemius muscle fascicles only a few millimeters long, hence the length change of the muscle-tendon complex, which occurs with locomotion, must be almost entirely due to elastic recoil of the tendon.

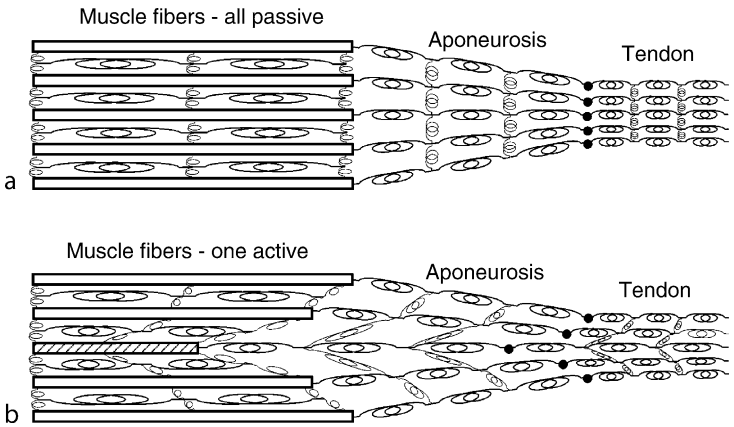
Not all animals make use of the tendon for energy storage. The kangaroo rat showed much lower stress in the gastrocnemius during hopping and this resulting in little stretch of the tendon. These animals are capable of large jumps, involving much larger forces than steady hopping. Because the tendons have to be large enough for jumping, they can't be flexible enough for hopping. Thus they don't save much elastic energy in the tendon.

The muscle tendon unit can be optimized for a particular purpose. The short muscle fascicles and flexible tendon of the wallaby save energy, but have limited use for other purposes than hopping. Short fascicles are a poor design for animals that climb trees because the uneven footholds forces them to use their limbs in a wide range of positions. Hence, the narrow length-tension properties of the muscle limit the force produced (see essay on length-tension).

## Recruitment of Motor Units – Common Tendon Model

Tendon is an anisotropic material that it is much stiffer along the longitudinal axis (the direction of the collagen fibrils) compared to the transverse axis (across the collagen fibrils). When a single motor unit is active there is a differential strain (shear) of the aponeurosis and tendon near the active motor unit. They are strained more than other parts of the tendon (Fig. 4). During normal activation of a muscle, when multiple motor units are active, nonuniform strain has been reported but it is not clear if it is physiologically significant. This nonuniform strain may alter the apparent stress-strain properties of the tendon seen by motor units. Further complications come from the change in pennation angle of the muscle fibers and the change in cross sectional area of the muscle fibers during shortening. These effects are not fully understood and they can alter the apparent material properties of the aponeurosis.

To determine the effective tendon properties governing the interaction between motor units, muscle was stimulated in two parts using the ventral roots [9]. A simple model was assumed with a linear elastic element representing the tendon. No assumptions were made about the location of the common-elasticity. The parameter was estimated by measuring the interaction between two separate parts of the muscle. The magnitude of the common-tendon was estimated in three ways: (i) the shift in the length-tension relation; (ii) by using the muscle puller to mimic the extra stretch of the elasticity when both parts of the muscle were active; and (iii) as an algebraic calculation based



**Tendon. Figure 4** Differential strain in aponeurosis and external tendon when a muscle is partially active. (a) All muscle fibers are inactive. (b) A single muscle fiber is active. This differential strain may complicate the properties of the aponeurosis and tendon when a muscle is partially active and only some motor units are recruited.

on whole muscle stiffness measurements when one or both parts of the muscle were active. When smaller portions of the muscle were activated interaction was consistent with the same common-tendon. Thus, the common-tendon measured by the interaction of the parts is more linear than expected from the isolated tendon with stress-strain properties shown in Fig. 3. The good fit of this simple model suggests it can be used to model motor unit recruitment, where motor units are assumed to be parallel and independent force generators, connected to a common-elasticity.

### *Higher Level Structures*

Limbs.

### *Lower Level Components*

Microfilaments.

*Structural Regulation.* The regulation of tendon strength is not fully understood.

*Process Regulation.* It is unknown if it is different from musculo-skeletal control.

## Function

Transmit the force from muscle fibers to the skeleton. The compliance of the tendon helps to protect the muscle from injury during quick stretches. The tendon can also store energy during locomotion.

## Definition

Tendon is a dense fibrous tissue that connects muscle to bone. The primary function of tendon is to transmit force from muscles to bones, thereby producing movement.

## Characteristics

Anatomically, tendons have a hierarchical structure of cell layers and arrangements of extracellular matrix molecules. The tendon has three primary structural zones: the ►myotendinous junction (MTJ), the tendon proper, and ►osseotendinous junction (OTJ). The MTJ at the proximal end focuses muscle force through an ►epimysium to the tendon. The tendon proper is comprised of an outer ►paratenon structure of loose connective tissue comprised of fibroblastic paratenon cells (PC) that is 25% collagen (75% collagen type I, 25% collagen type III), 25% proteoglycan and 50% lipid [1]. The paratenon acts as a conduit for blood vessels, nerves and lymphatics. The ►epitenon is a second circumferential layer surrounding the tendon proper and is comprised of 3–8 biologically distinct surface cells (ESC) that secrete an abundance of fibronectin and promote cell migration and healing [2–4]. The epitenon is continuous with a 3–8 cell-thick ►endotenon layer (ENC), whose cells have not been well characterized. The endotenon acts as a conduit for blood vessels, nerves and lymphatics, and surrounds the tensile load bearing collagen fascicles with linear and circular bundles of collagens. Finally, the tendon fascicles are comprised of linear, millimeters-long collagen ►fibrils having a periodic, zig-zag crimp pattern with elastin fibers attached to allow stretch and return of the non-elastic collagen fibrils [5]. The cells within the fascicles are internal ►fibroblasts (IF) that secrete the fibrillar collagens which are covalently crosslinked at lysines and hydroxylysines to add strength [3]. The distal tendon end attaches to bone at the osseo-tendinous junction (OTJ) where it assumes a fibrocartilagenous phenotype especially where it compresses against bone (e.g., at calcaneous in Achilles tendon) [6]. ►Tenocytes are interconnected by gap junctions that facilitate intercellular communication [7].

Tendons generally have a limited blood supply, more so in the flexor tendons of the hand where the vinculae supply blood to the digital tendon. Tendons are sympathetically innervated and have localized regions that have substance P- and neuropeptide Y-positive nerves [8]. Tenocytes in the paratenon, epitenon and internal compartments express receptors for growth factors such as PDGF, IGF-1, and TGF-β1. Tenocytes also express purinoceptors that react with ATP, UTP, and ADP, cytokine receptors that react with IL-1β and TNFα, and adrenoceptors that react with neurotransmitters such as norepinephrine [9,10]. Results of gene array experiments indicate a complex expression profile, including expression of genes previously thought to be exclusively expressed in muscle (such as titin). However, gene markers enriched in tendon include COMP (cartilage oligomeric protein), tenomodulin, and scleraxis. Mechanosensor organelles including Golgi tendon organs, Pacinian corpuscles and Ruffini endings are present and detect and transmit changes in muscle tension and pressure to the nervous system. There is no anatomically described functional tendon unit or proven markers that can be used to stage normal development or disease progression. These two areas are important to further understanding tendon biology and biomechanics.

Functionally, tendons are either biomechanically strong, power-transferring and energy-returning spring components or biomechanically weak apposing positional organs. The Achilles tendon linking the gastrocnemius and soleus muscles in the lower limb to the foot is an example of a high force-transferring tendon. The flexor digitorum profundus (FDP) tendon in the hand is an example of a low force-transferring and positional tendon. The extensor pollicis longus tendon in the hand is an example of a weak, positional return tendon in the hand. Power transferring flexor tendons, such as the Achilles tendon, have breaking strengths ranging from 80 to 130 MPa. Equine flexor tendons can withstand up to 15% strain; otherwise, tendons usually are subjected to strains of 1–5%. Tendons also act as springs to store and return energy.

# Tendon Jerk

►Tendon Reflex

# Tendon Organ

## Definition

Golgi tendon organs are encapsulated structures 0.2–1 mm long, usually located at musculo-tendinous junctions. Their sensory endings, which become group Ib afferent axons, are entwined amongst the tendinous strands of 10–20 motor units, a given motor unit affecting 1–6 tendon organs. Most tendon organs respond sensitively to force actively generated by the motor units with which they are associated.

►Feedback Control of Movement

## Tendon Reflex

### Definition

A tendon reflex (also called "tendon jerk," "stretch reflex," or "spinal stretch reflex") is the earliest response of a muscle to being stretched by a sudden brief deformation of its tendon, which is typically produced by tapping the tendon. For example, the kneejerk reflex is the tendon reflex of the quadriceps muscles that is elicited by tapping the patellar tendon just below the knee. A tendon reflex is produced by an entirely spinal pathway consisting mainly of group 1a afferents from the muscle spindles, their excitatory synapses on the muscle's motoneurons, and the motoneurons. Oligosynaptic (i.e., di- and tri-synaptic) excitatory and/or inhibitory inputs to the motoneurons from group 1 or 2 afferents may also contribute. Because it is largely monosynaptic, the latency of a tendon reflex depends mainly on the lengths and conduction velocities of the afferent and efferent axons in the peripheral nerve.

►Conditioned Reflexes

## Tenrec

### Definition

Echinops telfairi, a small mammalian species endemic to Madagascar. Also known as the lesser hedgehog tenrec, this species bears a physical resemblance to the better-known European hedgehog. Tenrecs have very little neocortex in comparison to other mammals.

►Evolution of Association Pallial Areas: Parietal Association Areas in Mammals

## Tension-type Headache

### Definition

A mild to moderate bilateral pressing or squeezing headache not made worse by physical activity and not accompanied by nausea and/or vomiting.

►Headache

## Tensor Tympani Muscle

### Definition

One of two muscles in the middle ear of mammals that is involved in the middle ear muscle reflex. (The other middle ear muscle is the stapedius muscle.) The tensor tympani muscle arises from the auditory tube and inserts onto the malleus, or hammer, which is the middle ear bone situated closest to the tympanum. The tensor tympani muscle is innervated by the trigeminal nerve. Its contractions dampen sound-induced oscillations of tympanum and middle ear bones and reduce sound amplitude, thus protecting the ear from intense sound signals.

►Auditory-Motor Interactions

## Teratogen

### Definition

Substance or pharmaca that when taken by a pregnant female, can reach and harm development of the fetus by inducing birth defects or malformations.

►Endocrine Disorders of Development and Growth

## Terminal Arbor

### Definition

The final pattern made by axonal endings as they terminate on their target neurons.

## Terminal Bouton

### Definition

Terminal bouton is the specialized presynaptic terminal at the end of an axon. Terminal boutons contain necessary organelles, proteins and molecules needed to

transmit chemical/electrical information to the postsynaptic cell. During development, they form from growth cones that undergo a morphogenesis after target selection.

►Synapse
►Synaptogenesis

## Terminal Cisternae (Junctional SR, Heavy SR)

### Definition

Compartment of the sarcoplasmic reticulum that makes direct contact with the t-tubule membrane and from which $Ca^{2+}$ is released through the ryanodine receptor during excitation-contraction coupling. In skeletal muscle, 2 terminal cisternae border a t-tubule and form a triad.

►Excitation–Contraction Coupling

## Terrestrial Magnetic Field

►Geomagnetic Field

## Territorial Motivation

### Definition

Motivational aspects derived from the spatial location of the animal. In territorial species, an individual defends an area against other members of its species. The animal's location in its territory or in a competitor's territory may radically alter the behavioral response to a conspecific, changing from aggressive (when the animal is located within its own territory) to defensive/submissive (when it is located outside its territory).

## Test and Inducing Stimuli

### Definition

Visual illusions and after-effects are often characterized as the effect of one part of a visual display on another part.

►Visual Illusions

## Tetanus in Muscle Contraction

### Definition

Mechanical response generated when a train of closely spaced stimuli is applied to muscle. An unfused tetanus occurs when the stimulation rate produces partial summation of individual twitches. A fused tetanus occurs when the stimulation rate produces full summation of individual twitches.

►Force Potentiation in Skeletal Muscle

## Tetanus (Pathological)

### Definition

Characterized by augmented muscle tone and spasms and caused by *tetanospasmin*, a protein toxin produced by the anaerobic Clostridium tetani, which in the form of spores is prevalent in soil and enters the body via badly oxygenized wounds. Here the vegetative cell form produces the toxin that is retrogradely transported in ►motoneuron axons to ►brainstem and ►spinal cord, where it migrates transneurally to presynaptic terminals and blocks the release of inhibitory transmitters

such as glycine and GABA, thereby producing ►spasms. ►Preganglionic sympathetic neurons may also be disinhibited resulting in sympathetic hyperactivity and high concentrations of circulating ►catecholamines. Like ►botulinum toxin, tetanospasmin may also block the ►neuromuscular junction and produce muscle weakness and paralysis.

## Tetany

### Definition

Tetany manifests itself as contractions of predominantly distal muscles in the hand (carpal ►spasms) or feet (pedal spasms), and occasionally as ►laryngospasm. With prolonged contractions, tetany may cause muscle damage with subsequent pain; and severe tetany, when involving the spine musculature, may entail ►opisthotonus. Tetany usually results from increased excitability of peripheral nerves, occurring during hypocalcemia, hypomagnesemia or severe respiratory alkalosis. ►Spasmophilia is an idiopathic normocalcemic tetany, which may be hereditary of acquired.

## Tetracycline-Regulated Transgenics

►Conditional Transgenics

## Tetraethylammonium Chloride (TEA)

### Definition

Tetraethylammonium chloride (TEA) is a simple ammonium ion. When applied from the cell outside, it blocks some types of voltage-dependent $K^+$ channels, especially those of the Kv3 and BK family channels.

►Action Potential
►Neuronal Potassium Channels

## Tetrahydrocannabinol

### Definition

►Δ1-tetrahydrocannabinol, is the main psychoactive substance found in the Cannabis sativa plant. It was isolated by Raphael Mechoulam's laboratory at the Hebrew University in Jerusalem in 1964. A synthetic version of it – dronabinol, is also available.

►Cannabinoids

## Tetrapod

### Definition

Vertebrates that have four feet, i.e., the amphibians, mammals, reptiles and birds. (Snakes are tetrapods that secondarily have lost this character.)

## Tetrodotoxin (TTX)

### Definition

Tetrodotoxin (TTX) is a toxin derived from bacteria. It is concentrated in certain organs of puffer fish (fugu) and fishes of the order Tetraodontiformes and has given rise to the Chinese proverb "To throw away life, eat blowfish" (puffer fish). Its effects are said to have been discovered by the legendary Chinese emperor Shun Nung (2838–2698 B.C.) who, while compiling a pharmacopoeia, personally tasted 365 drugs and yet lived an amazing 140 years to tell the tale. Similar to saxitoxin (STX), tetrodotoxin is a very potent blocker of most voltage-gated $Na^+$ channels, thereby preventing the conduction of action potentials along nerves and/or muscle membranes.

►Action Potential
►Saxitoxin (STX)

## Texture Discrimination in Touch

### Definition

The most common perceptual descriptor of surface texture is the sensation of roughness. Stimuli employed to measure the resolution of this perceptual feature have ranged from common materials such as sandpaper and fabrics to surfaces which can be manufactured and defined precisely – gratings of alternating grooves and ridges, and embossed dots of differing spatial configuration. Discrimination thresholds range from 5 to 10% variation in the spatial period of the elements depending on whether the surface is scanned across the skin or simply indented into the skin with no lateral movement.

►Processing of Tactile Stimuli

## Texture Processing in Vision

### Definition

Texture processing refers to the brain's ability to respond to the local statistics of textured regions in a scene or picture. Texture processing includes texture segregation, and can generate recognizable percepts of object form (Form perception).

►Form Perception

## Texture Segregation in Vision

### Definition

A visual texture refers to the size, shape, and arrangement of different elements of a scene or picture. Texture segregation refers to the brain's ability to group into distinct regions and objects different parts of a scene that have different texture statistics. Boundary and surface processes in the brain can use texture, as well as edge, shading, depth, and color information to generate percepts of visual form.

# Thalamus

## Definition

The thalamus consists of a large ovoid mass of gray matter forming the larger dorsal subdivision of the diencephalon located medially to the internal capsule and caudate nucleus. It is a complex collection of cell groups (nuclei), through which sensory information (except for olfactory information) is relayed and processed on its ascending path to the cerebral cortex (also thought of as the "gate-keeper" to the cerebral cortex). It also transmits and processes information to the cortex from the basal ganglia and cerebellum.

# Theories on Motor Learning

Hirokazu Tanaka, Mitsuo Kawato
ATR Computational Neuroscience Laboratories, Kyoto, Japan

## Definition

Motor learning is an assortment of adaptive processes in motor control by which a new movement skill is being acquired (skill acquisition) or motor performance is being restored even under novel kinematical or dynamical environment (motor adaptation). Computational theories of motor learning often describe motor learning as a relaxation process toward a desirable behavioral goal (i.e., a tradeoff between task performance, body stability, and energy consumption).

## Characteristics

### Optimality Principles for Motor Control and Learning

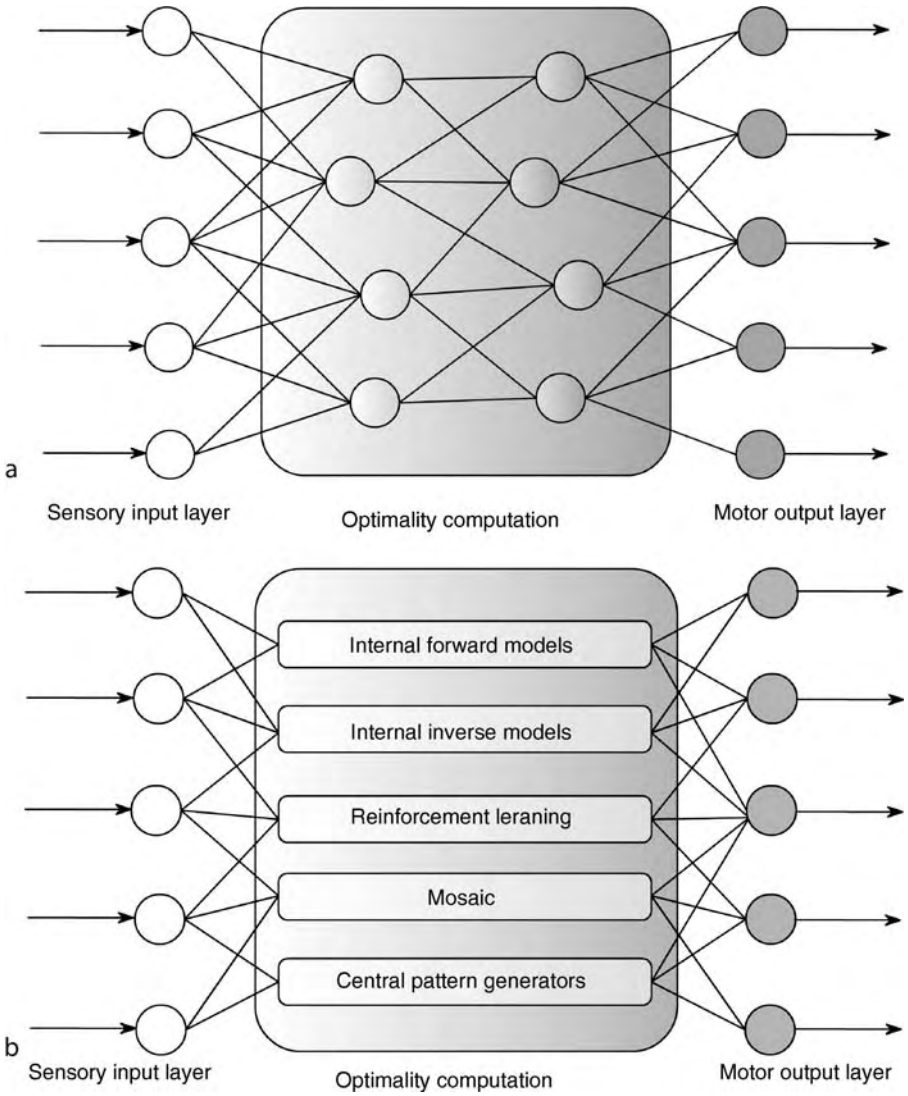
Lively movements define what animals are. Control and coordination of body movements have evolutionarily necessitated elaborate central nervous systems, the idea supported by the fact that the brain is a luxury that motionless plants needed not to develop. An important aspect about body movements is that those appear to be purposive for certain behavioral goals and to have invariant features such as straight trajectories in arm reaching and specific rhythms in locomotion, implying underlying optimality goals. Several computational models explain motor control as achieving optimality of behavioral goals, namely a tradeoff between task performance, body stability, and energy consumption. Voluntary arm reaching has offered a test bed for assessing several successful optimization models such as the minimum jerk, minimum torque change, and minimum variance models. Locomotion may be understood as optimization of gait so as to maximize traveling distance using minimal energy. Also, movement control must be adaptive to ever-changing environments, and the process of adaptive motor control is defined as motor learning. Optimality principles regard motor learning as a relaxation process toward optimization goals.

### Motor Learning as a Composite of Subsystems

The current prevailing view in computational motor control and learning (►Optimization model for motor control and learning) is that, once an optimization goal is specified, motor control may be solved with a network composed of homogenous units, possibly in the primary motor cortex (Fig. 1a) [1].

This approach has been most successful in explaining quite a few invariant movement properties. This striking success, regrettably however, misguided some neuroscientists to be convinced that a homogeneous optimality computation suffices for motor control and learning. This view, simple and attractive though it appears, overlooks biological concerns in motor learning.

We, here, propose an alternative view that the brain seems to employ several parallel and hierarchical subsystems specialized for their designs so as to achieve overall optimality (Fig. 1b). Although optimality principles furnish a general and conceptual framework, there are several concrete computational problems specific to biological motor control that could not easily be solved in



**Theories on Motor Learning. Figure 1** Schematic diagram for optimality computation. The widespread view claims a single, homogenous network (a). We contrariwise propose the computation as a composite of subsystems, each developed for certain computational problems specific to biological motor control and learning (b).

a single, homogeneous network. One may follow the successful approach in science for handling a difficult large-scale problem, namely the "divide-and-conquer" strategy: separate an original problem into multiple, more tractable subproblems, solve those subproblems per se, and then assemble the solutions of subproblems to form the sought solution to the original problem. We will consider three difficulties that the biological motor system must overcome, and how those difficulties are solved by various computational approaches. First of all, the delay time of sensory feedback is significant and makes a naive use of feedback control unstable or oscillatory. Visual signals, for instance, need approximately up to 100 ms to reach higher visual areas mainly due to the sluggishness in retinal photoreceptor reactions and the hierarchical structure of visual system. Therefore, if dependent only on sensory signals, the motor system sees only past position of an effector (limb or eye ball) and must develop a predictive mechanism that estimates a current effector state for reliable control. Second, sensory signals may not always specify direct information about how movement can be improved, the difficulty known as the distal-teacher problem [2]. Learning based on teacher signals is called supervised learning, and movement errors measured between desired and actual states are often used as a teacher signal in supervised learning. Nevertheless, movement errors perceived in visual coordinates do not readily dictate whether and how much a muscle activity involved in that movement should be potentiated or depressed in such a way as to reduce

the visual errors at later movements. This becomes exacerbated when a movement outcome is evaluated only through a reward or a punishment in so-called reinforcement learning in which the teacher signal is least informative. In addition to sensory delay and insufficient teacher signals, the motor system must control very high degree-of-freedom effectors, making the number of possible motor control commands more than astronomical. Computation seeking optimality in such large systems will be unattainable in practical time frame, so the motor system needs to constrain possible search spaces. We, hereafter, provide an overview on several computational approaches to overcome these difficulties and their connection to biological motor learning.

## Internal Forward and Inverse Models

For a reliable control, the delay in sensory information transmission must somehow be compensated, and a reliable estimate of current effector state must be computed ahead of time. Internal model is proposed as a neural mechanism that mimics an input–output relationship of an environment or a body to be controlled [3]. There are two kinds of internal models: *forward* one for estimating a current state, given current sensory signal reporting previous limb state and efference copy of motor command, and *inverse* one for producing motor commands that realize a desired effector state. The forward model (►Internal forward model), on one hand, computes a current state (e.g., position and velocity of eye or limb), essentially by solving equations of motion using current sensory signal and efference copy of motor commands. The computation is called forward because current state is computed in a causal manner. Predictions with forward models have a few advantages: estimation of current effector state, prediction of motor outcome, and comparison with actual sensory signals to produce error necessary for motor learning. The inverse model, on the other hand, maps a desired effector state onto necessary motor commands that accomplish that desired state. The control signal produced by inverse model is called feedforward, in contrast to feedback control that depends purely on sensory signals. Both forward and inverse models must have knowledge about body dynamics that is to be controlled. Fast and reliable body control becomes possible by combining the forward and inverse models; initially, the forward model estimates the current state given most recent sensory signals and efference motor copies, and then the inverse model produces necessary motor commands by comparing the desired state to the estimate of current state by the forward model.

One may then wonder how internal models are to be acquired when there is no direct teacher signal available. Our body and its dynamics are subjected to inevitable modifications caused by development, fatigue or injury, and internal models must accordingly be adaptive to take those changes in consideration. Also, internal models ought to be retrained when subjected to novel environments, such as those using altered visual field by prisms or feeling no gravitational field in space. If an explicit teacher signal was provided, a supervised learning process would be achieved without great efforts. The problem is, the teacher signals for internal models must be represented in coordinate systems of their outputs (e.g., joint angles or motor commands), whereas errors are usually obtained through visual coordinates (Cartesian positions) or joint-angle space of proprioception. Teacher signals for inverse models are, hence, not obviously given. A possible solution was given by Kawato and coworkers; feedback control signals, though delayed, can approximate teacher signals and afterward be utilized to train inverse models [4]. In the initial phase of motor learning, an ►internal inverse model for a certain movement is not suitably trained and thus actual movement is most likely to deviate from a desired one. Feedback control comes into play when sensory signal alerts the deviation of current state from the desired one. That feedback control signal reports how well or badly the inverse model produced feedforward motor command in that movement and can then be used to update the inverse model properly in the next movement. In this ►feedback error learning (FEL), in an initial phase of motor learning before the inverse model is well trained, feedback control guides movement and trains the inverse model, and then feedforward control comes to be more dominant as the inverse model becomes trained. Eventually, movement will become feedforward-control dominant and need not rely exclusively on delayed sensory signals.

The next question is to ask where, if any, internal models are located in the brain. Now, there is substantial evidence from anatomy, electrophysiology, and human brain imaging that the cerebellum possesses at least certain form of internal models and that the cerebellar cortical circuit realizes FEL-type learning to train internal inverse models [5]. First, three anatomical observations about cerebellar cortical circuits support this: the circuit is feedforward from the input layer (granular cells) to the output (Purkinje cells) via parallel fibers, Purkinje cells receive tens of thousands of inputs from granular cells, and there is only one teacher signal (climbing fiber) for each Purkinje cell. This circuit structure appears analogous to a multilayered neural network in artificial intelligence, which is known to be able to approximate any nonlinear function, so it is in particular appropriate for learning general input–output relations. Also, electrophysiological studies of behaving animals revealed that simple spikes of Purkinje cells generated by parallel fiber inputs represent inverse models of eye or arm, and that complex spikes

generated by climbing fiber input represent error signal in the motor-command space, both in agreement with the FEL model. In addition, synaptic strengths were shown to have plasticity in conjunction with motor learning. Finally, recent human imaging studies found activations in the cerebellum that correlated well with error signals and with the formation of an internal model while participants were learning novel computer interfaces.

## Reinforcement Learning

Motor learning often encounters situations where teacher signals, either direct or indirect, are not available at all, and movement outcome is evaluated only through a reward or a punishment. Infants learning to walk will be rewarded with a toy if they succeed in traveling to their parents but will be punished by falling down to the floor if they fail. Here, note that there is no explicit teacher signal on how walking could be improved but only evaluation of movement, called (either positive or negative) reinforcers, is given later, so a learner must learn by trial and error so as to discover best control strategies that maximize the reward. Reinforcement learning (RL), initially motivated by the Pavlovian associative learning and later on developed in the field of machine learning, provides an appropriate strategy, or policy, using only reinforcers [6]. In RL, finding an optimal policy is pursued by a tradeoff of exploration among possible search directions and exploitation of current best sources known through previous explorations. RL has become very popular since an efficient algorithm called the temporal difference (TD) error algorithm was proposed, and various problems have been solved by RL methods, including both discrete-time problems such as maze solving and backgammon and continuous-time problems such as cart-pole stand up and pendulum swinging up. On the top of practical use, RL rekindled neuroscientists' attention when dopamine neuron activity in midbrain was found to represent TD error signals [7], and how RL is realized in the basal ganglia circuit has since been argued. RL becomes desperately useless, however, in case that a problem to be solved involves many degrees of freedom. This is because the space of possible states and actions grows exponentially and becomes too gigantic to be explored within reasonable time, and also because most trials will produce no reward or punishment, that makes no information available as to improve a policy. Therefore, a naive application of the standard RL algorithm to a large-scale problem is doomed to fail.

## MOSAIC Model

The difficulty in extending RL to a large-scale problem, also known as curse of dimensionality, can be alleviated by hierarchizing or modularizing the original problem. This approach has been proven to work efficiently within shorter computational time in, for example, composite Q, feudal RL, SMDP learning, and max Q algorithms. Nevertheless, in those studies, structures of hierarchy and modularity were assigned manually by researchers from problem to problem, so it was needed to develop an algorithm that automatically and correctly decomposes an original problem into smaller, more tractable subproblems. A modular selection and identification control (MOSAIC) model, proposed initially as a model of supervised learning and extended to RL, attempts this automatic problem decomposition naturally by self-organizing multiple parallel modules, each consisting of a predictive forward model and a paired control inverse model [8]. Which controllers will be used depends on how satisfactorily paired predictive models predict movement outcome or an immediate reward. The fitness of prediction to actual sensory signal is termed a responsibility signal, which in turn determines to what extent modules are updated with given error signals. Initially, before motor learning, all modules are set to random initial conditions, and all predictors produce almost equally bad estimates, resulting in similar amount of responsibility signals distributed all over the modules. During learning, predictive models that happen to produce good predictions become updated and specialized for particular tasks or situations. Finally at the end of learning, each unit becomes an expert for its own purpose, and only a small subset of the responsibility signals takes nonzero values at one point of time. In other words, all modules are novices at first, and grow differentiated toward their own specialities. In this way, the ►MOSAIC model automatically self-organizes large-scale problem into small subproblems without direct human assignments. Although the MOSAIC model still suffers when a problem is large, it points a right direction for further investigation.

## Nonlinear Dynamical Approach

Although degrees of freedom (DOFs) are enormous in body dynamics, all muscles and joint angles do not operate independently but cooperate and regulate each other to some extent. Indeed, electromyography measured from a frog hindlimb while kicking, jumping, swimming, or walking, consists of no more than six principal components. Likewise in animal locomotion, hip, knee, and ankle angles are not randomly controlled but are either inphase or antiphase to each other. This effective reduction in DOFs is called movement synergy, and resultant DOFs are referred to as ►motor primitives, collective variables, or order parameters. Self organization of nonlinear, nonequilibrium systems was proposed by Kelso and coworkers as dynamics of those low-dimensional systems, and experimentally well-defined movement patterns were assumed to correspond to nonlinear dynamical attractors [9]. In this framework, a transition from one motor pattern to another when an experimental parameter is modified can be regarded as a bifurcation process from an unstable equilibrium point to

another stable one. Predictions from this approach have been confirmed in a variety of psychophysical experiments including human bimanual finger coordination and animal gait patterns. An important implication here is that the motor system itself should have internal nonlinear dynamics in the synergistic low-dimensional space, consistent with biological rhythmic generators in the brain stem and spinal cords. This phenomenological approach was further extended successfully by Schaal and coworkers to real-time motor learning in humanoid robotics [10]. Although in Kelso's approach the nonlinear dynamics was manually fixed so as to explain observed movement patterns, Schaal incorporated a learning process of dynamics on stable and unstable attractors ("attractor landscape") from human movements monitored by motion capture equipment. Also, ►motor synergy was not a priori assumed there but emerged spontaneously as a result of excitatory and inhibitory couplings between DOFs. This dynamical-system-based control is proven to scale up to motor learning of humanoid full-body movements in various tasks such as walking, drum beating, and tennis ball hitting. Whether and how the brain realizes motor synergy and the nonlinear dynamical approaches, however, still remain little investigated.

In this essay, we presented our view that the motor cortex has evolved to recruit computational subunits for motor optimality, and reviewed a few difficulties in biological motor control and learning, their possible computational solutions, and relations to the motor system in the brain. We have fulfilled reasonably the first two stages of the divide-and-conquer strategy. The next challenge will be to integrate individual computational approaches into a coherent, unified theory that fulfills optimality on the whole. Therefore, close collaborations between psychophysical, electrophysiological, computational, and robotics approaches should carry on for further development in motor learning.

# Theory – Theoretical Expression

## Definition

Theoretical expressions are expressions that occur, in addition to logical and mathematical vocabulary, in the formulation of a theory. In a narrow sense, a theoretical expression refers to theoretically postulated entities (electron) or states (being charged). Many philosophers think that the meaning of, e.g., "being charged" is constituted by the role charged particles play according to physics, which is partly captured by Coulomb's law of electrostatic interaction (State, functional).

## Synonyms

Theory on Pavlovian conditioning; Theory on stimulus-outcome learning; Theory on CS-US associations

## Definition

Theory on ►classical conditioning seeks to characterize the conditions under which learning about the

relationship between conditioned and unconditioned stimuli occurs, the nature of ►conditioned stimulus (CS) and ►unconditioned stimulus (US) encoding, and the rules for conditioned performance.

## Characteristics

### Conditions for Classical Conditioning

Many of the most important theoretical developments to have occurred in the field of associative learning find their origin in studies of the rules by which one event comes to be treated as a signal for the occurrence or omission of another event. What this work has suggested is that an association will not develop between two events simply because they were delivered contiguously in time. Three lines of research have contributed to dissatisfaction with the classical notion prevalent in philosophy, psychology and neuroscience of temporal contiguity as the principle governing the formation of associations.

#### *Cue Competition Effects*

Studies of cue competition or stimulus selection include ►blocking, ►overshadowing and relative validity effects. The Kamin blocking effect [1] is widely regarded as one of the principal challenges to a simple temporal contiguity learning rule. The original experiments showed that it was possible to prevent or block learning about the relation between a visual cue and shock despite the fact that they bore an adequate temporal relation simply by conducting those pairings in the presence of a previously established signal for the shock. Blocking has been replicated many times, in a variety of conditioning situations and with a range of species. A related phenomenon called overshadowing demonstrates that learning about a stimulus can also be reduced if its pairings with the US are carried out in conjunction with another neutral stimulus [1,2]. These cue competition effects demonstrate that despite perfect temporal contiguity between a CS and an US, learning about their relation may fail to occur.

#### *Contingency*

Another observation that contributed to the demise of a simple temporal contiguity principle was that the strength of an association was a function of the actual ►contingency between the two events and not the number of their pairings [3]. Learning about a stimulus was quite different in rats that experienced the same number of CS-US pairings but that received different rates of the US in the absence of the CS. When USs were presented only during the CS, that CS was treated as a good signal for the US. However, as the rate of USs in the absence of the CS approximated the rate during the CS, conditioning declined. This finding has also been replicated in different species and across a range of conditioning situations. Subsequent studies have found that signaling the US presentations that occur in the absence of the CS can restore conditioning to the CS further supporting the idea that contingency degradation operates by weakening the predictive value of the CS.

#### *Inhibitory Learning*

Just as important as procedures showing that learning may fail to occur despite temporal contiguity of the stimulus and the outcome is the finding that learning occurs under circumstances where the stimulus and the outcome are never presented at the same time. Such learning is described as inhibitory and is most powerful when a stimulus is presented at a time when an expected outcome is omitted. The Pavlovian ►conditioned inhibition paradigm [2] consists of a mixture of two trial types; on some trials a CS is paired with the US and on other trials, the CS is presented with another stimulus (conditioned inhibitor) and not followed by the US. Under these conditions, the conditioned inhibitor comes to signal that the US will not occur. There have been many replications of Pavlovian conditioned inhibition across a variety of species and conditioning preparations. For example, one study with rabbits found that a tone that had been nonreinforced in the presence of a light that signaled paraorbital shock came to suppress responding to that light. Moreover, the tone stimulus not only transferred its suppressive properties to another stimulus signaling the shock outcome (summation test) but was resistant to being trained as a signal for that outcome (retardation test).

The collective impact of these results was to highlight the inadequacy of the traditional temporal contiguity principle for the formation of associations. For classical conditioning to occur, a CS had to provide otherwise unavailable information about the US. For example, in the blocking paradigm, the added stimulus signaled no new information beyond that given by the previously trained stimulus; consequently it could not become associated with the US. Learning models were developed to incorporate the need for a mechanism superior to one that was only sensitive to the temporal relationship between the events to be associated but they did so by devising ingenious elaborations on the traditional contiguity-driven system.

### Theoretical Perspectives

Initially, two contrasting theories emerged to organize the empirical evidence that CS-US learning was not a straightforward function of CS-US contiguities. The ►Mackintosh model [4] attributed variations in learning about CS-US contiguities to variations in CS processing and the ►Rescorla-Wagner model [5] attributed them to variations in US processing. Revised

models and new theories have since followed to address the shortcomings of these approaches and to incorporate new empirical findings [6–10] but the Rescorla-Wagner model remains arguably the most influential theory of classical conditioning. This is due in part to the similarity between its discrepancy algorithm and the independently derived error-correction (delta) rule of many ►connectionist networks, and to the overall success of this approach to stimulus competition effects.

### The Rescorla-Wagner Model

Although the Rescorla-Wagner model retains the essential notion of CS-US temporal contiguity, it specifies the need for the contiguous US to be surprising, in other words not predicted by any other stimulus. At a casual level, surprise is represented as the discrepancy between what actually happened on a trial and what was expected. The cleverness of the theory lies in the development of a simple but elegant algorithm to determine just how surprising an outcome is.

According to the Rescorla-Wagner model, CS-US learning is represented as the associative strength of the CS ($V_{CS}$). The current associative strength of a CS is the accumulation of changes in its associative strength ($\Delta V_{CS}$) calculated on each trial that the CS was previously presented using the expression:

$$\Delta V_{CS} =_{CS} US(\lambda - V_T)$$

where $V_T$ represents the total or sum of the individual associative strengths of all CSs present on that trial; $\alpha$ and $\beta$ are fixed rate parameters determined by the salience (physical properties) of the CS and US, respectively; $\lambda$ is the maximum conditioning that the US can support.

The iterative application of this equation across a series of conditioning trials with a single CS produces a CS-US learning curve that follows a negatively accelerated path towards an asymptote. Increments in associative strength early in training are large relative to those on later trials because $V_T$ grows over training which reduces the size of the discrepancy ($\lambda - V_T$). The model also predicts that a trained CS will extinguish if it is repeatedly presented without the US. On extinction trials, the discrepancy term ($0 - V_T$) is initially negative and adjustments in associative strength will occur until $V_T$ is equal to zero. Empirical phenomena (spontaneous recovery and disinhibition) strongly suggest that ►extinction does not involve the erasure of original excitation but rather its masking by the acquisition of inhibition.

The Rescorla-Wagner model accounts for cue competition effects by including the associative strengths of all CSs present on a trial in the calculation of $V_T$. Blocking, for example, is attributed to the fact that prior training of one stimulus (A) in the compound (AX) causes $V_T$ to grow so that the discrepancy term ($\lambda - V_T$) is effectively zero on the first AX training trial. Consequently, there is no surprising US to condition X when it is paired with the US in the presence of A. Degradation of the CS-US contingency is treated as a special case of blocking by the context or background cues associated with the USs presented in the absence of the CS.

The Rescorla-Wagner model treats conditioned inhibition as the opposite of excitation. Thus, conditioned inhibition is characterized as the acquisition of net negative associative strength by the inhibitor. For example, on trials when the inhibitor is presented with a CS that has been paired with the US but no US is given, the discrepancy is negative ($0 - V_T$). The cumulative effect of these negative changes in associative strength is to drive the associative strength of the inhibitor from zero to a negative value that offsets the associative strength of the excitatory CS.

The Rescorla-Wagner model generated some novel predictions about classical conditioning that were subsequently confirmed by experiments. For example, CS-US learning is superior in the presence of an inhibitor (superconditioning). An inhibitory stimulus will also shelter a CS that is no longer paired with the US in its presence from undergoing a decrement in associative strength (protection from extinction). The model also correctly predicted a condition under which a CS will lose associative strength despite continued pairing with the US (overexpectation).

Subsequent research did not support the prediction by the Rescorla-Wagner model that a conditioned inhibitor would extinguish when repeatedly presented alone. Moreover, conditioned inhibition is no longer regarded as the opposite of excitation. Current research suggests that conditioned inhibition involves a modulatory process and is more properly conceptualized as the opposite of its positive counterpart known as facilitation or positive occasion-setting. There is debate about the locus of action of modulators; some data support the idea that modulators act as a gate on specific CS-US pathways whereas other data suggest that modulators act more generally by altering the threshold for US activation by a CS.

## The Nature of CS and US Encoding

There is general agreement that classical conditioning involves the ►acquisition of an association between internal representations of the CS and the US rather than the ►reinforcement or strengthening of an association between internal representations of the CS and a response. Random and explicitly unpaired control procedures are used to show that the changes in behavior to the CS result from its pairing with the US rather than from experience with the events per se. Other procedures (US devaluation, US inflation, transfer) are used to reveal the presence of a CS-US association and to shed light on the nature of the encoding of the US. Post-conditioning changes in the value of the US have specific and

appropriate effects on responding to the CS that was paired with that US. The transfer procedure demonstrates that a CS trained with one outcome has an effect on an instrumental response trained with that same outcome that is different from its effect on an instrumental response trained with a different outcome. The selectivity of such results reveals detailed learning about the sensory characteristics of the US in classical conditioning. Research has also shown that CS-US temporal arrangements and CS-US similarity relationships can influence which features of the US are selected for association with the CS.

The difference in theoretical approaches to encoding of the CS becomes apparent when the CS is a compound cue consisting of two or more stimuli. Elemental theories like the Rescorla-Wagner model [5] assume that the representation of a compound CS consists of the simultaneous activation of the representations of its constituent components. In contrast, configural theories like the Pearce model [10] assume that there is a single internal representation of the compound CS that is distinct from the representations of its constituent components. Neither approach has been completely satisfactory in predicting the results of the entire set of stimulus summation studies and all discrimination learning studies including negative patterning (the XOR problem) and CS similarity experiments. Further elaboration of the replaced elements model [6], a hybrid approach that blends configural and elemental encoding of the CS, promises to remedy the shortcomings of these elemental and configural models.

### Rules for Conditioned Performance

Expression of a ►conditioned response (CR) has generally been considered a simple direct function of the strength of the CS-US association. The Pearce model [10] departs slightly from this principle by asserting that conditioned responding is determined by the associative strength of the CS together with any generalized strength from other similar stimulus configurations. Other models [8,9] have developed predictive-driven performance rules to explain apparent failures of CS-US contiguities to produce learning. This approach has also been successful in addressing the temporal dynamics of conditioning. Among the regularities that have been observed is the fact that the speed of acquisition of conditioned responding is relatively constant for constant values of the intertrial interval/trial duration (ITI/TD) ratio.

## Definition

### *Theory of Mind*

Theory of mind denotes the conceptual system that underlies the ability to understand, predict and interpret the thoughts, feelings and behavior of self and others by reference to specific ►mental states (states of mind). Originally introduced by primatologists, the term "Theory of mind" (ToM) is used to refer to (1) the ability to impute mental states, i.e. to mentalizing or mind-reading (►Mentalizing, mind-reading), (2) the study of children's understanding of mind in developmental and cognitive psychology, and (3) the "Theory Theory" account of mental state attribution.

### *Theory Theory*

Theory theory accounts for the cognitive abilities of humans in terms of a body of implicit knowledge, constituted by a representational system in the form of law-like generalizations or ►innate mechanisms. The central claim is that this internally represented knowledge is theory-like, because it consists of an abstract, coherent and causal-explanatory framework that enables explanation and prediction.

In the Theory of mind, Theory Theorists claim that psychologically competent humans understand and predict thought and action by inferentially applying a body of implicit knowledge, a folk-psychological Theory of mind. On this view, the attribution of mental states both to self and others is based on knowledge of a theory, which deploys mental state concepts like perception, belief and desire within a network of causal-explanatory generalizations. The theory in question is conceived as a set of generalizations or laws for the deployment of mental concepts, as a theory analogous to any empirical scientific theory or as a special purpose body of knowledge in a mental ►module. However, all versions emphasize the inferential basis of mental state attribution.

### *Simulation Theory*

Simulation theory maintains that humans understand and predict others' mental states and behavior not by deploying a body of internally represented knowledge structured like a theory, but by employing their own cognitive capacities and mechanisms to mentally model others' cognitive processes. Simulationists claim that mental state attribution does not require theory-mediated inference. Rather, one uses one's own mental processes to simulate the other's mental processes, by pretending or imagining oneself to be in the other's position and then generating the thoughts or actions attributed.

## Description of Theory

### *Theory Theory in Philosophy*

The Theory Theory, originating in the philosophy of mind, claims that everyday mental state terms like "believe" or "want" denote theoretical concepts whose contents are fixed by the role they play in a substantive theory of the causal structure and functioning of the mind. The idea is that mental state terms and concepts are definable in terms of their connections to other concepts in a coherent theoretical framework, much as theoretical, non-observational terms and concepts are defined in science. On this view, the meaning of a term like "belief" and the content of the concept of belief are given by their role in common sense generalizations, or a collection of laws like "Seeing that $p$ leads to the belief that $p$" or "A person who wants $p$ and believes that $q$ is a means of obtaining $p$, will generally do $q$." These generalizations are taken collectively to form a naive theory, a ►folk psychology (common sense psychology, mentalistic psychology), which relates sets of mental states and specifies causal relations between these mental states, inputs from the environment and behavior.

To understand a mental concept like belief is to know a sufficient amount of the folk-psychological theory within which the concept is embedded. Philosophical theory theorists claim that ordinary people predict and explain behavior and mental states by inferentially applying the generalizations or laws of the common sense theory. The theory is conceived either as a set of folk-psychological generalizations or laws for the deployment of mental concepts in ►common sense functionalism (Folk Functionalism), or as an empirical theory like any other scientific theory.

### *Theory Theory in Psychology*

The Theory Theory approach in developmental and cognitive psychology evolved against the background of philosophical Theory Theory, applied to the question of whether children have a Theory of mind. Theory Theories of cognitive development construe everyday mental concepts as theoretical constructs, but differ from the philosophical Theory Theory in that they propose specific acquisition mechanisms.

Theory Theory in psychology encompasses two different and opposing accounts – the theory-formation

account and the modularity account. The scientific Theory Theory account claims that children construct theories of mental states that resemble scientific theories. Some proponents construe the acquisition process as analogous to theory construction and revision in science, while others take the end-state theory to result from the child's increasingly sophisticated capability to represent mental states. Innate module accounts of development hold that the child's Theory of mind results from the maturation of innate modules and processors which are part of humans' biological endowment, not from theorizing. Although both accounts claim that mental state attribution rests on internally represented knowledge which is theory-like, they disagree over its source, acquisition mechanisms and character.

### Scientific-Theory Theory

Often called the "child-as-scientist view," this version of developmental Theory Theory employs the model of scientific theory change to explain the acquisition of a Theory of mind. The basic claim is that children acquire a Theory of mind by deploying ►domain-general learning mechanisms, similar to the general theory-forming capacities employed by adult scientists. On this view, the everyday conception of the mind is an implicit naive theory, and children's conceptions of the mind are also implicit theories which posit mental state concepts as theoretical constructs to provide causal explanations and facilitate predictions. Changes in these conceptions are construed as theory changes, because concepts undergo theoretical revision by processes similar to those employed in scientific theorizing. It is claimed that the child's conceptual system changes in predictable ways when contrary evidence cannot be assimilated to the current conception, or when children acquire a more sophisticated capacity to represent mental states [1].

Infants start with initial innate theories, which are revised and restructured in the light of accumulating evidence. At 2 1/2 years, children are said to have nonrepresentational notions of desire and perception, which exclude the notion of misrepresentation or false belief. This explains their failure on ►false-belief tasks. Subsequently, children formulate a succession of implicit naive theories and revise them on the basis of evidence and experience to develop increasingly accurate Theories of mind. By the age of four, when the false-belief tasks are passed, normal children's Theory of mind is said to involve genuinely representational mental concepts like belief just as normal adults' implicit Theory of mind does.

The transitions from one developing Theory of mind to another are understood in analogy to transitions in scientific theorizing, like the development of the heliocentric theory of planetary movement from Copernicus to Kepler. New theories are inferred from accumulating evidence and change as a result of experience. Advocates of scientific Theory Theory argue that the child's understanding of mind is a theory, because it exhibits the characteristics of theoretical knowledge, e.g. it is coherent, exhibits a complex relation to evidence, postulates mental states as unobservable, explanatory entities, is defeasible and undergoes systematic changes [2]. The widely documented shift in children's ability to attribute false beliefs between two and four years of age is adduced as evidence for the theory-formation account.

### Modularity Theory

Modularity theories of the child's Theory of mind are construed as versions of Theory Theory, because they postulate a representational information base in innate mechanisms which is theory-like. However, they differ from the theory-formation view of development, because the core process is not theorizing, but biological maturation. Modularity theories take cognitive structures like the apparatus of mental state attribution to be the result of innately specified modules and developmental processes, not the product of an acquired theory. The child's Theory of mind is created from predetermined representations of input, triggered by experience from the environment, not developed from evidence. On this view, the Theory of mind is a ►domain-specific ability, supported by an innate, encapsulated and dedicated module, whose functioning is segregated from the other intellectual capacities of the individual.

Proponents of modularity differ in their views on modular mechanisms. The basic claim is that the Theory of mind is a special purpose body of knowledge contained in a mental module, which matures through a process of ►ontogenetic development and starts developing in infancy. It develops from the growth and functioning of one or more modules which come on-line as the child matures. The information in these modules is stored as special processing algorithms and/or as a set of mentally represented propositions. Innate processor theories postulate pre-specified processors which come on-line serially until the child arrives at mentalistic understanding of thought and action [3]. These processors take information about other's behavior as input and generate explanations and predictions as output. Another view attributes mentalizing abilities to a modular Theory-of-Mind-Mechanism (ToMM), which operates with innate concepts of pretense, belief and desire and produces domain-specific learning [4]. This mechanism is an information-processing device that computes data structures called ►metarepresentations, which relate agents to information. It is hypothesized to form the basis for ToM-acquisition. Mind-reading deficits in autism (►Autism (Autistic

Disorder, Childhood Autism)) are cited in support of the modularity account of development [5].

## Simulation Theory

There are different varieties of Simulation Theory, but all maintain that one uses one's own mental processes to attribute mental states to others without deploying theoretical knowledge. The central claim is that people use their own mental mechanisms to generate predictions and explanations of others' thoughts and behavior, drawing on their capacity to mimic or replicate others' reasoning and decision-making; they do not deploy a theory.

### *Simulation Theory in Philosophy*

In the philosophy of mind, mental simulation approaches argue that one need not employ a Theory of mind to understand and predict others' behavior. Instead, one uses one's own mind as a model for understanding the minds of others, e.g. by pretending or imagining oneself to be in their situations and using one's own mental mechanisms to generate the thoughts and actions attributed to the other within a simulation. Approaches differ as to whether simulation involves introspective access to one's own mental states, analogical inference, prior possession of mental state concepts or automatic, non-conscious processes. Some proponents do not consider simulation an empirical thesis, but most take empirical findings to be relevant to claims about simulation processes and mechanisms.

On the ►introspection-simulation approach, one attributes mental states to others by using one's own cognitive and inferential mechanisms to match those of the other person [6]. In a simulation, one's cognitive system operates off-line on pretend or surrogate states and does not issue in action. No knowledge of how the system works is required; one must only possess such a mechanism and be able to feed in appropriate inputs and to construe its outputs. To determine what decision someone will take, one feeds pretend beliefs and desires into one's practical-reasoning system, which operates off-line and generates further mental states as outputs. The output of the simulation process provides the basis for attributing a decision to another. The simulation terminates in an inference from oneself to the other, in which one infers the other's mental state from one's recognition of the pretend state which issues from simulating the other. This version of simulation assumes a prior understanding of mental state concepts, and proposes an account in terms of introspection or self-monitoring. The existence of neonate imitation and ►mirror neurons are cited in support.

The non-introspectionist version of simulation claims that one makes other-attributions by re-centering one's cognitive map and imaginatively identifying with the other. The belief or decision generated within the scope of simulation is directly attributed to the other [7]. On this view, an egocentric shift on the part of the attributor lies at the core of simulation, not introspection coupled with analogical inference; one imagines oneself to be the other who is acting in a particular situation. After imaginative transformation, attributing a mental state to another is a case of mental "self"-attribution to oneself-as-the-other within the context of simulation. The notion of an "ascent routine" is introduced to obviate the need for introspection and prior possession of mental state concepts. An ascent routine is a procedure which allows one to get the answer to a question about one's own mental states by answering a question that is not about a mental state, e.g. answering the question "Do you *believe* that Mickey Mouse has a tail?" by answering a question about the world, "*Does* Mickey Mouse have a tail?". Non-introspectionist Simulation Theory claims that embedding an ascent routine within a simulation of another allows one to attribute mental states to the other directly without theorizing.

### *Simulation Theory in Psychology*

In developmental psychology, the simulation account of the child's understanding of the mind emphasizes the role of subjective experience and imagination in explaining and predicting thought and action. Proponents argue that children use their first-hand experiences of beliefs, desires and perceptions in imagination to understand the minds of others, not a theory [8]. They propose that children develop an understanding of mental states through their direct, personal experiences of them, i.e. through introspection. Such experiences are of the child's own mental states; they are not theoretical constructs. On this view, children use introspective access to their own mental states and the exercise of the imagination to make mental state attributions; theory and inference are not required.

## Hybrid Theories

Theory Theory and Simulation Theory were originally conceived as competing empirical accounts of mentalizing abilities, which necessarily exclude each other. It was assumed that either Theory Theory or Simulation Theory would prove correct. In recent years this assumption has been revised in the face of mounting evidence that mentalizing abilities and deficits are complex and multifaceted phenomena. A number of accounts have been proposed, which combine aspects of Theory Theory and Simulation Theory [9,10]. These hybrid theories suggest that humans' ability to understand and predict mental states and behavior are subserved by several different processes. Some aspects of mentalizing may rely on simulation processes, others on bodies of knowledge based on general learning mechanisms or embodied in modules, and still others on neurophysiological mechanisms.

## Threshold Control in Motor Control

### Definition
Centrally-elicited changes in the threshold configuration of the body or its segments, i.e., the configuration at which activity of muscles is nullified but any deviations from this configuration meet active muscle resistance; underlies posture and movement control; a major empirical observation underlying the λ model for motor control; a solution to the posture-movement problem.

►Equilibrium Point Control

## Threshold in Psychophysics

### Definition
The minimum of stimulus intensity required to elicit a percept (absolute threshold) or to just notice a change of a given percept or between two percepts (difference threshold).

►Psychophysics

## Threshold Tests

### Definition
One way of testing olfaction is to present an odorant in very low concentration which is hardly smelt by the

subject. If the subject is repeatedly able to detect the odor, he is presented an even lower concentration up to the moment when he does not detect the presence of an odor anymore. Then the odorant concentration which is presented is increased again until the subject detects it presence again. This procedure is done several times. This leads to an up and down around a concentration which is called the threshold. The threshold concentration of an odorant is the minimal required concentration at which it can reliably be detected by a subject. The threshold test indicates that threshold vary among people and are different between different odorants.

### Definition

Acquired disease secondary to hyperthyroidism (predominantly in Asian populations) and results from a sudden shift of $K^+$ into the cells, which leads to hypokalemia and muscle weakness. The pathophysiology is not well understood.

## Thyrotropin Releasing Hormone

### Definition

A tripeptide with hormonal and neuromodulatory actions.

## TIA (Transient Ischemic Attack)

### Definition

ATIA is like a temporary ischemic stroke. An artery is temporarily blocked, preventing blood from reaching a part of the brain. This lack of blood flow causes that part of the brain to stop functioning, producing the symptoms. The symptoms of a TIA are the same as symptoms of an ischemic stroke. In a TIA, the blood vessel opens up again, before any permanent injury to the brain occurs and the patient recovers completely. Most TIA symptoms last less than 30 minutes, but by Definition, all deficits must have cleared within 24 hours.

►Ischemic Stroke
►Stroke

## Tic Douloureux

### Definition

Also known as trigeminal neuralgia, sudden onset stabbing excruciating pain occurs in attacks lasting from less than 1 s to 2 min several times a day. Location is usually in the trigeminal distribution of V2 or V3.

►Headache

## Tics

### Definition

Brief coordinated movements that are repetitive though irregular, e.g., winking, shrugging.

## Tilt Reaction

### Definition

Activation of body and/or eye muscles induced by whole-body tilt.

►Vestibulo-Spinal Reflexes

►Temporal Coding in Electroreception

## Time Constant in Eye Movement

### Definition

The time course of changes in eye position or the firing rate of neurons can sometimes be described mathematically by an exponential, $X = X_0\, e^{-(t/T)}$, where X is the position or firing rate, $X_0$ is the initial value of X, t is time, and T is the "time constant" of the exponential.

The time constant is equivalent to the amount of time required for X to decay to 36% (1/e) of $X_0$.

## Time Constant in Membrane Biophysics

### Definition

The time constant of a cell membrane is determined by the product membrane resistance and membrane capacitance. The time constant determines how rapidly the membrane potential can change in response to a current injection, or to synaptic inputs. The time constant is measured from voltage trajectory in response to a current step from the resting potential.

# Tolerance and Dependence

MacDonald J. Christie
Pain Management Research Institute, Kolling Institute, The University of Sydney at Royal North Shore Hospital, St Leonards, NSW, Australia

## Definition

The clinical utility of many psychoactive drugs is limited by development of tolerance and dependence during chronic use. Tolerance and dependence contribute to the induction and maintenance of ►drug addiction. ►Drug tolerance is defined by a reduced responsiveness of the organism to the drug, usually manifest by the need to use increasing doses to achieve the desired effect. Use of the term drug tolerance usually refers the long-term loss of responsiveness that develops after days to weeks of drug use. "Acute" tolerance, which develops rapidly (seconds to minutes) during the course of a single episode of ►drug intoxication is often explained by rapid mechanisms of ►receptor desensitization and/or ►internalization but other homeostatic processes can also be involved. ►Drug dependence often (but not always) develops in parallel with tolerance. Dependence is defined by the emergence of a ►withdrawal syndrome, usually aversive, upon cessation of chronic drug use. Specific withdrawal syndromes are characteristic of the class of drug used and are known to result from unmasking of neural adaptations that have developed to achieve homeostasis during chronic drug use. For the major drugs of ►addiction, withdrawal symptoms almost invariably include craving which can be very persistent.

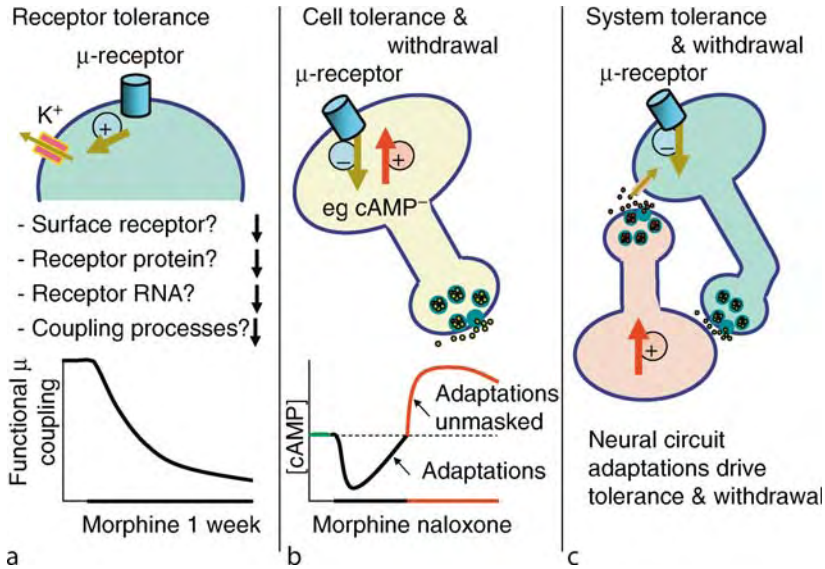
## Characteristics

### Quantitative Description

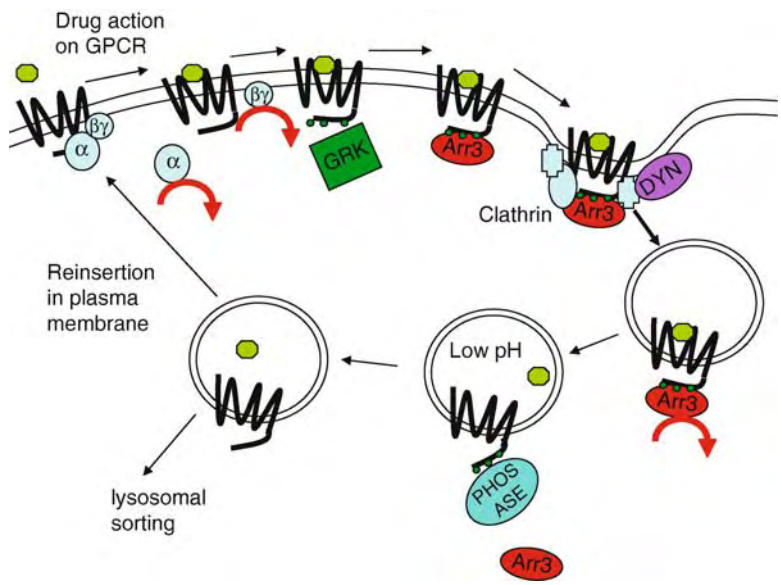
Tolerance results from adaptive mechanisms at the level of the drug target (receptor), as well as at the cellular, synaptic and network levels, where adaptive changes occur due to homeostatic mechanisms tending to restore normal function in spite of the continued perturbations produced by the drug. Metabolic tolerance, usually due to hepatic enzyme induction makes a minor contribution to behavioural tolerance for some drugs, eg. ►alcohol. Associative, or conditioned tolerance, where drug use is always paired with a distinctive environment also plays an important role and is mediated by specific neural systems in behaving animals. While the present discussion is confined to tolerance, it should also be noted that some behavioural responses to drugs are enhanced (►sensitization) with chronic use which is thought to contribute to drug addiction [1].

Tolerance can arise from metabolic depletion of ►neurotransmitters or neurotoxicity. Some drugs, most notably 3,4-methylenedioxy ►methamphetamine (MDMA or ►ecstasy) produce profound tolerance via neural metabolic mechanisms [2] that involve depletion of the target neurochemical and anatomical structures, ►serotonin and serotonin containing nerve terminals (see Chapter on Stimulants). MDMA acts principally by releasing serotonin from nerve terminals in the brain. Acute doses of MDMA profoundly deplete serotonin from nerve terminals. Replenishment is thought to be delayed because MDMA also inhibits tryptophan hydroxylase, a key serotonin synthesizing enzyme. In animal models (and probably humans) MDMA damages serotonergic nerve terminals, which partially or fully recover function over periods of weeks to months. The substantial tolerance that develops after single or repeated doses of MDMA persists for weeks and is almost certainly due to these mechanisms. Tolerance to some other drugs that release ►brain monoamines, such as methamphetamine may, in part, involve similar mechanisms.

Adaptive mechanisms at multiple levels of organisation of the nervous system can contribute to tolerance. These can be roughly divided into the three kinds of adaptive processes outlined in Fig. 1. In panel A of Fig. 1, "receptor tolerance" refers to loss of responsiveness of the target receptor over time. For ►G-protein coupled receptors (►GPCRs), loss of function of the receptor may be due to reduced receptor expression on the cell surface or loss of functional coupling to effectors, such as ►potassium-selective channels in the case of opioid drugs interacting with the μ receptor [3]. Loss of cell surface receptor expression over periods of days to weeks, termed ►downregulation, can arise from multiple cellular mechanisms. Receptor activation of many GPCRs, particularly by high agonist concentrations induces their internalization and recycling (see Fig. 2). A net loss of surface receptors may occur during agonist stimulation because a large proportion of receptors may be in the intracellular stage of the cycle at any one time, particularly when tolerance is already profound and receptor occupancy is high. Disruption of capacity of ►μ-receptors to internalize by germline knockout of a key protein in the pathway, β-arrestin (Arrestin 3), prevents opioid tolerance development [4], suggesting this process is important for behavioural expression of tolerance. A net loss of receptor protein can also develop because a proportion of receptors internalized during each cycle are targeted to lysosomes for degradation. Some GPCR agonists stimulate receptors strongly but do not activate internalization cascades and produce little downregulation. For example, morphine and etorphine are both efficacious μ-receptor agonists but morphine only very weakly induces internalization [5]. This difference has been postulated to produce differences in rate or extent of tolerance development [5]. Chronic treatment



**Tolerance and Dependence. Figure 1** Uses the example of opioid tolerance at μ-opioid receptors to show the general levels of neural organization where tolerance develops. In Panel A tolerance can arise from a direct loss of target receptor function, which can be due to any of the mechanisms listed. In Panel B adaptive processes within the cell, either downstream of the receptor or via general cellular homeostatic mechanisms, adapt to chronic perturbation to restore (near) normal function. On removal of drug, or application of receptor antagonists (naloxone for μ-receptors) these adaptations rebound to cause cellular withdrawal. In Panel C broader homeostatic adaptations can develop throughout neural networks to produce tolerance and then withdrawal on removal of drug.



**Tolerance and Dependence. Figure 2** Shows the general cycle of GPCR cycling that can contribute to desensitization and downregulation [4]. Red arrows indicate points in the cycle where active receptor signaling occurs (G protein α and βγ subunits signal to many effectors such as potassium channels, calcium channels and adenylyl cyclase, and the receptor-β-arrestin (Arr3) complex signals through other effectors). G-protein receptor kinase (GRK) phosphorylation is thought to initiate desensitization, following which Arr3 associates, driving dynamin (DYN) dependent endocytosis. It should be noted that the details of these signaling processes have not been fully established for all of the GPCRs relevant for addiction or clinically.

with etorphine produces moderate downregulation of μ-receptors but morphine does not, possibly because a small proportion of μ-receptors are degraded during each internalization cycle driven by etorphine but not by morphine. It should also be noted that alternatively spliced GPCRs, which often vary in the C-terminal domains involved in association with ►receptor trafficking proteins may be cycled at different rates. Tissue specific expression of splice variants could therefore differentially affect tolerance development in different neural systems. Other GPCRs, for example the ►cannabinoid receptor (CB1), are preferentially targeted to lysosomes after internalization. Tolerance to ►cannabinoids may be largely due CB1 receptor degradation by lysosomes and is prevented by blockade of lysosomal targeting the receptor [6] (see Chapter on Cannabinoids). For some GPCRs persistent activation may decrease mRNA synthesis although this has generally been found not to be the case for many receptors including the μ-receptor (author to correct).

For ►ionotropic receptor agonists, most notably nicotine, receptor tolerance and its contribution to dependence is very complex [7]. Neuronal ►nicotinic receptors are composed of varying combinations of multiple subunits that a differentially expressed in the nervous system. Different subunit combinations have different rates of rapid receptor desensitization. Paradoxically, chronic nicotine treatment increases cell surface expression of some subunits but this is thought to occur because receptors accumulate at the cell surface in a persistently desensitized state.

Panel B of Fig. 1 illustrates cellular tolerance using cyclic-AMP (►cAMP) as an example of a specific set of adaptations that develop downstream of receptor activation. Inhibitory GPCRs interacting with the Gi/o class of ►G-proteins that couple to inhibition of ►adenylate cyclase activity thereby reducing cAMP concentrations (e.g. all ►opioid receptors, ►dopamine D2 and cannabinoid receptors) produce adaptive superactivation of adenylate cyclase with chronic drug exposure [8]. Depressed cAMP concentrations return to normal during continued exposure to the drug because adenylate cyclase is superactivated. Other components of the cAMP and ►cAMP-dependent kinase (protein kinase A; ►PKA) cascade (e.g phophodiesterases) also appear to adapt to return cAMP concentrations to normal. Downstream effectors of cAMP therefore develop tolerance. Chronic disturbances of ►cAMP-►PKA activity and other protein kinases downstream from receptor activation can produce myriad cellular adaptations. Considerable attention has focussed on transcriptional control via phosphorylation state of the ►cAMP response element-binding protein (CREB), which affects protein synthesis of neurotransmitter receptors, adenylate cyclase isoforms and other signaling proteins [1,8,9]. Cycles of intoxication and withdrawal may produce different adaptations than persistent drug exposure via these mechanisms. Cellular adaptations are not limited to events downstream of the receptor. Other homeostatic mechanisms, such as altered transmembrane chloride gradients, calcium homeostasis or synaptic structure and strength of synaptic transmission, are activated within neurons by the persistent changes in neural excitability produced by various drugs [10].

System tolerance and withdrawal is shown in Panel C of Fig. 1. Homeostatic adaptations to neural firing, synaptic strength and neurochemical balance can develop throughout neural and neuron-glial networks to compensate for depressed or enhanced activity produced by chronic drug exposure of one component of the network [10]. For some signaling systems quite specific antagonistic or compensatory neural mechanisms have been postulated. For ►μ-opioids, various peptide containing neural systems have been proposed to function as "anti-opioid" systems including the ►dynorphin-κ-opioid system, ►neuropeptide FF, orphanin FQ/nociceptin and cholecystokinin [5]. Such systems may develop compensatory or functionally antagonistic actions during morphine tolerance development to mediate tolerance.

Drug dependence and the emergence of a ►withdrawal syndrome on cessation of drug use (or administration of drug antagonists) are believed to result from many of the adaptations described above. Receptor tolerance (Panel A, Fig. 1) is largely passive in terms of development of dependence for receptor systems that exhibit low or subtle basal activity. For example, μ-receptor tolerance can be dissociated from dependence under some circumstances because simply reducing sensitivity of the receptor does not produce withdrawal rebound on cessation of drug use. For neural systems where tonic activity of the receptor in question is critical for normal function, eg. ►$GABA_A$ receptors, loss of receptor sensitivity can contribute substantially to withdrawal. Loss of $GABA_A$ receptor function associated with alcohol tolerance almost certainly contributes to reduced ►seizure threshold and other signs of the ►alcohol withdrawal syndrome. Partially restoring $GABA_A$ receptor function during withdrawal using benzodiazepines attenuates many of these signs and symptoms.

Adaptations downstream from receptor activation, or receptor independent homeostatic adaptations in neurons or neural networks produce drug withdrawal signs and symptoms, which can be very persistent. During opioid withdrawal, rebound elevation of cAMP signaling mechanisms drive withdrawal behaviour (See Panel B, Fig. 1, [3]). Similar mechanisms are also likely to occur for other GPCRs that couple to inhibition of adenylate cyclase [3]. Multiple downstream or circuit adaptations may persist for weeks to months or years

after cessation of drug use. Some are of a general structural nature, such as altered neuronal and synaptic architecture, dendritic morphology and axonal branching may be driven by transcriptional effects of phospho-CREB, other phosphorylation-transcriptional cascades or neuron-glial interactions [1,8–10].

# Toll-like Receptor

## Definition

The Toll-like receptors (TLRs) are transmembrane proteins that recognize pathogens and activate immune cell responses. TLRs are activated following the binding of small, conserved molecular sequences found on pathogens called pathogen-associated molecular patterns or PAMPs.

# Tonic Activity of Sympathetic Nerves

Gerard L. Gebber
Department of Pharmacology and Toxicology, Michigan State University, East Lansing, MI, USA

## Definition

"Tonic" refers to a state of continuous activity that exists in both the sympathetic and parasympathetic divisions of the autonomic nervous systems under a wide variety of conditions. Strictly defined, "autonomic" or "autonomous" signifies independence or freedom from control by external forces. In actuality, this definition should not be applied to pre- and postganglionic autonomic neurons because their tonic discharges are synaptically driven. In the case of the sympathetic division, many of the inputs that are now referred to as "presympathetic" originate in the brainstem.

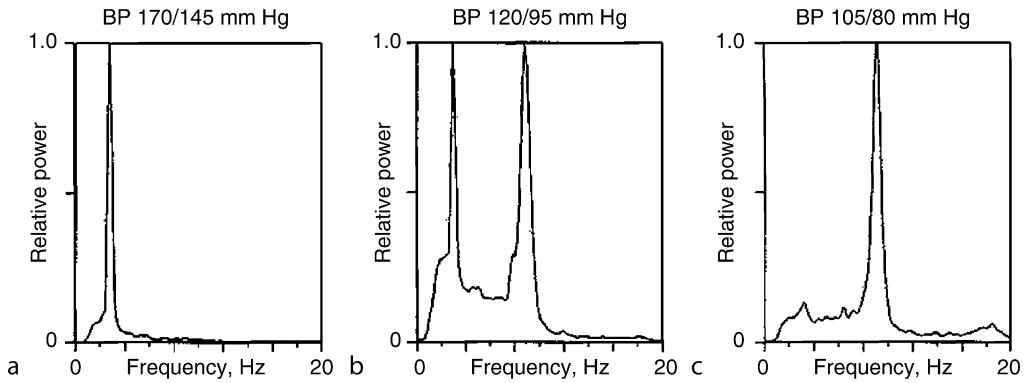
This essay deals exclusively with the tonic activity of sympathetic nerves with cardiovascular targets.

## Characteristics

### Quantitative Description

Recordings from pre- and postganglionic sympathetic nerve bundles with cardiovascular targets reveal a complex and variable mixture of rhythmic and aperiodic components. Depending upon experimental conditions, rhythmic discharges with frequencies equal to or less than that of the respiratory rate, and equal to or higher (~10 Hz) than the heart rate have been observed in several species. The rhythmic discharges are superposed on a background of ►broad-band noise whose nature will be discussed later in this essay.

Fast Fourier transform is used to decompose sympathetic nerve discharge (SND) into its frequency components. The results are depicted as a ►power density spectrum, in which power (watts) of the signal is plotted as a function of frequency. Figure 1 shows a series of power density spectra of inferior cardiac



**Tonic Activity of Sympathetic Nerves. Figure 1** Frequency composition of naturally occurring discharges recorded from inferior cardiac postganglionic sympathetic nerve at three different blood pressure levels (in mmHg) in a urethane-anesthetized cat. Each of the power density spectra of inferior cardiac sympathetic nerve discharge (SND) is an average 32 5-s windows with a frequency resolution of 0.2 Hz per bin. Relative power on a scale of 0–1.0 is plotted as a function of frequency.

postganglionic SND obtained at different blood pressure levels in a urethane-anesthetized cat.

The respiratory-related rhythm in SND was purposely filtered from this recording to draw the reader's attention to the two more rapid (cardiac-related and 10 Hz) rhythms. The frequency composition, as well as the absolute power of SND, is highly dependent upon the level of negative feedback from the arterial baroreceptors to the central generators. When negative feedback was very strong at a high blood pressure level (170/145 mmHg), almost all of the power in SND appeared in a peak at the frequency (~3 Hz) of the heart beat (Fig. 1a). When blood pressure was lowered to 120/95 mmHg, thereby reducing the negative feedback, a ~10-Hz rhythm appeared in combination with the cardiac-related rhythm (Fig. 1b). Moreover, these rhythms were superposed on a broad-band of background noise. Total absolute power was increased as expected when baroreceptor-mediated central inhibition of SND is reduced. Further lowering of blood pressure to 105/80 mmHg all but eliminated the cardiac-related rhythm, but led to a further increase in 10-Hz as well as broad-band power (Fig. 1c). The changes in absolute power in these bands are not directly evident because power in each of the spectra is normalized on a scale of 0–1.0.

## Higher Level Structures

As first observed in Ludwig's laboratory in the nineteenth century [1], blood pressure in anesthetized animals is little affected by midbrain transection at the midcollicular level (i.e. decerebration), but is profoundly reduced by transection of the cervical spinal cord. The fall in blood pressure is attributable to the loss of tonic SND generated in the lower brain stem. As reviewed below, the mechanisms involved in generating tonic SND remain controversial. Information on the influences exerted on SND by peripheral afferents and forebrain regions is beyond the scope of this essay. These subjects have been reviewed by Sato and Schmidt [2] and in the book edited by Loewy and Spyer [3].

## Lower Level Components

The properties and anatomical distribution of pre- and postganglionic sympathetic neurons are described in the book edited by Lopwy and Spyer [3].

## Higher Level processes

Chemical inactivation of an anatomically circumscribed region of the rostral ventrolateral medulla (RVLM) by microinjection of the γ-aminobutyric acid (GABA) agonist, muscimol, leads to reductions in SND and blood pressure to levels approaching those observed after cervical spinal cord transection. Thus, the integrity of the RVLM is essential for maintenance of the normotensive state. Neurons in the RVLM send their axons to the intermediolateral cell column (IML) of the thoracolumbar spinal cord, which contains the somata of the preganglionic sympathetic neurons.

Two contrasting views have been offered on the origin of the discharges of RVLM presympathetic neurons and, thus, tonic SND. The view of Guyenet et al. [4] is based on data from the rat. They found that some RVLM presympathetic neurons exhibit endogenous ►pacemaker properties, leading to clock-like discharges at a frequency near 20 Hz either in slice or after blockade of excitatory synaptic transmission in vivo with kynurenate. On this basis, they attribute tonic SND, at least in part, to RVLM pacemaker neurons, and ascribe the cardiac- and respiratory-related rhythms in SND to resetting of pacemaker discharges by synaptic inputs from baroreceptor circuits and the respiratory oscillator.

In contrast, Barman and Gebber [5] have proposed that the rhythmic components of SND in the cat are generated by networks of anatomically distributed brain stem neurons of different types, none of which necessarily has pacemaker properties. They view the rhythmic components of SND as arising in ►network oscillators that may become entrained to their baroreceptor and respiratory inputs under some conditions and not in others. The neurons comprising the network oscillators are located in at least four distinct regions of the medulla oblongata. These are the RVLM, caudal ventrolateral medulla (CVLM), lateral tegmental field (LTF) and raphe nuclei. Those in the RVLM and raphe send their axons to the IML, whereas LTF and CVLM do not. Antidromic mapping has been used to trace the axons of the LTF neurons to the RVLM and raphe. Barman and Gebber [5] have reviewed the interconnections of the four cell groups and the methodology used to demonstrate correlation of their discharges to the cardiac-related and/or 10-Hz rhythms in SND. Strikingly, none of the medullary neurons in the cat with sympathetic nerve-related activity exhibit the clock-like activity expected of pacemaker neurons. Rather, cat medullary neurons with activity correlated to the cardiac-related and/or 10-Hz rhythms miss firing in a variable number of cycles of postganglionic SND. As a consequence, interspike intervals are quite variable as evidenced by their exponential or γ-like distributions. Thus, the strong rhythms characteristic of SND are not readily apparent at the level of the single neurons comprising the generators of the cardiac-related and 10-Hz rhythms. Rather, the rhythms in SND appear to be ►emergent properties of brain stem networks composed of irregularly firing neurons. Figure 2 illustrates this point.

Bursts of postganglionic inferior cardiac nerve activity were locked 1:1 to the arterial pulse in this baroreceptor-intact cat (Fig. 2a). The cardiac-related rhythm, however, was not readily apparent in the spike train of a LTF neuron whose activity was recorded along with SND. Note that the LTF neuron missed firing in a variable number of cardiac-related bursts of SND (Fig. 2a). As a consequence, the interspike interval histogram for this LTF neuron was γ-like in shape (Fig. 2b). Nonetheless, the LTF spike-triggered average of SND (Fig. 2c) and the ►coherence function relating LTF unit activity to SND (Fig. 2e) demonstrated that the two signals were correlated. When active, the preferred firing time of the LTF neuron was near the beginning of the rising phase of the cardiac-related burst of postganglionic SND (Fig. 2c). It follows that the strong rhythm in SND emerges from the synchronized discharges of a small and continuously changing segment of the total population of such brain stem neurons.

The debate on whether the rhythmic components of SND are generated by cellular pacemakers or network oscillators likely will continue for some time. Regarding the pacemaker theory of Guyenet et al., Lipski et al. [6] have argued that RVLM presympathetic neurons are normally synaptically driven rather than intrinsically active. Specifically, their intracellular recordings made in vivo from rat RVLM neurons did not show pacemaker potentials in preparations in which their synaptic inputs were left undisturbed. The implication of this finding is that the pacemaker potentials recorded intracellularly from these cells in slice are not normally involved in generating SND.

In the cat, LTF neurons projecting to the RVLM fire earlier during the cardiac-related burst of postganglionic SND than do RVLM-spinal neurons projecting to the IML [5]. Thus, it is unlikely that the cardiac-related rhythm is generated by RVLM pacemaker neurons. Nonetheless, the existence of a pacemaker mechanism has not been absolutely ruled out in the cat. It is possible that the brain stem networks described by Gebber and Barman's group are driven by pacemaker neurons located in an as of yet unexplored region of the cat brain stem.

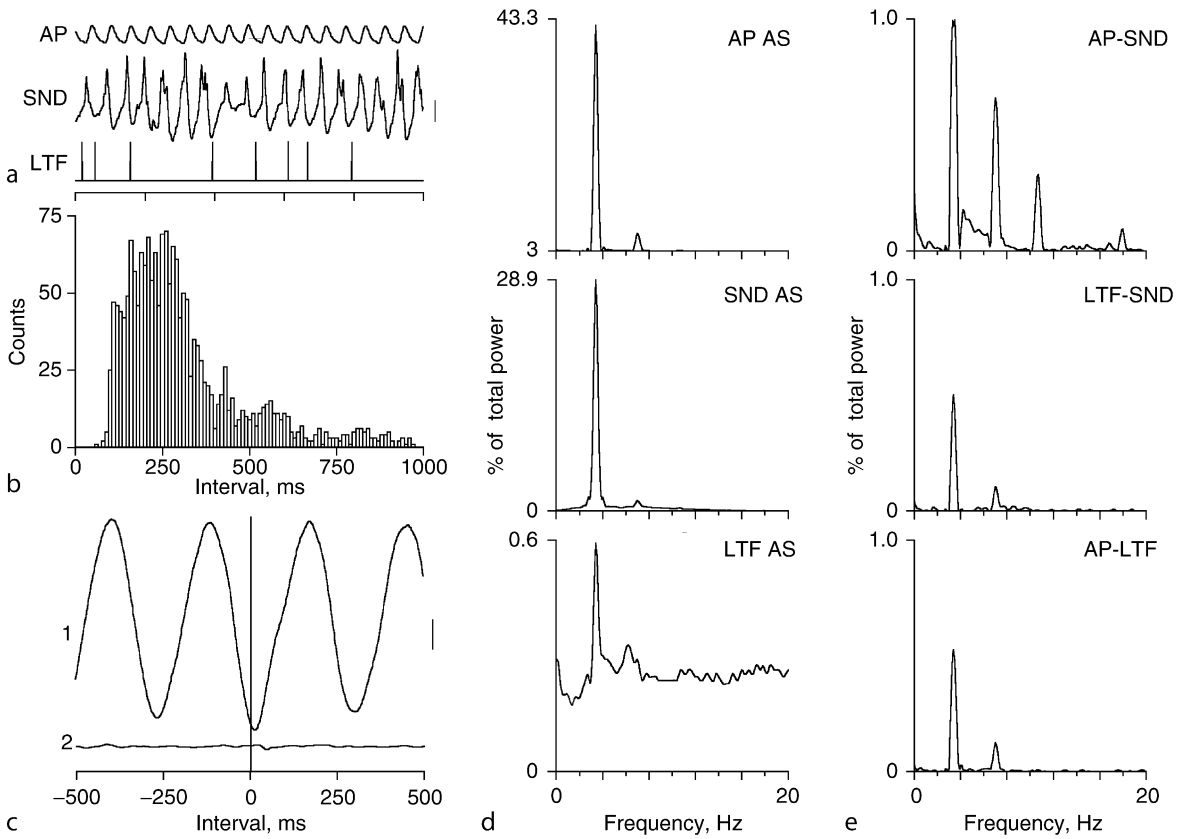
As already mentioned, the rhythmic components of SND are superposed on a broad frequency band of background noise. The characteristics of the noise in SND have recently come under scrutiny. Two possibilities have been considered to explain the noise. The first is that the noise might be a ►random process comprised of uncorrelated events. The second possibility is that long-term correlations exist among the fluctuations in brain stem unit interspike intervals, population burst intervals and/or burst amplitudes. If the correlations extend over more than one time scale, the fluctuations would be best modeled as a ►fractal process in which the current value of the measured parameter is related to those in the distant past (i.e. long-term memory exists). Gebber and Barman [7] have reviewed the analytical techniques used to distinguish between random and fractal processes. They and their colleagues have provided conclusive evidence that the broad-band components in the SND are fractal rather than random in nature. The physiological implications of this finding are dealt with later in this essay.

## Lower Level Processes

The level of the tonic SND after acute cervical spinal cord transection is only a small fraction of that present in animals with an intact neuraxis. Residual SND in spinal cats is broad-band in frequency and lacks rhythmic components. Whereas the level of residual SND is low, the importance of spinal circuits in mediating changes in SND and blood pressure produced by activation of somatic and visceral afferent nerves is clear [2].

## Function

Because blood pressure is significantly reduced to hypotensive levels after cervical spinal cord transection, the importance of the continuous state of activity in the



**Tonic Activity of Sympathetic Nerves. Figure 2** Coherence of the discharges of a single neuron in the medullary lateral tegmental field (LTF) to the cardiac-related rhythm in inferior cardiac SND of a barbiturate-anesthetized cat. (a) traces (top to bottom) are oscilloscopic records of the femoral arterial pulse (AP), SND, and standardized pulses representing the action potentials of the LTF neuron. Time marker is 1 s/division; vertical calibration is 40 μV. Blood pressure was 145/105 mmHg. (b) interspike-interval histogram for this LTF neuron, bin width is 10 ms. (c) averages of SND triggered by the spikes of the LTF neuron (1) and random pulses (2), each series containing 1,622 events; bin width is 5 ms. (d) power density autospectra (AS) of AP, SND, and LTF unit activity. (e) coherence functions relating pairs of signals. The autospectra and coherence functions are averages of 125 5-s windows with a frequency resolution of 0.2 Hz per bin (reproduced from Ref. [5] with the permission of Sage Publications, Thousand Oaks, CA).

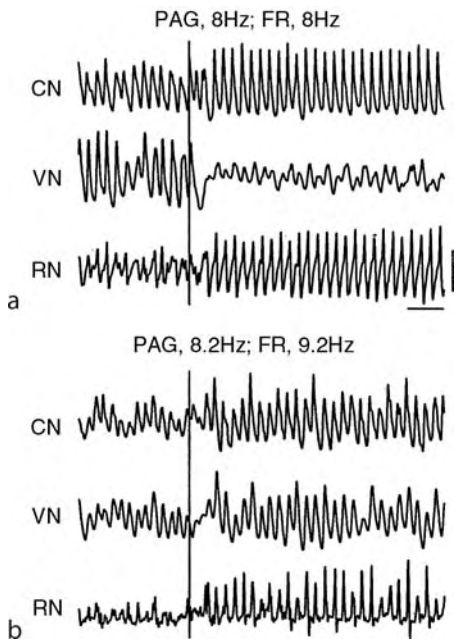
sympathetic nervous system is unquestioned. However, there is no general agreement currently as to whether one or another component (rhythmic or aperiodic) provides additional benefits. Some investigators view the rhythmic components as epiphenomena in the sense that they reflect the fundamental organization of the networks generating SND, but subserve no special role in cardiovascular regulation. However, others have proposed that the networks generating the rhythmic components of SND serve as the substrate for formulation of highly differentiated patterns of spinal sympathetic outflow. One such response pattern is the ►defense reaction whose cardiovascular components include an increase in blood pressure and heart rate, decreased blood flow to viscera due to vasoconstriction and increased blood flow to skeletal muscle due, in part, to a reduction in vasoconstriction sympathetic outflow to that tissue [8].

The mechanisms responsible for the increases in sympathetic outflows to the heart and vasculature of the viscera in the face of decreased vasoconstrictor outflow to skeletal muscle has been the object of recent investigation. The classic view that this pattern involves activation of a point-to-point hard-wired pathway, which excites some sympathetic outflows while inhibiting others, has been questioned. The model offered by Gebber and Barman [9,10] attributes the defense reaction and perhaps other highly differentiated cardiovascular response patterns to the dynamic reorganization of the strong coupling of multiple brain stem oscillators responsible for the 10-Hz rhythm in SND. The model is briefly described here.

Rather than arising from a single source, the 10-Hz rhythm is generated by a family of dynamically coupled brainstem oscillators, each of which primarily controls a different portion of the spinal sympathetic outflow and, thus, a different cardiovascular target. The defense reaction is viewed as an ►emergent property of the system of strongly coupled 10-Hz oscillators. More specifically, the ►phase relations among the coupled oscillators are considered as an important determinant of relative 10-Hz burst amplitudes in different sympathetic nerves. Switches from one pattern of spinal sympathetic outflow (e.g. defense-like) to another (e.g. generalized increase in sympathetic outflow) is envisioned to occur when the level of some ►nonspecific control parameter (e.g. inputs from the defense region of the midbrain periaqueductal gray (PAG)) reaches a critical point at which the phase relations among the coupled oscillators are abruptly changed. Importantly, increased phase lag of one oscillator relative to another leads to a decrease in the output of the lagging oscillator and, thus, vasodilatation due to reduced vasoconstrictor outflow to its target organ. The basic observations leading to this model are presented in Figs. 3 and 4.

In anesthetized cats, the sympathetic and cardiovascular components of the defense reaction can be simulated by electrical or chemical activation of the midbrain PAG. Strikingly, whether or not electrical activation of the PAG elicits a defense-like reaction is dependent upon the frequency of stimulation relative to that of the free-running (unstimulated state) 10-Hz rhythm. The amplitude of 10-Hz bursts of activity in the sympathetic nerves to the heart (CN) and kidney (RN) was increased when the frequency of electrical stimulation was equal to or greater than that of the free-running 10-Hz rhythm. In contrast, the amplitude of 10-Hz bursts in the vertebral sympathetic nerve (VN) to the vasculature of forelimb skeletal muscle was decreased (Fig. 3a). These changes were accompanied by an increase in the phase lag of VN 10-Hz activity relative to that in the CN and RN (Fig. 4). Importantly, when the same PAG sites were electrically activated using a frequency slightly below that of the free-running rhythm, a generalized increase in the 10-Hz discharges occurred in all three nerves (Fig. 3b). Under these conditions, the phase relations among the 10-Hz discharges of the three nerves were unchanged.

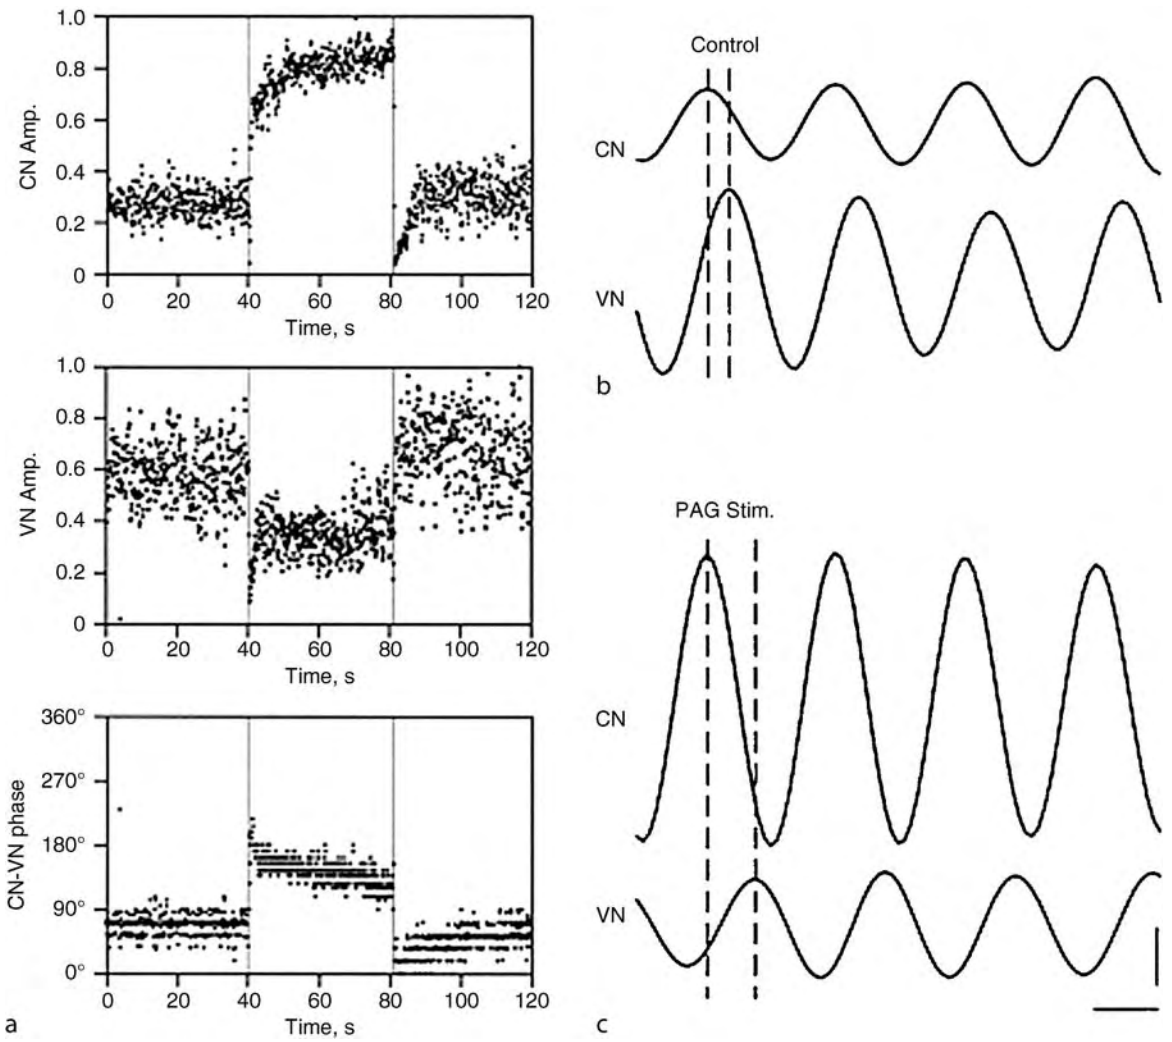
The PAG stimulus frequency at which the switch between the two patterns shown in Fig. 3 occurred was always at the frequency of the free-running rhythm. This is remarkable because the frequency of the free-running rhythm ranged from 8 to 12 Hz. Thus, the same frequency of stimulation could produce either pattern depending upon the momentary frequency of the free-running rhythm. This response characteristic virtually rules out the possibility that the defense-like pattern



**Tonic Activity of Sympathetic Nerves.**
**Figure 3** Patterns of spinal sympathetic outflow elicited by electrical activation of the defense region of the cat midbrain periaqueductal gray (PAG). Traces in (a) and (b) show the discharges of the inferior cardiac (CN), vertebral (VN), and renal (RN) postganglionic sympathetic nerves. (a) PAG stimulation at 8.0 Hz was started at vertical line; the frequency of the free-running rhythm was 8.0 Hz. (b) PAG stimulation at 8.2 Hz; free-running rhythm, 9.2 Hz (reproduced from Ref. [5] with permission of Sage Publications, Thousand Oaks, CA).

of reciprocal changes in VN versus CN and RN 10-Hz discharges arose from activation of point-to-point hard-wired connections that always reduce excitatory drive to some sympathetic nerves while increasing drive to others.

Other than reflecting long-term memory arising from nonlinear linkage of processes occurring on different time scales, the functions of the fractal noise in SND remain to be elucidated. At least two possibilities are open to future investigation. Linkage of processes operating on different timescales may prevent excessive mode-locking, which would restrict the functional responsiveness of the organism to unexpected challenges. For example, in some patients with low output congestive heart failure, there is a breakdown of fractal fluctuations in heart rate that is accompanied by the emergence of a dominant cardiac frequency mode near 0.02 Hz. Such patients are at a high risk for ventricular fibrillation. Whether fractal SND plays a role in promoting fractal fluctuations of heart rate in the healthy heart remains to be determined.



**Tonic Activity of Sympathetic Nerves. Figure 4** Defense-like changes in SND produced by PAG stimulation in a urethane-anesthetized, baroreceptor-denervated cat. (a) Amplitude and relative phase-time series of CN and VN activities. Data points are cycle-by-cycle measurements of peak-to-trough 10-Hz burst amplitude (normalized on scale of 0–1.0) and phase lag of VN 10-Hz activity relative to that in CN. Vertical lines mark start (left) and end (right) of PAG stimulation at a frequency (10-Hz) equal to that of the free-running rhythm. (b) Digitally filtered CN and VN 10-Hz slow waves in absence of PAG stimulation. (c) During PAG stimulation, vertical calibration, 40 μV; horizontal calibration, 50 ms in (b) and (c) (reproduced from Gebber et al. (1999) J Neurophysiol 82:841–854 with the permission of the American Physiological Society).

Noise is often viewed as detrimental to signal detection. However, in some neuronal circuits, low levels of random or fractal noise actually optimize the response of the system to its weak rhythmic inputs. This phenomenon is referred to as ▶stochastic resonance. Whether the fractal noise in SND subserves such a function, thereby promoting the pattern generating capabilities of the system of coupled oscillators generating the 10-Hz rhythm, remains open to investigation.

## Pathology

Hyperactivity of the sympathetic nervous system has been reported for certain animal models of hypertension, and has been suggested to play a role in congestive heart failure and cardiac arrhythmias. This topic is not within the scope of this essay.

## Tonic-clonic Seizures

### Definition

Tonic-clonic seizures (formerly referred to as *grand mal epilepsy*) may be preceded by an aura possibly indicating a focal origin. For example, tingling and numbness in a hand suggest involvement of the ►parietal cortex, etc. The seizure then usually starts with a *tonic phase* (of 15–30 sec duration) characterized by the opening of eyes and mouth, flexion and abduction of arms, extension of the legs, followed by jaw closure often leading to tongue laceration, respiratory arrest with cyanosis, urinary or fecal incontinence. The tonic phase is followed by vigorous jerks (cloni), rhythmic contractions of the entire body with continuing apnea, eye movements and grimacing. The seizure mostly terminates within 1–2 minutes and subsides into sleep and then confusion and lethargy. It may be the end-stadium of a primarily generalized seizure or a secondarily generalized partial seizure, and is indicative of damage or disease of the ►cerebral cortex of various causes (e.g., infectious, vascular and neoplastic lesions, ►metabolic encephalopathy, etc.).

## Tonic Discharge in Oculomotor System

### Definition

The steady-state firing rate of a neuron. In the oculomotor system, the term usually refers to steady firing that co-varies monotonically with the angular position of the eyes in the orbit in a preferred direction. For instance, abducens motoneurons on the left have a steady post-saccadic discharge that is proportional to leftward eye position.

►Brainstem Burst Generator

## Tonic Neurons Encoding Eye Position

### Definition

Some neurons present a very stable discharge rate (i.e., a very narrow interspike interval distribution) for their physiological range of action potential firing. Two representative examples of tonic neurons are skeletal and extraocular motoneurons. A special type of tonic neuron can be found mainly in the interstitial nucleus of Cajal and in the nucleus prepositus hypoglossi; these neurons seem to encode eye position signals. Their firing is very stable for a given range of discharge rates, in order to maintain a stable eye position in the orbit during observation of a visual target.

►Neuronal Integrator – Horizontal

## Tonic Vibration Reflex

### Definition

Muscle contraction elicited by surface vibration, each cycle of which elicits a spike in muscle spindle afferent fibers which normally have a very low resting activity.

Also refers to the postural changes and force generated in the limb controlled by the vibrated muscle.

►Proprioception Effect of Gravity

## Tonics

►Stimulants

## Tonotopic Organization (Maps)

Günter Ehret
Department of Neurobiology, University of Ulm, Ulm, Germany

### Synonyms

Sound representation; Auditory maps

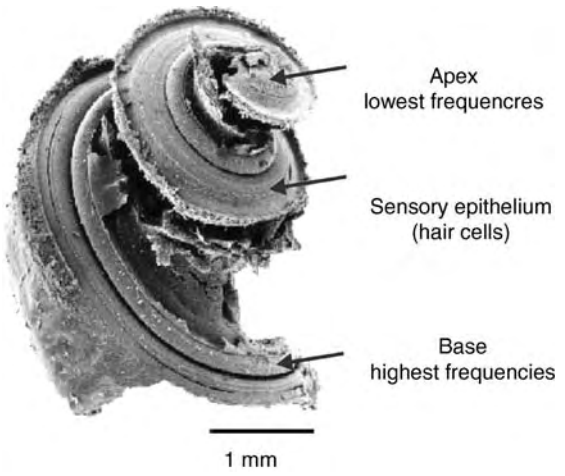
### Definition

Tonotopic organization expresses *gradients in the representation (maps) of sound properties*. Such properties are frequency of tones, frequency ratios between harmonics and the pitch of complex sounds, speed and direction of frequency sweeps, sound intensity and location of sound in space. Scales of these properties cover space of sensory and neural tissues at levels of the ►auditory system of animals including humans. In a strict sense, tonotopic organization refers only to *frequency maps* as established by pure tone stimuli. In a wider sense and beyond tonotopic organization, the term "auditory map" includes also *gradients in the representation of neural response properties* to sounds such as neuronal sensitivity or response threshold, response latency, ►dynamic range of the response and sharpness of ►frequency tuning.

### Characteristics

#### Quantitative Description

Frequency maps arise in the inner ears. The relevant structure in mammals is the ►cochlea (Fig. 1) of which the average length varies between about 6 mm in mice and 60 mm in elephants. The cochlear length is one of the factors determining over how many octaves frequency range a given species can hear. Except for some bats (e.g. mustached bat) with specialized cochleae, sound frequency can be transformed to cochlear position by the empirical equation: $f = A\ (10^{ax} - k)$ (Eq. 1 where f = frequency; x = cochlear position as distance in mm from the apex of the cochlea; A, a, k = species-specific constants [1,2]). The applicability of Eq. 1 indicates that the cochleae of most mammals are scale models of each other. Except for the cochlear frequency map, quantitative descriptions of maps exist only for the main nucleus of the auditory midbrain, the central nucleus of the inferior colliculus, with regard to modeling the maps for the representation of frequency, intensity and tonal phase [3].



**Tonotopic Organization (Maps). Figure 1** View of the cochlea of a rat (modified scanning electron microscopic picture by M. Lenoir). Frequency representation along the cochlear spiral starts with high frequencies at the cochlear base and ends with low frequencies at the apex. The number of coils of the cochlea and the frequency range covered are species-specific parameters.

#### Higher Level Structures

For the sense of hearing, frequency is the only sound property mapped at the level of the sensory epithelium. Hence, tonotopy in the strict sense is both the most basic and the highest-level map of all maps in the auditory systems. Tonotopies are found at all levels of the ►auditory pathways from the inner ear to the highest auditory centers of vertebrates from fish to mammals [4]. Sensory epithelia for hearing include the sacculus, utriculus and lagena in the inner ear of fish, the sacculus and the amphibian and basilar papillae in amphibians, the basilar papilla in reptiles and birds and the cochlea (elongated and coiled basilar papilla) in mammals. In mammals, the sensory epithelium extends only along one spatial dimension from cochlear base to apex (Fig. 1) resulting in a one-dimensional frequency map, i.e. every audible frequency is optimally transformed to a neural response only at a single spot (see Eq. 1).

Thus, the sensory cells (►hair cells) at a given spot on the sensory epithelium or neurons at a given location in an auditory brain center are distinguished by their place-specific ►characteristic frequency.

Frequency maps can also be found in the ears and in centers of the central nervous system of some sound-producing insects such as grasshoppers and crickets [4].

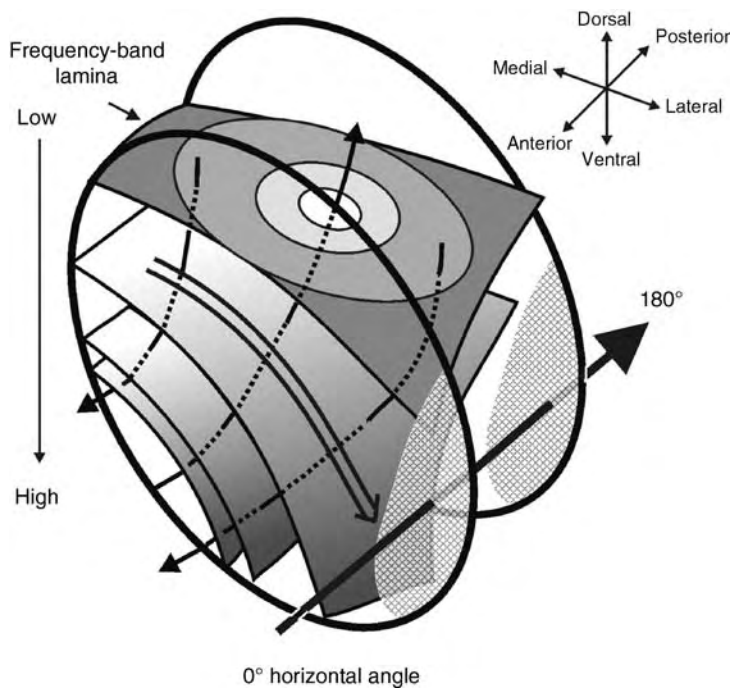
## Lower Level Components

The inner ear tonotopy is reproduced as an unchanged or expanded or compressed scale model in most centers of the auditory pathways of the brain. Studies on the central auditory pathways in mammals report additional *maps of sound properties* and *maps of neural response properties.* The most complete mappings exist for the auditory midbrain inferior colliculus (Fig. 2) [5–7] and the auditory cortex (Fig. 3) [8–10], especially those of the mustached bat (*Pteronotus parnellii*; (Fig. 4) [11].

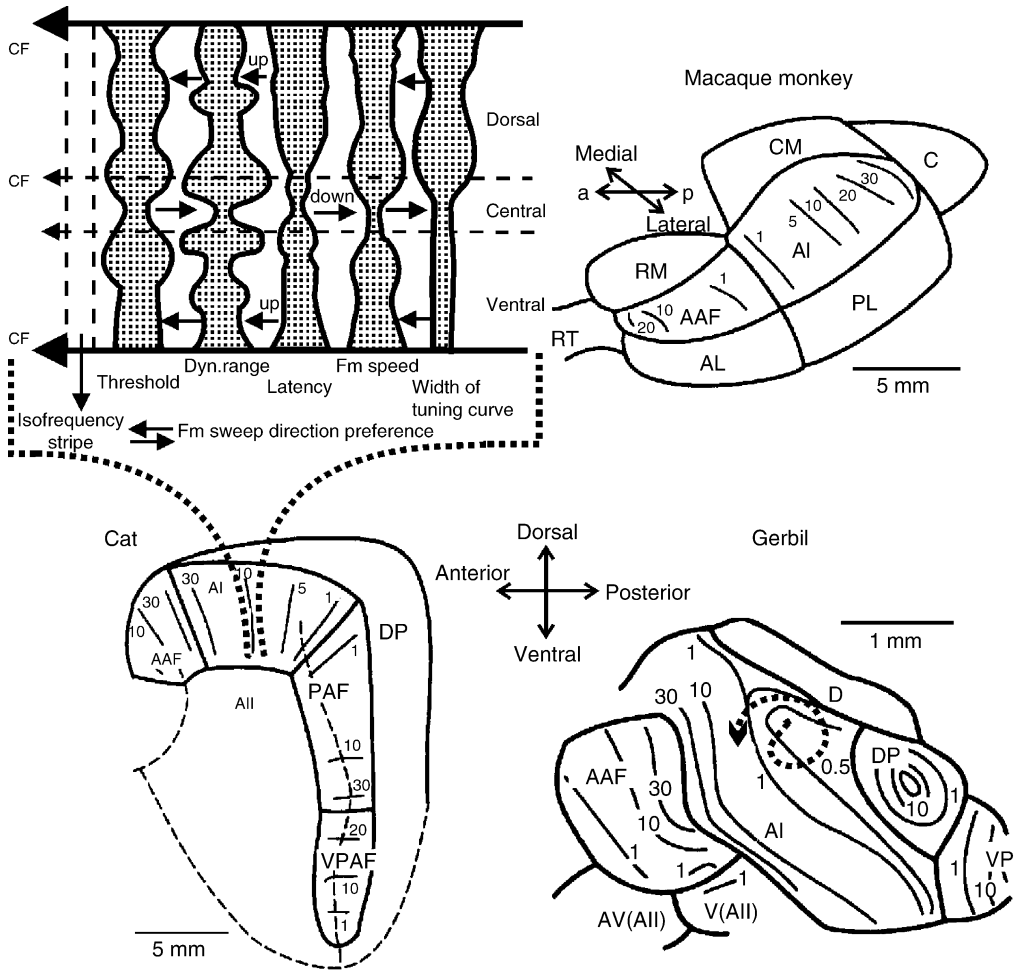
### *Midbrain Inferior Colliculus*

In the central nucleus of the inferior colliculus, the tonotopy consists of two frequency gradients. The first gradient is represented by ►frequency-band laminae containing neurons of characteristic frequencies in a small range almost identical with the frequency bandwidth within which the auditory system can resolve frequency components of a complex frequency spectrum such as vowels of human speech. Frequency-band laminae of low frequencies are located dorsally, those of high frequencies ventrally and medially (Fig. 2). Within a given frequency-band lamina, characteristic frequencies of neurons increase going from medial to lateral locations (see double-lined arrow in Fig. 2). Thus, the two frequency gradients together guarantee a continuous frequency representation in a zigzag pattern through the laminae from low (dorsal and medial) to high (ventral and lateral) locations in the three spatial dimensions of this midbrain nucleus. At the same time, the frequency-band laminae map with their frequency ranges the bandwidths of frequency resolution (critical bandwidths) in the hearing of a given species.

Further maps are indicated by gradients of shading in Fig. 2. The shading from light (medial) to dark



**Tonotopic Organization (Maps). Figure 2** Central part of the inferior colliculus of the midbrain whose anterior and posterior parts have been cut away. The frontal sectioning planes are indicated by the *two thick oval lines*. The remaining inferior colliculus shows the layered structure of the frequency-band laminae. Basically, the represented frequencies of the laminae increase according to the main tonotopical gradient from low (dorsal) to high (ventral). The *double-lined arrow* shows the frequency increase within a lamina from medial to lateral (minor tonotopical gradient). The *three arrows* passing through the laminae indicate the average location of neurons preferring upsweeps (lateral and medial positions) or down sweeps (central position) in frequency (from low to high or high to low, respectively). Gradients of the other maps of sound properties and neural response properties are indicated by *arrows* and *shadings*. They are explained in the text. Modified from figures and data in [5–7].



**Tonotopic Organization (Maps). Figure 3** General organization of auditory cortical fields of cats, monkeys and gerbils. Primary (*AI*) and anterior auditory fields (*AAF*) are always tonotopically organized (*small numerals* indicate the characteristic frequency (*CF*) of neurons in kHz). Other fields (AII, CM, PAF, etc.) may be tonotopically organized or not. The 10 kHz isofrequency stripe of the cat AI is enlarged. Every isofrequency stripe contains rather patchy maps of sound parameters and neural response parameters superimposed on each other (here, for better visibility they are placed side by side). Five are shown: tone response threshold and latency, size of the dynamic range, width of frequency tuning curve and preferred speed (fm speed) of an upsweeping (*up*) or a down sweeping (*down*) tone. The average locations of small values of the parameters are indicated by necks, those of large values by dilatations of the patterns [8–10]. The *dotted spiral* in the gerbil AI indicates a pitch map.

(lateral) shown in the high-frequency laminae expresses an increase in the represented tonal pitch from low (medial) to high (lateral) and a decrease of neural tone-response latencies from long (medial) to short (lateral). On average, neurons located medially respond best with a relatively long latency (more than 12 ms) to low-pitched sounds (less than 100 Hz amplitude modulation frequency) while neurons at a lateral position respond best to high-pitched (more than 500 Hz periodicity) sound with a short latency (less than 10 ms). In the low-frequency lamina, a concentric pattern from the center to the periphery of the lamina indicates (i) the increase of average tone-response thresholds of neurons, (ii) the increase in the average speed of frequency sweeps of tones to which the neurons can optimally respond and (iii) the decrease in the average sharpness of frequency tuning of neurons. The concentric threshold map may be part of a concentric representation of sound intensity from soft (center) to loud (periphery) [3]. Finally, the bold arrow passing from anterior to posterior through the lateral nucleus of the inferior colliculus (Fig. 2, cross-hatched area) shows a gradient of neurons responding best to a sound source located at a certain horizontal angle in the range of 0–180° in the sound field contralateral to the side of the midbrain shown.

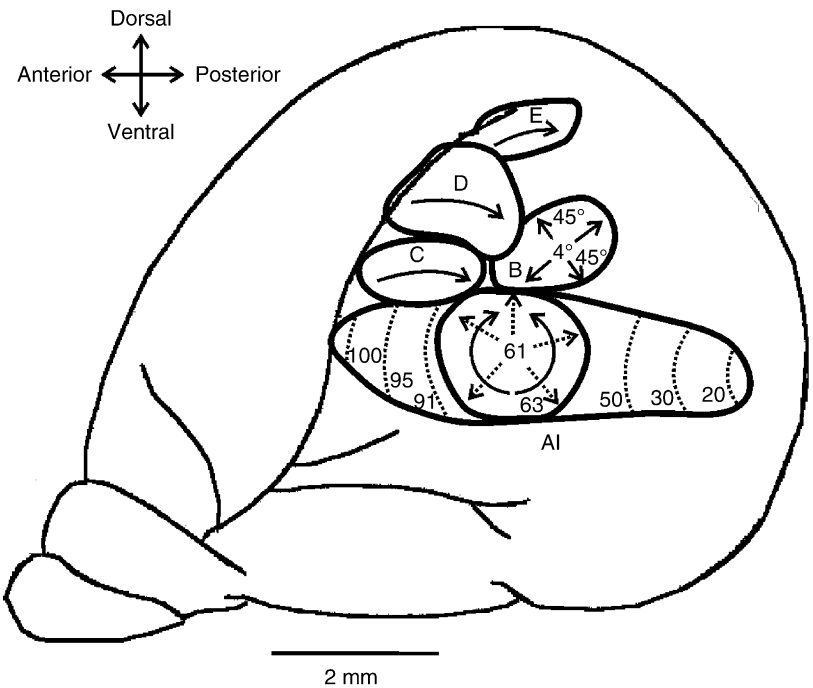
T

### Auditory Cortex

The auditory cortex is situated in the temporal region of the ►neocortex (Fig. 4). In mammals with non-specialized audition such as the cat, gerbil, macaque monkey and human, the auditory cortex consists of several fields of which at least the two primary fields, the primary auditory field (AI) and the anterior auditory field (AAF) are tonotopically organized (Fig. 3). Other higher-order fields may contain a clear frequency map as in the cat and gerbil or are without such a map. For example, neurons in higher-order fields may respond best to a combination of frequencies such as neurons in most fields of the mustached bat auditory cortex (Fig. 4).

Neurons located in a given ►isofrequency stripe of AI show gradients in the form of patches concerning the representation of the sound properties speed (slow vs. fast speed) and direction (up vs. down sweep direction) of frequency sweeps and the neural tone-response properties threshold, latency, dynamic range and sharpness of frequency tuning (Fig. 3, enlarged 10 kHz isofrequency stripe of the cat AI). Further, a rather spiral-like map of ►periodicity pitch (about 50–1,500 Hz) is shown in the low-frequency region of the gerbil AI tonotopy.

The auditory cortex of the mustached bat has been mapped extensively. The major maps are shown in Fig. 4 [11]. The primary auditory cortical field (AI) is divided into three parts. The frequency range between about 61 and 63 kHz is very much expanded in its representation. This specialized area of AI contains two half-circular maps of sound intensity i.e. neurons responding best to sound pressure levels between about 13–98 dB. Immediately dorsal of AI is a field (B) with a concentric map of locations of a sound source at horizontal angles of about 4–45° in the sound field contralateral to the auditory cortex shown. Also dorsal of AI is a field (C) in which the deviations between the first harmonic of the emitted bat's echolocation call and the second and third harmonic of the perceived echoes of this call are mapped in the best responses of the neurons. Two fields further dorsally in the cortex (D, E) contain maps of the time differences between the emission of the first harmonic of an echolocation call and the perception of the second, third and forth harmonic of its echo.



**Tonotopic Organization (Maps). Figure 4** Lateral view of the brain of the mustached bat. Five auditory cortical fields are shown on the temporal cortex. In the primary field (*AI*), the tonotopy extends from about 10 to almost 110 kHz (*small numerals*) with an expansion of the frequency range between about 61 and 63 kHz. Besides this tonotopy in AI, the other fields contain special maps in which combinations of features of the echolocation calls and their echoes are represented in order in the best responses of the neurons along the *arrows* shown. Field *B* indicates the horizontal position in flight direction (about 4–45°) of the prey or another object, field *C* contains a map of the relative speed between the bat and its pursued prey, fields *D* and *E* both contain maps of the distance between the bat and its prey [11].

### Structural Regulation

Tonotopies are established during the maturation of the inner ear. In mammals, the development starts with the responsiveness of hair cells to rather low frequencies in the middle and upper basal cochlear locations. There, the mapped frequencies increase and the tonotopy expands towards more basal and apical locations during the further development and thus leads to increases in the audible frequency range towards higher and lower frequencies respectively. Because the anatomical connections between the cochlea and the brain and along the auditory pathways of the brain are already established before the start of hearing, the tonotopic maturation of the cochlea is reflected by equivalent developments of frequency maps in the centers of the auditory pathways [12].

### Higher Level Processes

In mammals, the cochlear tonotopy emerges from mechanical properties of hair cell displacement by ►traveling waves along the sensory epithelium proceeding from the base to the apex. The main determinants of local displacement maximums are the stiffness gradient of the basilar membrane and the amplification of the displacement amplitude by the outer hair cells [1,2]. In the other classes of vertebrates, the hair cells are intrinsically tuned to respond best to a small range of frequencies in addition to the mechanical tuning along the sensory epithelium [4].

Tonotopies in higher auditory centers are due to the passing on, via homotopic anatomical connections, the point-like isofrequency information of the inner ear to two-dimensional frequency-band laminae, also called isofrequency planes, in auditory centers having three spatial dimensions (e.g. Fig. 2) or to one-dimensional isofrequency stripes in the two-dimensional auditory cortex (Figs. 3 and 4). Thus frequency maps in higher auditory centers such as midbrain and auditory cortex of the forebrain basically emerge from the patterns of anatomical connections and from the shapes and sizes of the auditory centers.

### Lower Level Processes

Auditory maps other than frequency representations are *computational maps*. They result from processing of the neural code of auditory nerve fibers in brain centers and from neural interactions in and between centers of the auditory pathways. For example, maps of auditory space concerning the horizontal plane (see Figs. 2 and 4) can be established only after inputs from the left and right ear have been compared in nuclei of the brainstem superior olivary complex. There, differences both in the arrival time and the amplitude of the signals from the ears, which are due to the horizontal angle of a sound source relative to the ears, lead to a differential activation of neurons in such a way that a given horizontal angle is represented as a response optimum of neurons at a certain location in the superior olivary nuclei. This sorting of horizontal angles of sound sources to places in neural tissues in the brainstem is the origin of maps of horizontal space in the midbrain (Fig. 2) and the auditory cortex (Fig. 4).

The various auditory maps on the frequency-band laminae of the inferior colliculus (Fig. 2) and on the isofrequency stripes of the auditory cortex (Fig. 3, expanded 10 kHz stripe of cat AI) are often superimposed on one another. Important consequences arise. (i) Only a few neural representations of sound properties and neural response properties exist independently of each other. The functional geometry of a brain area restricts the maximal number of independent maps to three in a given three-dimensional space (e.g. inferior colliculus) and to two in a given two-dimensional space (e.g. primary auditory cortex). (ii) The interdependence of mapped properties create slocus-specific combination sensitivities in the responses of the neurons. At a given place, combination-sensitive neurons may respond best to sounds of a certain frequency composition, intensity, pitch and location in space, all at the same time.

### Process Regulation

The shapes, even up to the loss, of auditory maps in a given brain center are regulated in several ways. Long-term exposure to a given sound, mainly in young subjects and experience with sounds of importance (learning) strongly influence auditory maps, especially in higher centers of the auditory pathways [11,13,14]. In general, the representations of the prevalent, discriminative or otherwise important sound characteristics are enlarged. This plasticity of auditory maps is mediated by changes in (i) the balance between converging excitatory and inhibitory input to neurons of a map, (ii) the connections between neurons at different levels of the auditory system and between neurons in a given auditory center, (iii) the influence of higher on lower auditory centers often correlating with the attention to and expectation of certain sounds and (iv) the influences of other sensory and modulating (e.g. hormonal, motivational, emotional) systems on the auditory system.

### Function

The formation of auditory maps in the brain answers the question as to how properties of sounds from the external world are transformed into internal neural representations on which the "brain can work", i.e. that can be used as the basis for sound perception and recognition. In this sense, all auditory maps are functional maps. The mere existence of a map for a

certain sound property indicates the parameter range over which this property can be perceived and discriminated. For example, the frequency range of the tonotopy covers the main frequency range of hearing and indicates that these frequencies can be discriminated. If a certain parameter range of a map is expanded or a map is restricted to a small parameter range only, this overrepresentation or selected representation indicates a special importance of this range in hearing and sound communication of a species. An example is the mustached bat's AI with the enlargement of the 61–63 kHz range (Fig. 4). In this range, the bat expects the main echo frequency of its echolocation call for getting information about the size and location (equivalent to the intensity of the echo) of the pursued prey or of other objects hit by the call.

Since auditory maps are *regulated* structures or processes, their appearances and shapes are dynamic, for example during maturation or due to learning. This plasticity of maps is a significant factor for individuals to be able to adapt to conditions of importance or unimportance of a given acoustic environment or of communication with congeners. Thus, auditory maps, especially in higher brain centers, are not pure sensory maps but rather perceptual maps permanently adjusted to an individual's auditory experience and life style [13–15].

### Pathology

Tonotopies may change in older subjects or subjects having been exposed to very loud sounds (more than about 110 phon) due to cochlear damage. With increasing age, hair cells are often lost at the basal portion of the cochlea with the effect that the high frequency part of the tonotopy is lost in the cochlea and therefore in all higher auditory brain centers. Exposure to a loud tone of a given frequency leads to hair cell damage at the place where this frequency is represented in the cochlea. The tone-frequency related part of the tonotopy is thus lost, i.e. the subject's perceptual threshold for the tone will be permanently increased.

In the course of and after cochlear damage, the phenomenon of ▶tinnitus may occur. Often a tone that is not physically present in a subject's environment and not even present in the activity of a subject's auditory nerves is heard continuously and may lead to annoying feelings. It seems that by paying attention to sound percepts caused by cochlear disturbances these sounds are learned to be important and thus may cover an increased portion of the frequency maps in the brain [16]. It is not understood in detail how tinnitus-related activities in the tonotopies of the brain become established. Tinnitus appears however, to be a state of misregulation in the balance of excitation and inhibition and of ascending and descending information processing in the auditory maps and pathways respectively of the brain [16].

# Top-Down Approach

### Definition

The analysis of the processing of sensory systems and the meaning of stimuli can, in principle be

accomplished by two different approaches: bottom-up and top-down. Top-down means that the analysis is based on the behavioral relevance of stimuli and that only behaviorally relevant stimuli are used to unravel the processing in the brain. This is the approach taken by ethologists. It is in sharp contrast to the approach often taken by physicists that use theoretically well characterized stimuli (noise, tones, clicks in audition) without knowledge of their relevance. The advantage of the top-down analysis is that always the behavioral relevance is known. The disadvantage is that the stimuli may be so complex and unique that it is not possible to draw general conclusions (see also bottom-up approach).

## Topological Position

### Definition

Location of a division/subdivision or a cell group within the organism or part of the organism according to topological (internal) coordinates. For the basic divisions/ subdivisions of the organism or part (such as the radial histogenetic units in the brain), this position (and thus the relation to neighbors) remains the same throughout ontogeny. Further, in organisms (or parts of them) sharing the same configuration and basic organization plan (for example, vertebrates or the brain of vertebrates), the topological position of homologous divisions/subdivisions should be the same across species.

►Evolution and Embryological Development of the Forebrain

## Topology

### Definition

Geometric configuration of any given structure (such as the brain) according to internal coordinates, which remain unaltered independent of deformations or differential growth of subdivisions that occur during development.

►Evolution and Embryological Development of the Forebrain

## Torpor

### Definition

Natural state of animals characterized by inactivity with a low reactivity: suspended animation. Hibernators use torpor to minimize outside exposure. Euthermic hibernators suppress metabolism in torpor, thus reducing energy expenditure.

►Hibernation

## Torsion Dystonia

### Definition

Also known as idiopathic torsion dystonia may begin in childhood or young adulthood. Dystonia (sustained muscle contraction causing twisting or turning around one or multiple joints) usually begins at one limb and then becomes generalized.

►Dystonia

## Torsion in Eye Movement

### Definition

Torsion is the rotation of the eye about the line of sight. The line of sight is thus not displaced by torsional eye movements, in contrast to horizontal or vertical eye movements.

►Eye Orbital Mechanics

## Torus Semicircularis

### Definition

Caudal region of the midbrain roof corresponding to the mammalian inferior colliculus. This region is divided into subnuclei that each receive lemniscal projections from corresponding primary hindbrain nuclei. It is

devoted to processing of acoustic, mechanosensory, and electrosensory information.

►Evolution of Mechanosensory and Electrosensory Lateral Line Systems

## Total Internal Fluorescence Microscopy

►Evanescent Field Fluorescence Microscopy

## Total Internal Reflection

### Definition

A real-time imaging technique that makes use of an evanescent wave to monitor distances as small as 1 nm; in live cells, used to monitor vesicles at or very near the plasma membrane. Has enabled assessment of physical states thought to represent vesicle targeting and tethering, as well as direct observation of docking and fusion.

►Synaptic Proteins and Regulated Exocytosis

## Touch Dome

### Definition

The touch dome is a small part of the skin 150–300 μm in diameter with high mechanical sensitivity. This area of the skin is slightly elevated, and can be visible under a dissecting microscope. This dome-like elevated part contains many Merkel cell-neurite complexes arranged at the basal layer of the epidermis. The epidermis of the touch dome is thicker than the surrounding regular epidermis.

## Tourette's Syndrome

### Definition

Neuro-developmental disorder of pre-pubertal onset, with a higher prevalence in boys than girls. It is characterized by irrepressible motor and vocal ►tics: multiple brief muscular ►spasms (*convulsive tics*) in the face, neck and shoulder; repetitive, stereotyped, strongly emotional gestures or vocalizations (e.g., *vocal tics*, such as grunts and barking sounds); behavioral abnormalities (coprolalia and other obscene utterances). The Tourette syndrome often co-occurs with ►attention-deficit/hyperactivity disorder (ADHD), ►obsessive-compulsive disorder, and a range of other mood and anxiety disorders. Its etiology is not clear yet, but the pathophysiology may involve dysfunctions of the ►basal ganglia, where overactivity of the ►dopaminergic system may entail overactivity of clusters of ►striatal neurons in inappropriate contexts, which would lead to disinhibition of thalamo-cortical circuits and ultimately to the production of tics.

►Basal Ganglia
►Dopamine

## Trace Eyeblink Conditioning

### Definition

The eyeblink conditioning paradigm in which the conditioned stimulus (CS) terminates before the onset

of the unconditioned stimulus (US). The time interval separating the CS offset from the US onset is called the trace interval. It is presumed that for the subject to learn the association between the stimuli, a trace of the conditioned stimulus has to be stored in the brain until the unconditioned stimulus is presented. This paradigm is distinct from delay conditioning where the conditioned and unconditioned stimuli partially overlap and co-terminate.

►Motor Learning

## Tracking

### Definition

►Eye-Head Tracking
►SC-Tectoreticulospinal Neurons (TRSNs)

## Tract

### Definition

A tract is a collection of axons projecting from one nuclear group to another in the central nervous system.

## Trafficking

### Definition

Membrane recycling of receptors and synaptic vesicles.

►Membrane Components
►Transport

## Trafficking Adaptors

### Definition

These are generally multi-protein complexes in which one component recognizes and binds to a trafficking motif within a membrane protein, with other components of the complex mediating interactions with a specific sub-cellular compartment.

►Receptor Trafficking

## Trafficking Motifs

### Definition

These are linear peptide motifs within the cytoplasmic domain of a membrane protein that direct the movement of that protein from one compartment or membrane to another.

►Receptor Trafficking

## Training

### Definition

Training is defined as a process toward acquisition of a skill, memory and knowledge. Learning and memory have been thought to have encoding, retention and retrieval stages. Encoding is thought to occur during training. Generally training has been associated with an act with a goal directed will or intension. However, just exposure to input that leads to learning and memory is also regarded as training.

►Learning Curve
►Sensory Plasticity and Perceptual Learning

## Trajectory Attractors in Neural Networks

### Definition

Paths stored in a recurrent neural network along which the network state (firing pattern of units) moves smoothly and continuously. The network state is changed from a pattern to a slightly different pattern at one time, which characteristic is distinct from that of

a conventional neural network storing a sequence of almost orthogonal patterns whose state is changed from a pattern to a very different pattern at one time.

►Associative Memory

## Trajectory in Motor Control

### Definition

Equilibrium trajectory of an effector (e.g., of the hand during reaching movements); comprised of the effector's equilibrium positions at each instance of movement. Referent trajectory of an effector; comprised of the positions of the effector's associated with threshold configurations of the body at each instant of movement.

►Equilibrium Point Control
►Threshold Control

## Trans-acting Factor

►Transcription Factor

## Transactional Functionalism

### Definition

A school of psychology which claimed that the retinal image is always ambiguous so that perception is a function of past experience, which is used by the observer to make a "best bet" based upon that experience.

►Visual Illusions

## Transcortical Reflex

### Definition

A long-latency EMG response to muscle stretch or cutaneous stimulation that depends on rapid transmission of the sensory volley and evoked motor volley and involves the cerebral cortex. Also known as a long loop reflex.

►Long Loop Reflexes

## Transcranial Magnetic Stimulation

Milos Ljubisavljevic
Department of Neurophysiology, Institute for Medical Research, Belgrade, Serbia and Montenegro

### Synonyms

Magnetic stimulation

### Definition

Transcranial Magnetic Stimulation [1,2] is a non-invasive, nearly painless method of activation of human cortical neurons by applying a magnetic pulse over the scalp. It allows functional mapping of the human brain (►brain mapping) and creation of transient functional lesions. It has proved to be an unparalleled tool in its ability to alter cortical activity in awake, behaving man and has provided considerable advance to studies of brain function in the last decade.

TMS can be applied as:

1. Single-pulse TMS (sTMS) – traditional way of delivering magnetic stimuli in which single pulses are delivered to excitable structures of interest at random intervals and maximum frequency of 0.3 Hz. The corresponding minimal time interval is needed for conventional monophasic TMS machines to charge up between successive stimuli.
2. Paired-pulse TMS (pTMS) – paired-pulse stimulation involves applying two magnetic stimuli, of equal or different intensity, separated in time by a varying interstimulus interval (ISI). Magnetic pulses may be applied through one coil over the same cortical spot, or through two coils, each positioned over a different spot.
3. Repetitive (rapid-rate) TMS (rTMS) – refers to magnetic stimuli given more frequently than the usual 0.3 Hz available with most commercial single-pulse stimulators.

Most of the work elucidating basic mechanisms of TMS has been performed on the ►motor cortex, where the response to stimuli could be easily quantified by measuring the characteristics of the ►motor evoked potential (MEP). It is believed that the principles

derived from these studies would apply when stimulating other ►cortical areas, although demonstrating this has proved to be more difficult in practice.

## Purpose

Developed two decades ago [2], TMS has found a wide range of applications and has had a dramatic impact on studies of the healthy and diseased human brain. TMS is now widely used as a research tool, while in the clinical domain it has found only limited applications, being commonly used to study ►central motor conduction time (CMCT). More recently, it has been developed (rTMS) as a potentially useful therapeutic tool, particularly in ►psychiatry.

TMS produces two main types of responses when applied over brain; it can excite it or it can also induce inhibition (see later: Principles and Methods and measurements). It is by virtue of these two phenomena and their derived responses that TMS produces its effects, which then have to be assessed within the constraints of the experimental paradigm. TMS can be used within two major contextual frameworks: to produce interruption of brain activity, also referred to as ►virtual lesion; or to evaluate different aspects of cortical excitability, allowing the study of changes in cortical physiology in connection with ►cortical plasticity and brain disorders.

### Interruption of Brain Activity: Virtual Lesion

In virtual-lesion methodology, TMS is applied while the subject is trying to perform a task, thus introducing noise into the neural assemblies involved in signal processing of the given task, and disrupting the activity of focal brain regions and the task itself. In this way, it can be established whether a specific brain area plays a causal role in the specific type of processing. The virtual-lesion methodology was first used in studies of the motor system by applying single-pulse TMS over the motor cortex while subjects were instructed to perform flexion and extension movements of the wrist [3]. The "go" command to initiate the movement was coupled with a TMS stimulus delivered 100 ms later, but before the movement was expected to commence. The effect of TMS was to markedly delay the onset of wrist movement without altering its overall form, thus increasing the reaction time. In a similar paradigm, TMS was used to disrupt visual processing. When delivered 80–100 ms after the visual stimulus, TMS impaired subjects in seeing randomly generated letters on a monitor, indicating that the visual processing was disrupted during that interval.

In general, the choice of a dependent variable in TMS experiments will primarily depend on the function under investigation that is to be disrupted. Available experience suggests that reaction time is a more robust and versatile measure than error measurements.

### Cortical Physiology

TMS is generally used to evaluate different aspects of cortical excitability. Parameters such as ►motor threshold (MT) to a single magnetic pulse, or ►intra-cortical inhibition (ICI) and ►intra-cortical facilitation (ICF) evoked by double-pulse stimulation, or the duration of the ►silent period (SP) can be measured (for details on MT and SP see later). When TMS is delivered in a conditioning-test paradigm (pTMS), it can be used to assess cortical inhibitory and excitatory processes reflecting the activity of interneurons in the cortex. In this technique, the first (conditioning) stimulus is sub-threshold, and the test shock that follows after a short time interval is supra-threshold (in the original method, 80% and 120% of motor threshold, respectively [4]). The conditioning stimulus has no effect on the spinal ►motoneuron excitability, but initiates intracortical influences that modulate the amplitude of the MEP response elicited by the test stimulus. In normal subjects, at intervals shorter then 5 ms, the conditioning stimulus produces an inhibition of the test response, while at longer intervals, between 7 and 30 ms, the conditioning stimulus produces facilitation. It is believed that GABA-ergic cortical neurons mediate ICI, so that inhibitory processes tested with the paired-pulse technique and the SP probably reflect different aspects of cortical inhibition.

### Brain Plasticity

Although still loosely defined, brain ►plasticity generally describes the ability of the brain to change. Basically, it refers to processes of ►neural repair, ►learning and ►memory. TMS was successfully added to a battery of non-invasive techniques that are available to study these mechanisms. To study plasticity, TMS could be applied in a multitude of settings and experimental paradigms, the following lines only summarizing techniques and parameters (see also Methods and measurements) available to study ►reorganization in brain function by using TMS.

Mapping is effectively used to produce functional representations of primarily motor areas, but it can be used to map other cortical regions like somatosensory and visual cortex etc. With this technique, the number of excitable scalp positions, the location of the optimal position and several other parameters related to the representation of a particular muscle can be determined. In combination with other techniques (►PET, ►fMRI), these maps can be related to individual brain anatomy, thus enabling the combination of functional data and anatomical structures. Finally, measuring changes in maps under particular acute or chronic conditions allows the identification of changes associated with different forms of plasticity.

►Motor threshold (see later) can be used to provide indirect information on changes in membrane

excitability in motor cortex. Motor-threshold measurements can be complemented with the measurement of recruitment curves (see below), which provide information on another aspect of cortical excitability, the underlying mechanisms of which are still poorly understood, however. As described earlier, ICI and ICF provide sensitive estimates of the functions of inhibitory and excitatory interneuronal circuits in the motor cortex. TMS has also been used to study functional connectivity of different cortical regions and to disrupt task performance (see above).

Applications of these techniques have effectively led to identification of various patterns of neural reorganization in different conditions. For instance, TMS has been used to describe short-term plasticity associated with transient ►deafferentation, ►central fatigue, ►skill acquisition, implicit learning, etc. Lesion-induced plasticity associated with amputations, traumatic root and spinal cord injury, hemispheric lesions and other pathological conditions have also been studied [for review see [5]].

### Magnetic Stimulation in Disease

TMS has been used, with more or less success, to reveal intracortical processes in almost every neurological disorder. Abnormalities revealed by TMS are usually not disease-specific, but rather reflect general changes in cortical excitability. For example, studies with TMS have revealed abnormalities in ►Parkinson's disease and ►dystonia, showing a decrease in ICI and an increase in the slope of the MEP ►recruitment curve, but without significant changes in motor threshold. Similarly, ICI is reduced in ►epilepsy while threshold measurements have revealed conflicting results. Nevertheless, although the abnormalities revealed by TMS are not specific to these diseases, they are intrinsic parts of the underlying pathological processes and can be effectively utilized to guide the treatment strategies, or even to quantify the physiological effects of different drugs in individual patients.

### Therapeutic Use

The delivery of a single TMS pulse does not appear to have any lasting effects. However, ever since the advent of TMS, it has been anticipated that rTMS may produce effects that outlast the stimulation period and may thus be used to treat brain disease or reduce functional deficits. The first report showed that rTMS at frequencies of 5 Hz and higher transiently enhanced the motor excitability [6], to the extent of even evoking an epileptic seizure. Interestingly, slow rTMS at 1 Hz can transiently decrease the excitability, producing inhibition that is relatively long-lasting [7]. Lasting effects of rTMS on clinical symptoms have been demonstrated in Parkinson's disease, in patients with task-specific dystonia and in depression patients. The exact mechanisms underlying these effects are not known, although it has been suggested that they may be central equivalents of synaptic ►long-term potentiation (LTP) and ►depression (LTD). Although these early studies provided the initial impetus for studies aimed at modulating cortical tone, after a decade of experimentation, TMS has not yet yielded any treatments that effectively alleviate any neurological disorder. For instance, although early observations showed that rTMS affected ►mood in healthy individuals, and could be potentially effective in the treatment of mood disorders, it has failed so far to yield provable, significant therapeutic effects. In part, the problem might be associated with the very large number of possible combinations of magnetic stimulation parameters (frequency, intensity, train duration, inter-train intervals, number of trains, site of stimulation, etc.) or, more importantly, with the issue of safety (see later) that places stringent boundaries on the stimulation parameters that can be potentially used in therapy. Finally, another limitation is related to the depth of penetration of the effective stimulating current.

### Central Motor Conduction Time (CMCT)

Probably the only routinely used clinical application of TMS, CMCT allows neurologist to non-invasively estimate conduction time in the central segment of the motor pathway. CMCT is defined as the latency difference between the MEP evoked by stimulation of motor cortex and spine (motor root). It is usually less than 7 and 15 ms for upper and lower limbs, respectively. When TMS is used for spinal cord stimulation, it excites the nerve roots in the region of inter-vertebral foramina, so that the calculated CMCT will be slightly longer. To overcome this, electrical stimulation of peripheral nerves and calculation of CMCT by the ►F-wave method could be used (see below). However, this is associated with considerable discomfort and may not be optimal, particularly in children. CMCT is slightly faster in women and increases with age. Typically, CMCT is prolonged in ►multiple sclerosis and cervical ►spondylitic myelopathy.

## Principles

### Mechanisms of Action of TMS

The general principle of operation of a magnetic stimulator is to generate a rapidly changing magnetic field of the magnitude of several Tesla, which would then induce a flow of electric current in adjacent biological tissue, depolarizing excitable structures such as nerve axons. To generate such a magnetic field, a commercial magnetic stimulator consists of a storage capacitor, which allows high-peak current (in the kiloampere range) to be delivered with a very short rise time (100–200 μs) and an overall duration of less then 1 ms, to a coil of wire, called the magnetic coil. This produces the induction effect, generating a magnetic

field with the lines of flux passing perpendicularly through the plain of coil, which when placed above the scalp induces an electrical field oriented perpendicularly to the magnetic field. The characteristics of the induced electric field in the nervous tissue depend on the rate of change and on the intensity of the magnetic field. The probability of inducing the activation is proportional to the rate of change of the electric field [1]. The activation of axon occurs when the induced electric field generates a difference in the electrical potential between two points along the length of the axon. This occurs at points where the axon crosses the electric field lines by bending across them, which creates a difference in potential at points adjacent to the bend and induce stimulation at this point. Thus, the knowledge of orientation of the induced electric field and of the anatomical orientation of the cortical axons being stimulated may serve to deduce the site of stimulation. The precise extent of activation of cortical neurons is not known, but it has been established that TMS is more likely to stimulate neurons that run parallel to the cortical surface, which leads to the conclusion that corticospinal motor neurons are preferentially activated transsynaptically through other cortical cells, rather than directly. This was recently confirmed by direct observations showing that TMS produces descending corticospinal discharges, containing multiple indirect (I-waves) descending waves with longer latency rather than shorter-latency direct waves (D-waves) [8].

Commercially available magnetic stimulators can either generate monophasic or biphasic magnetic pulses, the biphasic form probably requiring lower field intensities to induce a current in the neural tissue.

Several different shapes of magnetic coils have been developed, which allow the generation of magnetic fields of different shapes and strengths. The three most commonly used types of coils are the standard round coil, the figure-of-eight coil and the double-cone (butterfly) coil. The round coils are powerful and produce the maximal electric field near the circumference and no current at the center of the coil. Assuming that the initial current flow in the coil is in one direction when viewed from above (e.g., clockwise), the induced current flows in the opposite, anti-clockwise direction, thereby preferentially activating neurons in the right motor cortex, and vice versa. Figure-of-eight coils consist of two windings that lie in the same plane, allowing current to flow in opposite directions in the two coils, so that the maximal electric field is induced at the intersection of the two round components. The geometry of the figure-of-eight coil makes it particularly suitable for selective stimulation of specific targets within the cortex. The double-cone coil was specifically developed to improve the stimulation of structures lying deeper in the central sulcus of the brain. The two windings of this coil are oriented at an angle, typically 100°, thus generating the highest-intensity field right below its center.

In conclusion, a TMS pulse randomly excites neurons that lie within the induced effective electrical field, and evokes both excitatory and inhibitory effects in the cortex. Several studies have shown that, although limited by the type of coil used, the optimal stimulation for the given task is crucially determined by the precise orientation of the coil. Thus, the functional localization of the TMS effects is to a significant degree controlled by the experimenter.

## Methods and Measurements

For routine studies, TMS is coupled with a standard ►electromyographic (EMG) recording setup registering surface or needle EMG. The standard parameters of the MEP response include cortical threshold, latency, amplitude of response, and silent period in the active muscle (SP) (see Fig. 1).

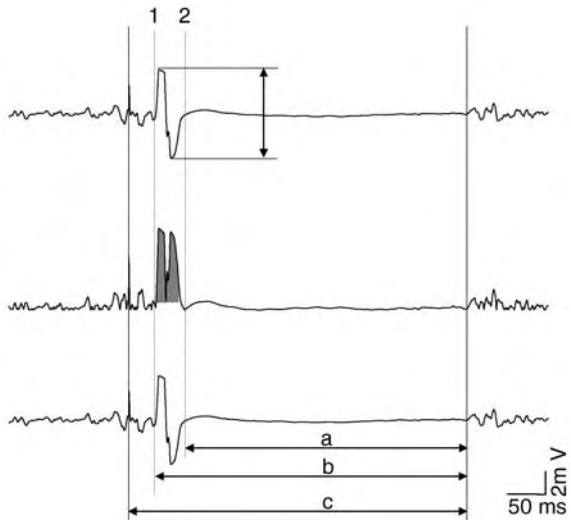
### *Cortical Threshold*

Cortical threshold refers to the minimal intensity of TMS that produces an MEP (see [10]). The threshold for producing an MEP in resting muscles reflects the global excitability of the motor pathway, including all interposed individual neurons along the pathway. At the cortical level, it would reflect the excitability of individual neurons and their density in a central core. The confirmation that it indicates membrane excitability has come from studies showing that drugs affecting sodium and calcium channels can influence the threshold. In addition, even slight voluntary preactivation of the target muscles reduces the cortical threshold. In general, in adults, the threshold is independent of age, gender and hemisphere but varies with different target muscles. In the same individual, the threshold usually follows a proximal-distal pattern, being lowest for distal arm muscles and highest for leg and axial muscles.

### *Latency, Amplitude of Response and Silent period*

Latency refers to the time elapsed from the stimulus onset to the beginning of the MEP. It reflects the time needed for the excitation to travel from the brain to the muscle(s). It depends on background voluntary activation of the muscle(s), which – if present – shortens the latency by several milliseconds. It may be prolonged in certain diseases, but in general, TMS does not have substantial diagnostic value in these diseases.

The amplitude of the MEP is usually expressed as peak-to-peak amplitude, between the two peaks of opposite polarity, or as an area under the rectified MEP curve. The MEP amplitude reflects the overall activity in the ►corticospinal tract at the moment of stimulation. Thus, it reflects the sum of cortical



**Transcranial Magnetic Stimulation. Figure 1** Electromyographic responses to cortical magnetic stimulation. *Top and bottom*: Unrectified traces. Motor evoked response (MEP) recorded from the first dorsal interosseus muscle during weak voluntary activation. *Middle*: Full-wave rectified trace. *Vertical continuous line at left*: time of magnetic stimulus; *vertical dashed lines* 1 and 2: beginning and end point of MEP, respectively; *single vertical arrow below bottom* trace: reoccurrence of EMG activity after the silent period (SP). The time from the magnetic stimulus to *vertical line* 1 corresponds to the latency of the MEP. The time between two *vertical dashed lines* corresponds to the MEP duration. The *vertical double-arrow* in the top trace indicates the peak-to-peak amplitude of the MEP. The *shaded area* under the rectified curve in the middle trace corresponds to the MEP area. *Horizontal arrows* a, b and c correspond to three different approaches for measuring the time to resumption of the EMG signal following an SP: a, from the end of the MEP; b, from the beginning of the MEP; c, from the magnetic stimulus. (With permission from [9]).

and spinal motoneuron activity. The MEP amplitude increases with increasing stimulus intensity and voluntary activation. The relations between stimulus intensity, voluntary activation and the growth of MEP amplitude are usually referred to as recruitment curves. These curves are not fully understood as they probably reflect the number and excitability of neurons other than those activated at threshold. The MEP amplitude usually shows considerable inter-trial and inter-individual variations, which probably reflects the complex interactions occurring in the corticospinal pathway. The MEP amplitude is also critically influenced by coil position, and even minimal changes in coil/skull alignment can drastically influence the amplitude of subsequent responses. To overcome the variability, a ratio of cortically evoked MEP to the response evoked by supramaximal stimulation of peripheral nerve (MEP/CMAP ratio) can be calculated. The recently developed triple-stimulation technique [11], which involves TMS of the cortex and electrical stimulation of the peripheral stimulation at two sites provides a better estimate of cortical motor neuron activation, but is at the same time cumbersome and can be uncomfortable.

Finally, TMS produces a period of electrical silence in the EMG recording of the voluntarily activated muscle. This is termed "silent period" (SP) and can be produced with both sub-threshold and supra-threshold stimulus intensities. Thus, the threshold for TMS inhibitory phenomena may be lower than that for the excitatory effects. If induced by supra-threshold stimuli, the SP follows the MEP, so that the duration of the SP can be measured from the stimulus artifact, from the onset latency or from the end point of the MEP, to the restoration of the EMG activity (Fig. 1). The duration of the silent period is usually directly related to stimulus intensity and relatively independent of background contraction. SP's are generally longer in small hand muscles than in proximal arm and leg muscles. Several factors contribute to SP. Its initial part probably depends on refractoriness of spinal motoneurons, ►Renshaw inhibition and peripheral reflex inputs, while its latter part is mostly due to various cortical inhibitory mechanisms.

## Transcranial Electrical Stimulation (TES)

The only other technique available for transcranial stimulation of the human brain is electrical stimulation. In ►transcranial electrical stimulation, a single high-voltage capacitative discharge that produces a twitch of contralateral body muscles when applied over the motor cortex. As compared with TMS (see before), electrical stimulation in man induces D-waves similar to those seen after electrical stimulation of exposed cortex in monkey. This indicates that TES activates ►pyramidal tract axons directly, probably several internodes away from the neuron body. The biggest disadvantage of electrical stimulation is that only a small portion of the applied current flows into the brain, while much of it flows between the electrodes on the scalp and induces contraction of the scalp muscles and activation of pain receptors, thus producing considerable discomfort to subjects.

## Advantages and Disadvantages

In contrast to electrical stimulation, magnetic stimulation is non-invasive and produces minimal discomfort to subjects, reasons for which it is used almost exclusively today. However, electrical stimulation may still be used when appropriate since it often yields information otherwise not available from either method alone.

The main advantage that TMS adds to other neurophysiological and imaging techniques is its ability

to probe the neural activity within relatively small volumes of neural tissue, in a small amount of time (less then one second). It should not be considered as superior but rather complementary to other methods, each of them allowing questions from a specific perspective to be addressed.

One of the main limitations of TMS pertains to the difficulty to limit the extent of the induced current flow, particularly when using powerful round coils, thus limiting its focus. This problem can partly be overcome by using the figure-of-eight coil and orienting it appropriately to the targeted structures. Current spread also limits the application of TMS for stimulation of peripheral nerves.

Other limitations pertain to safety issues. Single-pulse TMS has proven to be an extremely safe tool with no long-term adverse effects. As to short-term effects, the induction of epileptic seizures and ►kindling has caused major concerns. Only three reports on seizures induced with single sTMS have been published so far. However, it has been established that rTMS, as a more powerful stimulation modality with the potential to regionally block or facilitate cortical processes, can induce seizures [12]. Moreover, it should be noted that there is as yet little information on potential rTMS long-term effects. Thus, rTMS should be used with appropriate precautions and strict observation of the guidelines for its safe use (for details see [12] and http://pni.unibe.ch/maillist.htm).

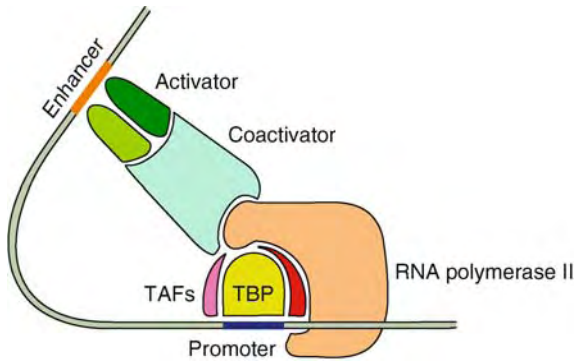
## Synonyms

Trans-acting factor

## Definition

Transcription factors control (activate or repress) transcription of genes by regulating the access of RNA polymerase to DNA. Most transcription factors bind to a specific DNA sequence and are grouped into transcriptional activators and repressors. Transcriptional activators bind to an enhancer of the genomic DNA and form a complex containing basal transcription factors and RNA polymerase II, which initiates transcription at a specific site (Fig. 1).

Many transcriptional activators also bind histone acetyltransferases, which activate genes by acetylating histones. Genes are inactivated by transcriptional repressors, which bind to a silencer of the genomic DNA and recruit histone deacetylases.



**Transcription Factor. Figure 1** Assembly of the transcription initiation complex on a promoter.

## Characteristics

### Quantitative Description

At least 1,850 genes encode transcription factors in the human genome [1].

### Higher Level Structures

Protein

### Lower Level Components

Transcription factors are classified into three major classes, basal transcription factors, transcriptional activators and repressors. TFIID, which contains the TATA-binding protein (TBP) and TBP-associated factors (TAFs) [2] are basal transcription factors. Transcriptional activators and repressors have DNA-binding and protein-protein interaction domains. They are grouped into several families based on their structural motifs, homeodomain, ►basic helix-loop-helix, zinc finger and leucine zipper, etc. (Table 1).

Homeodomain proteins are further divided into subfamilies by the amino acid sequence similarities of their homeodomains and additional motifs, some of which are crucial for protein-protein interaction [3]. Zinc finger proteins also comprise several subfamilies.

### Structural Regulation

Many transcription factors exert their functions by forming dimers with themselves or another structurally related factor. In some cases, their dimer formation and nuclear entry are regulated by their modification (mainly by phosphorylation).

### Higher Level Processes

Transcription factors control various processes from development to higher order function of the nervous system. At early stages of development, several types of homeodomain proteins, such as Pax6 and Emx2, control regional patterning of the brain [4]. Nkx2.2 and Nkx6.1 are involved in dorso-ventral patterning of the developing nervous system. Hox-subfamily proteins determine regional identity along the antero-posterior body axis. Then, proneural factors, including Mash1 and Math1, which are among the basic helix-loop-helix (bHLH) proteins, are expressed in distinct regions or populations of cells, specify neuronal progenitors and promote neuronal differentiation [5]. Members of HMG box proteins, Sox2 and Sox10, counteract the activity of proneural factors and inhibit neurogenesis, thereby maintaining progenitors. Proneural factors activate gene expression of another bHLH protein, NeuroD, which controls neuronal differentiation. These bHLH proteins form a heterodimer with a ubiquitous bHLH protein, E2a, to bind to DNA. There are bHLH proteins that inhibit neurogenesis, such as Hes1, by repressing expression of ►proneural factor genes or by preventing proneural factors from binding to DNA. Math1 directly activates the *Mbh1* gene, encoding a Bar-type homeodomain protein, which specifies commissural neuronal identity [6]. Several LIM- and Paired-like-type homeodomain proteins control specification of neuronal subtypes as well. Some of Dlx- and POU-type homeodomain proteins are required for proper differentiation of specific types of neurons. Many transcription factors have multiple functions at different stages. Nkx2.2 and En1 regulate differentiation of oligodendrocytes and axonal projection of postmitotic neurons respectively, as well as early regional patterning.

Axonal projection is also regulated by LIM- and Bar-type homeodomain proteins. When axons of motor and sensory neurons reach the vicinity of target muscles, expression of the ►ETS proteins Pea3 and ER81 is induced by peripheral signals and controls axonal branching.

$C_2H_2$-type zinc finger proteins, which are the largest family of transcription factors, are involved in many processes other than development. Neural restrictive silencer factor (Nrsf/Rest) represses expression of numerous neuronal genes, which encode ion channels and neurotransmitters etc. in non-neuronal cells [7]. Zif268 mediates extracellular signals and is associated with learning and memory [8].

Ubiquitously expressed Smad- and Stat-family proteins regulate proliferation and differentiation of cells in response to extracellular signals. Leucine zipper proteins, c-Fos and CREB, are also mediators of various extracellular signals and implicated in learning and memory [8,9].

### Lower Level Processes

In most cases, gene expression is regulated by multiple enhancers and silencers and the combination of active transcription factors determines which gene is expressed. A list of transcription factors can be obtained from the TRANSFAC database (http://www.gene-regulation.com). Potential binding sites of transcription factors in

**Transcription Factor. Table 1** Families of transcription factors in the nervous system

| Family (motifs) | Representative members | Function |
|---|---|---|
| Homeodomain | | |
| Hox | Hoxa1, Hoxc8 | Determination of regional identity |

a given DNA sequence can be searched using the MatInspector software (http://www.genomatix.de/index.html).

## Process Regulation

Extracellular signals regulate the function of transcription factors [10]. The transforming growth factor (TGF)-β binds to TGF-β receptors, which phosphorylate Smad2 and Smad3. These phosphorylated Smad proteins form heterodimers with Smad4 and enter the nucleus. Similarly, dimerization and nuclear entry of Stat proteins are regulated by JAK kinases, which associate with membrane receptors. CREB becomes active after phosphorylation by several kinases, including the cAMP-dependent protein kinase and $Ca^{2+}$ -calmodulin-dependent protein kinases, downstream of various signals. A novel transcription factor, CaRF, is specifically activated by calcium influx. The binding of Wnt proteins to Frizzled membrane receptors leads to release of β-catenin, which forms a heterodimer with Lef1 and functions as a transcription factor. Gli proteins are downstream effecters of the Patched membrane receptor, which binds to the Hedgehog protein. The RBP-J/CBF1 protein becomes active by interacting with the cytoplasmic domain of the Notch receptor, which is released after binding to its ligand.

## Function

Basal transcription factors support the initiation of transcription. A subunit of TFIID, TBP, binds to a core promoter of the genomic DNA, such as the TATA box. TAFs stabilize TFIID on the promoter and interact with RNA polymerase II to form the transcription initiation complex.

The efficiency and rate of transcription are upregulated by an enhancer, which is located upstream or downstream of the promoter. Transcriptional activators bind to enhancers and interact with the basal transcription factors through coactivator proteins, thereby stabilizing the transcription initiation complex on the promoter (Fig. 1). A member of the coactivator proteins, p300/CBP, acetylates histones in nucleosomes. Acetylation of histones destabilizes nucleosomes and enhances the binding of transcription factors to DNA.

NRSF/REST binds to neural restrictive silencer elements, which control neuronal genes, and interacts with the corepressors, mSin3 and CoREST. They recruit histone deacetylases and inactivate genes by stabilizing nucleosomes.

### Pathology

Numerous developmental and physiological defects are caused by mutations of transcription factor genes (see the TRANSFAC database).

## Transcription Factor Codes

►Combinatorial Transcription Factor Codes and Neuron Specification

## Transcriptional Start Site (TSS)

### Definition

The first nucleotide of the major mRNA species for a gene. The TSS is surrounded by a small region of upstream and downstream flanking sequence that makes up the 10 bp Inr of the core promoter region.

►Promoter

## Transcriptome

### Definition

Transcriptome is the set of all mRNA molecules (or transcripts) in a cell or population of cells in a given set of circumstances. This means that unlike the genome, which is fixed for a given organism, barring mutations, the transcriptome can change depending upon the context of the experiment. Recent work has shown that a large portion of the genome is actively transcribed into non-protein-coding RNAs (ncRNA). Therefore the transcriptome could be considered to include both protein coding mRNAs and ncRNAs in the most general sense.

### Synonyms

Signal conversion; Stimulus translation

## Definition

Central process for all cells sensing the external environment. Conversion of an adequate stimulus into a signal of the cell, often mediated by cascades of biochemical reaction and second messenger systems. For ►chemosensation, the nature of the primary information that needs to be converted is chemical.

## Characteristics

### Description of the Process

Olfactory sensory neurons (OSNs) translate information about the type and concentration of volatile chemicals in the respiratory air stream into the electrical language of the nervous system. The molecular machinery mediating the chemo-electrical signal transduction process is located in the odor-sensing compartments of olfactory cells, the chemosensory cilia. These long ciliary protrusions of the apical dendritic knob form a complex mat in the mucus layer covering the nasal epithelium; this arrangement greatly increases the sensory surface area and thus raises the probability of odorant/receptor contact. Interaction of appropriate odorant molecules with receptor proteins in the ciliary membrane triggers a cascade of events within the cell that transforms the ligand/receptor binding into an excitation of the neuron. Experimental evidence indicate that this process is mediated via intracellular second messenger pathways and although in the various olfactory subsystems and multiple subpopulations of sensory neurons several mechanisms may be operating, compelling evidence points to a predominant role of the adenylyl cyclase/cyclic-AMP pathway in cells of the main olfactory system [1,2]. Upon an odorant/receptor interaction, the enzymatic cascade is triggered via the trimeric G-protein $G_{olf}$ which activates adenylyl cyclase III, the most active isoform for catalyzing the conversion of ATP to cyclic AMP, leading to an elevation of the intraciliary cAMP concentration. The basal concentration of cAMP appears to be just below the level that is required for activation of cyclic nucleotide-gated (CNG) cation channels in the ciliary membrane and is probably an equilibrium determined by the activities of adenylyl cyclase III and phosphodiesterase. Opening of the CNG channels allows the influx of $Na^+$- and especially $Ca^{2+}$-ions which provides the first electrical signal, a slight depolarization of the membrane. The main change of the membrane potential results from the flow of $Cl^-$-ions through $Ca^{2+}$-activated $Cl^-$-channels opened by the raising internal $Ca^{2+}$-concentration. Due to the unusually high concentration of intracellular $Cl^-$ there is an efflux of $Cl^-$-ions thus causing a strong depolarization of the olfactory sensory neuron. This is considered as an evolutionary adaptation to the fact that olfactory cilia reside in the mucus, where the ion concentrations are not as well controlled as in the interstitial fluid. In this way, olfactory neurons have a $Cl^-$-battery, which makes their electrical responsiveness independent from the actual $Na^+$-concentration in the mucus. Odorants not always elicit excitation but certain odorants induce an inhibitory response in distinct OSNs; in those cells, the cAMP cascade mediates the activation of ciliary $Ca^{2+}$-dependent $K^+$-currents leading to a hyperpolarisation of the membrane. The electrical response of OSNs to odorant application occurs with a time delay of at least 50 ms [3], this is consistent with the notion that the generation of receptor current is mediated via several biochemical steps and the formation of second messengers. The local change of the transmembrane potential spreads quickly with about $10^7$ µm/s due to the high input resistance of several GΩ [4].

When the membrane potential reaches the threshold at the axon hillock action potentials are generated which propagate along the axon and convey the electrically coded information into the olfactory bulb. Employing ►second messenger cascades as mechanisms for sensory transduction provides a strong potential for signal amplification since it is generally thought that an activated G-protein-coupled receptor activates multiple G-proteins and effector molecules. However, receptor-odorant complexes are too short-lived to activate several G-proteins, implying that signal amplification in olfactory transduction is rather low and fundamentally different from that of phototransduction [5]. Signal amplification in olfaction may be accomplished by repeated binding of odorant molecules to the same receptor and the high probability of odorant binding due to the high number of receptor proteins in the ciliary membrane of an OSN.

### Functional Elements

#### *Olfactory Cyclic Nucleotide Gated (CNG) Channels*

Central element in the process of converting an odorant stimulus into an electrical response of the olfactory neurons is the ►cyclic nucleotide gated (CNG) channel in the ciliary membrane which allows an influx of cations. The CNG channel of OSNs is composed of three distinct types of subunits: the rinciple CNGA2-subtype, and the modulatory subunits CNGA4 and CNGB1b; they form a heterotetrameric protein complex composed of two A2, one A4 and one B1b subunits. The principle CNGA2 subunit alone can form a functional channel that is activated by cyclic nucleotides; however, the channel properties differ considerably from that of heteromeric channels. This demonstrates the physiological roles of the modulatory subunits. In addition to fine tuning the functional properties of the channel, the B1b subunit seems also to participate in the correct targeting of the channel proteins to the ciliary compartment of the OSN.

The channel is activated by the direct binding of cyclic nucleotides and is only weakly sensitive to membrane voltage. It contains four binding sites for the cyclic nucleotides and although its activation has long been known to be a highly cooperative process, the mechanism of gating was not well understood until recently. Based on studies using novel caged nucleotides a model with three binding steps has been proposed, of which the first and the third have a high ligand affinity and the second step has a low affinity, but this one switches the channel's open probability from low to high. This model was very recently expanded to a four step model in which the first ligand induces small but noticeable opening, the second ligand switches the still mostly closed to a fully open channel, whereas the third and fourth ligand only stabilize the open conformation.

The native CNG channel conducts mainly $Ca^{2+}$-ions under physiological conditions which has at least two highly relevant consequences: first, the rise in internal $Ca^{2+}$ opens $Ca^{2+}$ activated $Cl^-$ channels which confers an inward current and acts as an efficient amplifier of the primary current (see below). Second, $Ca^{2+}$-ions entering the cell serve as a negative feedback modulator by reducing the sensitivity of the channel to its ligand cAMP which subsequently promotes channel closure. This $Ca^{2+}$-mediated negative feedback on the olfactory CNG channel is a major molecular mechanism responsible for the fast ►sensory adaptation of OSNs to constant stimuli [6]. The regulatory effect on the olfactory CNG channel appears to be mediated by $Ca^{2+}$–calmodulin (CaM). $Ca^{2+}$-free calmodulin, called apocalmodulin, is already constitutively bound to the heterologously expressed heteromeric olfactory CNG channels even in the absence of $Ca^{2+}$; when the $Ca^{2+}$ concentration rises, it can rapidly modulate the CNG channel sensitivity by directly binding to the pre-associated calmodulin. Since $Ca^{2+}$-ions enter the olfactory cilia through the CNG channel itself, the pre-association of calmodulin clearly contributes to a very fast feedback modulation at the channel level. A mathematical model of adaptation based on direct negative regulation of CNG channels by $Ca^{2+}$–calmodulin in olfactory cilia is well in line with the experimental data.

### *Chloride-Channels*

The influx of cations through the CNG channel contributes only slightly to cell depolarization; the major contribution is mediated via $Ca^{2+}$-activated $Cl^-$ channels. Due to the unusually high concentration of intracellular $Cl^-$ in the lumen of the cilia opening of these channels leads to a $Cl^-$ efflux and thereby to a depolarization of the membrane [7]. The high intracellular $Cl^-$ concentration is a prerequisite for this mechanism and an uncommon feature of adult neurons which implies that OSNs have unique transport systems for accumulating $Cl^-$-ions. Intracellular chloride concentrations in OSNs may be as high as 40–50 mM. The chloride concentration seems to be higher in the olfactory knob than in the dendrite and the cell body, suggesting that the primary site for $Cl^-$-uptake is at the knob and/or the cilia. The uptake of $Cl^-$-ions is mediated through a $Na^+2Cl^-K^+$ cotransporter (NKCC1). In contrast, the main transporter for $Cl^-$ extrusion operating in other neurons, KCC2, was not expressed in OSNs. NKCC1 is mainly located in the dendrite and soma of OSNs suggesting that these serve as a large $Cl^-$ reservoir of the cell, which is utilized to maintain the intralumenal $Cl^-$-concentration of the cilia elevated during the response to odors [8]. Isolated OSNs from NKCC1 knockout (NKCC1-ko) mice show drastically reduced odor-activated currents probably due to a decreased influx of $Cl^-$ through $Ca^{2+}$-activated $Cl^-$ channels. The intact epithelium of NKCC1-ko mice however shows responses to odor stimuli which are only moderately reduced [9], suggesting that additional, not yet identified, $Cl^-$ transport mechanisms exist in OSNs.

The fact that a rise in intracellular $Ca^{2+}$ elicits the $Cl^-$ efflux has led to the hypothesis that this might be a CaM-mediated process. Transfection of mutant CaM into the Odora cell line which is derived from OSN precursor cells indeed affects the $Ca^{2+}$ sensitivity of the $Cl^-$ efflux, indicating the involvement of CaM in the gating mechanism. As a candidate gene which might encode the $Cl^-$-channel in mouse OSNs, a member of the bestrophin family of channels has been presented. Major electrophysiological properties of the Best2 channel heterologously expressed in HEK293 cells resemble those of $Cl^-$ currents measured from OSN cilia.

## Regulation of the Process

### *Role of Calcium*

Calcium-ions entering the cilia through the CNG channel play a central role in olfactory transduction not only in activating the $Cl^-$ channels and thus eliciting the major part of the receptor potential but in addition, it has profound negative feedback effects on various elements of the signal transduction cascade. Most notably are the contributions of $Ca^{2+}$ in mediating adaptation processes occurring after prolonged odor stimuli. On the first level, calcium acts with calmodulin via direct feedback on the CNG channel (see above), thereby mediating a rapid adaptation. In addition, there seem to be further $Ca^{2+}$–CaM dependent adaptation mechanisms. This notion is based on two observations: first, response kinetics after prolonged odor stimulation are substantially different from short repetitive stimuli and secondly, after long odor stimulation the kinetics

differ from those induced by direct activation of the CNG channel, indicating that other elements of the transduction cascade are also affected during longer odor exposure. As a candidate target ACIII emerged; the activity of ACIII and the capacity to generate cAMP is inhibited upon phosphorylation through CaM dependent Kinase II (CaMKII) and blocking of CaMKII activity impairs the adaptation process to long odor stimuli. In contrast, the counterpart of ACIII, the cAMP–hydrolysing phosphodiesterase (PDE1C2), seems not affected by $Ca^{2+}$–calmodulin and not immediately involved in olfactory adaptation. A tight control of the intracellular $Ca^{2+}$-level is thus critical for the response characteristics of OSNs. The transient rise of the $Ca^{2+}$ levels subsequent to influx has to be restored to pre-stimulus conditions. The $Na^{+}/Ca^{2+}$ exchanger mediates efficient $Ca^{2+}$ extrusion. Inhibition of the exchanger leads to greatly prolonged responses to odor stimulation, probably due to the persistent elevation of $Ca^{2+}$-levels and $Cl^{-}$-permeability. During prolonged odor exposures the interplay of influx and extrusion of $Ca^{2+}$-ions generates oscillatory receptor currents [10] allowing the cell to periodically fire burst of action potentials.

# Transfer Function

## Definition

A function, which describes the relation between the output of a system and its input. The transfer function is usually expressed in the frequency domain or using the Laplace transform.

►Signals and Systems

# Transfer Tests

## Definition

Confrontation with novel stimuli or conditions that have not been experienced before to see whether a subject transfers a concept (see conceptualization) to a new situation. Learning wants to be excluded, thus choice behavior is not reinforced.

►Cognitive Elements in Animal Behavior

# Transfer-appropriate Processing

## Definition

The concept that memory performance is a function of the degree to which cognitive operations engaged at encoding are recapitulated at retrieval.

►Episodic Memory

# Transforming Growth Factor Alpha (TGF-α)

## Definition

A 17 kDa mitogenic polypeptideis expressed in the majority of neurons, and in maturing astrocytes, in the developing and adult brain of humans, and different species of animals. It is closely related to epidermal

growth factor (EGF), and can also bind to the EGF receptor with similar effects. TGF-α is expressed in the suprachiasmatic nucleus (SCN) in a circadian fashion, and, when infused into the third ventricle, reversibly inhibits locomotor activity and disrupts circadian sleep-wake cycles. These actions are likely mediated by epidermal growth factor (EGF) receptors on neurons in the hypothalamic subparaventricular zone, a major relay station for SCN efferents. Mice with a hypomorphic EGF receptor mutation exhibit excessive daytime locomotor activity and fail to suppress activity when exposed to light (so-called "masking").

►Clock Coupling Factors
►Sleep-wake Cycle
►Suprachiasmatic Nucleus

## Transgene

### Definition

The (recombinant) gene that is introduced.

►Gene Therapy for Neurological Diseases

## Transgenic Animal

### Definition

An animal that has been engineered to result in a stable, inheritable change in its genome, usually at the level of a single gene.

## Transgenic Mouse

### Definition

A mouse in which a hybrid gene is introduced artificially into the genome and is capable of being transmitted to successive generations. Commonly, transgenic mice can be classified as having either a gain of function where a gene of interest is forcefully expressed (commonly referred to as "transgenic") or a loss of function in which an endogenous target gene is functionally deleted ("knock out").

## Transient Global Amnesia

### Definition

A type of memory disorder characterized by a sudden onset of simultaneous anterograde and retrograde amnesia, without the presence of other cognitive disturbances (e.g., verbal or visuospatial difficulties). The person remains fully conscious and aware, but complains of a noticeable memory impairment. The episode can last for a few to several hours, but usually resolves within a day. Its causes are still unknown, but have been linked to focal ischemic lesions, brain tumors, and migraine headaches.

►Amnesia

## Transient Internal Desynchrony

### Definition

Loss of synchrony between two or more endogenous circadian rhythms, originally defined to describe dissociation between multiple circadian rhythms in humans following transmeridian travel or shiftwork rotation.

►Internal Desynchrony

## Transitions between Electroencephalographic Stages

### Definition

Refers to a switch from one electroencephalogram (EEG) stage to another. Transitions can occur between wakefulness and sleep, between sleep stages and between sleep and wakefulness.

Neuronal cell groups in the brainstem and midbrain actively promote wakefulness and sleep. The switch between wakefulness and sleep states is thought to be controlled by mutual inhibition among these cell groups.

►EEG in Sleep States
►Electroencephalography
►Sleep Stages

## Translational Regulation

►mRNA Targeting: Growth Cone Guidance

## Translational Vestibulo-Ocular Reflex

### Definition

The translational or linear vestibulo-ocular reflex (TVOR, LVOR) is the compensatory eye movement generated in response to a linear displacement of head. The reflex is mediated by the otoliths and semicircular canals and the vestibular nuclei.

►Vestibulo-Ocular Reflexes

## Transmembrane Recording

►Intracellular Recording

## Transmembrane Voltage

►Membrane Potential: Basics

## Transmissible Spongiform Encephalopathies (TSEs)

### Definition

Fatal neurodegenerative disorders associated with an accumulation of abnormal isoforms of prion protein (PrP) in neurons. They include bovine spongiform encephalopathy in cattle ("mad cow" disease), and ►Creutzfeldt-Jakob disease (CJD) and ►Kuru in humans.

## Transmission Channel

### Definition

In communication theory the medium that allows the signal to travel from the sender to the receiver.

## Transneuronal Tracers

### Definition

Transneuronal tracers, such as barley lectin, are molecules that are transported through the axons and/or dendrites of neurons and that can be transferred to other neurons at or near synapses. Transneuronal tracers can be visualized by histochemical techniques, thereby revealing the locations of connected neurons.

## Transplantation of Artificial Materials for Nerve Regeneration

Masayoshi Ohta[1,2], Yoshihisa Suzuki[1,2], Chizuka Ide[1,3]
[1]Department of Anatomy and Neurobiology, Kyoto University Graduate School of Medicine, Kyoto, Japan
[2]Department of Plastic and Reconstructive Surgery, Kyoto University Graduate School of Medicine, Kyoto, Japan
[3]Department of Occupational Therapy, Aino University Faculty of Nursing and Rehabilitation, Osaka, Japan

### Definition

Artificial materials for nerve regeneration represent manufactured biological and non-biological materials for transplantation: the former includes collagen, polyglycolic acid, polylactic acid, poly-ε-caprolactone, ►alginate, and ►chitosan, while the latter comprises, for example, silicone, rubber, and plastic.

Collagen is one of the most common fibrous components of connective tissue.

►Glycolic acid, lactic acid and ε-caprolactone (ε-caproic acid) are naturally occurring hydroxyl acids. These have been utilized to synthesize biodegradable polymers (polyglycolic, polylactic and poly-ε-caprolactone) in medicine. The degradation speed of

poly ε-caprolactone under physiologic conditions is slower than that of polyglycolic or polylactic acid.

Alginate derived from brown seaweed is a long chain of polysaccharide composed of two monosaccharides, β-D-mannuronic acid and α-L-guluronic acid.

Chitosan is the deacylated derivative of chitin, a polysaccharide extracted from crustacean exoskeletons or generated via fungal fermentation processes. Chitosan is a β-1,4-linked polymer of 2-amino-2-deoxy-d-glucose. It carries a positive charge from amine groups.

## Characteristics

The peripheral nerve is composed of nerve fibers and surrounding connective tissues called the endoneurium. The endoneurium includes Schwann cell basal laminae and adjacent connective tissue. Schwann cell basal laminae are extracellular matrices synthesized by Schwann cells themselves. It is well known that basal laminae of Schwann cells [1] and muscle fibers serve as an effective conduit for the growth of regenerating axons. This fact provides the biological basis for the use of artificial materials including extracellular matrices as a conduit for regenerating nerves in repairing injured nerves. In clinical cases of peripheral nerve injury, autogeneic nerve grafts have usually been used for bridging a large gap between proximal and distal nerve stumps of injured nerves. However, autogeneic grafts have problems including the sacrificing of healthy nerves, resulting in a non-sensation zone of the relevant area. On the other hand, allogeneic nerve grafts may lead to serious immunological problems throughout the patient's entire life. In this respect, artificial materials have been studied in order to overcome these drawbacks of auto- and allogeneic nerve grafts.

### Silicone

Silicone, a non-biological material, has been used as a tube for bridging the stumps of injured nerves. There is a clinical study involving the transplantation of silicone tube bridging a short nerve gap of 3–5 mm in the human median and ulnar nerves [2]. The silicone tubes were removed because of local discomfort experienced by some patients 1–3 year after surgery. A new nerve structure was formed within the tube bridging the nerve gap. The success of this study might have been due to the tubulization of the short gap between the proximal and distal stumps. A non-biological material exists for a long time without any degradation tendency. Biodegradable material can be removed by degradation from the lesion after a certain period of time around which nerve regeneration has been completed. In this sense, biodegradable materials have extensively been studied as the guiding scaffolds of regenerating nerves.

### Collagen

Collagen, one of the most common components of connective tissue, is considered to be an appropriate material as a guide for growing axons. In clinical peripheral nerve regeneration, regenerating axons should traverse the connective tissue gap between the proximal and distal stumps in which collagen fibers may serve as a guide for the growth of axons. In this respect, collagen fibers can be one of the most suitable biological materials for guiding regenerating axons. However, the result is not necessarily desirable in terms of the efficacy of the collagen fibers. In an experiment in which the nerve gap was short (5 mm long), and the postoperative period was long (3.5 years), there was no difference between the collagen guides, autografts, and direct suture repair surgery in the monkey median and ulnar nerves [3]. Collagen fibers coated with laminin and fibronectin were shown to be an effective conduit in the rat.

### Polyglycolic Acid

A polyglycolic acid conduit was used in a multicenter clinical study, in which nerve stumps were connected by standard repair either end-to-end or with a nerve graft, or repair using polyglycolic acid conduits [4]. There was no difference in two-point discrimination between the control (standard repair by either end-to-end or with a nerve graft) and polyglycolic acid conduit group. The overall results of this study showed no significant difference between the two groups. However, in the case of a short (4 mm) nerve gap, the mean moving two-point discrimination was much shorter in the glycolic acid conduit repair group than in the control group.

### Copolymer of Polyglycolic Acid and Polylactic Acid

A copolymer of polyglycolic acid and polylactic acid has been used as a material to make a tube for bridging nerve stumps in peripheral as well as central nerve regeneration. The mesh tube made of these biodegradable materials is believed to inhibit connective tissue infiltration into the tube. The tube can be filled with the cellular or non-cellular materials as the direct conduits of axons that extend through the tube. Collagen fibers filled in the polyglycolic/polylactic acid copolymers serve as effective guide bridging the 80 mm long gap in the cat sciatic nerve [5]. There is a study in which multiple-channel scaffolds (tubes) were made with the copolymer of polyglycolic acid and polylactic acid, and, used, after the distribution of Schwann cells within the tubes, as a transplant for spinal cord regeneration [6]. Considering that peripheral nerve fibers are bundles of small channels made of basal lamina scaffolds, multi-channel scaffolds can also be effective conduits for peripheral nerve regeneration.

### Poly-ε-Caprolactone

Poly-ε-caprolactone is used alone or in copolymer with polylactic acid as a scaffold for the growth of regenerating axons. The tube is coated with other materials or filled with effective cells such as Schwann cells or effective extracellular matrix such as basal laminae derived from muscle fibers [7]. In denatured muscle segments, basal laminae of muscle fibers remained in the form of a tube after cellular components of muscle fibers had been removed. Regenerating axons extended through muscle fiber-derived basal laminae. A polylactic acid-ε-caprolactone copolymer served to protect muscle fiber basal laminae from early degradation to be used by regenerating axons for several months after grafting.

### Alginate

Alginate is a unique material derived from brown seaweed. Calcium alginate gel has been used as a food additive. However, due to its toxicity, calcium alginate has been limited in terms of its medical application. In our laboratory, a new type of alginate gel was produced by treatment of ethylenediamine and carbodiimide, which covalently cross-links the carboxyl groups of alginate. The resulting alginate gel has a higher transparency and higher water content than calcium alginate gel. This covalently cross-linked new alginate gel has been shown to be useful for skin repair and nerve regeneration [8], and as a bone scaffold.

Bridging the nerve gap by freeze-dried covalently cross-linked alginate gel promoted nerve regeneration in rat sciatic and cat facial nerves. We analyzed nerve regeneration through alginate gel in the early stages within 2 weeks and in the late stages up to 21 months after transplantation. Alginate is not fabricated into the tube, but used in the form of a disc by which the injured nerve is sandwiched bridging the proximal and distal stumps. When put into the lesion, the freeze-dried alginate disc absorbs the body fluid to become softer.

In the very early stage, regenerating axons grow without Schwann cell investment through the partially degraded alginate gel, being in direct contact with the alginate without a basal lamina covering. Numerous mast cells were found infiltrating the alginate. Later, regenerating axons were surrounded in small bundles by common Schwann cells. Some axons at the periphery were partly in direct contact with alginate. At the distal stump, numerous Schwann cells had migrated into the alginate 1–2 weeks after surgery. Though regenerated myelinated fibers were thin (approximately 1 μm in diameter) at 8 weeks, they had a distribution pattern similar to that of normal nerves at 21 months after surgery. It can be said that alginate gel has good biocompatibility for axonal outgrowth and Schwann cell migration. Alginate gel served as an effective conduit for the growth of regenerating axons of the central nervous system including the spinal cord [9].

### Chitosan

Chitosan is another unique material that is a derivative of chitin. Chitosan has a polycationic carbohydrate structure, which provides a suitable scaffold for cell adhesion. Chitosan degrades into saccharides including glucosamines, metabolites normally found in mammals. Chitosan is considered to lead to minimal foreign body reaction. Presently, chitosan is clinically applied to protect burned skin in plastic surgery.

Transplantation of a cell adhesive laminin-conjugated chitosan tube enhanced nerve regeneration. The tube structure is not necessarily required for chitosan or alginate for bridging the nerve gap. In our study, the proximal and distal nerve stumps with 8-mm gap were sandwiched by freeze-dried chitosan gel sponge. By 14 days, regenerating axons had reached and extended through the distal stump. Numerous macrophages accumulated in a dense cell layer on the chitosan and phagocytosed it. Regenerating axons were not in touch with chitosan nor with macrophages, but extended through the loosely woven connective tissue compartment between the chitosan. Two to 4 months after surgery, regenerated myelinated fibers were as thick as normal fibers. Chitosan is considered to be usable as a conduit for peripheral nerve regeneration [10].

## Synonyms

Mesenchymal stem cell

## Definition

Bone marrow stromal cells (BMSCs) are included in the so-called ►mesenchymal stem cells [1] that give rise to various kinds of cells including osteocytes, chondrocytes, tenocytes, adipocytes, and smooth muscle cells [2]. BMSCs were initially referred to as plastic-adherent cells.

## Characteristics

### Preparation of BMSCs

Usually the femur and tibia of the rat are used as a source of bone marrow. The bones are cut off at both ends, and the marrow is flushed out withα-MEM using a needle. The collected bone marrow tissue is dissociated, and then filtered. The suspension is centrifuged, and the pellets are suspended with α-MEM, and cultured in medium. Forty-eight hours later, non-adherent cells are removed by replacing the medium. Plastic-adherent cells, referred to as stromal cells [3], grow to confluence, and are passaged to maintain the proper conditions.

### Characterization of Isolated BMSCs

Cell surface markers were assessed using FACS to characterize isolated rat and human BMSCs. BMSCs expressed CD29 (β1-integrin), CD90 (Thy-1), and CD54 (ICAM-1), but not CD34 (a hematopoietic stem cell marker), CD11b/c (macrophages), or vWF (human endothelial cells), consistent with previous reports [4]. Basically identical results were obtained by immunocytochemical examination. BMSCs were also immunopositive to mesenchymal progenitor markers; 95% of BMSCs showed immunopositivity to PDGF receptor β and 45% to smooth muscle actin. In contrast, vascular (CD31) and hematopoietic (CD45, leukocyte common antigen) lineage markers were negative. As for neuronal markers, only 0.5% of BMSCs showed neurofilament immunoreactivity.

### Cell Differentiation

BMSCs differentiate into osteocytes, chondrocytes, adipocytes, and other cell types including skeletal muscle fibers, cardiomyocytes, hepatocytes, neural cells and epithelial cells of the lung and intestinal tract in specific experimental conditions [1,2,5]. On the other hand, there are reports that the apparent trans-differentiation might at least in part be due to cell fusion.

### Cytokines and Trophic Factors

BMSCs secrete cytokines such as macrophage colony-stimulating factor-1 (MCSF-1), interleukins, stem cell factors, and trophic factors including nerve growth factor [NGF], brain-derived neurotrophic factor [BDNF], hepatocyte growth factor [HGF], and vascular endothelial-derived growth factor [VEGF] [6]. It is also reported that BMSCs induce glial cells to produce neurotrophic factors like BDNF and NGF. BMSCs also express receptors for many molecules including interleukin 6 or 7, leukemia inhibitory factor, stem cell factor, granulocyte and macrophage colony-stimulating factors, thrombopoietin, tumor necrosis factor β1 and β2, and interferon γ.

### Cell Transplantation

Transplantation of BMSCs has been studied in CNS injury including spinal cord injury [7–9], and traumatic and ischemic brain injuries [10] of the rat. BMSCs are transplanted by direct injection into the spinal cord lesion [7] or via blood flow.

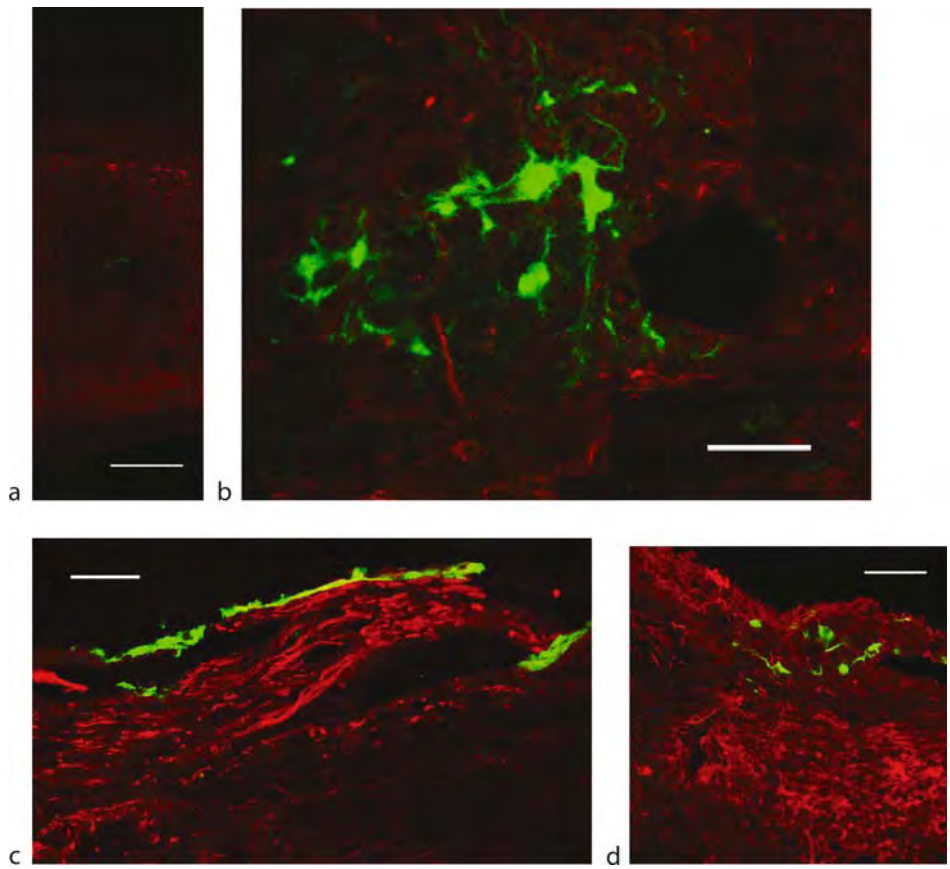
BMSCs were directly transplantated into the injury site in animal models of traumatic and ischemic brain injuries, Parkinson's disease and spinal cord injury. BMSCs directly transplanted into the injured spinal cord 1 week after injury led to significant recovery.

It was suggested that grafted cells differentiated into neurons and integrated into neuronal networks.

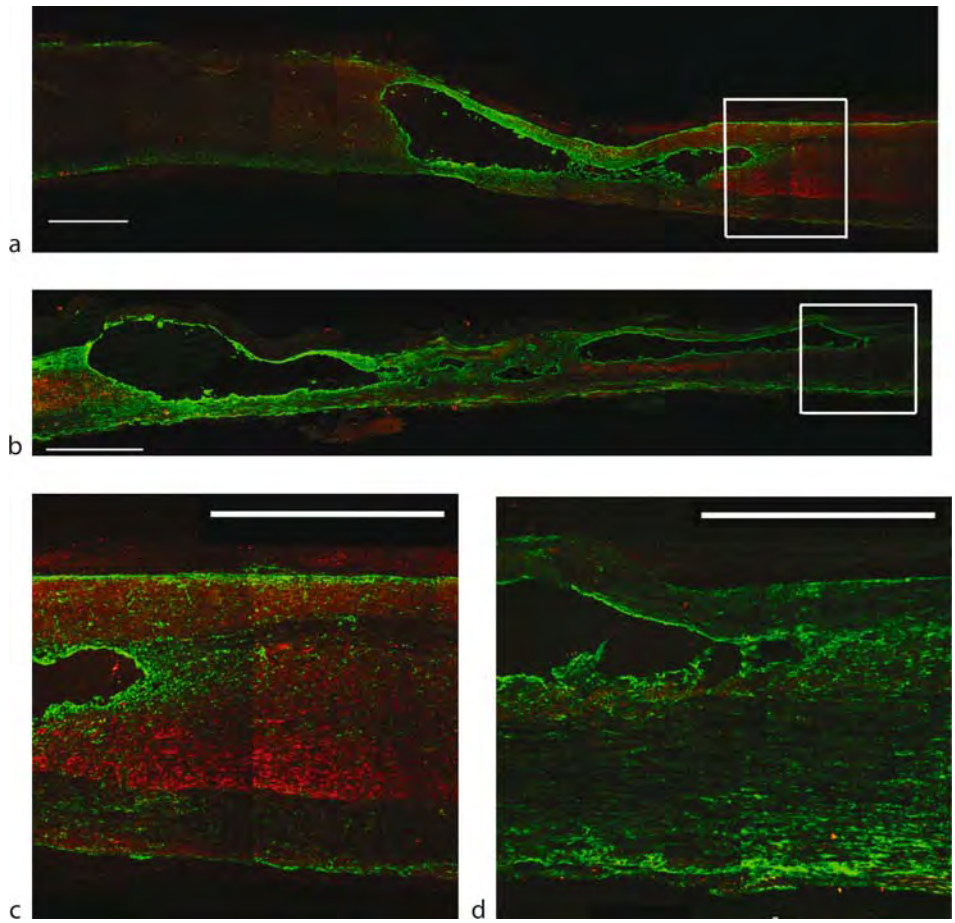
However, the direct injection of transplants might cause secondary damage to the surviving tissues at the lesion site. Therefore, we have proposed that the infusion of BMSCs through ►cerebrospinal fluid is more appropriate and practical than direct cell injection into the lesion [8]. In our experiment, the spinal cord of the rat was contusion-injured at T8–9, and BMSCs (approximately $1 \times 10^6$ viable cells) derived from the bone marrow of the same strain were infused into the cerebrospinal fluid (CSF) via the fourth ventricle through a hole drilled at a site 3.5 mm caudal to the lambda suture in the midline. The injected cells were conveyed to the subarachnoidal space of the spinal cord though the CSF, and some of them invaded the contusion-injured site, while most were attached to the spinal cord surface (Fig. 1a–d).

There is no finding suggesting the proliferation of BMSCs within the lesion or on the surface of the spinal cord. BMSCs disappeared before 3–4 weeks after infusion from the recipient. BMSCs did not differentiate into any neural cells in the host tissue, as examined by immunohistochemistry. Although BMSCs did not survive for a long time nor differentiate into neuronal cells, the cavity in the spinal cord decreased in volume (Figs. 2 and 3a, b), and the behavior of the rats with transplantation improved compared with the control rats as based on the ►BBB score (Fig. 3c, d).

It is probable that BMSCs release some trophic substances into the CSF effective for the rescue of degenerating tissues, resulting in the volume reduction



**Transplantation of Bone Marrow Stromal Cells for Spinal Cord Regeneration. Figure 1** These micrographs show the immunohistochemistry of the contusion-injured spinal cord of the rat 2 weeks after cell infusion. BMSCs were infused through the fourth ventricle into the cerebrospinal fluid immediately after contusion. The host spinal cord tissue was stained for GFAP (*red*) in a–b. (a) Low magnification of the GFP-positive cells (*green*) located within the lesion. (b) BMSCs in (a) are shown at higher magnification. BMSCs are partly integrated into the host tissue. (c, d) The transplanted BMSCs (*green*) are also seen attached to the roots (c) and located within the spinal cord near the surface (d). Scale bar; 1 mm in (a), and 240 μm in (b–d).



**Transplantation of Bone Marrow Stromal Cells for Spinal Cord Regeneration. Figure 2** Immunohistochemistry of the spinal cord with cavities from the BMSC-infused rats 5 weeks after transplantation. Rats were injured by weight-drop from a height of 25 mm. The spinal cord was double-stained for GFAP (*green*) and β-tubulin (*red*). (a, b) Low magnification of the spinal cord cavities of BMSC-infused rats (a) and control rats (b). The cavity is bordered by GFAP-stained astrocytes both in BMSC-transplanted (a) and control spinal cord (b). (c, d) The boxed parts of the cavities in (a, b) are enlarged in (c, d), respectively. The red-stained neuronal elements are distinct in the BMSC-transplanted spinal cord rats (c) as compared with the control spinal cord (d). The β-tubulin-stained neuronal elements are abundant in areas close to the cavity in the spinal cord from BMSCs-transplanted rats (c), while they are sparse in the spinal cord from the control (d). Scale bar; 1 mm in (a–d).

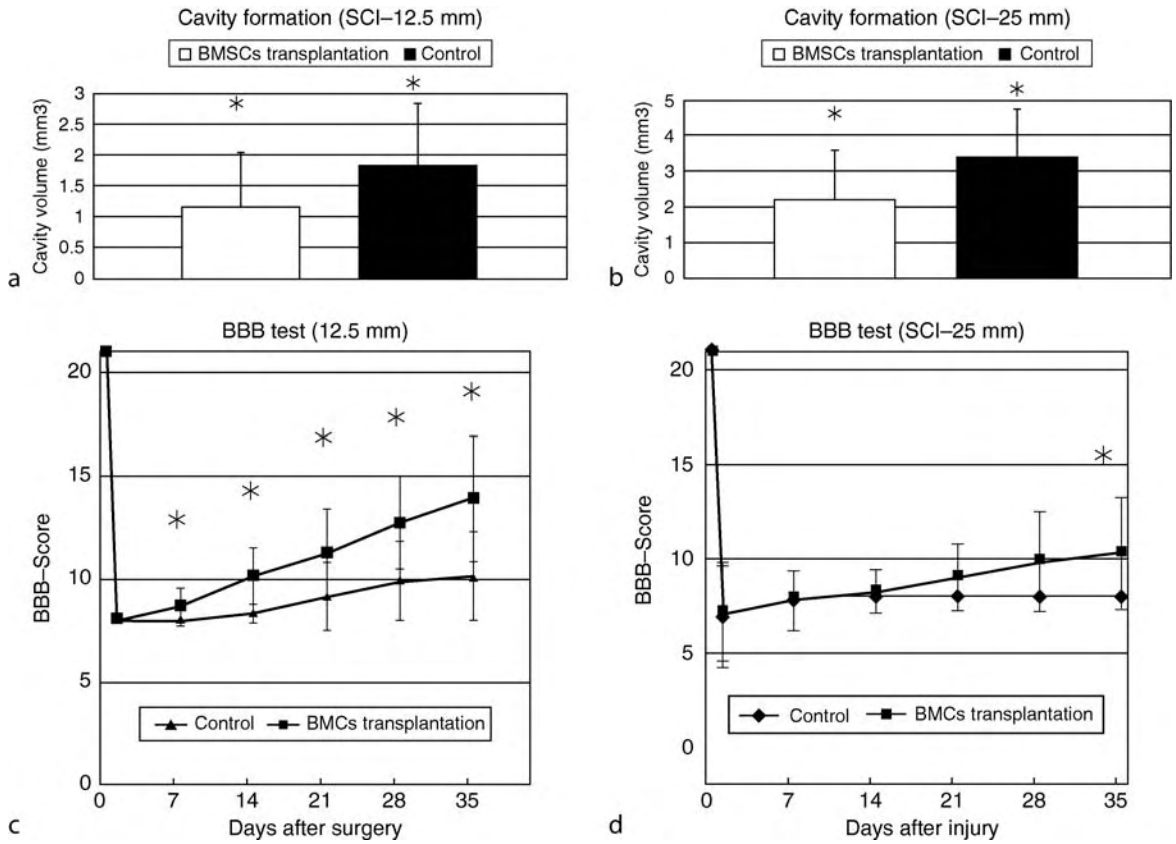
of cavities and leading to the behavioral improvement of rats (Figs. 2 and 3). The finding that CSF from the rats, into which BMSCs had been injected 2 days prior, enhanced the attachment and differentiation of neurosphere cells *in vitro* suggests that some trophic substances might be released from BMSCs into the CSF.

Considering that BMSCs can be used for autologous transplantation, and that the CSF-infusion of transplants imposes a minimal burden on patients, the above results indicate that the transplantation of BMSCs is a promising clinical treatment of CNS injury.

## Clinical Application

The clinical application of bone marrow stromal cells is ready to commence based on the work in our laboratory. After discussion for more than 2 years, the Medical Ethics Committee of Kansai Medical University approved our application on July 1, 2005: the treatment of acute spinal cord injury by infusing autogeneic bone marrow stromal cells through the CSF of patients within 1–2 weeks after injury.

Transplantation of autogeneic bone marrow stromal cells was carried out by lumbar puncture to the first patient with spinal cord injury at C5 on March 23, 2006. There has been no harmful implication with respect to cell transplantation through the cerebrospinal fluid. The patient is now under observation for the evaluation of the sensory as well as motor function improvement by the effect of cell transplantation.



**Transplantation of Bone Marrow Stromal Cells for Spinal Cord Regeneration. Figure 3** (a, b) These graphs show the difference in cavity volume between the BMSC-transplanted and control groups at 5 weeks after cell infusion. The spinal cord was injured by weight-drop from a height of 12.5 mm ($n$ = 8: control group $n$ = 8: BMSC injection group) (a) and from the height of 25 mm ($n$ = 8: control group $n$ = 8: BMSC injection group) (b). The cavity volume values were significantly different between the BMSC-grafted and control rats (*$p$ < 0.05). (c, d) These graphs show the analysis of locomotor recovery as measured by BBB scores. The experimental designs of (c, d) correspond to (a, b), respectively. BBB scores are significantly higher in the BMSC-transplanted rats at all time points in (c), and at 5 weeks after injection in (d) (*$p$ < 0.05).

# Transplantation of Neural Stem Cells for Spinal Cord Regeneration

Hideyuki Okano
Department of Physiology, School of Medicine, Keio University, Tokyo, Japan

## Definition

Transplantation of in vitro expanded ►neural stem cells into a damaged site of the spinal cord in vitro, aimed at axonal regeneration, replenishment of lost neural cells, and functional restoration.

## Characteristics

### Background

It has long been believed that the damaged adult central nervous system (CNS) cannot regenerate. However, it is now an important target of study in the field of regenerative medicine. In fact, to *recapitulate* normal neural development has become a vital strategy for ►regeneration of the CNS. During normal CNS development, stem cells or stem-like cells appear at the earliest stage. Based on this knowledge, there is increasing interest in the usefulness of stem cells in the CNS (neural stem cells, NSCs) as a tool to recapitulate normal CNS development and achieve regeneration.

NSCs have multilineage potential and self-renewing capability. Since there are no definitive molecular markers for NSCs, it is practically difficult to distinguish NSCs from neural progenitor cells. In such cases, these cells are collectively referred to as neural stem/progenitor cells (NSPCs).

Establishment of experimental evidence of the existence of NSCs with multilineage potential and self-renewing capability has been aided by one of the major breakthroughs in CNS stem cell biology: clonogenic expansion of NSCs by neurosphere formation in serum-free medium containing EGF and/or FGF-2 [1]. This excellent culture method has enabled the definition of the NSCs experimentally and the quantification of the multilineage potency and self-renewing capability of these cells. The availability of a method for the expansion of stem cells in vitro is currently limited to the stem cells of the nervous system. Furthermore, using this culture method, NSCs or NSPCs have been shown to proliferate in an undifferentiated state in vitro, allowing mitotic expansion of the cells and cell harvesting in bulk. Taking advantage of the ease with which NSPCs can be harvested from ►neurosphere cultures (or similar methods) in vitro, numerous attempts have been made to transplant NSPCs into animals in an attempt to treat damaged brains and spinal cords [2]. In this study, we shall describe attempts at transplantation of NSPCs into an injured spinal cord with the aim of achieving spinal cord regeneration.

### Traumatic Injury of the Spinal Cord and the Current Standard Clinical Treatments for this Condition

The spinal cord is a part of the CNS and its structure is characterized by full preservation of the primitive segmental arrangement established in the embryonic neural tube. The spinal cord extends from the lower end of the brainstem, down the vertebral canal to the upper margin of the second lumbar vertebra, conducting and modulating impulses back and forth between the brain and the rest of the body. Ascending sensory pathways transfer sensory information from the nerve endings in the skin, muscles, joints and systemic organs to the brain. Descending motor pathways, including the corticospinal tracts (CSTs), control the voluntary movements and reflex functions of the limbs and trunk. Other descending pathways modulate the output of the autonomic nervous system, which controls body homeostasis, as well as the bowel, bladder and sexual functions. Based on this functional structure, traumatic spinal cord injuries can result in severe damage, such as the loss of motor and sensory functions caudal to the level of injury, because of severance of the descending and ascending fiber tracts. Disruption of fibers that control the autonomic nervous system could also lead to impairment of vascular, exocrine and endocrine gland, bowel, bladder, and sexual functions.

The current standard clinical treatment for spinal cord injury consists of surgical stabilization of the vertebral column to prevent posttraumatic instability of this column, and administration of high doses of steroids to decrease the amount of tissue damage. However, these treatments have modest effects at best, and there is a great need for novel “regenerative” treatment strategies that could significantly protect and/or restore the functions of the spinal cord following SCI.

### Experimental Regenerative Treatments for the Injured Spinal Cord

The presumed lack of self-regenerative properties of the adult mammalian spinal cord could be attributable

to a combination of factors, including the inhibitory characteristics of CNS myelin and injury-induced ►glial scars, the apparent inability of endogenous adult NSCs in the spinal cord to initiate de novo neurogenesis after injury, and the lack of sufficient trophic support. However, since the1980s, numerous studies have reported on the beneficial effects of transplantation of peripheral nerves and the fetal spinal cord for spinal cord injuries. These studies have indicated that the introduction of an appropriate environment into the injured site can induce the injured axons to regenerate. Although researchers first focused on the effectiveness of fetal spinal cord transplantation for spinal cord injuries, donor shortage and ethical problems preclude the practical clinical application of this approach. On the other hand, recent progress in the understanding of the biology of NSCs has made it possible to routinely harvest NSCs from small amounts of fetal CNS tissue in vitro, e.g., by the neurosphere culture method [1]. Therefore, expansion of NSPCs in vitro may, at least be partially of use to overcome the practical and ethical problems associated with fetal tissue transplantation, and such cells may provide a potential source for the graft material needed for attempts aimed at regeneration of the injured spinal cord.

In addition to NSPCs, there have been numerous attempts at regeneration of the spinal cord using transplantation of other cells, including genetically engineered NSPCs, Schwann cells, marrow stromal cells, olfactory ensheathing glia, activated macrophages (reviewed in [3]) and embryonic stem cells-derived oligodendrocyte progenitor cells [4], the effects of which have been described in other essays in this Encyclopedia and elsewhere.

## Possible Obstacles in the Transplantation of NSCs into the Injured Spinal Cord

One of the most important issues that must be addressed with regard to the transplantation of NSPCs into the injured spinal cord is that the adult spinal cord appears to be a non-neurogenic site, i.e., endogenous NSPCs existing in the adult rat spinal cord proliferate and differentiate exclusively into astrocytes, but not into neurons, in situ following injury [5]. However, these observed lacks of neurogenesis are not likely to be an intrinsic characteristic of adult spinal cord-derived NSPCs, since these cells have been shown to be able to differentiate into neurons, both in vitro and following transplantation into neurogenic sites, such as the hippocampal dentate gyrus [6]. Thus, it is likely that the microenvironment plays an important role in the differentiation of NSCs and their progenies. Naturally, these observations raised the possibility of successful treatment of spinal cord injury by transplanting NSCs into the sites of injury of the spinal cord.

## Therapeutic Time Window for NSPC Transplantation in a Model of SCI

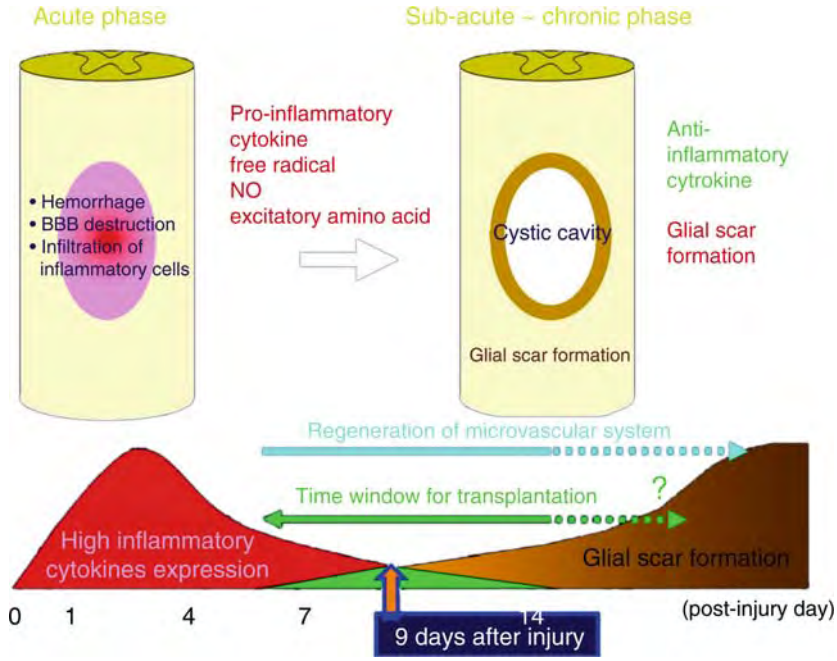
Considering the microenvironment within the injured spinal cord, it was shown that in the adult spinal cord, transplanted exogenous NSPCs may not be absolutely non-neurogenic, and that transplantation during a narrow therapeutic time window may allow successful neurogenesis [7]. This window of opportunity may be rather brief, because the microenvironment in the host spinal cord changes rapidly after injury. Recent reports have shown that transient severe inflammation occurs around the injured site of the cord during the acute phase, immediately following the injury. During this time, the levels of many ►pro-inflammatory cytokines that have neurotoxic or astrocyte-inducing effects, such as IL-1, IL-6, and TNFα, increase, to then decline sharply within 24 h [8], indicating that the microenvironment during this acute phase may not be suitable for the survival of grafted cells. Thus, the immediately post-traumatic microenvironment of the spinal cord, which is in an acute inflammatory stage, may not be favorable for the survival and differentiation of NSPC-transplants. On the other hand, in the chronic stage after injury, glial scars form at the injured site in the spinal cord and inhibit the regeneration of neuronal axons. Thus, the optimal timing for transplantation may be 1–2 weeks after the injury (Fig. 1).

Based on this evidence, in this study, in-vitro-expanded rat fetal spinal cord-derived NSPCs were transplanted into an adult rat spinal cord ►contusion injury model [at the C4–C5 level] nine days after the injury, to examine the ability of the transplanted NSPCs to differentiate into neurons in vivo and the consequent improvement of the motor functions [7] (Fig. 2).

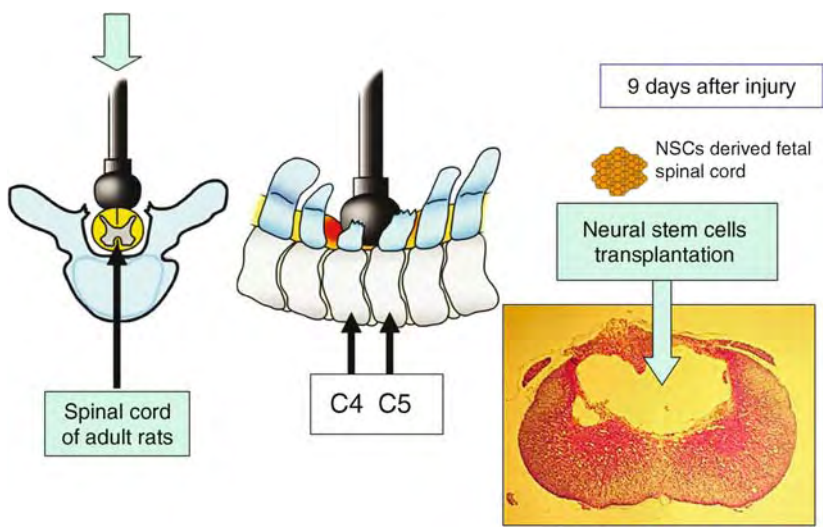
Following transplantation at this time point after the injury, it was found that the transplanted neurosphere cells, cultured from the rat embryonic spinal cord on Day 14.5 (E14.5) and pre-labeled with bromodeoxyuridine (BrdU) in culture, could introduce neurons, astrocytes and oligodendrocytes into the injured adult rat spinal cord. Furthermore, the transplantation resulted in mitotic production of new neurons in vivo, and these neurons extended their processes into the host tissue to form synaptic structures. In addition, we observed behavioral improvement in the rats transplanted with neurosphere cells as compared with the control rats.

## Efforts to Enhance the Therapeutic Effects of NSPC-Transplantation

To achieve even better effects of cell therapy using NSPCs in various types of CNS damage, including SCI, efforts have been made to improve the therapeutic actions of NSPCs by genetic engineering (stem cell gene therapy) [9], developing convenient methods



**Transplantation of Neural Stem Cells for Spinal Cord Regeneration. Figure 1** Therapeutic time window for transplantation of NSCs into injured spinal cords (adapted from reference [2]). The time schedule of various events after spinal cord injury. Ogawa et al. [7] found that delaying NSPC transplantation until nine days after rat spinal cord injury resulted in the production of new neurons, oligodendrocytes, and astrocytes, as well as functional recovery. In contrast, the transplantation during the acute phase, that is, within a week of the injury, failed to induce these effects, probably due to the high expression level of inflammatory cytokines, including IL-1α and β, TNF-α and IL-6. Taking into consideration previous findings concerning the transplantation of fetal neural tissues into the cerebral cortex, which showed the important contribution of micro vascularization to the success of such transplantation, it is suggested that the beneficial effects of delayed NSC transplantation could result from microvascular regeneration in the host. Delaying of the transplantation until the chronic phase is unlikely to lead to functional recovery, due to enlargement of the cystic cavities at the site of injury and glial scar formation.



**Transplantation of Neural Stem Cells for Spinal Cord Regeneration. Figure 2** NSPC transplantation into an adult rat model of SCI. Contusive injury was induced at the level of C4/C5 in adult rats. This SCI model showed cavity formation in the dorsal part of the spinal cord. In-vitro-expanded NSPCs were transplanted into the cavity nine days after the induction of the injury.

for administrating NSPCs into injured spinal cord, or using combinations of various other therapeutic interventions (e.g., scaffolds for cell therapy) with NSPC transplantation.

### Genetically Engineered NSPCs

Here, as an example, I would like to introduce a recent development of Neurogenin-2 gene-based stem cell gene therapy in a SCI model. It was reported that transduction of adult NSPCs with Neurogenin-2 (Ngn-2), a neuronal basic Helix-Loop-Helix gene, before transplantation into a rat thoracic spinal cord weight-drop injury model, suppressed astrocytic differentiation of the engrafted cells and prevented graft-induced sprouting and allodynia-like hypersensitivity of the forepaws [9]. On the other hand, transplantation of NSPCs without the Ngn-2 transgene caused aberrant axonal sprouting associated with allodynia. Thus, transduction with Ngn-2 improved the beneficial effects of the engrafted stem cells, including the increase in the amounts of myelin in the injured area, and recovery of hindlimb locomotor functions and hindlimb sensory responses, as confirmed by functional magnetic resonance imaging.

### Convenient Methods for Administrating NSPCs into Injured Spinal Cord

Instead of injecting cell suspension of NSPCs into the intraspinal cavity that resulted from the secondary injury, a recent report suggests a novel and convenient method of supplying cultured neurosphere cells to the injured spinal cord, by injection of cells into the cerebrospinal fluid (CSF) through the fourth ventricle or cisterna magna. GFP-tagged hippocampus-derived NSPCs were transplanted into the CSF of a rat with SCI. Notably, injected cells were extensively transported by CSF within the subarachnoidal space, survived as clusters on the pial surface of the spinal cord, migrated into the lesion site and integrated into the injured spinal cord tissues, indicating the efficacy of this new method.

### Scaffolds for Cell Therapy

To better direct repair following spinal cord injury (SCI), an implant modeled after the intact spinal cord consisting of a multicomponent polymer scaffold (including poly(lactic-*co*-glycolic acid) (PLGA)) seeded with a murine NSPC-line (clone C17.2) was developed [13]. Implantation of the scaffold-C17.2 cells unit into an adult rat hemisection model of SCI promoted long-term improvement in function (persistent for 1 year in some animals) relative to a lesion-control group. Other types of scaffolds, including various types of extracellular matrixes, are also being developed together with NSPC transplantation in order to enhance the tissue-integration and survival of transplanted NSPCs-derived cells within the host tissues.

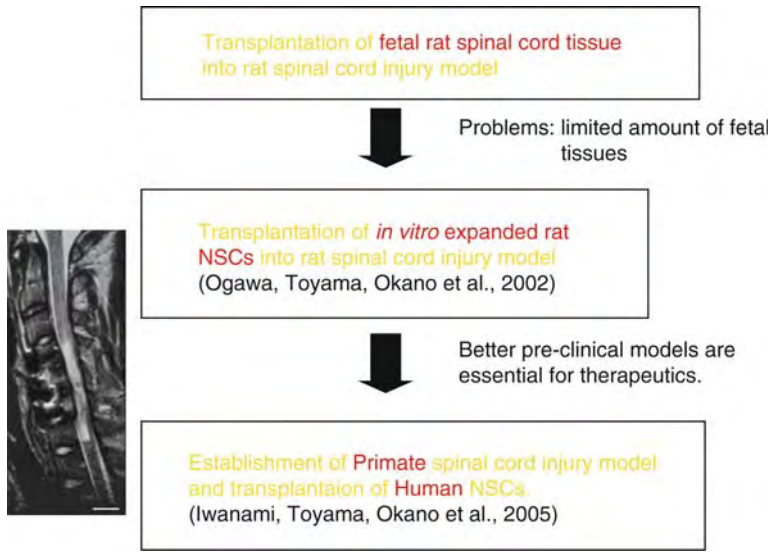
## Primate SCI Model and NSPC Transplantation

Direct extrapolation of the results obtained in rodent experiments to clinical cases is difficult, because of species differences of the spinal cord between rodents and primates, in terms of the structure and functions. Therefore, preclinical studies using nonhuman primates, are necessary before NSPCs can be applied in clinical trials to treat human patients with spinal cord injury (SCI). Therefore, we conducted a preclinical study on ►common marmosets (*Callithrix jacchus*), taking advantage of the fact that these animals can be bred in experimental colonies, their supply is stable and reliable, and that adequate genetic and microbiological control is possible to minimize biases. We then established a common marmoset model of graded-contusive SCI, which had characteristics quite similar to those of human SCI, and examined the effectiveness of human NSPC transplantation on the recovery of motor functions in the contusive SCI models of the primates with tetraplegia [10]. Cervical-contusion SCI was induced in ten adult common marmosets using a stereotaxic device. Nine days after the injury, in-vitro-expanded human NSPCs were transplanted into the spinal cord of five randomly selected animals, and the other sham-operated control animals received culture medium alone. Eight weeks after the transplantation, histologic analysis revealed that the grafted human NSPCs survived and differentiated into neurons, astrocytes, and oligodendrocytes, and that the cavities in the spinal cord of the experimental animals were smaller than those in the sham-operated control animals. The motor functions of the transplanted animals were also significantly better than those of the sham-operated control animals. These findings suggest that NSPC transplantation was effective for the restoration of structure and function after SCI even in primates, and that NSPC transplantation might also be feasible in the treatment of SCI in humans.

## Mechanisms of Functional Recovery of the Injured Spinal Cord Following NSPC Transplantation

Based on the recent results of NSPC transplantation into SCI models, the mechanisms underlying the functional improvement in the rat and primate SCI models may be explained as follows:

1. Neurons derived from the grafted cells “relayed” signals from the disrupted fibers in the host, including ascending fibers that existed in the dorsal column. Alternatively, grafted NSPC-derived inhibitory (GABAergic and/or glycinergic) interneurons established synapses with the host neurons and functionally restored the neuronal circuits disrupted by the SCI, to attenuate the spasticity and/or excitotoxicity [15].



**Transplantation of Neural Stem Cells for Spinal Cord Regeneration. Figure 3** Progresses in cell therapy for SCI. Historically, fetal spinal cord tissues were transplanted into rat SCI models (*upper panel*). Obviously, these studies had the problems of limited availability of fetal tissues and ethical problems, interfering with their clinical application. On the other hand, transplantation of in-vitro-expanded NSPCs nine days after the injury resulted in functional recovery of the injured spinal cord in adult rats (*middle panel*) [4]. As a further step, a primate SCI model was established, in which functional restoration was achieved after transplantation of human NSPCs [6].

2. Oligodendrocytes derived from the grafted cells might have remyelinated the fibers that had been demyelinated as a result of injury, and restored the salutatory conduction along the neuronal axons of the long-projection neurons.
3. Astrocytes derived from the donor neural progenitor cells might have played active roles in the generation of neuronal cells, axonal regeneration of host neuronal axons, enhancement of axonal extension of donor-derived neurons, synapse formation, and/or physiological maturation of the neuronal cells.
4. ►Trophic effects (indicating that the functional improvement may not be dependent on the transplanted human NSPCs becoming functional neurons and making the right connections, but rather on the secretion of trophic factors from the transplanted cells) might also be effective for the survival and differentiation of the host cells in the injured spinal cord, leading to functional recovery.

## Conclusions and Perspectives

The progress of the stem cell therapy for SCI can be summarized in Fig. 3.

However, the underlying mechanisms for functional improvement or other benefits associated with most of the cell-based transplants, including NSPC transplantation, are not currently precisely understood. Elucidation of the mechanisms underlying the possible benefits and disadvantages of cell-based transplantation may be expected to guide further development of improved therapeutic interventions for patients with SCI patients [4].

# Transplantation of Olfactory Ensheathing Cells

Giles W Plant
Red's Spinal Cord Research Laboratory, School of Anatomy and Human Biology, The University of Western Australia, Crawley, Perth, WA

## Synonyms

Spinal cord; Glia; Injury

## Definition

Olfactory ensheathing cells: a specialized cell from the nose to support nerve growth within the spinal cord.

Brain and spinal cord injuries have severe consequences for human patients, but these injuries have considerable financial and social consequences, particularly to their families. The field of spinal cord injury (SCI) in particular has provided the scientists and clinicians of today a very challenging problem. To address the problem of SCI, numerous attempts have been developed to treat these injuries in mammalian research models. Axonal regeneration within the central nervous system can be influenced in a number of ways; this review will concentrate on the transplantation of cells isolated from adult tissues only. These cells include a number isolated from both the peripheral and central nervous systems. The main focus of this essay is one cell type isolated from the primary olfactory system (center for smell processing in the brain), called olfactory ensheathing cells, and their potential role in SCI repair.

## Characteristics

### What are Olfactory Ensheathing Cells?

The olfactory ensheathing cells are specialized glial cells found in the olfactory system. They are located specifically within the olfactory epithelium/Lamina propria and olfactory bulb. The ensheathing cell surrounds sensory axons as they leave the olfactory epithelium and accompany these axons from the nose all the way to their targets in the brain. The ensheathing cells share properties of other glia ("glue") such as astrocytes and Schwann cells, which are the two main glial types found in the central nervous system (CNS) and peripheral nervous system (PNS) respectively. This shared property makes the ensheathing cell quite original, because it can function in both the PNS and CNS well. The primary olfactory system is also unusual in its ability to replace its neurons throughout adult life. This process is known as neurogenesis and the olfactory ensheathing cells are thought to play a very important role in this mechanism. The roles within the olfactory system and their properties have made the olfactory ensheathing cells promising candidates for nervous system repair particularly SCI.

### Olfactory Ensheathing Cell Transplants

Numerous SCI models have been used to test the efficacy of olfactory ensheathing cell transplants. These models have involved dorsal root lesions, partial tract lesions, contusion/compression or complete transections. Additional models involving photochemical damage of the spinal cord have also included the use of ensheathing cell transplants to mediate repair.

Numerous experiments have been carried out over the last 11 years, utilising olfactory ensheathing cell transplants to the injured spinal cord. The first experiment demonstrating that OEC were able to support regenerative growth of lesioned axons within the damaged CNS (particularly spinal cord) was performed by [1] in a model of dorsal root injury. Following the lesioning of the dorsal root and their re-adjoining to the spinal cord, ensheathing cells were injected into the spinal cord close to where a dorsal root had been cut. Sensory axons were able to regenerate into the spinal cord from the peripheral nerve and functional contact was made with target neurons. Two concerns arose from this study, the first being that Hoechst 33342 dye used in the study has a propensity to leak into surrounding tissue giving inaccurate monitoring of transplanted cells and secondly, appropriate functional activity is most accurately measured by physiological and behavioural methods not used in the original study. Other laboratories have supported the original findings, but two recent studies have not been able to confirm the original results. Of particular interest was the lack of physiological active contacts made by any sensory axons in this paradigm [2]. The lack of similarity and outcomes between projects may be due to cell transplantation, cell origin, cell purity and even rat versus mouse models.

This initial work by [1] was closely followed by two publications reporting the regeneration of supraspinal motor axons into grafts of olfactory ensheathing cells and in combination with Schwann cells grafts [3,4]. Li and colleagues [4] described the use of olfactory ensheathing cells isolated from the adult olfactory bulb and reported the return of function of the forelimb after a unilateral lesion of the corticospinal tract at a cervical level of the spinal cord. However, a cell purification protocol was not used, unlike Ramon-Cueto et al. [4] who used a p75 antibody purification protocol used in original publication [1]. These results raise an important question of whether OEC are the true regenerative cell in some experiments. Further published reports using lesions of the CST tract have also had mixed results when using OEC transplants. Studies have utilised OEC transplants from the olfactory bulb, but differ in purity and isolation techniques; this may have influenced the end results. Ruitenberg and colleagues [5] recently described the use of p75 purified OEC transplants engineered to secrete NT-3 or a reporter gene *LacZ* but showed no return of forepaw function when compared to medium controls when a lesion of the C4 spinal cord was carried out. Although forepaw behaviour was not changed, it was intriguing to observe that axonal regeneration/sparing was seen in the CST projection and axons were found long distances from the lesion (up to 1 cm). Other combinational therapies with OEC have been used to repair the corticospinal tract, including treating the animal with methylprednisolone with some measure of success.

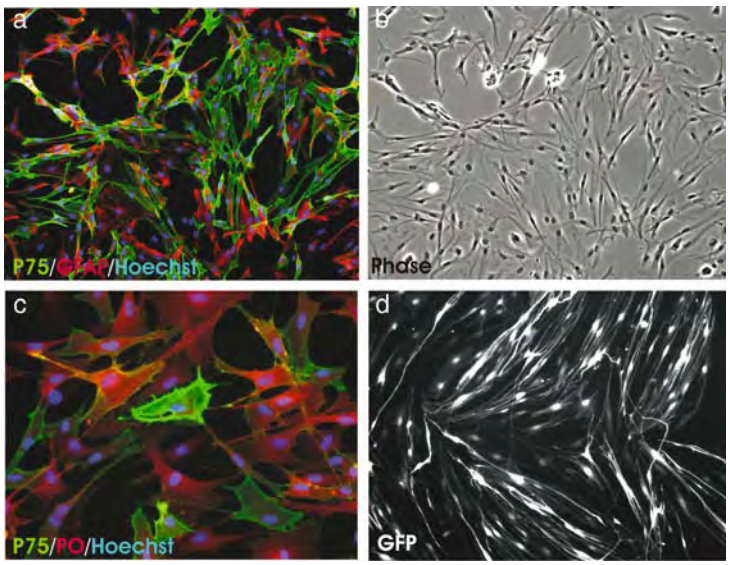
Ramon-Cueto and colleagues [4] showed in a first experiment using a complete transplantation of the spinal cord that OEC could accompany axons descending in the spinal cord to re-innervate the distal spinal cord. This report combined the growth promotional abilities of Schwann cells with OEC transplants at either end of the Schwann cell grafts. Previous reports using Schwann cells had showed that spinal cord axons can enter these grafts, but cannot exit due largely to the expression of inhibitory molecules. OEC transplants in this experimental model enabled 5HT-positive raphe axons in particular to enter the distal spinal cord segments via an unusual and rather unexpected route, the connective fibroblast/OEC tissue surrounding the Schwann cell filled man made polymer tube (►PAN/PVC tube). This propensity of raphe axons to grow near or through OEC grafts has also been shown in complete transection and contusion injuries of the spinal cord. Further to this initial work combining Schwann cells with OEC, [6] produced a report of the effectiveness of p75 purified OEC transplants on the complete trans-Ected spinal cord without Schwann cells added. The authors reported successful behavioural recovery of the transplanted rat's hind limb after a complete spinal cord transection. Interestingly the authors had to wait 8 months for the effect to be seen involving climbing activity of the rat. Another result observed with this novel experiment was the regeneration of a number of other important motor tracts, including the corticospinal tract.

An important advance in OEC transplantation was the use of the New York University contusion device to injure the rat spinal cord, aiming to mimic the injury seen in the majority of human spinal cord cases. OEC transplants were injected into a ►contusion injury after 30 min or 7 days after the initial impact [7]. An increase in behavioural recovery (using the open field ►BBB test) was seen in the 7 day transplant group but not the 30 min group, when compared to control medium injected groups. In addition, numerous descending motor populations of axons, in particular rubrospinal and raphespinal, were found to be in larger numbers distal to the contusion injury. Further to this study, a combined use of Schwann cells with OEC did not improve behaviour or increase myelination. However interpreting these results is difficult, because these experiments were relying on the use of immunohistochemical markers not exclusive to OECs. How many OEC had survived transplantation, what roles do they really play in the repair mechanisms and how do they effect Schwann cell invasion into the injury site from the periphery?

This problem of identifying OECs within *in vivo* spinal cord models is acknowledged and has been an experimental concern for many years. However, this was elegantly answered by Ruitenberg and colleagues [8] by using gene therapy to label the transplanted cells with a reporter gene. Cell labelling was carried out in two ways, either by adenoviral or lentiviral vectors, with the latter being the most stable and successful. Green fluorescent protein (GFP) – positive OECs were seen within transplant sites even after 4 months post transplantation and could be easily identified from the host glia. In addition this labelling technique allows cells to be tracked throughout the CNS neuropil and provide absolute evidence of migration. Other reports have used gene therapy to label OEC, both for *in vivo* identification and for secretion of additional growth factors supplied to a lesion site [9]. OEC have also been identified via xenografting; human, pig or mouse cells and used in conjunction with specific antibodies, metal nanoparticles, and in situ hybridization to locate these transplanted cells or recently transgenic animals with reporter genes (eg GFP mice or rats) have been used (Fig. 1).

## Additional Benefits of OEC Transplantation

The physical and molecular interaction of transplanted cells within the host spinal cord is vital to the overall success of repair. Schwann cells in contrast to OEC cause upregulation of matrix molecules, particularly proteoglycans (PGs) and are physically isolated by the



**Transplantation of Olfactory Ensheathing Cells. Figure 1** Olfactory ensheathing cells isolated from the adult olfactory bulbs of rats. (a) Immunocytochemically stained primary olfactory ensheathing cells *in vitro*. Olfactory ensheathing cell cultures are very pure when p75-immunoselected by adhesion. Cells are immunopositive for Glial Fibrillary acidic protein (red) and for the low affinity nerve growth factor receptor (p75) (Green). (b) A phase brightfield picture of the same field as (a). (c) Olfactory ensheathing cells also express large basal amounts of the myelin protein PO (red) and sometimes without a significant downregulation of the receptor p75 (green). This is quite different to the PO expression if primary Schwann cells which has significant downregualtion of p75 with upregulation of PO. Olfactory ensheathing cells can also be genetically modified by viral vectors such as Lentiviral vectors. (d) Olfactory ensheathing cells engineered to produce green fluorescent protein (GFP *in vitro*. These labelled cells can then be transplanted into the injured spinal cord and their function monitored.

host astrocytes. *In vitro* co-culture experiments have showed that OEC interact well with astrocytes and do not increase production of chondroitin sulphate PGs. Further evidence of the unique mechanism by which OEG interact with astrocytes was provided by experiments controlling levels of N-cadherin and showed this molecule to be a key player in OEC cell adhesion/migration while in the presence of astrocytes. Understanding the mechanism of OEC cell interaction in the host spinal cord and the molecules involved will in the future help translational scientists design optimal cell transplants. Indeed, recent publications have suggested combinational approaches to overcome the scar tissue by use of OECs with and the enzyme cocktails to degrade inhibitory molecules. Results obtained from these studies have shown improvement in both axonal regeneration and behavioural outcomes.

Spinal cord injury repair strategies not only will be designed to improve regeneration of axons into the denervated distal spinal cord but scientists also believe that mechanisms of repair are important. A number of reports have suggested that OEC transplants have a tissue sparing effect on spinal tissue and this has been closely correlated with improved behaviour not axonal regeneration [9]. OEC transplants also may increase angiogenesis within the spinal cord and therefore improve function by preventing cell losses and provide nutrients for injured tissue. Lastly, a new area of interest is the effect OECs may have on inflammatory responses within the CNS tissue after injury. They are hypothesised to play a key role in the olfactory system during neurogensis but is this via local control of the ►inflammatory cascade when a neuron dies and is replaced? Only time will tell if these roles are true and can be utilised. Further to axonal regeneration and tissue sparing it is also believed that an increase in the number of injured axons being remyelinated by a cell transplant would significantly improve the functional activity of the spinal cord after injury. How remyelination can occur has been a target of many authors over the years and has included the use of OEC transplants to remyelinate denuded axons. Methods have included isolating cells from embryonic [10] and adult animals but direct evidence was inconclusive that OEC can form myelin (Rev 10). However, these results cannot explain the myelination reported when a clonal line has been used isolated from postnatal rats. It may be that OEC obtained from younger animals have a more plastic nature and are able to form myelin around axons, even though in the normal *in situ* environment they cannot. This is a very important area of research and recent documented evidence has indicated the age of the cell may well be a key determinant of the OEC myelination capacity. Recent

advances as mentioned earlier in gene therapy techniques and transgenic rodents has helped the field in tracking the myelinating capacity of OEC *in vivo*. Myelination of spinal cord axons (monitored by protein zero expression and electron microscopy) have been shown, but how pure are the transplanted cells? In addition ►protein zero (P0) is expressed by OEG without the formation of a compact myelin segment, whereas myelin basic protein (MBP) is not. What role does P0 have in the olfactory system? The tantalising possibility is that P0 may be a growth promotive protein? These results indicate an urgent need for standardised protocols in which all laboratories can use. Of particular interest in the future will be the source of the OEC in adult systems, either from the olfactory bulb or lamina propria. The isolation and purification of OECs and the role the supporting cells around them have will give valuable insight into the different cell phenotypes. What role do OEC play in olfactory neurogenesis, axonal growth and guidance of olfactory exons to their appropriate targets. These important details will help us to design better and more appropriate glial transplants in the future. In addition the use of genomic screening techniques will provide unique insights to the genes involved in neurogenesis and axonal growth.

## Summary

OEC cells are one important part of the translational scientist's tools in spinal cord injury research. They have shown immense promise in a number of publications over the last decade in stimulating central nervous system repair. However, little is known of the true mechanisms involved in the OEC transplant results. Are the results truly a direct effect? Are OECs stimulating endogenous repair mechanisms? Can OECs modulate inflammatory cascades within the injured tissue? The answer to these questions may be "all of the above", but what is needed in this field of neural regeneration is correct identification of the OEC within the *in vivo* model and to distinguish these cells from the rest of the host cellular make up. If one can truly do this and one can isolate novel molecules from these cells and mechanisms of repair be ascertained, then the field will truly advance.

# Transplantation of Schwann Cells

Xiao-Ming Xu
Kentucky Spinal Cord Injury Research Center, Department of Neurological Surgery, School of Medicine, University of Louisville, Louisville, KY, USA

## Synonyms

Transplantation

## Definition

The term ►Schwann cell is named after Theodor Schwann (1810–1882), a German physiologist and histologist. Schwann cell is a type of peripheral nerve glial cell that surrounds axons. A Schwann cell can enclose a number of individual axons (ensheathment) or surround a single axon with a compact spiraled sheet of its own plasma membrane (myelination). Axons ensheathed by a single layer of Schwann cell processes are called ►unmyelinated axons. Axons surrounded by a compact spiraled sheet of Schwann cell plasma

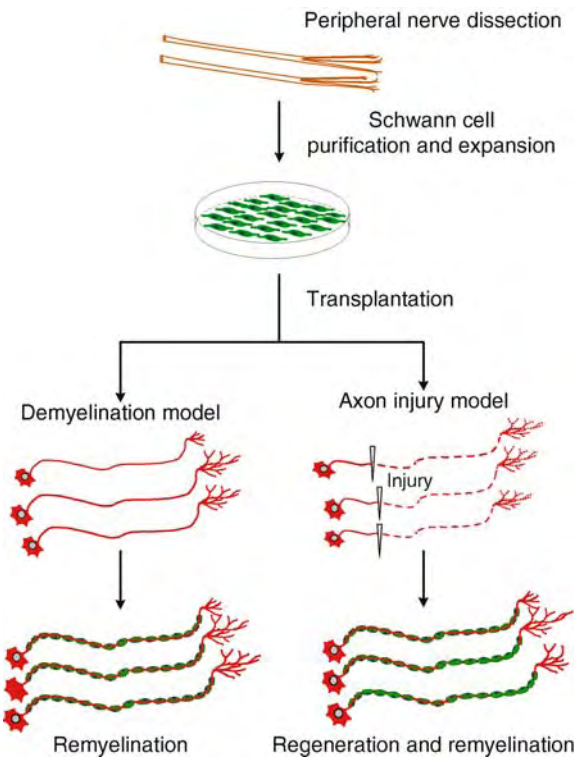
membrane are called ►myelinated axons. Schwann cells, harvested from the peripheral nerves of rodents [1], primates [2] or humans [3], can be purified and expended in culture. Transplantation of Schwann cells has been considered as one of the most promising repair strategies for the regeneration and/or remyelination of damaged axons of the central (CNS) and peripheral (PNS) nervous systems (Fig. 1).

## Characteristics

### Quantitative Description

The ability of Schwann cells to substantially influence axonal regeneration and remyelination in both the CNS and PNS derives, at least in part, from the following three unique properties:

1. *Schwann cells produce a variety of ►neurotrophic factors*: Schwann cells are a source of numerous neurotrophic factors. Many of them are known to play critical roles in the regeneration and remyelination of damaged nerve fibers. The factors produced by Schwann cells include nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), ciliary neurotrophic factor (CNTF), insulin-like growth factor (IGF), glial cell-line derived neurotrophic factor (GDNF) and platelet-derived growth factor-BB (PDGF-BB).
2. *Schwann cells express a number of ►cell adhesion molecules*: Schwann cells are known to produce an array of well-characterized cell adhesion molecules (CAM) such as N-cadherin, N-CAM, and L1/Ng-CAM. Schwann cells also produce a number of extracellular molecules (ECM) such as laminin and collagens. Many of these molecules have been shown to promote neurite outgrowth in vitro and axonal regeneration in vivo.
3. *Schwann cells form myelin on regenerated or demyelinated axons*: Myelin, a multi-lamellar membrane sheath elaborately wrapped around axons by Schwann cells, is required for efficient and rapid propagation of action potentials by saltatory conduction. Schwann cells, after being grafted into the CNS, can form myelin on demyelinated [2,4] or regenerated axons [3,5–8]. Successful conduction of remyelinated axons by grafted Schwann cells can be found in the adult CNS [9].



**Transplantation of Schwann Cells. Figure 1** Models of Schwann cell-based remyelination and regeneration therapies. Schwann cells can be harvested from neonatal or adult peripheral nerves, and purified and expanded in culture. Purified populations of Schwann cells can be transplanted into demyelinated or axotomized CNS regions. Grafted Schwann cells can promote remyelination of demyelinated axons or regeneration and remyelination of injured axons.

## Function

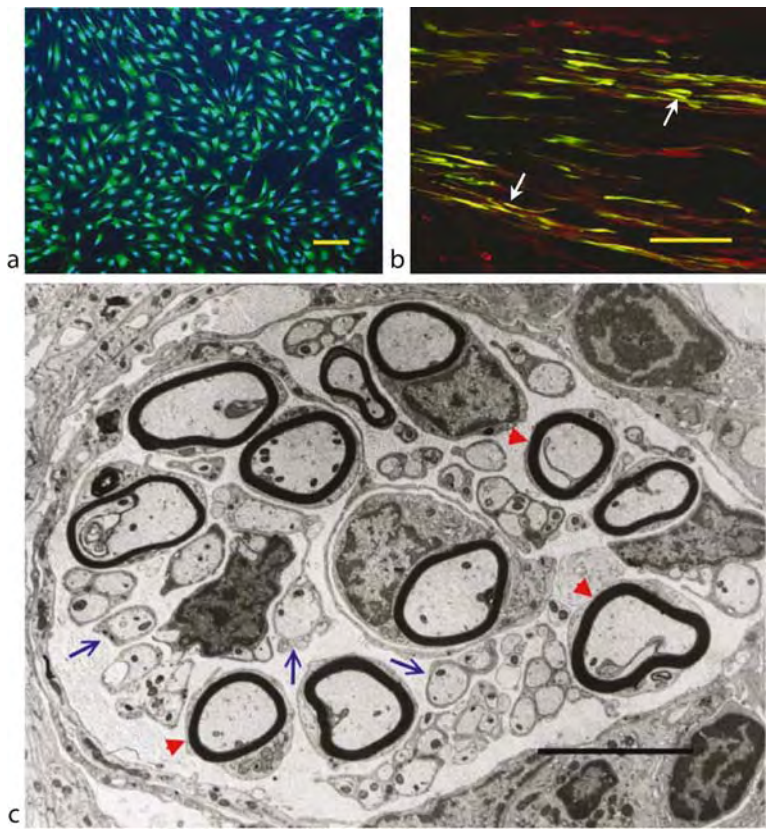
Although Schwann cells are not normally present in the CNS, they function normally after being grafted into this location. Transplantation of Schwann cells into the CNS may play the following functional roles:

1. *Promotes remyelination of demyelinated axons*: Demyelination of central axons can occur in a number of diseases, such as multiple sclerosis. Schwann cells can be effective in repairing areas of central demyelination and restore effective conduction. When persistent demyelination was created in the spinal cord, implantation of cultured autologous Schwann cells into the lesion site resulted in Schwann cell remyelination of demyelinated, but not severed, axons [2,4]. Such remyelination by grafted Schwann cells could re-establish normal conduction velocity across the lesion [9]. No remyelination occurred if Schwann cells were not introduced.
2. *Promotes regeneration of injured axons*: It is well accepted that injured axons in the adult mammalian CNS do not regenerate spontaneously. These axons, however, are capable of regeneration if a peripheral nerve graft is provided. It is now clear that the major cellular component of the peripheral nerve that promotes axonal regeneration is the Schwann cell. Schwann cells, after being transplanted into various regions of the injured adult mammalian CNS, survived, promoted axonal regeneration, and ensheathed or myelinated regenerated axons [6].

3. *Bridges the gap of CNS injuries*: CNS injury incurs disconnectional damage to the axons and a successful repair strategy requires reconnection of those disconnected axons to their appropriate functional effectors. Grafts of guidance channels seeded with Schwann cells can provide the necessary cellular alignment and environment to guide and support axonal growth in the bridge across the injury aftermath. In cases where axons were severed, as in the transected [5] or hemisected [10] thoracic spinal cord model, grafts of Schwann cell-seeded semipermeable polymer channels created a bridge between the stumps of the injured cord and promoted axonal regeneration and remyelination (Fig. 2). At one month post-grafting, the cord stumps were united by a tissue cable that contained Schwann cells, axons at different stages of myelination or ensheathment by Schwann cells, blood vessels, and perineural fibroblasts [3,5,10]. Robust regeneration of host axons occurred from both the rostral and caudal directions into the Schwann cell graft environment. In addition to the axons that originated from neurons in the spinal cord, those from different brainstem regions also regenerated into the graft [10]. Clear evidence was shown that grafted Schwann cells survived and supported axonal regeneration and remyelination in this model. The absence of Schwann cells in control bridges resulted in scarce axonal growth, indicating that a key role is played by Schwann cells in promoting axonal regeneration in the injured CNS.

## Pathology

Although Schwann cells are not normally present in the mammalian CNS, they can enter the central nervous system under certain pathological conditions. For example, following traumatic CNS injuries, Schwann cells from the host peripheral nerve could migrate into the damaged CNS after the glial limiting membrane between the CNS and PNS has been interrupted. Aberrant



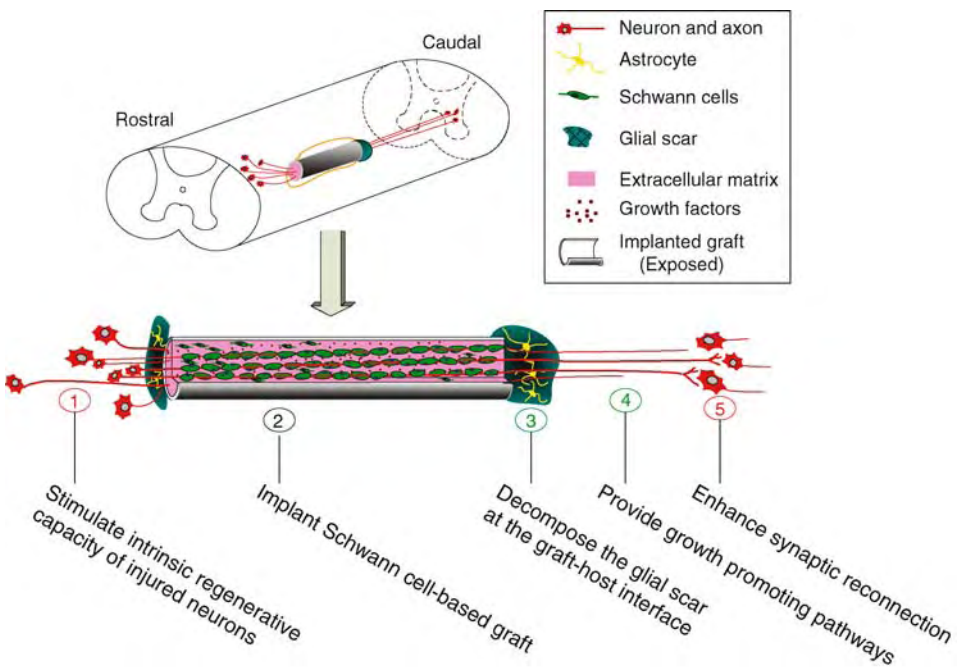
**Transplantation of Schwann Cells. Figure 2** Schwann cell characterization, transplantation and evaluation. (a) Schwann cells, purified from adult rat sciatic nerves, are immunopositive for S100, a marker for Schwann cells (*green*). The cells are counterstained with Hoechst 33342, a fluorescent nuclear dye (*blue*). (b) Grafted Schwann cells (*arrows*), transduced with an adenoviral vector encoding green fluorescence protein (*green*), are associated with regenerating axons (neurofilament-positive; *red*) within the guidance channel being grafted into the injured spinal cord. (c) At the ultrastructural level, grafted Schwann cells either ensheath (*arrows*) or myelinate (*arrowheads*) regenerated axons.

proliferation of Schwann cells and nerve fibers, namely Schwannosis, occurs frequently in humans with spinal cord injuries. The invading Schwann cells may also contribute to certain degrees of endogenous repair, since these cells can myelinate or ensheath surviving axons at and beyond the lesion cavities. The contribution of migrating Schwann cells in this endogenous repair process reaffirms the strategy of transplanting exogenous Schwann cells, since such a repair strategy may represent a natural feature of the spontaneous recovery.

## Therapy

Schwann cells are a unique cell type that holds promise as a cellular source for the regeneration and remyelination of injured axons in the CNS. These cells have demonstrated several significant advantages for transplantation. For example, Schwann cells can be prepared easily in a purified form and expanded homogeneously in culture in rodents [1], primates [2] and humans [3]. Transplantation of Schwann cells was reported to be safe for both autologous [2,5,10] or xenologous [3] transplants. The longitudinal alignment of Schwann cells within the graft, and the neurotrophic factors, extracellular matrix molecules and cell adhesion molecules that they produce, all contribute to the efficacy of Schwann cells in promoting axonal regeneration and remyelination in the injured adult CNS. Moreover, Schwann cells can reliably myelinate central axons in the lesioned CNS milieu, which is critical for functional recovery after successful axonal regeneration.

Schwann cells have been implicated as an efficacious therapy for the repair of various CNS degenerative diseases. In demyelination injuries of the CNS, grafted Schwann cells survive, migrate, form myelin and promote function of remyelinated axons. In traumatic CNS injuries, transplantation of Schwann cells provides necessary cellular bridging to guide and support axonal growth across the lesion site. Although Schwann cells have many advantages and are considered a promising cell type for transplantation, limitations also exist. For example, Schwann cell-promoted axonal regeneration is mainly confined within the graft region, and only a limited number of axons are able to exit from the graft and enter the host CNS environment [5,10]. This is because other factors, such as the presence of inhibitory cues associated with the glial scar and CNS myelin, prevent further growth of regenerating axons from the Schwann cell graft back into the host CNS environment. For this reason, a complete therapy for functional regeneration after CNS injury may involve the use of combinatorial strategies, including the Schwann cell bridge transplantation and other efficacious treatments



**Transplantation of Schwann Cells. Figure 3** Combinatorial strategies using Schwann cells and other therapies for the repair of CNS injuries. As a promising cell type for transplantation, Schwann cells can be used in combination with other repair strategies such as boosting the intrinsic regenerative capacity of injured neurons, decomposing the glial scar at the graft–host interfaces, generating growth promoting pathways in the host spinal cord, and enhancing synaptic reconnection between regenerating axons and their targets to achieve better anatomical regeneration and functional recovery after various CNS injuries.

such as boosting the intrinsic regenerative capacity of injured CNS neurons [6], decomposing the glial scar [8], generating growth promoting pathways along the course of axonal regeneration [7], and enhancing synaptic reconnection between regenerating axons and their targets (Fig. 3).

# Transporter (Biophysics)

## Definition

Denotes many types of transporters or carriers. Neurotransmitter transporters remove neurotransmitters from synapses and stop signaling among neurons and glial cells. As an example, glutamate transporters have high affinity for the substrate, are sodium-dependent and are expressed in most cell types within the central nervous system.

# Transverse Temporal Gyrus (Heschl)

## Synonyms

Gyrus temporalis transversus

## Definition

The floor of the lateral sulcus is formed by the upper side of the temporal lobe. This almost flat plane is called the temporal plane. It has characteristic, transverse gyri (transverse temporal gyrus (Heschl) which are called Heschl's transverse convolutions. In this cortex area (area 41 and 42) terminates the auditory tract, hence the term auditory cortex or primary auditory cortex. This area is tonotopically organized and has large efferents in the surrounding auditory cortex.

►Telencephalon

# Trapezoid Body

## Synonyms

►Corpus trapezoideum

## Definition

Efferents originating in the ventral cochlear nucleus decussate in a broad fiber band to the contralateral side. As soon as it reaches the contralateral side this band, the trapezoid body, kinks upwards in a 90° angle, and is now called the lateral lemniscus. As such, it passes on to the inferior colliculus.

►Myelencephalon

# Traube–Hering Waves

## Definition

Blood pressure oscillations entrained with respiration. Often grouped with Mayer waves and were described

around the same time historically (1860s), but we consider these to be separately entrained with respiration as is sympathetic nerve activity.

►Pontine Control of Respiration

## Definition

Neuroinflammation plays a significant role not only in repair, but also in secondary brain damage after traumatic brain injury (TBI). Hyperbaric oxygen therapy (HBOT) demonstrates anti-inflammatory and neuroprotective properties in our rat model of TBI.

## Characteristics

### Traumatic Brain Injury (TBI)

►Traumatic brain injury is one of the major medical and socioeconomical problems in the modern world, due to the growing numbers of patients suffering from immediate and remote complications and neurological damage as a result of head trauma.

### Brain Damage Following TBI

The brain damage following TBI is the result of direct mechanical disruption of brain tissue and indirect (secondary or delayed) mechanisms. The brain tissue surrounding the damaged area (so called "traumatic penumbra") is the stage for the reparative process and also of secondary brain damage which may develop after hours or days. Observations of the time-dependent increase in the volume of the cortical lesion in TBI and the presence of degenerating neurons in chronic post-traumatic lesions support the hypothesis that delayed cell death may be a very important component of post-traumatic pathology [1]. The mechanisms of delayed brain damage after TBI are not clearly understood, but recent studies implicate the acute inflammatory response to the destruction of brain tissue as an important factor in secondary brain damage [2].

### Cell Death Mechanisms After TBI

In the past it was believed that the main mechanism of cell death after cerebral stroke and trauma was necrosis. Recently, increasing evidence has been accumulating on the involvement of apoptosis (programmed cell death) in delayed post-traumatic neuronal death [3] Positive ►TUNEL (►Terminal deoxynucleotidyl transferase biotin-dUTP Nick End Labeling) staining of cells in pathological specimens from cortical contusion lesions, together with obvious activity of caspases (effective enzymes of apoptosis) in human and experimental TBI, were regarded as the evidence of apoptotic death pathway. Today, more and more experimental data reveal the appearance of morphologic features of both necrosis and apoptosis in the same neural cell, and this fact has led to the possibility of a continuum between apoptosis and necrosis in TBI lesions. Because apoptosis is an energy-dependent process, some researchers have suggested that the apoptotic process may be active as long as ATP is present in the damaged cell but, later, when the progressive mitochondrial damage leads to depletion of ATP, the injured cell may shift to necrosis [1].

### Neuroinflammation and its Role in TBI

It is becoming increasingly clear that acute inflammation in traumatic penumbra area, characterized by infiltration of brain tissue by neutrophil leukocytes recruited from the blood flow, has a dual significance: it is essential to the repair process around the irreversibly damaged brain area and, at the same time, it can be harmful for partially damaged brain tissue, playing a role in post-traumatic delayed neuronal death [4,5]. Neutrophils cause tissue damage by the effects of their toxic enzymes, such as myeloperoxidase. They may contribute to secondary injury by causing microvascular occlusion, releasing free oxygen radicals, cytolytic proteases, and proinflammatory cytokines. Generally, acute inflammatory reaction has three major components: (i) alteration of blood caliber – vascular dilatation – that increases blood flow; (ii) structural changes in the blood microvessel wall that permit the plasma proteins and leukocytes to leave the circulation;

(iii) emigration of leukocytes from microcirculation and their accumulation at the focus of injury. The dilatation of microvessels in the area of injury and leakage of proteins, accompanied by increased blood viscosity, cause a decrease in blood flow, thereby increasing the ischemic damage. During inflammatory reaction, there is also early activation and tissue expression of metalloproteinases which facilitate penetration of neutrophils through the blood-brain barrier.

## Matrix Metalloproteinases (MMPs) as Important Players in Secondary Brain Damage after TBI

The natural inhibitors of ►matrix metalloproteinases (MMPs) are tissue inhibitors of metalloproteinases (TIMPs) [6,7]. Leukocytes and macrophages are major sources of MMP production. MMPs released by leukocytes play vital roles in extravasation and migration of leukocytes into tissues – the key event in the inflammatory process. MMPs were shown to be upregulated, especially MMP-2 and -9, in various types of brain injury – ischemia and reperfusion, hemorrhagic injury and TBI [6,7]. It was also established that, after TBI, the influx of inflammatory cells provides the major source of MMP activity, and that MMPs in the damaged brain and in ►neuroinflammation play a deleterious role, directly and indirectly promoting cell death, including apoptosis, through death receptors.

## Hyperbaric Oxygen Therapy (HBOT) After TBI

The search for neuroprotective treatment that will reduce secondary brain damage caused by TBI has become a critical issue, due to the grave medical and socio-economic consequences of the growing numbers of patients suffering from remote complications and neurological damage as the result of head trauma. One of the promising methods applied in this area is HBOT. In clinical practice, HBOT remains a controversial issue, mainly due to the absence of a large randomized multicenter study. Nevertheless, supportive data have been provided by several authors showing reduced mortality and improved vital brain functions in severely brain injured patients treated by HBOT [7]. Numerous experimental studies have provided evidence supporting the neuroprotective effect of HBOT in various models of brain injury [7,8]. The basic mechanisms of the beneficial effects of HBOT are not clearly understood, but it has been demonstrated that hyperbaric oxygen (►hyperbaric oxygen treatment) reduces the extent of secondary brain damage in models of TBI and ischemia.

## Anti-Inflammatory Effects of HBOT

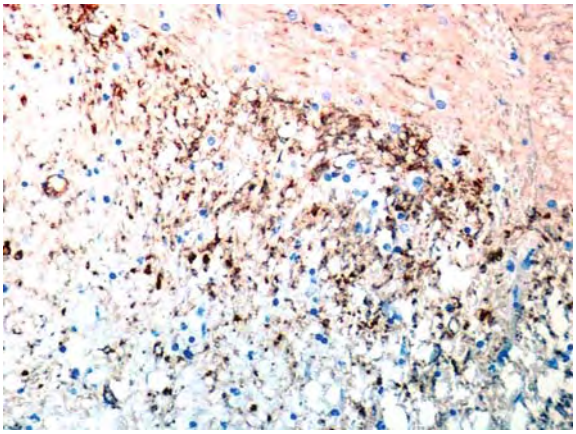
It has been shown experimentally in tissues other than brain that HBOT has anti-inflammatory properties. It decreases neutrophil adhesion to the endothelium of postcapillary venules, reduces tissue myeloperoxidase activity in experimental colitis, and inhibits proinflammatory cytokine production. In the model of focal cerebral ischemia, HBOT reduces neutrophil infiltration and local myeloperoxidase activity, improves neurological outcome, and decreases the volume of necrosis [9].

## Anti-Inflammatory and Neuroprotective Role of HBOT in TBI

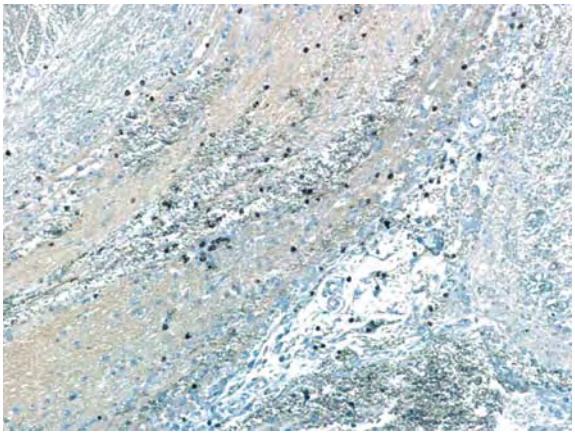
Taking into account the known anti-inflammatory effects of HBOT, it was suggested that it may reduce secondary neuroinflammation after TBI. The study was performed to evaluate the effects of HBOT on inflammatory infiltration by neutrophils in the traumatic penumbra area in our model of focal brain injury in rats, correlated to the extent of cellular death in brain tissue. Immunohistochemical expression of MMPs (2 and 9) and TIMPs (1 and 2) in untreated and treated animals was examined by computerized image analysis. We used a model of TBI called "dynamic cortical deformation" (DCD) and described by Shreiber et al. [10]. Forty Sprague-Dawley rats were divided into three groups: ten animals underwent DCD only, ten animals were treated by normobaric oxygen following DCD, and 20 animals received HBOT after the injury (for a detailed protocol of the treatment, see [2]).

DCD caused a highly reproducible brain lesion consisting of a necrotic core and a perilesional area. This area was divided virtually into four successive layers at a distance 0.5, 1.0, 1.5 and 2.0 mm from the necrotic core. In each of these layers, we counted the number of neutrophils stained by myeloperoxidase, the percent of TUNEL-positive brain cells (index of cell death), and the intensity of immunohistochemical staining for MMP-2 and -9 and TIMPs (1 and 2), measured by computerized image analysis. Counting the myeloperoxidase-stained neutrophils in the different layers of the traumatic penumbra revealed a significant decrease in neutrophil infiltration in the group of HBO-treated animals, most striking in the inner layers of the perilesional zone (Graph 2). This was accompanied by a significant decrease in the percentage of TUNEL-positive brain cells (index of cell death) in the layers of the perilesional brain tissue (Graph.1). To a significantly lesser extent, normobaric oxygen treatment also proved to reduce neutrophil infiltration, although this effect was limited to the immediate perilesional neighborhood. The index of TUNEL-positive cells did not decrease significantly after normobaric oxygen treatment.

The expression of MMP-2 and MMP-9 was increased around the traumatic necrotic lesion, but MMP-9 showed much higher levels (Figs. 1 and 2). Only weak positivity for TIMP-1 was revealed, and there was no staining for TIMP-2. After treatment with hyperbaric oxygen, there was a substantial decrease in the intensity and extent of staining for MMP-9, but MMP-2 and TIMP-1 expression remained unchanged (or the changes were insignificant).



**Traumatic Brain Injury: Rat Model of Neuroinflammation and Expression of Matrix Metalloproteinases. Figure 1** High expression of MMP-9 around the traumatic lesion (traumatic penumbra) in the rat's brain. Immunoperoxidase, x200.



**Traumatic Brain Injury: Rat Model of Neuroinflammation and Expression of Matrix Metalloproteinases. Figure 2** Marked decrease in MMP-9 expression in traumatic penumbra after HBO treatment. Immunoperoxidase, x200.

## Conclusions and Perspectives

The results of this study demonstrate marked parallelism in the decrease of cell death extent, reactive neuroinflammation, and the expression of MMP-9 following HBOT. This proves that, in the acute period after TBI, HBOT substantially decreases the harmful effects of inflammation and MMP-9 overexpression that promotes delayed cell death in the traumatic penumbra.

It remains unclear if the decrease in the number of apoptotic TUNEL-positive cells in traumatic penumbra is the result of the anti-apoptotic effects of hyperbaric oxygen or the secondary consequence of the reduction of the harmful inflammatory reaction. Both anti-apoptotic and anti-inflammatory effects of HBOT in non-traumatic conditions are well documented in the literature, and further research will eventually disclose the complex mechanism of hyperbaric oxygen effects in the traumatic penumbra area.

It is well established that inflammatory perilesional reaction in TBI and stroke has a dual effect – it not only provides additional damage to the brain tissue, but is also essential for the repair process. A large body of evidence has been collected, showing that the inflammatory response in the ischemic or traumatized brain has detrimental effects in the acute phase and beneficial effects in the chronic phase [4]. This means that early (within hours) and late (days-weeks) post-injury inflammatory response may play different roles and, therefore, the inflammatory reaction must not be suppressed but rather modulated, with special emphasis on the timing and dosage of treatment modalities.

## Traveling Waves

### Definition

The traveling wave is a hydromechanical event in the fluid spaces of the cochlea. The basilar membrane with the sensory hair cells sitting on it is stiff at the cochlear base and very flexible at the cochlear apex. Induced by fluid motions at the cochlear base due to a tonal stimulus, this stiffness gradient leads to displacements of the basilar membrane traveling towards the cochlear apex. At a certain locus between base and apex corresponding to the frequency of the tone, the traveling wave leads to a maximum displacement of the basilar membrane and, by that, to a maximum stimulation of the sensory cells.

## T1-Relaxation

### Definition

T1 or equivalently, spin-lattice relaxation, is a phenomenological time constant that describes the how fast the protons in a magnetic resonance imaging experiment after excitation with an electromagnetic pulse return to thermal equilibrium. T1 relaxation is together with the T2 relaxation process the major contributors to image contrast in Magnetic Resonance images.

►Magnetic Resonance Imaging

## T2-Relaxation

### Definition

T2 or equivalently, spin-spin relaxation, is a phenomenological time constant that describes the exchange of energy between neighboring atomic nuclei in magnetic resonance imaging experiments. T2 relaxation is together with the T1 relaxation process the major contributors to image contrast in MR images.

►Magnetic Resonance Imaging

## Tremor

### Definition

Rhythmic oscillation of a body part by alternating or synchronous contraction of agonist and antagonist muscles. It usually involves the hands, but the head, jaw, voice, tongue, and the lower limbs may also have tremor. Resting tremor occurs while the limb is not active, such as the asymmetric tremor of the hand while it is resting on the lap in a patient with Parkinson disease. Action tremor can be postural (hands in the outstretched position), intention (finger-nose-finger), or task-specific (seen while performing a specific activity, e.g, writing). Action tremor is typically seen in essential tremor.

## TRH

### Definition

►Thyrotropin releasing hormone, a tripeptide with hormonal and neuromodulatory actions.

►Hypothalamo-pituitary-thyroid Axis

## Triad

### Definition

A membrane compartment in skeletal muscle consisting of intracellular junctions between 2 SR terminal cisternae flanked on either side of a t-tubule.

►Excitation–Contraction Coupling

## Triadin

### Definition
A 95-kDa transmembrane glycoprotein of the junctional sarcoplasmic reticulum (terminal cisternae) that forms a supramolecular complex with calsequestrin, junctin and RyRI, the sarcoplasmic reticulum $Ca^{2+}$ release channel in skeletal muscle, that plays an important role in ensuring rapid $Ca^{2+}$ release during excitation-contraction coupling in skeletal muscle.

►Excitation-Contraction Coupling

## Trichromacy

### Definition
Normal human observers possess three independent channels for conveying color information, based upon the outputs of three different retinal cone types, which generate the initial steps in color vision by differentially absorbing long, medium and short wavelengths of light. A single set of three appropriately chosen primaries is sufficient to match the color appearance of any stimulus for a trichromat. To some extent, then, trichromats are color blind but not so color blind as dichromats who lack one cone type and can match the color appearance of any stimulus with only two primaries; and not so color blind as rod monochromats who can match any two lights by adjusting the intensity of one of them.

## Trigeminal Autonomic Cephalalgias (TACs)

### Definition
This is a group of cyclical, short-lasting, severe headaches located in the trigeminal nerve distribution and autonomic parasympathetic activation. Cluster headache is the most common of the TACs.

►Headache

## Trigeminal Complex

### Definition
A group of brainstem and spinal cord nuclei that receive inputs from the trigeminal nerve subserving the face and mouth.

►Evolution of the Somatosensory System: in Mammals

## Trigeminal Ganglion (Gasseri)

### Synonyms
Ganglion trigeminale (Gasseri)

### Definition
In the middle of the cranial fossa is situated the ganglion of the trigeminal nerve (V). Here autonomic fibers synapse and here the nerve divides into its three major branches: ophthalmic nerve (V1), maxillary nerve (V2) and mandibular nerve (V3).

►Nerves

## Trigeminal Lemniscus

### Synonyms
Lemniscus trigeminalis

### Definition
Once the afferents have left the principle nucleus of the trigeminal nerve, they cross to the contralateral side as the ventral tegmental fasciculus, and form bundles here called the trigeminal lemniscus. The latter then passes together with the medial lemniscus and the spinothalamic tract to the thalamus.

►Mesencephalon

## Trigeminal Nerve (V)

### Synonyms
N. trigeminus (N.V)

### Definition

The trigeminal nerve is the largest cranial nerve and has sensory/somatomotor functions. It provides sensory innervation for the entire face as well as for large parts of the cranial meninges and mucosa.

It provides motor innervation for the masticatory muscles.It emerges laterally from the pons, passes to the petrous bone, forming the trigeminal ganglion there in a dural fold. From here, three branches continue further: ophthalmic nerve (V1), maxillary nerve (V2) and mandibular nerve (V3).

►Nerves

## Trigeminal Neuralgia (Paroxysmal Facial Pain, Tic Douloureux)

### Definition

Characterized by excruciating paroxysmal pain attacks (of seconds up to few minutes duration) in the gums, lips, cheek and skin, occurring mostly in middle-aged and elderly people. They tend to recur all around the clock, often for weeks, and may be triggered by touch or movements of the afflicted body parts, with no sensory loss being apparent. Although a few pathological changes close to the trigeminal nerve can occasionally be identified, the cause often remains undetected.

## Trigeminal Olfactory Function

### Definition

The trigeminal nerve is the fifth cranial nerve. This nerve supplies the entire facial skin as well as the oral and nasal cavity with sensory innervation. The information about touch, temperature, pain and irritation are mediated by this trigeminal nerve. Accordingly, all volatiles reaching the nasal cavities which have stinging, prickling or even irritating properties (e.g., pepper) will stimulate the intranasal trigeminal function. Since most odorants do, to some extent stimulate the trigeminal nerve, this system is often co-stimulated with the olfactory system.

►Olfactory Perception
►Smell Disorders

## Trigeminal System

### Definition

The trigeminal system refers to the motor and sensory components of the trigeminal nerve, the fifth cranial nerve (V). The trigeminal nerve has the following functional components: branchial motor (special visceral motor) — muscles of mastication supplied by the motor nucleus of V; and somatic sensory — afferents from the face via the mesencephalic nucleus of V (proprioception), the main sensory nucleus of V (touch), and the spinal nucleus of V (pain and temperature).

## Trigger Neurons

### Definition

Trigger Neurons are a class of neurons that are thought to initiate the burst in the saccadic burst generator and thereby trigger a saccade. Their existence is suggested by the finding that omnipause neurons had to be silenced before saccadic burst neurons could begin discharging. Hence inhibitory "trigger" interneurons are thought to be interposed between higher saccadic command centers (the superior colliculus and frontal eye fields, whose efferents are excitatory) and the omnipause neurons. Indeed, pre-saccadic inhibition of omnipause neurons has been observed, and microstimulation near long-lead burst neurons in the pontine reticular formation can inhibit omnipause neurons, but a precise identification of the hypothetical trigger neurons has not yet occurred.

►Brainstem Burst Generator
►Omnipause Neurons
►Ponto-Pontine Long-Lead Burst Neurons
►Saccade, Saccadic Eye Movement
►Superior Colliculus

## Trigger Point

### Definition

Hyperirritable loci of skeletal muscle that are very sensitive to mechanical manipulation.

►Viscero-Somatic Reflex

# Trinucleotide Repeat Disease

Simon C. Warby, Alicia Semaka, Michael R. Hayden
Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, Canada

## Synonyms

Triplet Repeat Disorders; Trinucleotide Repeat Expansion Disorder

## Definition

Trinucleotide repeat diseases are a group of heritable disorders that result from an expanded number of tandemly repeated trinucleotides at specific genomic loci. The number of trinucleotide repeats tends to be unstable and can result in disease when it exceeds a specific threshold length.

## Characteristics

### Clinical and Genetic Features

Collectively, the common clinical features of trinucleotide diseases include neurodegeneration, ataxia, mental retardation, and muscle weakness or wasting [1]. The average age of onset differs for each disorder and ranges from infancy to adulthood. Disease symptoms can vary within a family and reduced ►penetrance or variable ►expressivity is frequently observed. Most trinucleotide disorders are inherited in an autosomal dominant fashion although some follow either an ►autosomal recessive or an ►X-linked inheritance pattern (Table 1).

The trinucleotide repeats can be located throughout the gene in either coding (i.e., exon) or noncoding (i.e., intron, 5′/3′ untranslated (UTR)) sequences. Both the type of trinucleotide repeat and the location of the repeated sequence in the gene influence the disease mechanism. A large proportion of trinucleotide repeat disorders are caused by ►CAG repeats which encode the amino acid glutamine. These trinucleotide repeats diseases are often referred to as ►polyglutamine disease or ►polyQ disease because the repeated CAG tract encodes long stretches of glutamine in the protein. Trinucleotide repeat diseases can also be caused by other triplet repeat sequences such as CGG, GAA, and CTG. For each gene, the number of repeats observed in the general population is polymorphic, but for each trinucleotide disease, there is a specific threshold of expansion (i.e., repeat size) that is required to develop the disorder.

Polyalanine repeat disorders are emerging as another class of diseases [2], and differ from other trinucleotide repeat disorders in that polyalanine tracts are far less polymorphic and dynamic compared to the large repeat expansions seen in other trinucleotide repeat diseases.

### Instability of Trinucleotide Repeats

A defining feature of trinucleotide repeat disorders is the dynamic nature of the genetic mutation [3]. The trinucleotide repeats are a ►microsatellite that can undergo somatic and gametic instability, resulting in changes in the number of tandem trinucleotide repeats in different tissues of the body or when passed to the next generation. Within each disorder, the size of the trinucleotide tract is important clinically, as there is an inverse relationship between the trinucleotide repeat length and age of onset in many trinucleotide diseases, particularly those involving CAG repeats (Fig. 1).

Another characteristic feature of trinucleotide disorders is the phenomenon of anticipation. ►Genetic anticipation refers to an increasing disease severity and a decreasing age of onset as the disease gene is transmitted to the next generation of a family. It is the gametic repeat instability observed in trinucleotide disorders that is the molecular basis of anticipation. The instability bias towards repeat expansion can result in a more severe disease phenotype in the next generation.

There are multiple mechanisms that can lead to repeat instability. Trinucleotide repeat instability is associated with DNA metabolic processes including recombination, repair and replication. In the case of gametic instability, these repeat size changes can occur before, during or after gametogenesis through a combination of these mechanisms [5].

Factors that influence the likelihood of trinucleotide repeat expansion have been identified. Primarily, the degree of repeat instability is dependent on the number of tandem repeats; where larger trinucleotide tracts tend to be unstable and prone to further repeat expansion. “Pure” trinucleotide tracts that are uninterrupted by other sequences or degenerate codons (i.e., codons that differ in sequence but code for the same amino acid) are particularly unstable. The amount of trinucleotide instability may also depend on the sex of the transmitting parent, where expansion preferentially occurs when the gene is inherited from either the maternal or paternal lineage. Other factors, such as paternal age or environmental conditions may also influence repeat instability.

### Premutations of Disease

Another important feature of trinucleotide disorders is the occurrence of *de novo* or sporadic cases of the disease in a family with no previous history of the condition. New mutations are caused by intermediate alleles or genes with repeat numbers in the ►premutation range. Individuals with an intermediate allele or premutation repeat size do not display clinical features of the disease.

**Trinucleotide Repeat Disease. Table 1** At least 19 diseases are caused by unstable trinucleotide repeats

| | | OMIM | Inherit | Gene | Chromo | Triplet | Normal | Expanded |
|---|---|---|---|---|---|---|---|---|
| DRPLA | Dentatorubral-Pallidoluysian Atrophy | 125370 | D | *ATN1* | 12q | (CAG)n | 7–34 | 49–93 |
| HD | Huntington Disease | 143100 | D | *HD* | 4p16.3 | (CAG)n | 6–34 | 36–121 |
| SBMA | Spinal and Bulbar Muscular Atrophyb (Kennedy Disease) | 313200 | Xr | *AR* | Xq11-12 | (CAG)n | 9–35 | 36–62 |
| SCA1 | Spinocerebellar Ataxia 1 | 164400 | D | *ATXN1* | 6p22-23 | (CAG)n | 6–38 | 39–91 |
| SCA2 | Spinocerebellar Ataxia 2 | 183090 | D | *ATXN2* | 12q23-24 | (CAG)n | 15–24 | 32–200 |
| SCA3 | Spinocerebellar Ataxia 3 (Machado-Joseph disease) | 109150 | D | *MJD* | 14q24-31 | (CAG)n | 13–47 | 53–86 |
| SCA6 | Spinocerebellar Ataxia 6 | 183086 | D | *CACNA1A* | 19p3 | (CAG)n | 4–18 | 19–33 |
| SCA7 | Spinocerebellar Ataxia 7 | 164500 | D | *ATXN7* | 3p12-21 | (CAG)n | 4–19 | 34–306 |
| SCA12 | Spinocerebellar Ataxia 12 | 604326 | D | *PPP2R2B* | 5q31-33 | (CAG)n | 4–32 | 40–78 |
| SCA17 | Spinocerebellar Ataxia 17 | 607136 | D | *TBP* | 2q13 | (CAG)n | 25–42 | 43–63 |
| FRAXE | Fragile XE Mental Retardation Syndrome | 309548 | X | *FMR2* | Xq28 | (CCG)n | 4–39 | >200 |
| FRAXA | Fragile X Mental Retardation Syndrome | 300624 | XD | *FMR1* | Xq27.3 | (CGG)n | 6–58 | >200 |
| FXTAS | Fragile X Tremor/Ataxia Syndrome | 300623 | XD | *FMR1* | Xq27.3 | (CGG)n | 6–58 | 59–200 |
| HDL2 | Huntington Disease-Like 2 | 606438 | D | *JPH3* | 16q24.3 | (CTG)n | 6–28 | 41–78 |
| DM1 | Myotonic Dystrophy 1 (Dystrophia Myotonica 1) | 160900 | D | *DMPK* | 19q13.3 | (CTG)n | 5–35 | 50–10,000 |
| DM2 | Myotonic Dystrophy 2 (Dystrophia Myotonica 1) | 602668 | D | *ZNF9* | 3q21 | (CCTG)n | 10–26 | 75–11,000 |
| SCA8 | Spinocerebellar Ataxia 8 | 608768 | D | *ATXN8/OS* | 13q21 | (CTG)n | 15–50 | >71 |
| FRDA | Friedreich Ataxia 1 | 229300 | r | *FXN* | 9q13 | (GAA)n | 6–32 | 66–1700 |
| SCA10 | Spinocerebellar Ataxia 10 | 603516 | D | *ATXN10* | 22q13 | (ATTCT)n | 10–29 | 280–4500 |

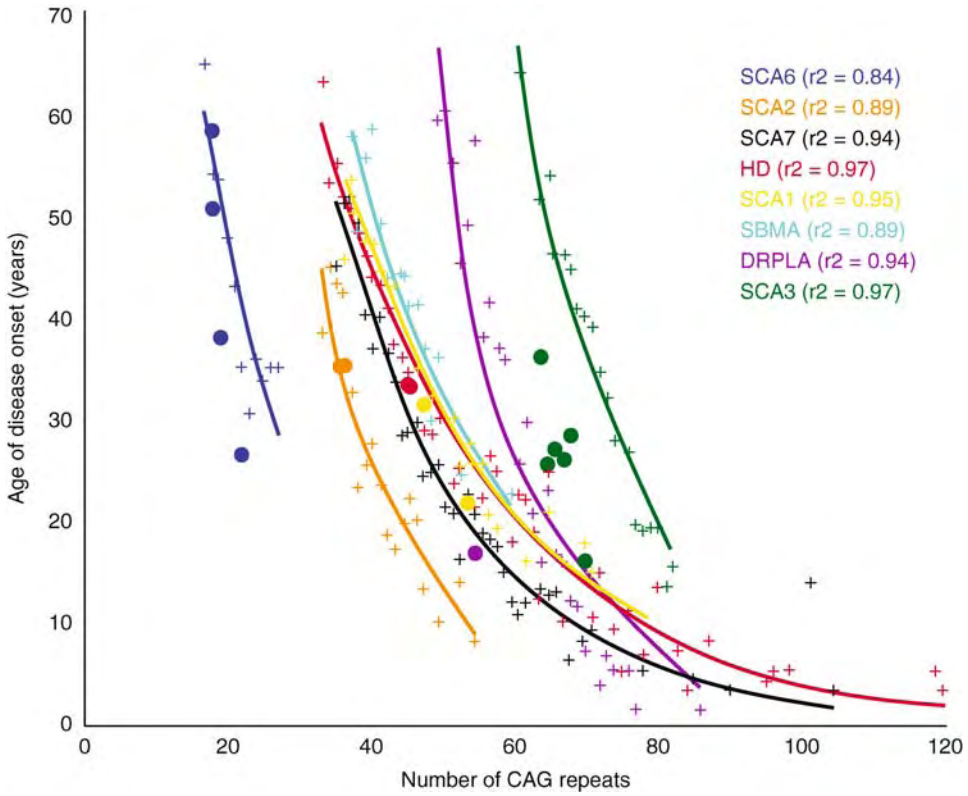
Online Mendelian Inheritance in Man (OMIM) reference number, pattern of inheritance, affected gene, chromosome location, type of trinucleotide repeat and the range of normal and expanded (disease-associated) alleles are listed1. Although DM2 and SCA10 are microsatellite repeat disorders with more than three tandemly repeated nucleotides, they are included here because they are hypothesized to have mechanisms of pathogenesis similar to other trinucleotide repeat disorders. Inheritance patterns are dominant (D) or recessive (r) and can be X-linked (X).

However, given the dynamic nature of the repeated sequence, the number of repeats can increase into the disease-associated range upon transmission to the next generation resulting in a sporadic case of the disease.

## Gain of Protein Function Trinucleotide Repeat Diseases

At least nine trinucleotide repeat disorders are the result of elongated CAG repeats leading to expression of a polyglutamine-expanded protein (Table 2). The similarities in CAG disease characteristics and genetic etiology suggest similar mechanisms of pathogenesis involving an acquired “toxic function” in each of the polyglutamine-expanded proteins. Most polyglutamine disorders are inherited in an autosomal dominant fashion. Collectively they show germline repeat size instability leading to anticipation, particularly with paternal transmission. Each disease usually begins in mid-life and results in death 10–20 years after onset. Early and late onset variants of each disease exist, as there is a strong inverse relationship between CAG length and age of onset.

Notably, each of the polyglutamine expansion disorders result from a mutation in a different gene encoding a protein that is widely expressed, yet lead to degeneration of a unique subset of neurons. This is consistent with a gain-of-function mechanism, although the factors that dictate the specificity of each disease is not yet clear. Aside from the polyglutamine tract, the mutant proteins show little or no sequence or structural similarity to each other, and each disorder results in a unique pattern of neuropathology and clinical symptoms.



**Trinucleotide Repeat Disease. Figure 1** Inverse relationship between trinucleotide length and age of onset for the CAG disorders. Mean age of onset (+) for different CAG repeat sizes for eight of the CAG disorders. Age of onset of homozygotes (largest CAG allele) is indicated with a filled circle (●). Best fit line is calculated using a simple exponential decay model, $r^2$ value is indicated. Adapted from Gusella and Macdonald [4].

The prototypical CAG repeat disease is ►Huntington disease (HD), which results from polyglutamine-expansion in the ►huntingtin protein. HD is clinically distinguished by progressive motor disability featuring ►chorea but may involve both involuntary and voluntary movements, mental disturbances including cognitive decline, and changes in personality and mood. Medium spiny neurons containing γ-amino butyric acid (GABA) in the striatum are most susceptible to neurodegeneration, although there may be atrophy in the cortex and other regions of the brain as the disease progresses.

►Spinal and Bulbar Muscular Atrophy (SBMA) is an X-linked progressive neuromuscular disease that affects males. SBMA is caused by polyglutamine-expansion in the androgen receptor (AR) gene product which results in progressive muscle weakness, fasciculations and degeneration of lower motor neurons.

►Dentatorubral-Pallidoluysian Atrophy (DRPLA) and numerous ►Spinocerebellar Ataxias (SCAs) are also caused by gain-of-function CAG mutations. Ataxia, tremors, and dysarthria are common clinical findings.

Interestingly, there are many other CAG-containing genes in the genome that have not been associated with disease and the genes that cause the majority of clinically-defined SCA disorders remain unknown. In order to rapidly identify new CAG-expansion disorders, the normal distributions of CAG tract size have been established in genes encoding polyglutamine-containing proteins [6].

## Loss of Protein Function Trinucleotide Repeat Diseases

Inhibiting the expression of specific genes is a second mechanism by which expanded trinucleotide repeats can cause disease (Table 3). Since the following disorders result from a loss of specific protein expression, any mutation that results in loss of protein function or expression will produce the disorder; the trinucleotide repeat expansions that are described here are the most frequent of these mutations.

►Fragile X mental retardation syndrome (FRAXA) is an X-linked developmental disorder that results in moderate-to-severe mental retardation, characteristic facial features, and autistic behavioral problems. FRAXA

**Trinucleotide Repeat Disease. Table 2** Polyglutamine repeat disorders

| | Protein | Mutation location | Clinical phenotype |
|---|---|---|---|
| HD | Huntingtin | Coding | Chorea, dystonia, cognitive deficits, psychiatric problems |
| SCA1 | Ataxin1 | Coding | Ataxia, slurred speech, spasticity, cognitive impairments |
| SCA2 | Ataxin2 | Coding | Ataxia, polyneuropathy, decreased reflexes, infantile variant with retinopathy |
| SCA3 | Ataxin3 | Coding | Ataxia, parkinsonism, spasticity |
| SCA6 | CACNA1A | Coding | Ataxia, dysarthria, nystagmus, tremors |
| SCA7 | Ataxin7 | Coding | Ataxia, retinal degeneration, cardiac failure in infantile form |
| SCA17 | TBP | Coding | Ataxia, cognitive decline, seizures, and psychiatric problems |
| SBMA | Androgen Receptor | Coding | Motor weakness, swallowing, gynecomastia, decreased fertility, proximal muscle atrophy |
| DRPLA | Atrophin-1 | Coding | Ataxia, seizures, choreoathetosis, dementia |

**Trinucleotide Repeat Disease. Table 3** Trinucleotide repeat expansions that result in a loss of function disease

| | RNA | Mutation location | Clinical phenotype |
|---|---|---|---|
| FRAXA | *FRMP* | 5′YTP | Mental retardation, speech delay, autistic behavior, macroorchidism, connective tissue defects |
| FRAXE | *FMR2* | 5′YTP | Mental retardation |
| FRDA | *FXN* | intron | Ataxia, loss of proprioception, slurred speech, cardiomyopathy, diabetes, scoliosis |

occurs most frequently in males but can result in mild mental retardation in females. The gene involved is *FMR1*, which encodes the protein FRMP. Expansions greater than 200 repeats in the unstable CGG tract located in the 5′ UTR of *FMR1* results in increased methylation and decreased histone acetylation and ultimately the loss of FRMP expression. Interestingly, premutations in FMR1 (59-200 CGG) result in FXTAS (see below) (Fig. 2).

►Fragile XE Mental Retardation (FRAXE) is a similar, although less common disorder compared to FRAXA. It is characterized by mild mental retardation and lacks any physical abnormalities. FRAXE results from loss of expression of the FMR2 protein due to CCG repeat expansion in the 5′ UTR of *FMR2*. With greater than 200 CGG repeats, *FMR2* is hypermethylated, resulting in transcriptional silencing and loss of protein function.

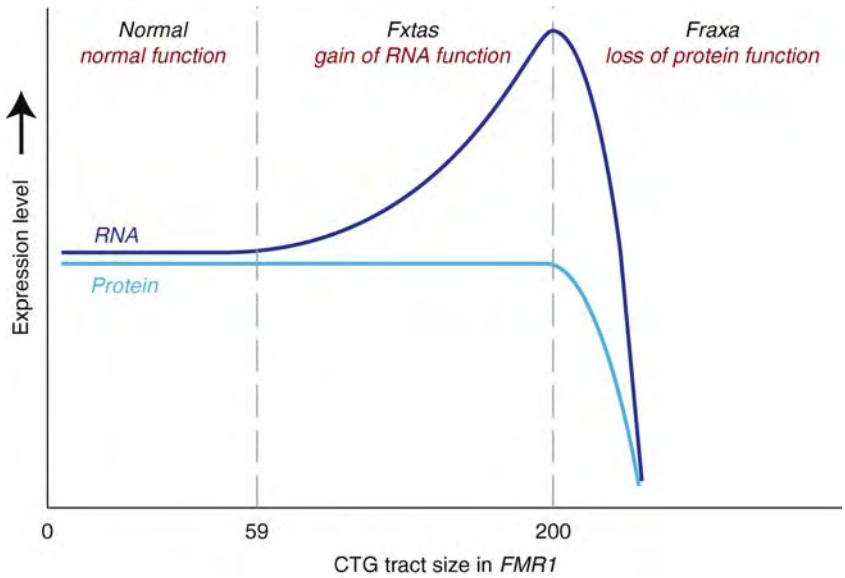
►Friedreich ataxia (FRDA) is an autosomal recessive disorder with symptoms typically beginning in childhood or adolescence. The phenotype includes progressive ataxia, gait disturbances, severe heart abnormalities, speech and vision problems, scoliosis, and diabetes. The progression of symptoms usually plateaus in early adulthood and death occurs by the fourth or fifth decade. FRDA results from the expansion of an unstable GAA repeat in the first intron of the *FRDA* gene which encodes frataxin. The GAA repeat expansion inhibits the transcriptional elongation of *FRDA* and reduces the expression of frataxin. Frataxin is believed to be involved in mitochondrial iron metabolism and is implicated in oxidative stress. The disease is likely due to a partial loss of frataxin expression.

## RNA-Mediated Dominant Trinucleotide Repeat Diseases

A third category of trinucleotide repeat diseases involve the expanded trinucleotide tract conferring a specific gain-of-function of the RNA transcript [7]. In addition to those diseases mentioned below (Table 4), a similar mechanism may play a role in a growing number of dominantly-inherited noncoding expansion disorders including spinocerebellar ataxia type 8 (SCA8), SCA10, SCA12, and Huntington disease-like 2 (HDL2).

►Myotonic dystrophy 1 (DM1) is a progressive, multisystem disorder that most prominently features dysfunction, weakness and degeneration of the skeletal and smooth muscles. The eye, heart, endocrine system, and central nervous system may also be affected. DM1 is an autosomal dominant disorder that demonstrates genetic anticipation due to instability in a CTG tract in the 3′ UTR of the *DMPK* gene. Both onset and severity of DM is correlated to the size of the CTG repeat which results in three clinical categories of DM1; mild, classic, and congenital. Notably penetrance and expressivity of the disease are variable within and between families.

How mutations in RNA can result in dominantly inherited disease is not fully resolved. However, the proposed mechanism of pathogenesis in DM1 may serve as a model for the other diseases in this category. The



**Trinucleotide Repeat Disease. Figure 2** Expanded *FRMP1* gene alleles can result in disease by two separate disease mechanisms. Alleles with greater than 50 CTG repeats in the 5′ UTR of *FMR1* result in increased expression of *FMR1* RNA, are believed to interfere with the processing of other RNA transcripts in a dominant-negative manner, and are associated with FXTAS. Alleles with CTG repeats of greater than 200 repeats result in the loss of *FMR1* expression and are associated with FRAXA.

CTG expansion in *DMPK* is transcribed as CUG repeats in the RNA transcript, and seems to result in abnormal RNA processing. Studies of *DMPK*-overexpressing or *DMPK*-null mice suggest the disease is not a direct result of alterations to DMPK protein. Rather, it supports the hypothesis that expanded CUG-repeats alters the activity of specific RNA binding proteins that function to regulate the alternative splicing of RNA transcripts other than *DMPK*. Interestingly, DM1 is the result of a single mutational mechanism; other mutations in *DMPK* (deletions, point mutations, etc.) do not result in DM.

►Myotonic dystrophy 2 (DM2) is a clinically similar but genetically distinct disorder that results from CCTG expansion in intron 1 of the *ZNF9* gene. In general, DM2 is milder and most often has a later average onset when compared with DM1. DMPK is a protein kinase and does not have functional similarity to ZNF9, a zinc finger protein. However, the presence of expanded CUG/CCUG repeats in their respective transcripts suggests a common mechanism of pathogenesis.

►Fragile X Tremor/Ataxia syndrome (FXTAS) is the result of "premutation" alleles for FRAXA in *FMR1*. Unlike many other trinucleotide repeat disease where premutation alleles have not been associated with disease, FMR1 premutation alleles that contain 59-200 CGG repeats are associated with increased risk for FXTAS and ►premature ovarian failure (POF). FXTAS typically occurs in males older than 50 years and clinically features cerebellar gait ataxia and intention tremors. In contrast to the loss of FRMP function in FRAXA, the premutation allele of FXTAS seems to confer a gain of toxic RNA function. The mechanism of toxicity is not clearly understood, but supported by the observation that FRMP RNA is elevated in FXTAS patients, and that expression of FMR1 RNA containing 90 CGG repeats is neurotoxic in model systems.

**Trinucleotide Repeat Disease. Table 4** Trinucleotide repeat disorders that result from dominant negative RNA transcripts

| | RNA | Mutation location | Clinical phenotype |
|---|---|---|---|
| DM1 | *DMPK* | 3′YTP | Muscular weakness and dystrophy, myotonia, cataracts, cardiomyopathy, insulin resistance |
| DM2 | *ZNF9* | Intron | Similar to DM1 but no congenital form |
| FXTAS | *FRMP* | 5′YTP | Cerbellar gait ataxia, intention tremor, Parkinsonism, cognitive and psychiatric alterations |

### Genetic Counseling and Testing

Given the inherited nature of trinucleotide repeat disorders, families may benefit from genetic counseling services. Through genetic counseling, families are provided information on the natural history, inheritance, and specific implications of the disease. This is of particular importance given the complexities of trinucleotide repeat disease inheritance and pathogenesis. Genetic counseling is also advisable when individuals are considering undergoing genetic testing [8], which is available for a large proportion of the trinucleotide repeat disorders. Given the later onset of some trinucleotide repeat disorders, genetic testing can be predictive in nature and a discussion of the various psychosocial and ethical issues surrounding predictive testing can assist the patient in making informed decisions.

### Treatment

At this time, medical management of trinucleotide repeat diseases is directed towards controlling disease symptoms. The future remains promising with many researchers around the globe working towards understanding mechanisms and finding treatment for the various trinucleotide repeat disorders. Research efforts utilizing animal models continue to shed light on the molecular pathogenesis of the disease allowing the identification of potential therapeutic targets. Similarities in the pathogenic mechanisms of the gain-of-function trinucleotide repeat diseases suggest similarities in possible treatments. Therapeutic compounds of interest include those that regulate neuronal excitability or neurotransmission, protein misfolding or aggregation, caspase activity and apoptosis, RNA interference, trophic support, oxidative stress, transcriptional dysregulation and histone de-acetylase inhibitors [9]. Cell transplantation studies have also shown promise [10]. For diseases featuring a loss-of-function, focus is on therapeutics that can restore or compensate for lost protein function.

## Trochlear Nerve (IV)

### Synonyms

N. trochlearis (N.IV)

### Definition

The trochlear nerve is the thinnest cranial nerve and is purely somatomotor in nature. It emerges as the sole cranial nerve on the dorsal side of the brainstem, beneath the inferior colliculus, and innervates only one muscle, the superior oblique muscle of the eyeball. By a change in tension, contraction of this muscle generates eye movement, laterally and downwards. The nerve reaches the orbita together with the oculomotor nerve (III) and abducens nerve (VI). Skull: superior orbital fissure.

►Nerves

## TRP

### Definition

Transient receptor potential

►TRP Channels

## TRP Channels

Christian Harteneck
Molekulare Pharmakologie & Zellbiologie, Charité Universitätsmedizin Berlin, Thielallee, Berlin, Germany

### Definition

►TRP channels are ►non-selective cation channel proteins with six transmembrane domains and a pore-forming loop between the fifth and the sixth transmembrane domain. The ion-permeating pore is formed by multimerisation of four proteins and allows the permeation of $Ca^{2+}$ and $Na^{+}$ ions. TRP proteins are assigned to distinct subfamilies based on sequence similarities to Drosophila TRP (►TRPC, ►TRPM, ►TRPV, ►TRPN ►TRPA channel family) or structural and functional features (►TRPP and, ►TRPML channel family).

### Characteristics

The mystery of the molecular basis for the hormone-induced $Ca^{2+}$ transient in nonexcitable cells in mammals began to be unraveled with the molecular characterization of the *trp* locus in the genome of ►Drosophila melanogaster. Blind flies of the *trp* phenotype have been characterized by recordings of the visual nerve and have been named as ►**t**ransient **r**eceptor **p**otential (*trp*) due to the shape of obtained electroretinogram recordings (for review see [1]). The positional cloning of the *trp* gene results in the identification of a protein, TRP, having structural and sequence similarities to voltage-gated calcium channels [2]. The growing number of sequences entries from genome as well as expressed-sequences tag (EST) sequencing approaches enabled the identification of TRP-homologous protein in worm and mammals shortly after the cloning of ►Drosophila TRP. Structural characteristics of the proteins identified by sequence analysis lead to the classification of the new proteins into different subfamilies [3]. According to the unified nomenclature, the term "TRP channels" represents nowadays a collecting term for proteins of the TRP superfamily comprising at least seven different subfamilies (TRPC, TRPM, TRPV, TRPA, TRPN, TRPML, TRPP) [4]. The initial sequence-based classification has meanwhile been supported by functional differences.

#### TRP Channels Involved in Hormonal Signaling Cascades

Since the cloning of Drosophila TRP as a channel protein involved in the ►receptor-mediated ►phototransduction pathway of flies, it is known that TRP channels play an important role in receptor-induced cellular signaling pathways [1,5–7]. Detailed analysis

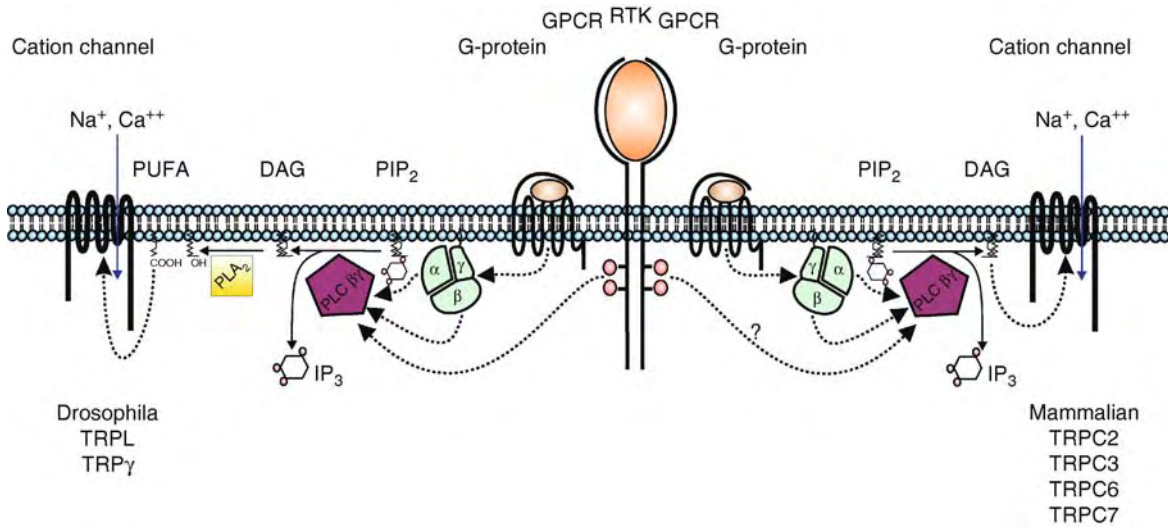
of the activation mechanism of TRP channels of the classic TRP channel (TRPC) family showed that the mammalian as well as the fly ►TRPC proteins are activated by different ►second messengers generated by receptor-induced signaling pathways (Fig. 1).

Hormones, ►neurotransmitter and ►growth factors binding to G protein-coupled receptors or receptor tyrosine kinases induce the breakdown of phosphoinositides by the activation of phospholipase C (PLC) isoforms leading to the formation of inositol-1,4,5-trisphosphate ($IP_3$) and diacylglycerole (DAG). While $IP_3$ increases intracellular $Ca^{2+}$ concentration by a release mechanism via stimulation of $IP_3$ receptors, DAG mediates $Ca^{2+}$-entry via channels of the TRPC family (TRPC2, TRPC3, TRPC6, TRPC7). The activation by DAG of TRPC2, TRPC3, TRPC6, TRPC7 is a direct effect of DAG in a ligand-dependent manner independent of enzymes of the proteinkinase C (PKC) family (see Fig. 1 right part). In contrast to the mammalian TRPC channels, the *Drosophila* proteins (TRPL and TRPγ) are activated by polyunsaturated fatty acids resulting from phospholipase $A_2$-mediated breakdown of DAG subsequent to PLC activation (see Fig. 1 left part). Like many other TRP channels, TRPC4 and TRPC5 have been discussed to be involved in ►capacitative $Ca^{2+}$ entry. Whereas for other TRP channels, detailed analysis revealed $Ca^{2+}$-dependent pathways independent of the filling status of the endoplasmic reticulum as $Ca^{2+}$ stores, the situation for TRPC4 and TRPC5 is still unclear.

In addition to the immediate involvement of TRPC channels in hormonal signaling pathways, it became clear that hormonal activation pathways modulate a variety of other TRP channels by indirect mechanisms like phosphatidylinositiol-4,5-bisphosphate ($PIP_2$), $Ca^{2+}$, phosphorylation pathways etc. $PIP_2$ as substrate of PLC and the precursor of DAG inhibit TRPM7, TRPM8 and TRPV1 and sensitize the activity of TRPM4 and TRPM5. Whether this modulation is based on direct lipid-protein interaction or on subsequent enzymatic-triggered pathways is a topic of current scientific discussion. TRP channels as $Ca^{2+}$-permeable non-selective cation channels are dually regulated by $Ca^{2+}$. The role of $Ca^{2+}$ is complex and depends on the properties of the analyzed protein. TRPM4 and TRPM5, as $Ca^{2+}$-activated $Na^+$ channels are stimulated by elevated intracellular $Ca^{2+}$ concentrations, whereas TRPV5 and TRPV6 as $Ca^{2+}$-transport proteins with high selectivity for $Ca^{2+}$ are stimulated by low intracellular $Ca^{2+}$ concentrations. Finally, as auto-regulatory mechanism, $Ca^{2+}$ potentiates the activity of TRPC6, TRPC7, TRPM2, TRPM8, TRPV4 and TRPL in a $Ca^{2+}$/►calmodulin-dependent manner.

## Trafficking of TRP Channels

TRP channels as ►integral plasma membrane proteins (►Cell Membrane – Components and Functions) are synthesized at the endoplasmic reticulum and subsequently transported via the *trans*-Golgi network to the plasma membrane. In order to control the ion transport activity across the plasma membrane, cells developed several mechanisms. The concentration of inserted proteins can be regulated either by the control of the insertion mechanism or the control of removal of channel proteins by modulating protein stability (for review see [8]). The insertion of TRPP2, TRPC3, TRPM2 and TRPV4 is controlled by the protein-protein



**TRP Channels. Figure 1** Receptor-induced activation mechanisms of TRP channels in fly and mammals. *RTK* receptor tyrosine kinase; *GPCR* G protein-coupled receptor; *PLC* phospholipase C; *$PLA_2$* phospholipase $A_2$; *$PIP_2$* phosphatidylinositol-4,5-bisphosphate; *$IP_3$* inositol-1,4,5-trisphosphate; *DAG* diacylglycerol; *PUFA* polyunsaturated fatty acid.

interaction of ►phosphofurin acidic cluster sorting proteins (PACS) with a C-terminal domain of the channel proteins characterized by a serine or threonine residue embedded in a cluster of acidic amino acids. The interaction is regulated by protein phosphorylation of TRPP2, TRPC3, TRPM2 and TRPV4 by the protein kinase casein kinase 2 (CK2). The plasma-membrane concentration of TRPV4 is strongly controlled. In addition to control mechanisms for membrane targeting, protein stability is also modulated via posttranslational modification and addition of ►ubiquitin resulting in increased proteolysis of TRPV4. It is likely that this or other mechanisms also tightly regulate the membrane concentration of other TRP channels.

Trafficking or shuttling of TRP channels as regulatory mechanism has not only to be discussed in terms of protein synthesis and degradation, but also in terms of recycling of the TRP channel protein removed from the plasma membrane by vesicular transport mechanism triggered by small GTPases. The activity of Drosophila TRPL is changed by such a mechanism in order to enable light-dependent adaptation of fly ►photoreceptor cells. Light stimulation induces the translocation of TRPL from the plasma membrane into rhabdomeric storage compartment by vesicular transport, whereas during darkness and dim light, TRPL is recycled and transported to the plasma membrane. Activation-dependent regulation of plasma membrane concentration has also been shown for TRPC3 and TRPC6.

## Integration of TRP Channels in Macromolecular Protein Complexes

Fly phototransduction as a model system for the structure and function of TRP channels enabled not only the identification of TRP channels but also the understanding that TRP channels are integrated in macromolecular protein complexes [1,7]. In the fly eye, the proteins of the fly phototransduction pathway, TRP, PLC, and PKC, are clustered via INAD, a PDZ domain protein. Via homomultimerisation and binding of ►myosin III protein, INAD forms a sub-membrane network clustering the signal-transduction proteins. A variety of interaction partners have been identified for mammalian TRP channels (for review see [7]). Besides the interaction of TRP channels with cytoplasmic or other membrane proteins, another feature of channel proteins has to been discussed. Based on the fact that four TRP channel proteins are necessary to form an ion-permeating pore, the hetero-multimerisation of TRP channel proteins would allow increasing the variability of TRP channels. Despite the large number of putative possible channel proteins, the experimentally detectable variety is much smaller. In heterologous systems, TRP channels assemble into heteromeric channel complexes within the narrow confines of phylogenetically closely related channels. Furthermore, only for very small numbers, the heteromerisation is accompanied by detectable changes in electrophysiological parameters. Heteromerisation of TRPC1 and TRPC5 result in a pore-forming channel complex with attenuated ►current-voltage relationship, whereas the TRPM6/TRPM7 complexes form a pore with an increased ►conductance. In all other cases, interaction can be detected in recombinant systems; however, the physiological relevance needs to be shown.

## TRP Channels as Targets of Secondary Plant Compounds

An exciting feature of TRP channels is that many different plant compounds modulate the activity of TRP channels [5–7,9]. Although nearly all synthetic compounds tested so far are not selective in modulating the function of a distinct TRP channel, the naturally occurring structures of plant origin are highly selective for one or two different TRP channel proteins. ►Capsaicin activates selectively TRPV1, camphor TRPV3, menthol TRPM8, hyperforin TRPC6. As active principle of remedies used in different cultures of traditional medicine, the identification of the natural compounds as TRP channel activators enabled to clarify the physiological role of TRP channels involved in ►thermosensation as well as in neuronal differentiation processes. Furthermore, the high selectivity of natural compounds suggests to develop selective synthetic compounds for research as well as for clinic applications.

## TRP Channels in Thermosensation

TRPV1 or capsaicin receptor 1 has been identified by expression cloning based on the knowledge that capsaicin induces the sensation of warmth and modulates pain sensation. Meanwhile, it is clear that the complete spectrum of relevant temperatures for our body is covered by at least six different TRP channels [5–7]. ►TRPA1 and TRPM8 are the cold sensors in our body, being activated by temperatures at 0 to 18 °C and 8 to 28 °C, respectively. Moderate temperatures between 23 and 29 °C activate TRPV3, mainly expressed extra-neuronally in keratinocytes. The next temperature window is occupied by TRPV4 modulated by temperatures above 27 °C. Temperatures above 42 °C activate TRPV1, whereas noxious heat (above 52 °C) induces TRPV2-mediated currents.

## TRP Channels in the Brain

Neuronal and glial cells express a variety of TRP channels; however, the physiological role of the expressed TRP channels in the particular context is often unclear [5–7]. For some TRPC channels, the physiological role has been clarified. TRPC5 is discussed to participate in ►growth cone guidance, whereas TRPC3 and TRPC6 mediate cation entry in growth factor-mediated pathways triggering neurite outgrowth. TRPC1 and TRPC5 are involved in synaptic activity. The function of the ADP-ribose activated

TRPM2 in ►microglia physiology is discussed in the context of ►oxidative stress. Oxidative stress via hydrogen peroxide induces the activation of poly-ADP-ribose-polymerase (PARP) and subsequent elevated levels of ADP-ribose via ADP-ribose-glucohydrolase leading to the activation of TRPM2. Elevated intracellular $Ca^{2+}$ concentrations mediated by TRPM2 are proposed to regulate microglia activity. As oxidative stress and microglial dysfunction is discussed in the context of ►neurodegenerative diseases, TRPM2 forms a putative therapeutic drug target for the treatment of neurodegenerative diseases like ►Parkinson' disease, ►Alzheimer's disease or ►multiple sclerosis.

### TRP Channels in Volume Regulation and Mechanotransduction

Besides the sensory role of TRP channels in thermosensation, TRP channels function also as mechanosensors and proteins sensing extracellular hypoosmolarity [5–7,10]. In flies, the protein encoded by the *no mechanoreceptor potential C* (►nompC) gene, NOMPC, is involved in the mechanosensory signal transduction pathway of sensory hair cells, and in *C. elegans* loss of function of the *osm-9* gene results in defects in avoidance behavior in response to hyperosmolar solutions. The high sequence similarity of OSM9 to mammalian TRPV4 enabled the discovery of osmolarity-dependent regulation of TRPV4 activity. In addition to TRPV4, TRPV2 and TRPM3 have been shown to respond to hypoosmolar solutions. The assignment of TRPC6 as mechanically or osmotically activated channel is mainly based on the use of a tarantual toxin and is discussed controversially. The underlying mechanism has to be clarified thoroughly in future. Another candidate for mechanotransduction is TRPA1. Based on the structural similarity with NOMPC, both channel proteins encode for a large number of N-terminal ankyrin repeats, TRPA1 was proposed to be the mechanically gated transduction channel mediating the auditory responses in the stereocilia of mammalian hair cells. However, $TRPA1^{-/-}$ mice have no defect in auditory function, and therefore the putative mechanosensory function in other physiological contexts remains to be unraveled.

### Conclusion

Within the short period since the description of the first TRP channel, enormous progress has enabled us to get an idea of the multiple functions of TRP channels in physiology. Their role in thermosensation as well as sensor proteins to detect mechanic stress or changes in osmolarity has been identified. Other TRP channels are essential for the $Ca^{2+}$ and $Mg^{2+}$ homeostasis in our body, whereas another group of TRP channels participates in receptor-induced signaling cascades. Nevertheless, we are still at the beginning of understanding the role and importance of TRP channels in physiology and pathophysiology.

## TRP Receptors

### Definition

A family of trans-membrane molecules which form unspecific cation channels, e.g., in nociceptor terminals. Some members of this receptor family play a major role in transduction of noxious stimuli, e.g., the TRPV1 and TRPA1 receptors.

►Nociceptors and Characteristics
►TRP Channels

## TRPA1 Protein

### Definition

The mammalian TRPA1 protein has been named according to the high number of ankyrin repeats in

the N-terminal region of the protein. In mammals, TRPA1 forms a cold sensing channel protein. The question whether or not TRPA1 mediates noxious cold is still in discussion.

►TRP Channels

## TRPC Proteins

### Definition

The members of the classic TRP (TRPC) channel family are activated by intracellular mediators released upon ligand-induced receptor-activation leading to the stimulation of phospholipase C isoforms. The name "classic TRP channels" is based on the high sequence similarity to the founding member, Drosophila TRP, and the common function as channel proteins mediating $Ca^{2+}$ entry upon receptor activation. The direct activation mechanism of individual TRPC proteins is often unclear and discussed controversially. Drosophila TRPL and TRPγ are activated by polyunsaturated fatty acids, whereas the activation mechanism of Drosophila TRP is still unclear. In contrast to this activation mechanism of the fly TRPCs, the mammalian members TRPC2, TRPC3, TRPC6 and TRPC7 are stimulated by diacylglycerols resulting from the breakdown of phosphoinositides by phospholipase C activation.

►TRP Channels

## TRPM Proteins

### Definition

The eight members of the melastatin-like TRP (TRPM) channel family are named according to their sequence similarity to melastatin. The function of melastatin, TRPM1, is still mysterious. Melastatin or TRPM1 was first cloned in 1998 and since then suggested to function as a tumor suppressor protein in melanocytes. TRPM2 forms an ADP-ribose-activated channel in macrophages, pancreatic β-cells and dopaminergic neurons. ADP-ribose accumulation can be induced by hydrogen peroxide-dependent activation of poly-ADP-ribosepolymerase. TRPM3 is activated by the application of extracellular hypoosmolar solutions or sphingosine. TRPM4 and TRPM5 form $Ca^{2+}$ -activated $Na^{+}$ channels, impermeable for $Ca^{2+}$. TRPM6 and TRPM7 are the $Mg^{2+}$-permeating channels. TRPM6 mediates intestinal absorption and renal reabsorption of $Mg^{2+}$, whereas the ubiquitously expressed TRPM7 is involved in cellular $Mg^{2+}$ homeostasis. TRPM8 forms one of the cold receptors in mammals and is activated by cooling compounds like menthol.

►Melanocyte
►Sodium Channels
►TRP Channels

## TRPML Proteins

### Definition

The three members of the mucolipidin-like TRP (TRPML) channel family are named according to their participation in mucolipidosis IV, a hereditary disease caused by mutations in TRPML1. Mucolipidosis is a disease caused by the intracellular accumulation of carbohydrates and lipids. According to this storage disease, an involvement of mucolipidin-like proteins in intracellular, lysosomal transport processes is discussed.

►TRP Channels

## TRPN Proteins

### Definition

Like TRPA1, TRPN proteins can be characterized by the occurrence of many ankyrin repeats in the N-terminal region. As TRPN proteins have only been identified in Drosophila, C.elegans and zebra fish, TRPN channels may be the counterparts to the mammalian TRPA1. NOMPC forms a $Ca^{2+}$-permeable channel in Drosophila mediating sensory hair cell mechanotransduction.

►TRP Channels

## TRPP Proteins

### Definition

The three members (TRPP2, TRPP3, and TRPP5) of the polycystin-like TRP (TRPP) channel family or

polycystins are named according to their participation in polycystic kidney disease (PKD). PKD results from mutations in proteins of a channel complex. The central components of the complex are a protein with proposed receptor function PKD1 (TRPP1, TRPP4) and a direct interacting channel protein with six transmembrane domains (TRPP2, TRPP3, TRPP5). Loss of function mutations in the channel complex formed by PKD1 and TRPP2 results in alterations in polarization and function of cyst-lining epithelial cells, leading to autosomal dominant PKD. In additional, TRPP3 has been described as sour taste sensor in mammals.

►Sour Taste
►TRP Channels

## TRPV Proteins

### Definition

The members of the vanilloid receptor-like TRP (TRPV) channel family are named according to the sequence similarity to the vanilloid receptor 1, the channel protein activated by the vanilloid capsaicin. The involvement in thermosensation is the common characteristic of TRPV1 to TRPV4, whereas TRPV 5 and TRPV6 mediate intestinal absorption and renal reabsorption of $Ca^{2+}$ in mammals.

►TRP Channels
►Ubiquitin

## TRPV1 Receptors

### Definition

TRPV1 receptors are members of a subfamily of transient receptor potential (TRP) ion channels that respond to vanilloid agents such as capsaicin, the pungent ingredient in hot peppers. These channels respond to hot temperatures and acid pH as well as certain endogenous substances such as anandamide. The channels were first discovered in nociceptive afferent neurons but were later identified in epithelial cells in the urinary bladder.

## Truncal Ataxia

### Definition

Ataxia is impaired motor coordination usually related to disorders of the cerebellum or its connections with the brain and spinal cord. Truncal ataxia refers to the unsteadiness of posture and the wide based gait seen as part of the overall ataxic syndrome. Impaired tandem gait is an early feature of truncal ataxia.

## Truth Conditions

### Definition

The conditions under which a sentence is true. According to an influential tradition in semantics, the

sense or meaning of an assertive sentence can be identified with its truth conditions.

►Representation (Mental)

## Truth Value

### Definition

In classical bivalent logic there are exactly two truth values: truth and falsity. Two sentences which are both false therefore share the same truth value. And the sentences "1 + 1 = 2" and "London is the capital of Italy" therefore differ in truth value.

►Representation (Mental)

## Tryptamine

### Definition

A simple molecule that serves as the framework for many biologically-active molecules, including the neurotransmitter serotonin, as well as the tryptamine class of hallucinogens.

►Hallucinogens
►Serotonin

## Tryptophan

### Definition

*Tryptophan* (abbreviated as *Trp* or *W*) is one of the 20 standard amino acids essential in the human diet. It is encoded in genetic code as the codon *UGG*. The distinguishing structural characteristic of tryptophan is that it contains an indole functional group. Tryptophan is a biochemical precursor for the compounds such as serotonin (neurotransmitter), melatonin (neurohormone) and niacin (essential for cell survival and DNA repair).

## TTX

### Definition

►Tetrodotoxin (TTX)

## Tubercle, Olfactory

### Definition

Conspicuous eminence on the ventral surface of the brain of macrosmatic mammals located between the anterior olfactory nucleus and preoptic region which receives inputs from the olfactory bulb and olfactory cortex. Comprising a superficial molecular layer, dense cell layer and superficial and deep polymorph layers, the olfactory tubercle represents the ventral most extent of striatopallidum containing both ventral striatum, in the dense cell and superficial polymorph layers, and ventral pallidum in the deep polymorph layer.

►Olfactory Bulb
►Olfactory Cortex
►Striatopallidum

## Tuberculoventral System

### Definition

An intrinsic fiber tract that reciprocally interconnects the dorsal and ventral cochlear nuclei.

►Cochlear Nucleus

## Tuberomamillary Nucleus

### Definition

Group of neurons in the hypothalamus, the only neurons that produce histamine as neurotransmitter.

►Drinking Disorders and Osmoregulation

## Tuberomammillary Nucleus (TMN)

### Definition

Subnucleus of the posterior hypothalamus composed by a cluster of magnocellular neurons that produce the neurotransmitter histamine. Histamine producing neurons project widely throughout the brain and are involved in the control of arousal, attention, appetite and learning.

►Histamine
►Hypocretin/Orexin
►Hypothalamus
►Ventrolateral Preoptic Nucleus (VLPO)

## Tuberous Sclerosis Complex (TSC)

### Definition

Severe autosomal-dominant disorder usually diagnosed in childhood and characterized by the development of benign tumors (hamartomas) distributed throughout the body, heart, kidneys, liver, lungs, skin and brain. TSC can thus lead to renal or heart failure, ►epilepsy, autism, mental retardation and neurocutaneous syndrome. The classic triad consists of ►seizures, mental retardation, and cutaneous angiofibromas. Facial angiofibromas are highly suggestive of TSC. The cause is an inactivating mutation in either of two tumor-suppressor genes – TSC1 gene on chromosome 9 and TSC2 on chromosome 16, with TSC2 mutations accounting for 80–90% of all mutations.

## Tubular Repair of Nerves

### Definition

Repairing nerves by enclosing both the nerve ends in a tubular structure of biological or synthetic nature, leaving a short distance between the nerve ends.

►Regeneration: Clinical Aspects

## Tubulin

### Definition

The basic protein building block of the microtubule. Tubulin is found as a dimer of the structurally similar α-tubulin and β-tubulin. These tubulin protomers then assemble in a linear, end-to-end fashion forming protofilaments, which can then be assembled to form a microtubule. Given the dimeric nature of tubulin, the resultant microtubule has a polarity (one end terminating with α-tubulin, the other with β-tubulin).

►Axonal Pathfinding and Network Assembly

## Tufted Cells in Olfactory Bulb

### Definition

Glutamatergic projection neurons situated in the external plexiform layer and the glomerular layer of the olfactory bulb. There are several subclasses, but those cells that receive sensory input in the glomerulus and project out of the olfactory bulb to other brain areas are often grouped together with mitral cells in studies using extracellular recording in intact mammals. They receive direct input from olfactory sensory neuron terminals, and project directly to olfactory cortex, as well as to intrabulbar targets. Like mitral cells, they also have multiple, complex interactions with periglomerular cells, through conventional and dendrodendritic synapses.

►Olfactory Cortex
►Olfactory Nerve

## Tumor Necrosis Factor

►Brain Inflammation: Tumor Necrosis Factor Receptors in Mouse Brain Inflammatory Responses

## Tumor Necrosis Factor-α

### Definition

Tumor necrosis factor-α is a potent paracrine and endocrine mediator of inflammatory and immune functions. It is secreted by activated monocytes and macrophages, and many other cells, including B cells, T cells and fibroblasts. It provides a rapid form of host defense against infection but is fatal in excess. Exerts cytotoxic as well as differentiation and growth modulatory activities on many different target cells.

►Brain Inflammation: Tumor Necrosis Factor Receptors in Mouse Brain Inflammatory Responses
►TNF: Differential role of TNF receptors in mouse brain inflammatory responses

## Tumor Suppressor Gene

### Definition

Tumor suppressor genes have important roles in normal cellular function, such as cell cycle regulation, DNA repair and apoptosis. Cancer may develop subsequent to inactivation of both alleles (known as the "two-hit" hypothesis), such as through mutation of one allele with loss of heterozygosity of the other allele. Well studied tumor suppressors are encoded by the p53 and retinoblastoma (Rb) genes.

►Chromatin Immunoprecipitation and the Study of Gene Regulation in the Nervous System

## Tuning Curve of Visual Neurons

### Definition

A tuning curve to some feature of a visual stimulus (e.g., orientation, speed, disparity, etc.) is a curve that shows the average response of a neuron to different feature values. Typically, the curve is bell shaped: the neuron responds maximally to a particular feature value and gradually less and less as the value moves away from the most preferred stimulus, in either direction.

►Visual Illusions

## Tutor Song

### Definition

The song that is or has been perceived during the sensory period.

## TVOR (Translational VOR)

►Vestibulo-Ocular Reflex

## Twitch (Muscle)

### Definition

Generation of a single action potential at the sarcolemmal membrane of a skeletal muscle fiber produces the characteristic mechanical response known as twitch. The muscle twitch is characterized by a single rise and fall in force with a rapid time course (~100 ms for rodent muscle at 35 °C and ~500 ms for amphibian muscle at 3 °C). The twitch to tetanus force ratio ranges from 0.10–0.50, increasing with lowered temperature.

►Force Potentiation in Skeletal Muscle

## Two-Point Discrimination and Threshold in Cutaneous Mechanosensation

### Definition

Two-point discrimination is a term used to describe our ability to perceive two neighboring stimuli contacting the skin as two separate points rather than one. This ability is quantified by determining the minimum distance between two stimuli that are perceived as two distinct stimuli, a measurement referred to as the two-point threshold. Thresholds vary from about 2 mm on the finger tip to around 40–50 mm on the upper arm

and leg. Although commonly used in the clinic, this is a relatively crude and unreliable measure that does not reflect the true spatial resolution of the system.

►Haptics
►Processing of Tactile Stimuli

## Two-Process Model of Sleep Regulation

### Definition

The two processes of Alexander Borbély's two process model of sleep regulation (Hum Neurobiol 1:195–204, 1982). A propensity for sleep increases during wakefulness and dissipates during sleep. In the model this homeostatic sleep process was referred to as Process S, and its dynamics are derived from the sleep-wake dependent changes in electromyographic (EEG) slow-wave activity. Process S interacts with a circadian process, Process C. Process C defines an upper and a lower threshold between which Process S oscillates. Sleep onset is triggered when Process S reaches the upper threshold and sleep continues until Process S reaches the lower threshold. The thresholds were estimated on the relationship between sleep duration and circadian time at which sleep is initiated and on the dynamics of EEG slow wave activity (see Process S).

►Electromyography

## Two-Third Power Law

### Definition

The two-third power law prescribes that the angular velocity $\omega$ and curvature $k$ of curved movements are related by the power law $\omega = Ck^{2/3}$ with $C$ a constant. Using tangential velocity $v$, this relation can be rewritten as $v = Ck^{-1/3}$. This relation has a phenomenological basis but can be derived under the assumption that curved movements are produced by sine and cosine modulated orthogonal components. It can also be derived with the assumption that movements minimize jerk (optimize smoothness).

►Motor Control Models

## Tylotrich Hairs

### Definition

Hairs are classified in terms of stiffness; down hair, guard hair, a Tylotrich hair. Tylotrich hairs are most biggest and strong hairs except vibrissae, and often associated with touch dome. But they are lacking in primates.

►Cutaneous Mechanoreceptors, Anatomical Characteristics

## Tympanal Organ

### Definition

A type of mechanoreceptor used to detect acoustic signals that is normally associated with a thinned region of cuticle – the tympanic membrane – whose motion directly corresponds to the pressure changes of an acoustic stimulus in the surrounding medium.

►Invertebrate Ears and Hearing

## Type 1 and Type 0 Resetting

Till Roenneberg[1], Martha Merrow[2]
[1]The Univeristy of Munich, Munich, Germany
[2]The University of Groningen, Haren, The Netherlands

### Synonyms

Weak and strong resetting

### Definition

Type 1 and Type 0 resetting describe two qualitatively different response-types of a ►circadian rhythm to a ►zeitgeber stimulus. Circadian rhythms are circa 24-h oscillations in, e.g., sleep-wake behavior, secretion of certain hormones, gene expression and a multitude of other processes; zeitgebers are those signals from the environment which organisms can use to synchronize (entrain) their biological clock to the 24-h day. When circadian rhythms "run free" in constant conditions, their period often deviates from 24 h. Stable ►entrainment is

achieved when a zeitgeber stimulus can shift the phase of the circadian rhythms each day by the exact amount that compensates the difference between the ►free-running period and that of the zeitgeber (normally 24 h).

## Characteristics

When a free-running period is shorter than 24 h (e.g., 22 h), the circadian rhythm has to be delayed (in this case by 2 h, every day); if it is longer, it has to be advanced. This type of entrainment is called type 1. To achieve a type 1 entrainment, the rhythm has to respond differently to a zeitgeber stimulus (with a given duration and a given strength) depending on its internal phase. In general, circadian clocks are advanced when they receive a light pulse during the second half of their internal night, are relatively unresponsive during their internal day, and respond with a delay in the first half of their internal night. The characteristic which represents this phase-dependent response is called ►phase response curve (►PRC). In type 1 ►resetting, the resulting phase (i.e., where it ends up after having been shifted) depends on when during its cycle it received the light pulse.

Another possibility to synchronise circadian rhythms with their cyclic environment is if every zeitgeber stimulus – no matter when it is received – resets the rhythm to the same internal phase (e.g., to the beginning of the internal day). This type of resetting is called type 0. In type 0 resetting, the resulting phase is independent of the timing of the zeitgeber stimulus. In analogy to a board game, type-1 resetting is like drawing cards that tell you to move x spaces forward or backward, while type 0 refers to the cards that always send you back to "Go." Type 1 resetting refers to weak responses where even the maximal advance or delay is less than half a cycle while in type 0 resetting the maximal phase shift is always as long as the entire cycle. Since the response to a zeitgeber stimulus depends on its strength (both intensity and duration), a type 1 resetting characteristic can be transformed into a type 0 by increasing the zeitgeber strength.

## Circadian Clocks are Built for Entrainment

►Circadian rhythms are biological oscillations that occur with a frequency of approximately once per 24 hours when an organism is held in constant conditions (hence, circadian from *circa dies, Latin,* or about a day). These self-sustained rhythms occur in organisms from all phyla, regulating biology from the level of gene expression to behavior (see also ►chronobiology).

Considering that virtually all living things have evolved in a cycling environment, the "constant conditions" often used to investigate circadian clocks are rather artificial. In nature, circadian clocks are virtually always entrained to their cyclic environment [1,2]. In nature ALL zeitgebers are caused directly or indirectly by the rotation of the Earth around its axis thereby regularly exposing different parts of the globe to sunlight. Thus, all non-photic cyclic parameters, from temperature to the availability of food or the threat of predators, ultimately depend on light. It is, therefore, not surprising that light is the most prominent zeitgeber for circadian clocks although, theoretically all other, light-dependent parameters could also be used as (non-photic) zeitgebers [3]. In addition to the richness of the temporal physical environment, the daily alternations of light and darkness alone have complex characteristics. They can change in amplitude (for example, for organisms that are either exposed to direct sunlight or those living in shaded niches); their duration (►photoperiod) can change over the course of the year, or the duration of dawn and dusk periods can be different at higher latitudes compared to the equator. Even their spectral characteristics can be different (for example, for organisms living in the ocean compared to those living on a glacier).

The question of how exactly the alternating exposure to light and darkness entrains circadian clocks remains a topic of debate. Are only the changes (transitions) from light to dark and vice versa important cues for entrainment, or does the cyclic light environment entrain the clock by continuously influencing its progression? The former is called non-parametric entrainment, the latter parametric. These two hypotheses for explaining entrainment had prominent representatives among the pioneers of our field. While Pittendrigh favored the non-parametric hypothesis, Aschoff favored the parametric view [4,5]. While the former heavily relies on the phase response curve, the latter believes that entrainment is achieved by a continuous influence of the changing light levels on the rhythm's period, thus using a ►velocity or *tau* ►response curve. As always, the truth probably lies in between the two hypotheses. Depending on the niche of an organism or depending on the time of year, a combination of parametric and non-parametric will eventually explain how circadian clocks are entrained. The fact that both parametric and non-parametric entrainment occur in nature is demonstrated by the finding that some organisms entrain perfectly without ever experiencing dawn or dusk [6].

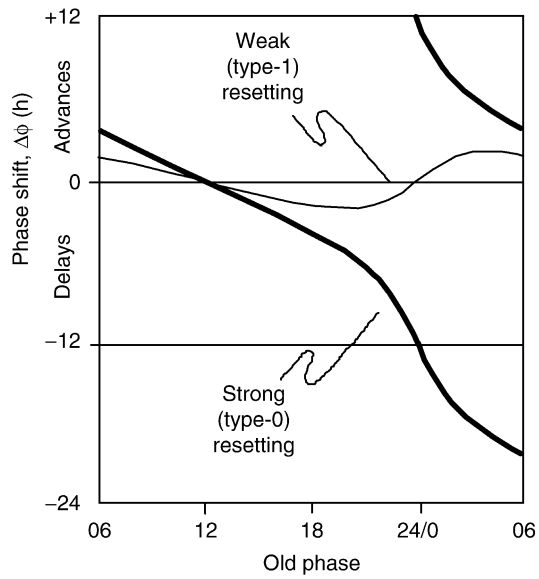
## Phase Response Curves Come in Different Shapes

The non-parametric hypothesis favors the lights-on and -off signals as the key to entrainment. Although natural photoperiods consist of extended blocks of light and darkness, single steps (from light to darkness or from darkness to light) or even light pulses as short as a flash can predictably shift (reset) the phase of a circadian rhythm, and if they occur in regular intervals, they can entrain the clock. A prerequisite for such an entrainment mechanism is that the clock responds differently to the same stimulus (e.g., pulse of light) depending on when it

receives the stimulus during its cycle resulting in a phase response curve (PRC). While entrainment protocols involve a regular repetition of a zeitgeber, PRCs are constructed by measuring the direction and magnitude of phase shift to a single stimulus given at different internal phase in otherwise constant conditions.

Internal phase refers to a time within the ►circadian cycle that corresponds to an arbitrarily designated but, nevertheless, identifiable "event" of the rhythm that is being measured. Such an "event" could be, for example, the trough of a circadian temperature rhythm or the onset of activity following the main sleeping bout. For the construction of a PRC, the zeitgeber (e.g., a light pulse) is applied – in separate experiments – at different phases of the cycle (2h, 4h, 6h, etc. after, e.g., the activity onset) and the resulting phase of the rhythm (e.g., of the activity onset) is compared to that of a control experiment where the rhythm ran free without a perturbation. This comparison yields the phase shift which is elicited by a light pulse given at a specific internal time which can be either delayed, advanced or not shifted at all. The resulting phase shifts induced over an entire circadian cycle are then plotted as a phase response curve (PRC, see Fig. 1). A typical type-1 PRC shows phase advances (in the second half of the internal night), phase delays (in the first half of the internal night) and a non-responsive "►dead zone" (in the middle of the internal day) [7]. For a collection of most known PRC's, see www.cas.vanderbilt.edu/johnsonlab/prcatlas/index.html).

PRCs can be plotted in two different ways. In most cases, the amount of phase shift elicited (y-axis) is plotted against the internal phase at which the pulse was given (x-axis). By convention, internal phase is either expressed as Circadian Time [8] (CT; anchored at the time at which lights would have been turned on, defined as CT0) or Internal Time [9] (IT, anchored at mid-night, i.e., at the mid-point between the times at which lights would have been turned off and on, defined as IT0). An alternative graphing method, called a Phase Transition Curve (PTC), plots the (new) phase which results from the perturbation of the zeitgeber stimulus (y-axis) against the internal phase at which the pulse was given (x-axis). The labels "type 1" and "type 0" resetting are derived from the slopes of the PTC. If the stimulus always resets the ►oscillator to a given phase, the slope of the PTC is zero ("go back to start," no matter where you are); if, however, the stimulus shifts the phase by a certain amount, which changes depending on the internal time when it was given, the slope will be close to one. The stronger the zeitgeber stimulus, the more it will shift the phase, the more the individual phase shifts within a PRC, the more the PTC will deviate from a slope of 1 With strong resetting, the slope approaches 0 (almost complete resetting).



**Type 1 and Type 0 Resetting. Figure 1** Phase response curves can show strong or weak resetting in response to a zeitgeber. The stimulus is delivered at a given circadian time (old phase) and, some days later, the new phase is determined. This phase shift is plotted either as an advance, a delay or no change. Reprinted from [2].

## PRC's and Circadian Entrainment

Experiments probing how a given zeitgeber affects the phase of a free running circadian rhythm have been remarkably successful in providing a theoretical basis for entrainment. To do this, one puts the zeitgeber period (T), the free-running period (τ), and the PRC into a systematic relationship. The daily phase shifts (ΔØ) necessary to ensure stable entrainment must (exactly) compensate for the difference between T and τ: $\Delta Ø = \tau - T$. Thus, by definition, delays are negative and advances positive. Stable entrainment can only be achieved if one point on the PRC represents the necessary ΔØ, and this is exactly the phase at which the zeitgeber pulse must be given to the oscillator every day. If entrainment was achieved predominantly non-parametrically, e.g., if it was the signal of dawn which ensures entrainment, then the phase of entrainment (chronotype) is determined by the period of the zeitgeber cycle (in nature 24 h), the shape of the PRC and the free-running rhythm.

## Significance of Type 1 and Type 0 Resetting in the Natural Environment

Entrainment is the basis for the variety in temporal aspects of human behavior (as well as that of most organisms on earth), exemplified by the well known

"early" or "late" type individuals (chronotypes), those who either retire and rise early or late within the day. Both the free-running rhythm and the shape and amplitude of a PRC can vary between species but it can also vary between individuals within a species. It can even change over the lifetime of an individual. Each species and each individual within a species and even an individual at different ages can, therefore, show a different phase of entrainment (be a different chronotype). In real life, the strength of the stimulus (or the sensitivity to the stimulus) will have an impact on the free running period and the PRC, and will thus also contribute to chronotype. For humans, this would relate to people living and working predominantly indoors compared to those working outdoors.

The shape of the PRC which has evolved for a given species generally reflects the relationship between T and $\tau$. If for example, the $\tau < T$, the PRC should have a substantial delay portion; if $\tau < T$, the PRC will have to show a substantial advance portion. There is yet another parameter that influences the relationship between T, $\tau$ and the PRC – the more robust a rhythm, the larger its amplitude, the less it will be perturbed by a given zeitgeber stimulus. Robust (high amplitude) circadian clocks would, therefore, predictably show rather a type 1 than a type 0 resetting characteristic. Although this can be explained by simple mechanical oscillator theory, it may also make sense in biology, as can be shown by the example of aging. Young animals (including humans) generally have a more robust circadian oscillator, expose themselves to stronger zeitgeber stimuli and their input pathways are more sensitive compared to older animals, yet clocks of all ages need be entrainable. In this case, the decreased exposure to strong zeitgeber stimuli in the elderly would be compensated for by a decreased robustness (amplitude) of their circadian system.

# L-type $Ca^{2+}$ Channel

## Definition

The L-type calcium channel is the dihydropyridinesensitive Cav1.2 calcium channel, that is essential for smooth muscle contraction and the target for the calcium channel blocker/calcium antagonists.

►Calcium Channels – an Overview

# Type I Position-Vestibular-Pause (PVP) Neuron

## Definition

Neurons in the vestibular nuclei, which constitute most of the intermediate leg of the direct vestibulo-ocular reflex (VOR) pathway.

►Position-Vestibular-Pause Neurons
►Vestibular Nuclei
►Vestibulo-Ocular Reflexes

# Type I Secondary Vestibular Neurons

## Definition

Vestibular nucleus neurons that receive a primary afferent input from the ipsilateral horizontal semicircular canal. They show type I response to head rotation in

the horizontal plane: an increase in their firing rate during head rotations to the ipsilateral side and a decrease during rotations to the contralateral side.

►Burster-Driving Neurons
►Semicircular Canals
►Vestibular Nuclei

## Type II Restriction Endonucleases

### Definition

Restriction endonucleases catalyse the hydrolysis of the sugar-phosphate backbone of DNA. Type II Restriction enzymes cut double stranded DNA at a predictable location within or very near the nucleotide recognition sequence making them useful in molecular biology. Most Type II restriction enzymes cut within their palindromic recognition sites. For example EcoRI cuts within its recognition site of 5′-GAATTC-3′. Type IIs restriction enzymes on the other hand cleave DNA at a considerable offset from the recognition site. For example BmsFI cleaves 10 and 14 nucleotides away from its recognition site.

## D-type $K^+$ Current ($I_D$)

### Definition

D-type $K^+$ current ($I_D$) is activated by sub-threshold depolarizations, inactivates slowly, contributes to action-potential repolarization and is blocked by 4-aminopyridine, which broadens action potentials.

►Action Potential
►Neuronal Potassium Channels

## Tyrosine Hydroxylase

### Definition

The enzyme tyrosine hydroxylase (TH) catalyzes the conversion of L-tyrosine to L-dihydroxyphenylalanine (L-DOPA), which is the rate-limiting step in the production of dopamine and noradrenaline (norepinephrine).

►Dopamine
►Noradrenaline

## Tyrosine Kinase Receptors

### Definition

Large family of membrane spanning proteins that upon activation by ligand binding catalyze the transfer of phosphates from ATP to tyrosine residues on various substrates that act as signal transducers.

## Ubiquitin-proteasome System

### Definition

A complex system of degrading unwanted (e.g., misfolded) cellular proteins. Impairment in this system can lead to abnormal aggregation of intracellular proteins.

## Uhthoff's Phenomenon

### Definition

Transient worsening of neurological symptoms with elevation of body core temperature is known as Uhtoff's phenomenon. Worsening symptoms, such as visual blurring or leg heaviness can occur in a hot environment or with exercise. These symptoms, sometimes called pseudo-exacerbations, may result from transient nerve conduction block.

## Ultradian Rhythm

### Definition

Circadian rhythms are biological rhythms that occur with a periodicity of approximately 24 h. Ultradian rhythms are biological rhythms that occur with substantially shorter periodicity, such that multiple cycles occur during each 24 h day. Examples of ultradian rhythms include rhythms of parathyroid and insulin secretion, heart rate, blood pressure, and episodes of REM sleep. While circadian rhythms have been demonstrated to be based in all organisms on self-sustaining cellular oscillations, the mechanistic bases for ultradian rhythms – including whether any of them are self-sustaining – have remained obscure.

## Unconditioned Reflex

### Definition

A reflex is a stereotyped behavior that reliably occurs at a characteristic latency after a specific stimulus. An unconditioned reflex is a reflex that has not been modified by a well-defined conditioning experience, such as a classical or operant conditioning protocol.

Many (and perhaps all) unconditioned reflexes are in reality the products of interactions early in life between genetic endowment and activity-dependent central nervous system plasticity. Thus, the traditional distinction between conditioned and unconditioned reflexes is

meaningful only when defined in terms of a specific experimental protocol.

►Classical Conditioning (Pavlovian Conditioning)
►Conditioned Reflexes
►Operant Conditioning

## Unconditioned Response (UR)

### Definition

In classical conditioning, the unconditioned response (UR) is a response evoked by the unconditioned stimulus. The UR includes mostly reflexive autonomic response, such as salivary secretion and vasomotor responses, and muscle movements, such as flexion reflex and eyelid reflex.

►Classical Conditioning (Pavlovian Conditioning)

## Unconditioned Stimulus (US)

### Definition

In classical conditioning, the unconditioned stimulus (US) is a stimulus presented following the conditioned stimulus. The US is chosen to elicit innate reflexive responses (unconditioned response), such as food in the salivary conditioning protocol and airpuff in the eyelid conditioning protocol.

## Uncontrolled Manifold Hypothesis

### Definition

A hypothesis that states that the central nervous system created a subspace (an uncontrolled manifold, UCM) in the space of independent elemental variables and organizes co-variation of elemental variables to restrict much of their variability to the UCM.

►Coordination

## Uncorrelated Broadband Noises

### Definition

Two noises with flat magnitude spectra whose fine structures are uncorrelated. Specifically, noises are said to be uncorrelated if one is given the amplitude (e.g., in volts) of one of the noise bursts at an instant in time, one cannot predict the amplitude of the other noise burst at that instant or any other instant in time. Perfectly correlated noises, by contrast, have identical magnitude and phase spectra.

## Under- or Indeterminate System

### Definition

A mathematical system is called under- or indeterminate if it has fewer system equations than unknowns. Indeterminate systems typically have an infinite number of possible solutions.

## Uniformity

### Definition

The property of a material body such that all its points are mutually materially isomorphic. In an evolving uniform body (undergoing growth or remodeling) the material isomorphisms are functions of time.

►Logical

## Unloading Reflex

### Definition

The unloading reflex, or unloading response, is the automatic and stereotypical dis-facilitation of a homonymous muscle after it has been rapidly shortened/ unloaded. The response is caused by the removal of the afferent feedback component of the reflex control loop.

►Integration of Spinal Reflexes

## Unmyelinated Axon

### Definition

Axons ensheathed by a single layer of Schwann cell process are called unmyelinated axons.

►Myelin
►Schwann Cell

## Unmyelinated Mechanoreceptors

### Definition

A mechanically sensitive sensory ending which conducts slowly (~1 m/s). An afferent C-fiber. In the skin, a subclass knows as "tactile C fibers" possess mechanical thresholds similar to those of myelinated cutaneous mechanoreceptors.

►Electric Fish

## Unreinforced Learning

►Latent Learning

## Unsharp Mask

### Definition

In digital image processing, an unsharp mask is a simple method used to sharpen an image, effecting contrast enhancement. It does not increase image resolution, but rather improves small-scale ►acutance. A slightly blurred version of the original image is created and then subtracted from the original image, creating a highpass filtered difference image called the unsharp mask that emphasizes regions of transition (edges). This mask is then used to transform the original image to emphasize the contrast along these edges.

The scale of the contrast enhancement in this operation is determined by the blur distance. The more blurred the image that is initially subtracted from the

original, the lower the corner frequency of the resulting unsharp mask, and the larger the scale of the contrast enhancement. The effects of larger-scale contrast enhancement are broader and less restricted to the sharp edges of the original image.

►Contrast Enhancement

## Unsharp Masking

►Contrast Enhancement

## Unsupervised Learning

### Definition

Unsupervised learning is a form of learning in computational models such as connectionist (artificial neural network) models. In contrast to supervised learning, unsupervised learning algorithms work without providing explicit feedback on the error of the net with respect to its input (i.e., no teaching signal). Learning develops by using internal or statistical structure of data set, so that the responses (output) will be fully characterized statistical properties of inputs. Often, the aim of unsupervised learning algorithms is to cluster the input according to similarity. While this is biologically more plausible than providing an external teaching signal, problematic issues in this context are how many clusters to form, and when to stop training. Often, weights are adjusted until some internal constraint is fulfilled. It has been proposed that unsupervised learning occurs in cortex-based learning.

## Upper Respiratory Tract Infections (URTIs)

### Definition

The common cold is probably the most frequently occurring illness in humans worldwide. More than 200 different viruses cause colds, and rhinoviruses and coronaviruses are the culprits 25–60% of the time. Rhinoviruses often attack during the fall and spring seasons, while the coronavirus is common during the winter. The average adult has two or three respiratory infections each year. Epidemiological data suggest that endurance athletes are at increased risk for upper respiratory tract infection during periods of heavy training and the 1- to 2-wk period following race events.

## Urodeles

### Definition

Urodeles are one of three orders of living amphibians (order Caudata). They are commonly referred to as salamanders and newts depending on the taxonomic group within the order. Urodeles are the most generalized of the amphibians, and in their basic body appearance most similar to known fossil amphibians. A number of urodele species diverge from the hypothesized amphibian ancestral state in interesting ways that have implications for evolutionary changes in the brain, including (in the same or different species) secondary reductions in brain size, large increases in genomic DNA content and subsequent increase in cell size, and the retention of juvenile characteristics in adults ("neoteny"). Others, such as the plethodontid salamanders, have highly specialized visual systems and tongue motor systems used for visually guided prey capture that is very similar to that used in the anurans.

►Evolution of the Brain: Amphibians

## Urogenital Reflexes

### Definition

The neural control of the lower urinary tract and reproductive organs (i.e., the urogenital organs) is dependent on autonomic and somatic nerves arising in the lumbosacral spinal cord. Many of the functions of these organs are regulated involuntarily by reflex mechanisms: the urogenital reflexes. Some reflexes are organized in the spinal cord, e.g., penile erection induced by tactile stimulation of the penis; whereas others require coordination between the brain and spinal cord, e.g., penile erections induced by visual erotic stimuli. Some reflexes are complex, requiring coordination between autonomic and somatic nerves, e.g., seminal emission-ejaculation; whereas others involve interactions between different organs, e.g., inhibition of micturition by stimulation of afferent nerves to the penis or vagina.

### Definition
A vago-vagal reflex is a reflex, for example for neural control of the stomach, that involves vagal sensory afferents that transmit information to the brain stem, integrative circuitry in the brain stem and vagal efferent fibers that transmit back to the target organ.

►Autonomic/Enteric Reflexes

## Vagus Nerve

### Definition
The vagus nerve is the tenth cranial nerve and arises from a number of nuclei in the medulla oblongata and caudal pons. The vagus nerve provides parasympathetic motor innervation to organs throughout the thoracic and abdominal cavities, and so plays a major role in regulating cardiovascular, respiratory and digestive system functions. Importantly, the vagus nerve also provides general sensory innervation of these same organ systems, and carries some information on taste from receptors at the base of the tongue and on the epiglottis. Special visceral efferent fibers of the vagus nerve regulate a number of muscles of the pharynx and larynx, giving the vagus nerve a role in speech and swallowing, and bilateral lesions of the vagus may lead to death by suffocation. Of uncertain significance are general somatic sensory neurons within the vagus nerve projecting to the skin of the external ear.

# Vagus Nerve, Motor Fibers

## Definition

Motor components of the vagus nerve (X). The somatomotor components come from nucleus ambiguus, the visceromotor from the dorsal nucleus of the vagus nerve.

# Vagus Nerve, Sensory Fibers

## Definition

Sensory components of the vagus nerve (X). The somatosensory fibers pass on to the spinal nucleus of the trigeminal nerve, the viscerosensory to the solitary nucleus.

# Value-Based Learning

John Philip O'Doherty
Computation and Neural Systems Program, Division of Humanities and Social Sciences, California Institute of Technology, Pasadena, CA, USA

## Definition

►Value-based learning refers to the process by which an animal learns about the ►rewards or ►punishers available in its environment, so that behavior can be organized in order to seek out the rewards and avoid the punishers. Value-based learning encompasses two broad categories of associative learning phenomena: Classical or Pavlovian conditioning, by which an animal learns passive associations between an initially affectively neutral stimulus and a rewarding or punishing outcome, and instrumental conditioning by which an animal learns to make responses in order to obtain rewards or avoid punishers.

## Characteristics

In order to survive, both humans and other animals need to be able to learn about the affective value of stimuli in their environment and to predict when and where stimuli of affective significance will occur, so that behavior can be organized prospectively in order to seek out rewards and avoid punishers. This capacity seems to depend on at least four distinct processes: (i) The ability to encode the value of rewarding or punishing stimuli, (ii) The ability to encode predictions of future rewarding or punishing events, (iii) The ability to learn to predict future rewarding or punishing outcomes, and (iv) The ability to modify action selection in order to choose those actions which lead to a greater probability of obtaining rewards or avoiding punishers.

### Neural Substrates of Stimulus Reward Value Encoding

Single-unit neurophysiology studies in animals and functional neuroimaging studies in humans have revealed a contribution of one brain structure in particular: the orbitofrontal cortex in encoding stimulus-reward value. Neurons in monkey orbitofrontal cortex respond to the taste or odor of a food reward when the animal is hungry, but such responses decrease to the same taste or odor once the animal has been sated on that food [1]. Brain imaging studies in humans have also suggested a key role for this area in encoding stimulus reward-value for a variety of rewards in different modalities, such as odors, tastes, touch, as well as for rewards in the visual or auditory domains. Human orbitofrontal cortex also responds to the receipt of more abstract rewards not tied to a specific sensory modality, such as monetary reward. [2]. Orbitofrontal cortex has been found to respond also to the receipt of aversive or punishing stimuli in different modalities, including unpleasant odors, tastes and monetary loss, suggesting a role for this region in encoding both positive and negative value.

### Neural Responses Related to Prediction of Future Rewards

Reward prediction in its simplest form can be studied through the phenomenon of appetitive classical conditioning whereby an arbitrary affectively neutral stimulus acquires affective value by virtue of being repeatedly paired with the subsequent presentation of reward. Following conditioning, such a stimulus can be said to be predictive of subsequent reward. Single unit studies in rats and monkeys have revealed neural responses in a number of brain regions such as the amygdala in the medial temporal lobes as well as the orbitofrontal cortex in response to stimuli predictive of subsequent reward, or that respond in anticipation of a reward outcome [3,4]. Other neurons have been found in these areas that respond to cues predictive of the subsequent presentation of aversive or punishing stimuli. Human neuroimaging studies have also confirmed a role for the amygdala and orbitofrontal cortex in responding to cues predictive of subsequent rewards as well as punishers [2]. These predictive representations appear to track the current value of the associated reward, such that responses to cues predictive of a particular food outcome decrease if the subject no longer

values that outcome as a result of having previously consumed it to satiety. Another region that has been found to respond in human imaging studies during reward anticipation is the ventral striatum, including the nucleus accumbens as well as ventral parts of the putamen [5].

## Learning of Reward Predictions: the Role of Dopamine

How are predictions of reward learned? A candidate mechanism may be via the phasic activity of dopamine neurons present in the substantia nigra and ventral tegmental area in the midbrain, that project widely to the striatum, amygdala and prefrontal cortex including the orbital surface. Recordings from dopamine neurons in non-human primates reveal that the phasic activity of these neurons seem to encode the difference between expected and actual reward. That is, these neurons increase their firing when a reward is presented unexpectedly but decrease their firing from baseline when a reward is unexpectedly omitted [6]. During reward-learning these neurons have also been found to respond initially at the time of reward presentation, but once learning is complete to respond instead at the time of the presentation of the predictive stimulus. The response profile of these neurons has been suggested to resemble a prediction error signal found in theoretical models of conditioning such as the Rescorla–Wagner learning rule and its real time extension: temporal difference learning. The error signal in such models is used to update expectations of future reward, and thus plays a crucial role in learning. According to this proposal, the phasic activity of dopamine neurons acts to modulate learning of stimulus-reward and/or stimulus-response associations in target regions such as the striatum. Indeed, consistent with this proposal, dopaminergic input has been found to facilitate neuronal plasticity in the striatum. Human neuroimaging studies have also reported activity in target areas of dopamine neurons such as ventral striatum during reward-learning, that resemble the prediction error signals thought to be conveyed by dopamine neurons [2]. Moreover, systemic administration of dopamine antagonists have been found to decrease prediction error related responses in human striatum.

However, the role of dopamine in learning has also been challenged by others. There is some evidence to suggest that mice lacking in dopamine can perform normally on some tasks designed to probe reward-learning. Furthermore, mice with increased tonic dopamine levels do not show any evidence of an enhanced ability to learn to obtain rewards. This suggests that at least some aspects of reward-learning may be dopamine independent. An alternative view is that dopamine is involved not in learning per se, but instead in mediating the degree to which an animal "wants" or is motivated to obtain reward [7]. Another proposal is that that dopamine may play a role in signaling and facilitating learning about salient and/or novel events in general as opposed to playing a specific role in reward-learning [8]. Evidence of a role for dopamine in responding during aversive learning is mixed. Single-unit studies have generally failed to observe strong dopaminergic activity in response to aversive events, and indeed it has been found that dopamine neurons may in fact inhibit responding during aversive stimulation such as tail pinch in rats. On the other hand, a number of studies measuring dopamine release in the striatum in rats have found evidence for increased dopamine levels during aversive as well as ►appetitive conditioning. However, as termination of an aversive stimulus can in itself be rewarding, the implications of these studies for understanding the role of dopamine in aversive learning are still debated.

## Action Selection for Reward

Once predictions of future reward are established, the next step is to use these predictions to guide behavior. More specifically, humans or other animals need to be able to bias their action selection so that they choose those actions which in a given context lead to the greatest probability of obtaining future reward or avoiding punishers. The problem of choosing responses in order to obtain reward or avoid punishers is often termed instrumental conditioning. Two distinct mechanisms have been proposed to underlie this form of learning: goal-directed learning whereby responses are associated with the ►incentive value of outcomes (response-outcome or stimulus-response outcome learning), and habit learning whereby a particular response comes to be favored in a particular context without any link to the value of the outcome (stimulus-response learning). Behavior under goal-directed control can be flexibly modified following changes in the incentive value of the associated outcome, whereas habit learning is less flexible in that behavior under control of the habit system will persist even after the outcome is no longer valuable to the animal [9]. These two distinct forms of learning have been suggested to control behavior at different times during instrumental conditioning, with goal-directed learning controlling behavior early on in training, while habit learning takes control once an action has been performed extensively. Lesion studies have implicated a part of the dorsal striatum, specifically its dorsolateral aspect in habit learning in rats, whereas a part of the prefrontal cortex (prelimbic area) and dorsomedial striatum have been implicated in goal-directed learning. Less is known about the specific neural systems involved in goal-directed and habit learning in humans and other primates. Neurons in primate dorsal striatum have been found to encode specific response-reward associations, for both saccadic eye-movements and hand movements. Human neuroimaging studies of reward-based action selection have

implicated the dorsal part of the striatum which is activated when a contingency is established between responses and reward or even when such a contingency is merely perceived. Flexible reward-based action selection may also depend on prefrontal cortex, specifically its ventromedial aspect, including the orbitofrontal cortex. Damage to this area in humans impairs the ability to choose advantageously on tasks that probe the ability to choose actions for reward under uncertainty, or to reverse previously learned stimulus-response-reward associations [10]. Furthermore, human imaging studies have revealed activity in this region related to behavioral choice [2]. These findings suggest that a distributed network of regions including the dorsal striatum and ventromedial prefrontal cortex may be particularly involved in guiding reward-based action selection.

## Vascular Endothelium

### Definition

The internal lining of the vascular bed consisting of a continuous layer of cells that maintains the vascular bed in a vasodilatory, anti-thrombotic, and anti-inflammatory state.

## Vasculitis

### Definition

Inflammation of blood vessels, marked by infiltration of inflammatory cells within the blood vessel wall, leading to damage of the blood vessel and of the tissue being supplied by the blood vessel.

## Vasoactive Intestinal Peptide (VIP)

### Definition

Also known as vasoactive intestinal polypeptide, VIP is a potent 28-amino acid vasodilator peptide, originally isolated from intestinal extracts. Widely distributed in the peripheral and central nervous systems, a huge

number of biological effects are attributed to VIP such as smooth muscle relaxation, fluid secretion from the pancreas and inhibition of gastric acid secretion. VIP is the principal transmitter in atropine-resistant parasympathetic vasodilatation within the salivary glands. VIP is also produced in the suprachiasmatic nuclei (SCN) of the hypothalamus. VIP is found in the ventral part of the SCN, while its main neuronal target, the VPAC2 receptor, is expressed throughout the SCN. The SCN coordinates daily timekeeping in the body and VIP, along with gastrin-releasing peptide (GRP), plays a key role in communication among individual SCN oscillator cells. Mice bearing a mutation in VIP or in its receptor, show substantial abnormalities in circadian rhythmicity. VIP is involved in synchronizing the timing of SCN function with the environmental lightdark cycle. After exposure to light, up-regulation of the Per clock genes in the SCN is first apparent in the area of ventral GRP/VIP containing cells and later in the rest of the SCN. In contrast to arginine-vasopressin (AVP), it appears that neither VIP nor GRP is rhythmically expressed in the SCN under constant conditions, although in light/dark cycles, VIP is elevated at night and GRP is elevated in the day.

## Vasocongestion

### Definition

Increased blood flow or swelling of, for example, the pelvic organs.

## Vasoconstriction

### Definition

Vasoconstriction is the constriction of blood vessels, i.e. the reduction of their diameter induced by contraction of transversal and longitudinal smooth muscles surrounding them.

## Vasopressin (VP) or Antidiuretic Hormone (ADH)

### Definition

Vasopressin is a peptide hormone found in most mammals including humans, is also known as arginine vasopressin (AVP) and as antidiuretic hormone (ADH). There are two forms of vasopressin, differing in the amino acid at position 8: arginine vasopressin is widespread, while lysine vasopressin is found in pigs. VP has antidiuretic and vasopressor actions, and is used in the treatment of diabetes insipidus. VP is synthesized from a pre-prohormone precursor in neurons of the hypothalamus, and has many actions in the brain. VP is released into the brain in a circadian rhythm by neurons of the suprachiasmatic nuclei (SCN) of the hypothalamus. VP released from these and other centrally-projecting hypothalamic neurons is involved in aggression, blood pressure regulation and temperature regulation. Hypothalamic neurons also transport VP to the posterior pituitary gland where it is stored and from which it can be released into the blood stream of the pituitary portal system.

## Velocity Response Curve (VRC)

### Definition
A construct devised to explain why and how the circadian period lengthens when rodents are exposed to constant light (LL). Under LL, all phases of the phase response curve (PRC) are light-stimulated. Assuming no LL-induced change in the shape of the underlying PRC, each momentary effect of light exposure will cause a change in the measured circadian period equal to the amount of added phase delay or subtracted phase

advance. Accordingly, the period will lengthen most rapidly at times with greatest phase delays and shorten most rapidly at times with greatest phase advances. This effect will be compounded as light intensity becomes greater. House mice have a PRC that does not allow large phase advances, but does allow relatively large phase delays; the PRC of the hamster is the opposite.

Thus, the mouse is predicted to lengthen its circadian period dramatically as intensity increases. In contrast, the hamster is predicted to have no net change in period as intensity increases from dim to very bright, but at intermediate intensities, is actually expected to shorten. There are few studies of this phenomenon, but the limited data are generally consistent with expectation, although the intensity-related decrease in period has not been observed in hamsters.

Brooklyn, NY, USA

## Definition

Conceptually, ►velocity storage is a central vestibular mechanism that stores incoming velocity information about head and body movement and activates the oculomotor system. Velocity storage has been modeled as an integrator, with inputs from the canals, visual and somatosensory systems and generates a low frequency component of eye velocity that compensates for motions that activate these systems. Initially, it was hypothesized that the major function of velocity storage was to extend the time constant of the cupula and eighth nerve dynamics during continuous rotation in darkness, store information about surround velocity to generate optokinetic after-►nystagmus, and serve as a focus for visual-vestibular interaction. Further work has shown that it has a three-dimensional mathematical structure that can be modeled as a three-dimensional integrator with orientation properties linked to the spatial vertical and ►gravity. It has proven useful in explaining a wide range of data on lesions. It also explains data in the vestibular nuclei on visual-vestibular interaction. The orientation properties of velocity storage now show promise of shedding light on the underlying mechanisms associated with motion sickness.

## Description of the Theory

### *Introduction*

The central nervous system stores information over a wide range of modalities including storage of visual and spatial information utilized in subject navigation through the environment. Within the last thirty years, inertial storage of velocity has been shown to be a critical component of the vestibulo-ocular reflex (VOR), which maintains ocular stability during head and body movement in space [1–4]. This storage not only has a profound affect on the time course of compensatory ocular responses, but also on spatial orientation [5,6]. The purpose of this paper is to review the work that has given rise to the concept of velocity storage, and how models of velocity storage have enhanced our understanding of the VOR and spatial orientation.

### *Overview of the Vestibular Ocular Reflex*

Early work on the vestibular system established the ►semicircular canals and otoliths (►Otolith organs) of the vestibular labyrinth as important elements of vestibular system processing. Somewhat later, Breuer, Crum Brown and Mach discovered, almost simultaneously, that the semicircular canals perceived angular motion (See [7,8] for comprehensive review). Mach further inferred that the canals were transducers of angular acceleration, not angular velocity from experiments in which subjects were rotated in darkness and in light. The subjects sensed angular movement only at the beginning and end of rotation in darkness and felt that they were stationary while rotating at a constant velocity. In contrast, if subjects were rotating in light, they never lost the sensation of motion. This demonstrated that vestibular receptors in the semicircular canals were activated only at the beginning and end of rotation, and that the visual system supplied the activity during the constant velocity portion of the rotation to maintain the sense of motion. Later work by Ter Brak and Mowrer showed that the slow phase eye velocity of post-rotatory nystagmus could be canceled by the previous rotation in light (Reviewed in [1,2]). Thus, the critical relationship between vision and the vestibular system in generating eye velocity arose.

Models of the VOR were initially confined to one dimension and were largely concerned with defining the processing of the ►angular vestibulo-ocular reflex (aVOR) by the semicircular canals. Early models of the aVOR were based on its input-output behavior in response to sinusoidal angular velocity, and aVOR processing was mainly attributed to the properties of the endolymph and elastic properties of the cupula.

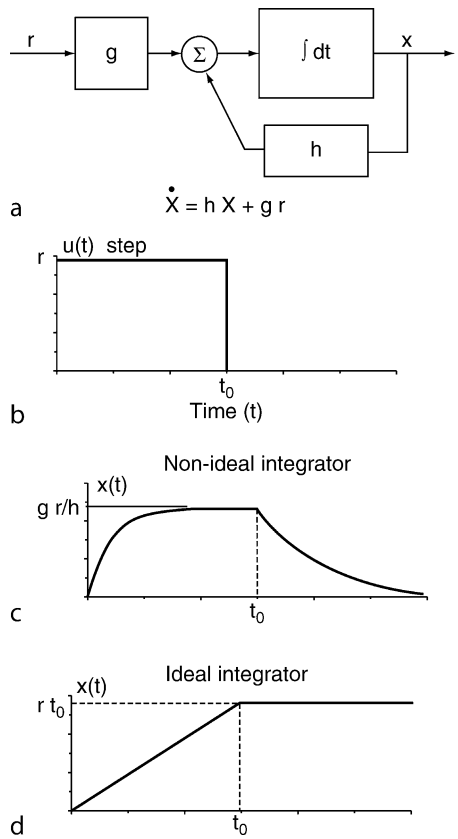
The central processing was attributed to the ►three neuron arc as defined by Lorente de No, which was not assigned any specific dynamic properties (See [7,8]). With the ability to record activity of semicircular canal afferents, it soon became clear that for steps of constant velocity rotation, afferent firing rates decayed more rapidly than the nystagmus that was generated. The time constant of decay of the afferents was about 3–5 s [9], while the nystagmic slow phase velocity had a time constant of 12–20 s [2]. This finding led to the postulate that there was a central neural network that stores velocity information, prolonging the time constant of the nystagmus generated by the semicircular canals [2]. Because it was modeled as an integrator, it has been referred to as "the velocity storage integrator" [2].

In addition to activation by the semicircular canals, velocity storage is also activated by the visual, otolithic and somatosensory systems [1,4]. Optokinetic nystagmus (►Nystagmus – optokinetic (OKN)), induced by continuous full field surround motion, produces an ►optokinetic after nystagmus (OKAN) in darkness, which has a time course similar to that of vestibularly induced nystagmus by a step of rotation. OKN enhances eye velocity when rotating in light, and cancels what would have been a robust post-rotatory eye velocity after stopping in darkness [2]. This has been modeled as visual activation of the same velocity storage integrator as is activated by the semicircular canals [2]. The otoliths activate velocity storage during off-vertical axis rotation (OVAR) (See [8]), and the somatosensory system activates velocity storage during continuous circular locomotion [3,4].

Over the last decade, it has become clear that velocity storage does more than just lengthen the time constant of vestibular responses and act as a focus for visual, otolithic and somatosensory information. Velocity storage has a three dimensional structure that can be characterized by an orientation vector, which tends to align vestibular and optokinetic responses with the ►equivalent acceleration due to gravity, i.e. the spatial vertical [5,6]. That is, regardless of head tilt, this orientation vector tends to align with the spatial vertical or with the acceleration field generated by combinations of linear acceleration from centrifugation and gravity (►Gravito-inertial acceleration (GIA)) (See [7,8] for review). The orientation vector has characteristics that are closely linked to the perception of the spatial vertical in humans [5]. Individual components of the model of the VOR have been found to be represented in the function of various structures in the central or peripheral nervous system, and to predict the effects of lesions or drugs on vestibular and oculomotor function.

### *Modeling of Velocity Storage in One Dimension*

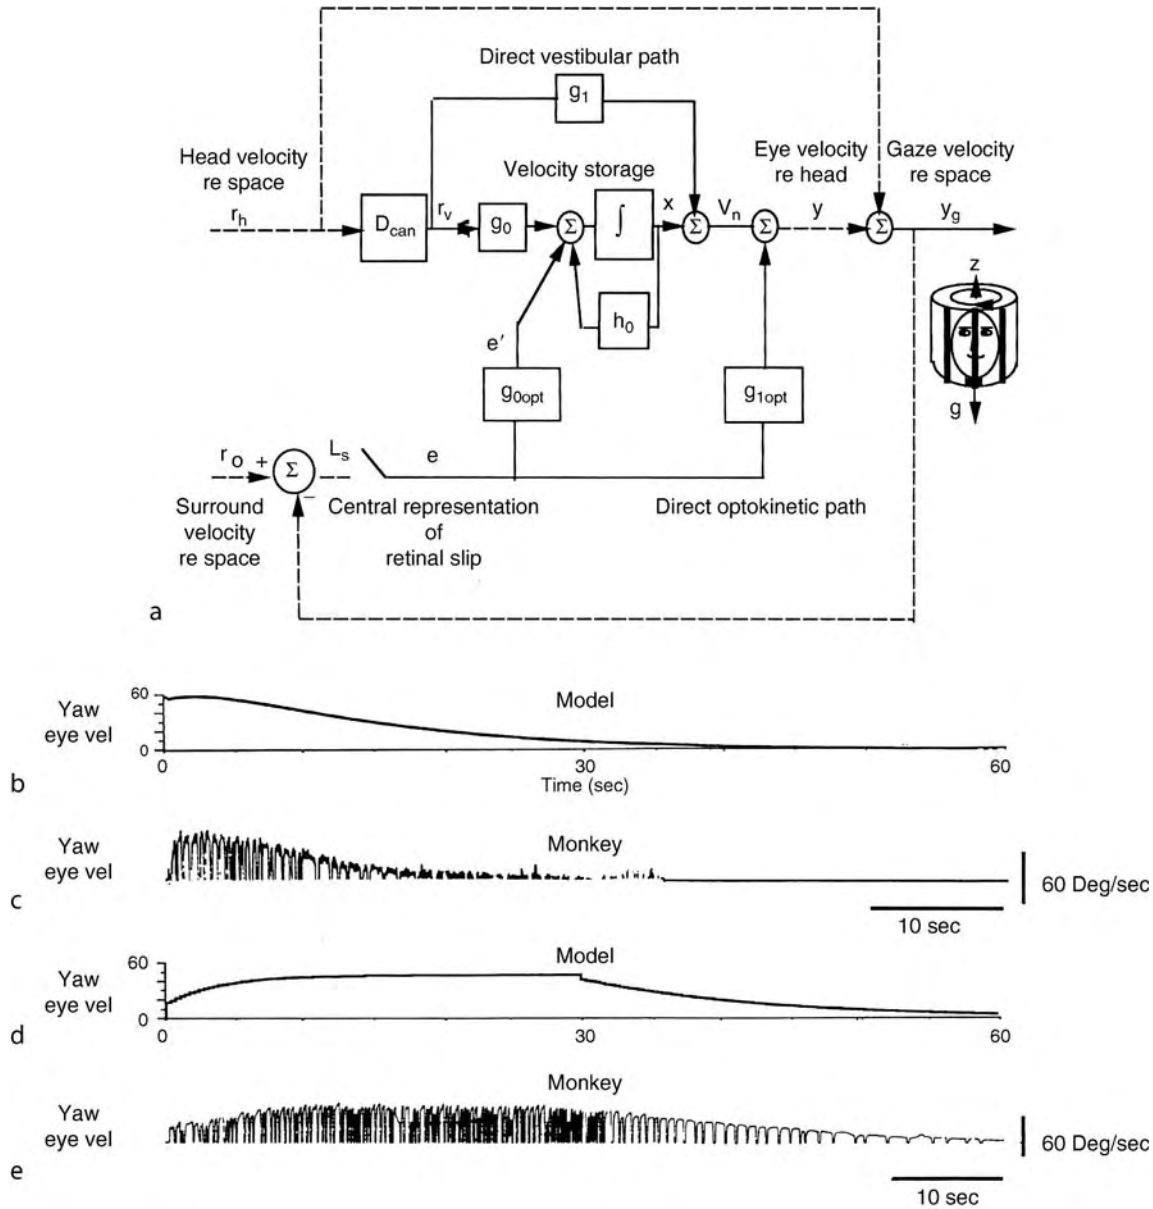
Velocity storage has been modeled in one dimension by a single integrator, which is characterized by a single parameter, $h$ (Fig. 1a). The value $h$ specifies the "leak" of the integrator and determines its time constant. If $h$ is negative, it is said to have negative feedback. Thus, when a step input is applied to the integrator (Fig. 1b), its state, $X$, rises exponentially (Fig. 1c). Similarly, when the step is dropped to zero (Fig. 1b), the integrator state falls exponentially to zero over the same time course (Fig. 1c). The rise and fall characteristics are determined by its time constant, $1/h$. If $h$ is small, i.e. the integrator time constant is large, the integrator becomes ideal. An ideal integrator charges linearly for a step input and maintains its charge following the cessation of the stimulus (Fig. 1d).



**Velocity Storage. Figure 1** (a) One dimensional integrator and its corresponding dynamic system equation, which determines its temporal response. (b–d) Step response of the integrator. (b) Stimulus, which is a step ($r$) in velocity for $t_0$ seconds, then falls to zero. (c) Exponential rise of the state ($X$) to a steady state value produced by the step in stimulus in (b). When the stimulus falls to zero, the integrator output decays with a time constant of $1/h$. (d) Response of an ideal integrator ($h = 0$) to the same stimulus. The state $X$ rises linearly during the stimulus and is held constant for all time when the stimulus drops to zero (Adapted from Raphan and Cohen, 1996).

### *Fitting the Integrator into Visual-Vestibular Interactions*

Figure 2a shows how the integrator would fit into a model of the AVOR and visual-vestibular interaction in one dimension. The model has as one input HEAD VELOCITY relative to space, $r_h$ which is transduced by the semicircular canals $D_{can}$ to generate the eighth nerve signal, $r_v$ (Fig. 2a). This signal is processed over a direct path, $g_1$ and activates the velocity storage integrator. The direct pathway and the integrator state sum to generate the signal, $v_n$ that in part generates the eye



**Velocity Storage. Figure 2** (a) One dimensional model of visual-vestibular interaction with the velocity storage integrator acting as the focus for the interaction (See text for detailed description). Model simulations (b, d). and corresponding data (c, e) from a monkey in response to the same stimulus. (a, b) Per- and postrotatory response to a step in head velocity during darkness. Note the rapid rise at the onset of the stimulus, a slower rise during the plateau phase, and a decay to zero during the constant velocity rotation (Per-rotatory phase) or during the stationary period following stopping after rotation (post-rotatory phase). (d, e). Response to a step in surround velocity that induced optokinetic nystagmus (OKN) for 30 s. Note the initial rise and slower rise to a steady state velocity during OKN. At the end of OKAN. There was a decrease in slow phase velocity to zero with the time constant of the velocity storage integrator. The model predicts the dominant aspects of both responses (Adapted from Raphan and Cohen, 1996).

velocity command signal, y. Head velocity and eye velocity $y_h$ are mechanical signals that summate to give gaze velocity in space $y_g$.

The input, $r_o$, represents surround velocity relative to space generated by an optokinetic stimulus. Gaze velocity is subtracted from the stimulus velocity, and together with the switch, $L_s$, determine the central representation of retinal slip. In light, $L_s$ is closed and e is the difference between surround and gaze velocity. In darkness, $L_s$ is open, and e is zero. The retinal slip signal couples to the velocity storage integrator with a coupling parameter, $g_{0opt}$, and contributes to the activation of the state, x and to $v_n$. There is also a contribution to eye velocity, y, over a direct optokinetic path, $g_{1opt}$.

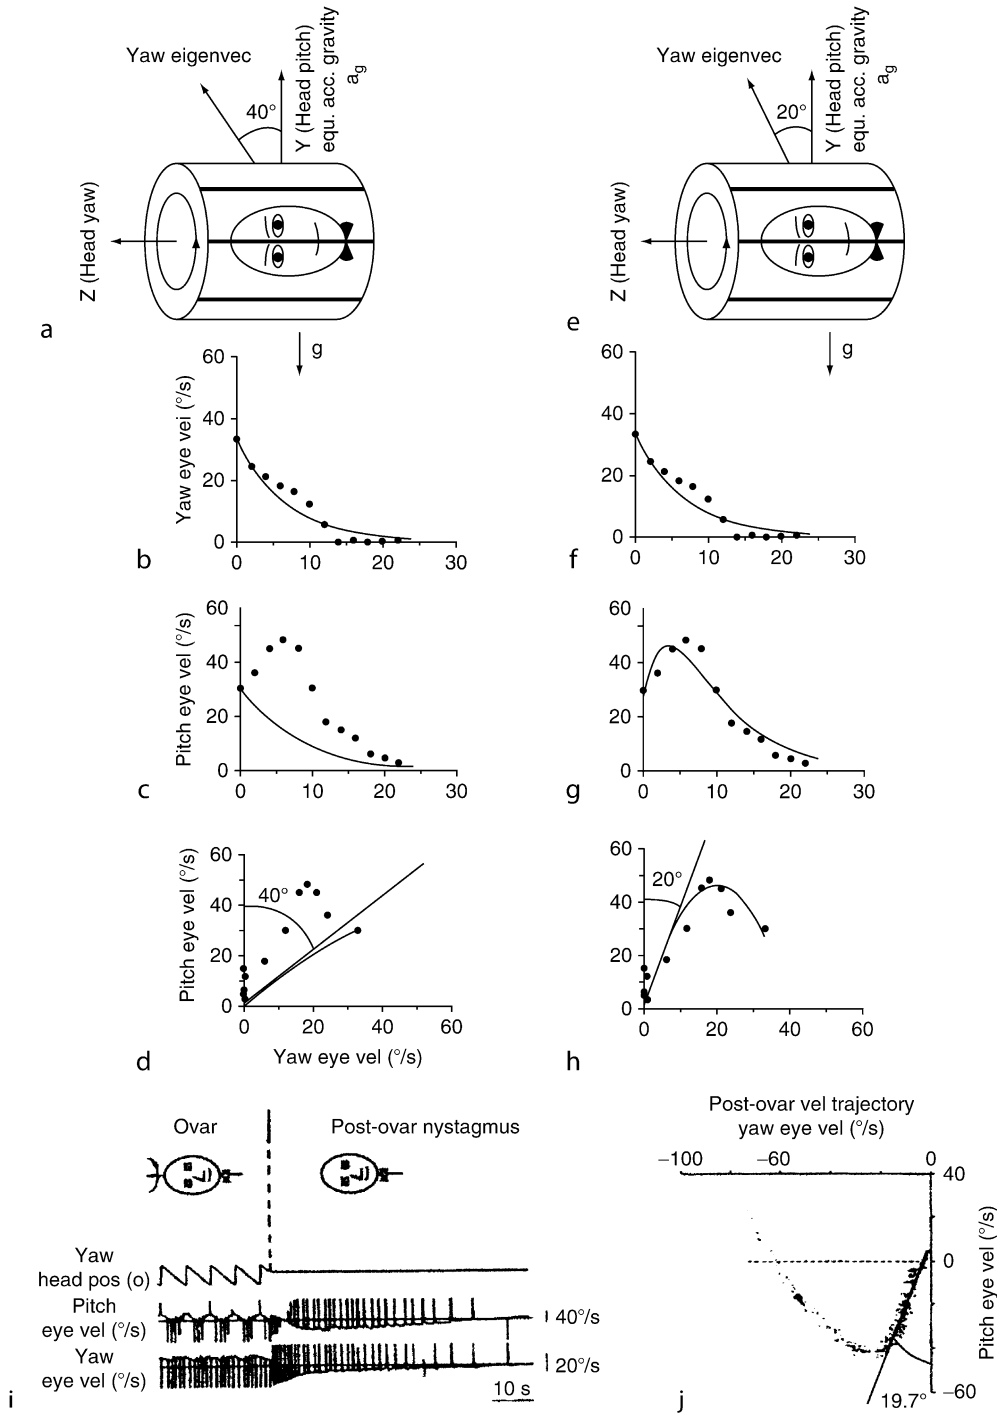
Simulations can be compared to experimental data to demonstrate how the VOR works for steps of both head and surround velocity (Fig. 2b–e). For a step in head velocity of $r_0 = -60°/s$, the parameter $g_1$ determines the initial jump in the direct vestibular path (Fig. 2b), which is also the initial jump in eye velocity. Since the cupula dynamics are fixed, the time constant of the integrator, $1/h_0$, and the coupling to the integrator $g_0$ determine the shape of the integrator response, i.e. how fast it rises to a peak, the value of the peak and the time course of the decay (Fig. 2b). There is a plateau in the response, which is either a flattening or a small overshoot in eye velocity. Saturation of the integrator would flatten the plateau, but this has been neglected here for simplicity. The corresponding data from a monkey (Fig. 2c) show that the per- or post-rotatory response (►Nystagmus – per-rotatory vestibular, ►nystagmus – post-rotatory vestibular) to a step in head velocity is predicted accurately.

The response of the model to a step in surround velocity during OKN is shown in Fig. 2d. Eye velocity jumps to an initial value determined by the surround velocity and the direct pathway gain, $g_{1opt}$. A signal related to retinal slip causes the integrator to accumulate activity. The rate at which activity is accumulated is dependent on the time constant of the integrator, $1/h_0$, and the feedback from eye velocity. As the activity in the integrator builds up, the retinal slip is reduced and the direct pathway contributes less to the response. Thus, when the lights are extinguished at the beginning of OKAN, there is a small drop in eye velocity, which is much less than the initial jump in eye velocity at the start of OKN. In dark, the integrator decays with its characteristic time constant and is expressed as OKAN. Figure 2e shows the OKN and OKAN response of a monkey in response to a step of surround velocity of 60°/s. All of the essential characteristics, i.e. the initial rapid rise, the slow rise to steady state velocity, and the slow decay during OKAN are inherent in the one dimensional optokinetic response and are predicted by the single integrator model of velocity storage.

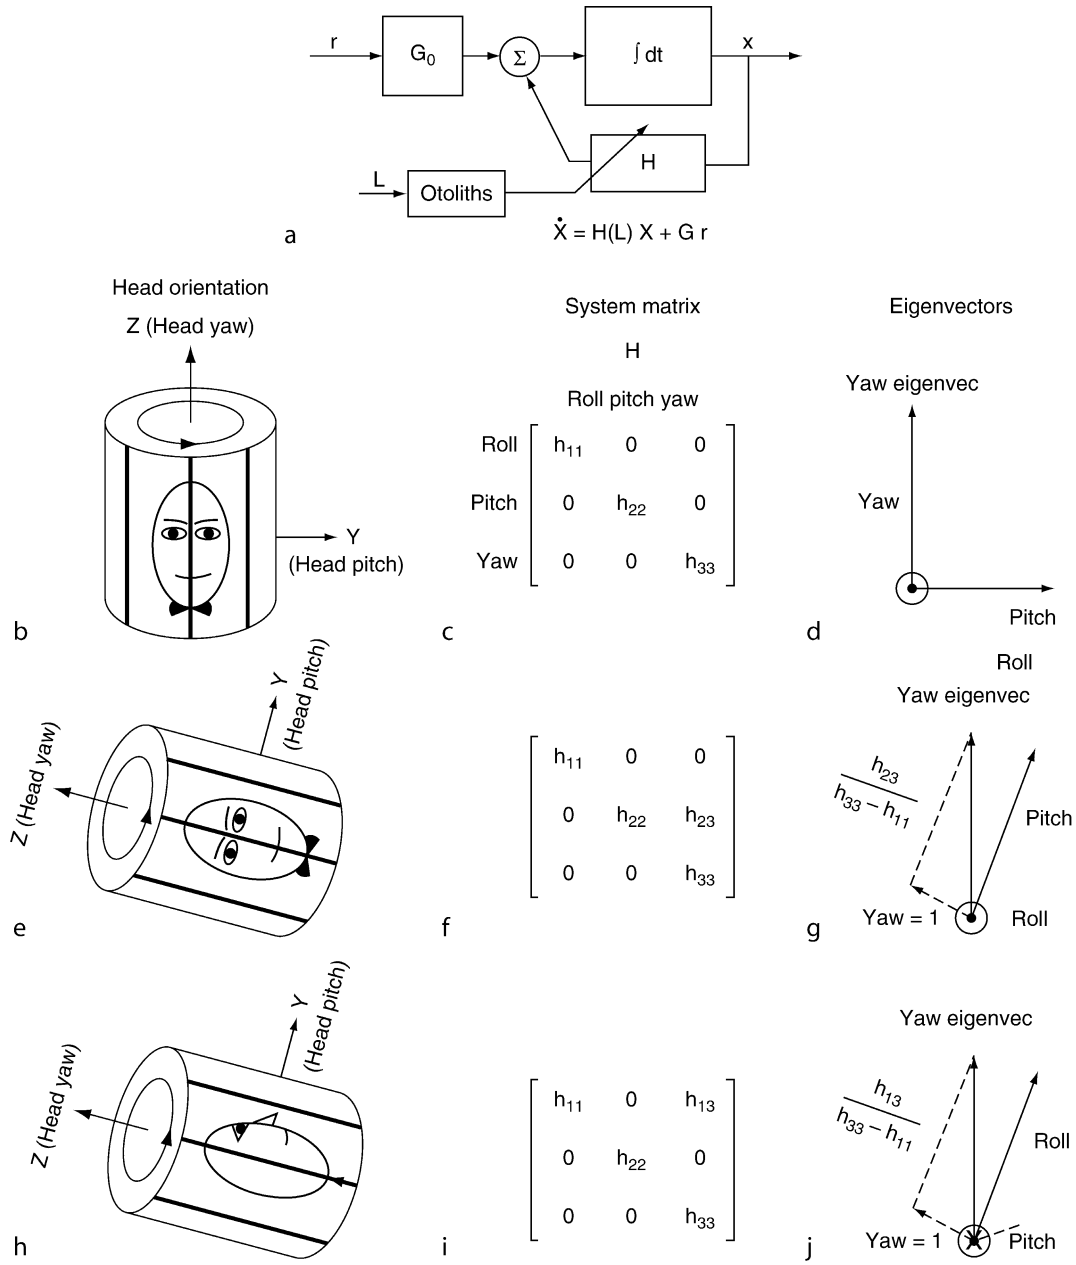
Identification of the central neural structures that govern the behavior of these parameters can shed light on how OKN is mediated and has clinical significance. Thus, the model can be used "diagnostically" by identifying differences in the response with parameter modifications in the model in altered states of the system. For example, adaptation has been associated with the parameter $g_1$ and habituation with the parameter $1/h_0$. Effects of lesions of the flocculus and paraflocculus have been modeled by a simple elimination of $g_{1opt}$ and by defining the nonlinear properties of $g_{0opt}$. Similar associations can be made following occipital lobectomies. Lesions of the nodulus and uvula can be modeled as a modification of $h_0$. Effects of administration of baclofen, which are associated mainly with $h_0$ and $g_{1opt}$, have also been simulated. The coupling to the integrator $g_{0opt}$ is likely to be mediated through the nucleus of the optic tract (NOT). This pathway is also an important input to the flocculus and nodulus, which control the direct visual pathway gain and the integrator time constant (See [7,8] for a review). Thus, the modeling of velocity storage and the pathways that interact with it have consolidated our understanding of visual-vestibular interactions.

### *Modeling of Velocity Storage in Three Dimension*

The three-dimensional characteristics of velocity storage bring into evidence its spatial orientation properties, suggesting that it might function in maintaining body orientation during natural movement [5,6], although the link between velocity storage and maintenance of orientation during walking has not yet been clearly delineated. The spatial orientation of velocity storage is present during optokinetic or vestibular activation, and is present in all mammalian species that have been tested including man, monkey and rabbit. When subjects are upright, so that their yaw or body axis is aligned with gravity (Fig. 2a), vestibular or visual motion about the long axis of the body produce pure horizontal or yaw eye movements (Fig. 2c and e) [5]. Since eye movements are rotations of a globe in the orbit, these are rotations of the eyes around axes that are about the spatial vertical. If subjects are tilted and the visual surround is rotated around the yaw axis of the head (Fig. 3a and e), however, a small vertical or pitch component of eye velocity appears [5,6], and becomes prominent during the OKAN (Fig. 3c and g Dots). The pitch component builds up and decays in conjunction with the decay in yaw eye velocity (Fig. 3b and f). The eye velocity vector follows a curved trajectory, which asymptotically approaches a vector that is along the ►eigenvector and tends to align with the spatial vertical (Fig. 3d and h). This has been modeled by extending the parameter $h_0$, for the one dimensional model to a matrix, $H(L)$, which is dependent on the linear acceleration, $L$, activating the otoliths, and that couples the yaw component of eye velocity to pitch or roll, depending on head position (Fig. 4a). When the head is



**Velocity Storage. Figure 3** Fits to eye velocity data during OKAN following an OKN stimulus along a monkey's yaw or z axis while tilted right side down. (a) Fit of yaw eye velocity for an eigenvector direction at 40° relative to the spatial vertical (a) and eigenvalues $h_{22} = -0.2$/s (Pitch Time Constant = 5 s) and $h_{33} = -0.133$/s (Yaw Time Constant = 7.5 s), the yaw velocity vector was fit quite well (b). However, the pitch velocity was fit poorly (c). The trajectory in velocity space also fit the data poorly (d). When the eigenvector direction of the system matrix was changed to 20° (e) and the eigenvalues were kept the same, the data for both horizontal (f) and vertical (g) were fit well. In trajectory space, the data were fit well and asymptotically approached the yaw eigenvector direction. (i) Post OVAR velocity also had cross coupling from yaw to pitch velocity. (j) In trajectory space, the eye velocity had a curved trajectory and asymptotically approached the yaw eigenvector direction (Adapted from Raphan and Sturm, 1991; Cohen and Raphan, 2004).



**Velocity Storage. Figure 4** (a) Extension of the integrator model (Fig. 1a) to three dimensions. The inputs ($r$, $L$) and state ($X$) and the forward gain ($G_o$) and feedback ($H$) are matrices. The state equation is a vector equation and H is a function of linear acceleration input, $L$. For upright orientation (b), the system matrix, H, is diagonal (c), with no cross-coupling. The yaw eigenvector is along the yaw axis of the head. When the head is tilted side down (e), a yaw-to-pitch cross coupling ($h_{23}$) is introduced that reorients the yaw eigenvector towards the spatial vertical (g). Similarly, when tilted supine (h), a cross-coupling component from yaw to roll, $h_{13}$, is introduced into the system matrix that again orients the yaw eigenvector towards the spatial vertical (j) (Adapted from Raphan and Sturm, 1991).

upright (Fig. 4b), there is no coupling from yaw to roll or pitch. The velocity-storage matrix is diagonal (Fig. 4c) and the yaw eigenvector is aligned with the head yaw axis (Fig. 4d). This generates pure yaw OKN-OKAN in response to yaw stimulation. When the head is tilted side down (Fig. 4e), there is coupling from yaw to pitch, giving rise to the parameter $h_{23}$ in the system matrix, H (Fig. 4f), inducing a realignment of the orientation vector with the spatial vertical. When the head is supine (Fig. 4h), the coupling is from yaw to roll, giving rise to the parameter $h_{13}$ in the system matrix, H (Fig. 4i) and a concomitant realignment of the

eigenvector towards the spatial vertical (Fig. 4j). An important outcome of this extension of velocity storage to three dimensions was the understanding that velocity storage has an internal representation of the spatial vertical, which governs eye velocity and is represented by the yaw eigenvector or orientation vector. If the surround velocity is along this orientation vector, eye velocity during OKAN decays along it [5,6].

A critical feature of the orientation of the eigenvector is how it contributes to the cross-coupled eye velocity. For example, when the yaw eigenvector is deviated from the spatial vertical by 40° (Fig. 3a), the model predicts the yaw component of eye velocity, but fails to predict the dynamics of the pitch component (Fig. 3c). The trajectory in velocity space is then not fitted accurately (Fig. 4d). On the other hand, when the eigenvector is 20° relative to the spatial vertical (Fig. 4e), the yaw and pitch components of the eye velocity vector are accurately predicted (Fig. 4f and g). The trajectory in velocity space approaches the eigenvector (Fig. 3h). An interesting outcome of this study was that an inverse procedure was developed, whereby the direction of the eigenvector could be estimated from the three-dimensional eye velocity vector [6], and this orientation vector could then be compared to the orientation vector of velocity storage as it is activated from the vestibular system.

As predicted, the same declines along orientation vectors occur during post-rotatory nystagmus (nystagmus – post-rotatory vestibular) when the head is tilted with regard to gravity. Thus, when monkeys are stopped in side down positions after constant velocity rotations during off-vertical axis rotation (OVAR) (Fig. 4i), the post-OVAR eye velocity trajectory approaches the orientation vector established during OKAN (Fig. 4j). This shows that velocity storage is the primary orienting component of velocity in the aVOR. This conclusion is supported by studies utilizing centrifugation as well as by orientation of the eyes to gravity during caloric stimulation in canal-plugged animals (See [7] for review). Thus, the alignment of eye velocity towards the vector sum of the linear accelerations occurs during both vestibular-induced nystagmus and OKN. In both cases, it depends on the spatial orientation of velocity storage.

The spatial orientation of velocity storage is under control of the nodulus and uvula of the vestibulocerebellum, and the eyes no longer reorient to the GIA vector when these structures are damaged. Recently, it has been shown that the time constant and orientation properties of velocity storage play a critical role in motion sickness, which is also dependent on the nodulus and uvula [10].

## Conclusion

The work on velocity storage, which was initially conceived to explain OKN and OKAN and the enhancement of the low frequency characteristics of the aVOR beyond that of the cupula and eighth nerve dynamics, now has the potential of giving us insight into the mechanisms that govern maintenance of spatial orientation during circular walking. Its dynamics and orientation properties and how to control them may also give us insight into the management of motion sickness.

Motor fibers emerge from the spinal cord to the periphery in the ventral root of a spinal nerve.

►Medulla spinalis

## Ventral Striatopallidum

Daniel S. Zahm
Department of Pharmacological and Physiological Science, Saint Louis University School of Medicine, Grand Blvd., Saint Louis, MO, USA

### Synonyms
Ventral striatopallidal system; Ventral parts of the basal ganglia

### Definition
Ventral striatopallidum is a rostroventral extension of the ►basal ganglia within the ►basal forebrain that subserves motivational aspects of behavior.

### Characteristics
The concept of ventral striatopallidum emerged during the late 1960s and early 70s when Lennart Heimer, using a combination of superficially limited heat lesions in combination with the Fink–Heimer silver

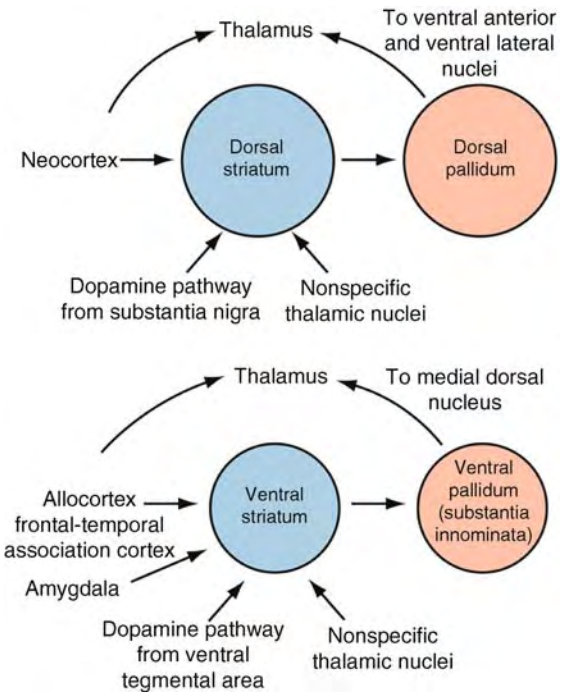
method for degenerating axon terminals, convincingly demonstrated a ►cortico-basal ganglia-thalamocortical circuit involving the ►piriform (primary olfactory) cortex [1]. Prior to this discovery, the olfactory cortex had been thought to ►project directly to the ►hypothalamus, via terminations in the ►lateral preoptic area and anterolateral hypothalamus. The new findings revealed instead that the olfactory cortex projects to superficial and intermediate layers of the ►olfactory tubercle, which do not return a reciprocal corticocortical projection to the olfactory cortex, as would be expected if the tubercle were a part of the cortical mantle, which at the time was the consensus viewpoint. Rather, the parts of the olfactory tubercle that are densely innervated by the primary olfactory cortex, project to a rostroventral extension of the ►globus pallidus within the basal forebrain and deep parts of the tubercle. Studies of the somatodendritic architecture (size, shape and distinctive characteristics) of neurons in the olfactory tubercle that received inputs from the olfactory cortex revealed that they are identical to those of striatal neurons in the ►caudate nucleus and ►putamen [2]. Likewise, the striatopallidal synaptic relationships established by the ►projections of these olfactory tubercle striatal neurons in what became known as the ►ventral pallidum were identical to those in the globus pallidus [1].

These striatopallidal relations of the olfactory system had been demonstrated so convincingly as to influence thinking on a related structure, the ►nucleus accumbens. Although the intrinsic organization of the nucleus accumbens had for many years been compared favorably to that of the caudate nucleus and putamen [3], the "accumbens" had never been regarded formally as a part of the basal ganglia and indeed was instead lumped with the ►limbic system. However, realization that the massive projection from the nucleus accumbens to the ventral pallidum utilizes synaptic differentiations identical to those of striatopallidal terminations in the globus pallidus [4] cemented the conclusion that the nucleus accumbens and its termination field in the ventral pallidum, like the striatopallidal districts in the olfactory tubercle, are bona fide basal ganglia structures in terms of intrinsic organization and extrinsic connectivity. Together, the accumbens, striatal parts of olfactory tubercle and ventral pallidum substantially expanded the territories within the forebrain that can be regarded as occupied by basal ganglia and, simultaneously, reduced the amount of basal forebrain territory long known as ►substantia innominata due to the undetermined nature of its organization. More significantly, the identification of these functional-neuroanatomical relationships indicated that the entire cerebral cortex, including the olfactory cortex and ►hippocampus, is subserved by basal ganglia mechanisms. Thus, just as the caudate nucleus and putamen, collectively referred to as ►dorsal striatum, receive massive inputs from the neocortex and a number of subcortical structures, such as ►midline-intralaminar thalamic nuclei and dopaminergic neurons in the ►substantia nigra pars compacta, so the ventral striatum receives massive projections from ►allocortex, including the hippocampus and ►orbitofrontal cortex and subcortical projections from thalamic midline-intralaminar nuclei and dopaminergic neurons in the ►mesencephalic ventral tegmental area. The nuclei of the ►basal complex of the amygdala, which have been widely regarded as cortical-like in terms of their connectional and intrinsic organization, also project massively to ventral striatum. Just as the caudate nucleus and putamen project via massive "striatopallidal" projections to the globus pallidus, so ventral striatum projects massively, via "ventral striatopallidal" projections, to the ventral pallidum.

Furthermore, the dorsal and ventral parts of the basal ganglia exhibit fundamentally similar outputs to [1] the cortex, via the thalamus and [2] motor effector sites in the brainstem. The "reentrant" pathway to the cortex belonging to the dorsal striatopallidum originates in the medial segment of the globus pallidus, which, via a synaptic relay in the rostroventral thalamus, projects to ►premotor and ►supplemental motor cortex [5]. Ventral pallidum projects to frontal association cortex via a synaptic relay in the ►mediodorsal nucleus of the thalamus [6]. Thus, reentrant pathways associated with dorsal and ventral striatopallidum were regarded from their inception [4] as parallel, segregated circuits through the basal ganglia (Fig. 1), a concept that has been further refined and popularized in the ensuing years (see essay on Striatopallidum). Descending outputs from dorsal and ventral striatopallidum terminate in the ventral mesencephalon and ►mesopontine tegmentum [5,7].

Despite the conformance of both dorsal and ventral striatopallidum to a fundamental pattern of organization, these two major divisions or territories of the basal ganglia nonetheless also differ significantly in certain aspects of neurochemical composition, intrinsic structure and extrinsic connections. Generally speaking, such differences relate to the abundance and diversity of classical and peptidergic neurotransmitter/neuromodulators and their receptors and less apparent compartmentalization of ventral striatopallidal organizational features as compared to dorsal striatopallidum.

One example of this involves the chemospecificity and connectional specificity of striatal ►medium spiny neurons (MSNs), which in the dorsal striatum fall into two distinct, approximately equivalently sized categories [9]. The MSNs comprising one of these groups express dopamine D-1 receptors and the neuropeptides ►substance P and ►dynorphin and project prominently to the medial segment of the globus pallidus and substantia nigra reticulata, which, because they emit the characteristic dorsal striatopallidal outputs – to



**Ventral Striatopallidum. Figure 1** Modification of figure first published in Heimer and Wilson [4] illustrating the parallel, segregated character of cortico-basal ganglia-thalamocortical pathways traversing dorsal (*above*) and ventral (*below*) striatopallidum (further modified from [8] with permission).

the ►thalamus and ►brainstem as noted above – are recognized as basal ganglia "output nuclei." These MSNs are said to give rise to a "direct" pathway to the output nuclei. The remaining MSNs express dopamine D-2 receptors and the neuropeptide ►enkephalin and project to the lateral segment of the globus pallidus, which in turn utilizes a synaptic relay in the ►subthalamic nucleus to reach the output nuclei by an "indirect" pathway. Dense accumulations of dynorphin and substance P versus enkephalin characterize the terminations of these pathways in the output nuclei and lateral pallidal segment respectively. In ventral striatum, D-1 and D-2 dopamine receptors and these peptides are not obviously segregated in subpopulations of MSNs and are associated poorly if at all with direct and indirect pathways. Consequently, substance P, dynorphin and enkephalin are distributed coextensively throughout the ventral pallidum [10].

Another form of neurochemical and connectional compartmentalization observed in dorsal, but not ventral, striatum involves ►opioid receptor rich, ►acetylcholinesterase poor figures (called patches or striosomes), which in sectioned material are dispersed, island-like, within an acetylcholinesterase rich, mu opiate receptor poor matrix [9]. A variety of other neurochemical markers, such as a number of neuropeptide and calcium binding protein immunoreactivities, also conform to the patch-matrix pattern, but it is not characterized by obvious structural heterogeneity, such as might involve different sizes or clustering of neurons. In the ventral striatum, the patch-matrix pattern is absent, but heterogeneous clusters of MSNs sometimes associated with elevated expression of opioid receptors or other neurochemical markers are present [9]. In addition to the clustering of MSNs, a variety of other medium and small types of neurons form clusters in ventral, but not dorsal, striatopallidum. The connectional relationships and functional significance of these "small celled islands," which are conspicuous in the olfactory tubercle, are largely unknown.

The accumbens part of the ventral striatum exhibits distinctive subterritories, designated as accumbens core and shell, which are characterized by different patterns of afferent and efferent connections and preferential distributions of various neurochemical markers, such as calcium binding proteins and neuropeptides and neurotransmitters and their receptors and transporters [10]. The core of the accumbens, which is directly continuous with the overlying dorsal striatum, has connections that much resemble those of the dorsal striatum. The shell, which wraps around the medial, ventral and lateral aspects of the core, is characterized by robust connections with the lateral hypothalamus that must be regarded as anomalous by the standard of the rest of the striatal complex.

Ventral striatopallidum appears to be an integral component of the "reward" system of the brain. Its functions are inextricably linked to the actions of dopamine released by the dense "mesolimbic" dopaminergic innervation, which arises from dopaminergic neurons located in the mesencephalic ventral tegmental area. Circumstances associated with increased activation of dopaminergic neurons and elevated extracellular concentrations of dopamine in the ventral striatum, particularly the accumbens, are accompanied by increased locomotion and positive modulation of ►affect, whereas reductions in dopamine neuron activation and decreased extracellular concentrations of ventral striatal dopamine are associated with ►bradykinesia and ►anhedonia. Ventral striatal dopamine release appears to be necessary for ►Pavlovian conditioning and the establishment of learned ►instrumental responses, i.e., actions that lead to the acquisition of ►reinforcement, i.e., ►reward. The capacity of ventral striatal dopamine release to "stamp-in" behavior that culminates in reinforcement leads to the idea that the ventral striatum is involved in processes subserving memory consolidation. Much evidence indicates that the medial parts of the accumbens and olfactory tubercle, including the medial accumbens shell, contribute more to the

affective and drive components of motivated behaviors, while the lateral parts, including the core of the accumbens, are involved in processes through which environmental cues come to guide actions so as to achieve the dictates of such drives.

# Ventral Tegmental Area, Mesencephalic

## Definition

The mediobasal part of the ventral mesencephalon which contains a substantial portion of the neurons that give rise to the ascending dopaminergic projection system. The formation of dopaminergic neurons in the ventral tegmental area merges laterally and caudolaterally without detectable boundaries with the formations of dopaminergic neurons in the substantia nigra pars compacta and retrorubral field respectively. The dopaminergic neurons in all of these formations are intermingled with other neuronal types, particularly expressing γ-amino butyric acid (GABA) and glutamate as transmitters. The ventral tegmental area gives rise to the mesocorticolimbic system, comprising largely dopaminergic, but also GABAergic and glutamatergic, projections to a number of basal forebrain structures, including ventral striatopallidum, extended amygdala, basal amygdala, septum, the magnocellular basal forebrain system and orbitofrontal cortex.

# Ventral Thalamic Nuclei

## Synonyms

Nuclei ventrales thalami; Ventral nuclei of thalamus

## Definition

The ventral nuclear group of the thalamus is composed of four nuclei. Whereas the ventral anterior nucleus and ventral lateral nucleus are integrated in the somatomotor control system, the ventral posterior nucleus is the main thoroughfare for all somatosensory information on its way to the cerebral cortex. The ventral posterolateral thalamic nucleus conveys protopathic and epicritic information from the trigeminal complex, the ventral posteromedial nucleus from the spinal cord.

►Diencephalon

# Ventricular System

## Definition

A system of interconnected chambers and channels within the central nervous system that are filled with cerebral spinal fluid.

►Meninges & Cisterns

## Ventricular Zone

A pseudo-stratified mitotic compartment lining the ventricle. Radial glial cells divide in this region.

## Ventriculitis

### Definition

Inflammation of a ventricle, especially of a ventricle of the brain.

## Ventriloquist Effect

### Definition

Ventriloquist effect denotes the subjective impression of an observer that the ventriloquist's puppet speaks rather than the ventriloquist, evoked by the strong cross-modal interaction between vision and audition.

►Audition (Hearing)
►Vision

## Ventrolateral Funiculus

### Definition

In the spinal cord, an area of white matter in which many of the nociceptive ascending pathways travel.

►Ascending Nociceptive Pathways

## Ventrolateral Medullary Reticular Formation

### Definition

The ventrolateral medullary formation is that portion of the medullary reticular formation containing neurons that control sympathetic vasomotor tone, cardiac function, respiration, and endocrine function. Neurons in the rostral ventrolateral medullary reticular formation provide the major tonic excitatory input to the sympathetic preganglionic vasomotor neurons and mediate most descending and reflex influences controlling arterial pressure.

## Ventrolateral Preoptic Nucleus

Matt Carter, Luis de Lecea
Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, CA, USA

### Synonyms

VLPO

### Definition

A region of the mammalian brain thought to play a major role in the promotion of sleep.

The ventrolateral preoptic nucleus (VLPO) is a region of the mammalian hypothalamus thought to play a major role in the promotion of sleep [1–3]. Many studies have used a variety of anatomical, pharmacological, and electrophysiological techniques to demonstrate that the VLPO is mostly active during sleep, is necessary for normal sleep, and works primarily by inhibiting other subcortical areas of the brain that promote arousal. Here, we summarize the current state of knowledge about the VLPO and its role in the regulation of the ►sleep/wake cycle.

### Characteristics

#### Anatomy

The VLPO is a subdivision of the lateral preoptic area (LPOA) located in the anterior hypothalamus. To date, the VLPO has been studied almost exclusively in rats, where the volume of cells is roughly 600 μm in diameter [2]. The VLPO can be further anatomically and functionally subdivided into a dense cluster of neurons (VLPOc) and a more diffuse, extended component (VLPOe) [3]. Neurons in the VLPO are multipolar and have a characteristic triangular shape with three primary dendrites [4]. Over 90% of VLPO neurons express the inhibitory ►neuropeptide galanin, as well as the GABA biosynthetic enzymes GAD65 and GAD67 [4]. Thus,

the galaninergic and GABAergic outputs of the VLPO to other brain regions are inhibitory.

## Connectivity

The VLPO forms major reciprocal, inhibitory connections with other regions of the brain that promote the awake state. This includes the monoaminergic nuclei that maintain arousal, such as the histiminergic ►tuberomammilary nucleus (►TMN), the serotoninergic dorsal and median ►raphe nuclei, and the noradrenergic ►locus coeruleus (LC) [5–7]. Anatomically, the VLPOc projects most heavily to the TMN, while the VLPOe projects to the raphe nuclei and LC. The VLPO also sends inhibitory projections to the cholinergic pedunculopontine (PPT) and laterodorsal tegmental nuclei (LDT), as well as the ►hypocretin -containing neurons in the lateral hypothalamus (LH). Because all of these brain regions play a major role in promoting and maintaining wakefulness, inhibitory projections from the VLPO are hypothesized to promote sleep by decreasing their excitation of other brain regions.

These wake-promoting brain regions also send inhibitory projections to VLPO neurons [7]. VLPO neurons are inhibited by acetylcholine (ACh) and norepinephrine (NE) outputs from the PPT/LDT and LC, respectively. Although the TMN inhibits VLPO neurons, histamine does not affect VLPO activity. However, the TMN also contains GABA, galanin, and endomorphin, all of which may be inhibitory to VLPO neurons. Interestingly, serotoninergic projections from the raphe nuclei have different effects on different VLPO neurons [8]. Roughly half of VLPO neurons are inhibited by ►serotonin, referred to as Type I neurons, while the other half, Type II neurons, are excited. Different serotonin receptors are located on these two distinct cell types, revealing the probable mechanism by which serotonin causes these opposite effects.

The VLPO also receives projections from multiple other brain areas that are involved in the circadian, homeostatic, and metabolic drive for sleep [7]. For example, the VLPO receives projections from the ►suprachiasmatic nucleus (►SCN), the mammalian ►circadian pacemaker. The VLPO also receives substantial GABAergic projections from the dorsomedial hypothalamus (DMH), a region of the body that integrates information about food intake and organismal homeostasis from visceral sensory inputs, cognitive information from the prefrontal cortex, and emotional information from the limbic system.

## Pharmacology

As mentioned above, VLPO neurons are inhibited by ACh, NE, and are differentially excited/inhibited by serotonin. Some wake-promoting drugs work, at least in part, by perturbing inputs to the VLPO [1]. For example, the wake-promoting drug modafinil blocks the reuptake of noradrenaline at noradrenergic terminals on VLPO neurons. The stimulant nicotine also enhances the noradrenergic inhibition of VLPO neurons. VLPO neurons are also affected by endogenous somnogens [1]. For example, adenosine reduces the inhibition of VLPO neurons through the $A_1R$ receptor and directly excites Type II neurons through the $A_{2a}R$ receptor. Prostaglandin D2, a well-characterized somnogen, indirectly excites VLPO neurons. Many sleep-promoting drugs, such as barbiturates, benzodiazepines, chloral hydrate, ethanol, and most gaseous anesthetics, may enhance the GABAergic projections of VLPO neurons to arousal-promoting nuclei by enhancing the action of GABA at their receptors. Additionally, the sleep-promoting drug Gaboxadol has been shown to increase expression of the immediate early gene *c-fos* in VLPO neurons.

## Hypothesized Role in Promoting Sleep

Recent studies support the idea of the VLPO as a key sleep-promoting center in the brain. As mentioned above, the VLPO sends inhibitory projections to all of the major nuclei in the ►brainstem and hypothalamus that promote arousal. Thus, activation of the VLPO suppresses the wake-promoting properties of these activating systems. Furthermore, VLPO neurons are primarily active during sleep. Electrophysiological recordings of VLPO neurons across wake- ►sleep states show that these neurons fire twice as much during sleep as during wakefulness [9]. Animals sleeping prior to sacrifice show an increased expression of the immediate early gene *c-fos*, a marker of neural activity, within the VLPO [3]. The intensity of Fos staining in the VLPO correlates with the amount of sleep prior to sacrifice. Little Fos staining occurs in rats prior to sleep, even in sleep-deprived rats, suggesting that VLPO neurons are active during sleep but that this activity does not build up to cause homeostatic pressure to produce sleep. Interestingly, expression of Fos in the VLPOc appears to correlate with the amount of non-REM sleep while expression of Fos in the VLPOe correlates with REM sleep [6].

These correlational studies are further supported by lesion studies in rats in which physical ablation of the VLPOc was found to cause deficits in ►non-REM sleep while ablation of the VLPOe caused deficits in ►REM sleep [5]. Animals with lesions to the entire VLPO region show much more frequent transitions between sleep and wakefulness, with up to 60% loss of total sleep and profound ►insomnia [1,5]. These loss-of-function studies demonstrate that the VLPO is necessary for normal sleep/wake patterns. Future studies in which neural activity in the VLPO is artificially stimulated will demonstrate the sufficiency of the VLPO to cause transitions from the awake state to the sleep state.

The inhibitory, reciprocal connections between the VLPO and other arousal-promoting nuclei establish a model of sleep regulation that seeks to explain why sleep is an all-or-none event (either an organism is asleep or it is not) [1,10]. In the model, when VLPO neurons are active during sleep, they actively inhibit the arousal promoting nuclei. Thus, the VLPO neurons also relieve their own inhibition. When arousal-promoting nuclei are active during waking states, they actively inhibit the VLPO, additionally relieving their inhibition. Thus, activity in one competing side in the sleep circuit decreases inhibitory outputs from the other side, disinhibiting its own action. This "flip/flop" circuit model may explain why there is virtually no intermediate transition state from sleep to wakefulness (and vice versa), and why these transitions are so abrupt. Interestingly, many arousal-promoting nuclei sit at one end of this model circuit (LC, TMN, LH, raphe nuclei, etc.), whereas the VLPO and the median preoptic area are, to date, the only known subcortical sleep-promoting centers.

## Definition

Verbal memory is a rather broad concept that refers to memory for verbally presented information. There are a variety of tasks for measuring verbal memory capability, including learning of word lists, story recall (or logical memory), and learning of sequences of paired words. In list learning, the subject is required to recall an auditorily presented word list immediately or several minutes after the list presentation. The former recall condition is referred to as "immediate recall" and the latter as "delayed recall." With story recall, the subject listens to a short story and is asked to tell anything about the story under immediate and delayed (usually 30 min) recall conditions. In paired word learning, a sequence of word pairs is presented and recall of the second word of each pair is demanded when the tester utters each of the first words. As these tasks suggest, verbal memory primarily indicates acquisition or registration of memory for spoken materials.

## Characteristics

### Acquisition of Verbal Information

#### *Verbal Memory is Classified as Episodic Memory*

Current memory theory classifies long-term memory into declarative and non-declarative types [1,2]. Declarative memory is further divided into episodic and semantic memory. Episodic memory is memory of events or personal experiences, so one can identify when and where his or her episodes happened. Verbal memory falls into this category. A brain mechanism that closely associates with episodic memory is the medial

temporal cortex including the hippocampus. The left medial temporal cortex is specialized for memory for verbal information, and the right medial temporal cortex for memory for visuospatial information [3].

The medial temporal region works as a hub for episodic memory, but presumably does not include memory content which is stored elsewhere in the brain. As medial temporal cortices contribute to consolidate episodic memory, damage to these areas results in the severe memory impairment referred to as "amnesia." People who suffer from amnesia are unable to acquire memory for events that occurred after the onset of amnesia. This is known as "anterograde amnesia." They also cannot remember events which arose in the period of several years before the onset (partial "retrograde amnesia"), since the medial temporal areas are assumed to participate in retrieval of episodic memory during that period. But they are able to recall older memory before this period. Amnesic patients generally have not only anterograde but also partial retrograde amnesia. Function of other memory (semantic memory, short-term memory and non-declarative memory) and cognitive abilities are preserved in (pure) amnesia.

### Verbal Memory Reflects Left Hemisphere Function

As mentioned in its definition, verbal memory is a catch-all concept referring to memory for verbally given information, and more specifically acquisition of episodic memory. There are a wide range of tasks used to evaluate verbal memory ability. In studies that deal with verbal memory, multiple tasks on memory, perception and cognition are generally conducted at the same time: visuospatial perception and memory, short-term memory, procedural memory, verbal fluency, orientation and so on. This enables researchers to find out characteristic profiles of performances on the tasks for, e.g. brain-damaged and normal aged people, and to gain a clue to estimate brain functions. It is well confirmed that the left hemisphere processes verbal information and the right hemisphere visuospatial information. Deficient verbal memory is a sign of anomaly in the left hemisphere or the left medial temporal cortex, and decreased nonverbal visuospatial memory implies damage to the right medial temporal region [3].

### Retrieval of Semantics and Lexical Information in Word Finding

What we often observe in daily life concerning memory for verbal information is word-finding difficulty, otherwise known as the "tip of the tongue (TOT) phenomenon." This may happen in such situations as when you suddenly meet an old friend. You can immediately identify who he or she is, but often cannot remember his/her name quickly. Occasions of encountering this difficulty gradually increase as one gets older. Finding people's proper names (e.g. Salinger, Mozart) is more difficult than finding common nouns (e.g. rye, flute) in both young and aged people [4].

The term "word finding" means that, based on word semantics, the mental lexicon is accessed to retrieve word information necessary to utter the word in question. The mental lexicon is assumed to be a memory store for syntactic, morphological, and phonological information of words which was acquired in past years, which contrasts with verbal memory for just-acquired episodes (events, word list, short story, etc.). As such, the mental lexicon is a member of neither verbal memory nor episodic memory. Since, however, access to or retrieval from semantic memory (see below) and the mental lexicon is a topic central to human memory, let us take a brief look at how a word is found in the brain.

### Word-Finding Difficulty and Semantics

►Anomia, which is synonymous with word-finding difficulty, is widely seen in pathological cases like aphasia, Alzheimer's disease, semantic dementia, and herpes simplex virus encephalitis (HSVE or HSE). Semantic dementia results from progressive but circumscribed degeneration of the inferolateral anterior temporal lobe bilaterally (left-side atrophy is usually prominent) [5,6], beginning from the anterior temporal cortex and extending posteriorly with the medial region being disproportionately retained [7].

Patients with semantic dementia reveal a profound semantic memory loss. Semantic memory refers to the memory for facts and general knowledge, including word meanings. In picture naming, the concept or meaning represented by the picture is activated in the semantic memory, and the activation, in turn, transmits to the phonological form of the word relevant to the concept. Accordingly, semantic memory loss engenders naming difficulty.

In semantic dementia, episodic memory is disproportionately well preserved. Deficient semantic memory and retained episodic memory in semantic dementia are in sharp contrast with preserved semantic memory with defective episodic memory in amnesia. In neuropsychology such contrast is called "double dissociation." The dissociation suggests that episodic and semantic memory are independent, and furthermore that the medial temporal region responsible for episodic memory and the inferolateral temporal region responsible for semantic memory have separate functions.

### Category-Specific Naming Deficits in HSVE

Patients recovering from HSVE exhibit a special semantic memory impairment known as "category-specific semantic deficits," in which memory loss is observed for specific semantic categories (e.g. living things, mainly animals) with relatively spared semantics for inanimate objects (e.g. knife, bicycle) [8,9]. Since word finding as in picture naming, or retrieval of word phonology from

the mental lexicon, is based on semantics of the word to be uttered, this particular semantic memory loss results in ►category-specific naming deficits, i.e. deficient naming for living things with spared naming for inanimate things. Curiously, the reverse profile of naming or semantic impairments, i.e. better naming for living than for non-living objects, is rare. Brain lesions in patients recovering from HSVE are usually found in the bilateral temporal cortices, including the anterior and medial temporal regions.

### *Anomia in Aphasia*

Aphasia designates language impairment caused by brain damage to language-related areas (usually in the left hemisphere). Several subtypes exist: for example, Broca's aphasia, Wernicke's aphasia, conduction aphasia, transcortical sensory and motor aphasia, and ►amnesic aphasia, each showing distinctive speech and language deficits. Anomia is ubiquitous in almost all aphasic patients irrespective of their subtypes. Aphasia whose language disorder is unnoticeable except for anomia is called "amnesic or anomic aphasia."

Anomia refers to a retrieval problem for nouns, but it is also found for other grammatical word classes. Interestingly, there is a tendency that patients with non-fluent aphasia such as Broca's aphasia who may show deficient syntactic ability (agrammatism) have more difficulty with verb recall than noun recall. Contrarily, patients with fluent aphasia such as amnesic and Wernicke's aphasia exhibit the reverse.

Underlying mechanisms of anomia in aphasia are thought to be caused by impairment (i) in word semantics as in semantic dementia, or (ii) in retrieval of word phonology from the mental lexicon due to disconnection between semantics and word phonology [10]. Episodic memory in aphasic patients is well preserved even in "amnesic" aphasia.

# Vergence Eye Movements

## Definition

Vergence eye movements rotate the lines of sight of the two eyes by the same amount but in opposite directions (mostly horizontal) in order to maintain binocular fusion during changes in viewing distance. They are driven by binocular disparity and by blur from inappropriate accommodation (defocused retinal image). Vergence movements are generally slow but can considerably speed up when occurring in conjunction with saccades.

## Vermilion

### Definition
Red portion of the lip, bordered by hairy skin extraorally, and oral mucosa intraorally.

## Vermis Cerebelli

### Synonyms
Vermis of cerebellum (I–X)

### Definition
Vermis cerebelli is the name given to the entire middle region between the two cerebellar hemispheres. It receives its afferents from the spinocerebellar tracts and is thus also called the spinocerebellum. Some of its efferents (from zone A) course via the fastigial nucleus to the thalamus and to the vestibular nucleus. Another part (from zone B) passes without synapsing to the lateral vestibular nuclei.

►Cerebellum

## Versican

### Definition
Versican is a chondroitin sulfate proteoglycan (q.v.). It is found as three splice variants, V0, V1, V2. As with many chondroitin sulfate proteoglycans it is inhibitory to axon regeneration. In the adult central nervous system it is found in the general extracellular matrix and in perineuronal nets, the main form being V2 made by oligodendrocyte lineage cells. During development all the splice variants are produced in several parts of the developing embryo.

# Verticality Perception

Adolfo M. Bronstein
Imperial College London, Charing Cross Hospital, London, UK

## Synonyms

Perception of uprightness; Sense of uprightness; Perception of verticality; Feeling or sense of what's up and what's down; Gravity perception; Graviception

## Definition

The perception of verticality is the multi-sensory mediated sense that allows human beings to accurately ascertain what is up and what is down and deviations thereof, in a gravitational field.

## Description of the Theory

►Gravity has provided a formidable evolutionary drive for postural and locomotor mechanisms, as life on earth demands a permanent battle with the gravitational force. How verticality is perceived influences how standing and moving are carried out, but the intimate link between gravitational perception and action has not been fully elucidated yet. Apart from any theoretical interest, this field has practical implications in clinical medicine and aerospace exploration.

Although even the simplest organisms are able to orient with respect to gravity, vertebrates have developed complex sensory systems capable of detecting this ubiquitous force. Since according to the Relativity Theory there is no conceptual distinction between linear acceleration and gravity, the problem that organisms face is how to differentiate the linear acceleration associated with translational movements of the body (e.g. accelerating whilst standing on a train), which may require ocular and body compensatory movements, from body tilt with respect to the gravitational vector, which requires a different set of compensatory movements or none at all. Partly this distinction is possible thanks to the different dynamic properties of the sensory channels involved in gravity perception and partly to complex neural computations [1].

The sensory systems involved in gravitational processing are the *vestibular*, the *somatosensory* and the *visual* systems. The vestibular input arises from two sensory organs in the inner ear labyrinth (the utricle and the sacculus), collectively referred to as the otolith organs. These organs sense both the gravitational pull and linear accelerations with a wide frequency range, that is they can sense slow and prolonged tilts as well as high frequency brief accelerations.

The somatosensory system comprises both tactile superficial cutaneous inputs and information about deep somatic pressure, stretch and tension in joints, muscles and tendons (proprioception). Simple introspection should allow a person to feel the pressure on their buttocks if they are seated or the tension in their ankles if they are standing; information that they can use to sense if they are seated/standing truly upright or tilted to one side. These receptors (e.g. muscle spindles) also have a wide response range so they are thought to provide accurate input over a broad frequency range. However, tactile and to some extent proprioceptive inputs experience sensory adaptation, so the absolute accuracy of the input may decay over time.

The visual system is also capable of providing information about verticality but its ability is diminished by the inherent ambiguity present in the visual stimulus. Visual processes *per se*, i.e. working in isolation, cannot tell if a person is tilted with respect to the visual world or if the visual world is actually tilted. In practice this ambiguity is resolved by cross-referencing the visual input with respect to the gravito-inertial systems (the vestibulo-proprioceptive input).

Each of these sensory systems can contribute to the perception of verticality or uprightness by two different mechanisms. One is by directly estimating the actual deviation of the body or of an external object from actual (gravitational) vertical, a position based or "tonic" mechanism. A second, indirect mechanism does not necessarily measure position or tilt angle with respect to gravity but senses the dynamic components of movement. Additional CNS processing can then reconstruct position, in this case angle with respect to the gravity vector. An example is obtaining head position information by central mathematical processing of the raw dynamic head acceleration and velocity signals present in the vestibular nerve [1] or by cross-referencing to other sensory signals. By way of example, imagine a person sitting sideways on a car that suddenly accelerates sideways at say 1G. The summation of this lateral (orthogonal to gravity) acceleration with the gravitational vector will lead to a tilt of the resulting gravito-inertial vector of 45°. However, the lack of concurrent visual and semicircular canal input signaling head rotation (which would have occurred if they had tilted away from vertical) would be centrally interpreted as having accelerated sideways rather than tilted sideways. In conditions where additional sensory inputs are absent or impoverished, e.g. flying amidst thick clouds, unusual accelerations can result in pilot disorientation and accidents [2,3].

Numerous experiments have shown that it is possible to assess the perception of verticality within individual sensory modalities. This has led to the concept of SVV, SHV, SPV (subjective visual, haptic, postural vertical respectively). The application of these measurements to neurological patients has been a fruitful area of applied neuroscience.

### Subjective Visual Vertical

The svv is usually measured with subjects seated in the dark facing a luminous rod that can pivot around the line of sight. Subjects are required to bring the rod to upright; usually 5–10 discrete measurements are taken. Several hundred papers have been written using this inexpensive and simple technique. Unilateral lesions to the peripheral (labyrinth) and central vestibular structures induce abnormal tilts of the svv [4]; this was assumed to depend on damage to the graviceptors (otolith organs). By extension, tilts of the svv have been thought to indicate unilateral otolith disease. However, selective stimulation of the vertical semicircular canals also induces tilt of the svv [5]. The conclusion is that the main variable capable of provoking visual (i.e. svv) tilt is ocular tilt (i.e. torsion of the eyes). Since stimulation and lesions of the otolith and the vertical semicircular systems induce torsional eye movements, tilts of the svv alone cannot distinguish between the two.

Whereas svv tilts indicate tilts of the visually mediated perception of verticality, claims that the svv measures an "internal representation of gravity" [6] are questionable. Whilst such a hypothetical internal representation of verticality may well exist, clinical research has failed to prove its existence. Indeed, patients with ►central vestibular lesions can have severe tilts of the svv (in agreement with the ocular tilt present in such patients) but otherwise normal verticality perception via postural and haptic means [7]. Each sensory channel can sense uprightness independently. When the different sensory estimates do not agree with each other in health or disease, ►*sensory conflict* (see this term under "Central Vestibular Disorders") arises, in turn leading to disorientation and motion sickness-like symptoms.

### The Effect of Postural and Visual Stimuli on the svv

#### Visual Stimuli

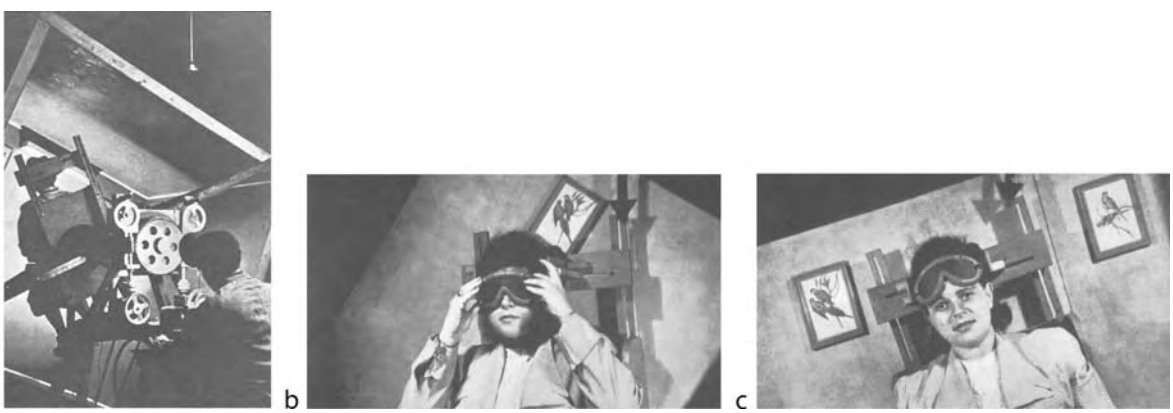
A useful development of the basic svv protocol is the so-called "rod and frame test." The concepts behind this protocol were initially developed by Witkin [8] who observed that individuals differed considerably in the amount of "weight" they placed on vision for verticality orientation. Based on experiments in which subjects faced sensory conflict between visual and gravito-inertial (vestibulo-proprioceptive) cues, Witkin classified subjects as visually dependent, if vision was capable of overriding gravito-inertial cues or visually independent if they preferably relied on gravito-inertial cues (see Fig. 1).

The rod and frame test consists of a luminous rod as for conventional svv surrounded by a larger luminous frame that can be tilted. The svv is then measured in two conditions, without frame in total darkness and with the frame tilted to one side and then the other. The amount of svv tilt induced by the tilted frame therefore allows a measurement of how much peripheral vision influences the perception of visual verticality. Subjects with large frame induced tilts of the svv are thus considered visually dependent.

A disk rotating about the visual axis placed behind the svv line has an even stronger tilt effect on the svv. This "rod and disc" test is particularly useful of assessing the influence of dynamic visual cues on verticality perception, with practical implications for patients with vestibular disorders of balance (*see visual vertigo*) [9].

#### Postural Stimuli

If the svv is measured in the upright body position most subjects are extremely accurate, placing the svv line within 1–2° of true gravitational vertical. However, if measurements are taken with subjects lying



**Verticality Perception. Figure 1** Witkin's experimental set up (a) in which the subject and the room could be tilted independently. Below a visually depent subject is depicted. When the SPV was assesed in the dark (b) the subject was accurate. When, assesed in the tilted room the subject is largely driven by the tilted visual surroundings (c). The arrow indicates true gravitational vertical. Taken from Witkin (1959), reproduced with permission of Scientific American.

sideways, significant biases of svv readings appear. A clear-cut effect is observed when subjects setting the svv line are lying sideways in the region of 60–90°. At these large tilt angles, subjects set the line with a bias of 10–20° in the same direction as the body tilt (this is called the Aubert or "A" effect). This implies that at such body tilt angles, the visual world is not perceived upright but is seen as tilted away from vertical in the opposite direction to body tilt, i.e. the amount of body tilt is underestimated. With small degrees of body tilt (10–30°) there is a smaller, less consistent effect in which the svv settings are biased in the opposite direction of body tilt (the "E" effect). It is thought that the A and E effects are induced by an asymmetric adaptation of somatosensory afferents during body tilt overriding the more veridical otolith signals; in agreement patients with absent vestibular function show a larger A effect [10].

As a footnote, most studies measuring the subjective visual horizontal show similar results to svv measurements but occasional discrepancies are present that are not reviewed here. The subjective visual horizontal should not be confused, however, with the subjective horizon or gravity referenced eye level (grel). This parameter is assessed by asking subjects in the dark to indicate the plane "where the sea meets the ski." In contrast to the svv, which is an entirely geocentric concept (the concept of verticality is expressed in external, gravitational coordinates), grel is eye level referenced and therefore semi-geocentric [11].

### *The Subjective Postural Vertical (spv)*

Subjects standing or seating in a tilting device in the dark can estimate whether they are "upright" or not within 2–3° of the true gravitational line. If body tilts are delivered in different planes away from the vertical, a "cone" of verticality or uprightness can be defined [12]. Most studies of the spv are conducted with seated and strapped subjects and, in these conditions, contact, pressure and other somatosensory cues are prominent. Accordingly patients with unilateral vestibular lesions do not show a clear bias in their spv as could be expected. However, peripheral and central vestibular lesions provoke a small decrement in the accuracy of the spv (data scatter) indicating that vestibular input is also contributory to some extent. Intra-abdominal receptors also seem to add to the formation of the spv [13]. The assessment of the different sensory modalities of verticality perception may have a practical clinical role in the prognosis and rehabilitation of patients with neurological lesions especially stroke and this topic is actively being investigated at present.

# Vertigo

## Definition

An abnormal sensation of motion. The illusion of motion can be rotational such as a spinning sensation or can involve a feeling of being tilted or pulled to one side. Vertigo is most often due to disturbances of ►vestibular function. Vertigo may occur under physiological conditions (mismatch of sensory inputs including somatosensory, vestibular and visual; unfamiliar head movements, e.g. in seasickness; unusual head/neck positions) or in many pathological conditions (e.g., acute vestibular vestibulopathy, ►Menière's disease,

►acoustic neuroma, intoxication (e.g., ►alcohol-induced vertigo), psychogenic vertigo.

►Central Vestibular Disorders
►Disorders of the Vestibular Periphery

## Vesicular Neurotransmitter Transporter

Hiroshi Omote, Yoshinori Moriyama
Department of Biochemistry, Faculty of Pharmaceutical Sciences, Okayama University, Okayama, Japan

### Definition

Many neurotransmitters are secreted from neural and non-neural cells through exocytosis of vesicles. Vesicular neurotransmitter transporters are membrane transporters responsible for the accumulation of neurotransmitters in such secretory vesicles [1–3]. Typical neurotransmitters secreted through exocytosis are acetylcholine, dopamine, histamine, GABA and glutamate. The vesicular neurotransmitter transporters are located in the vesicle membrane, and transport neurotransmitters across the membrane using an electrochemical gradient of protons generated by V-type $H^+$-ATPase (Fig. 1).

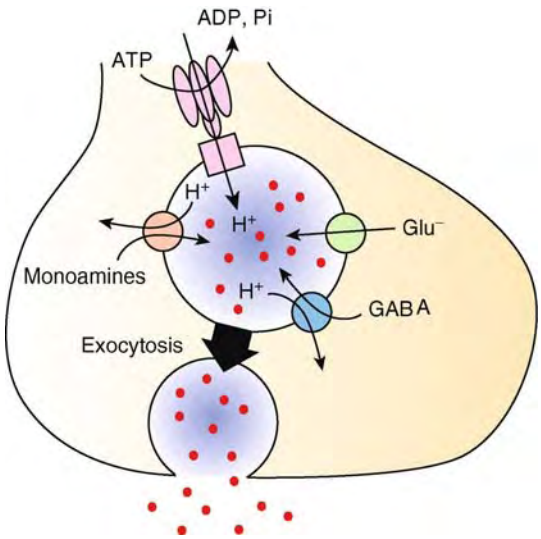
### Characteristics

#### Quantitative Description

Typical vesicular neurotransmitter transporters consist of 500–600 amino acid residues with molecular weights of 550–650 K.

#### Higher Level Structures

Vesicular neurotransmitter transporters are secondary active transporters that transport substrates across membranes using an electrochemical gradient of ions. Membrane transporters are classified into primary and secondary active transporters based on the energy source for transport. Primary active transporters are directly coupled to metabolism. Typical primary transporters use the energy of ATP hydrolysis. On the other hand, secondary active transporters use the electrochemical gradient of ions established by primary active transporters. The secondary active transporters include $Na^+/H^+$ exchanger and $Na^+$/glucose co-transporter in the plasma membrane, and are widely distributed from bacteria to human. Most of these transporters in human are classified into solute carrier families (SLC).



**Vesicular Neurotransmitter Transporter.**
**Figure 1** Neurotransmitters are sequestered to vesicles by the vesicular neurotransmitter transporters using an electrochemical gradient of protons established by V-ATPase. Concentrated neurotransmitters are secreted through exocytosis.

#### Lower Level Components

Vesicular neurotransmitter transporters comprise of three families including ►VGAT, ►VAChT/►VMAT and ►VGLUT (Table 1).

VGAT, vesicular GABA transporter, transports inhibitory amino acids such as GABA and glycine to vesicles [4]. Although glycine uptake by VGAT needs further demonstration, histochemical and transport experiments with synaptic vesicles have indicated VGAT transports glycine [5]. ►VIAAT and SLC32 are aliases for VGAT. This family consists of a single member.

VAChT and VMAT are members of the SLC18 family [6,7]. VAT, vesicular amine transporter, is a synonym for VMAT. This family of transporters consists of three members, VMAT1, VMAT2 and VAChT. Vesicular monoamine transporters VMAT1 and VMAT2 mediate the accumulation of monoamines such as 5-hydroxytryptamine, dopamine, adrenaline, noradrenaline and histamine. These two transporters were identified by expression cloning for organic amines. Biochemical and histochemical studies have indicated that VMAT2

**Vesicular Neurotransmitter Transporter. Table 1** Vesicular neurotransmitter transporters

| Family name | Protein name | Substrates | Coupling | Tissue distribution | Inhibitors | Amino acid residues | Sequence accession ID |
|---|---|---|---|---|---|---|---|
| SLC32 | VGAT | GABA, glycine | $H^+$ antiport | Central nervous system, pituitary, pineal gland, testis | | 525 (57.4k) | NP_542119 |
| SLC18 | VMAT1 | Serotonin, dopamine, adrenaline, noradrenaline, histamine | $H^+$ antiport | Adrenal gland, sympathetic ganglia, skin, carotid body | Reserpine | 525 (56.3k) | NP_003044 |
| | VMAT2 | Serotonin, dopamine, adrenaline, noradrenaline, histamine | $H^+$ antiport | Brain, adrenal gland, sympathetic ganglia, carotid body, intestine, stomach, endocrine pancreas, basophils, mast cells, platelets | Reserpine, tetrabenazine | 514 (55.7k) | NP_003045 |
| | VAChT | Acetylcholine | $H^+$ antiport | Brain, intestine, peripheral nervous system | Vesamicol | 532 (57.0k) | NP_003046 |
| SLC17 | VGLUT1 | L-Glutamate | Δψ driven uniport | Brain, pineal gland, islets of Langerhans, bone | | 582 (64.4k) | NP_065079 |
| | VGLUT2 | L-Glutamate | Δψ driven uniport | Brain, pineal gland, islets of Lagerhans, testis | | 560 (61.6k) | NP_064705 |
| | VGLUT3 | L-Glutamate | Δψ driven uniport | Brain, liver, kidney | | 589 (65.0k) | NP_647480 |

makes a major contribution to the uptake of these amines to the synaptic vesicles of neurons. VAChT, vesicular acetylcholine transporter, accumulates acetylcholine in synaptic vesicles.

The third family, VGLUT, comprises of vesicular glutamate transporters that mediate glutamate uptake into the vesicles [8,9]. So far, three isoforms of VGLUT have been found, which are named VGLUT1, VGLUT2 and VGLUT3. All of these glutamate transporters belong to the SLC17 family. Other members of the SLC17 family are the type I phosphate transporters and sialic acid transporter. Among the members, only VGLUTs are involved in glutamate accumulation in vesicles. Similar to type I phosphate transporters, VGLUTs are able to transport inorganic phosphate when an artificial $Na^+$ gradient is applied. In this respect, VGLUTs are multifunctional transporters.

In addition to these transporters, vesicular transporters for ATP and D,L-aspartate are present in secretory vesicles, but have not been identified yet.

## Higher Level Processes

Exocytosis is the principle mechanism of neurotransmitter secretion at the chemical synapses of neurons. In addition to those of the central nervous system, many peripheral neural and non-neural cells secrete neurotransmitters through exocytosis. Such a system needs machinery for the concentration of neurotransmitters in secretory vesicles, exocytosis of vesicles, signal detection through receptors and signal termination by reabsorption of neurotransmitters in cells. The vesicular neurotransmitter transporters and ►V-ATPase cooperate to concentrate neurotransmitters in vesicles. In some cases, cells contain multiple types of secretory vesicles that contain different neurotransmitters. Therefore, vesicular neurotransmitter transporters must be correctly localized in specific vesicles to release appropriate ligands upon stimulation. Concentrated neurotransmitters are released through exocytosis initiated by stimulation. Vesicles fuse with the plasma membrane and open up into the extracellular space, and neurotransmitters inside of vesicles are released. This process must be tightly controlled to avoid unexpected signal generation. The released neurotransmitters are detected by receptors on the targeted cells and trigger responses to ligands. Vesicular neurotransmitter transporters that appear on the plasma membrane are recycled to vesicles through endocytosis. Plasma membrane transporters reuptake neurotransmitters into the cells to terminate signal response. In the case of acetylcholine, hydrolysis by acetylcholine esterase eliminates signaling.

As vesicular neurotransmitter transporters are an indispensable part of signaling through exocytosis, these transporters are good markers for determining the type of signal transmission. In other words, vesicular neurotransmitter transporters determine the mode of signal transmission. For example, VGAT is responsible

for GABA and glycine accumulation in vesicles. Hence, VGAT is localized in GABAergic and glycinergic neurons. VGAT is also found in the pituitary, pineal gland, pancreas and testis, indicating the presence of GABAergic or glycinergic systems in these organs. In the case of vesicular monoamine transporters, a cell's adrenergic, noradrenergic, serotonergic, dopaminergic or histaminergic function is determined by coexpression of other factors such as plasma membrane transporters of these amines and the enzymes for the synthesis of these amines. VMATs are found in various cells that use monoamines as neurotransmitters. In contrast to VMAT, VAChT only transports acetylcholine. The vesicular acetylcholine transporter is co-expressed with choline acetyl transferase that synthesizes acetylcholine, and that is used as a marker for cholinergic neurons. L-Glutamate is the major excitatory neurotransmitter in the central nervous system. The complimentary localization of VGLUT1 and VGLUT2 in the central nervous system suggests functional differences between these transporters. Recent studies on signaling systems revealed that glutamatergic systems play important roles in the peripheral system [8]. VGLUTs are found in such glutamatergic cells as α cells of islets of Langerhans and pineal cells of pineal glands.

## Process Regulation

The amino acid sequences of vesicular neurotransmitter transporters include potential phosphorylation sites. Although there have been reports for the phosphorylation of these vesicular neurotransmitter transporters, its function is not currently understood. In addition, gene expression control of VGAT and VMAT has been reported, but further study is required to reveal their roles.

## Function

The vesicular neurotransmitter transporters are responsible for the accumulation of substrates using the energy generated by V-ATPase. V-ATPase uptakes $H^+$ to vesicles through ATP hydrolysis. The uptake of $H^+$ by secretory vesicles generates an electrochemical gradient of $H^+$ across the membrane. This gradient is composed of chemical and electrical gradients, and is used by vesicular neurotransmitter transporters. Depending on the transporter, both or one of these components is used as an energy source for transport. For instance, VGAT is an antiporter that transports GABA into vesicles, and $H^+$ is translocated to the outside of the vesicles. In this case, VGAT utilizes membrane potential as well as the $H^+$ gradient for substrate transport. Thus, ionophores that dissipate the electrochemical gradient of $H^+$ inhibit GABA uptake. Similarly, VMAT and VAChT uptake one substrate molecule and translocate two $H^+$ in the other direction. The substrate specificity of VMAT is not strict, and thus it transports various biological monoamines into vesicles. Contrary to these transporters, VGLUTs are uniporters and only use the electrical component. The substrate specificities of VGLUTs are strict and they cannot transport D-glutamate or aspartate. Details of transport mechanism of these transporters are not well understood because of the lack of a good assay system and structural information. However, recent progress in structural biology has indicated that alternate change between inward-facing and outward-facing conformations involve substrate transport by the bacterial homolog [10]. A similar mechanism must be involved for the vesicular neurotransmitter transporters.

As the electrochemical gradient of $H^+$ generated by V-ATPase drives vesicular neurotransmitter transporters, inhibitors of V-ATPase such as bafilomycin and *N*-ethylmaleimide, ionophores that collapse gradients, diminish neurotransmitter accumulation in vesicles.

## Pathology

Since neurotransmitters are correlated with higher functions of the neural systems, improper functioning of vesicular neurotransmitter transporters may cause neuropsychiatric disorders. Although no disease triggered by mutation of a vesicular transmitter transporter has been reported, future work may reveal a genetic disorder directly related to the function of these transporters.

The vesicular monoamine transporters are able to sequester various amines in vesicles. Such a functionality of VMAT is correlated with vulnerability to addiction, schizophrenia, depression and the neurotoxicity of Parkinsonism-inducing agents such as MPTP (*N*-methyl-1,2,3,6-tetrahydropyridine). Vesicular neurotransmitter transporters are good markers for neural systems like the cholinergic and glutamatergic ones. Thus, high affinity ligands for VMATs and VAChT are good tools for revealing neural damage due to neurodegenerative diseases. Radio labeled ligands, vesamicol and tetrabenazine have been successfully used to visualize VMATs and VAChT in the brain in Parkinson's disease.

## Therapy

The VMATs are the site of reserpine and tetrabenazine actions. Reserpine is used as an antihypertensive reagent to control the heart rate. These reagents shut the dopaminergic system down through inhibition of VMAT activity.

## Vestibular Apparatus

### Definition

Sensory system in the inner ear for detecting linear and rotational accelerations of the head.

►Peripheral Vestibular Apparatus

## Vestibular Commissural Inhibitory System

### Definition

The functionally inhibitory pathways that link the bilateral vestibular nuclei concerned with eye movements (particularly the medial vestibular nuclei and the superior vestibular nuclei). Commissural neurons in each of these nuclei project to the approximately equivalent region of the contralateral nuclei, where they inhibit the contralateral neurons via inhibitory interneurons.

This reciprocal, inhibitory commissural system is functionally important in optimising the responsiveness of the vestibular neurons to slow or small head rotations and also contributes to determining the time-constant of the vestibulo-ocular reflexes.

Neurons in the lateral vestibular nuclei of the two sides, which deal predominantly with otolith (macular) afferent inputs, also participate in a functionally analogous but less well characterized commissural inhibitory system.

### Definition

"►Vestibular compensation" (VC) is a broad term for the overall behavioral and functional recovery that takes place in the control of eye movements and posture

after damage to the vestibular system. In its most widely investigated form, VC refers to the behavioral recovery that follows the permanent loss of the peripheral semicircular canal and macular receptors of one inner ear (e.g. after ►unilateral labyrinthectomy, UL) or their de-afferentation (e.g. after unilateral vestibular neurectomy). Because the loss of afferent input from the vestibular receptors on the lesioned side is permanent, it is accepted that the behavioral recovery in VC must involve extensive synaptic and neuronal plasticity in the brainstem vestibular nuclei, cerebellum and related areas of the brain (for reviews, see [1–8]).

Related forms of VC, which no doubt share common brain plasticity mechanisms, also take place after the partial or incomplete loss of peripheral afferent input from one inner ear. In the clinical context, peripheral vestibular damage may often occur gradually over a prolonged time, in which case VC is also a continuous process, which continuously attempts to normalize oculomotor and postural motor control.

## Characteristics

The vestibular system has a fundamental role in the control of eye movements and stabilization of gaze, the control of posture and locomotion and in cognitive aspects of balance, self-orientation and spatial navigation. Information from the vestibular, visual and proprioceptive systems converges in the first instance on neurons in the brainstem vestibular nuclei. Vestibular nucleus (VN) neurons transform these inputs into motor commands for eye and head movements and also project to higher brain areas including the hippocampus and thalamus, reaching the vestibular cortex. The correct temporal and spatial integration of these input signals by brainstem VN neurons is therefore critical both for oculomotor and postural reflex function, as well as spatial cognition and navigation.

Damage to the peripheral vestibular receptors in the inner ear of one side or to the vestibular nerve precipitates a complex and debilitating syndrome of oculomotor, postural and cognitive deficits. Since there is no regeneration of the damaged vestibular receptors or nerve, the behavioral recovery during vestibular compensation is attributed to neural and synaptic plasticity in the vestibular pathways. Detailed studies of the behavioral deficits that follow UL in animals and humans have emphasized that VC is by no means a single process. There are wide differences in the time course and ultimate level of compensation for the range of oculomotor, postural and cognitive deficits that follow UL. Thus although the term "vestibular compensation" refers to the overall behavioral recovery, it is clear that the underlying physiological mechanisms are diverse, with differences in the signals that initiate and drive them, their time course and end-points.

## Behavioural Consequences of Unilateral Vestibular Deafferentation

The signs and symptoms that follow UL have been characterized in a range of species using a wide range of techniques including ►posturography, video oculography and 3D-search coil recordings of eye movements and X-ray cinematography. Although there are species differences, the nature of the vestibular deafferentation syndrome and the subsequent behavioral recovery are broadly similar in various animals from the goldfish and frog to monkey and man, indicating that the underlying processes share many commonalities.

The deficits observed immediately after UL can be divided into two categories on the basis of their relationship to head movement. "Static" signs are observed in the absence of head movement, affecting head and body posture and eye movements. In addition "dynamic" signs are observed during head movements (that is in response to vestibular stimulation) and result from abnormalities in the amplitude and timing of the vestibulo-ocular, vestibulo-collic and vestibulo-spinal reflexes. In general static symptoms show a rapid recovery following UL, with many of the initial severe static symptoms disappearing within a few days, while compensation of the dynamic symptoms is much slower and incomplete.

In mammals the most prominent static symptom is a high-frequency spontaneous horizontal ocular nystagmus (SN), seen as a slow drift of the eyes towards the lesioned side (slow phase) followed by a fast beat towards the intact side (quick phase). Soon after UL the frequency of SN in rats and guinea pigs is around 80–180 beats per minute. The frequency of SN begins to decrease soon after UL, declining to about half of its initial value within 6 h in the rat and disappearing completely within about 60 h. In the monkey and man SN may persist for up to a week. In amphibians, SN does not occur.

UL also results in disturbances in the position of the eyes, head and body. Ocular torsion and ocular skew deviation cause the eye on the affected side to rotate and deviate downwards in its orbit relative to the eye on the intact side. The deviated position of the eyes causes a systematic error in the perception of horizontal and vertical lines, which are seen as being rotated towards the affected ear in proportion to the ocular torsion. Humans show relatively little head and body rotation after unilateral vestibular loss, but many other species show a tilting of the head towards the lesioned side in the roll plane ("roll head tilt," RHT) and a turning of the head towards the lesioned side in the yaw plane ("yaw head tilt," YHT). Other static postural symptoms in animals include a curvature of the upper spine towards the lesioned side, circular walking and barrel rolling and an asymmetric extensor muscle tone in the ipsi- and contra-lesional limbs with a tendency to

fall to the lesioned side. Along with the disappearance of SN after UL, most static signs ameliorate remarkably rapidly. Barrel-rolling and circular walking subside within 4 h in the rat, while ocular torsion, skew deviation and YHT have largely disappeared within a few days.

By contrast the recovery of dynamic symptoms is slow and incomplete. UL results in severe abnormalities in the gain, symmetry and phase of the hVOR. After UL, hVOR gain is significantly lower than its normal value of approximately 1.0 and is severely asymmetric; hVOR gain in response to rotations towards the side of the lesioned ear (the "ipsi-lesional" side) is much lower than that in response to rotations towards the intact side (the "contra-lesional" side). During rotations towards the ipsi-lesional side the hVOR gain falls to approximately 0.3–0.4 in humans and guinea pigs, while during contra-lesional rotations hVOR gain is higher, around 0.7–0.8. These abnormalities in hVOR performance appear to be permanent – they do not significantly compensate in the long term and can be observed months and years following ►labyrinthectomy.

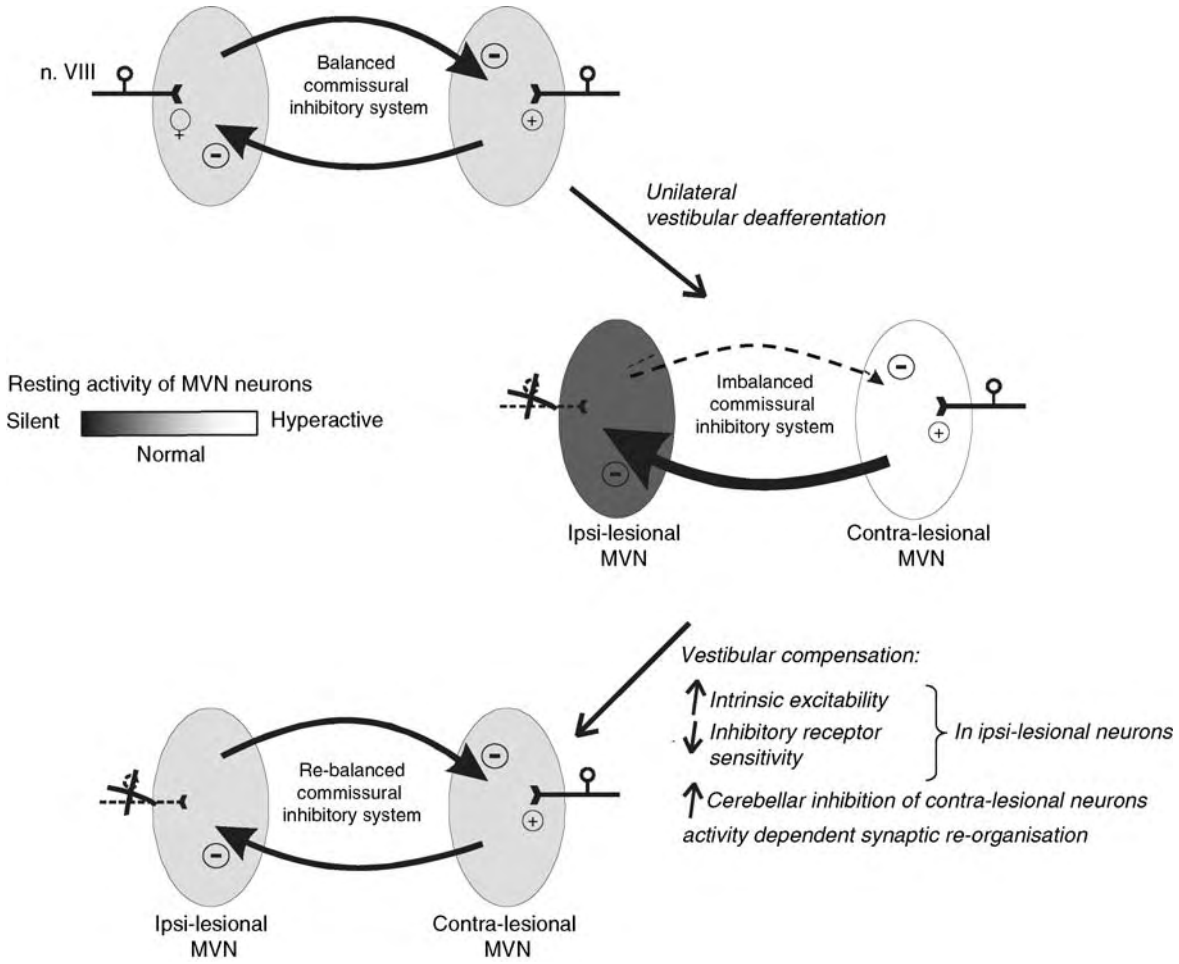
Despite the incomplete recovery of dynamic deficits in vestibular reflex performance, the majority of animals or patients are able to return to a near-normal lifestyle after unilateral vestibular loss. Presumably high-level, cognitive and behavioral strategies are developed in order to minimize the effects of the permanently compromised vestibular reflexes. Thus patients may learn to minimize head turns or to blink or fixate on a visual target during head rotations so as to suppress the VOR or generate compensatory saccades during voluntary head rotations towards the deficient side. Potentially, different subjects may develop individual compensatory strategies and indeed use different strategies in particular circumstances and these strategies may be learnt and refined over varying times during VC. The behavioral compensation of *dynamic* deficits after UL is therefore a complex, multifactorial and potentially individualistic process and the underlying mechanisms are at present largely unexplored.

## Effects of Unilateral Vestibular Deafferentation on Neuronal Activity in the Vestibular Nuclei

Unilateral vestibular loss has profound effects on the activity of neurons in the brainstem vestibular nuclei and the severe behavioral symptoms induced by UL are believed to arise directly from these effects. Of the four main vestibular nuclei in the brainstem, the most extensively studied is the medial vestibular nucleus (MVN). Immediately after UL, the normally high resting discharge rate of the majority of MVN neurons on the ipsi-lesional side is virtually abolished, while the activity of MVN neurons on the contra-lesional side is either normal or increased (Fig. 1).

Furthermore, the amelioration of the static symptoms is broadly correlated with a recovery of the resting activity of the ipsi-lesional MVN neurons to near-normal levels. MVN neurons are the major CNS target of primary vestibular afferents from the semicircular canals; they occupy a central position in the VOR pathway providing a major input to abducens motoneurons and also project to the cervical spinal cord and the forebrain, relaying information to the vestibular cortex. It is therefore generally accepted that the profound loss of resting activity in these neurons immediately after UL is an important factor in generating the initial static symptoms, as well as the behavioral and cognitive deficits that immediately follow UL. Much research has therefore focussed on understanding the causes of the initial silencing of the resting discharge of ipsi-lesional MVN cells after UL and the mechanisms that may bring about the recovery of their resting activity early in VC. However it should be borne in mind that other brain centres may also be important in the early behavioral recovery after UL.

Interestingly, recent experiments have shown that after ►bilateral labyrinthectomy, where the MVN neurons of the two sides are equally disfacilitated by the interruption of the primary vestibular afferents on both sides, the resting activity of MVN cells is not abolished; instead, it decreases to only about 50% of normal on both sides. This implies that after UL, the reason for the silencing of the ipsi-lesional MVN neurons is not the deafferentation itself, since one would then expect the resting activity in both MVNs to be abolished after bilateral deafferentation. Instead, the silencing of the ipsi-lesional MVN neurons after UL is probably because these cells are subjected to not only the loss of excitation from the lesioned primary vestibular afferents, but also a continued and enhanced commissural inhibition from contra-lesional MVN neurons, which tend to become hyperactive because of the collapse of inhibitory drive from the lesioned side (Fig. 1b). Normally, the reciprocal commissural inhibitory pathways that link the MVN of the two sides are important in optimizing the dynamic responsiveness of the MVN neurones to head movements and the time constant of the brainstem neural integrator. After UL however, the commissural inhibitory system is pushed into marked imbalance as a result of the disfacilitation of the ipsi-lesional MVN cells (Fig. 1b). Thus a fundamental cause of the silencing of the deafferented MVN neurons appears to be the commissural inhibitory input to the ipsi-lesional cells. In this light, it is reasonable to hypothesize that cellular mechanisms that may relieve the ipsi-lesional MVN cells from excessive commissural inhibition after UL would promote the recovery of their resting discharge and the restoration of their inhibitory control of the contra-lesional MVN neurons and that this would help



**Vestibular Compensation and Plasticity. Figure1** Schematic representation of the effects of unilateral vestibular deafferentation on the commissural inhibtory system and the neuronal activtiy in the medical vestibular nuclei in the brainstem. During vestibular compensation, several cellular processes have been identified which may contribute to the re-balancing of the commissural system and the restoration and mainteance of neural activity in the deaffereated vestibular neurons.

to "re-balance" the levels of neuronal activity in the MVN of the two sides.

## Mechanisms Involved in the Recovery of Ipsi-lesional Vestibular Neuronal Activity After UL

Experimental evidence accumulated over the past 10 years has indicated at least four candidate mechanisms, which may operate in parallel and synergistically, to bring about the restoration of resting activity in the deafferented ipsi-lesional MVN neurons after UL.

1. *Changes in the Responsiveness of Vestibular Nucleus Neurons to Inhibitory Synaptic Inputs*

Evidence for adaptive changes in the intrinsic properties of MVN neurons after UL has come from studies of *in vitro* brain slice preparations of the brainstem. Such studies have significantly increased our understanding of the electrophysiological characteristics of MVN neurons and the actions of many neurotransmitters that influence vestibular function. Analysis of the responsiveness of MVN neurons to the inhibitory neurotransmitters GABA and glycine (which are the main transmitters involved in the commissural inhibitory system) in slices from normal animals and animals that had compensated for various times after UL showed that the sensitivity of the ipsi-lesional MVN neurons to these inhibitory transmitters is significantly down-regulated after UL. Thus the same doses of GABA and glycine cause a much smaller inhibition of ipsi-lesional MVN neurons from animals after UL than normal MVN neurons. This reduction in the sensitivity to inhibitory inputs is appropriate to counteract the enhanced commissural inhibition to which the ipsi-lesional MVN cells are subjected after UL (Fig. 1b).

This has been proposed as one plausible mechanism that may help to restore their resting discharge early in VC (Fig. 1c).

Interestingly, MVN neurons possess both the muscimol-sensitive GABA-A subtype and the baclofen-sensitive GABA-B subtype of GABA receptors and both subtypes are down-regulated immediately after UL. However, the GABA-A receptor mediated inhibition recovers within a few days, while the responsiveness to GABA-B receptor mediated inhibition remains down-regulated in the long term. The functional importance of the altered function of GABA-B receptors in compensated animals has been confirmed in behavioral experiments, in which the GABA-B receptor agonist baclofen was administered to animals that had partially or fully compensated after UL.

2. *Changes in the Electrophysiological Excitability of Vestibular Nucleus Neurons After Deafferentation*

In parallel with the changes in their sensitivity to inhibitory neurotransmitters after UL, after deafferentation the ipsi-lesional MVN cells also up-regulate their intrinsic electrophysiological excitability (Fig. 1c). This was first observed simply as an increase in the mean spontaneous discharge rate of the ipsi-lesional MVN cells in brain slices taken from animals that had compensated for various times after UL. Subsequent studies using intracellular recordings have shown that there are changes in their input resistance and resting membrane potentials, but the responsiveness to synaptic inputs is also potentiated through the up-regulation of appropriate ion channels. In particular there is an increase in the number of cells that show low-threshold calcium spikes (LTS) after UL. This is of interest because it can be strongly activated by small depolarizing inputs when the membrane potential is hyperpolarized. Thus the increased expression of LTS in the ipsi-lesional MVN neurons, which are indeed hyperpolarized and silent immediately after UL may significantly increase their responsiveness to their remaining synaptic inputs from other, non-vestibular sources. In the longer term, these changes in the intrinsic electrophysiology of the ipsi-lesional MVN neurons persist and additional changes also occur in the electrophysiological properties of contra-lesional MVN neurons. The excitability and signal-processing characteristics of the vestibular neurons are therefore modified permanently after deafferentation.

3. *Adaptive Changes in Synaptic Connectivity in the Vestibular Reflex Networks*

In addition to the changes in the properties of MVN neurons after deafferentation after UL, the synaptic connectivity of excitatory and inhibitory pathways in the brainstem vestibular nuclei also undergoes gradual, activity-dependent re-organization. Thus 2 months after unilateral vestibular neurectomy, the strength of excitatory synaptic inputs to the ipsi-lesional MVN neurons from the contra-lesional, intact side was significantly increased. After partial vestibular neurectomy in which only one branch of the vestibular nerve is sectioned leaving the innervation of the remaining end-organs intact, there is an expansion of the excitatory synaptic inputs from the intact afferents to the ipsi-lesional MVN cells. Thus MVN neurons that are deprived of their original synaptic inputs as a result of the sectioning of the vestibular nerve branch that normally supplies them become responsive to excitatory inputs from the other, remaining intact vestibular afferents. This substitution of inputs through the re-organization of synaptic connectivity is similar to that seen in other sensory systems after partial deafferentation, for example the area of the somatosensory cortex concerned with a particular body part gradually becomes responsive to inputs from adjacent regions if its normal input region is deafferented. In the vestibular nuclei, such "re-wiring" of synaptic connectivity has the beneficial effect that the deafferented MVN neurons receive substitute excitatory inputs that may help to restore and maintain their resting discharge. However the re-wired connections may now generate quite inappropriate vestibular reflexes, since the MVN neurons which were previously concerned with for example horizontal canal afferent inputs may now receive synaptic excitation from utricular afferents and so generate horizontal eye movements in response to head movements in the vertical plane. Thus while synaptic re-wiring may help to restore resting activity in the deafferented MVN neurons and contribute to their long-term survival after UL, the generation of new and inappropriate reflexes as a consequence of re-wiring suggests that the suppression of such reflexes, by for example alternative non-vestibular strategies for gaze stabilization, may be an important part of the overall process of VC.

4. *Post-lesional Changes in the Control of Vestibular Nucleus Neurons by the Cerebellum*

While the cerebellum and in particular the flocculus has long been known to be important in calibrating the gaze-stabilizing function of the VOR, the role of the flocculus in VC has been unclear. Recent studies by Kitahara and colleagues have demonstrated that the flocculus plays an important role in the early compensation of static symptoms, particularly ocular nystagmus. An important role for the flocculus is also indicated by the finding that in a knock-out mouse lacking the delta-2 subunit of the glutamate receptor, which is selectively localized in cerebellar Purkinje cells and which is essential for cerebellar cortical plasticity, the severity of ocular nystagmus after UL is exaggerated and the time-course of recovery is

prolonged. Consistent with this are the findings that indicate that cerebellar cortical plasticity in the flocculus occurs after UL and is required for compensation. However the flocculus is not essential for VC, as even in flocculectomized animals the ocular nystagmus eventually disappears completely; thus other processes, such as the changes in intrinsic properties of MVN neurons and synaptic re-organization of the brainstem vestibular pathways may be sufficient to achieve compensation, but over a longer recovery time. In the normal development of VC and the relatively rapid subsidence of nystagmus within a few days however, the flocculus appears to play an important but as yet unclear role. As proposed by Kitahara and colleagues, the flocculus may act to inhibit the activity of contralesional MVN neurons (Fig. 1b) and so reduce the commissural inhibition they project to the deafferented ipsi-lesional MVN cells after UL.

## Interactions Between Stress, the Neuroendocrine System and Brain Plasticity During Vestibular Compensation

The development of vestibular compensation after UL is significantly affected by stress and stress-related steroids, as well as conditions such as anxiety and depression, where the normal function of the hypothalamo-pituitary-adrenal (HPA) stress axis is altered. Glucocorticoids (GCs) released by the adrenal cortex in response to HPA activation in response to stress have widespread actions throughout the body; in addition they have important modulatory effects on the function of neurons and synapses in the brain. GCs may act directly on membrane ion channels and neurotransmitter receptors to regulate their function or they may alter gene expression in neurons through specific intracellular receptors (glucocorticoid receptors, GRs or mineralocorticoid receptors, MR). GCs may also be rapidly converted by a range of enzymes to active neurosteroids. In addition to stress steroids, neurosteroids derived from the sex steroid progesterone also affect neuronal and synaptic function in the vestibular system and cerebellum.

A number of studies suggest that glucocorticoids and neurosteroids may modulate vestibular system function and compensation. Anxiety and stress in patients with vertigo significantly delays the recovery from vestibular symptoms. Conversely, treatment of patients with the glucocorticoid steroid methylprednisolone has been reported to improve vestibular compensation. Yamanaka and co-workers showed that administration of the synthetic GR agonist dexamethasone facilitated behavioral recovery following UL in rabbit; in contrast, administration of the GR antagonist RU38486 delayed compensation. Glucocorticoids and neurosteroids have direct excitatory actions on MVN neurones. However in a recent study, systemic administration of dexamethasone was found to have no effect on the rate of compensation of spontaneous nystagmus in the guinea pig.

At the neuronal level, the development of the increase in excitability of MVN neurons after UL (Fig. 1c) is dependent on activation of GRs. Thus the increase in excitability of the ipsi-lesional MVN neurons was prevented by administration of the GR antagonist RU38486 and did not develop in animals that remain anaesthetized after UL. However, in anaesthetized animals that were treated with the synthetic GR agonist dexamethasone simultaneously with UL, the increase in excitability did occur. These findings suggest that the acute stress that normally accompanies the behavioral symptoms immediately after UL may have a role in facilitating the cellular plasticity in MVN neurons. An important site of action of glucocorticoids during VC would appear to be the cerebellar flocculus. However, a critical optimal level of GR activation appears to be required, since additional stress in the form of restraint applied to a compensating animal after UL causes a retardation of the behavioral recovery.

The interactions between the stress axis, glucocorticoids and vestibular plasticity may have potentially important implications for the treatment and management of patients with balance disorders. Perhaps a factor in the known effectiveness of vestibular rehabilitation exercises in promoting VC may be the acute stress that accompanies the performance of initially aversive movements, which may facilitate the plasticity mechanisms in the brain that are necessary for VC. It is also possible that patients who are unable to compensate adequately after UL, may have pre-existing alterations in their stress axis function through depression or anxiety or develop changes in their stress axis as a result of the vestibular dysfunction and the associated symptoms. This may result in too low or too high levels of stress responses to vestibular, visual and postural challenges that may impede the cellular plasticity in the vestibular pathways necessary for VC. Further investigations to reveal the cellular mechanisms of action of stress steroids on VC are necessary in animal models, as well as studies of stress axis function in patients with balance disorders.

## Studies of Changes in Gene and Protein Expression in the MVN During VC

In a search for the molecular mechanisms of plasticity in MVN neurons during vestibular compensation, a number of studies have looked for changes in gene and/or protein expression after UL. The changes in amino acid neurotransmitter receptor efficacy, the intrinsic properties of MVN neurons and the re-organization of neural connectivity that are implicated in VC as reviewed above may be brought about by a range of molecular mechanisms. These include changes dependent on alterations in gene expression, e.g. changes in

neurotransmitter receptor subunit expression or composition or the expression of molecules regulating neural growth and axon guidance and changes not necessarily dependent on alterations of gene expression, e.g. involving changes in protein phosphorylation or other post-translational modifications of proteins. A number of studies have reported such changes in the MVN after UL (Table 1), but no clear picture has yet emerged which appears to link many of the individual findings.

In particular, painstaking and detailed analyses by Eleore and co-workers on glycine and GABA receptor gene expression in the MVN after UL have not detected significant changes that might account for the functional down-regulation of these receptors during VC. Similarly no significant changes in voltage-gated Na channels and calcium-activated K channels, which might correlate with the changes in intrinsic excitability of MVN neurons, were detected at the gene level. On the other hand, administration of protein kinase C (PKC) inhibitors has been shown to retard VC, implying that protein phosphorylation in the MVN or related sites is necessary. At present the molecular mechanisms of VC remain intriguing but largely unclear.

## Drugs and Treatment of VC

No single drug treatment for the debilitating symptoms of unilateral vestibular loss and the promotion of vestibular compensation exists, no doubt reflecting its multifactorial and complex nature. Anticholinergics and neuroleptics are often used for their anti-emetic effects, but experimental evidence that these drugs promote vestibular compensation is lacking. Histaminergic drugs have long been used to treat vestibular disorders in man and their mechanisms of action have also been investigated. Vestibular compensation is facilitated by histamine and is associated with increased central histamine release and alterations in histamine H3 receptor expression in the vestibular nuclei. Histamine has widespread actions in brain, affecting alertness and arousal as well as modulating neurotransmitter release and actions at many types of synapses. Antagonists of the H1-receptor that pass the blood brain barrier (typical compounds are diphenhydramine, promethazine and dimenhydrinate) have sedative as well as vestibulodepressant effects. Their use for motion sickness is well established and the mechanism of action is believed to include anti-emesis via histaminergic effects on emetic

**Vestibular Compensation and Plasticity. Table 1** Summary of studies investigating changes in gene and protein expression in MVN during vestibular compensation

| Main finding | References |
|---|---|
| Asymmetric changes on c-fos expression during VC in rat | Kaufman et al. 1992, Cirelli et al. 1996 |
| Increased phosphorylation of several likely protein kinase C substrates in the MVN+ prepositus hypoglossi 10–53 h post-UVD | Sansom et al. 1997 |
| Intracerebroventricular administration of protein kinase C (PKC) inhibitors retards recovery of spontaneous nystagmus in rat up for to 8 h post-UVD | Balaban et al. 1999 |
| Up-regulation of three unidentified proteins in guinea pig ipsilateral VN 1 week after UVD | Ris et al. 1999 |
| No change in PKC-mediated phosphorylation in guinea pig MVN, but increased phosphorylation in contra-lesional prepositus hypoglossi, 10–53 h post-UVD | Kerr et al. 2000 |
| Increased immunoreactivity for phosphorylated form of cAMP/calcium response element binding protein (pCREB) bilaterally in the rat VN, 1–24 h post-UVD | Kim et al. 2000 |
| Inhibition of protein kinase C (PKC), but not $Ca^{2+}$ /calmodulin-dependent kinase II (CaMKII), in the VN affects recovery from spontaneous nystagmus but not postural symptoms in guinea pig | Sansom et al. 2000 |
| No change of GAP-43 protein or mRNA in rat vestibular nuclei after UVD | de Waele et al. 2000 |
| Down-regulation of NR2A, GluR2 and GluR7 mRNA in ipsi-lesional MVN 6 h post-UVD, but not at 50 h post-UVD, in the rat | Horii et al. 2001 |
| Increase in expression of GAD65 mRNA bilaterally, and GABA-A receptor alpha-1 subunit mRNA ipsilaterally, in rat VN 6–50 h post-UVD | Horii et al. 2003, Neuroreport 14, p2359 |
| No change in voltage-gated Na channels or Ca-activated K channels in VN after UVD | Patko et al. 2003 |
| Microarray analysis showed differing gene expression between ipsi- and contra- rat VNC, 6 h after UVD | Horii et al. 2004 |
| Increased asymmetrical expression of pERK1/2 in rat VN 5–90 min post-UVD | Kim et al. 2004 |
| No change in glycine receptors and gephyrin protein in VN after UVD in rat | Eleore et al. 2004 |
| Increase in histamine H3 receptor expression in rat ipsi-lesional VN within 48 h post-UVD | Lozada et al. 2004 |
| No change in GABA-A and GABA-B receptor mRNA after UVD in rat | Eleore et al. 2005 |

centres in the brain, as well as unspecific sedative effects of the drugs. However it is likely that the overall sedative effect of H1-antagonists retards rather than promotes vestibular compensation, but this issue has not been investigated. The anti-vertigo effects of two calcium channel antagonists, flunarizine and cinnarizine have also been attributed to H1-receptor antagonism. Betahistine, a histamine analogue displaying partial H1 agonism and H3 antagonism, has been widely used for the treatment of Meniere's disease and vestibular disorders. Its mechanism of action may include the modulation of central histamine release and its excitatory actions on H2 receptors.

Effective vestibular rehabilitation after vestibular loss is achieved by exercise and training which involves stimulation of the visual and somatosensory systems, presumably allowing and promoting activity driven sensory substitution in the central vestibular pathways. It may also be relevant that such exercises also stimulate a moderate stress response, which may facilitate brain plasticity. Slow or incomplete compensation in some subjects may also involve altered responses to stress, as in depression or anxiety as discussed above, though this remains to be established.

## Vestibular Disorders

►Disorders of the Vestibular Periphery

## Vestibular Ganglion

### Synonyms

►Ganglion vestibulare

### Definition

In the vestibular ganglion are situated the somas of the bipolar ganglion cells which receive the signals from the sensory cells and conduct them in the direction of the brainstem. In doing so, they project to the vestibular nuclei (medial, superior, inferior) and to the cerebellum.

## Vestibular Ganglion Cells

### Definition

These cells comprise bipolar vestibular primary afferents. One process of these afferents receives excitatory signals from vestibular hair cells. The other process forms the vestibular nerve that projects to the brainstem. The somas of vestibular ganglion cells are clustered peripherally in Scarpa's ganglion.

►Vestibular Primary Afferent Pathways

## Vestibular Nerve

### Synonyms

N. vestibularis

### Definition

Part of cranial nerve VIII, the vestibulocochlear nerve.

Predominantly sensory nerve whose fibers convey information from the vestibular parts of the inner ear (sacculi, utricles and semicircular canals) to the vestibular nuclei (medial, superior and inferior) and the cerebellum. The somas of the bipolar ganglion cells are located in the vestibular ganglion.

►Nerves

## Vestibular Neuritis

### Definition

Disorder of the labyrinth which causes the sudden onset of severe rotatory vertigo often accompanied by nausea and vomiting. The vertigo usually subsides over the course of several days although disequilibrium and unsteadiness may persist for a longer period of time. A viral etiology has been proposed. The differential diagnosis of acute vertigo includes central causes such as cerebellar hemorrhage or infarction.

►Disorders of the Vestibular Periphery

## Vestibular Nuclei

### Definition

Clusters of cells near the dorsal surface of the brainstem (near the entry zone of the vestibular nerve within the cerebellar peduncle) that receive projections from primary vestibular afferents. There are seven such nuclei including: medial, descending, superior and lateral vestibular nuclei (MVN, DVN, SVV, LVN), parasolitary nucleus (Psol), Y-group and nucleus intercalatus.

►Vestibular Primary Afferent Pathways in Mammals
►Vestibular Secondary Afferent Pathways
►Vestibulo-Spinal Reflexes

## Vestibular Nystagmus

### Definition

A physiological nystagmus that occurs generally involuntary when the head is rotated. It consists of two components of eye movements: slow phase, which is compensatory movement to keep the visual image stationary on the retina (called vestibulo-ocular reflex; VOR), and quick phase, which rapidly reset the eye position deviation by slow phase. The proprioceptors of the vestibular system for VOR are the semicircular canals of the inner ear. There is also a pathological form resulting from damage to the vestibular system. The direction of the slow phase is toward the labyrinth that has sustained damage.

## Vestibular Primary Afferent Pathways in Mammals

Adel Maklad, Feng Feng, Bernd Fritzsch
Department of Biology, University of Iowa, Iowa City, IA, USA

### Synonyms

Vestibular system

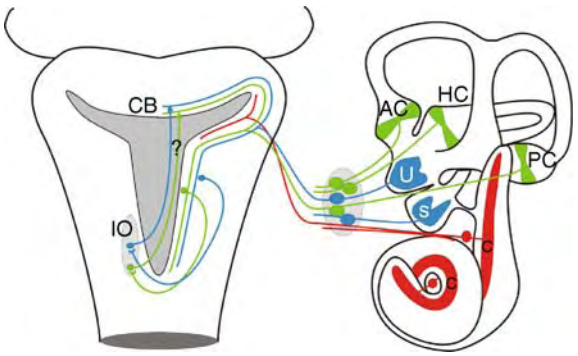
### Definition

The primary vestibular and auditory neurons delaminate from the ventromedial aspect of the otocyst and migrate away to the presumptive vestibular (Scarpa's) and auditory (spiral) ganglion connecting the ear with the hindbrain. Primary vestibular afferents, which innervate the ►otolith organ and cristae sense linear and angular accelerations and thus help control a variety of motor and visceral systems. Vestibular primary afferent fibers enter the brainstem at the ponto-medullary junction. These fibers pass below the restiform body and then bifurcate into ascending and descending branches. The bundle containing thicker axons enters the medulla between the ventral aspect of the inferior cerebellar peduncle and the dorsal aspect of the spinal tract of the trigeminal nucleus. It turns caudally and then passes into the vestibular complex. The bundle with thinner axons ascends to the cerebellum by passing through the superior vestibular and lateral ►vestibular nuclei. The thin axons then distribute to several folia within the cerebellum, but primarily to the ipsilateral uvula-nodulus. The vestibular complex and uvula-nodulus are responsible for the initial processing of vestibular information by the central nervous system.

### Characteristics

The ear develops from placodal thickenings of the ectoderm on both sides of the hindbrain into a complex structure of ducts and recesses that contains the five vestibular endorgans (three canal cristae, the saccule and utricle) and the cochlea (Fig. 1).

From the ventromedial aspect of this otocyst, a group of neuroblasts delaminate under the influence



**Vestibular Primary Afferent Pathways in Mammals.**
**Figure 1** Schematic of the vestibular pathway connections. Vestibular neurons (*green and blue ovals*) terminate with their distal processes in a given endorgan (*green* to angular acceleration sensitive cristae organs, *blue* to linear acceleration sensitive gravistatic organs). Central projections of these neurons reach the vestibular nuclei of the brainstem and the cerebellum (*CB*). In contrast, auditory neurons (*red circles*) project from the cochlea (*C*) to the auditory nuclei of the brainstem. Vestibular neurons in the vestibular nuclei receive partially overlapping angular and linear information from several canal cristae and otolith organs. Second order vestibular neurons project to distinct subnuclei of the inferior olive (*IO*), which in turn may project in a partially segregated fashion to the vermis. Abbreviations: *AC* anterior crista; *C* cochlea; *CB* cerebellum; *HC* horizontal crista; *IO* inferior olive; *PC* posterior crista; *S* saccule; *U* utricle.

of specific genes [1] and migrate away to form the vestibular ganglion between the ear and the hindbrain. There they differentiate into bipolar neurons, which contact the hair cells of the labyrinth and the second order vestibular neurons of the brainstem, the vestibular nuclei [1]. The vestibular neurons are located in the vestibular ganglion, also called Scarpa's ganglion, which is divided into two parts, the superior and the inferior divisions. The centrally projecting axons from the vestibular ganglion form, together with axons projecting from the auditory (spiral ganglion) neurites, the eighth (stato-acoustic) nerve. The central processes of the primary afferent vestibular neurons divide into an ascending and descending branch after entering the brain stem at the inner aspect of the restiform body (Fig. 1). The primary afferents terminate in the vestibular nuclei. Some primary vestibular neurites pass directly to the cerebellum, in particular the nodulus and uvula of the vermis [1].

## Topology of Vestibular Ganglion

Largely based on older techniques for tracing and on non-mammalian data, a clear-cut segregation of the vestibular ganglion neurons has been proposed based on their endorgans and the sensations they convey [2]. In the last two decades however, several reports have been published that do not agree with this traditional notion [1]. These reports concluded that the vestibular ganglion neurons of rodents are not exclusively organized in an endorgan specific fashion. They are only partially segregated with some random distribution. Neurons from different endorgans that convey different information show an overlapping distribution (Figs. 1, 2).

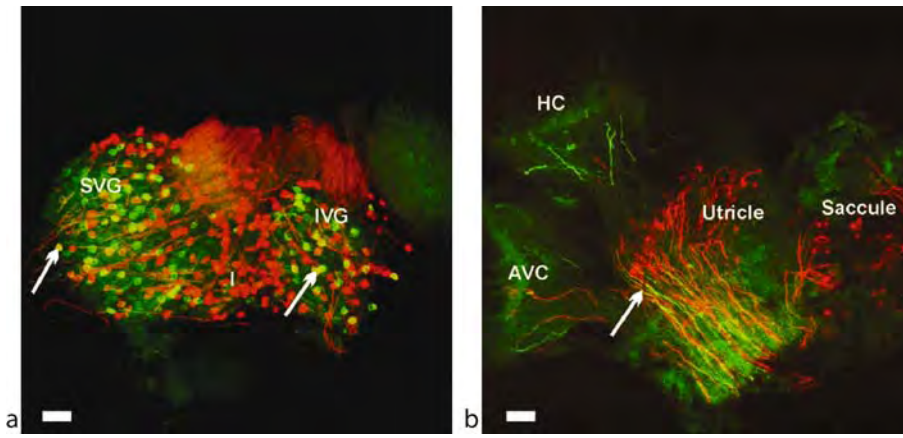
Based upon ultrastructural characteristics, vestibular ganglion neurons can be classified into two main types, large neurons and small neurons. ►Vestibular ganglion cells vary in size with mean diameters ranging between 21 and 15 μm depending on the species. These two size classes correspond to different functions based on their termination in the sensory epithelia [3]. Vestibular neurons are among the largest ganglion cells and can be 50 μm in diameter. Quantification using various counting procedures has revealed numerical differences between studies as well as across development of a given species. For example, total numbers of the vestibular ganglion cells in mouse rise to peak with a mean of 9200 at E19, although there is a subsequent decline to an average of 4600 at P0 in rats, which is maintained through adult life. Whether or not this reported decline in numbers is mediated by the neurotrophic factors that are essential for vestibular ganglion survival [4] remains unclear. Using unbiased counting procedures, others reached different numbers for mice and humans.

A detailed mapping study of vestibular neuron location with respect to endorgans using selective dye applications [1] showed that the distribution of the vestibular ganglion cells for a given endorgan is not entirely random. Most of the ganglion cells labeled from a specific endorgan are tightly packed and surrounded by an area of sparse distribution, shared with other primary neurons that project to other endorgans (Fig. 2).

Having migrated to their definitive location, vestibular ganglion cells send axons to second order neurons in the vestibular nuclei and the cerebellum. Migration seems to depend on a number of factors [5] and the molecular basis of peripheral projection development shows an increasing list of very different molecules that are involved in finding the right endorgan and terminating there [5].

## Vestibular Primary Afferent Projection to Vestibular Nuclei

The primary afferent vestibular neurons project to four nuclei that comprise the vestibular complex. The four nuclei of the vestibular nuclear complex are the lateral vestibular nucleus (also called Deiter's nucleus), the medial vestibular nucleus, the superior vestibular nucleus and the inferior (or descending) vestibular nucleus. Several smaller nuclei not included in the



**Vestibular Primary Afferent Pathways in Mammals. Figure 2** Retrograde labeling of vestibular primary afferent projection to cerebellum. Retrograde filling of sensory neurons (a) and of afferents in the vestibular epithelia (b) is shown after a double application in the nodulus (*green*) and in the uvula (*red*) of a 10-day-old mouse. Note the few double labeled sensory neurons in the vestibular ganglion (a *arrows; yellow cells*) that suggests that only few sensory neurons have branches to both folia of the cerebellum. The sensory neurons to the uvula (*red,* a) show an aggregation in the isthmus region (*I*). Fibers to the gravistatic maculae derive predominantly from the uvula (*red,* b) whereas fibers to the cristae are more often labeled from the nodulus (*green*, b). Bar indicates 100 μm.

classical groups, the parasolitary nucleus, Y-group and X-group also receive vestibular primary afferents [6].

It is generally agreed that, in vestibular central representation, each endorgan has a domain of almost exclusive projection and a domain of sparse projection overlapping with other endorgans (Fig. 2), reproducing the peripheral distribution pattern at the level of the ganglion [7]. Such a partial functional as well as anatomical overlap is best studied in the frog [8]. In rats and mice, anterior and lateral cristae, utricle and saccule maculae are in relation with neurons largely overlapping in the superior ganglion. Neurons localized in the inferior ganglion and connected to the posterior crista and saccular macula show tighter clustering but incomplete segregation [1]. This central overlapping pattern may be a universal functional feature of the vestibular system in which monosynaptic afferent canal and otolith inputs [8] converge. These convergent inputs are capable of responding in a finely graded fashion to signals originating from more than one endorgan [7].

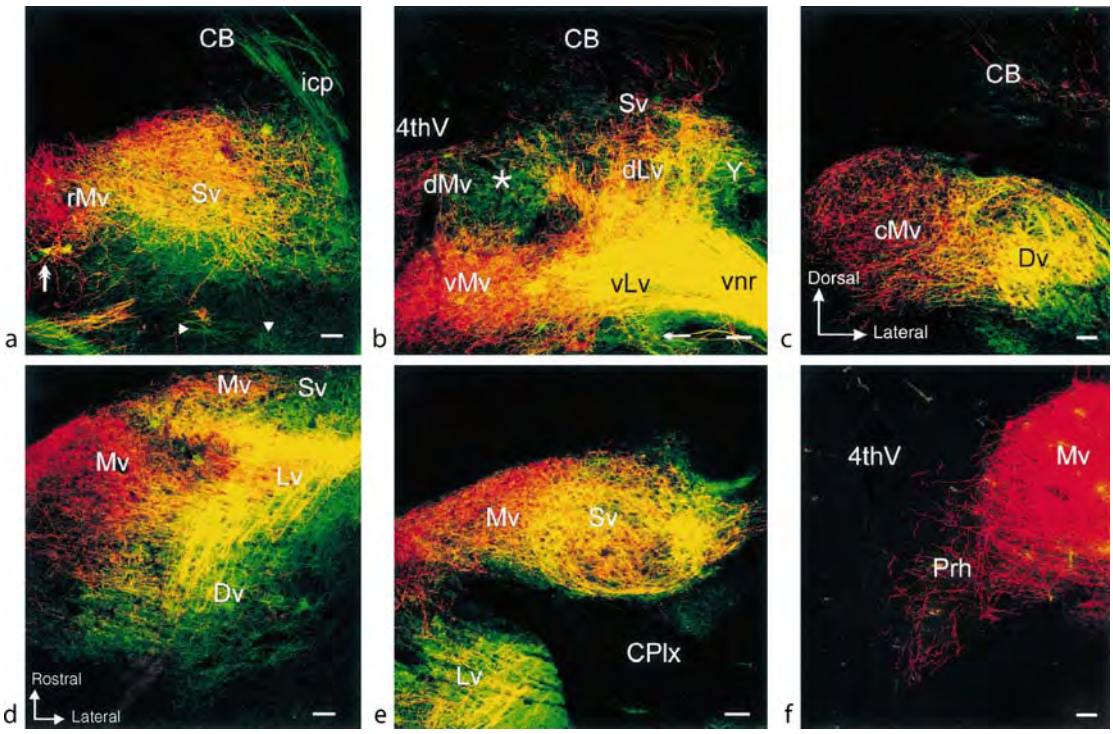
## Superior Vestibular Nucleus

Mice show an extensive overlap of fibers of gravistatic and cristae afferents (Fig. 3).

Despite the overlap of these endorgans throughout the nucleus, saccular terminals tend to be more in the lateral and ventral region of the nucleus, while the posterior canal terminals concentrate in the dorsal and medial regions [9]. In the gerbil, saccular projections are sparse [7] and utricular nerve terminations are seen primarily in the lateral part of the nucleus [7]. The posterior canal projects to the medial superior vestibular nucleus. Lateral canal afferents project to the larger part of the nucleus, with heavier projections rostrally and medially while anterior canal afferents project most heavily medially, centrally and inferiorly [7]. Anterior afferents project most strongly to the medial portion of the nucleus in the pigeon [7], squirrel monkey and cat [2] though in the latter species anterior canal terminals are present throughout that nucleus. Lateral canal afferents project primarily to the central [2] or medial portion of the nucleus in the pigeon, the medial and ventral portion in the squirrel monkey [7] and ventrally in the cat, though terminals are present through the nucleus [7].

## Lateral Vestibular Nucleus

The lateral vestibular nucleus is classified into two divisions based on cytoarchitecture and afferent and efferent connections. The dorsal division of the lateral vestibular nucleus contains multipolar giant cells [7]. Previous reports stated that the dorsal lateral vestibular nucleus does not receive primary vestibular afferent in birds, gerbils [7], cats and monkeys [7]. Others suggested the existence of a minor primary vestibular input in opossum, chinchilla and guinea pig. The mouse data reported substantial overlapping projection from the saccule and posterior canal [1]. There is still argument about primary vestibular afferent projection to the ventral lateral vestibular nucleus. Some investigators reported exclusive gravistatic projections [7] or exclusive utricular projection. Others reported a projection common to otolith and canals [2].



**Vestibular Primary Afferent Pathways in Mammals. Figure 3** Central projection of vestibular endorgans. Central projection of the saccule and posterior crista (*PC*) at P7 mice as shown in transverse (a-c) and horizontal (d-f) sections. (a) Section of the brainstem at the rostral nuclear level, showing the segregation and overlap of the saccular and PC projections in the superior (*Sv*) and medial (*rMv)* vestibular nuclei. Note the single and double-labeled efferent neurons near the rMv (*arrow*). (b) A section of the brainstem at midnuclear level shows the saccular and PC projections to the various components of the vestibular nuclear complex. Note that there are areas of segregation (indicated by *asterisk*, Y, vMv, *double arrow*) as well as areas of overlap. (c) A section of the brainstem at the caudal nuclear level shows the overlapping projection of the saccule and PC projections to the Dv and Mv. (d) This section demonstrates the vertical segregation of the saccule and PC projection. Note that the saccular projection is more prominently to the more lateral parts compared to the medial projection of the PC. (e) This more dorsal section shows the distribution of the saccule and PC fibers in the Sv and rMv. Note the segregation in the Mv and Lv, but overlap in Sv. (f) A more ventral section shows only the PC projection throughout the rostrocaudal extent of the Prh. Abbreviations: *CB* cerebellum; *cMV* caudal medial vestibular nucleus; *Dv* descending vestibular nucleus; *icp* inferior cerebellar peduncle; *Lv* lateral vestibular nucleus; *Mv* medial vestibular nucleus; *Prh* prepositus hypoglossi; *Sv* superior vestibular nucleus; *vLV* ventral lateral vestibular nucleus; *vMV* ventral medial vestibular nucleus; *vnr* vestibular nerve root. Orientation of (a-c) is indicated in (c) and (d-f) is indicated in (d). Bar indicates 100 µm.

## Medial Vestibular Nucleus

This nucleus has medium to small size neurons and is involved in projections to the extraocular motor nuclei, the medial vestibulospinal tract and the vestibular commissural system [6]. In birds, otolith and canal projections are topographically organized with variable degrees of overlap [2]. In mammals, the anterior and posterior canals project heavily and completely to the medial vestibular nucleus. The densest posterior canal projections were reported rostro-laterally in the cat, while in the gerbil, mouse and guinea pig these projections were more distributed throughout the nucleus [1]. The otolith projection has a circular region in the dorsal lateral quadrant of the medial vestibular nucleus that is surrounded by the posterior canal fibers [1].

## Inferior Vestibular Nucleus

The inferior vestibular nucleus projects to the spinal cord, contralateral vestibular nuclei, cerebellar vermis and ▶cerebellar nuclei [6]. In pigeon, overlapping, but more topographically organized projections from the canals and otolith organs were reported [2]. In mice, terminals from both endorgans were obvious in the central and lateral part of the inferior vestibular nucleus where the more numerous saccular terminals overlap with the posterior canal fibers [1]. Similar arrangements were found in the monkey. This nucleus also receives fibers from the vermis of the cerebellum and appears to be a site where vestibular inputs are integrated with inputs from other sensory systems and inputs from the cerebellum [6].

V

### Cell Group Y and X

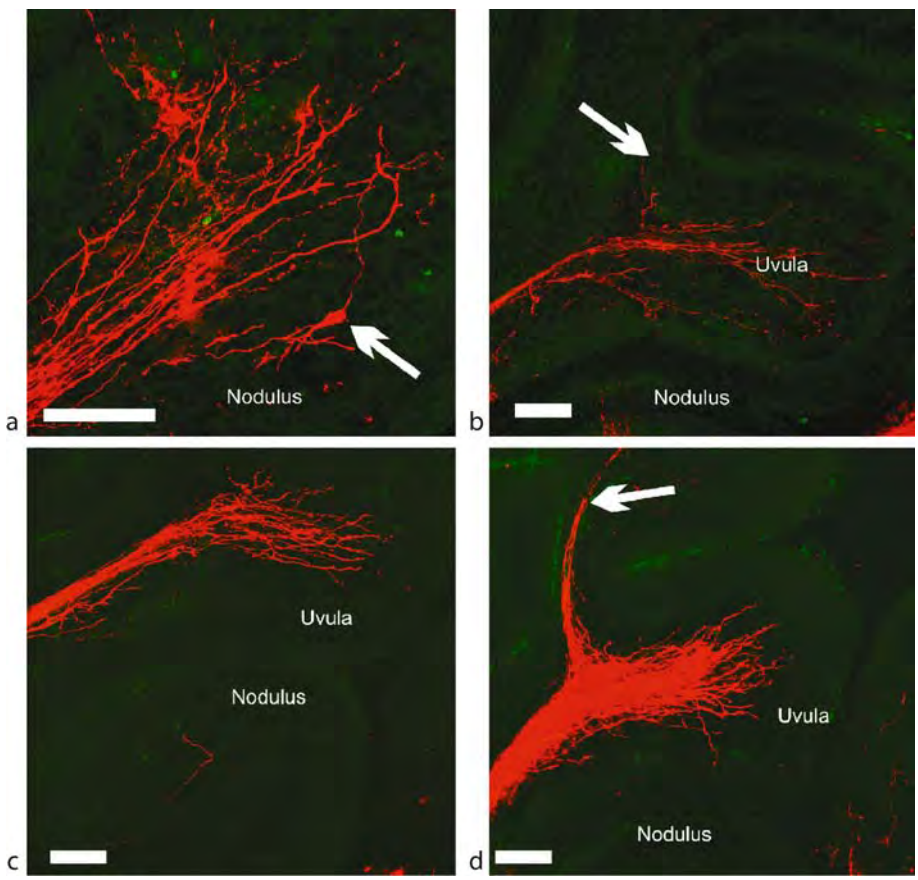
Cell group Y is a small cell group positioned dorsal to the restiform body, medial to the dorsal cochlear nucleus and lateral to the lateral vestibular nucleus. Exclusive saccular projection to group Y was described in cat, gerbil and monkey. The most profound saccular input is to the ventral portion of Y [7], while much less is targeted to the dorsal portion. However, more dorsolateral projections from the posterior canal are reported in mice [1]. Cell group X receives spinal input from C1 to C3 dorsal roots and projects to the cerebellum. In macaque, opossum and cat, this nucleus is also reported to receive cerebellar afferents from the fastigial nucleus. More recent data showed a minor input to this nucleus largely from the saccule and posterior canal in the newborn mouse [1].

### Vestibular Primary Afferent Projections to Cerebellum

Although, several cerebellar folia receive scattered projections from vestibular primary afferents, the terminals of more than 90% are restricted to the ipsilateral uvula-nodulus [6]. Only a fraction of vestibular afferents projects to other cerebellar folia [1]. Vestibular afferent fibers are among the earliest in development to reach the cerebellum [1] and contact the granule cells and the unipolar brush cells as mossy fibers in neonates [10]. Brodal and Hoivik suggested that primary vestibular afferents reach the flocculus, nodulus, ventral and lateral cerebellum nucleus. Subsequent reports suggested different vermal folia as receiving primary vestibular afferent projections.

### Cerebellar Nucleus

The topography of vestibular primary afferent projections to the cerebellar nuclei is still unclear. Carpenter described primary vestibulocerebellar afferent fibers to the medial cerebellar nucleus of cat while others saw fibers passing through but were not able to determine if they were fibers of passage or terminals. In rat, fibers detected by degeneration methods appear



**Vestibular Primary Afferent Pathways in Mammals. Figure 4** Projection of vestibular primary afferents to the cerebellum. The tracer application was restricted to the posterior crista (a and b) or saccular macula (c and d) in P7 mice. Primary afferent projections to the cerebellum from the posterior crista are most prominent to the nodulus (b) with fewer fibers to the uvula (a). In contrast, primary saccular afferents projected mainly to the uvula, with only occasional fibers extending to nodulus (c and d). Fibers terminate in the inner granular layer with a prominent projection to unipolar brush cells shown transcellularly filled in (b). Bar indicates 100 μm.

to project only to caudal portions of the medial cerebellar nucleus. Dye tracing studies have demonstrated saccular projections to the lateral and interposed cerebellar nuclei and utricular projections to the medial and anterior interposed cerebellar nuclei [7]. Lateral and anterior canal afferents also terminate in the interposed nucleus [7].

### Vermis

Primary vestibular afferents end in a common and overlapping pattern in the vermis, particularly in the uvula and nodulus [10]. Other data suggested that only 60% of all primary afferents project directly to the cerebellum, almost exclusively to the nodulus and uvula [1]. Physiological data demonstrate that primary vestibular neurons convey angular and linear motion to the vestibulo-cerebellar cortex in specific, partially segregated patterns (Fig. 3).

The nodulus receives a much more prominent input from the canal cristae. In contrast, the uvula receives mixed projections biased toward fibers from the maculae and, to a lesser extent, from the canal cristae [1,2,10]. Some reports mention utricular projections to the dorsal uvula in some species [7], while anterior and lateral canal afferents project primarily to uvula and nodulus [7]. Retrograde tracing studies support the notion of a segregated cerebellar projection [1,6]. The primary afferent vestibular input is largely restricted to the vermis, mainly to the nodulus and uvula, with very sparse projection to other vermal folia [1]. Earlier reports of an extensive and topographic projection of the ear to the flocculus and paraflocculus [6] were not confirmed by others. The vermis also receives vestibular climbing fibers originating from two subnuclei of the contralateral inferior olive, the β-nucleus and dorsomedial cell column (Fig. 4). They cross the midline to synapse on Purkinje neurons in the contralateral uvula-nodulus [6].

### Conclusion

The topology of vestibular afferent inputs to the vestibular nuclei and cerebellum is both segregated and overlapped. The overlap of primary afferent terminals from several endorgans provides opportunities for sensory integration. Overall, the lateral vestibular nucleus receives inputs from the utricle and ►semicircular canals. The medial and superior vestibular nucleus receives inputs primarily from the semicircular canals. The inferior vestibular nucleus receives inputs from semicircular canals, utricle, saccule and cerebellar vermis. Several cerebellar folia receive scattered projections from vestibular primary afferents; the terminals of more than 90% are restricted to the ipsilateral uvula-nodulus. Vestibular ascending fibers originate from two subnuclei of the inferior olive, the β-nucleus and dorsomedial cell column. It is possible that the differential information processing of angular and linear acceleration information in vestibular nuclei is related to these subnuclei, which in turn project to the cerebellar vermis, which receives a segregated input from primary vestibular afferents (Fig. 4). While some evidence for such a parallel and convergent processing system exists, not all the details have been verified through multicolor tract tracing.

## Vestibular Secondary Afferent Pathways

Neal H. Barmack
Neurological Sciences Institute, Oregon Health & Science University, Beaverton, OR, USA

### Synonyms

Vestibular nuclei; Secondary vestibular circuitry

## Definition

Vestibular secondary afferent pathways are neural circuitry that includes the afferent and efferent connections of vestibular nuclear neurons. The vestibular nerve branches as it enters the brain stem into two fiber bundles containing axons of unequal thickness. One branch, containing thicker axons, enters the medulla between the ventral aspect of the inferior cerebellar peduncle and the dorsal aspect of the spinal tract of the trigeminal nucleus. This branch turns caudally and passes into the vestibular complex. The branch with thinner axons ascends to the cerebellum by passing through the superior vestibular and lateral ►vestibular nuclei (SVN, LVN). This review focuses on secondary vestibular neurons, their afferent and efferent connections and some of the reflex functions of the central nervous system to which this circuitry contributes.

## Characteristics

### Vestibular Nuclei

The vestibular complex has four "classical" nuclear groups, (i) medial vestibular nucleus, MVN, (ii) descending (or spinal) vestibular nucleus, DVN, (iii) lateral vestibular nucleus (Deiter's), LVN and (iv) superior vestibular nucleus, SVN. The borders of the individual vestibular nuclei are difficult to distinguish based on cytological characteristics (Fig. 1).

Several smaller nuclei, not included in the "classical" group, nonetheless receive vestibular primary afferents. These include (i) the parasolitary nucleus (Psol), (ii) Y-group and (iii) the nucleus intercalatus (Staderini). The Psol lies wedged between the MVN and DVN in the most caudal part of the vestibular complex. It consists of a compact cluster of small GABAergic neurons extending from the tract of the solitary nucleus to the surface of the fourth ventricle (Fig. 2).

The Y-group is divided into dorsal and ventral divisions. The ventral division lies in a crescent that encapsulates the inferior cerebellar peduncle, lateral to the caudal aspect of LVN. The dorsal division lies below the interpositus nucleus, caudal to where the cerebellum joins the brainstem. Rostrally, the dorsal and ventral divisions merge.

Dorsal Y-group neurons receive ipsilateral vestibular primary afferents, as well as bilateral projections from vestibular secondary afferents. The ventral division of the dorsal Y-group projects to the ipsilateral flocculus, nodulus and contralateral oculomotor complex. The dorsal division projects contralaterally to the dorsal cap and beta nucleus of the inferior olive (Fig. 2a,b).

Three nuclei adjacent to the vestibular complex lack primary afferent vestibular projections, but are nonetheless often included in discussions of the vestibular complex. The ►nucleus prepositus hypoglossi (NPH) receives most of its input from secondary vestibular neurons, as well as projections from cerebellum and cerebellar nuclei. Cells in the NPH project bilaterally to the vestibular nuclei, most densely to the ipsilateral MVN, DVN and ventrolateral LVN. The NPH also projects to the flocculus, reticular formation, medial rectus subdivision of the ipsilateral oculomotor nucleus (III), contralateral abducens nucleus (VI) and contralateral ►dorsal cap of the inferior olive (Fig. 2a). The descending projection to the dorsal cap is composed of cells expressing acetylcholine and GABA.

Single unit recording from NPH neurons suggests that the NPH encodes vestibular and eye movement-related information. In the monkey, the activity of NPH neurons is not modulated by either vestibular or optokinetic stimulation when the monkey is trained to maintain fixation. Rather NPH neurons encode eye position exclusively.

Two other nuclei lie adjacent to the vestibular complex. Nucleus x, is a small-celled nucleus lateral to the caudal DVN. Nucleus z consists of a cluster of small cells rostral to the anterior pole of the nucleus gracilis. The functions of these nuclei remain unknown.

### Topography of Primary Afferent Projections to the Vestibular Complex

Topography within the vestibular complex exists, but it does not conform to the cytoarchitecturally defined boundaries. Within the SVN, secondary neurons responsive to stimulation of the ipsilateral anterior semicircular canal are found more laterally than are neurons responsive to stimulation of the ipsilateral horizontal semicircular canal.

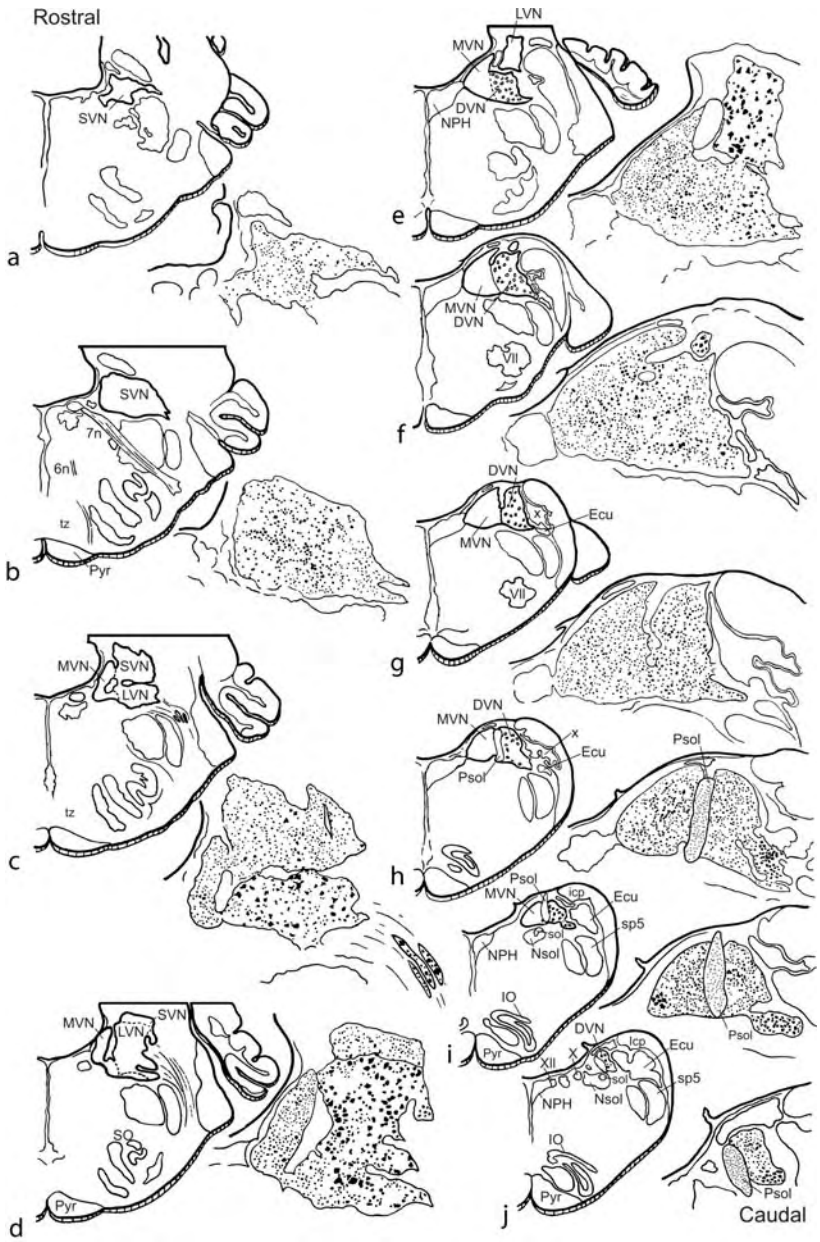
A second kind of "negative topography" is indicated by the projection of horizontal semicircular canal afferent terminals to all vestibular nuclei *except* the LVN and Psol. Psol neurons are driven exclusively by stimulation of the ipsilateral *vertical* ►semicircular canals and ►otoliths. Secondary neurons within the LVN receive vestibular primary afferents from the ipsilateral sacculus.

### Vestibular Primary Afferent Convergence

While vestibular primary afferents may convey information from single end organs, the discharge of secondary vestibular neurons indicates convergence of information from more than one end organ. This convergence combines information from semicircular canals and otoliths. Some secondary neurons may retain inputs only from single otoliths. Such "private lines" might be useful in discriminating stimuli that fall within the frequency ranges of both semicircular canals and otoliths.

### Vestibular Internuclear Projections

The pattern of interconnections within the vestibular complex has been mapped with microinjections of HRP into the vestibular complex of the rabbit. Interconnections between the SVN–DVN and SVN–MVN are



**Vestibular Secondary Afferent Pathways. Figure 1** Vestibular nuclei of the cat. Transverse sections extend from the rostral (a) through the caudal (j) poles of the vestibular complex. reciprocal. A group of larger neurons in the rostro-ventral MVN, SVN and LVN receive inputs from smaller cell regions of MVN, SVN and DVN, but do not reciprocate. The MVN has a non-reciprocal projection to the DVN. The dorsal Y-group receives projections from both ipsilateral and contralateral SVN.

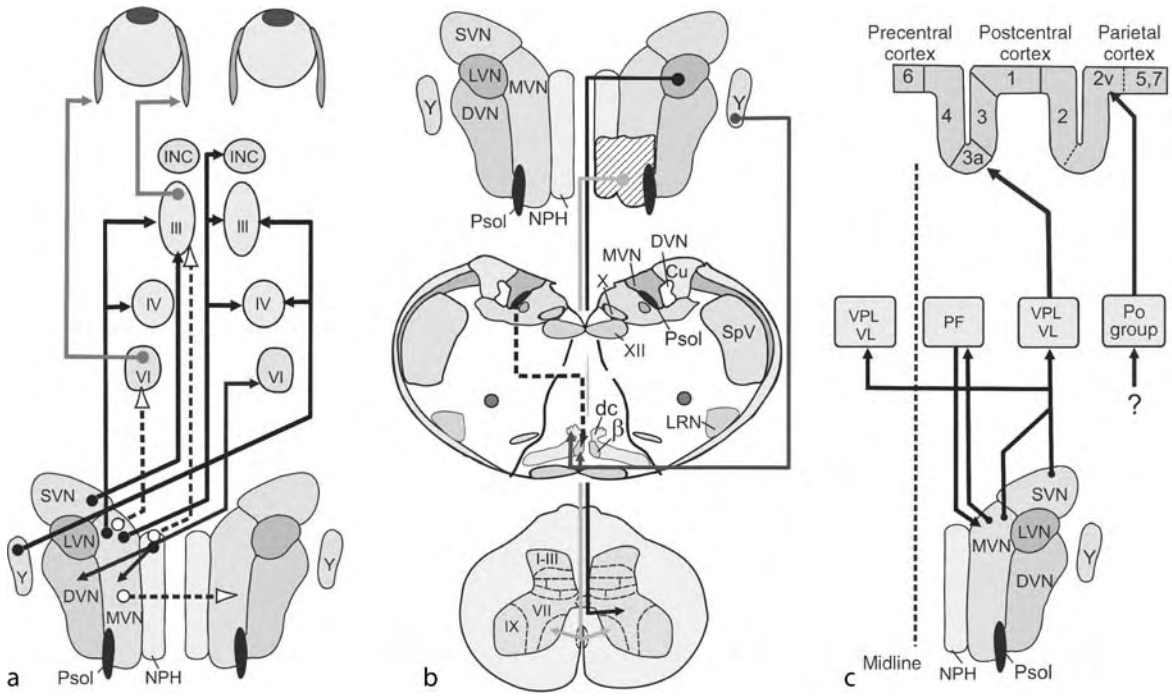
## Vestibular Commissural Projections

The vestibular nuclei, with the exceptions of the LVN and Psol, are topographically interconnected through the commissural system. However, the commissural connections are not restricted to homologous nuclei (Fig. 3).



**Vestibular Secondary Afferent Pathways. Figure 2** Ascending and descending connections of the vestibular complex. (a) Projections of vestibular complex onto oculomotor apparatus. (b) Descending projections of vestibular complex to spinal cord and to inferior olive. (c) Ascending projections of vestibular complex to thalamus and cortex. Abbreviations: *β*, β-nucleus; *Cu*, cuneate nucleus; *dc*, dorsal cap of Kooy; *DVN, MVN, LVN, SVN*, descending, medial, lateral and superior vestibular nuclei; *INC*, interstitial nucleus of Cajal; *LRN*, lateral reticular nucleus; *NPH*, nucleus prepositus hypoglossi; *PF*, parafascicular nucleus; *Psol*, parasolitary nucleus; *SpV*, spinal trigeminal nucleus; *PO group*, posterior thalamic nuclear group; *VL*, ventrolateral nucleus; *VPL*, ventral posterior lateral nucleus; *III, IV, VI*, oculomotor cranial nuclei; *X*, dorsal motor nucleus of vagus; *XII*, hypoglossal nucleus; *Y*, Y-group. Modified from [2–4,5].

Rather, cells within a nucleus on one side of the brainstem, say the left MVN, project to the contralateral SVN and DVN as well as the contralateral MVN. Electrical stimulation of the utricular macula evokes excitation in ipsilateral secondary vestibular neurons and inhibition in more than 50% of the contralateral secondary vestibular neurons excited by ipsilateral utricular stimulation. Only 10% of ipsilaterally saccular-sensitive secondary vestibular neurons are inhibited by contralateral saccular stimulation.

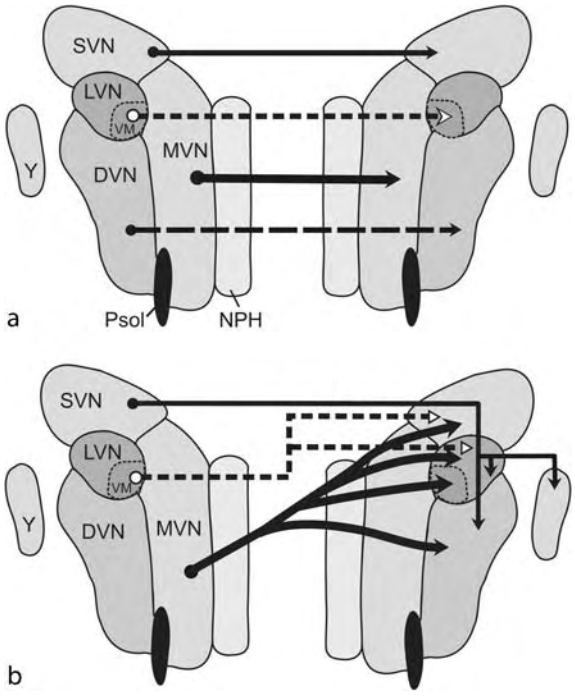
## Ascending Projections of Vestibular Nuclei

Targets of secondary vestibular afferents are diverse. The rostral halves of DVN, MVN and SVN provide an ascending input to cranial motor nuclei III, IV and VI, controlling the reciprocal contractions of extraocular muscles. Other brainstem nuclei that receive ascending projections from secondary vestibular neurons include nucleus Darkschewitch, sensory trigeminal nucleus, interstitial nucleus of Cajal and the subparafascicular complex. The subparafascicular complex projects reciprocally back to the ipsilateral MVN (Fig. 2c).

Several ascending projections to the thalamus-cortex originate from the rostral part of the vestibular complex to the ventrobasal thalamus (VPL, VPM, VPI and VPL) (Fig. 2c). Neurons in the ventrobasal complex are driven by stimulation of deep proprioceptors and joint receptors as well as vestibular inputs.

Vestibular thalamo-cortical projections terminate in areas 3aV and T3 and parietal visual cortex. These cortical areas receive optokinetic and somatosensory as well as vestibular inputs (Fig. 2c). Humans with damage to parietal cortex do not recognize true vertical. Deprived of surrounding visual cues, they cannot correctly align a disk with a line on it so that the line has a true vertical orientation. Cortical vestibular areas project back to the vestibular complex, suggesting that these cortical regions may supersede reflexes evoked by activity in vestibular primary afferents.

The caudal aspect of the NPH and MVN project to several folia within the cerebellum, including the anterior and posterior vermis and flocculus. Immunohistochemical surveys show that most, if not all of these ascending projections are cholinergic and originate from the caudal MVN and NPH. Immunohistological



**Vestibular Secondary Afferent Pathways.**
**Figure 3** Commissural projections within the vestibular nuclei of the gerbil. (a) Three vestibular nuclei (SVN, MVN and DVN) have homologous and reciprocal connections. The LVN and Psol do not. (b) The vestibular nuclei also have divergent connections to non-homologous contralateral vestibular nuclei. Abbreviations: *DVN, MVN, LVN, SVN*, descending, medial, lateral and superior vestibular nuclei; *NPH*, nucleus prepositus hypoglossi; *Psol*, parasolitary nucleus; *Y*, Y-group. Modified from [6].

results are consistent with radiochemical measurements of choline acetyltransferase (ChAT) activity in tissue samples obtained from the vestibular nuclei using the "micropunch" technique. Enzymatic measurements of ChAT activity in the MVN show that activity is higher by at least a factor of 10 than the ChAT activity of the SVN, DVN or LVN. The cholinergic projection to the uvula-nodulus, determined by immunohistochemistry and a regional assay for ChAT activity, is greatest to folia 9d and 10. The ventral paraflocculus also receives a dense cholinergic projection. The flocculus and folia 1 receive less.

## Descending Projections of Vestibular Nuclei

Descending lateral and medial vestibulospinal tracts originate from the LVN and MVN and DVN. The lateral vestibulospinal tract is organized within the LVN topographically. Fibers to the lumbosacral spinal cord originate from the dorsocaudal LVN. Fibers to the cervical cord originate from the rostroventral LVN (Fig. 2b). Axons in the lateral vestibulospinal tract terminate in the ipsilateral lumbosacral region where they make monosynaptic and polysynaptic connections with motoneurons. Axons in the medial vestibulospinal tract terminate bilaterally in the medial part of the cervical ventral horn. The bilateral representation of vestibulospinal axons is most dense in the cervical enlargements from which motoneurons supplying the suboccipital muscles originate. These motoneurons participate in vestibulocollic reflexes.

Outputs of vestibular nuclei not only evoke reflexes mediated by skeletal muscles, they evoke autonomic reflexes as well. Vestibulo-sympathetic reflexes modulate local changes in blood flow, respiration rate and heart rate. These reflexes are abolished by lesions of the caudal MVN and DVN in cats.

The circuitry by which these vestibular-autonomic effects are induced includes projections from the caudal vestibular nuclei (DVN, MVN and Psol) to the solitary nucleus (Nsol). The Nsol receives autonomic afferents from the heart, esophagus and stomach, carried chiefly by branches of the IX and X cranial nerves. Neurons in the cerebellar fastigial nucleus respond to changes in blood pressure, heart rate and respiration. Moreover, electrical stimulation of the cerebellar uvula or fastigial nucleus modifies blood pressure, heart rate and respiration.

## Visual Influences on Vestibular Nuclei

Vestibular primary afferents comprise only one of the sensory inputs to the vestibular complex. Most secondary vestibular neurons are driven by visual (optokinetic) as well as vestibular stimulation. Although visual signals to the vestibular nuclei originate from a variety of brainstem and cortical sources, the best-understood pathways by which optokinetic signals reach the vestibular complex comprise the ►accessory optic system (AOS) (Fig. 4).

The AOS includes the medial, dorsal and lateral terminal nuclei, MTN, DTN, LTN and the nucleus of the optic tract, NOT. Each nucleus within the AOS receives projections from direction selective retinal ganglion cells having large receptive fields and preferred stimulus vectors. For example, NOT neurons respond to temporal-to-nasal optokinetic stimulation of the contralateral eye at velocities of 0.1–30°$s^{-1}$ and have receptive fields larger than 50.

These receptive field characteristics suggest that AOS neurons detect self-motion rather than the motion of external objects, such as the flight of a bird or a baseball. This information is combined with the spatial information provided by vestibular primary afferents at the level of the vestibular nuclei, NPH, nucleus reticularis tegmenti pontis, dorsolateral pontine nuclei and inferior olive.

While the anatomy and physiology of the AOS have been described most extensively in mammals such as the rabbit, the same fundamental details have been confirmed in primates. In all mammals there is a

Modified from [7].

descending projection from the visual cortex to the AOS. In primates this projection originates from the pre-striate cortex (areas OAa and PGa). Selective stimulation or inactivation of this region modifies the directional selectivity of neurons in the AOS.

## Neck-Proprioceptive Inputs to Vestibular Nuclei

Signals from proprioceptors embedded in the inter-transverse muscles at the base of the cervical vertebrae also activate secondary vestibular neurons. Injection of HRP into the caudal MVN and DVN retrogradely

labels neurons ipsilaterally in the $C_2$–$C_3$ spinal ganglia, contralaterally in the central cervical nucleus and bilaterally in $C_1$–$C_6$ dorsal horn cells. Cells in the dorsal horn, cervical nucleus and spinal ganglia do not project to the LVN, SVN and most of DVN. Neurons in the vestibular complex also receive secondary cervical afferents relayed through the external cuneate nuclei. Movement of the head with respect to the body stimulates neck proprioceptors and evokes reflexive eye movements as well as postural adjustments of the limbs.

## Cerebellar Projections to the Vestibular Complex

Cerebellar projections to the vestibular complex include, but are not restricted to, nodular efferents. Purkinje cells located within sagittal zones in the uvula, as well as the nodulus project to different regions within the vestibular complex.

While regions of the vestibular complex receiving Purkinje cell projections overlap with the same regions providing bilateral, mossy fiber, cholinergic projections to the uvula-nodulus, the overlap is far from perfect. The dorso-caudal MVN and DVN receive dense projections from uvula-nodular Purkinje cells. This region partially overlaps the areas within the MVN, DVN and ventral LVN from which the medial vestibulo-spinal tract originates. The uvula-nodulus also projects to the SVN.

Within the vestibular complex, only LVN neurons receive a uniformly dense cerebellar projection. This projection arises from the "b zone" of the vermis; a zone defined on the basis of its climbing fiber projections from the forelimbs and hindlimbs of the cat. The non-uniform immunolabeling of the MVN, NPH, SVN, DVN and Psol suggests a functional specialization within each nucleus that is determined not only by its efferent projections, but also by whether it receives direct cerebellar projections.

## Reflexive Movements Evoked by Activity in Secondary Vestibular Neurons

Natural stimulation of the vestibular, optokinetic and neck proprioceptive systems evokes reflexive movements. These movements include those of the eyes, ears, head and trunk as well as reflexive contractions of gut smooth muscle and reflexive changes in heart rate, blood pressure and respiration. Secondary vestibular neurons participate in several different "field-holding reflexes," the purpose of which is to maintain a stable spatial environment. These reflexes include the vestibuloocular reflex (VOR), optokinetic reflex (OKR), cervicoocular reflex (COR), vestibulocollic reflex (VCR) and other postural reflexes involving forelimb muscles and axial musculature of the trunk.

Each reflex has a unique gain (response amplitude/stimulus amplitude) and frequency range over which it operates. In rabbits, for stimulus amplitudes of 20, the VOR evoked by stimulation of the semicircular canals operates over a frequency range of 0.02–5.00 Hz, with a peak gain of 0.90 at a frequency of 0.40 Hz. The otolithic component of the VOR operates over a lower frequency range (0.005–0.10 Hz), with a peak gain of about 0.50 at a frequency of 0.02 Hz. The frequency ranges of the OKR, COR and VCR are comparable to that of the otoliths.

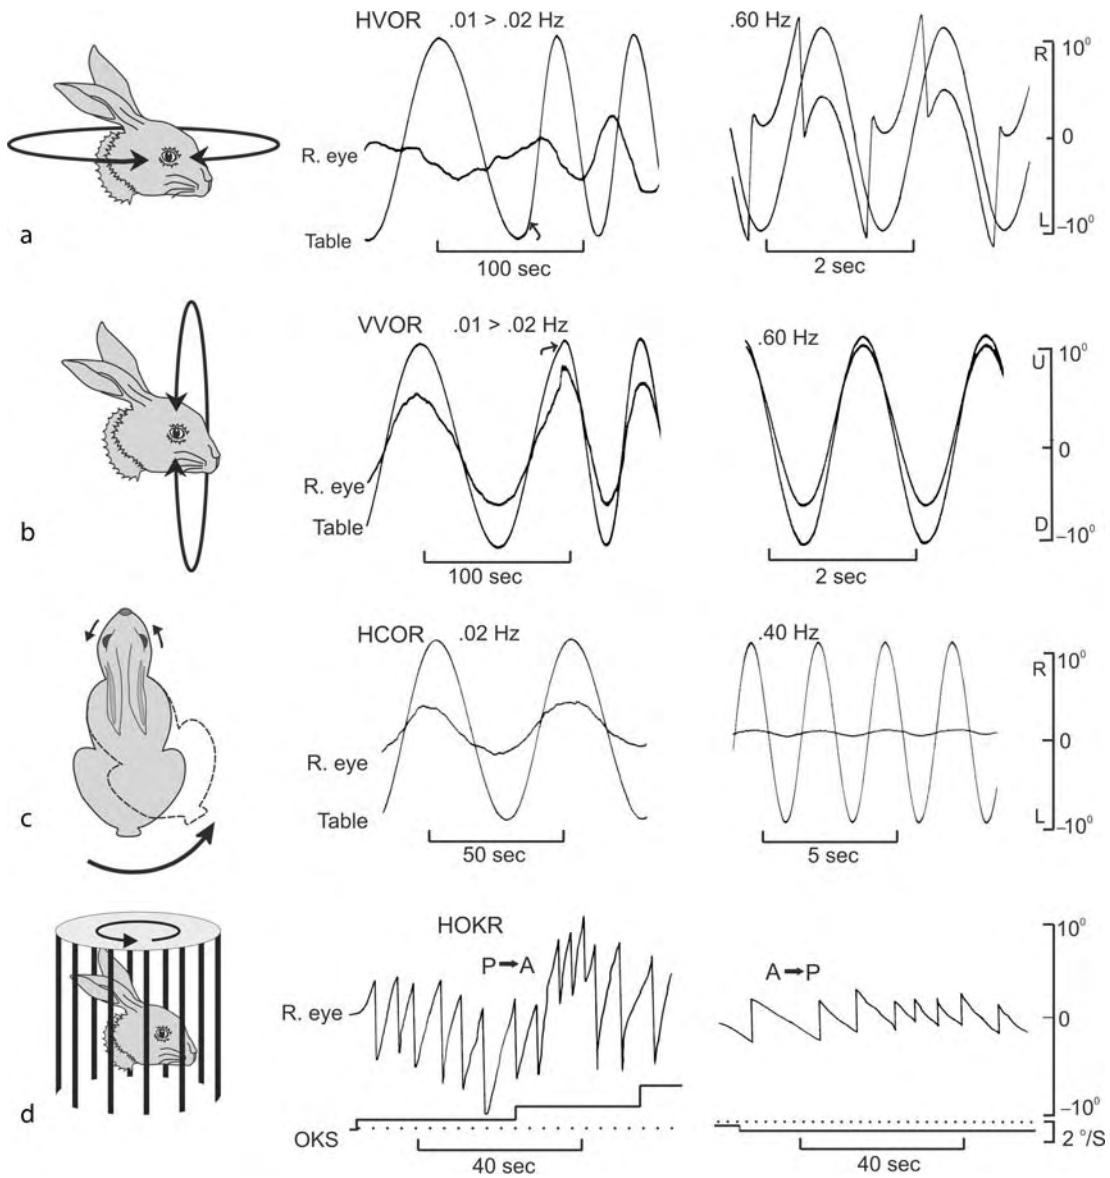
Head movements activate four reflexes synergistically (VOR, OKR, COR, VCR) (Fig. 5).

Movement of the head to the left stimulates the hair cells in the ampulla of the left horizontal semicircular canal. If the eyes are open during the leftward head movement, directionally selective ganglion cells in the left eye are stimulated as the visual field drifts across the left retina in the temporal-nasal direction. Finally, neck proprioceptors embedded in the transversospinal muscles at the base of the right cervical vertebrae are stretched. Each of these signals converges on the vestibular nuclei and acts synergistically, causing a rightward, conjugate eye movement.

## Reflexes Involving the Vestibular Nuclei

The functions of the secondary vestibular neurons are certainly more complicated than the classical "three neuron arc" first described by Lorente [9]. This can be appreciated by observing the effects of gravity on the orientation of post-rotatory nystagmus or optokinetic afternystagmus (OKAN II) in space. In such experiments the slow phase of the nystagmus remains horizontal in space, despite changes in head position about the inter-aural axis. Although the orientation of nystagmus in space remains constant, it is generated by different pairs of extraocular muscles, contingent on head position. When the animal is in a prone orientation, the nystagmus is expressed by the horizontal rectus muscles. When the animal is pitched nose-up or nose-down, the nystagmus is expressed by the vertical rectus muscles. At present, little is understood about the participation of the vestibular nuclei in generating nystagmus. Even less is understood about how an otolithic head position signal can cause an ongoing nystagmus to be completely re-routed to different pairs of extraocular muscles.

Two different aspects of nystagmus may reveal fundamental properties of circuitry in which secondary vestibular neurons are embedded. First, nystagmus may be generated by circuitry that includes secondary vestibular neurons as well as other brain stem neurons. Activity induced in this circuitry may be independent of head position. Second, a topographic conversion must occur, allowing the nystagmic rhythm to be channeled into different circuits controlling horizontal and vertical eye movements. This conversion is under the control of otolithic as well as optokinetic and neck proprioceptive inputs.

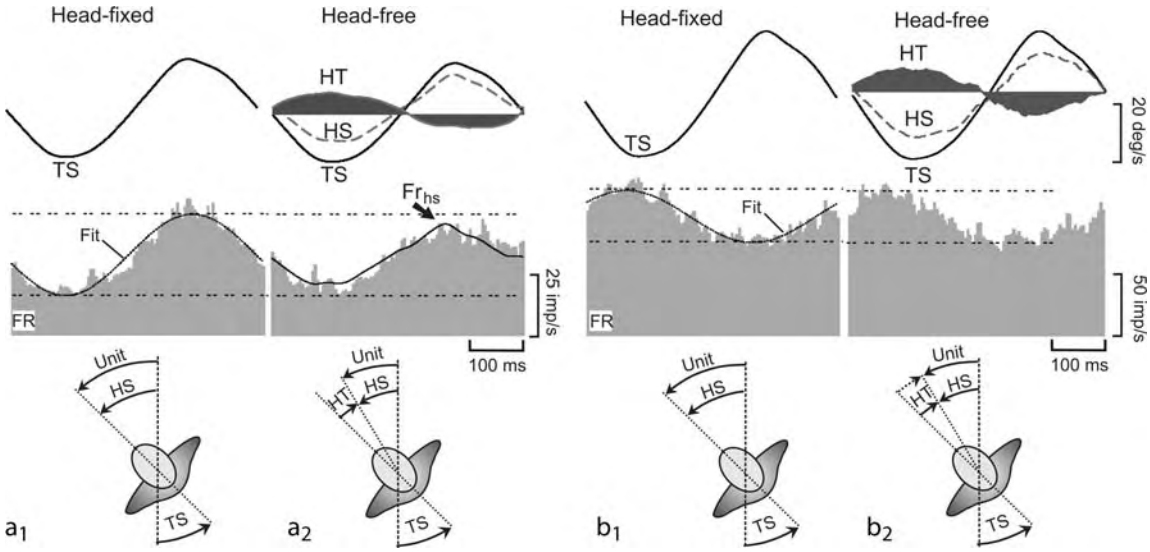


**Vestibular Secondary Afferent Pathways. Figure 5** Reflexive eye movements evoked by vestibular, optokinetic and neck proprioceptive stimulation. (a) Horizontal vestibuloocular reflex (HVOR) is evoked by rotation of the rabbit about the vertical axis (yaw), stimulating the horizontal semicircular canals. Note that the gain of the HVOR increases with stimulus frequency. (b) Vertical vestibuloocular reflex (VVOR) is evoked by rotation of the rabbit about a longitudinal axis (roll). Note that the gain of the VVOR is relatively high even at lower frequencies due to the contribution of the utricular otoliths. At higher frequencies the VVOR can be attributed to stimulation of the posterior and anterior semicircular canals. (c) Horizontal cervico-ocular reflex (HCOR) is evoked by rotation of the body of the rabbit in the horizontal plane about the fixed head. This is done in total darkness. Note that the gain of the HCOR even at the optimal frequency of 0.02 Hz is only about 0.25. (d) Horizontal optokinetic reflex (HOKR) is evoked by unidirectional, constant velocity, movement of a contour-rich stimulus. Only one eye views the rotating optokinetic stimulus (OKS). Eye movements of higher gain are evoked by stimulation in the posterior–anterior direction (P→A) compared to the gain of eye movements evoked by OKS in the anterior–posterior direction (A→P). Modified from [8].

## Central Motor Commands to Vestibular Secondary Neurons

Secondary vestibular neurons not only respond to vestibular, optokinetic and neck proprioceptive signals, they distinguish between passive and active rotation of the head (Fig. 6).

The ability to suppress information concerning the vestibular consequences of active head and eye



**Vestibular Secondary Afferent Pathways. Figure 6** Discharge differences in a secondary vestibular neuron caused by "active" and "passive" vestibular stimulation. The activity of two secondary vestibular neurons was measured during whole body rotation, with the head restrained ($a_1$, $b_1$) or unrestrained ($a_2$, $b_2$). When the head was unrestrained, horizontal rotation of the body evoked a vestibulocollic reflex (VCR). Responses were averaged during several cycles of horizontal vestibular stimulation. The *dashed lines*, bracketing the averaged responses, show the change in response modulation with respect to the head-fixed condition. The *cartoon* below each panel represents the head movement during each condition. In the head-fixed condition, head on trunk movements were eliminated (HT = 0) and the velocity of the head in space (*HS*) was the same as the turntable or trunk velocity (*TS*). In the head-free condition, a compensatory head on trunk movement (*HT*) was evoked by turntable rotation (TS), which reduced the head velocity in space (HS, in this case TS plus HT). The model, superimposed on the unit's firing rate ($FR_{hs}$) during the head-free condition, is the vector product of the unit sensitivity during the head-fixed condition (*dashed line labeled fit*) and the head velocity in space during the head-free condition (HS). The modulation of discharge of the secondary vestibular neuron in (a) was reduced when the VCR reduced the velocity of the head in space. The modulation of discharge of the neuron in (b) was unaffected by the reduction in velocity caused by the VCR. This implies the existence of a centrally generated signal capable of altering the gain of the evoked discharge. Modified from [10].

movements implies the central regulation of discharge rather than a mere summation of sensory influences. Similarly, the discharge of a subset of secondary vestibular neurons can be modified by central eye movement commands. In monkeys trained to suppress eye movements, vestibular stimulation evokes reduced discharge of secondary vestibular neurons.

## Functions of Vestibular Nuclei

Although they receive primary vestibular afferents, the vestibular nuclei receive information from other sensory systems as well. The discharge of secondary vestibular neurons is clearly influenced by vision, neck proprioception and centrally generated commands. Secondary vestibular neurons contribute to the control of balance by influencing the discharge of motor and pre-motor neurons. The linkage of the vestibular nuclei and the autonomic nervous system is often overlooked. This linkage is vital for effective support of postural reflexes evoked by changes in regulation of skeletal muscle. Secondary vestibular neurons have reciprocal connections with cerebral and cerebellar cortices. The vestibular nuclei are at a sensory-motor crossroads. Vestibular compensation may reflect the properties of secondary vestibular neurons within the context of a larger system that uses vestibular, visual, cutaneous and proprioceptive information. This larger system also includes the cerebellum and cerebral cortex.

## Vestibular Statokinetic Reflex

### Definition

Activation of body and/or eye muscles due to stimulation of ampullar and macular receptors of the vestibular system induced by head movements in space.

►Peripheral Vestibular System
►Vestibulo-Spinal Reflexes

## Vestibular System

Neal H. Barmack[1], Vito E. Pettorossi[2]
[1]Neurological Sciences Institute, Oregon Health and Science University, Beaverton, OR, USA
[2]Department of Internal Medicine, Section of Human Physiology, University of Perugia, Perugia, Italy

The vestibular system detects motion and position of the head in space. It uses this information to regulate postural reflexes and control movement.

### Peripheral Vestibular Receptors

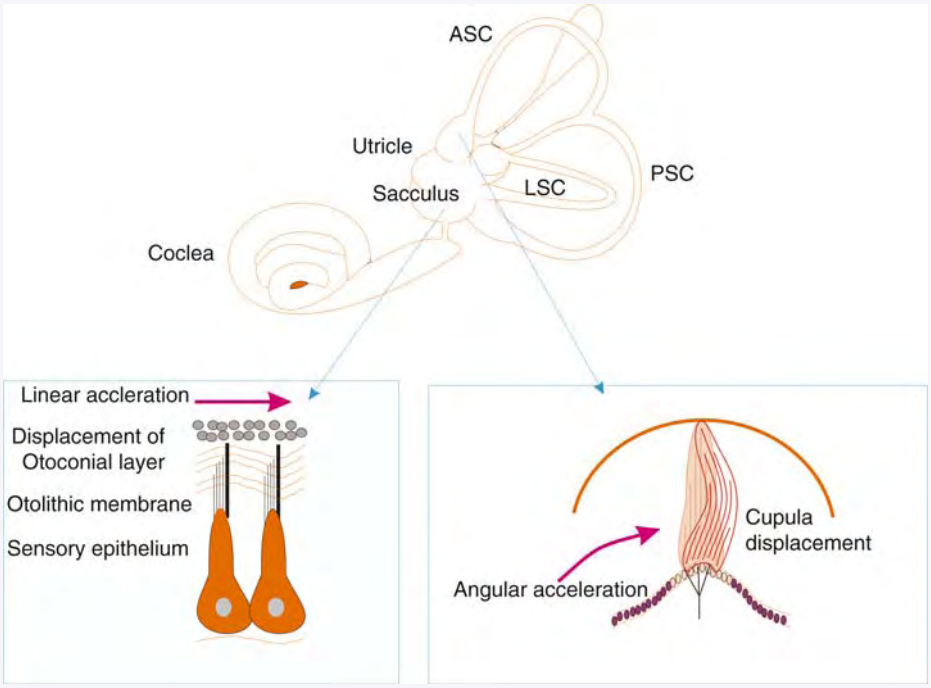
Embedded in bone behind the ears, the labyrinth consists of five separate sensors. Three of these comprise the ►semicircular canals, a series of three membranous and interconnected "hula hoops" oriented in three different planes, roughly at right angles with respect to one another. Each senses angular acceleration of the head in a different plane. The semicircular canals contain a fluid, endolymph. When the head rotates, the endolymph lags behind, much as a raw egg lags when the egg shell is rotated. The lagging endolymph pushes against a thin gelatinous matrix membrane, the ►cupula into which ►hair cells are embedded. These hair cells transduce submicron movements of the cupula and depolarize the hair cells. All hair cells in the cupula have the same anatomical orientation determined by the spatial orientation of the singular ►kinocilium to the multiple ►stereocilia in each hair cell (Fig. 1).

►Otoliths (►Otolithic receptors) comprise a second class of vestibular sensors. Otoliths have a specialized neuroepithelium, the ►macula, composed of a polysaccharide membrane surface onto which small crystals of calcium carbonate (►otoconia) adhere. On the other side of the macular membrane are hair cells. The multiple stereocilia and single kinocilium of hair cells are embedded in the macula. When the head moves a linear acceleration is imparted to the otoconia, deflecting embedded ►cilia of the hair cells, altering their excitability and modulating the release of transmitter. Hair cells are excited when the stereocilia are bent towards the single kinocilium. Head movements alter the orientation of the macula with respect to the linear acceleration of gravity, displace the embedded cilia and change the membrane potential of the hair cells (Fig. 1). One of the otoliths, the ►utricle, lies in the horizontal plane. The other, the ►saccule lies in a near sagittal plane.

Within the macula of each otolith, hair cells have a range of spatial orientations. Consequently they can detect linear accelerations in several directions. Within the ►crista ampullaris of each semicircular canal, hair cells have a single orientation. They detect the force exerted by endolymph in only one plane.

Depolarization of hair cells causes increased release of the synaptic transmitter, glutamate. This excites primary afferents at the base of the hair cells. The cell bodies of these primary afferents are located in ►Scarpa's ganglion, just outside the caudal brainstem. Axons from the bipolar cells in Scarpa's ganglion form the superior and inferior branches of the ►vestibular nerve.

The vestibular nerve enters the brain stem and divides into two fiber bundles containing axons of unequal thickness (Fig. 2a) [1]. The bundle containing thicker axons enters the medulla between the ventral aspect of the inferior cerebellar peduncle and the dorsal aspect of the spinal tract of the ►trigeminal nucleus. It turns caudally and then passes into the ►vestibular complex (Fig. 2b).



**Vestibular System. Figure 1** Schematic drawing of the labyrinth. Spatial orientation of the semicircular canals, utricle and sacculus. In the left insert, the effect of linear acceleration on macular epithelial cells and overlying structures is shown. In the right insert, the effect of the angular acceleration on the crista ampullaris is shown. The arrows indicate the direction of acceleration. *Abbreviations*: ASC, LSC and PSC, anterior, lateral and posterior semicircular canal.

The bundle with thinner axons ascends to the ►cerebellum by passing through the superior vestibular and lateral ►vestibular nuclei (SVN, LVN). The thin axons then distribute to several folia within the cerebellum, but primarily to the ipsilateral ►uvula-nodulus. The vestibular complex and uvula-nodulus are responsible for the initial processing of vestibular information by the central nervous system.

## Vestibular Nuclei and Vestibular Secondary Afferent Pathways

The vestibular complex has four "classical" nuclear groups: (i) ►Medial vestibular nucleus, MVN, (ii) Descending (or spinal) vestibular nucleus, DVN, (iii) ►Lateral vestibular nucleus (►Deiters), LVN, and (iv) Superior vestibular nucleus, SVN (Fig. 2b).

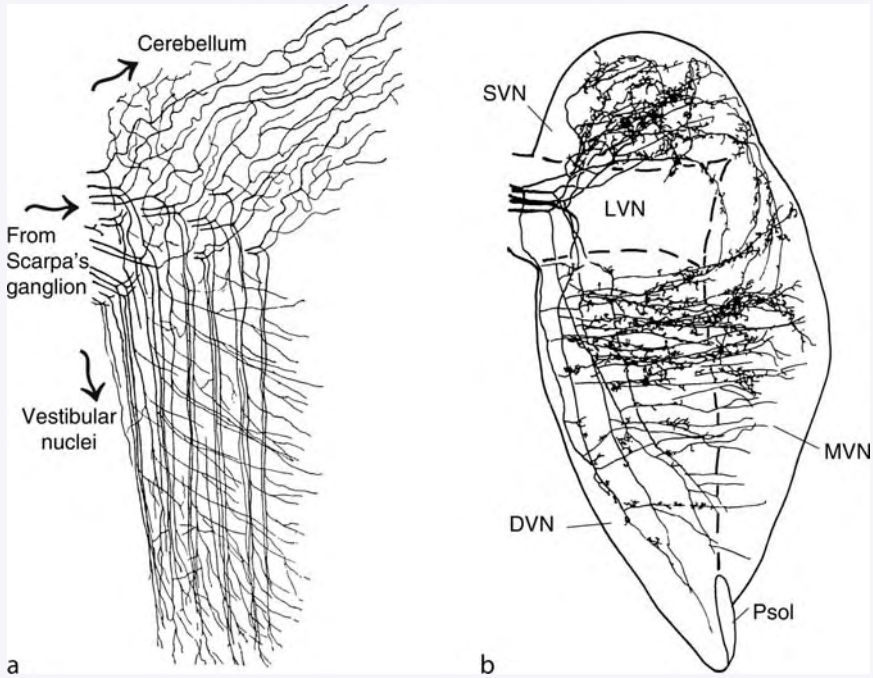
Several smaller nuclei, not included in the "classical" group, nonetheless receive ►vestibular primary afferents. These include: (i) ►Parasolitary nucleus (Psol), (ii) ►Y-group, (iii) ►Nucleus intercalatus (Staderini) (see Fig. 3). Y-group neurons receive ipsilateral vestibular primary afferents, as well as bilateral projections from vestibular secondary afferents (for review, see [3]).

## Ascending Vestibular Projections

DVN, MVN and SVN project to cranial motor nuclei III, IV and VI. These nuclei control the reciprocal contractions of ►extraocular muscles. Secondary vestibular neurons also project to ►nucleus Darkschewitsch, sensory trigeminal nucleus, ►interstitial nucleus of Cajal and the ►subparafascicular complex.

Secondary vestibular neurons in the rostral part of the vestibular complex project to the ►ventrobasal thalamus (VPL, VPM, VPI and VPL). These thalamic nuclei project to areas 3aV and T3 and parietal visual cortex. Humans with damage to parietal cortex do not recognize true vertical. Deprived of surrounding visual cues, they cannot correctly align a disk with a line on it so that the line has a true vertical orientation. ►Cortical vestibular areas project back to the vestibular complex, suggesting that these cortical regions may supersede reflexes evoked by activity in vestibular primary afferents.

The caudal aspect of the ►nucleus prepositus hypoglossi (NPH) and MVN project to several folia within the cerebellum, including the anterior and posterior ►vermis and ►flocculus. Immunohistochemical surveys show that most, if not all of these ascending projections are cholinergic and originate from the caudal MVN and NPH (for review, see [4]).



**Vestibular System. Figure 2** Projection of vestibular primary afferents to the vestibular complex and to the cerebellum. (a) Vestibular primary afferents bifurcate as they enter the brainstem. Modified from [1]. (b) The terminal fields within the cat vestibular complex of five horizontal semicircular canal afferents, intra-axonally labeled with HRP, are illustrated. The terminals are mapped onto a schematic that represents a horizontal section through the vestibular complex. *Abbreviations*: DVN, descending vestibular nucleus; LVN, lateral vestibular nucleus; MVN, medial vestibular nucleus; NPH, nucleus prepositus hypoglossi; Psol, parasolitary nucleus; SVN, superior vestibular nucleus. Modified from [2].

## Descending Vestibular Projections

Descending lateral and ►medial vestibulo-spinal tracts originate from the LVN and MVN and DVN. Fibers to the lumbosacral spinal cord originate from the dorsocaudal LVN. Fibers to the cervical cord originate from the rostroventral LVN. Axons in the lateral vestibulospinal tract terminate in the ipsilateral lumbosacral region where they make monosynaptic and polysynaptic connections with motoneurons. Axons in the medial vestibulospinal tract terminate bilaterally in the medial part of the cervical ventral horn.

Secondary vestibular neurons also evoke ►autonomic reflexes. Vestibulo-sympathetic reflexes modulate changes in blood flow to skeletal muscles, respiration, blood pressure and heart rate (for review, see [3]).

## Visual-Vestibular Interactions

Secondary vestibular neurons are driven by visual as well as vestibular stimulation (►Visual-Vestibular Interaction). Visual input to the vestibular complex originates from both brainstem and cortical sources. Brainstem visual signals come primarily from the ►accessory optic system (AOS).

The visual cortex provides a descending projection to the AOS. In primates this projection originates from the ►pre-striate cortex (►areas OAa and ►PGa). Selective stimulation or inactivation of this region can modify the directional selectivity of neurons in the AOS (for review, see [5]).

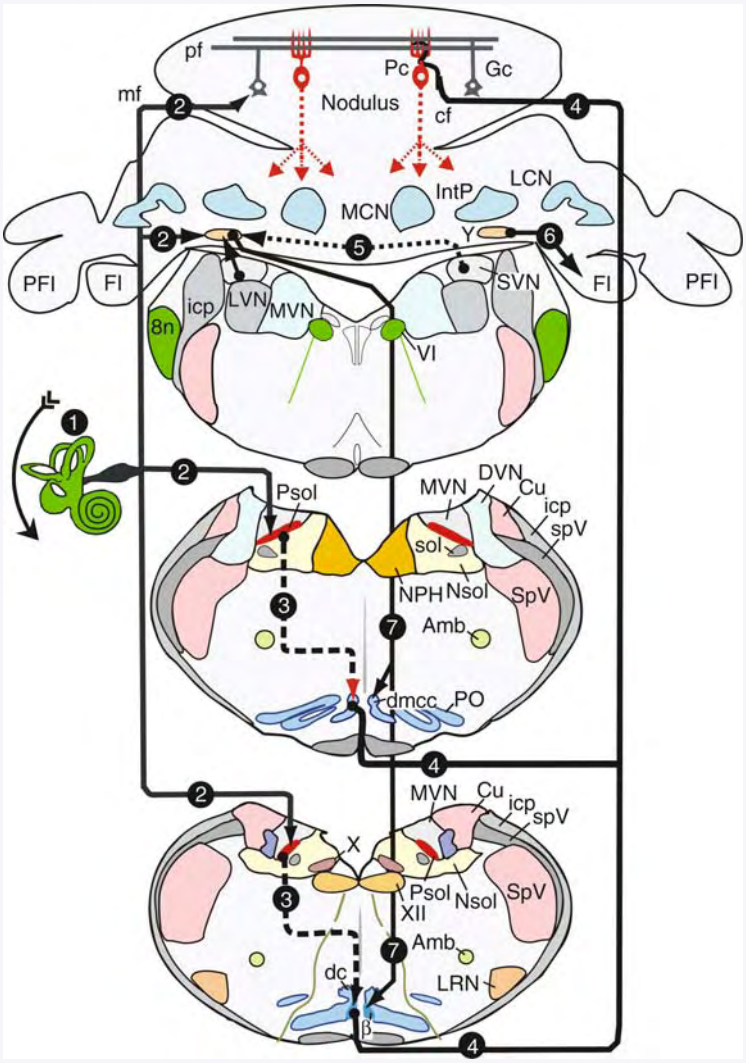
Signals from ►proprioceptors embedded in the intertransverse muscles at the base of the cervical vertebrae activate secondary vestibular neurons. The vestibular complex also receives secondary cervical afferents relayed through the external ►cuneate nuclei. Movement of the head with respect to the body stimulates neck proprioceptors and evokes reflexive ►eye movements as well as ►postural adjustments of the limbs.

## Functional and neurochemical orgnization of vestibule-motor pathways

Secondary vestibular neurons express several synaptic transmitters, including: acetylcholine, GABA, glycine, aspartate, glutamate and taurine.

## Secondary Vestibular Neurotransmitter Receptors

AMPA receptor (alpha-amino-3-hydroxy-5-methyl-ioxyzole-4-propionic acid) subunits GluR1, 2, 3 and 4 have been localized to secondary vestibular neurons using both immunohistochemistry and hybridization histochemistry. Subunits NR1, NR2A and NR2C of



**Vestibular System. Figure 3** Circuitry for activation of vestibular climbing fiber projections to cerebellar ►nodulus. Sequences in activation are indicated by solid lines for excitatory pathways and dashed lines for inhibitory pathways. Pathways are listed numerically. 1. Roll tilt onto the left side increases vestibular primary afferent discharge. 2. Primary afferents project as mossy fibers to ipsilateral granule cell layer of nodulus, parasolitary nucleus (Psol) and dorsal Y-group. 3. Descending GABAergic projection from Psol inhibits activity of olivary neurons in ipsilateral β-nucleus and dorsomedial cell column (dmcc). 4. Climbing fibers from β-nucleus and dmcc project to contralateral nodulus. 5. Vestibular nuclei bilaterally project to dorsal y-group. 6. Dorsal Y-group projects to ipsilateral flocculus. 7. Dorsal Y-group projects to contralateral dorsal cap, β-nucleus and dmcc. *Abbreviations*: Amb, nucleus ambiguus; β, β-nucleus; cf, climbing fiber; Cu, cuneate nucleus; dc, ►dorsal cap of Kooy; dmcc, dorsomedial cell column; DVN, descending vestibular nucleus; Fl, flocculus; Gc, granule cell; icp, inferior cerebellar peduncle; IntP, Interpositus nucleus; LRN, lateral reticular nucleus; mf, mossy fiber; LCN, lateral cerebellar nucleus; LVN, lateral vestibular nucleus; MCN, medial cerebellar nucleus; MVN, medial vestibular nucleus; NPH, nucleus prepositus hypoglossi; Nsol, nucleus solitarius; Pc, Purkinje neuron; pf, parallel fiber; PFl, paraflocculus; PO, principal olive; Psol, parasolitary nucleus; sol, tractus solitarius; SpV, spinal trigeminal nucleus; spV, spinal trigeminal tract; SVN, superior vestibular nucleus; X, dorsal motor nucleus of the vagus; XII, hypoglossal nucleus; VI, abducens nucleus; Y, Y-group: 8n, auditory-vestibular nerve.

N-methyl-D-aspartate (NMDA) receptors are widely distributed within the vestibular complex. A subset of GABA-expressing secondary vestibular neurons in the MVN, SVN and DVN comprise the commissural system of the vestibular complex.

## Movements Evoked by Secondary Vestibular Neurons

Natural stimulation of the vestibular, ►optokinetic and neck proprioceptive systems evokes reflexive movements of the eyes, ears, head and trunk. Secondary

V

vestibular neurons participate in several "►field-holding" ►reflexes, the purpose of which is to maintain a stable spatial environment. Reflexes to which the vestibular nuclei contribute include: ►vestibuloocular reflex (VOR), ►optokinetic reflex (OKR), ►cervicoocular reflex (COR), ►vestibulocollic reflex (VCR) and ►vestibulospinal reflex (VSR). The VOR represents an important subsystem that contributes to gaze stability during head movement. The basic structure of the VOR reflex arc is simple in the sense that the arc contains only three neurons in series: the primary fibers of the vestibular nerve, the secondary neurons in the vestibular nuclei and the motoneurons of the extraocular muscle. However, it is complex with respect to its multiple parallel arrangements. The activation of the receptors of the semicircular canals elicits eye movements in the same plane, but in directions opposite to head movements. Reflex eye movements are compensatory since they reduce retinal slip of images during head rotation. In addition to VOR, the vestibular system contributes to optokinetic reflexes (OKRs). OKRs stabilizes gaze during slow head displacement. Optokinetic and vestibular responses combine to assure gaze stability in a wide range of head movement (Visual-vestibular Interaction). OKRs are closed-loop reflexes. Compensatory eye movements reduce the retinal slip that evokes them. VORs are open-loop reflexes since head movements are not necessarily reduced by eye movements. Moreover, the optokinetic input through the flocculus causes long-term effects on the vestibular neurons connected with the VOR to increase or decrease the excitability depending upon the functional requirement (Visuo-vestibular calibration).

In some animals vestibular nuclei mediate also the cervicoocular reflex (COR), that contribute to eye position within the orbit. Another important function of the vestibular nuclei is to control posture and body movement. This control is exerted either by direct efferent projections of the vestibular neurons to the spinal cord or by indirect activation of ►reticulospinal and ►propriospinal neurons. The labyrinthine receptors sensitive to angular and linear acceleration detect head movement and position and are connected with a descending network that activate neck muscle for eliciting vestibulocollic reflex (VCR) and vestibulospinal reflex (VSR) involving forelimb muscles and axial musculature of the trunk. The neck and body muscle activation is responsible of head stability and body equilibrium and, in general, tends to oppose the effect on the posture of the gravity force.

Secondary vestibular neurons not only respond to vestibular, optokinetic and neck proprioceptive signals, they distinguish between passive and active rotation of the head. The ability to suppress information concerning the vestibular consequences of active head and eye movements implies the central regulation of discharge rather than a mere summation of sensory influences. Similarly, the discharge of a subset of secondary vestibular neurons can be modified by central eye movement commands. (For review, see [6]).

## Functional Vestibular tests

To investigate vestibular function a variety of tests have been developed for vestibuloocular reflex (caloric test, Head shaking test, ocular tilt reaction) and for vestibulospinal reflex (Romberg test, posturography, Galvanic test, VEMP).

## Vestibular Compensation and plasticity

Unilateral loss of vestibular function creates an imbalance in both postural and oculomotor control. The oculomotor deficit is characterized by a conjugate ocular ►nystagmus composed of slow and fast segments. The slow phase is directed towards the side of the damaged labyrinth. The fast phase is directed away from the damaged labyrinth. A unilateral labyrinthectomy also produces head tilt in the roll and yaw planes, spinal cord curvature, circular walking, barrel rolling, asymmetric muscle tone and a reduction in gain of the VOR, VCR and VSR. Several hours, days or weeks after UL, spontaneous ocular nystagmus subsides. This disappearance of nystagmus is termed "compensation." By contrast loss of reflex gain of the VOR, VCR and VSR recovers slowly if at all (for review, see [7]).

## Vestibular Cerebellum

More than 90% of vestibular primary afferents (►Vestibular cerebellum) project to the ipsilateral uvula-nodulus where they terminate as ►mossy fibers in the ipsilateral granule cell layer. Secondary vestibular afferents project bilaterally onto granule cells in the uvula-nodulus and also onto granule cells in the flocculus, paraflocculus and folia 1 of the anterior lobe. In both the cat and the rabbit, the uvula-nodulus sends reciprocal projections to the caudal MVN. In the cat, the rostral and lateral regions of the MVN receive projections from the flocculus.

Vestibular information reaches the uvula-nodulus over ►climbing fiber as well as mossy fiber afferents (Fig. 3). Vestibular climbing fibers originate from two subnuclei of the ►inferior olive, the Y-nucleus and ►dorsomedial cell column (dmcc). They cross the midline to synapse on ►Purkinje neurons in the contralateral uvula-nodulus. The ►β-nucleus and dmcc receive secondary vestibular projections from the *ipsilateral* parasolitary nucleus, a small GABAergic nucleus that receives a primary vestibular afferent projection and from the *contralateral* dorsal Y-group (Fig. 3). β-nucleus and dmcc neurons respond to roll-tilt.

Modulation of cerebellar Purkinje cell discharge is contingent on interactions between mossy and climbing

fiber vestibular projections. Climbing fibers directly evoke "complex spikes" (CSs) that discharge at 0.2–8.0 imp/s. The proximate cause of higher frequency "►simple spikes" ►(SSs) is less well understood. SSs discharge at ~20–60 imp/s. SSs reflect the summed synaptic actions of ~150,000 parallel fibers on each Purkinje cell. Since parallel fibers have lengths of 3–7 mm, the signal their combined signal to individual Purkinje cells cannot be topographically precise. Rather each Purkinje cell probably receives parallel fiber synaptic signals that reflect the excitatory influence of otoliths and semicircular canals from both labyrinths. Purkinje cell activity is also influenced by inhibitory interneurons such as basket, Golgi and stellate cells (for review, see [6]).

## Motion Sickness and Vestibular System

►Motion sickness is the autonomic consequence of sensory stimulation that induces spatial disorientation. In humans and many mammals, acute motion sickness reaches a climax with retching. This ballistic event is heralded by subthreshold peristaltic contractions that can be recorded from either the esophagus or the lower intestines. Motion sickness is preceded by increased concentrations (10–20-fold) of arginine ►vasopressin, possibly secreted by the ►hypothalamus.

A popular view of motion sickness is that it is produced by sensory conflict between vestibular receptors or between vestibular and non-vestibular receptors. A good example of such conflict is when one is sitting in a train and an adjacent train begins to move. One's vestibular system informs us that we are not moving, while the optokinetic system informs us that we are. For many people, exposure to just a few minutes of unidirectional optokinetic stimulation is sufficient to induce nausea. Individuals who have bilateral loss of labyrinthine function tend not to experience motion sickness.

Motion sickness is often treated pharmacologically. One modestly effective antimotion sickness agent is the anti-muscarinic compound, ►scopolamine. Scopolamine increases tolerance for sensory stimulation without inducing nausea. The benefit of reduced sensitivity to nauseogenic stimulation is countered by non-specific muscarinic effects, such as: dry mouth, blurred vision, dizziness, drowsiness and anxiety.

A second strategy for preventing motion sickness blocks at a more central level the sequence of steps leading to an overproduction of vasopressin. Administration of the centrally acting antimuscarinic agent, ►atropine, reduces the release of vasopressin, which in turn reduces gastric disrhythmias.

## Peripheral Vestibular Disorders

Normal vestibular function depends on a balanced encoding of head movement by ten different vestibular endorgans. When these endorgans become impaired, dizziness, ►ataxia and imbalance occur. Some of the possible causes of peripheral abnormalities include: alcohol intoxication, temporal bone trauma, exposure to certain ototoxic antibiotics, invasive tumors of the vestibular nerve, virally induced damage to the vestibular nerve and pathology of unknown etiology (such as ►Ménière's disease). The extent of functional loss can often be accurately estimated and diagnosed based upon careful monitoring of movements of the patient under conditions of controlled vestibular stimulation.

Often unilateral labyrinthine damage can be pinpointed by recording the direction and amplitude of spontaneous ocular nystagmus. Recovery of full vestibular function following traumatic or disease-induced damage often occurs, but it is never complete. Over a period of weeks, nystagmus disappears. This recovery is termed "compensation." However, vestiges of damage can still be detected in reflex function if the patient is tested with rapid accelerations [8].

## Central Vestibular Disorders

Central vestibular disorders are caused by pathological processes inside the neural axis including pathological states of the vestibular nerve. Their descriptive etiology includes: demyelinating, tumoral, vascular, degenerative, traumatic. Their topography includes: medullary, cerebellar, cortical. Systemic descriptions include: vestibulo-spinal, vestibulo-autonomic, vestibulo-ocular, vestibulo-cortical. Functional symptoms include: ►vertigo, dizziness, ataxia, ►oscillopsia and unsteadiness.

# Vestibular Tests: Caloric Test

Catherine de Waele
Laboratoire de Neurobiologie des Réseaux Sensori-moteurs, CNRS, Paris, France

## Synonyms

Bithermal tests of inner ear

## Definition

Caloric stimulation is a test, which uses differences in temperature to diagnose uni- or bi-lateral vestibular dysfunction. It allows determination of the function of the horizontal semicircular canals at low frequencies.

## Characteristics

This test is performed in subjects placed in a supine position with the head tilted at 30° from the horizontal to make the lateral canals horizontal. The external ear canal is irrigated with hot (44°C) water for 30 s first on the left and then on the right side with an interval of rest of at least 5 min between the two sides. Then, a similar procedure is performed with cold water (33°C) on both sides with an interval of rest of at least 5 min between the hot water and cold water irrigations. An ocular nystagmus is normally induced, which builds in 30 s and which gradually decreases over 2 min. Patients should avoid eating a heavy meal before the test and avoid caffeine, alcohol, allergy medications and sedatives for at least 24 h, as these can affect the results. In addition, they should have no tympanic membrane perforation. The test is of minimal discomfort. However, some people find cold and hot water in the ear uncomfortable and complain of vertigo and nausea; this always disappears after 2 min.

Eye movements are measured using videonystagmography. In normal patients, the quick phase of the induced-ocular nystagmus beats toward the non-irrigated ear with cold water whereas it beats toward the irrigated ear with hot water. The peak slow-phase velocities of each nystagmus are measured for each condition, warm right, warm left, cold right, cold left. These four numbers are then used to compute three additional numbers:

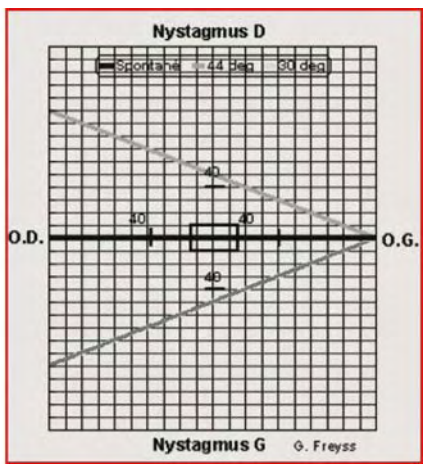
- *The total response on one side with cold and warm water* is calculated by summing all responses on one side. It should be >20°/s. Responses of <10 are suggestive of a canalar hyporeflexia.
- *Directional preponderance* represents the differences between the two ears: right-beating minus left-beating/total left and right-beating. It should be <35%.
- *Unilateral canalar paresis*, i.e. responses on the intact side minus responses on the lesioned side/sum of the responses on the intact and the lesioned side. The Jonkee index is considered as normal when less or equal to 20%.

Several authors have tried to model the caloric responses. The response theoretically results from a combination, possibly nonlinear, of convection induced stimulation of the canal, a direct effect of temperature on the nerve, transduction responses in the mechanics of the cupula, adaptation responses in the nerve and brainstem and other central processing effects, mainly including velocity storage. A descriptive curve-fitting approach to the response is exemplified by that of Formby et al. [1,2].

## Characteristics

Although caloric stimulation exhibits considerable inter- and intra-variability responses in the same subject

Caloric test



**Vestibular Tests: Caloric Test. Figure 1**

[3], this test is of great value in patients suffering from vertigo or dizziness since it is ~80% accurate in differentiating horizontal canalar dysfunction at low frequencies.

## Vestibular Tests: Head-Shaking Test

Catherine de Waele
Laboratoire de Neurobiologie des Réseaux Sensori-moteurs, CNRS, Paris, France

### Synonyms

Canalo-ocular test at medium frequency

### Definition

The head-shaking test allows determination of an asymmetry between the two horizontal canals [1]. The head of the patient is shaken in the horizontal plane for 20 s and at the end of the stimulation the induced eye movements are recorded using videonystagmography.

### Characteristics

In case of asymmetry between the two sides, a horizontal ocular nystagmus with the fast phase oriented toward the healthy side appears (first phase), which can reverse after a variable time (3–10 s: secondary phase). It results from both an asymmetry between the two horizontal canal ampullae and the velocity stockage mechanism. This test can be performed easily in young patients but may be more difficult to perform in old patients with cervical arthrosis.

The head-shaking test is easy to perform at the bedside to detect a potential asymmetry between two horizontal semicircular canals. Compared to the caloric test, which detects a potential asymmetry in the low frequency range, the head-shaking test measures the function of the horizontal canalar ampulla in a middle frequency band.

## Vestibular Tests: Myogenic Potentials Induced by Short Duration Galvanic Currents

Catherine de Waele
Laboratoire de Neurobiologie des Réseaux Sensori-moteurs, CNRS, Paris, France

### Synonyms

Galvanic test

### Definition

This test allows to appreciate the excitablity of the spike trigger zone of the primary vestibular neurons [1,2].

### Characteristics

This test allows the appreciation of the excitability of the spike trigger zone of the primary vestibular afferents [1,3]. Vestibular evoked myogenic potentials (VEMPg) are induced by using bilateral short duration and high intensity transmastoid galvanic currents. The galvanic current is delivered through large surface retroauricular electrodes of ~900 $mm^2$, individually coated by electro-surgical plating (3 M), generously coated with electrode gel and placed over each mastoid process [3]. Galvanic current duration was of about 1 ms, intensity 8 mAmp and frequency of delivery 5 Hz. VEMPg were then recorded after amplification, low-pass filtered filtering (5 and 1.6 kK) and averaging (200 events) from the sterno-cleido-mastoid (SCM) muscle ipsilateral to the cathode through a surface electrode in the middle of the SCM muscle. The test is performed under two different experimental conditions. In the first condition, the head is laid on a pillow and patients are asked to relax. In this case, only the stimulation artifact can be detected. In the second condition, patients in a supine position are asked to raise their head from the pillow and to rotate their head on the side contralateral to the cathode to maximally contract the studied SCM muscle.

In the first condition, only the stimulation artifact can be detected since the SCM is not contracted. In the

second condition, both the artifact of stimulation and VEMPg are recorded. A subtraction between these two traces allows detection of VEMPg and decreases the stimulus artifact. VEMPg are composed of two components, first a positivity (P13g) with a latency of about 10 ms followed by a negativity (N23g) with a latency of about 15 ms. The latency of the evoked potentials and of the amplitude of the P13g/N23g peak is then precisely measured. The ratio 100×(amplitude healthy minus amplitude lesioned side)/(amplitude healthy side plus amplitude lesioned side) can also be calculated to compare galvanic responses on the two sides.

### Summary

VEMPg allow appreciation of the excitability of the vestibular nerve. This test is particularly interesting in the case of uni- or bi-lateral areflexia detected by other vestibular tests. In the follow-up of patients treated by intratympanic gentamycin injections because of intractable Meniere's disease, it can predict the possible reoccurrence of rotatory vertigo [4]. It will be also useful in the near future in bilateral areflexic patients before a potential vestibular implantation.

## Vestibular Tests: Ocular Tilt Reaction

Catherine de Waele
Laboratoire de Neurobiologie des
Réseaux Sensori-moteurs, CNRS, Paris, France

### Synonyms

Headtilt; Skew deviation; Deviation of the perception of the visual vertical and horizontal

### Definition

The ocular tilt reaction (OTR) is a compensatory postural reflex, which arises from the stimulation of the otoliths [1,2].

OTR is a postural synkinesis consisting of:

1. A skew deviation and binocular eye torsion.
2. Head tilt.
3. Deviation of the perception of the visual vertical and horizontal, all to the same side.

### Characteristics

Each deficit could be measured. OTR results from injuries such as stroke, multiple sclerosis or trauma [1] to brainstem vestibular or cerebellar nuclei conveying otolith afferents.

## Vestibular Tests: Romberg Test

Catherine de Waele
Laboratoire de Neurobiologie des Réseaux
Sensori-moteurs, CNRS, Paris, France

### Synonyms

Equilibrium neurological test

### Definition

The Romberg test is a neurological test to detect imbalance. It detects the inability to maintain a steady standing posture with the eyes open or closed. This test consists of standing with the feet together and the findex pointed forward with eyes either open or closed.

### Characteristics

A positive Romberg's sign could be the sign of:

1. A dysfunction of organs involved in postural control: inner ear, vestibular nerve, pons region of the brainstem where the CN VIII arises or damage to other central nervous system pathways which connect to the pons, such as cerebellum.
2. A proprioceptive dysfunction. A lesion anywhere along the pathway from the proprioceptive sensors to the cerebellum can give rise to cerebellar ataxia.

The Romberg test gives information about receptors involved in the control of balance. It should always be included in a battery of other vestibular and neurological tests.

# Vestibular Tests: Static and Dynamic Posturography

Catherine de Waele
Laboratoire de Neurobiologie des Réseaux Sensori-Moteurs, CNRS, Paris, France

## Synonyms

Measure of equilibrium

## Definition

Quantification of the postural oscillations when the subject was located on a stable or unstable plotform.

## Characteristics

During the last decade, static posturography on stationary platforms or dynamic posturography on moving platforms has become widely used to probe balance in patients suffering from dizziness. The subjects are instructed to stand straight and motionless with arms along the sides of the body and head erect when placed on a static or moving plate-form. Strain-gauge force transducers provide the displacement of the center of foot pressure (COP) at a 40 Hz sampling frequency.

Dynamic posturography can be performed on different moving platforms with eyes either open or closed. A sea-saw platform moving either in the medio-lateral or in the antero-posterior directions or a motorized platform generating linear horizontal displacements in different directions can be used. A computerized dynamic posturography (Equitest) including both a sensory organization test (SOT) and a motor control test can also be used. The

**Vestibular Tests: Static and Dynamic Posturography. Figure 1** Figure illustrating on the right side the equitest and on the left side the sea-saw platform.

SOT uses six different conditions, (i) eyes open, (ii) eyes closed, (iii) visual-referenced, (iv) sway-referenced with eyes open, (v) sway-referenced with eyes closed and (vi) visual- and sway-referenced with eyes open. It allows testing of the subject's ability to use vestibular, visual and tactile-proprioceptive inputs in motor response coordination appropriate to external conditions (Fig. 1) [1].

### Analysis

Based on the results of Fourier analysis, three principal variables are considered in both static and dynamic conditions.

1. *The total length of the elementary displacements (in mm)*, which is the sum of the distances covered between each point of the stabilogram (static condition) or the absolute value of the sum of "pivot" elementary displacements of the moving platform (dynamic condition).
2. *The sway area (in $mm^2$)* Body sway is evaluated by computing the position of the center of force over time and by measuring the sway area of the confidence ellipse that contained 90% of the positions of the center of force sampled.
3. *The total power spectrum of the oscillations (in $volts^2$)* which is calculated by fast Fourier transform (FFT) of the total length of the "pivot" displacement.

For all these variables, higher values correspond to more unstable subjects.

For the Equitest, a score was attributed during the sensory test, for each of the six tested conditions.

### Conclusion

Posturography is the only quantified test, which allows assessment of balance in patients suffering from dizziness. In unilateral vestibular loss patients, patients fall in conditions 5 and 6 of the Equitest, when tested at early stages following the lesion. Finally, a recent study [2] showed that investigating dynamic balance using a non-motorized seesaw platform with eyes closed is a useful and robust test for assessing the effects on balance of a unilateral vestibular deficit. Body sway in the medio-lateral direction was found to be greater than in the antero-posterior condition for up to 1 year following the lesion.

# Vestibular Tests: Vestibular Evoked Myogenic Potentials Induced by High Level Sounds

Catherine de Waele
Laboratoire de Neurobiologie des Réseaux Sensori-Moteurs, Faculté de Médecine CNRS, Paris, France

### Synonyms

Saccular test

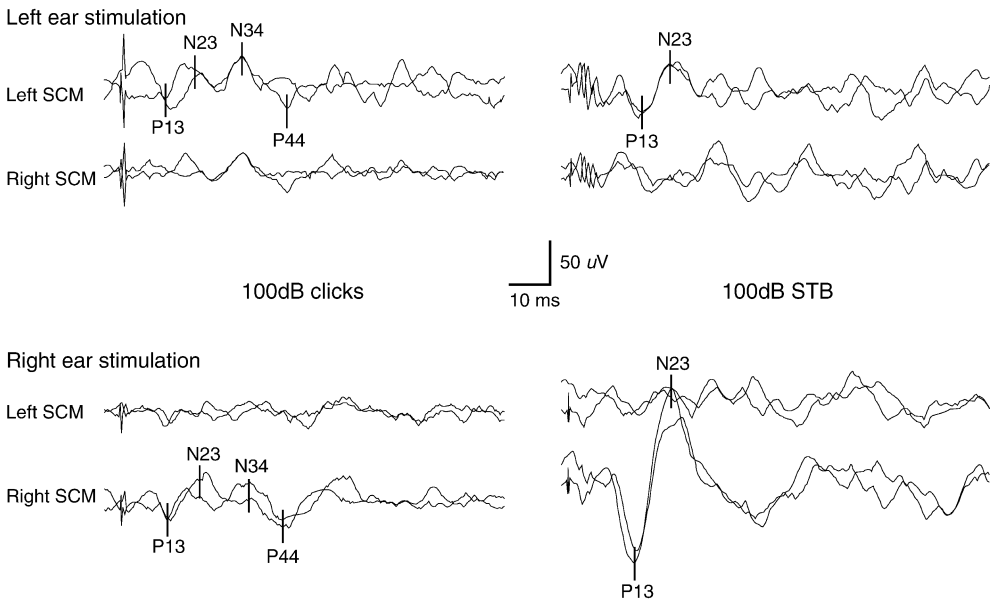
### Definition

This test allows appreciation of the function of the sacculus and the sacculo-spinal pathways [1].

### Characteristics

Subjects undergo vestibular evoked myogenic potential (VEMP) testing using a standard protocol with a nerve monitoring system (Nicolet, Madison). Surface electrodes are placed on the midline forehead (ground electrode), on the skin overlying the mid portion of the sternocleidomastoid muscle bilaterally (SCM: active electrode) and on the skin of the sternum (reference electrode). Prior to each test run, impedances are measured from each electrode to ensure adequate electrode contact and symmetrical measures of impedance between sides. During the test, patients are placed in the supine position, with the head raised from the pillow and turned on the side contralateral to the stimulated side in order to maximally contract the SCM muscle ipsilateral to the stimulated side. Air-conducted high level 100 dB short tone bursts (STB: 500 Hz) or 100 dB clicks are presented to the tested ear through a headphone. The analysis time is 100 ms with a stimulation rate of 5 Hz. The EMG signal from the stimulated side is amplified, bandpass-filtered (2–1.6 kHz) and averaged (250 events). In the case of conductive hearing loss, VEMP's cannot be detected since the signal has become too low to stimulate the sacculus. In this case, STB should be delivered using a bone vibrator (Fig. 1).

Two early waves can be detected, a positivity called P13 occurring with a mean latency of 10 ms followed by a negativity called N23, detected with a mean latency of 14 ms. The threshold, the latency and the peak-to-peak amplitude of these two waves are carefully recorded. Since the amplitude of the response is linearly related to the intensity of the SCM activation during the period of averaging, the peak-to-peak amplitudes can be expressed relative to the level of background mean rectified EMG to create a ratio that largely removes the effects of differences in muscle activity. The ratio 100×(amplitude healthy amplitude lesioned side)/(amplitude healthy side



**Vestibular Tests: Vestibular Evoked Myogenic Potentials Induced by High Level Sounds. Figure 1** Illustration of the VEMP's induced by 100 dB high level click or 500 Hz short tone burst. Notice the early waves, P13 and N23 induced by this stimulation at the level of the ipsilateral SCM.

plus amplitude lesioned side) may also be calculated to compare the saccular responses of both sides. The P13/N23 peak-to-peak amplitude also depends on the type of stimulus; it is always bigger when induced by STB than by high level clicks. This could be due to a better recruitment of the saccular cells and/or of the saccular nerve.

The amplitude is the best parameter for indicating a potential dysfunction of the saccular nerve and of the sacculus. In particular, asymmetries of >2.5:1 of P13g/N23g peak amplitudes signal a dysfunction of the sacculus and the sacculospinal pathways on one side. In contrast, the latency is rarely changed in cases of peripheral vestibular dysfunction.

VEMP's are the consequences of the activation of paucisynaptic and inhibitory sacculo-collic pathways with a first synapse at the level of the primary vestibular afferents, a second at the level of the second order vestibular neurons and a third at the level of the spinal motoneurons innervating the SCM muscle.

VEMP's induced by high level sounds (STB or clicks) allow appreciation of the function of the sacculus and the sacculo-collic pathways. This test is important in peripheral vestibular disease such as Meniere's disease, acoustic neurinomas and dizziness. In case of vestibular neuronitis, it allows appreciation of the functioning of the inferior vestibular nerve.

# Vestibulocerebellum

## Definition

Several classifications are used to subdivide the cerebellum based on anatomical, phylogenetic and functional (i.e. termination of cerebellar afferents and efferents) findings. The flocculo-nodular lobe and adjoining parts of the caudal vermis have been named vestibulocerebellum because of heavily projecting vestibular afferents. The vestibulocerebellum corresponds to the archicerebellum based on phylogenetic and embryological studies.

►Cerebellar Functions
►Cerebellum – Role in Eye Movements

# Vestibulocochlear Nerve (VIII)

## Synonyms

►N. vestibulocochlear (N.VIII)

## Definition

Vestibulocochlear nerve (VIII) is composed of two parts:

- Vestibular nerve: it is responsible for innervation of the vestibular structures of the inner ear (sacculi, utricles and semicircular canals).

  Nucleus: vestibular nuclei.

- Cochlear nerve: it innervates the cochlea and is the first element of the auditory tract. Nucleus: cochlear nuclei.

  Skull: internal acoustic meatus.

# Vestibulocollic and Cervicocollic Control

Emily A. Keshner
Department of Physical Therapy, College of Health Professions and Department of Electrical and Computer Engineering, College of Engineering, Temple University, Philadelphia, PA, USA

## Definition

Control of the neck is exerted primarily by two sensory systems, the vestibular system in response to the signals received by the vestibular end organs (the otoliths and the semicircular canals within the vestibular labyrinths) and the proprioceptors of the cervical spine. Two automatic and stereotypical responses can be elicited by direct stimulation of these receptors. The vestibulocollic reflex (VCR) is a compensatory response of the neck muscles when head motion is sensed by the vestibular organs in the inner ear. The cervicocollic reflex (CCR) is a compensatory response of the neck muscles that is driven by neck proprioceptive inputs during motion of the body.

## Description of the Theory

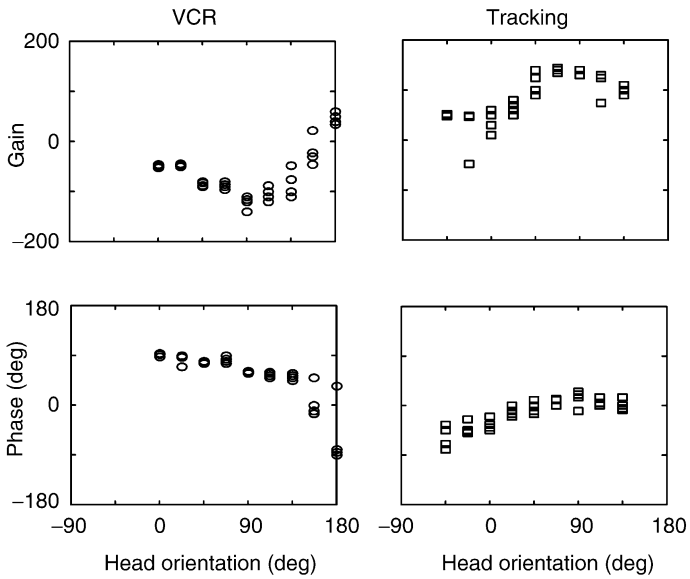
The function of the VCR is to stabilize the position of the head in space and thereby stabilize gaze in space [1]. The function of the CCR is to stabilize the head on the body and, thereby, provide information about motion of the head with respect to the trunk [2]. These reflexes are unquestionably evoked in decerebrate animals, but their contribution to head stabilization in alert animals and during functional motion are not as clear. In the accompanying essay, the physiological and behavioral data that support the presence of these reflexes in alert animals is presented together with the argument for their contribution to the control of posture and balance.

## Characteristics of the VCR

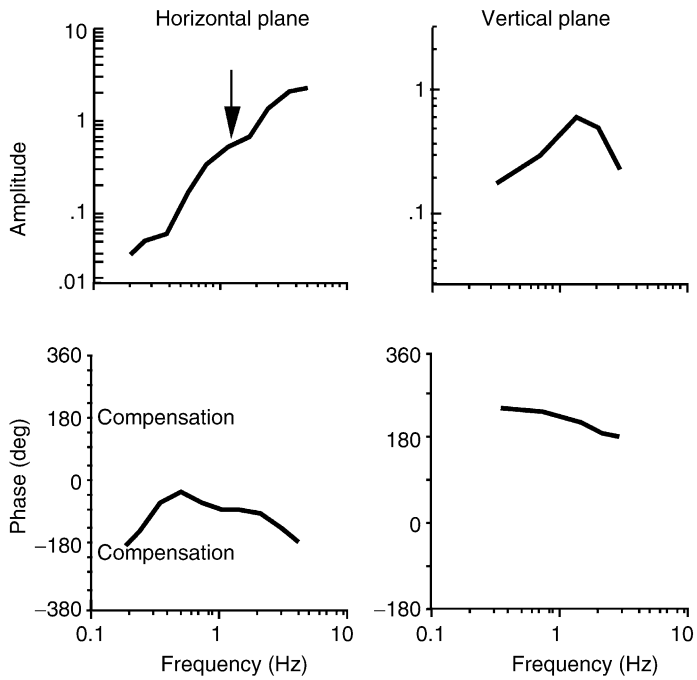
The VCR is not a simple monosynaptic reflex pathway. The majority of neurons that may produce the VCR response have disynaptic and trisynaptic connections between the vestibular labyrinths and the neck muscles through the medial and lateral vestibulospinal pathways projecting on to the cervical motoneurons. Other inputs to the motoneurons include the reticulospinal pathways which have been shown to be capable of producing the short latency VCR behaviors when vestibulospinal pathways are interrupted [1]. Inputs from the vestibular afferents (the semicircular canals and the otolith organs) converge on to single vestibular neurons in the vestibular nuclei before descending to the neck motoneurons. More than 30% of vestibular neurons receive convergent inputs from the vertical semicircular canal and the otolith nerves. About 15% of vestibular neurons receive convergent inputs from the horizontal semicircular canals and the otolith nerves. Convergence of canal and otolith inputs will produce an accurate reception of and an appropriate compensatory reaction to complex head movements that are both rotational and linear. Vestibular neurons also receive input from the cerebellum, which has been shown to adjust the gain of the VCR. Monosynaptic inputs from somatosensory afferents in the cervical spine also converge on to the vestibular neurons. This compound convergence indicates an extensive integration of signals at the second order neurons, which will then activate the appropriate set of muscles in order to orient the head in the correct direction. The result is that the central representation of head movement is controlled at the initial stages of sensory processing in the brain stem [3].

The second order vestibulospinal neurons respond to externally applied movements of the head by encoding the angular velocity of the movement which reflects the head velocity in space signaled by the semicircular canal afferents [3]. Typical neck motoneurons receive input from all six of the semicircular canals, which makes them capable of generating reflex movements that are compensatory for three dimensional velocity perturbations. Branches from vestibulospinal fibers may also terminate on motoneurons of more than one muscle [1], suggesting that the reflex head movements support head stabilization about multiple degrees of freedom and implicating vestibulospinal fibers in the formation of neck muscle synergies. The functional result of this convergence of descending inputs with body oriented and head oriented afferent signals is that responses to passive and active head perturbations are differentially organized (Fig. 1).

Dynamic properties of a VCR tested in alert cats [2] are suggestive of a linear second order system that demonstrates an increase in gain (amplitude) and a phase (timing) lead as frequency increases. Open loop dynamics of the VCR have been characterized in healthy young adults by fixing the trunk to a chair that was rotated in a ►pseudorandom fashion in ►yaw [4] or ►pitch [5] (Fig. 2). Very low gains of the VCR



**Vestibulocollic and Cervicocollic Control. Figure 1** Gains and phases of right complexus muscle EMG responses against angle of orientation during a voluntary head tracking task or passive VCR rotations of the whole body (0° = yaw, 90° = pitch) are plotted for four trials of one animal. A 90° phase advance during the VCR relative to tracking indicates a velocity rather than position related response. Unique patterns of activity can be selected by each animal for active tracking responses, indicating that the CNS can generate movements in the same direction using different muscle patterns.



**Vestibulocollic and Cervicocollic Control. Figure 2** Bode plots of the amplitude and phase of the average neck with respect to trunk response to horizontal and vertical plane pseudorandom sum of sine rotations during a mental distraction task in healthy subjects. Phases of ±180° and amplitudes equal to one indicate that the head is perfectly compensating for motion of the trunk to stay stable in space. A phase of 0° indicates that the head is moving with the trunk. Amplitudes greater than one indicate that the head is moving more than the trunk. The *vertical arrow* indicates the plateau in the horizontal plane dynamics that appeared around 1.5–2.5 Hz.

emerge below 0.5 Hz. At 1–3 Hz, the VCR appears to play a predominant role in stabilizing the head as gains move toward unity and compensatory phases are almost 180° out of phase with the rotational disturbance. This is a functional bandwidth for reflex control, as the preferred frequency for natural gait occurs around 1.8 Hz [6]. Above 3–4 Hz, resonant behaviors indicate that control by head inertia and mechanical properties of the neck are predominant. Human head stability during pitch exceeded that during yaw at the low end of the frequency range, implying a contribution of a static otolith VCR. These findings are supported by dynamical models of the head stabilization system [2,7].

## Characteristics of the CCR

When the neck was rotated while the head was held fixed in space [2], open loop dynamics of the CCR were very similar to those of the VCR in alert cats, but with increased torques which could be attributed to the viscoelastic properties of the neck muscles. Both the dynamic behavior of the CCR and its high sensitivity to small motions of the cervical spine resemble the properties of muscle spindle primary afferents, signifying that these afferents provide the major input responsible for the CCR. In fact, short latency reflexes in the neck muscles of alert cats are attenuated or abolished by partial or complete dorsal ►rhizotomy at the first cervical vertebra. The high density of muscle spindles in the cervical musculature insinuates a high degree of sensitivity into relatively small cervical stimuli so that rapid cervical postural corrections can be made. Evidence of these immediate changes was observed when subject maintained the position of their head in space during simultaneous postural and cognitive tasks with and without a weight placed on top of their heads [8]. Adding weight to the head did not significantly change head or neck position, suggesting that there was an immediate and compensatory response for the added weight. This compensatory response was explored through dynamic models of the head and neck that predicted that the mechanism that controlled the position of the head in space was an alteration in the system mechanics through an increased contribution from the CCR for modulating stiffness and the viscoelastic properties of the head-neck system [7,8].

## Contributions of the VCR and CCR to Behavior

Data from both decerebrate and alert animals indicate that the CCR and VCR behave approximately linearly, both individually and in combination [2]. When the head was driven by a ►servomotor while the body remained stationary, EMG activation by the two reflexes added linearly to produce a large response. When the body was rotated and the head was allowed to counter-rotate about the first and second cervical joints, the two reflexes combined linearly in an antagonistic fashion; the CCR acted to oppose head rotations produced by the VCR. Acting together, the two reflexes assisted each other in preventing oscillation of the head on a stationary body. But although the characteristics of these two reflexes are well characterized in constrained animals, the contribution of these responses during functional activities is not as clear. It is known that the disynaptic vestibular pathways are not sufficient to produce the dynamics of the VCR. Furthermore, the muscle torques generated by the VCR are not adequate to produce the forces necessary to counteract external disturbances [1]. The simple responses identified in reduced preparations such as decerebrate cats are not as readily elicited in alert animals. Both alert cat and human subjects have the ability to suppress or modulate the appearance of the VCR and it has been demonstrated that the reflex dynamics can be modified by mental set. Even when subjects were fixed firmly to a turntable and rotated with a pseudorandom ►sum of sines while distracted by mental arithmetic, a time domain analysis revealed that the contribution to head stability by the short latency CCR and VCR was negligible. Long latency stabilizing mechanisms with onset times around 140 ms emerged as the primary influence on head stabilization [9]. Thus the concept of the VCR and CCR emerging as short latency stimulus evoked reflexes does not explain the response dynamics during functional behaviors.

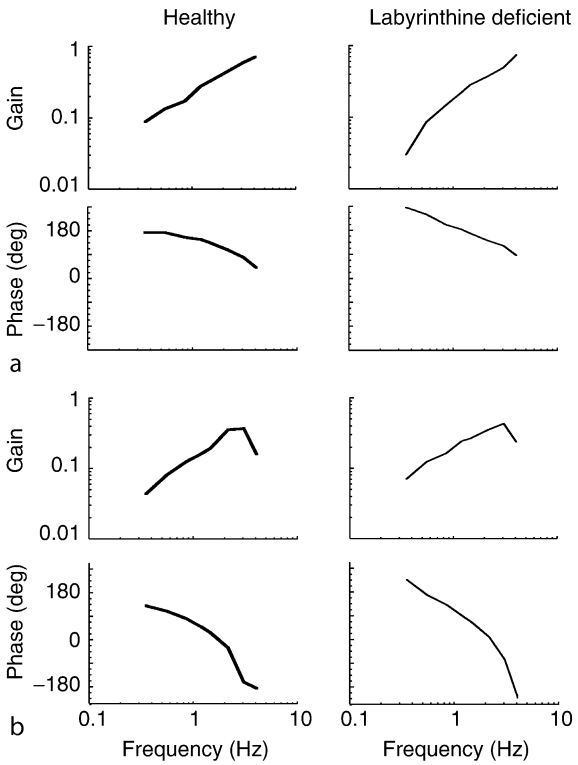
Strong behavioral evidence of head instability in both animals and humans with acute loss of vestibular signals however, strongly implicates vestibular input in the process of maintaining head stabilization. During transient free fall of the head or during whole body ascent and descent, the sternocleidomastoid muscle can be activated at about 24–44 ms in healthy subjects compared to about 67–80 ms in labyrinthine deficient subjects. The shorter latency response of the muscle in the healthy subjects might be vestibular in origin, while the longer neck muscle response in the labyrinthine deficient subjects might have been a stretch reflex rather than a response due to activation of vestibular receptors. When subjects were standing on a platform that was linearly translated in the anterior or posterior direction, EMG responses of the neck and upper trunk muscles appeared in the direction that would appropriately compensate for motion of the head [10]. These responses were elicited at the same latencies as the automatic postural reactions in the lower limb (Table 1) suggesting that stabilization of the head and neck was not controlled by ascension of proprioceptive inputs from the lower limb. It is unlikely that these longer latency muscle EMG responses were a startle response because they did not adapt across trials. More probably, stabilization of the head and upper trunk was being independently controlled by vestibular and cervical proprioceptive signals. Cervical afferent signals converge on the vestibular nuclear complex and adjacent reticular

**Vestibulocollic and Cervicocollic Control. Table 1** Means and standard deviations of muscle EMG latencies during platform translations

| Muscles | Anterior translations | Posterior translations |
|---|---|---|
| ***Short latency responses (ms)* | | |
| Soleus | | 60 ± 6 |
| Neck extensors | | 54 ± 14 |
| *Long latency responses (ms)* | | |
| Soleus | 149 ±39 | 95 ± 11 |
| Neck extensors | 103 ± 25 | 135 ± 25 |
| Tibialis anterior | 98 ± 14 | 117 ± 22 |
| Neck flexors | 107 ± 18 | 95 ± 19 |

formation and the intimate connections between these inputs and cerebellar pathways may be responsible for transforming vestibular inputs from head centered to body centered coordinates. Vestibulospinal control of the trunk and lower limb has been described in the accompanying essay of this Encyclopedia.

Longer latencies of the response imply that even if the stabilizing responses are of vestibular origin, their influence on head stabilization could be under descending control. Rather than directly producing the muscular forces for direct stabilization of the head in space, the vestibular inputs may be involved in changing the control parameters for stabilization of the head and neck. For example, damping parameters could be altered through changes in both VCR and CCR reflex activation or through changes in the viscoelastic properties of the system [8]. A loss of damping by vestibular inputs would explain the increased magnitudes of the later components of trunk and head angular and linear motion in labyrinthine deficient subjects during seated linear accelerations [6] (Fig. 3). With the trunk fixed so that it moved in phase with the accelerating seat, low response gains in the labyrinthine deficient subjects and phases close to 0° at low frequencies imply that the head is moving with the trunk as would occur with control by the CCR acting alone, whereas a 90° phase advance in healthy subjects indicates that the head is compensating for the motion of the body. With the trunk free to move however, the flattened phase responses at frequencies below 1 Hz in the healthy subjects suggest a neural controller that is damping the system mechanics [8]. In the LD subjects, a steep phase descent was continuous across the frequency range as would be expected if the only controller were system mechanics and there were no neural delays present in the response. Steeply descending phases and gain drops observed above 2 Hz when the trunk was free to move might also be due to increasing time delays in the control system, as would occur if the descending controllers required more processing time than simple reflex mechanisms.



**Vestibulocollic and Cervicocollic Control. Figure 3** Bode plots of the average gains and phases of head angular position with respect to sled linear position in healthy and labyrinthine deficient subjects during linear sum of sines translations. Responses in each group are plotted for trunk fixed (a) and trunk free (b). According to the phase conventions, 0° indicates the head rotating in downward pitch as the sled moved forward; ±180° indicates the head rotating in upward pitch as the sled moved forward; ±90° indicates a lag or lead of the head with respect to the sled.

Thus the vestibular system does not appear to be directly implicated in generating the initial head stabilizing response during functional motion. The role of the vestibular system may actually be one of damping

V

the response to the mechanics of the system and of monitoring the position of the head and trunk in space, secondary to feedback from segmental proprioceptors, in order to minimize the sustained effects of destabilization and maintain orientation in space. Although the response properties of the VCR to linear motions of the body are less well defined than those of rotational motion, suggestive evidence will be addressed in the accompanying essay in this Encyclopedia that the linear vestibular reflexes play a significant role in head and gaze stabilization during locomotion.

# Vestibulo-collic Reflex

## Definition

Activation of neck muscles induced by labyrinthine (vestibular) stimulation. In general, it is aimed at stabilizing the position of the head in space.

►Peripheral Vestibular System
►Vestibulo-Spinal Reflexes

# Vestibulo-Ocular Reflex (VOR)

J. VAN DER STEEN
Department of Neuroscience, Erasmus MC, Rotterdam, The Netherlands

## Synonyms

Vestibulo-ocular reflex; AVOR (angular VOR); RVOR (rotational VOR); LVOR (linear VOR); TVOR (Translational VOR)

## Definition

The vestibulo-ocular reflex (VOR) is a short latency reflex system, which ideally generates a rotation of the eye with an amplitude equal and opposite to the direction of a head movement as a result of vestibular stimulation.

## Characteristics

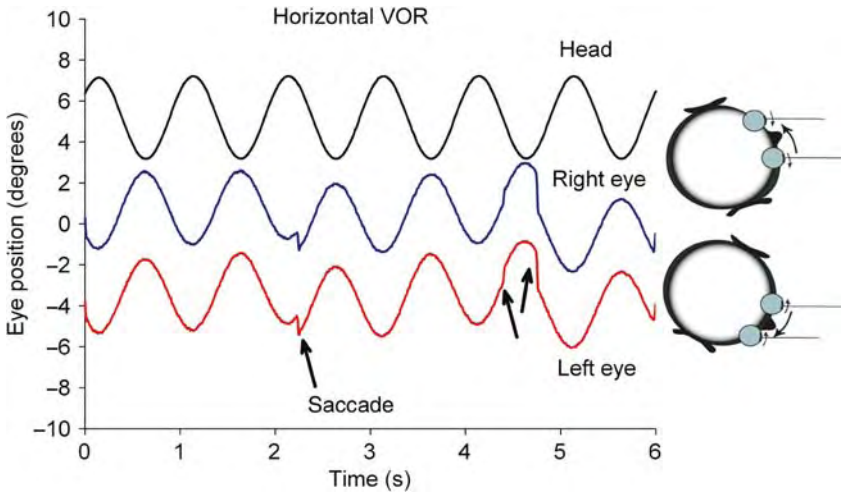
### Quantitative Description of the VOR

Angular or linear movements of the head cause an oculomotor response that compensates for the head movement. The eyes make a counter rotation in the head such that the line of sight (gaze) remains stationary. The generated eye movements consist of smooth components (slow phases) interrupted by fast resetting movements (fast phases or saccades).

Based on their function three major forms of vestibulo-ocular reflexes exist.

1. The *rotational* or ►*angular vestibulo-ocular reflex* (RVOR or AVOR) provides ocular stability during head rotations. It receives its main input from the semicircular canals.
2. The *ocular counter roll reflex* (tilt reflex) helps to maintain an upright position in relation to the earth's vertical. This reflex invokes ocular counter rolling movements of the eye that are held during a static change in the position of the head with respect to gravity. This reflex is mediated by the otolith organs.
3. The ►translational vestibulo ocular reflex (TVOR or LVOR) assists in maintaining fixation stability during linear movements of the head. This reflex arises from sensory information from both the semicircular canals and otolith organs.

A typical AVOR response is illustrated in Fig. 1. The figure shows recordings of eye and head movements of a subject who was oscillated about a vertical axis with a frequency of 1 Hz and amplitude of 4 degrees peak-to-peak. Eye movements are in opposite direction to the head movement. When the head rotates to the left, the eye counter-rotates to the right with respect to the head and vice versa. The efficacy of the reflex is determined



**Vestibulo-Ocular Reflex (VOR). Figure 1** Horizontal eye movements in response to sinusoidal vestibular stimulation about the vertical axis. Stimulus frequency was 1 Hz, peak-to-peak amplitude 4°. Notice that when the head goes to the right (upward deflection) the eye rotates to the left (downward deflection).

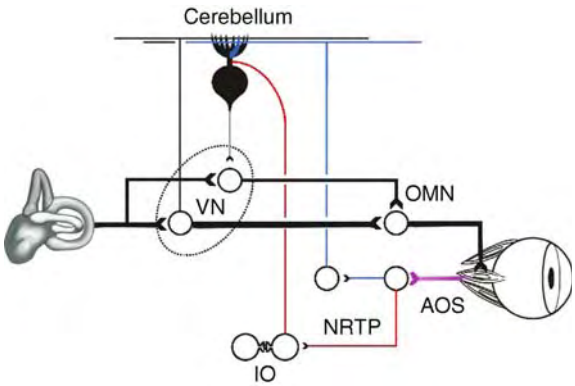
by the ►VOR gain and ►VOR phase, where gain is the ratio between eye and head motion and phase is the delay between head motion and eye movement onset.

## The Vestibular System

The VOR is mediated by the vestibular system. The backbone is the three-neuron reflex arc (see Fig. 2). At the input side the system senses the forces generated by linear and angular accelerations of the head. These sensors are situated in five organs located within the cavities of the vestibular labyrinth hidden in a bone structure (os petrosum) on each side of the skull. The sensory signals are conveyed to the vestibular nuclei located in the brainstem. The vestibular nuclei are the interface between sensory signals from the vestibular organ and motor command signals generated by the oculomotor nuclei. They transform the sensory signals into command signals for the eye muscles. The vestibular nuclei add and process information coming from a variety of additional neuronal sources and send their output to the oculomotor nuclei, which provide the command signals for the eye muscles (*see higher level organization*).

## What Processing Is Necessary to Generate a VOR?

Angular accelerations of the head cause a displacement of the fluid (endolymph) in the semicircular canals. This causes a bending of the hair cells located in the cupula of each canal. Each canal is only maximally sensitive to angular motion of the head in the plane of that canal because hair cells are unidirectionally selective and all the hair cells in one semicircular canal are oriented in the same direction. Although displacement of the cupula system during natural head movements is an adequate stimulus for the semicircular canals, angular acceleration is proportional to head velocity rather than to head acceleration. This is because the mechanical response of the canal system is determined by its hydrodynamic properties. Angular acceleration in the plane of the canal imposes inertial forces on the mass of the endolymph fluid contained by that canal, resulting in a relative fluid flow in opposite direction [1]. Because the fluid flow is opposed by viscous forces proportional



**Vestibulo-Ocular Reflex (VOR). Figure 2** The connections from the vestibular organ via the vestibular nucleus (*VN*) to the oculomotor nucleus (*OMN*) forming the three-neuron reflex arc (*bold black lines*). This feed forward connection, which is the basis of the VOR receives inhibitory input from the cerebellum at the level of the VN. The amount of cerebellar activity is determined by the retinal slip information coming into the cerebellum via the accessory optic system (*AOS*) via the nucleus reticularis tegmenti pontis (*NRTP*) and inferior olive (*IO*). These two inputs project onto the Purkinje cells via respectively parallel and ascending fiber pathways.

to the velocity of the flow, each canal effectively integrates the angular acceleration imposed on the head. Thus, within the range of natural head movements (0.1–5 Hz) the semicircular canals act as sensitive speedometers, which send angular velocity information via nerve signals (see higher level organization) to the vestibular nuclei.

An important role in the vestibular system is played by a special circuit called velocity storage. Velocity storage holds or stores the activity from the semicircular canals and releases this activity over a more extended period of time. Both a fast "direct" and a slow "indirect" velocity storage pathway are involved in the generation of the AVOR. The effect is an increase in the time constant of the AVOR to 20–40 s (this is a 4–6 fold increase with respect to the cupula time constant of the canal) [2].

The AVOR eye movement response is thus the result of the combination of peripheral and central information processing. At the periphery, the canal hydrodynamic properties determine that between 0.1 and 5 Hz the AVOR is approximately 180° out of phase with the head movement and has almost unity gain. Outside this frequency band specific gain and phase changes occur, such that there is a phase lead and decrease in gain at very low frequencies, whereas there is a phase lag at very high frequencies.

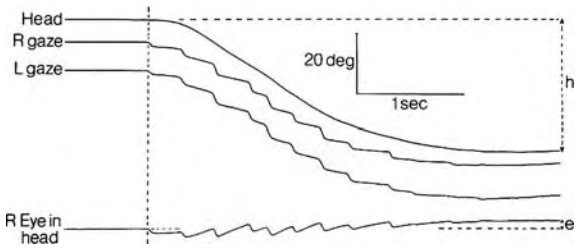
Central processing in the brainstem in the form of velocity storage effectively integrates velocity signals into position signals, thus providing the necessary information to control the eye muscles. It also lengthens the period that vestibular activity is present in the vestibular system.

## What Processing Is Necessary to Generate a Linear VOR?

*Linear accelerations* of the head (including gravity) are detected by the otolith organs.

These organs have a macula with sensory hair cells placed in multiple orientations. The tips of the hair cells are placed against a heavy load, the otolith. Whenever there is a linear displacement of the head, a shear force is exerted between the macula and otolith, which deflects the hair cells. A static position change with respect to gravity results in a counter roll of the eyes, which is maintained as long as the head is in that position (see Fig. 3). In fish, amphibians and rodents otolith-ocular reflexes compensate for up to 60% of the angle of head tilt [3]. In humans, the gain of static otolith-ocular reflexes is much smaller viz. 0.1–0.2 [4].

Under dynamic conditions the situation is different. Most lateral eyed species have only a very limited response to linear accelerations at higher frequencies. In frontal eyed species (humans and primates) the TVOR has developed in line with foveal vision and stereopsis. This enables us to stabilize the eyes when we drive a car, run or walk. Under these activities linear accelerations occur all the time. Therefore, the TVOR is regarded as a foveal stabilization mechanism that works in close synergy with foveal visual pathways (smooth pursuit). The goal is to minimize binocular disparities by minimizing the retinal slip in both eyes. The role of the TVOR in foveation also shows from the fact that the TVOR scales with viewing distance [5]. Interestingly the properties of TVOR such as scaling with viewing distance occur particularly at higher stimulus frequencies (>1 Hz). Although recently much progress has been made, the pathways and neuronal processing of LVOR are complex and still only partially known. Both otolith-ocular and canal-ocular pathways are involved. As a result, the linear vestibular system is not only capable of stabilizing the eyes during linear accelerations, but is also capable of distinguishing whether a change in activity is due to tilt or inertia induced by linear motion (for a review see Angelaki [6]).

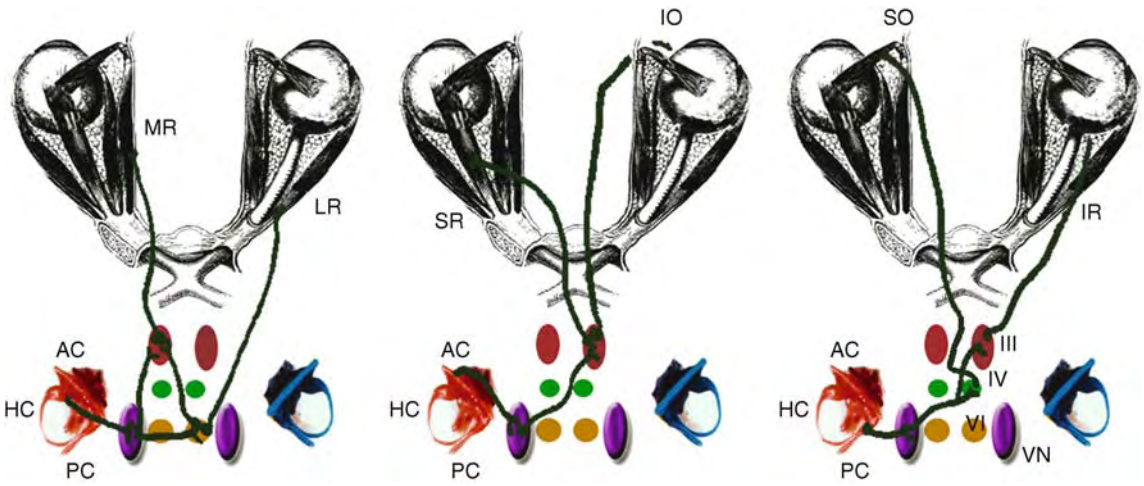


**Vestibulo-Ocular Reflex (VOR). Figure 3** Torsional eye movements of a human subject who made a large (40°) roll movement to the left. During the rotation there are compensatory torsional eye movements. With the head stationary at 40° roll, there is only a very small residual compensation of the eye, which is maintained as long as the head remains in that position.

## Higher Level Organization

### *The Intrinsic Coordinate System of the Vestibular System*

The anatomical arrangement of the canals is such that two canals on both sides of the head are paired. Each pair works in a push-pull fashion: When one canal is excited, the other canal is inhibited. The VOR is organized in a head centric system allowing three degrees of freedom. Both the anatomical organization of the sensors and that of the eye muscles allow compensation in all three dimensions. Fig. 4 shows a top view of the arrangement of the three canal pairs in relation to the eye muscles that are innervated by each pair. Notice that both the vertical canal planes and the vertical and oblique eye muscles are oriented at approximately 45° angles. Depending on the plane of motion different groups of eye muscles are activated. Rotation about the vertical axis involves the medial and lateral rectus muscles, whereas rotation about a horizontal axis activates the superior recti and oblique muscles.



**Vestibulo-Ocular Reflex (VOR). Figure 4** Excitatory connections of the individual semicircular canals via the vestibular (*VN*) and oculomotor nuclei (*III, IV* and *VI*) to specific eye muscles. *Left panel*: horizontal canal (*HC*) connections to medial rectus (*MR*) and lateral rectus (*LR*) muscles. Projections run via the VN to contralateral abducens nucleus (*VI*) and ipsilateral oculomotorius nucleus (*III*). *Middle panel*: Anterior canal (*AC*) projects from III to ipsilateral superior rectus (*SR*) and contralateral inferior oblique (*IO*) (not visible). *Right panel*: Posterior canal (*PC*) projects to contralateral inferior rectus (*IR*) and ipsilateral superior oblique muscle (*SO*) via the contralateral trochlear nucleus (*IV*) and oculomotorius (*III*). Notice that the plane of pulling action of individual muscles lines up with the canals to which they are connected.

Although ideally vestibular eye movements should be fully compensatory during rotations about any axis, gain of the AVOR about the nasal-occipital axis, evoking torsional eye movements has been found to be systematically lower than for yaw and pitch. In lateral eyed species, the situation for roll and pitch is reversed, which relates to the different orientation of the eye and attachment of the ocular muscles relative to the skull.

### Matching Visual and Vestibulo Ocular Reflexes

An important question is how the VOR is matched within the brain with other sensory modalities such as vision. Although the eye is an object with three rotational degrees of freedom, visual stabilization systems (pursuit, fixation saccades) occur in a single plane i.e. there are only two degrees of freedom for ocular torsion. This behavior is formulated in ►Listing's ►Law and states that any eye position in the orbit can be reached from the primary position by rotation about a single axis in the so called Listing's plane. This is problematic during head motion because an ideal AVOR stabilizes retinal images by rotating the eye about an axis parallel to head motion. But head movements occur in three dimensions and are not confined to Listing's plane. Currently there are different results and opinions about 3D behavior of the AVOR. Some researchers suggest a head centric organization of the AVOR with primary axes that closely follow Listing's plane and which are optimal for retinal image stabilization [7]. Others have reported that the AVOR employs axes that form a compromise between Listing's Law and the axis of head rotation. It is currently also still debated as to whether specific kinematic behavior is time limited to a specific phase of the VOR response and if it is neuronally or more peripherally implemented in the oculomotor plant (for a review see Crane et al. [8]).

### Plasticity of the VOR

The VOR is a very fast feed forward reflex system with a delay of about $8\times10^{-3}$s. Because the vestibular organs do not directly receive feedback, information on the accuracy of the response must come from other sources. The most important information comes from the visual system. Retinal slip information projects via a subcortical pathway called the accessory optic system (AOS) and via the inferior olive (IO) to the flocculus, which is part of the cerebellum. The flocculus also receives vestibular information from the semicircular canals via special neurons in the vestibular nucleus.

The two sources of information are compared by the Purkinje cells (the only output cells from the cerebellum), which project back onto the vestibular nuclei. The cerebellar loop thus forms an essential part of the vestibular system, which can modulate the activity of the three-neuron reflex arc system. It is therefore essential for plastic behavior of the VOR. Patients with cerebellar lesions fail to show adaptive behavior.

### *Function*

The VOR is very important for stabilizing vision particularly during locomotion. Because slight head movements are present all the time, patients whose VOR is impaired cannot read, because they cannot even stabilize the eyes during small head tremors.

The VOR evolved early in evolution and has changed very little since its origin. The same basic design found in humans has been found in fossils of dinosaurs.

Vestibular eye movements are generated with much smaller latencies than visually generated eye movements. This is due to the much larger time needed for the visual system to detect and process motion. So the dinosaurs already relied on vestibular input to compensate for linear and angular accelerations during locomotion.

Although the VOR reflex does not depend on visual input and works even in total darkness or when the eyes are closed, in daily life situations the VOR works in close synergy with visual stabilization systems. Visual information is continuously monitored by the brain to assure retinal image stability. If vision gets blurred during head movements, the VOR undergoes plastic changes that restore visuomotor performance via cerebellar loops.

The vestibular system responds to movements that have angular or linear acceleration components. In healthy persons all parts of the vestibular organ are in balance and work together to give the appropriate VOR response. However, when unilateral damage occurs to the vestibular organ or even to one canal, the balance is disturbed. This is reflected in spontaneous eye movements (nystagmus, drift).

# Vestibulo-Oculomotor Connections

Werner M. Graf
Department of Physiology and Biophysics, Howard University College of Medicine, Washington, DC, USA

## Synonyms

Elementary vestibulo-ocular reflex arc – three-neuron arc

## Definition

Compensatory eye movements are embedded in a system of three-dimensional geometry that characterizes both the sensory periphery (semicircular canal orientations) and the motor effectors (extraocular muscle pulling directions). This framework organization is also reflected in the anatomical networks mediating compensatory eye movements, linking each of the semicircular canals to a particular set of extraocular muscles (so-called principal vestibulo-ocular reflex connections to ►yoked muscles). These connections are identical across species throughout evolution. These short latency connections consist of three neurons, i.e., primary vestibular neurons of the vestibular nerve, second-order vestibular neurons in the vestibular nuclei, and the respective extraocular motor neurons.

## Characteristics

The production of eye movements requires precise space-time coordination of all moving elements, i.e., head, body and two eye balls. This function is subserved by a neuronal network that is conserved across species and possesses a high degree of adaptability, or motor learning. In the case of the vestibular-oculomotor connectivity, very precise sensory-motor relationships are established, that are only matched to some degree by vestibulo-spinal connections. While we have intricate maps of the visual, auditory and somatosensory spaces, the corresponding sensory-motor relationships have not been elaborated to the same degree of exactness. Clearly, vestibulo-motor projections must have played a primordial role in spatial orientation and postural control throughout vertebrate history, while other sensory systems subserved accessory functions (e.g., visual input eliciting the dorsal light reflex in fishes). One important phylogenetic requirement must have been to ensure a rapid response: vestibular reflexes can be as fast as 16 ms from stimulus to motor reaction. One way to ensure such rapid responses is to employ hard-wired connections, and we see such a system in operation in vestibulo-motor relationships. The fast response time of this system allows precise motor action to keep visual images constantly unblurred or prevent injuries by fast reflexes, e.g., when breaking a fall or preventing a fall

altogether. Nevertheless, the system retained a remarkable adaptability to cope with internally and externally imposed changes. Once the spatial components of this system were put in place during vertebrate evolution, fundamental changes were no longer possible, only modifications of the original blue print.

## Vestibulo-Ocular Connectivity

The conservation of similar spatial geometries of semicircular canals and eye muscle pulling directions is also reflected in a stereotypical innervation pattern of the principal neuronal connections for the production of compensatory eye movements across vertebrates. This innervation scheme has been termed the "elementary vestibulo-ocular reflex arc" [1], or the "three-neuron arc" [2] (principal vestibulo-ocular reflex connections to yoked muscles). The three neurons involved in this reflex arc are the primary vestibular neurons, the second-order vestibular neurons in the vestibular nuclei in the brain stem, and the respective extraocular motoneurons.

As we have already mentioned in the chapter devoted to "Vestibulo-oculomotor System: Functional Aspects", the ipsilateral superior rectus and the contralateral inferior oblique muscles are activated from the anterior semicircular canal, the ipsilateral superior oblique and the contralateral inferior rectus muscles from the posterior canal, and the ipsilateral medial rectus and the contralateral lateral rectus muscles from the horizontal canal. The antagonists of these muscles are inhibited by the same semicircular canals. The entire three-neuron arc connections of the vestibulo-ocular reflexes are summarized in Fig. 1a–c.

The innervation pattern of the vestibulo-ocular three–neuron-arcs together with the stereotypical three-dimensional geometry of the sensory and motor periphery (Fig. 1d) is the basis of space-time coordinated compensatory eye movements.

While the reflex arcs from the semicircular canals to extraocular motoneurons pools indeed are fairly stereotypical, otolith projections usually are more heterogeneous in nature. In particular, such projections do not seem to follow the classical three-neuron arc scheme. In general, otolith-ocular input is weak by contrast to, for instance, vestibulo-spinal projections. Nevertheless, otolith pathways seem to be embedded in the spatial reference frame of the semicircular canals.

## Primary Neurons

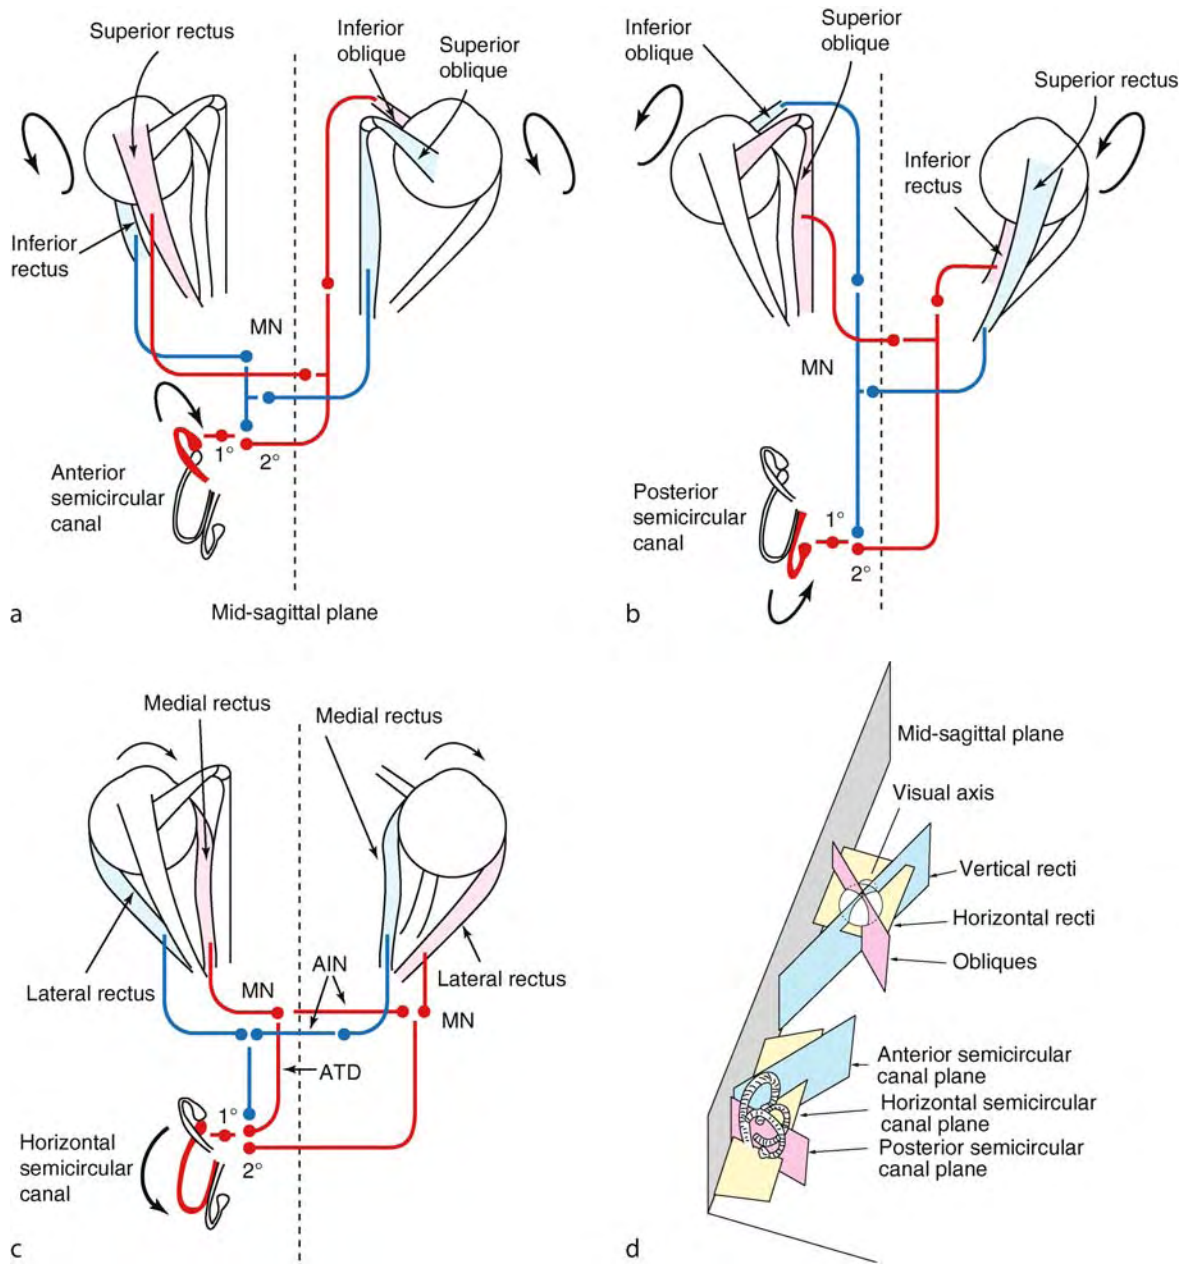
The first leg of the three-neuron-arc is composed of the primary vestibular neurons linking the receptor ►hair cells of the semicircular canals and the otoliths to vestibular nucleus neurons (Fig. 2).

In general, semicircular canal units terminate in the superior, medial and descending (inferior) vestibular nuclei. There are no terminals in the lateral vestibular nucleus (Deiters) (Fig. 2a). Canal afferents also project directly to the cerebellum, namely the nodulus, uvula and the anterior vermis, but, interestingly enough, not to the flocculus. Otolith-related primary neurons send few collaterals into the superior vestibular nucleus and almost none to the medial vestibular nucleus. Their major projections reach the lateral (Deiters) and the descending vestibular nucleus (Fig. 2b). Some terminations are also found outside the vestibular complex proper. Saccular afferents target neurons in the reticular formation near the abducens nucleus and the spinal trigeminal nucleus. Utricular afferents also project to the area adjacent to the abducens nucleus and even contact abducens motoneurons directly [3]. All in all, otolith afferents seem to display more caudal vestibular termination sites than semicircular canal afferents. Thus, there is a clear qualitative difference between the canal and otolith systems. Functionally, excitatory vestibulo-ocular relay neurons are principally found in the medial vestibular nucleus, inhibitory ones in the superior vestibular nucleus, and canal afferents project largely to these areas. Otolith inputs, by contrast, seem to have reduced direct vestibulo-ocular relevance, except for the monosynaptic utriculo-abducens projections. Their major targets regions largely contain vestibulo-spinal neurons, in particular the lateral vestibular (Deiters) nucleus, the origin of the lateral vestibulospinal tract. The otolith projection pattern therefore is in keeping with the weak direct otolith influences on extraocular motoneurons.

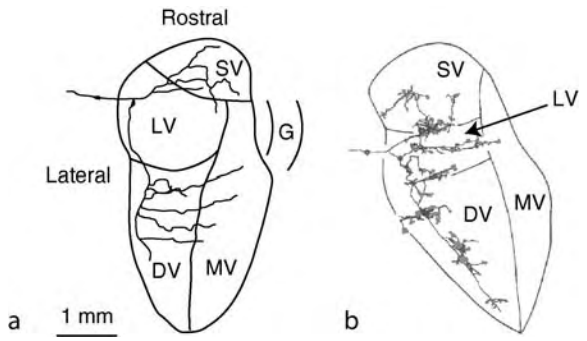
## Spatial Coordination of Compensatory Eye Movements

Conjugate eye movements including those about the optic axis i.e., torsion, are subserved by the "classical" vestibulo-ocular innervation pattern (see Fig. 5 in the previous chapter "Vestibulo-Oculomotor System: Functional Aspects"). Primary vestibular neurons typically transmit semicircular canal-specific information to second-order neurons in the vestibular nuclei. In the ►vertical systems, these latter neurons project either to two principal ►contralateral extraocular muscle motoneurons for excitatory innervation (see Fig. 5a and b in the previous chapter "Vestibulo-Oculomotor System: Functional Aspects"), or to two ►ipsilateral motoneurons pools for inhibitory innervation (the principal vestibulo-ocular reflex connections to yoked muscles) (Fig. 1a and b). One of these motoneuron pools projects to a muscle in the ipsilateral eye, the other one to a muscle in the contralateral eye. This particular crossed and yoked innervation pattern assures conjugacy in the vertical eye movement systems. The specific excitatory and inhibitory connectivity exemplifies the reciprocal excitatory/inhibitory (or push-pull) organizational nature of the VOR system.

Specifically, neurons of the anterior semicircular canal system contact the contralateral superior rectus



**Vestibulo-Oculomotor Connections. Figure 1** The neural and geometrical basis for spatial coordination of compensatory eye movements. The reflex arc between individual semicircular canals and four extraocular muscles typically consists of three neurons, the primary neuron (1°, vestibular nerve), the second-order vestibular neuron (2°, vestibular nucleus neurons), and the oculomotor neuron (MN, in oculomotor, trochlear and abducens nuclei. Excitatory connections are shown in red, inhibitory connections are shown in blue. Contralaterally projecting vestibular neurons are in general excitatory, ipsilaterally projecting ones inhibitory. The respective semicircular canals ((a) anterior canal; (b) posterior canal; (c) horizontal canal) and their primary nerve pathways are marked in red. The on-directions of the semicircular canals are illustrated by thick black arrows. The connectivity of the horizontal system has a few peculiarities, such as an ipsilaterally projecting excitatory connection, the “Ascending Tract of Deiters” (ATD), and the abducens internuclear neuron pathway (AIN). (d) Semicircular canals and extraocular muscles form a three-dimensional intrinsic reference frame system for the production of vestibulo-ocular reflexes. This ensemble and the particular VOR connectivity constitute the basis for compensatory eye movement coordination in physical space.



**Vestibulo-Oculomotor Connections. Figure 2** Axonal arborization of individual primary vestibular neurons. (a) Horizontal semicircular canal unit. Terminations are found in the superior (SV), descending (inferior) (DV) and medial (MV) vestibular nuclei. The lateral (LV) vestibular nucleus does not receive semicircular canal projections. The axonal arborization of this neuron is typical for all semicircular canal-related units. G: genu of the facial nerve (modified after Mannen H, Sasaki S-I, Ishizuka N (1982) Trajectory of primary vestibular fibers originating from the lateral, anterior and posterior semicircular canal in the cat. Proc Jpn Acad Ser B 58:237–277). (b) Sacculus unit. Terminations are found in the superior, descending (inferior) and lateral (Deiters) vestibular nuclei. The medial vestibular nucleus does not receive otolith projections. The axonal arborization of this neuron is typical for all otolith-related units (modified after Imagawa M, Graf W, Sato H, Suwa H, Isu N, Izumi R, Uchino Y (1998) Morphology of single afferents of the saccular macula in cats. Neurosci Lett 240:127–130).

and inferior oblique motoneurons via an excitatory projection, and the ipsilateral superior oblique and inferior rectus motoneurons via an inhibitory projection (Figs. 1a and 3a). For instance, left anterior semicircular canal stimulation produces a contraction of the left superior rectus and of the right inferior oblique muscle. In such case, excitatory input reaches the right-side oculomotor nucleus, specifically the superior rectus and inferior oblique motoneuron pools, via a second-order neuron in the left vestibular nucleus whose axon crosses the midline to the right side of the brain (Figs. 1a and 3a).

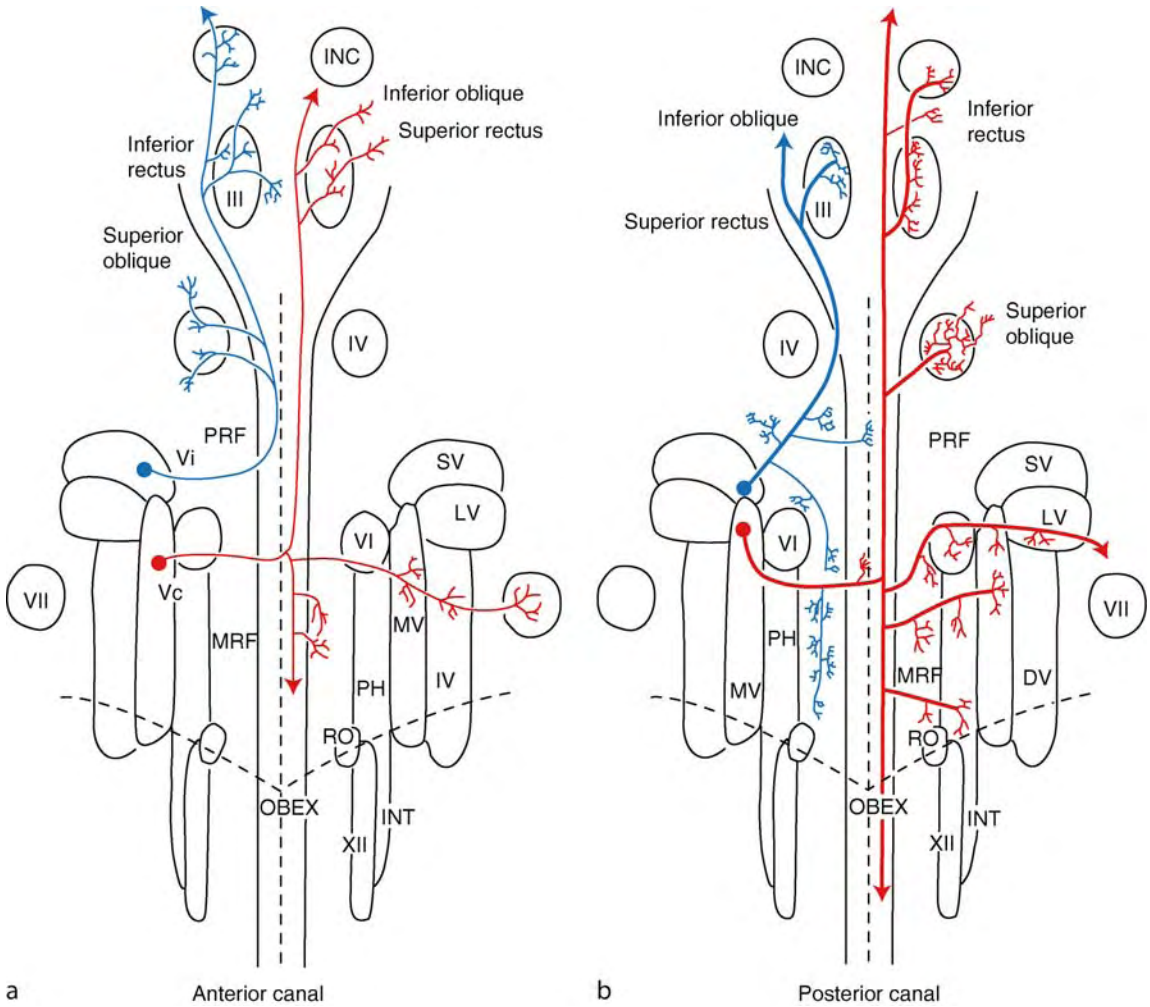
Conjugacy of anterior canal elicited eye movements is assured by the contralateral projection of superior rectus motoneurons (see Fig. 4 in the previous chapter "Vestibulo-Oculomotor System: Functional Aspects"), and the ipsilateral projection of inferior oblique motoneurons. Inhibition of the antagonists of above muscles, right superior oblique and left inferior rectus, is mediated by an inhibitory second-order vestibular neuron in the left nucleus that contacts superior oblique motoneurons in the left trochlear nucleus and inferior rectus motoneurons in the left oculomotor nucleus (Figs. 1a and 3a). For conjugacy, left-side superior oblique motoneurons project across the midline to the right-side superior oblique muscle. Left-side inferior rectus motoneurons innervate the left inferior rectus muscle.

A similar scenario holds for projections originating with the posterior semicircular canal (Fig. 1b). In such case, left posterior semicircular canal stimulation elicits a contraction of the left superior oblique and of the right inferior rectus muscle. Excitatory input reaches the right-side trochlear and oculomotor nuclei, specifically the superior oblique and inferior rectus motoneuron pools via second-order neurons in the left vestibular complex whose axons project across the midline to the right side (Figs. 1b and 3b). Again, inhibition of the antagonists of the above muscles, right superior rectus and left inferior oblique, is mediated by an inhibitory second-order vestibular neuron in the left nucleus. This neuron contacts superior rectus and inferior oblique motoneurons in the left oculomotor neurons (Figs. 1b and 3b). Again, conjugacy is ensured by the contralateral and ipsilateral projections of superior oblique and inferior rectus motoneurons, respectively in the excitatory sensory-motor link. In the inhibitory link, left-side superior rectus motoneurons project across the midline to the right-side superior rectus muscle, left-side inferior oblique motoneurons innervate the left inferior oblique muscle.

## The Horizontal Canal Pathways

►Horizontal conjugate eye movements are produced by the simultaneous contraction of the lateral rectus muscle in one eye and the medial rectus muscle in the other eye. The neuronal networks underlying horizontal conjugate eye movements are the exception to the rule introduced above for vertical canal pathways. The fundamental difference between the two is the ipsilateral placement of medial rectus motoneurons (Fig. 4).

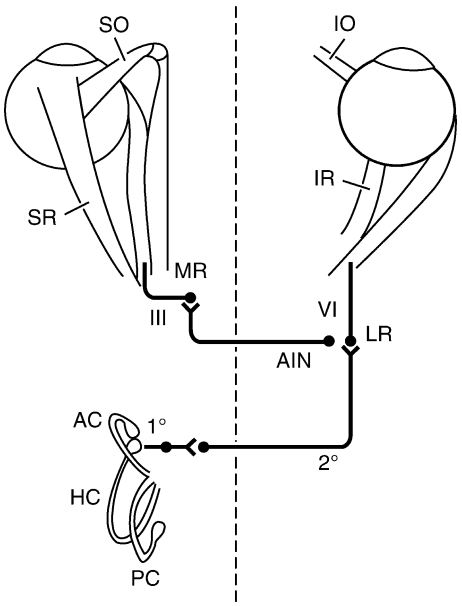
We have seen that in the vertical systems, two motoneurons pools, superior rectus and superior oblique always address their respective contralateral extraocular muscles (Fig. 4 in the previous chapter "Vestibulo-Oculomotor System: Functional Aspects"). Such an innervation scheme subserves conjugacy of eye movements, and is also in agreement with Hering's Law of equal innervation of yoked muscles. In the horizontal eye movement pathways, the same functional relationship applies (see Fig. 5c in the previous chapter "Vestibulo-Oculomotor System: Functional Aspects"). However, we find the two associated motoneuron pools, lateral rectus and medial rectus on opposite sides of the brain. Both of them innervate ipsilaterally located muscles. Vestibular information from the horizontal semicircular canal reaches the ipsilateral and the contralateral abducens nucleus, contralaterally projecting vestibular nucleus neurons being excitatory, ipsilaterally projecting ones being inhibitory (Fig. 1c). Thus, only abducens motoneurons, innervating the lateral rectus muscles receive direct vestibular input.



**Vestibulo-Oculomotor Connections. Figure 3** Morphology of individual second-order vestibular neurons visualized by intracellular injection of HRP. Neurons shown in red are excitatory, neurons shown in blue are inhibitory. (a) Anterior canal neurons in a cat. Note prototypical excitatory projections to contralateral superior rectus and inferior oblique motoneurons, and inhibitory projections to the antagonists (modified after Graf W, Ezure K (1986) Morphology of vertical canal related second order vestibular neurons in the cat. Exp Brain Res 63:35–48). (b) Posterior canal neurons in a rabbit. Note prototypical excitatory projections to contralateral superior oblique and inferior rectus motoneurons, and inhibitory projections to the antagonists. Besides motoneuronal projections a number of other brain areas are targeted by axon collaterals. In the illustrated cases, the inhibitory neurons are pure vestibulo-ocular neurons, the excitatory ones are vestibulo-ocular-spinal projection types (modified after Graf W, McCrea RA, Baker R (1983) Morphology of posterior canal related secondary vestibular neurons in rabbit and cat. Exp Brain Res 52:125–138). *DV* (*IV*), descending (inferior) vestibular nucleus; *INC*, interstitial nucleus of Cajal; *INT*, nucleus intercalatus; *LV*, lateral vestibular nucleus; *MRF*, medullary reticular formation; *MV*, medial vestibular nucleus; *PH*, nucleus prepositus hypoglossi; *PRF*, pontine reticular formation; *Ro*, nucleus Roller; *SV*, superior vestibular nucleus; *Vc*, contralateral vestibular neuron; *Vi*, ipsilateral vestibular neuron; *III*, oculomotor nucleus; *IV*, trochlear nucleus; *VI*, abducens nucleus, *VII*, facial nucleus, *XII*, hypoglossal nucleus.

Therefore, an additional pathway is necessary to transmit vestibular information to respective medial rectus motoneurons in order to ensure conjugacy of horizontal eye movements. This function is subserved by so-called abducens internuclear neurons located in the abducens nucleus (Fig. 4) [4]. Interruption of this pathway leads to the clinical symptom of internuclear ophthalmoplegia.

Medial rectus motoneurons do not receive direct inhibitory vestibular input. There is, however, an ipsilaterally projecting excitatory vestibular pathway to medial rectus motoneurons, the so-called Ascending Tract of Deiters (ATD) (Fig. 1c). The ATD seems to play an important role in viewing-distance related changes of the VOR.



**Vestibulo-Oculomotor Connections.**
**Figure 4** Horizontal vestibulo-ocular reflex circuitry. Medial rectus motoneurons are found ipsilaterally to their respective muscle, unlike superior rectus and superior oblique motoneurons. Therefore, eye movement signals to assure conjugacy of horizontal eye movements need to be transmitted via a surrogate neuron. The link between the yoked lateral rectus and medial rectus is assured by the abducens internuclear pathway. *SR*, superior rectus; *SO*, superior oblique; *MR*, medial rectus; *IR*, inferior rectus; *IO*, inferior oblique; *LR*, lateral rectus; *AIN*, abducens internuclear neuron; *1°*, vestibular nerve; *2°*, second-order vestibular neuron; *III*, oculomotor nucleus; *VI*, abducens nucleus.

## The Fine-Tuning of Compensatory Eye Movements

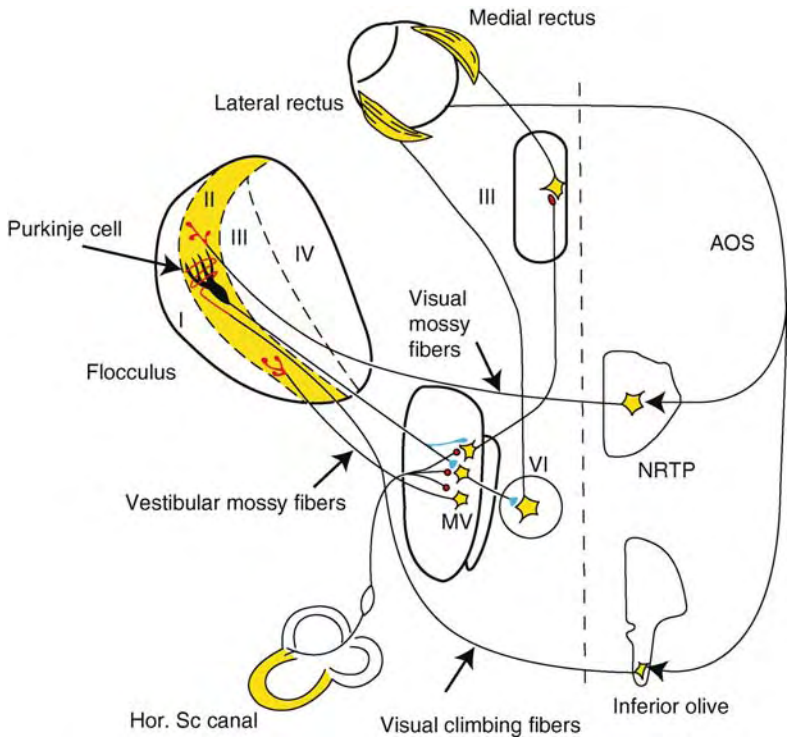
When examining the exact spatial arrangement between extraocular muscle and semicircular canal planes, we observe slight but noticeable deviations from strict co-planarity (Fig. 1d). Therefore, some compensatory mechanisms need to be enlisted to assure spatially correct compensatory eye movements. In general terms, other connections, the so-called accessory connections between semicircular canals and extraocular muscles in addition to the classical principal three-neuron arc have to be considered, and several modeling approaches have relied on this idea [5,6], When we look again at the examples of frontal- and lateral-eyed animals, the different geometrical arrangements and kinematic actions of the extraocular muscles in these species must be taken into account. While the neuronal machinery of the compensatory eye movement system of humans is not open to immediate experimental exploration that in cats and rabbits can be used to test these models. In general, there is good agreement of theoretical conclusions and experimental results in cats [6], but less so in rabbits [5,6]. For instance, anterior-canal related excitatory vestibular neurons not only send axons to contralateral superior rectus motoneurons, but some neurons also have re-crossing collaterals to ipsilateral superior rectus motoneurons. In a similar fashion, posterior canal-related neurons elicit accessory excitatory input to ipsilateral lateral rectus and contralateral medial rectus motoneurons, as well as inhibitory input to ipsilateral medial rectus motoneurons. While the same modeling analysis has not been performed to the same extent in monkeys, the pertinent literature also suggests that accessory connections play an important role in the spatial coordination of their vestibulo-ocular reflexes [7]. For instance, anterior-canal related excitatory vestibular neurons also project not only to contralateral superior rectus motoneurons, one of their principal targets, but also to the ipsilateral homonymous motoneurons as an accessory connection [8]. Such a projection is similar to that of the VOR system in cats, another frontal-eye species.

Some vestibular nucleus neurons may also not subserve the same functional role as others. For instance, regarding projection targets, at least four different types have been identified. There are neurons which project only to spinal cord areas, so-called vestibulo-spinal only types, and neurons which only project to extraocular motoneuron targets, so-called vestibulo-ocular only types. These neurons are thought to subserve only either vestibulo-spinal or vestibulo-ocular functions. A number of vestibular neurons project to both oculomotor and spinal cord areas, and are termed vestibulo-ocular-spinal neurons, and a role in eye-head coordination has been postulated for them. Finally, there are vestibular only neurons, for which no motoneuron projection area has been identified. Such neurons have been shown to project to the cerebellum and the pontine reticular formation. It should be noted that all the above described neurons contact multiple targets some of which are related to motor control while others subserve other functions (Fig. 3).

## Trajectories of Vestibulo-Ocular Neurons

Neurons related to eye movement functions are typically found in the medial (magnocellular), ventro-lateral (so-called ventral Deiters), descending and superior vestibular nuclei (Fig. 2a). Typically, the population in the superior vestibular nucleus is composed of inhibitory neurons, whose axons ascend ipsilaterally. An exception is the so-called extra-MLF anterior canal pathway, which is excitatory, and crosses the midline (see below).

Excitatory vestibular nucleus neurons making contact with trochlear or oculomotor nucleus neurons, i.e., anterior or posterior-canal related, typically ascend in the contralateral medial longitudinal fasciculus (MLF) after the midline crossing (Fig. 3a and b). In addition, the extra-MLF pathway of the anterior canal system



**Vestibulo-Oculomotor Connections. Figure 5** Modular organization of vestibulo-ocular processing loops (yellow). Elements involved in horizontal eye movements comprise the horizontal semicircular canal (hor. sc canal) and its projection neurons in the vestibular nuclei, notably the medial vestibular nucleus (MV), the accessory optic system (AOS) for horizontal visual feed-back projecting to the nucleus reticularis tegmenti pontis (NRTP) and the inferior olive, and the co-called "horizontal" processing zone in the flocculus of the cerebellum. Cerebellar horizontal zone out-put, in turn, is involved in adaptive learning and calibration (illustrated by the blue synapse symbols) of horizontal eye movements produced by reciprocal excitation/inhibition of lateral rectus motoneurons in the abducens nucleus (VI) and medial rectus motoneurons in the oculomotor nucleus (III) (after Ito (1971) Brain Res 40:81–85).

whose cell bodies are found in the superior vestibular nucleus, ascends initially through the reticular formation, crosses the midline at the level of the nucleus reticularis tegmenti pontis towards the red nucleus, and then addresses superior rectus and inferior oblique motoneurons. Inhibitory vestibular neurons ascend for some distance through the reticular formation to join the ipsilateral MLF further rostrally.

Horizontal canal vestibular neurons take a direct route to the contralateral (excitatory), or ipsilateral (inhibitory) abducens nucleus. The horizontal-canal related ATD (excitatory) joins the ipsilateral MLF to reach ipsilateral medial rectus motoneurons [9].

## Neuronal Signals in the Vestibular Nuclei encoding Eye Movements

Regarding the actual neuronal signals transmitted to oculomotor neurons by vestibular neurons, only limited structure-function data, i.e., linking the morphology and projection pattern of a given cell to its signal content, are available to date (see e.g., [8,9]). Regarding eye movements, several response types have been reported. So-called ►Position-Vestibular-Pause cells (PVP) carry signals related to head velocity and eye position in the head. In addition these cells pause for all saccades or fast phases of nystagmus. ►Position-burst cells code eye position, but burst for saccades in one direction and pause during saccades in the opposite direction. Position cells fire according to a given eye position in the head, but show no saccade relatedness, i.e., neither burst nor pause during a saccade. The so-called ►gaze velocity cells encode eye velocity. ►Vestibular pause cells carry a signal which is similar to that transmitted to the brainstem by the vestibular nerve, except that they pause for all saccades. While the above five response types seem to be clearly related to eye movement processing, a sixth cell type, so-called ►vestibular-only cells, carry a copy of the signals transmitted by the vestibular nerve without any eye movement relatedness.

## Modules of Visual-Vestibular Interaction

Clearly, there is a progression across species in terms of the importance of the neuronal pathways involved in

optokinetic reflex processing. Detection of visual movement of low velocities in fishes, amphibians and rabbits takes place in the retina and is transmitted via the pretectum and accessory optic system. In cats, non-human primates, and humans, in particular, cortical areas play an increasingly important role, notably for processing high-speed visual stimuli. In any case, the pretectum and the accessory optic system constitute a major pathway of visual input to the vestibular nuclei and the cerebellum. Visual movement information from the retina reaches the pretectum (nucleus of the optic tract) and the accessory optic system (medial, dorsal and lateral terminal nuclei in mammals; nucleus of the basal optic root in birds). Different components of the three-dimensional visual space are anatomically segregated and represented in these nuclei and sub-nuclei). From there, this information is relayed to the vestibular nuclei via the nucleus prepositus hypoglossi and/or the VTRZ (ventral tegmental relay zone) and to the cerebellum via the nucleus reticularis tegmenti pontis and the inferior olive.

Furthermore, the different coordinate axes of this intrinsic coordinate system seem to have given rise to a modular organization of certain motor processing functions. For instance, in the flocculus of the cerebellum, several modular zones were distinguished on the basis of electrical stimulation and visual coordinate axes analysis, i.e., one horizontal zone and two "vertical" ones (see e.g., [10]) (Fig. 5).

Visual input also plays an important role for the adaptation and calibration of the eye movement reflexes, and the cerebellum seems to play a basic role in this function. This function can readily be appreciated when receiving a new prescription of eye glasses. Initially, we often see blurred images, because our compensatory eye movements do not exactly match our head movements. However, after a few days, our eye movements have adapted to the new movement conditions.

## Conclusions

The generation of compensatory eye movements is subserved by an extremely conserved neuronal circuitry from fishes to humans. Vestibular innervation of eye muscles follows the stereotypical principal three-neuron-arc connectivity in a reciprocal excitatory-inhibitory innervation pattern. Fine-tuning of spatially coordinated VOR movements is assured by accessory connections other than the principal projections. These accessory connections are species specific and seem to depend on the placement of the eyes in the head of a given animal. The three-dimensional vestibulo-ocular reference frame also provides a blue print for a modular organization of sensory-motor transformations related to at least eye- and head-movement reflexes including motor learning. The latter is exemplified by its zonal expression in the cerebellum.

# Vestibulo-Oculomotor System: Functional Aspects

V

Werner M. Graf
Department of Physiology and Biophysics, Howard University College of Medicine, Washington, DC, USA

## Synonyms

Vestibulo-ocular reflex; VOR – Compensatory eye movements

## Definition

The ►vestibulo-ocular reflex produces eye movements via a sensory-motor transformation which originates in the vestibular system, our sense of balance. This reflex stabilizes the visual world during either self-induced movements or during that resulting from passive displacements of the head and/or the body.

## Characteristics

Eye movements are an essential prerequisite for many animals, including humans to survive and navigate in all life situations. A most important function of the oculomotor system is the stabilization of the visual image on the retinae during movement, and we are customarily unaware of such a function. This function, compensatory eye movements, or the vestibulo-ocular reflex (VOR) is an extremely fast sensory-motor transformation taking place within 16 ms from stimulation to motor execution (the corresponding reflex via the visual system, the ►optokinetic reflex, takes 80–150 ms). VOR deficits impair gaze stabilization and lead to the clinical sign of oscillopsia, a sensation that the world is moving about when walking or riding in a car (Fig. 1).

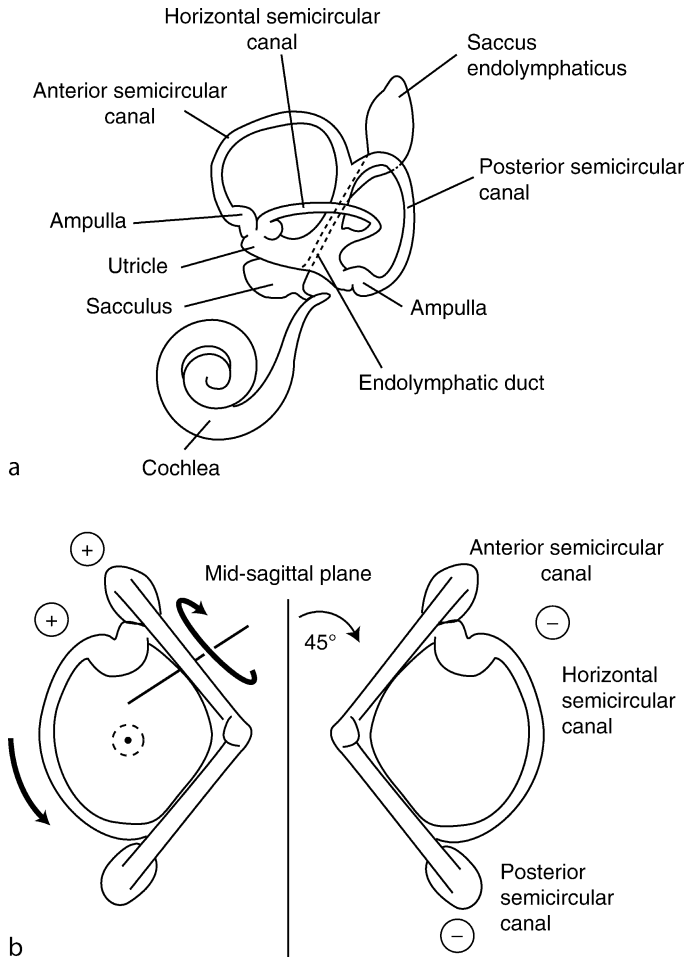
Such a sensation can be visualized by recording with a video camera while walking, mounting and descending stairs or performing fast panning movements. When playing back the film, only jerky and blurred images are seen. Our compensatory eye movement system prevents such occurrences, and typically we observe a stable world, even when running or jumping over an obstacle. The VOR is a function of the vestibular system, i.e., the labyrinth, and is mediated via short pathways to the effectors, the extraocular muscles.

### The Labyrinthine Receptors

The vestibular organ is part of the inner ear and consists of the ►semicircular canals and the ►otoliths (Fig. 2a). Semicircular canals and otoliths detect movement accelerations, the semicircular canals angular accelerations (rotations) the otoliths linear accelerations (translations). The otoliths function by signaling head or body displacements with reference to earth gravity (gravity vector).

The entire labyrinth is filled with a fluid, the endolymph. In the semicircular canals, the endolymph causes a so-called endolymph current, which, during a given head movement, displaces receptor cell sensors, the ►cilia of ►hair cells inside a specialized area of the canal lumen, the ►ampulla [1]. The operation of this system can be visualized when rotating a glass filled with liquid: the glass will rotate around the liquid, which remains more or less stationary. By a similar mechanism, the receptor organs inside the semicircular canals will be pushed against the temporarily stationary

**Vestibulo-Oculomotor System: Functional Aspects. Figure 1** Illustration of head movement during normal walking. Note vertical and lateral displacements of head trajectories as part of compensatory mechanisms to keep a stable gaze during locomotion. Without vestibulo-ocular and vestibulo-collic reflexes, unblurred vision would not be possible (photo courtesy of Ian Spooner – Photographer, The University of Sheffield, Student Recruitment, Admissions & Marketing, 1 Palmerston Road, Sheffield S10 2TE – UK/Professor Paul Dean, Dept. Psychology, The University of Sheffield, Western Bank, Sheffield S10 2TP – UK).



**Vestibulo-Oculomotor System: Functional Aspects. Figure 2** Anatomy of the vestibular system. (a) Lateral view of the left human labyrinth with semicircular canals and otoliths, and the hearing portion (cochlea). (b) Spatial orientation of an idealized semicircular canal system (*top view*) with vertically oriented anterior and posterior canals, and horizontally oriented horizontal canals. In this case, an idealized orthogonal system is depicted: the vertical canals are oriented 45° off the mid-sagittal axis ("diagonal" orientation), and the angle between ipsilateral vertical and horizontal canals is also shown orthogonal similar to a corner in a room. Three organizational principles characterize this arrangement: bilateral symmetry, mutual orthogonality between canals, and the push-pull operational mode illustrated here for the right posterior and the left anterior canals, and the right and left horizontal canals, i.e., when one canal becomes excited (+), its coplanar counterpart becomes inhibited (−). Canal on-directions are indicated by the directions of the arrows about the canal rotation axes (modified after Werner, Cl. Das Gehörorgan der Wirbeltiere und des Menschen. VEB Georg Thieme, Leipzig, 1960).

endolymph and thus the occurrence of movement is detected and signaled to the brain. An important characteristic of the macroscopic anatomy of the semicircular canals is their three-dimensional orientation. The ensemble of the six canals, three on each side forms a physical coordinate system to detect angular accelerations in three-dimensional space. This particular orientation provides a blueprint for the spatial coordination of a number of reflex functions and sensory interactions [2].

The semicircular canal system on each side of the head consists of a horizontal (lateral) canal and two vertical canals (one anterior and one posterior canal) (Fig. 2a). The vertical canals are oriented about 45° off the mid-sagittal plane of the head (Fig. 2b). The functional planes of the canals form angles of 90°, or close to that value, to ensure so-called mutual orthogonality (Fig. 2b). The arrangement of the three semicircular canals of one side can be compared to the walls and floor forming the corner of a room.

By contrast to the semicircular canals, the otoliths are receptors that depend on the presence of gravity ("graviceptors"). They detect linear accelerations, and do not function in microgravity. Most ►vertebrates,

V

including humans, posses two otoliths on each side, the horizontal utriculus and the vertical sacculus. At normal resting posture of the head, the utriculus is oriented earth horizontally [3]. The receptor cells of the otoliths are embedded in the so-called otolith membrane, which contains the ►otoconia. During a displacement of the head from normal upright position, the otoconia will slide across the hair cells and produce a shear force upon the cell cilia. The result will be righting reflexes, and static displacements of the eyes.

## The Extraocular Muscle Apparatus

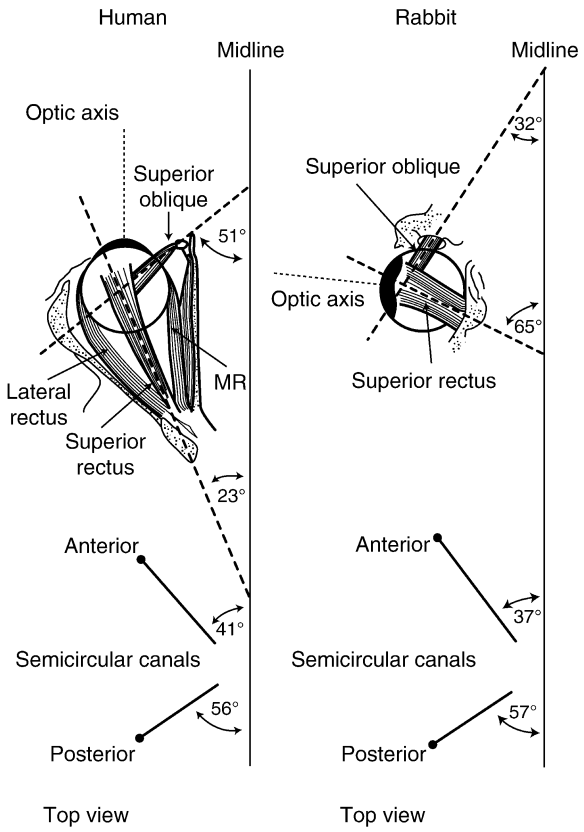
The eye ball is rotated by six extraocular muscles, two horizontal ones and four vertical ones (see also the chapter on "Extraocular Motoneurons"). The vertical eye muscles are superior rectus (SR), inferior rectus (IR), superior oblique (SO) and inferior oblique (IO); the horizontal eye muscles are lateral rectus (LR) and medial rectus (MR) (Fig. 3).

The motoneurons of the lateral rectus are found in the abducens nucleus (sixth cranial nerve), of the superior oblique in the trochlear nucleus (fourth cranial nerve), and for superior rectus, inferior rectus, inferior oblique and medial rectus muscles in the oculomotor nucleus (third cranial nerve). The central innervation of these muscles is quite conserved throughout vertebrate phylogeny with four motoneuron populations typically projecting ipsilaterally (IR, IO, MR, LR) and two projecting contralaterally (SR, SO) (Fig. 4).

The geometric arrangement of the six extraocular muscles and their innervation is also quite stereotypical across vertebrate species. The three-dimensional arrangement follows the spatial geometry of the vestibular semicircular canals, i.e., the typical diagonal, 45° off the mid-sagittal plane orientation of vertical canals (Fig. 3) is reflected in the pulling direction of the vertical eye muscles, the horizontal eye muscles are aligned with the horizontal semicircular canals (see also Fig. 1d in the chapter "Vestibulo-Oculomotor Connections").

## Vestibulo-Oculomotor Geometry

The conservation of similar spatial geometries of semicircular canals and eye muscle pulling directions is also reflected in a stereotypical innervation pattern of the principal neuronal connections for the production of compensatory eye movements across vertebrates. Since we have two eyes, their movements need to be space-time coordinated, i.e., they have to move in the same direction at the same time. This type of eye movement is called "conjugate" eye movement. It is important to emphasize that the vestibular system and its contextual motor effectors, the oculomotor and spinal-motor systems are bilaterally organized, i.e., their proper function can only be fully appreciated if both sides are of the brain are considered for their operations.

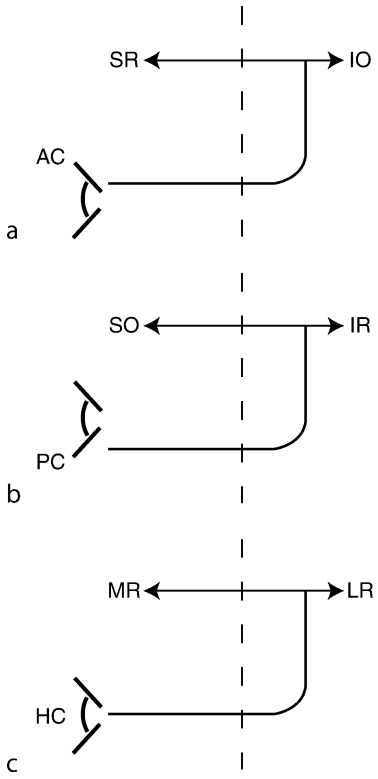


**Vestibulo-Oculomotor System: Functional Aspects. Figure 3** Spatial relationship between vertical semicircular canals and vertical extraocular muscles in frontal-eyed (human) and lateral-eyed vertebrates (rabbit). In all species, the superior rectus remains closely aligned with the ipsilateral anterior canal plane, the superior oblique with the ipsilateral posterior canal plane. Note, in particular, the differential insertion of the superior oblique muscle in humans versus rabbits, i.e., in front and behind the eye equator, respectively. MR, medial rectus (modified after 4).

Within this framework, excitatory connections are formed between the anterior canal and the ipsilateral superior rectus and the contralateral inferior oblique muscle (Fig. 5a), between the posterior canal and the ipsilateral superior oblique and the contralateral inferior rectus muscle (Fig. 5b), and between the horizontal canal and the ipsilateral medial rectus and the contralateral lateral rectus muscle (Fig. 5c).

Since the antagonists to these muscles will have to relax at the same time, we observe the existence of inhibitory connections to these antagonists arriving from the same semicircular canals. These stereotypical excitatory/inhibitory relationships form the basis of spatial coordination of compensatory eye movements. Stimulation of single canal nerves, therefore, readily elicits eye, even head movements in the plane of this particular semicircular canal [5]. Strictly speaking,

**Vestibulo-Oculomotor System: Functional Aspects. Figure 4** Photomicrographs of superior rectus (bright field) and superior oblique (dark field) motoneurons in goldfish following injection of the respective individual muscles with horseradish peroxidase (HRP). Note midline crossing of motoneuron axons in both cases. Superior rectus motoneuron axons travel directly across the midline to enter the contralateral oculomotor nerve, superior oblique motoneuron axons arch through the cerebellum and the anterior medullary velum to exit dorsally through the contralateral trochlear nerve.



**Vestibulo-Oculomotor System: Functional Aspects. Figure 5** Principal excitatory vestibulo-ocular reflex relationships of the three semicircular canals (a) Anterior canal (AC). (b) Posterior canal (PC). (c) Horizontal canal (HC). Each canal influences principally one ipsilateral and one contralateral eye muscle: the anterior canal the ipsilateral superior rectus (SR) and the contralateral inferior oblique (IO); the posterior canal the ipsilateral superior oblique (SO) and the contralateral inferior rectus (IR); the horizontal canal the ipsilateral medial rectus (MR) and the contralateral lateral rectus (LR). The dashed vertical lines represent the midline.

however, this innervation scheme applies only to angular compensatory movements.

While the reflex relationships from the semicircular canals to eye muscles are fairly stereotypical, otolith influences are usually less clearly defined. Utricular nerve stimulation may elicit ipsilaterally directed horizontal eye movements, and some vertical ones. Saccular stimulation usually causes bilateral or unilateral upward movements of the eyes, but also downward movements can be observed. In general, direct otolith-ocular input to the eyes is weak by comparison with canal-ocular or otolith-spinal influences.

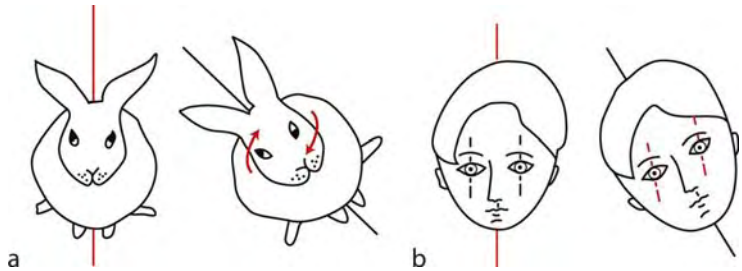
## Lateral- and Frontal-Eyed Animals

Head movements in animals with different interocular angles, e.g., the extreme examples of rabbits and humans (Fig. 3), seemingly require different compensatory eye movements. For instance, a head movement about the naso-occipital axis in a rabbit results in vertical eye movements, and ►torsional ones in a human (Fig. 6).

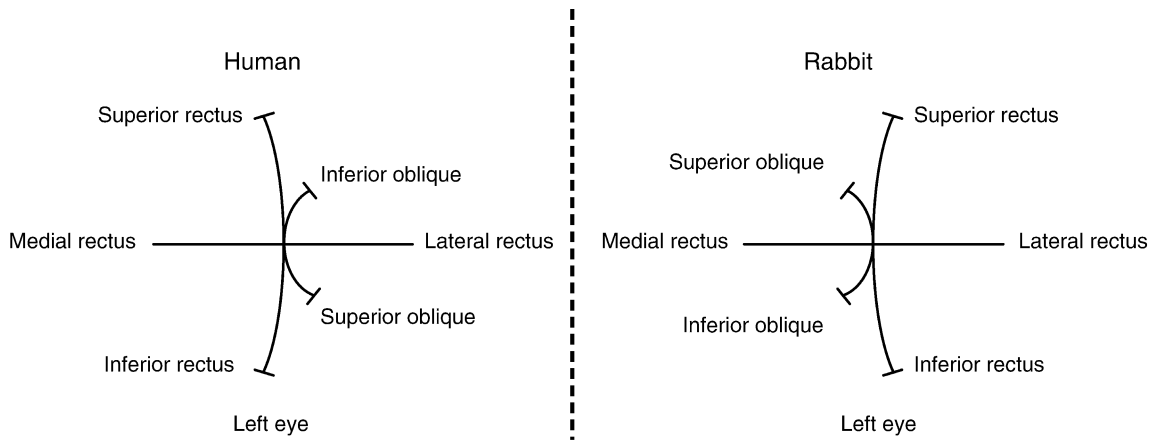
In fact, if the reference frame is tied to the ►optic axis this difference is observed, but if the reference frame is linked to the head, it is not. In all cases, such movements occur about the naso-occipital axis, i.e., in the transverse plane of the head, because all eye movements are just rotations of the eye ball in the head irrespective of a frontally or laterally directed optic axis.

The necessary requirements for compensatory eye movements in lateral and frontal-eyed animals have been elaborated in some detail [4,2]. Since there is no difference in the principal central reflex relationships as concerns the vestibulo-ocular reflexes, spatially correct compensatory eye movements occur because of subtle changes in eye muscle ►kinematics resulting from small changes in the insertions and pulling directions of

vertical eye muscles during the course of evolution and the process of eye frontalization (Fig. 3) [4]. In this context, we have to appreciate that the extraocular muscles can have more than one action, especially the vertical ones. In such case, we distinguish one primary and two secondary actions (Fig. 7). As a general principle, the primary actions of all extraocular muscles remain identical in all vertebrates. For instance, the



**Vestibulo-Oculomotor System: Functional Aspects. Figure 6** Compensatory eye positions in a rabbit (a) and a human (b) following a head tilt to the right. In the lateral-eye rabbit, the respective compensatory eye movements appear as vertical upward and downward movements of the right and left eyes, respectively (red arrows) to attain reorientation with the original upright head posture (solid red line). In the frontal-eyed human, the appropriate compensatory eye movements are torsions (rotations about the optic axes) to the left of both eyes (red dashed lines). In both cases, the compensatory rotations are identical, although they appear different because of the different placement of the eyes in the head in rabbits and humans (see also Fig. 3) (modified after Duke-Elder S, Wybar K (1973) In: Sir Stewart Duke-Elder (ed) Ocular motility and strabism. System of ophthalmology, vol 6. Kimpton, London).

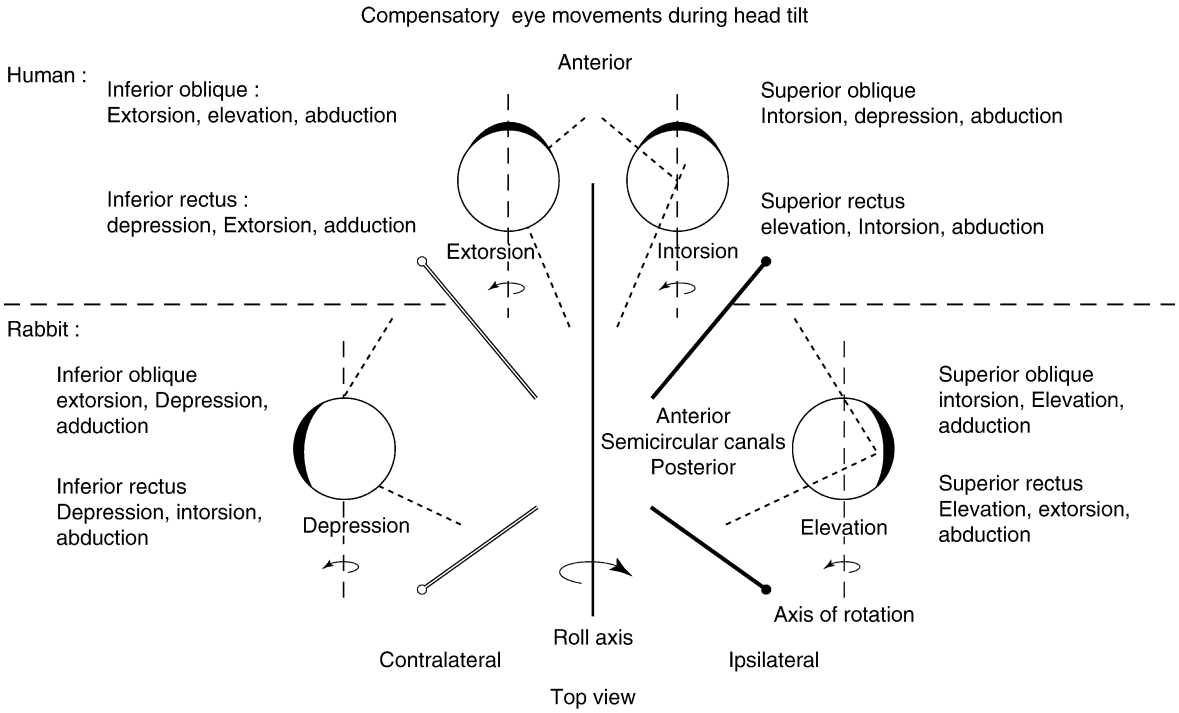


| | Human | | Rabbit | |
|---|---|---|---|---|
| | Primary action | Secondary actions | Primary action | Secondary actions |
| Superior rectus | Elevation | Intorsion, adduction | Elevation | Extorsion, abduction |
| Inferior rectus | Depression | Extorsion, adduction | Depression | Intorsion, abduction |
| Superior oblique | Intorsion | Depression, abduction | Intorsion | Elevation, adduction |
| Inferior oblique | Extorsion | Elevation, abduction | Extorsion | Depression, adduction |
| Medial rectus | Adduction | | Adduction | |
| Lateral rectus | Abduction | | Abduction | |

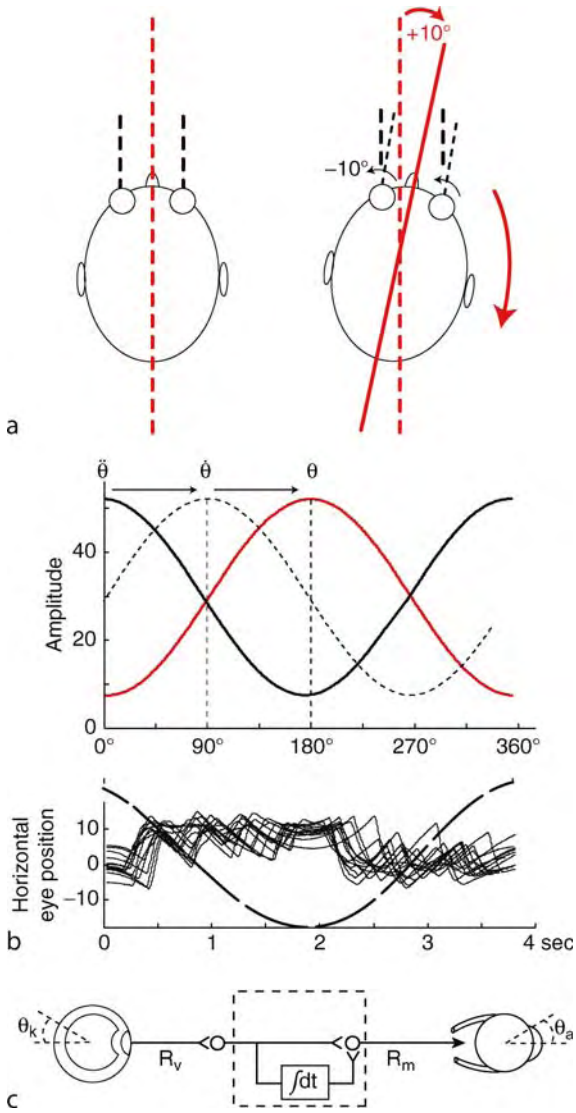
**Vestibulo-Oculomotor System: Functional Aspects. Figure 7** Kinematic actions of individual extraocular muscles in humans and rabbits. In the upper half of the figure, the kinematic actions are presented in the form of Hering diagrams, in the lower half in tables. The lines in the Hering diagram illustrate the relative magnitudes of vertical, horizontal and torsional components. Note similarity in primary actions between humans and rabbits, and complete difference in secondary actions (modified after 4).

primary action of the superior rectus is always an elevation of the eye ball, that of the superior oblique is always ►intorsion (i.e., a rotation of the upper aspect of the eye ball towards the nose). However, the secondary actions of the superior rectus in humans are intorsion and adduction (horizontal rotation towards the nose); in rabbits they are extorsion (rotation towards the ear) and abduction (horizontal rotation towards the ear). Likewise, the superior oblique produces depression and abduction in humans, but elevation and adduction in rabbits as secondary action. It is really the latter actions that account for the all-important correct spatial performance of the vestibulo-ocular reflex. The differences in secondary actions of these muscles result from differences in insertion and pulling directions. In case of the superior rectus, the change between extorsion and intorsion occurs because in rabbits the optic axis is oriented laterally, and in humans frontally (Fig. 3). As a consequence, the muscle's pulling direction changes across the optic axis from the extorsion side in rabbits to the intorsion side in humans. The change in the superior oblique kinematics is due to a change in the insertion of the muscles either in front of the eye's equator, as in rabbits, or behind, as in humans (Fig. 3). As a consequence, the superior oblique causes elevation in rabbits, and depression in humans, as a secondary action.

Let us consider an example of a particular compensatory eye movement following a head movement about its naso-occipital axis (Fig. 8). Since we rarely perform head or body movements in exactly semicircular canal coordinates, compensatory eye movements in any other plane are produced by a combination of inputs arising from all six semicircular canals. The actual spatial direction of these movements depends on the relative stimulation of these six canals by a given head/body movement. In our specific example of a head movement about the naso-occipital axis towards the right, the



**Vestibulo-Oculomotor System: Functional Aspects. Figure 8** Extraocular muscle co-contractions for the production of compensatory eye movements in humans and rabbits during a head tilt to the right (symbolized by solid canal representations) (compare to Fig. 6). In both cases, the right-side semicircular canals will be excited, the left ones inhibited. Thus, in both cases the ipsilateral superior rectus and superior oblique, and the contralateral inferior rectus and inferior oblique will contract (muscles are symbolized by thick dashed lines). Although stimulation and vestibulo-oculomotor connectivity are the same in the two species, the ensuing eye movements are seemingly different because of frontal- or lateral-eyed nature. The different requirements are subserved by different kinematic actions of extraocular muscles in the two examples: in humans, the required bilateral torsional eye movements are produced by reinforcement of intorsion in the right eye, and extorsion in the left eye; in rabbits, the required vertical eye movements are produced by reinforcing the elevation components of the co-contracting muscles in the right eye, and the depression components in the left eye. Synergistic components are indicated in capital letters, components that will cancel out in small letters (modified after 4).



**Vestibulo-Oculomotor System: Functional Aspects.**
**Figure 9** Dynamics and functional organization of the vestibulo-ocular reflex (horizontal plane). (a) Illustration of the principle of reflex operation: a head displacement to the right over 10° (red) will elicit an equal and opposite eye movement, i.e., –10° to the left (black). (b) Gain and phase plot of a sinusoidal head movement. The upper graph represents idealized sinusoidal phase shifts of movement parameters encountered in the vestibulo-oculomotor system: head acceleration (θ) is integrated by mechanical means into head velocity signal (θ) that is integrated a second time into a position signal (θ). In the lower graph, the slow phases of vestibular nystagmus are serially apposed to show eye position in space (thick black dashed curve) and to illustrate its compensatory nature vis-à-vis the eliciting head movement (head position curve in red in the upper graph). Head position and eye position in space are opposite to each other. (c) Conceptual representation of the neuronal integrator necessary to produce an eye position signal equal and opposite in direction as a head movement ($\theta_h$ vs. $\theta_e$). A head velocity signal coming from the vestibular nerve ($R_v$) undergoes a second integration (dt) to arrive at the required eye position signal ($R_m$) (modified after 1).

right-side anterior and posterior semicircular canals would be stimulated in an excitatory fashion, while the left-side anterior and posterior canals would be inhibited. The ensuing compensatory eye movements in a human would be conjugate torsional eye movements to the left (Fig. 8; see also Fig. 6b). Taking the innervation examples of the above introduced pathways (Fig. 5) and extraocular muscle kinematics into account (Fig. 7), the combined excitatory input from the two right-side canals would elicit contraction of the right-side superior rectus and superior oblique, and the left-side inferior rectus and inferior oblique.

In the right eye, the kinematic actions of the involved muscles, superior rectus (elevation, intorsion, adduction) and superior oblique (intorsion, depression, abduction) would be combined with elevation/depression and adduction/abduction cancelling one another, while the intorsion components would be reinforced to produce the required compensatory movement (Fig. 8). A mirror-action would occur in the left eye, producing pure extorsion. While the same vestibulo-ocular connections would be present in a rabbit, the compensatory eye movements for the same head movement would require elevation of the right eye and depression of the left eye (see Fig. 6a). As in the case of the human example, a combination of kinematic actions will take place, Because of the different kinematics of extraocular muscles in rabbits, the elevation components of superior rectus and superior oblique would be reinforced, while the extorsion/intorsion and abduction/adduction components of these muscles would cancel one another (Fig. 8). Again, a mirror-image scenario would hold for the left eye.

## Dynamic Aspects

The vestibulo-ocular reflex is defined as eye movements over the same angle (or distance), but opposite in direction as the eliciting head or body movement (Figs. 9a and b). Vestibulo-ocular reflexes may occur during angular movements of the head, i.e., rotations, or during linear movements, i.e., translations.

Semicircular canal receptors only detect angular accelerations, but because of the inertial characteristics of the ►cupula-endolymph system (so-called overdamped torsion pendulum), a mechanical integration of the acceleration stimulus takes place [1]. Thus, vestibular nerve fibers transmit a head velocity signal to their target neurons in the vestibular nuclei. However, when recording from oculomotor motoneurons, their

firing rates show an almost linear relationship between eye position and eye velocity. This observation subsequently led to the idea that a second integration from velocity to position had to take place centrally after the first mechanical integration form acceleration to velocity in the sensory periphery (Fig. 9b). This second integration is a function of neuronal computation (so-called neuronal integrator) (Fig. 9c), and is thought to consist of the nucleus prepositus hypoglossi/vestibular nuclei for horizontal eye movements, and of the interstitial nucleus of Cajal/vestibular nuclei for vertical eye movements (see also Chapters on Neural Integrators).

## Neurotransmitters

The neurotransmitters for excitatory vestibular neurons seem to be glutamate and aspartate, and the peripheral nerve input to vestibular nucleus neurons also seems to be mediated via glutamate. Within the inhibitory vestibulo-ocular projections, two neurotransmitters have been reported. Neurons involved in vertical vestibulo-ocular reflexes have been shown to express GABA, whereas neurons mediating the horizontal vestibule-ocular reflex express glycine. This dichotomy may have an explanation in the evolution of the vestibular system. Horizontal canals were not present in agnathan species of the Devonian period (400–350 million years ago), but were added to the two vertical canals when gnathostomes appeared, possibly as a result of the expression of the *Otx1* gene [6].

## Reflex Versus Voluntary Eye Movements

It should be noted here that vestibulo-ocular eye movements are reflex eye movements and cover all three dimensions of physical space, whereas voluntary eye movements, such as ►saccades (fast and jerky eye movements) and smooth pursuit eye movements (slow following movements) obey ►Listing's Law, and are therefore two-dimensional, i.e., Listing's Law removes the torsion components from a given eye movement. Listing's Law stipulates that all eye movements are performed about axes confined to Listing's plane, which coincides roughly with the equatorial plane of the eye ball (a plane bisecting the eye ball in the frontal plane). Indeed all eye positions can be attained by confining the ocular rotation axes to this one plane, but no true torsion movements, i.e., about the visual axis are possible. What can be observed are so-called "false" torsions (see also Chapters "Eye orbital mechanics" and "Listing's law").

## Active Versus Passive Movement

Clearly, each time we perform a head movement, vestibular receptors become activated, and central processing between commands and reflexes takes place. Vestibular receptors *per se* do not distinguish between active and passive movements, however second-order vestibular neurons, i.e., two synapses away from the receptor cells already react differentially to active and passive head movements. Thus, vestibular signals are strongly attenuated by self-generated movements as early as the first central projection neurons. For instance, neurons could stop firing during active head movements, while during passive movements, they would transmit a head velocity signal. The purpose of such attenuation is clearly related to suppressing unwanted reflex movements. Without suppression of reflexes, we could not move, since reflex action would always bring us back to our point of origin.

Furthermore, in the vestibular nuclei, neurons carrying eye and head movement-related signals have been found in a similar proportion as neurons that only signal head velocity, with no eye movement signals present. The latter are thought to be part of the vestibulo-cortical relay. Vestibular thalamic and cortical units have been reported not to carry eye movement signals.

Since the introduction of the concept of the reafference principle [7] to control and calibrate self-generated movements, numerous studies have sought to uncover the actual underlying neuronal elements and control signals for efference copy expressions and corollary discharges. This question was addressed by testing the responses of vestibular neurons to active movement, passive whole body rotation, and various combinations of head-in-space and/or head-on-trunk movements. Because neurons were suppressed only when the intended active movement and the actual displacement of the head in space were matched, the signal subserving active-passive differences in the vestibular nuclei must be of central origin, arising from a comparison of an efference copy – or an internal prediction – and the actual movement of the head. Posterior parietal cortex neurons may perform this function, or at least play an important role in it [8,9].

## Visual-Vestibular Interaction

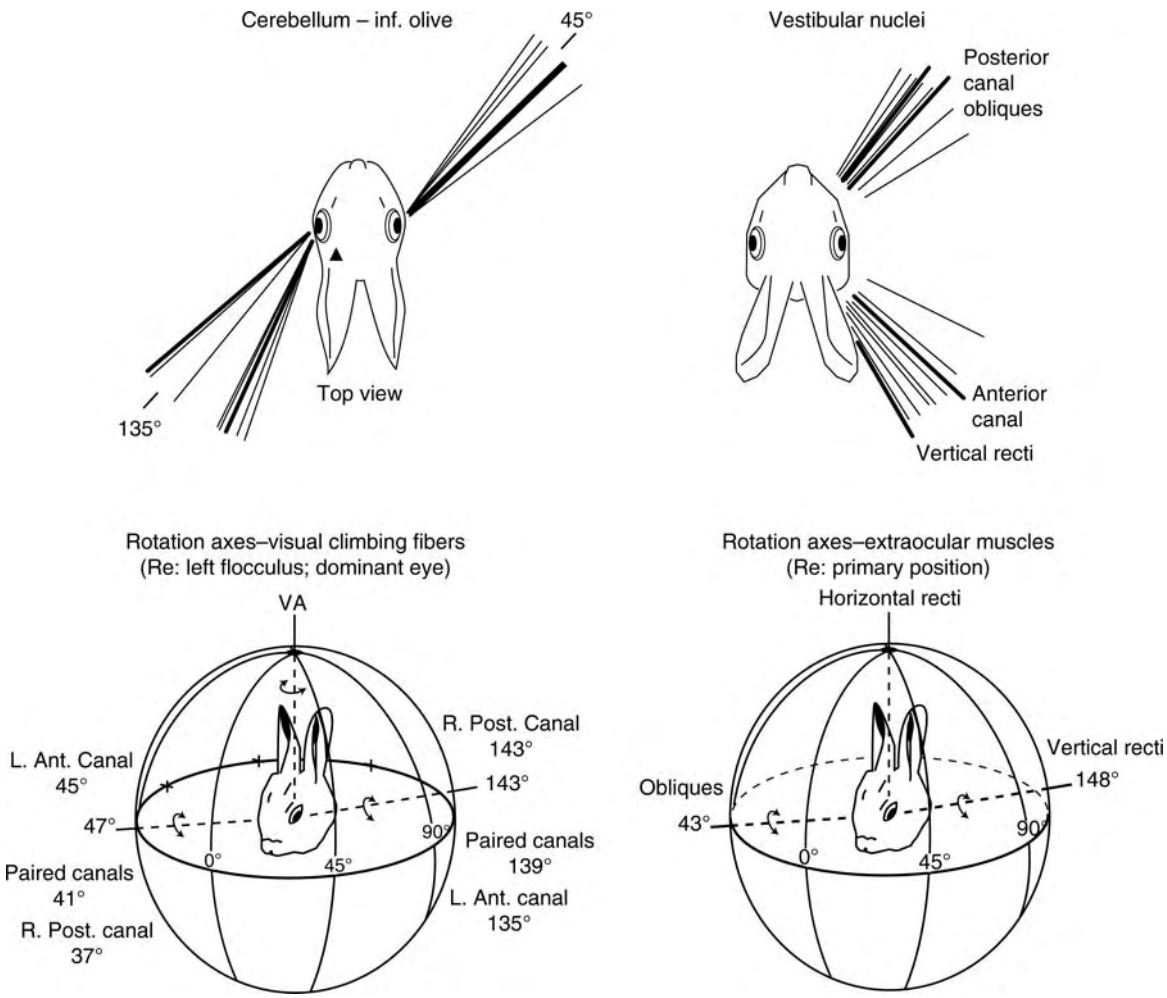
Under normal every-day living conditions, we move about with our eyes open. In circumstances such as these we perform visuo-vestibulo-ocular reflexes rather than vestibulo-ocular reflexes. The importance of vision, during slow and constant velocity movements, e.g., during human car driving, or bird soaring, when vestibular input becomes deficient, cannot be overestimated. The reason is that, as remarked earlier, vestibular receptors can only detect accelerations, i.e., changes in velocity, but not constant velocities. Therefore, during longer periods of constant velocity head movements (>8 s), vestibular information is reduced to nothing.

Visual information about movement reaches the vestibular nuclei, and ultimately no distinction between visual or vestibular derived information is possible [10]. Purely visual, i.e., optokinetic stimulation has to be in a

direction opposite to that of a corresponding head/body movement to be congruent with the perceived movement direction and to avoid eventual visual-vestibular conflicts. A number of studies have now also analyzed the three-dimensional characteristics of visual inputs to eye movement and postural control circuits in several species. The spatial coordinates of the visual signal closely match the sensory and motor coordinates of the VOR, i.e., of the semicircular canals and the extraocular muscles (Fig. 10). While none of the three geometries are completely identical with one another, the spatial orientation of semicircular canal, oculomotor and optokinetic stimulation axes are obviously quite similar.

## Conclusions

Vestibulo-oculomotor geometry in vertebrates is highly conserved and the almost congruent geometries on which it relies provide an organization principle for space-time coordinated movements. Self-motion detection and subsequent movement execution in the



**Vestibulo-Oculomotor System: Functional Aspects. Figure 10** Visual coordinate axes for global self-motion detection and compensatory eye movements. The upper graphs show a two-dimensional rendering of the visual response axes (thin lines) related to vertical movements in the inferior olive/cerebellum system and in the vestibular nuclei. Corresponding canal and extraocular muscle axes are symbolized by thick lines (modified after Graf W, Wilson VJ Afferents and efferents of the vestibular nuclei. The necessity of context-specific interpretation. Prog Brain Res 80. Eds.: J.H.J. Allum and M. Hulliger. Elsevier Science Publishers B.V. (Biomedical Division): Amsterdam – New York – Oxford, 1989; pp 149–157). In the lower half a three-dimensional view of the visual coordinate axes in the inferior olive/cerebellum is presented including the corresponding vestibular sensory and oculomotor motor axes. In all instances a close geometrical relationship is noticeable between the three interrelated systems (modified after Graf W, Simpson JI, Leonard CS (1988) Spatial organization of visual messages of the rabbit's cerebellar flocculus. II. Complex and simple spike responses of Purkinje cells. J Neurophysiol 60:2091–2121).

oculomotor system of vertebrates constitutes an ideal physical solution with optimal signal-to-noise ratio. The almost machine-like operational mode of the visuo-vestibulo-oculomotor system suggests that peripheral mechanisms are largely employed to simplify central nervous operations. This operational principle has been ideally demonstrated in the common reference frames of the vestibulo-oculomotor system, including its central nervous connectivity. As a consequence, the workload of the brain is decreased in favor of animal economy and presumably higher order operations (learning, perceptive functions, etc).

### Definition

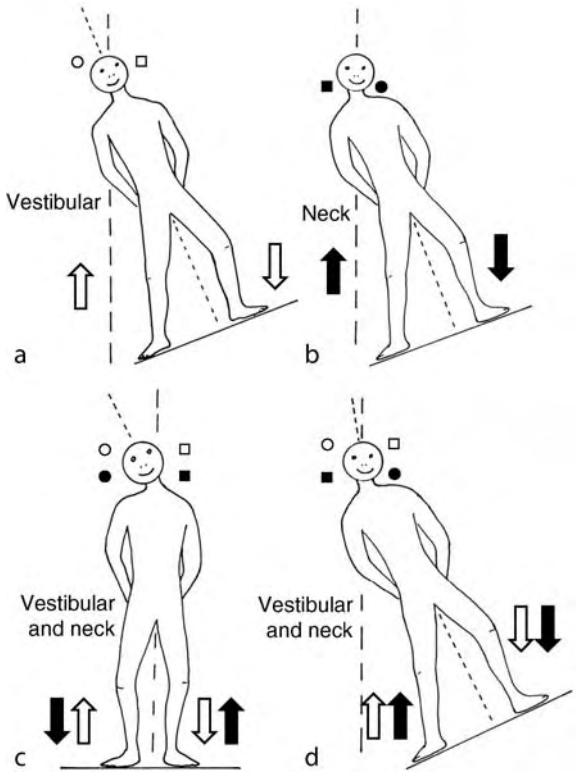
The vestibulospinal (VS) reflexes are changes in the activity of body muscles induced by movements of the head in space that stimulate ►labyrinthine receptors and aimed at stabilizing ►posture.

### Characteristics

#### Functions

The VS reflexes contribute to the control of postural orientation. In this task, they continuously collaborate with reflexes elicited by stimulation of visual and somatosensory receptors. Labyrinthine receptors are sensitive to modifications (i) of the head position with respect to the earth vertical or (ii) of the angular/linear velocity of head motion in space. This information can be used to monitor deviations from the maintained body position. Two functional categories of VS reflexes can be distinguished, those acting on the limb muscles that stabilize the position of the trunk in space and those

acting on the neck muscles (vestibulo-collic reflexes) that stabilize the position of head in space [1]. Trunk and head stabilization are two postural tasks that are pursued simultaneously, although not necessarily with the same efficacy [2]. For instance, when a stable base of support is lacking, it appears that the position of the head with respect to the vertical is very stable, while body orientation is more variable. This is the case in a monkey jumping from one branch to another or in a man standing upon an unstable surface [2]. VS reflexes are tightly coupled to ►cervicospinal reflexes [1], activations of body muscles elicited by stimulation of neck receptors following rotation of the head with respect to the trunk. This coupling can be expected, because movements of the head are likely to stimulate both neck and vestibular receptors and activity of vestibular afferents cannot be directly related to the position of the trunk in space. Vestibulospinal (VS) and cervicospinal (CS) reflexes acting on the limbs interact so as to modify the ►postural tone only when the position of the trunk in space is changed [1]. The goal of trunk stabilization could be also achieved by information that arises from (body) receptors directly activated by trunk displacement; it is currently matter of debate whether this process is actually occurring.



**Vestibulo-spinal Reflexes. Figure 1** Vestibulospinal and cervicospinal reflexes elicited by rotational stimuli in the frontal plane. *Arrows* represent increases (*upward arrows*) and decreases (*downward arrows*) in the limbs' extensor tone induced by stimulation of labyrinthine (*white arrows*) and neck (*black arrows*) receptors. The *long- and short-dashed lines* represent earth vertical and longitudinal head/body axes, respectively.
(a) Labyrinthine reflexes induced by whole-body tilt. The extensor tone increases during side-down (*white circle*) and decreases during side-up tilt (*white square*).
(b) Neck reflexes induced by the displacement of the body with respect to a fixed head. The extensor tone increases during side-up (*black square*) and decreases during side-down (*black circle*) neck rotation.
(c) Vestibular and neck reflexes elicited by rotation of the head over the fixed body are opposite in action and leave the extensor tone symmetrical on both sides.
(d) Vestibular and neck reflexes elicited by simultaneous rotation of the head and body in the same direction, but with a larger amplitude of body tilt, exert the same action on the limbs extensor tone.

## Description of the Process

VS and CS reflexes can be studied in both animals and humans by observing the changes in limb posture or in ►electromyographic (EMG) activity induced following passive displacement of the head and/or of the body. These postural modifications are characterized by tonic and/or phasic components. The former, due to stimulation of macular afferents are sustained changes in muscle activity lasting as long as a new position is maintained, while the latter, due to ampullar afferents [1] and to a population of macular dynamic afferents are transient modifications related to the movement period. The CS are elicited by stimulation of neck spindle afferents, particularly those located in the deep perivertebral muscles, which show tonic or tonic-phasic responses to neck displacement. Simultaneous coplanar rotation of the head and trunk (whole body) in the same direction can be considered a selective stimulus for the labyrinth (Fig. 1a).

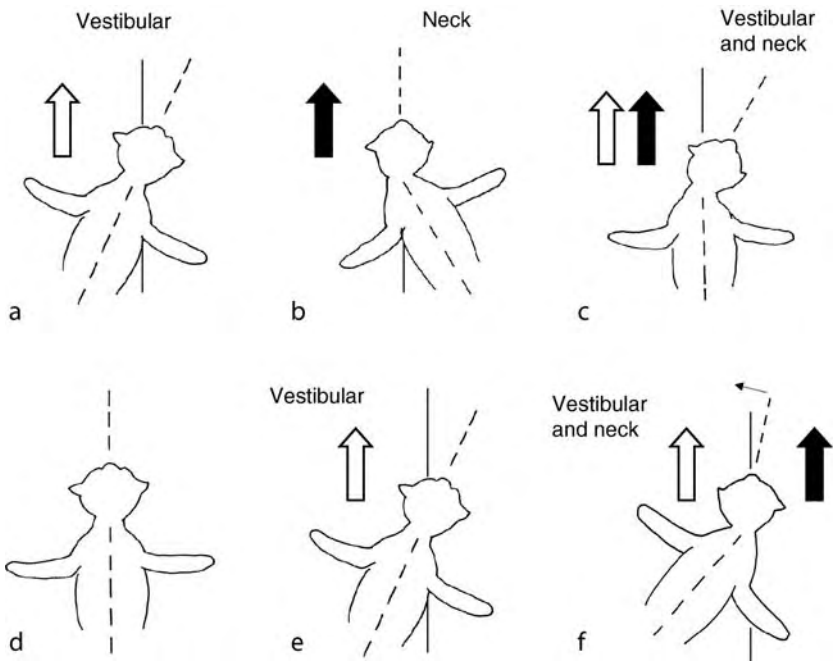
Rotation of the body with respect to a stationary head activates only neck receptors (Fig. 1b). Rotation of the head with respect to the body leads to costimulation of both receptorial systems (Fig. 1c). Information on VS and CS reflexes has been also obtained by comparing the limb posture to that of the head and body during spontaneous behavior. A fundamental property of VS (and CS) reflexes is their high degree of spatial organization; each muscle is maximally activated for a given direction of the stimulus, so that a head-in-space (or head-to-body) displacement will induce a pattern of muscle activation that depends critically upon the plane of rotation [3,4].

When VS reflexes acting at the level of limb muscles are taken into account, it appears that they increase the extensor tone of the limb(s) loaded by the displacement of the body in space [1]. For instance, whole-body rotation within the frontal plane increases the extensor tone of the side-down limbs, while decreasing

that of the side-up limbs (Fig. 1a). On the other hand, side-down and side-up rotations of the neck, elicited by rotation of the body with respect to a stationary head, decrease and increase the extensor activity, respectively (Fig. 1b). So, due to stimulation of vestibular and neck receptors, rotation of the head on a stationary body, which does not affect the loading condition of the limbs, leaves the postural tone unmodified. When the directions of head rotation in space and with respect to the trunk are opposite, the two reflexes act synergistically. This may occur when head and body are tilted in the same direction, but due to a partial righting of the head, the angle of body tilt is larger than that of head tilt (Fig. 1e). VS reflexes, particularly those elicited by stimulation of the sacculus, are involved in the landing reaction, i.e. in the increase in the activity of the plantar flexors of the foot which is induced by the linear acceleration associated with a fall [5]. This reflex response is aimed at increasing the stiffness of these muscles, thus allowing the absorption of a part of the energy of the impact on the ground.

The vestibulo-collic reflexes elicited by a whole body rotation in a given direction, will induce a contraction of the neck that will oppose the displacement of the head in space [3,1]. For instance, a rotation around the vertical axis towards the right side will activate the left neck muscles, displacing the head in the corresponding direction (Fig. 2a).

It is worth mentioning that vestibulo-collic reflexes elicited by vertical acceleration escape this general rule. For instance, an upward acceleration imposed on the whole animal will induce a contraction of the dorsal neck muscle, thus stabilizing the position of the head with respect to the trunk. Vestibulo-collic reflexes interact with cervico-collic reflexes, elicited by stimulation of neck receptors, that give rise to the contraction of the stretched muscles (Fig. 2b). So, during a passive displacement of the head on the trunk to the right side, vestibulo- and cervico-spinal reflexes will act synergistically to activate the left neck muscles, thus resulting in a strong stabilizing action on the position of the head in space and with respect to the trunk (Fig. 2c). On the other



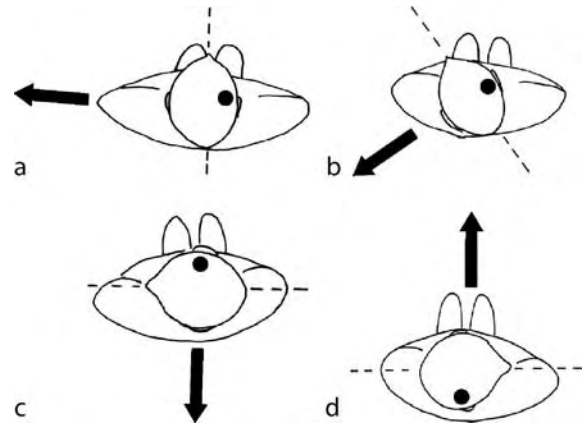
**Vestibulo-spinal Reflexes. Figure 2** ►Vestibulocollic reflex and ►cervicocollic reflex elicited by rotations in the horizontal plane. *Upward arrows* represent increases in the neck muscle activity induced by stimulation of labyrinthine (*white arrows*) and neck receptors (*black arrows*). *Dashed and continuous lines* represent the head/body longitudinal axes and the medial sagittal plane, respectively. (a) Whole body rotation to the right side stimulates vestibular receptors and induces an increase in the activity of the left neck muscles. (b) Rotation of the body with respect to a stationary head towards the right side stimulates neck receptors and increases the activity of the stretched muscles on the left side. (c) Rotation of the head to the right over a stationary body elicits vestibular and cervical reflexes that act synergistically on the neck muscles and induces their contraction on the left side. (d–f) Starting from the initial resting position (d), whole-body rotation to the right activates the neck muscles of the left side (e, *white arrow*) and induces a rotation of the head to the left (f, *dotted arrow*). This movement activates neck receptors that induce the contraction of the stretched neck muscles on the right side (f, *black arrow*).

hand, following whole-body rotation to the right (Fig. 2e), the left neck muscles will be activated by the vestibulo-collic reflex, turning the head to the left side. The cervico-collic reflex elicited by the latter movement, will induce the contraction of right side neck muscles (Fig. 2f), leading to an increase in the stiffness of the head-neck system. The characteristics of muscle activation observed during VS reflexes change with the stimulus frequency, due to the corresponding modification in the relative contribution of the tonic and phasic components of the reflex to the overall response. When low frequency sinusoidal rotational stimuli in vertical planes are considered, it appears that, due to stimulation of otolith receptors, the peak of muscle activity is close to (forelimb muscles) or leads, (neck muscles) the extreme angular position of the animal. By increasing the stimulus frequency there is a growth in the input from ►semicircular canals, which increases the amplitude of the muscle response and shifts the peak of EMG activity towards that of the angular velocity, thus increasing the phase lead with respect to position, particularly in the neck muscles. It is of interest that increasing the frequency of tilt produces little change in the preferred direction of individual limb muscles while those of neck muscles may show quite large variations. This finding has been attributed to the occurrence within vestibulo-collic pathways of a large convergence of labyrinthine signals endowed with different spatial and temporal properties. When rotational stimuli are applied in the horizontal plane, the responses are exclusively due to stimulation of canal receptors and their dynamic characteristics differ from those above described.

In standing human subjects, VS reflexes can be elicited by electrical stimulation of the labyrinth applied to the mastoid bone [6]. Cathodic current applied on one side increases the discharge of the corresponding labyrinthine afferents and when the subject is facing forward induces a body sway in the frontal plane (Fig. 3a), directed away from the stimulated labyrinth [6].

Direct measurements of the positions of the head and scapular and pelvic girdles indicate the recruitment of neck, trunk and limb muscles. It is of interest that when the subject is kept still, the same stimulus induces the perception of sway towards the activated labyrinth.

The neurophysiological mechanisms of neck and vestibular reflexes have been extensively investigated. They are due to changes in the activity of brainstem and cerebellar neurons, induced by stimulation of vestibular and/or neck receptors. Vestibular and/or neck signals reach the ►vestibular nuclei, the ponto-medullary reticular formation, the cerebellar nuclei and vermal/paravermal cortical regions and finally the monoaminergic neurons located in the ►locus coeruleus (LC) and in the ►raphe nuclei [7,8,9]. Within the above-mentioned structures, most of the recorded neurons are maximally activated for animal tilt and/or neck rotation



**Vestibulo-spinal Reflexes. Figure 3** The direction of the body sway induced by electrical ►cathodic stimulation of the labyrinth rotates by the same angle and in the same direction as the head over the body. The *dotted line* represents the naso-occipital head axis. The (right) labyrinth stimulated with cathodic current is marked by a *black dot*. The *arrows* show the direction of the body sway elicited by stimulation of the right labyrinth in different head positions (a–d).

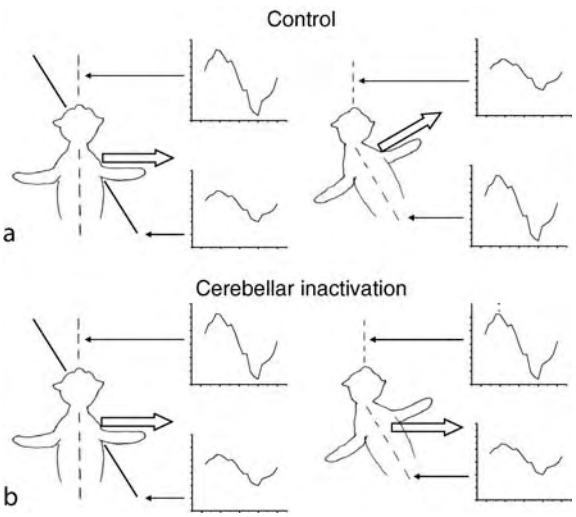
occurring in a particular, "preferred" direction [7]. In addition, the majority of the recorded units are affected by both vestibular and cervical input. The VS neurons that allow a fast transfer of information from the labyrinth to the spinal circuits are an important element of the reflex network [1]. Those located in the ►lateral vestibular nucleus of Deiters, which exert an excitatory action on limb extensor motoneurons and project to the whole extent of the spinal cord, are particularly involved in the development of VS spinal reflexes acting on the limb muscles. VS neurons located within the ►medial vestibular nucleus project only up to the upper levels of the spinal cord, where they inhibit ipsilateral neck motoneurons, while exciting the contralateral ones. They seem therefore well suited to eliciting the vestibulo-collic reflexes [1]. Their pattern of activity during whole-body rotation cannot however account for the dynamic characteristics of these reflexes. Moreover, since vestibulo-collic responses are not abolished by sectioning the medial VS tract, other descending systems must be involved in this reflex response.

## Regulation of the Process

VS reflexes are submitted to several regulatory processes. Their amplitude is dependent upon behavioral conditions, increasing when the amplitude of the support base is reduced and when visual and/or somatosensory information cannot be utilized for postural control. There is evidence that the vestibulo-collic reflex, which would oppose any voluntary head movement, can be depressed in the latter case. In

addition, VS reflexes interest a given muscle only when the latter is involved in a postural function [6]. In addition, modifications in VS reflexes are induced by changing the postural orientation. Accordingly, identical stimuli to the labyrinth may give rise to different postural responses. For instance, the postural sway elicited by ►galvanic stimulation of the labyrinth is modified according to the position of the head with respect to the body, signaled by neck afferents [6]. In particular, the direction of sway, which occurs in the frontal plane when the subject is facing forward, rotates by the same angle and in the same direction as the head over the body (Fig. 4 b–d).

So, different muscle synergies are induced by an identical stimulus to the labyrinth [6]. A corresponding phenomenon occurs in the decerebrate cat, where the preferred response direction of the forelimb extensors is modified by body-to-head displacement and rotates in the same direction and by the same amplitude as the body [8] (Fig. 4a). In both examples, neck information modifies the VS reflexes, making them appropriate to counteract the effects of the direction of sway signaled by vestibular receptors. We may therefore conclude that neck afferents exert not only a direct effect on postural tone (CS reflexes), but also modulate VS reflexes. Similar actions are also exerted by proprioceptive afferents signaling wrist position; it is known in fact that dorsal and ventral flexion of the forepaw not only increase and decrease respectively the firing of ipsilateral limb extensor motoneurons but also the gain of the VS reflexes acting at this level. Finally, proprioceptive afferents signaling the postural orientation may induce plastic changes of adaptive nature in the amplitude of VS reflexes. For instance, in decerebrate cats, a three hour period of continuous and simultaneous whole animal tilt and forepaw oscillation [10] may lead to a progressive increase in the amplitude of the VS reflex acting at the level of the forelimb extensors that persist for hours after the end of the adaptive stimulation. These changes manifest only when side-down animal tilt occurs simultaneously with dorsal flexion of the forepaw, as would be the case in a leg flexing under the body weight, thus requiring a strengthening of the VS reflexes in order to stabilize posture. Similar phenomena can be also elicited by appropriate costimulation of vestibular and neck receptors. The neurophysiological mechanisms underlying gain regulation, proprioceptive tuning and adaptive properties of VS reflexes are poorly understood. An important role in gain regulation could be exerted by those structures that modify the postural tone during the sleep-waking cycle. During waking, the reticulospinal inhibitory system fires at low level, while the noradrenergic LC neurons that support the postural tone are tonically active. During sleep, reticulospinal neurons are excited by descending influence from the pons,



**Vestibulo-spinal Reflexes. Figure 4** Proprioceptive tuning of vestibulospinal reflexes and its cerebellar control. The *dotted line* represents the longitudinal body and head axes. The *white arrows* represent the directions of whole animal tilt giving rise to the maximal response of a forelimb extensor muscles. The graphs show the modulation of activity of a forelimb extensor muscle elicited by a sinusoidal tilt around the axis indicated by the thin arrows. (a) When head and body axes are aligned (*left figure*) the forelimb muscle shows the maximal modulation of its activity (*upper graph*) during a side-down, whole-animal tilt around the longitudinal head axis. When the tilt occurs around an axis oblique with respect to the longitudinal one (*continuous line*), the modulation is smaller (*lower graph*). The preferred ►direction of stimulation is perpendicular to the head (and body) longitudinal axis. Rotation of the body around the stationary head (*right figure*) modifies the muscle responses to labyrinthine stimulation. The best responses are no longer obtained for tilt around the head longitudinal axis but rather around the body axis (*lower graph*). The preferred direction of stimulation is now perpendicular to the body (not head) longitudinal axis. (b) Following inactivation of the cerebellar anterior vermis, body-to-head displacement does not modify the orientation of the axis of rotation leading to the maximal response. The preferred direction of stimulation is always perpendicular to the head longitudinal axis.

while the LC discharge is depressed, leading to a reduction in postural tone, which disappears completely during REM sleep together with the LC discharge (see [9]). It has been shown that an increase in the activity of the reticulospinal inhibitory system or else a depression in the LC discharge (obtained by local microinjections of appropriate neurotransmitter agonists and antagonists) greatly enhanced the gain of VS reflexes acting on forelimb extensors [9]. It may well be that small changes in the activity of these neuronal systems may also occur during waking, thus leading to the appropriate

V

modification of the reflex response. Another structure possibly involved in the gain regulation of VS reflexes is the cerebellar vermal cortex of the anterior lobe, which keeps under its direct inhibitory control both lateral VS and fastigial neurons. The latter in turn excite lateral VS and reticulospinal neurons. It has been shown that the functional inactivation of this cortico-cerebellar region by a local injection of a GABA-A agonist greatly depresses the gain of VS reflexes (see [10]). The cerebellum is also involved in the tuning of VS reflexes exerted by proprioceptive neck afferents. In fact, functional inactivation of the cerebellar anterior lobe may abolish the changes induced, by rotating of the neck over the body, in the preferred response direction of the limb extensors to labyrinthine stimulation [8] (Fig. 4b). Moreover this procedure prevents the induction of plastic changes in VSR gain induced by costimulation of labyrinthine and proprioceptive afferents and, when performed after the adaptation process, abolishes the already established gain modification (see [10]). A suppression of the induction of VS reflex adaptation is also induced by blockade of noradrenergic beta-receptors within the same cerebellar region. In conclusion there is evidence that, acting through the cerebellum, proprioceptive afferents may (i) tune the VS reflexes according to body posture and (ii) induce plastic changes that adapt their gain to the behavioral condition

## Definition

The vestibular system operates as an integrator of multiple lines of feedback (e.g., visual, proprioceptive and labyrinthine) prior to signaling segmental mechanisms, through the medial and lateral vestibulospinal tracts to adjust the position of the trunk and lower limbs in order to keep the position of the head stable in space.

## Description of the Theory

Whereas vestibular control of motion at the head and neck can be isolated through the vestibulocollic reflex, vestibular control of postural responses of the whole body are not as clearly delineated. It is too restrictive to define the vestibulospinal system as controlled by only the vestibular afferents. The lateral nucleus of the vestibular nuclei is the primary origin of the lateral vestibulospinal tract (LVST), which projects to the lumbosacral cord. The medial vestibulospinal tract (MVST) descends bilaterally through the medial longitudinal fasciculus as far as the upper thoracic enlargements. But primary afferent input to the LVST and MVST pathways includes the utricle of the vestibular otoliths, the fastigial nucleus and vermal cortex of cerebellum and the same spinal motoneurons to which the vestibulospinal pathways project. Thus the vestibular signals are modulated both by descending (cerebellar) and ascending (spinovestibular) pathways before acting on spinal segmental motoneurons [1]. Cervical proprioceptive inputs provide a feedback signal about trunk velocity, so that the vestibular neurons could remain sensitive to perturbations of the body even as vestibular drive is reduced by a reduction of head

motion in space. A physiological correlate for the participation of the vestibular system in this process has been observed in secondary horizontal canal neurons that were specifically related to neck velocity [2].

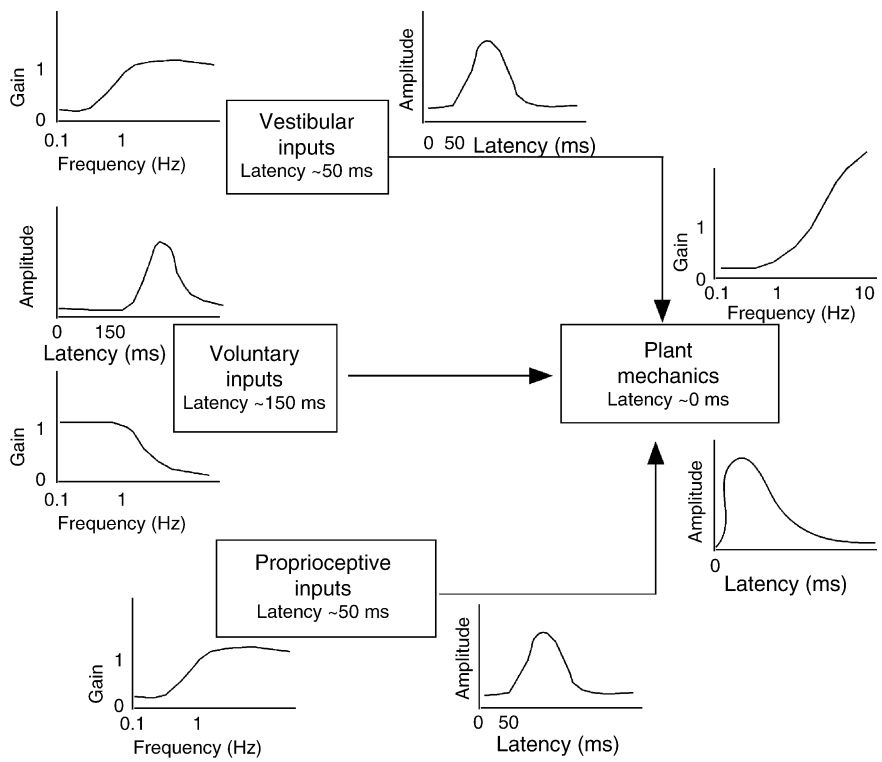
Precise descriptions of the anatomy and neurophysiology of the pathways involved in these actions are comprehensively described elsewhere [3]. But descriptions of isolated pathways' locations and actions cannot convey how all of these control pathways operate through the biomechanics of the system to produce functional postural dynamics (Fig. 1). In the accompanying essay, the physiological and behavioral data that signify contributions of the vestibulospinal system to the control of posture and gait are presented.

## Characteristics of the Vestibulospinal Responses

The principal role of the vestibulospinal system is to stabilize the head in space and it does this during both transient and stationary disturbances to the body by changing the arrangement of the limbs. The vestibular system measures the head's angular velocity and linear acceleration and detects head position relative to the gravitational axis. Head angular velocity is measured by the cristae of the semicircular canals, while the maculae of the labyrinths (utricle and saccule) register linear acceleration and changes in gravitational force. Electrical stimulation studies on decerebrate animals have presented evidence that descending impulses from the vestibular nuclei were primarily excitatory to proximal forelimb extensor muscle via monosynaptic pathways. Distal muscles of the forelimbs received excitatory and inhibitory influences via polysynaptic connections [3].

In order to keep the head stable in space, the vestibular system will combine the labyrinthine signals with those of the segmental proprioceptors to invoke changes in the limbs that will kept the head oriented in space. For example, in response to sustained tilts of the body, otolith signals generate limb flexion and extension patterns in cats, monkeys and humans, which would correctly restore the head to a stable vertical position. Vestibulospinal limb reflexes have also been shown to be responsible for counteracting dynamic tilts of the body. Numerous studies of postural sway following linear and rotational disturbances of the base of support have been performed with subjects having unilateral or bilateral labyrinthine deficit. The results of these studies have demonstrated impaired control of whole body sway and delayed and diminished responses of the muscles in the lower limb when labyrinthine inputs were absent [4].

Because the vestibular system primarily senses head motion, it is less sensitive to body sway than are the



**Vestibulospinal Responses. Figure 1** Flow diagram depicting the pathways that can influence vestibulospinal control of posture. Graphs surrounding each control box illustrate the expected activation of each control mechanism in the time (latency) and frequency domains.

V

visual or the somatosensory systems. It is a common belief that the vestibular system becomes the dominant controller of posture when there is a conflict between or impairment of visual and somatosensory information. But subjects with vestibular loss do not necessarily utilize somtatosensory cues to a greater extent than do normal subjects to attenuate sway. Thus, the disorientation exhibited by patients with labyrinthine loss when visual or somatosensory information is unreliable might be explained by the fact that neither signal can adequately specify the orientation of the body in all situations. Although different sensory pathways often provide congruent information, each sensory modality is only partially redundant with another because each transduces different stimulus parameters (e.g., velocity or position) and each is effective within a specific frequency domain. For example, control mechanisms for head stabilization have been clearly delineated as acting within well defined frequency bandwidths [5]. Voluntary mechanisms are the predominant controller at low frequencies (<1 Hz), vestibulocollic and cervicocollic reflexes predominate up to 2 Hz and head inertia and other mechanical factors predominantly control the head at higher frequencies. Thus vestibulospinal control of dynamic postures can only succeed with a convergence of sensory information from the vestibular, somatosensory and visual systems.

In alert animals and humans it is difficult to isolate the influences of the vestibular end organs on postural responses of the whole body. The otoliths have been implicated in providing the early muscle responses in the lower limb necessary to oppose a fall. Early responses (75–90 ms) in the gastrocnemius muscle have been recorded during a linear acceleration stimulus when alert animals and humans were unexpectedly dropped from some height. These responses disappeared when the animal was labyrinthectomized but remained intact with canal plugging, thereby supporting the assertion that these short latency responses were of otolith (most likely, saccular) origin [3]. These conclusions have been replicated in humans using galvanic vestibular stimulation (GVS), which delivers a pure disturbance at the vestibular receptor level uncomplicated by inputs to other sensory channels. Externally applied galvanic currents have been shown to act upon the most distal part of the vestibular nerve and produce direction specific body sway and a characteristic modulation of EMG activity in postural muscles in standing humans that requires the integrity of the vestibular nerve. When standing, GVS produces a sustained tilt in the direction of the anode, but immobilized subjects experience illusions of movement in the direction opposite to the sway response. GVS produces a vestibular signal similar to that produced by tilt of the whole body and evokes a corrective response to maintain the position of the head in space. The perception of roll and tilt is maximized when subjects received a long stimulus with the head at a specific pitch angle. Responses to GVS applied to the eighth nerve were recorded when the head was oriented in an upward or downward position while turned to the right so that stimulation of the canals would vary but stimulation of the otoliths remained constant. Results of this stimulation suggest that short latency (60–70 ms) responses in the leg muscles are most probably driven by the otolith organs and medium latency responses (120 ms) are most probably driven by the semicircular canals [6].

As mentioned in the accompanying essay on vestibulocollic and cervicocollic control in this Encyclopedia, forces generated by the vestibulospinal responses may not be adequate to counteract external disturbances. Similarly, responses to vestibulospinal stimulation during complex behaviors suggest that the vestibulospinal influences modulate rather than generate lower limb postural responses. When standing upright, the gravity sensors of the inner ear constantly monitor the position of the head and body and send any information about tilting movement to the vestibular nuclei. It can then be relayed down the spinal cord to the areas controlling limb muscles. It will usually tend to relax groups of muscles on one side of the body and contract similar groups on the other, which allows a person to resist a fall. But in patients with labyrinthine deficit, the magnitude of the lower limb muscle responses is significantly reduced and these individuals often cannot sustain a stable position following repeated disturbances to the base of support [4]. Studies of the H-reflex response in lower limb muscles that were not being used to maintain balance because the subjects were lying prone demonstrate that stimulating the vestibulospinal system, either with GVS or by changing the orientation of the body in space, affects the excitability of the lower limb motoneuron pool [7,8]. Electrophysiological evidence from intact cats indicates that lesions compromising the vestibulospinal and reticulospinal tracts lead to a loss of muscle tonus and these animals have problems in adapting their gait to walk on an inclined plane [9]. Thus the primary role of the vestibulospinal system may be to modify muscle tone rather than to elicit postural reflexes.

There is also evidence that the vestibulospinal pathways have modulating influences on gait in humans. For example, it has been observed that walking with the head tilted back modifies the lower limb EMG responses, which could imply an influence of otolith inputs on gait. In muscle, torques generated by the VCR are not adequate to produce the forces necessary to counteract external disturbances. In subjects walking on a treadmill, the head stayed stable in space relative to the trunk for speeds up to 1.2 m/sec. As walking velocity increased, a

significant head translation developed. The predominant frequency of head movement was restricted to a narrow range from 1.4 Hz at 0.6 m/s to 2.5 Hz at 2.2 m/s. The coordination of head and trunk movement was most coherent at walking velocities between 1.2 and 1.8 m/s and at frequencies between 1.4 and 2.5 Hz. Within the range of 0.8–1.8 m/s, subjects tended to increase their stride length rather than step frequency to walk faster, thereby maintaining the predominant frequency of head movement at close to 2.0 Hz [10]. These results suggest an intimate connection between the CNS mechanisms controlling a stable head and those that control walking velocity.

## Definition

## Characteristics

The skin is by far the largest sensory surface of the human body. It is approximately 1.75 $m^2$ in area and comprises about 6% of the total body weight. In addition to providing a protective barrier against hazardous agents in the environment (mechanical and chemical) and in assisting with the preservation of core body temperature through sweating, it is host to a number of sensory systems. These include mechanoreception (touch), temperature [1], and pain. Vibrotaction, the vibration sense, is a subset of the sense of touch which also included light touch, brushing and steady pressure. In addition to its function as a defensive mechanism, the sense of touch also plays a major role in sexual arousal and thereby is important to the procreative process and the preservation of the species. It is also capable of signaling complex blends of sensation such as itch and tickle.

When the skin is displaced mechanically the disturbance is transmitted through its outer layers (►epidermis) to the deeper layers (►dermis) where a number of different mechanoreceptors are located at various depths. In hairless skin (glabrous), located on the palms of the hands and soles of the feet, there are four principle receptors. These are the ►Pacinian corpuscles (PC), which are the largest mechanoreceptors in the body, ►Meissner corpuscles, Merkel cell neurite processes and ►paciniform endings (formerly Ruffini endings).

A fifth type of neural process found in skin is the ►free nerve endings, which has no organized end-organ structure. These nerve endings, ubiquitores throughout the interior and on the surface of the body, are considered primarily as pain receptors or high-intensity mechanoreceptors and will not be considered further in the current discussion.

►Hairy skin contains PCs, Merkel disc neurite processes, paciniform endings and hair follicle "basket" endings. All of these receptors respond to various configurations of mechanical disturbances imposed upon the surface of the skin.

Measurements of tactile sensitivity are made at two levels of stimulus intensities. Threshold measurements are made to determine the minimal amplitude of displacement that the observer is able to detect 50%

of the time. Suprathreshold measurements are made to determine the subjective judgments of intensity that the observer makes when the physical amplitudes of displacement are greater than the minimal-detectable level.

## Threshold Measurements

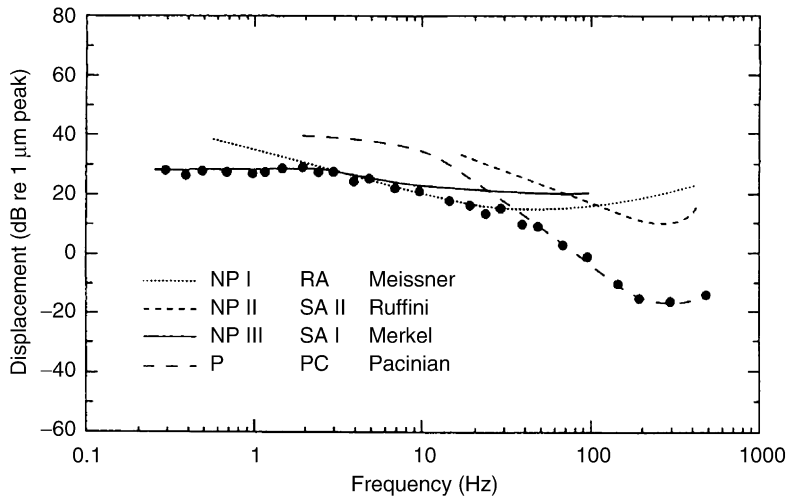
One of the basic operating characteristics of both the auditory and vibrotactile sense modalities is the response to different frequencies at the threshold of detection.

The methods used in making measurements of the human response to stimulation is called ▶psychophysics. Measurements are conducted with the subject located inside a sound and vibration proofed booth, comfortably seated with the arm and hand resting upon a firm surface. The vibrator is located beneath; a circular contactor mounted on the moving element of the vibrator protrudes through a hole in the surface which has a diameter 2.0 mm larger than that of the contractor so there is a 1.0 mm gap between the contactor and the rigid surface. This prevents the vibration from spreading across the surface of the skin beyond the immediate location of the contactor. This allows an exact specification of the size of the skin that is being stimulated. It is also necessary to control the temperature at the surface of the skin because temperature can have a profound effect on vibrotactile sensations; at low temperatures the skin is less sensitive. Typically, the subject wears headphones with narrow-band noise to mask the sounds of the vibrator. The subject responds by pressing buttons to indicate when the stimulus is felt, the responses are recorded by the investigator sitting outside of the booth.

The Pacinian corpuscle is sensitive to sinusoidal vibrations of between 0.4 and 700 Hz. It is able to follow at a 1:1 ratio the individual periodic displacements in a U-shaped sensitivity function with a maximal sensitivity at between 250 and 300 Hz. Exquisitely sensitive, it can be activated by a displacement as small as 0.1 μm (peak) at 250 Hz. The Meissner corpuscle is less sensitive to variations in frequency. Its curve of sensitivity is relatively flat, and it is most sensitive in the region around 30 Hz, able to detect displacement amplitudes of about 15 μm. The Merkel cell complex is also unresponsive to frequency changes, having a sensitivity curve that is relatively flat and most sensitive to frequencies around approximately 10 Hz. The frequency response of the paciniform receptors is similar to that of the PC, but very much less sensitive, having a maximal sensitivity in the region of 250–300 Hz. However, its threshold curve is about 25 dB higher (10 μm) than that of the PC. The psychophysical threshold measurements of the four principle cutaneous receptor channels are shown in Fig. 1.

The curves shown in Fig. 1 are based on measurements made on ▶glabrous skin located over the thenar eminence (palm of the right hand). Measurements made on hairy skin of the volar forearm have the same configuration, but are displaced upward (less sensitive) by about 15 dB. Although the Meissner corpuscle is not found in hairy skin, it is thought that the hair follicle endings subserve the same function.

Only the PC channel is capable of integrating energy over both time and space. In the spatial domain, if the area of stimulation is increased, the threshold of



**Vibration Sense. Figure 1** Thresholds of detection in dB re 1.0 μm of peak displacement plotted as a function of sinusoidal frequency in Hz, measured at the thenar eminence (palm). Decreasing thresholds (increased sensitivity) as the area of the contactor increases is indicative of spatial summation in the higher frequencies, which activates the Pacinian channel. From [2].

detection decreases in a direct, orderly fashion (increased sensitivity). When plotted as a function of contactor area the threshold curves obtained on both glabrous and ►hairy skin decrease by 3 dB per doubling of area. This indicates that there is a perfect integration of the energy imposed upon the surface of the skin [2]. Similarly, in the temporal domain, if the duration of the stimulus is increased, the threshold decreases in an orderly fashion in accordance with an excepted theory of temporal summation in sensory systems [3]. None of the non-Pacinian receptor channels is capable of either spatial or temporal summation [4]. The function of the Pacinian receptor channel is thought to be that of a highly sensitive "alerting" system to indicate that something is present on or near the surface of the skin. The non-Pacinian receptor channels are thought to signal the sight of stimulation and to enable the appreciation of surface textures and the roughness of objects touching or being touched by the surface of the skin; they are essentially feature detectors [5,6].

A four-channel model of cutaneous receptors has been proposed that is based on empirical data obtained from anatomical, electrophysiological and psychophysical experiments [7]. First proposed as a duplex model of vibrotaction [8,9], it was later expanded to a triplex form and finally to its current four-channel format [9]. Perceptions of the environment ultimately will be a blend of inputs from all of the cutaneous receptor systems as the signals from the periphery converge at higher levels of the central nervous system, probably within the somatosensory regions of the cortex.

## Suprathreshold Measurements

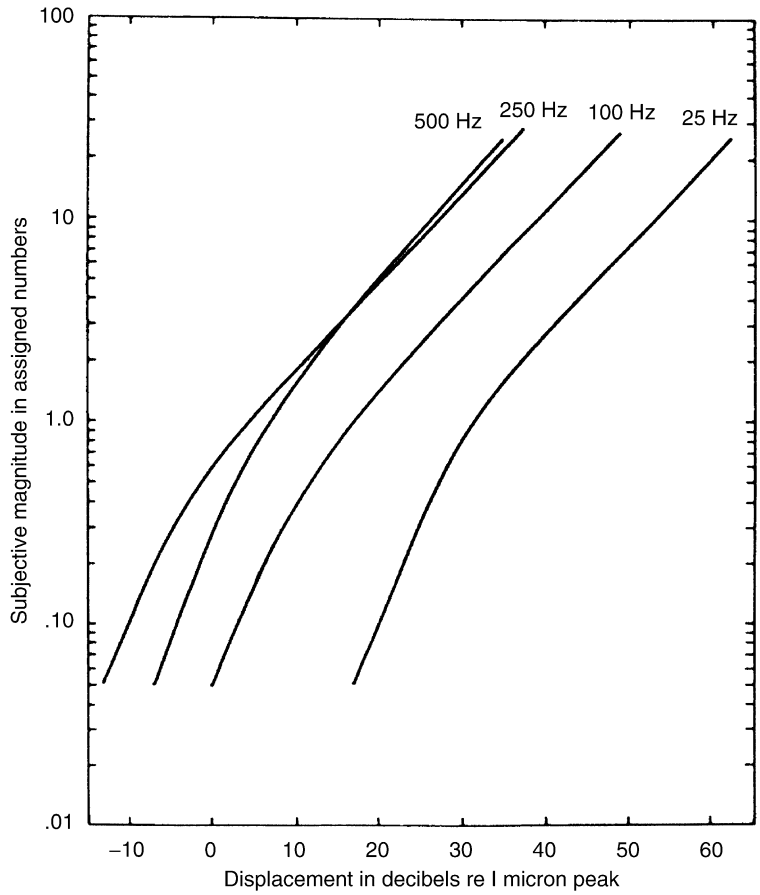
Interactions between humans and the environment occur primarily at supra-threshold levels of stimulation; that is, at intensities of the physical stimulus that are above the minimum displacements needed to elicit a response. These interactions are important for survival as well as for communication. Responses to suprathreshold stimuli have been studied by a number of methods, but the most useful has been the method of Absolute Magnitude Estimation (AME) in which subjects are asked to assign numbers whose subjective magnitude matches their impression of how intense the sensations feel. No standard or modulus is given. The numbers given by the subject are plotted as a function of the physical intensity of the stimulus. The resultant best-fit curve describes a power function with a slope that is different from one sense modality to another but is typically consistent within each modality. Figure 2 shows the results obtained at four frequencies [10], plotted as subjective magnitude in assigned numbers as a function of the amplitude of displacement in decibels. The measure of central tendency of a group of subjects is obtained by computing the geometric means of the group. The best–fit curves are drawn through the untransformed, raw judgments given by the subjects. In the mid-to high range of physical intensities the curves describe power functions with an exponent (slope) of about 1.0. It might be added that in vision, hearing and touch the results of AME experiments have always yielded power functions along a multitude of physical dimensions. Exponents vary from modality to modality, but within each modality the results are consistent.

## Subject Variables

Because humans vary in a number of important ways, including age, gender, hand preference, etc., studies have been performed to ascertain the effects of these variables on responses to vibratory stimulation. These experiments have determined that there is no difference between males and females in ►absolute threshold values in vibroatction, but at suprathreshold levels women perceive the same physical intensity of stimulation as being more intense than men. That is, women typically assign higher numbers to the same amplitudes of displacement than do men. The detection thresholds of women also vary systematically over the duration of the menstrual cycle. The sensitivity to a 250 Hz sinusoidal vibration increased up to the onset of menstruation. Then the women became less sensitive for 12–13 days when they reached a nadir of insensitivity. These changes were not observed in women taking birth-control pills. It is apparent that vibrotactile sensitivity is influenced by hormonal balance. Hand preference has no effect on the absolute threshold of detectability, but suprathreshold stimuli delivered to homologous sites on opposite sides of the body, the stimuli have an interactive effect on right-and left-handed subjects. That is, a stimulus delivered to one side of the body can affect the sensation resulting from a stimulus delivered to the opposite side. However, in ambidextrous persons there was no cross-body effect; it appeared that the two contralateral sites were functioning quite independently of each other. There is no difference in threshold values of the two hands nor is there a difference between right and left-handed individuals. The effects of aging are detrimental to the vibration sense throughout the life span, but these effects are considered in detail in another entry of this encyclopedia.

## Epilogue

It is legitimate to ask the question: "Why study the sense of vibration?" After all, in this sense humans are not afflicted with sensory deficits such as blindness or deafness that take an enormous toll in society, economically and on the quality of life of the individual. There are several answers to this question. First, to understand the functioning of any aspect of the body is a legitimate pursuit of any scientific endeavor. Improvements in the "way of life" are often made by the endeavors of individuals driven not by goals of practical



**Vibration Sense. Figure 2** Subjective magnitude of vibration of five frequencies is assigned numbers plotted as a function of displacement in dB re 1.0 μm peak. In the mid-to upper range of displacement the curves describe power functions with a slope (exponent) of about 1.0. From [10].

application but rather by insatiable curiosity. The more we understand about how the body works, the better our position to cure its ills and improve the general welfare.

Second, there are many practical applications for our knowledge about the vibration sense. Deficits in sensitivity, at threshold and at suprathreshold levels, are often precursors of neurological and metabolic disorders. The study of tolerance levels often leads to improvements in the safety and acceptability of the workplace environment. A very important application of knowledge about the vibration sense has been for the use of vibrotaction as a substitute or surrogate of the senses of vision and hearing. Time-honored systems for aiding the blind in reading the printed word are found in the use of Braille and more recently in the development of electronic reading devices. Aids to mobility for the blind that utilize the sense of touch have also been developed. For the deaf, alerting systems for potential hazards are in use and, of great importance, devices to aid the deaf in understanding the spoken word (Tactile Vocoders) are now commercially available. Tactile signals are also used to supplement the eyes and ears in environments in which they are overtaxed with information, such as in aircraft and space vehicles. The military applications include communication with personnel who would be exposed to danger should conventional channels be used. In the field of robotics, substitutes for the eyes and ears have for the most part successfully achieved, but the effort continues to enable robots to tactually feel the environment as do humans.

At the theoretical, basic and applied levels, there are a multitude of reasons for efforts to study and understand the vibration sense.

## Viral Central Nervous System Infection

### Definition

Virus infection in the central nervous system (CNS). Virus can spread to the CNS via the neural (using peripheral nerves), olfactory, or hematogenous routes. Most viruses, such as poliovirus and herpes virus, cause acute pathology, while some viruses, such as measles virus and lymphocytic choriomeningitis virus (LCMV), can persistently infect the brain, leading to chronic disease. Cell types that are infected by viruses in the CNS differ depending on the virus. For example, poliovirus infects neurons, JC virus infects oligodendrocytes, and HIV infects monocyte/macrophage lineage cells. Although some viruses can latently infect host cells without causing CNS damage, other viruses cause lytic infection or apoptosis of cells in the CNS. Antivirus immune responses in the CNS can be a double-edged sword; immune responses can eradicate virus from the CNS, while severe immune responses can damage CNS tissue (immunopathology), whose regeneration ability is limited.

## Viral Myelinopathy

### Definition

Any virus disease of the myelin; degeneration of the white matter of the brain of viral etiology.

## Viral Vector

### Definition

A virus that is genetically modified in such a way that it is still able to deliver its genetic contents to the cell nucleus but has lost its capacity to divide.

►Knowledge

# Viruses for Transneuron Tracing

## Definition

Neurotropic viruses reproduce inside living neurons and cross that neuron's synapses to the neurons connected to it. This property allows tracing of a pathway across one or more synapses. A solution containing a virus is injected into a target structure. After a survival time appropriate for the number of synapses in the pathway (1 day/synapse is typical) the animal is sacrificed and its brain histology treated with antibodies to reveal the presence of the virus. Some viruses travel in the retro grade direction and others in the anterograde direction.

# Viscera

## Definition

A general term that refers to the internal organs of the body. The contents of the four great body cavities: the cranium (skull), the thorax (chest), the abdomen, and the pelvis.

►Evolution of the Spinal Cord

# Visceral Afferents

## Synonyms

Vagal afferents; Splanchnic afferents; Pelvic afferents; Afferent innervation of the heart; Lungs; Airways; Gastrointestinal tract; Kidney; Ureter; Bladder; Reproductive organs; Mesenteries; Visceral sensation; Visceral reflexes

## Definition

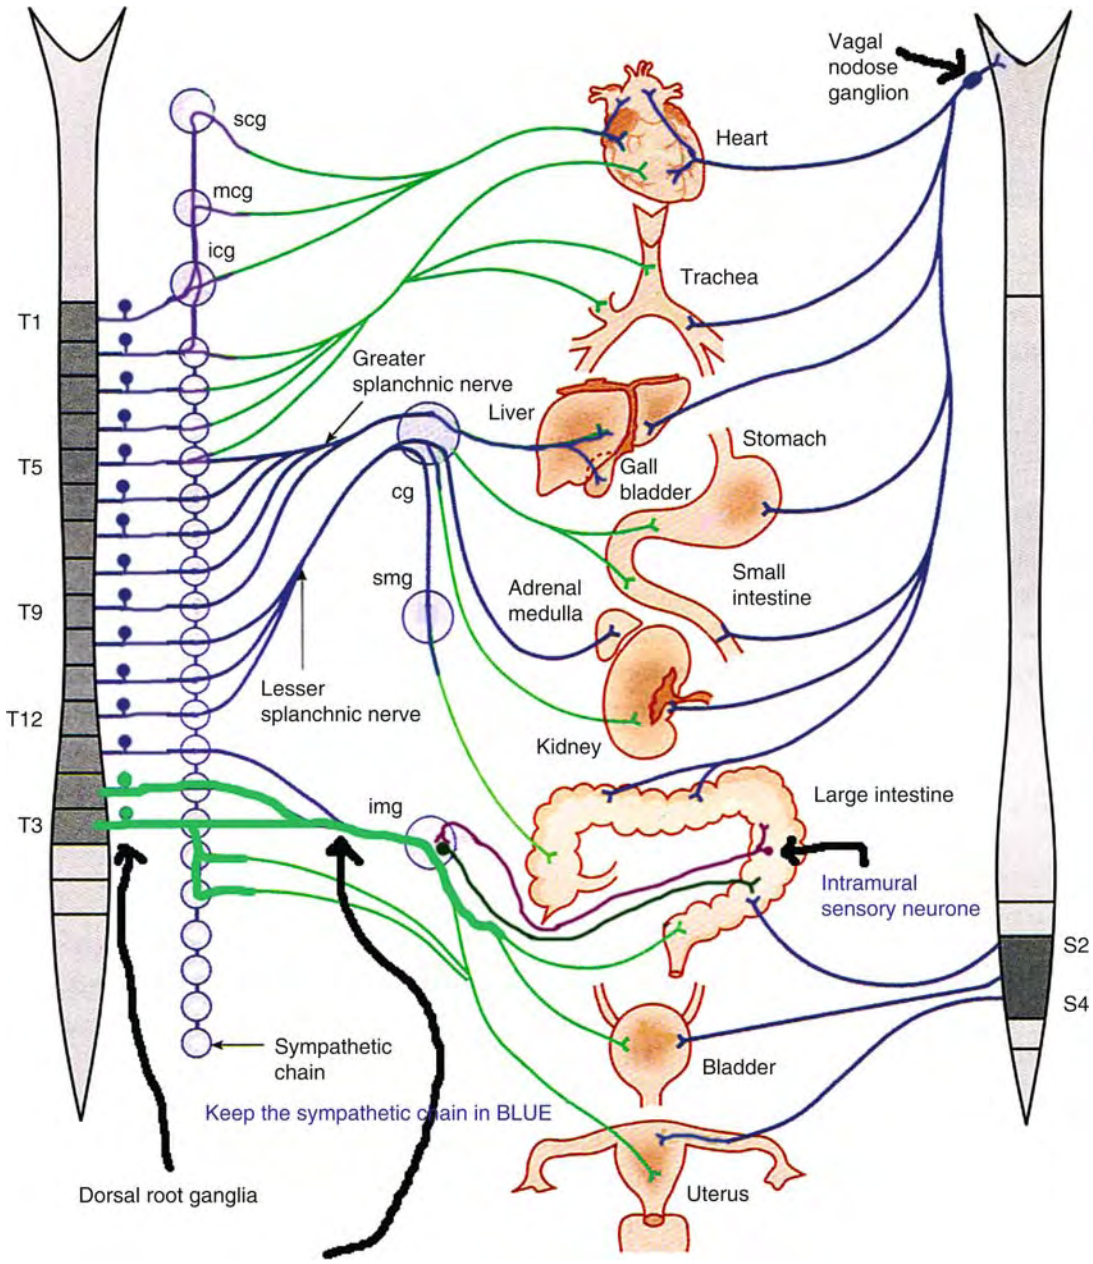
Visceral Afferents are neurons that sense events occurring within internal organs, the membranes that cover them or their attachments to the body wall. The information carried by visceral afferents is concerned with the physiological regulation of viscera such as the heart, lungs, gastrointestinal or urogenital organs, or may occasionally appear as a conscious sensation, often, but not necessarily, painful in nature.

## Characteristics

### Higher Level Structures

The thoracic, abdominal and pelvic viscera are the main sources of visceral afferent information, and nerve endings may be found in muscular walls, the inner lining, the surrounding membranes of these organs or in the ►mesenteries and ►omentum. Afferent information includes the movements or stretch of visceral walls, the composition of the visceral contents, events that occur within the external coverings of the organs, and stretch of the mesenteries. The pathways to the central nervous system (CNS) are twofold: the vagus (Xth cranial) nerve, which carries information from the thoracic and upper abdominal viscera to the brainstem, and the spinal afferent pathway, which innervates all abdominal and thoracic organs and enters the spinal cord via the dorsal roots. These pathways have cell bodies in the nodose and dorsal root ►ganglia (DRGs), respectively. The vagal neurones are particularly concerned with the physiological regulation of thoracic and upper abdominal organs and sensations such as satiety, breathlessness and stimuli that elicit cough; whereas the spinal innervation is concerned with pain and other normal sensations as well as some reflex activities; sensations and reflex activities arising within the pelvis are largely dependent upon the ►pelvic nerve. In addition to the visceral afferents with cell bodies in the DRGs or nodose ganglia, the enteric nervous system has sensory neurons with cell bodies embedded within the walls of viscera, and project to efferent neurons in the prevertebral sympathetic ganglia [1,2] (See Fig. 1).

Many events that occur inside the body, such as the beating of the heart or movements of the intestines, occur without any conscious knowledge of their existence. Exceptionally, individuals may become aware of irregularities of their heartbeat (palpitations) or of intestinal activity (colic); many people thankfully go through most of their lives without experiencing visceral pain, because that can be particularly intense and unpleasant. Other common visceral sensations, such as that of a full stomach, a full bladder or the desire to defecate depend on the activity of neurons



**Visceral Afferents. Figure 1** Diagram of the vagal, spinal and enteric afferent pathways.

that monitor distension or stretch of the walls of the stomach, bladder of rectum. While these may be regarded as warning signs that viscera are nearing a danger limit of distension, some sensations, such as satiety, also depend on afferent signals related to stomach volume and the hormonal changes associated with digestion. Some sensations are pathognomic of particular disorders, and arise from viscera in which there are inflammatory or other physical changes; for example, the substernal burning sensation of heartburn is associated with gastric acid secretion following food intake, but may indicate the presence of inflammatory or ulcerative changes within the affected tissues. The association between sensations of this type and inflammatory change may be related to sensitization of visceral afferents (see below).

Contractions of the walls of the intestine, ureter, biliary tract or uterus may give rise to spasmodic pains that wax and wane; this colicky pain is most marked when the contractions occur against some obstruction.

Contractions of viscera, however, are not always associated with noxious sensations - entirely the opposite is true during contractions of pelvic organs during an orgasm.

## Lower Level Processes

The vast majority of visceral afferent axons are unmyelinated C-fibers; virtually all the afferents in the abdominal vagus nerve are of this type; a small percentage of spinal visceral afferents are finely myelinated (Aδ fibers). Large myelinated axons are uncommon in visceral nerves, but in some species a few Aβ myelinated axons innervate Pacinian corpuscles in the mesenteries. The spinal visceral afferents innervate the serosal surface and mesenteric or omental attachments of viscera as well as the smooth muscle and mucosal lining of some organs, whereas the vagal afferents innervate mainly the muscle layers and the lining. The spinal visceral system divides into medial and lateral pathways around the dorsal horn to reach the autonomic preganglionic neurons and the area around the central canal. Transmission at these synapses is achieved by glutamate, tachykinins and other mediators e.g., ATP. The vagal afferents terminate in the medulla, in nuclei such as the tractus solitarius.

Neuropeptides are present in the majority of spinal C- and (to a lesser extent) Aδ− afferents, and have an important role to play at both their central and peripheral terminals in neurotransmission and neurogenic edema formation, respectively. The peripheral terminals release tachykinins, Calcitonin Gene-Related Peptide (CGRP) and other mediators, which cause vasodilatation, and increase capillary permeability. In some tissues, e.g., the stomach, the release of neuropeptides (e.g., CGRP) is believed to protect the mucosa against acid attack. The dual function of sensory transducer and neurotransmitter release at these peripheral terminals has sometimes been called a sensory-motor function. This process seems to be associated particularly with capsaicin sensitive C-afferents; capsaicin is a ligand for the TRPV1 receptor, which is also sensitive to protons and to heat. The TRPV1 receptor is present in a subgroup of visceral afferents and appears to be associated with visceral pain pathways (e.g., in the ►urothelium and the gastric mucosa); however, knockouts for TRPV1 not only interfere with sensation, but can also show modified physiological reflex responses [3]. A variety of other ligand binding sites can be identified in visceral afferent neurons [4,5].

The electrical properties of visceral afferents determine the impulse traffic in visceral afferents and depend largely on the properties of specific ion channels within their membranes; recent studies in this area focus mainly on the properties of the DRGs of afferents from bladder, colon, heart and stomach. The cell bodies of unmyelinated neurons commonly show TTX-resistant sodium channels and slow inactivating A-type $K^+$ channels. The larger neurons of Aδ fibers have lower thresholds to electrical stimulation and have TTX-sensitive sodium channels and fast inactivating A-type $K^+$ channels. It has been shown that the state of the A-type $K^+$ channels regulates afferent neuron excitability and the firing properties of the afferents (e.g., the phasic or tonic nature of the excitation during stimulation). High-voltage-activated calcium channels also exist in dorsal root ganglion neurons that innervate the bladder or the colon, and these channels, as well as the A-type $K^+$ channels, are potential targets in the development of drugs that can modify afferent input in order to control pain or overactive visceral reflexes.

## Process Regulation

Sensitization means that the gain of the mechano-sensory transducer is increased following the application of a sensitizing stimulus, and it is one mechanism by which painful states may be exacerbated, and reflex activity increased. Sensitizing stimuli include inflammation of the viscera and the presence of chemical mediators including ATP, nitric oxide and nerve growth factor (NGF; ►neurotrophin 1) [6–8]. During chronic inflammation, spinal afferents innervating the bladder or stomach and vagal afferents from the stomach increase the expression of in the Na(v)1.8 TTX-resistant channels; these changes may account for the resting activity and hypersensitivity associated with inflammation or ulceration. Following spinal cord injury (SCI), bladder afferents are also sensitized, a process which is dependent on production of NGF (and other neurotrophins) by these neurons. There is now good evidence that blockade of NGF production or release can reduce the sensitization and prevent the expression of the additional TTX-resistant sodium channels.

Certain mechano-transducer functions, e.g., stretch of the urothelium (the lining of the bladder), appear to be dependent upon a chemical mechanism. ATP may be released by stretching urothelial cells, and can act on P2X2/3 receptors within local nerve endings; it is the latter that determines the intensity of the response. Blockade of the P2X2/3 receptors (or their removal by gene knockout) can reduce considerably the mechanical sensitivity of these afferents, while P2X agonists have the opposite effect; ATP is now recognized as an important mediator in the normal transduction process at this site.

## Functions

The functions for visceral afferents arising from different organs may have specific functions with respect to visceral regulation, or may promote more generalized responses.

The vagus nerve contains afferent fibers that sense physiological changes within the heart, blood vessels, lungs, airways, and the upper gastrointestinal tract. Some vagal (and glossopharyngeal nerve) afferents monitor arterial blood pressure (baroreceptors) and the gaseous elements in the arterial blood (arterial chemoreceptors). The heart has atrial as well as ventricular receptors - the latter occur in the endocardium, muscle and epicardium. Within the lung, different receptors sense the presence of irritants in the airway, the lung volume, the distension of pulmonary capillaries or the presence of inflammatory mediators. Cough and breathlessness (dyspnoea, e.g., in cardiac failure) are subserved by pulmonary vagal afferents, and indicate that some noxious events may be signaled by this route.

Within the upper GI tract, the vagal afferent endings are situated largely within the smooth muscle or the mucosal lining of the viscera. There are several types of mucosal receptor which respond to mechanical stimuli, changes in luminal pH or fatty acid content. Others are excited by the local release of 5-HT or of cholecystokinin (►CCK): there is evidence in humans and animals that some of these intestinal receptors may have a role to play in satiety, possibly because of this relationship of afferent nerve endings with hormone-secreting cells [8].

In ruminants, the sequence of contractions in various parts of the stomach is signaled and regulated by vagal afferents, and normal rumination depends on the integrity of this innervation.

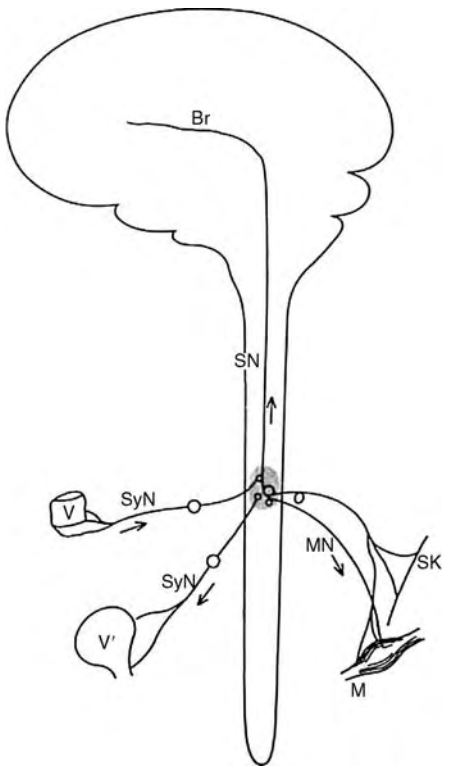
The spinal visceral afferents travel within the sympathetic and pelvic parasympathetic nerves and have their cell bodies in the DRGs. Many of these afferents are excited by mechanical changes in the viscera such as distensions or movements; tension on mesenteries causes intense pain, and many splanchnic nerve afferents innervate the serosal surface of the viscera and the mesenteries or omenta, and are excited by tension on these tissues. There are also reports of intra-abdominal thermoreceptors. The mechanoreceptors often show ongoing activity at rest that can be correlated with visceral movements. Low threshold afferents signal physiological changes within certain viscera, e.g., the bladder, and are also excited by the high pressures within the viscus. In addition, there are high threshold mechanoreceptors that are sometimes regarded as nociceptors; however, injury to viscera is not necessarily an adequate stimulus for visceral pain, and there are a number of well recognized conditions where injury to viscera does not result in pain. There remains some controversy over the nature of the signals that initiate visceral pain, and these may differ between different organs. Some authors have concluded that the encoding of visceral nociceptive events may occur by an intensity mechanism rather than a specificity mechanism (as in the skin), it may be that this is a key difference between viscerosensory and somatosensory processing [9,10].

A third group of spinal visceral afferents are the "silent" afferents, which do not respond to the intensities of stimuli that excite the low or high threshold afferents. However, they develop mechanosensitivity during inflammation. This sensitization is associated with changes in ion channel expression within the neuronal cell membranes (see above).

There are reports that the properties of afferents may be altered by ageing [11].

## Pathology

Referred Pain. The pain of gall bladder inflammation is often felt in the right upper quadrant of the abdomen and at the tip of the right shoulder, and this combination of symptoms is of some importance in coming to the correct diagnosis. The underlying mechanism that gives



**Visceral Afferents. Figure 2** Mackenzie's concept of the causal relationship between visceral afferent stimulation and referred pain, viscero-somatic and viscero-visceral reflexes (V-V′). Afferent discharge from a viscus (V) is carried by sympathetic nerve trunks (SyN), and then activates a pathway (SN) to the brain (Br) that initiates visceral pain; the pain is located in the somatic areas innervated by this pathway and may be associated with a segmental 'irritable focus' that gives rise to cutaneous hyperalgesia (SK) and changes in somatic muscle tone (M) mediated by motoneurones (MN).

rise to this diverse distribution of symptoms can be understood if one considers the segments of the spinal cord that innervate these areas of the body. The biliary tract is innervated by segments of the spinal cord that also supply the skin and muscle of the right upper quadrant of the abdominal wall, but when inflammation of the gall bladder impinges on the diaphragm it causes afferent input via the phrenic nerve, which arises within areas of the cervical segments that innervate the right shoulder. This idea of the common segmental origin of sensory nerves to all of the regions involved in this inflammatory process is stated in Ruch's Convergence-Projection Theory of Referred Pain. There appear to be no specific visceral sensory pathways in the central nervous system; rather, information concerning events in the viscera is carried from the spinal cord to the brain by neurones that also carry information about events affecting areas of the skin and body musculature innervated by the same segments of spinal cord. A potential confusion of the exact origin of sensation may therefore arise, because sensory inputs received by the brain may have arisen from viscera or skin or muscle, and the origin of these messages may be misinterpreted. Events in the biliary tract give rise to sensation in the right shoulder because the same central neurones transmit messages from both sites. This concept can be extended to sensory inputs from many viscera [12] (see Fig. 2).

Information provided by patients about the location and nature of their visceral pains may be subject to misinterpretation when it is transmitted along spinal pathways normally involved in some other sensory activity.

### Therapy

Most potential new therapies are experimental in nature; however, capsaicin and its analogs have been used in humans to modify afferent sensitivity.

# Visceral Nervous Function

►Ageing of Autonomic/Enteric Function

# Visceral Pain

Klaus Bielefeldt
University of Pittsburgh, Department of Medicine, Pittsburgh, PA, USA

### Definition

Visceral pain defines the complex sensory experience of pain arising from viscera within the thoracic, abdominal or pelvic cavity.

### Characteristics

#### Epidemiology

Visceral pain is a common and often chronic problem. Within the United States, it accounts for more than 12 million physician consultations annually. Epidemiologic studies suggest that about up to 50% of surveyed adults complain about pain at the time of the interview, with about one-fifth suffering from some type of visceral pain. In contrast to the documented age-dependent rise in most other types of pain, the prevalence of visceral pain decreases in persons over 60 years of age. Acute pain, such as chest tightness or pressure during cardiac ischemia, generally serves a

physiologically meaningful role, alerting the organism about a potential injury. In contrast, chronic pain is less clearly related to potentially noxious stimuli, does not trigger reactions to avoid harm to the organism, and is, therefore, often considered pathologic. Chronic pain syndromes involving visceral structures are common. In the majority of cases, no structural or biochemical abnormalities can be identified, leading to the diagnosis of a functional disorder, such as irritable bowel syndrome and non-ulcer dyspepsia, which have an estimated prevalence of up to 10% in the general population. As is true for several other chronic pain syndromes, women more commonly report chronic visceral pain than men [see Shinal and Fillingim essay]. While few prospective studies determined the natural history of such disorders, current data suggest that more than 60% of affected individuals will continue experiencing at least intermittent pain or discomfort for more than one year.

## Characteristics of Visceral Pain

Visceral pain is typically poorly localized and referred to distant cutaneous sites. This pattern of pain referral (►referred pain) often helps identifying the underlying problem. For example, upper abdominal pain radiating to the right shoulder blade suggests cholecystitis, while a belt-like radiation to the back points at a potential pancreatic origin. However, as is true for the vague localization of visceral pain, referral patterns overlap between different structures: patients with cardiac or esophageal problems can both experience pain radiating to neck or left shoulder. Visceral sensations and pain also poorly discriminate between different stimulus modalities, as shown in studies examining responses to esophageal distension, which is reported as heartburn by up to one third of healthy volunteers.

In addition to its discriminative power (localization, stimulus modality and intensity), sensory input, especially pain, generally carries an emotional dimension (valence) (see Gracely essay: Emotional Affective Aspects of Pain) Comparison between painful cutaneous and visceral stimuli of similar intensity reveal that visceral pain triggers stronger emotional reactions. Finally, the autonomic responses that characterize pain, such as changes in heart rate or blood pressure, are more pronounced in response to visceral pain and can secondarily affect organ function (e.g. vomiting, diarrhea, fecal urgency), which may further worsen the experience of discomfort and pain.

## Triggers of Visceral Pain

The currently accepted definition of pain refers to a complex sensory experience triggered by injurious or potentially injurious stimuli. This definition is based on its physiological role as an alarming experience that assures survival by leading to appropriate defensive or withdrawal reactions. Typical triggers of visceral pain are distension of hollow organs (stretch), strong contraction of visceral smooth muscle (tension), stretch or torsion of the mesenteric attachments of abdominal viscera, inflammation or ischemia. In contrast to cutaneous pain, the most common causes of visceral pain, stretch or tension, do not result in damage. Conversely, burning, pinching or cutting of internal organs – all obviously linked to injury or tissue damage – are not painful or not even perceived at all. While varying from organ to organ, the most common causes of visceral pain are stretch, tension or chemical signals generated during inflammation or ischemia (Table 1).

Most experimental approaches investigating mechanisms of visceral pain in humans or animals rely on distension of hollow organs as a reproducible stimulus. Distending pressures exceeding 30 mmHg typically elicit a sensation of pain and/or aversive responses. Human studies have demonstrated enhanced responses to mechanical stimulation in patients with visceral pain syndromes, thus providing evidence that they represent manifestations of visceral hyperalgesia. However, the invasive and time-consuming nature of these tests and their poor correlation with symptoms limit their utility as a diagnostic tool in clinical medicine. Chemical stimuli are less frequently used as experimental triggers of discomfort of pain because repeated stimulus applications and the identification of distinct sensory thresholds can not be performed. In addition, some chemical noxae (e.g. protons) may lead to injury, further arguing against their use as a stimulus in experimental pain research.

## Peripheral Pathways of Visceral Sensation and Pain

The organization of visceral sensory innervation differs from that of other structures in the body insofar as two anatomically distinct sensory pathways convey afferent input to the central nervous system. Most

**Visceral Pain. Table 1** Triggers of visceral pain

| Stimulus modality | Physiological correlate | Organ-specific examples |
|---|---|---|
| Stretch | Distension | Gastric fullness and bloating |
| | | Pain during ectopic pregnancy |
| Tension | Muscle contractions | Labor contractions |
| | | Renal colic |
| Chemical | Tissue acidosis | Ischemic pain (myocardial infarction) |
| Chemical | Inflammatory mediators | Cystitis, cholecystitis |

V

viscera receive a dual innervation (►dual visceral innervation) with vagal and spinal afferents extending to thoracic and abdominal organs except for the distal colon and pelvic viscera (e.g. urinary bladder). Two sensory nerves also convey information from the distal colon and pelvic viscera, with thoracolumbar and lumbosacral afferents, respectively. While these distinct sensory pathways share many important properties, important anatomical and physiological differences exist, suggesting differential contribution to conscious perception and pain.

Vagal afferents project via the nodose ganglion directly to the brain stem, where they terminate in the nucleus of the solitary tract. From there, fibers project rostrally to brain structures involved in autonomic regulation, such as the hypothalamus, supraoptic nucleus, and – via the parabrachial nucleus and ventro-medial thalamus – the insular cortex, anterior cingulate cortex and amygdala, areas that regulate arousal and the affective responses to different stimuli including pain. Spinal afferents traverse the prevertebral ganglia, where they may branch and provide afferent input to postganglionic sympathetic neurons. The cell bodies of spinal afferents are located within dorsal root ganglia, where visceral sensory neurons account for less than 10% of the neurons. The central terminations project to superficial and deeper layers of the dorsal horn. Second and higher order neurons send their axons through several ascending pathways (spinomedullary, spinopontine, spinomesehcephalic, spinohypothalamic and spinothalamic tracts) (see Giesler essay: Ascending nociceptive pathways) to medullary and higher brain structures, including hypothalamus, thalamus and cortical areas. While most sensory input contributes to autonomic regulation, changes in affect and arousal as described above, spinal afferents – via spinothalamic projections to the dorsolateral part of the thalamus – also provide discriminative input about visceral stimuli to the primary and secondary sensory cortex (see below). In addition to the spinothalamic tract, a post-synaptic dorsal column ascending pathway plays a role in visceral nociception (see Giesler essay: Ascending nociceptive pathways). Surgical or experimental interruption of this pathway results in significant improvement of intractable pain due to pelvic malignancies and abolishes aversive responses to noxious visceral stimuli in experimental models of visceral pain. Current evidence suggests that the dorsal column and spinothalamic tract pathways may differentially contribute to visceral nociception with a more significant role for spinothalamic projections in the autonomic and affective responses triggered by visceral pain.

The properties of the distinct afferent pathways have been investigated in vivo and in vitro. Using hollow organ distension as the stimulus, most studies have focused on acute responses to mechanical stimulation. Experiments demonstrated that animals rapidly learned to modify their behavior to avoid gastric distensions to a pressure that typically triggers an aversive response. While vagotomy did not affect these results, transection of spinal afferents through splanchnic nerve resection abolished this effect, suggesting that spinal rather than vagal afferents convey information about acute painful gastric mechanical stimuli. Recordings from teased nerve fibers further supported the role of spinal afferents in visceral pain. Vagal mechanosensory fibers form a relatively homogeneous group with essentially all having a low threshold for activation. While the majority of mechanosensitive visceral afferents projecting to the spinal cord have response profiles similar to vagal afferents, about 20–30% of spinal afferents only respond to high intensity stimuli. The activation threshold falls within the range of stimulus intensities that are perceived as painful and/or trigger aversive responses. Thus, behavioral and physiological data indicate that a specific pathway and perhaps even specific fibers play an important role in visceral nociception (specificity coding). However, most low threshold mechanosensitive fibers encode stimulus intensity well into the noxious range. Thus, it is possible that they contribute to the sensation of pain, if stimulus intensity (i.e. summation of input) rather than the activation of specific "nociceptors" (intensity coding) elicits pain perception.

The two distinct afferent pathways innervating pelvic organs also differ functionally. The majority of colonic afferents within the pelvic nerve respond to low intensity stimulation, particularly stretch, consistent with a role in defecation, which requires input about filling of distal colon and rectum. In contrast, most of the thoracolumbar colonic afferents appear to be located in the mesentery or serosa and only respond to high intensity stimuli, suggesting a potential role in nociception. Similarly, thoracolumbar afferents do not play a significant role in the regulation of micturition under physiologic conditions, but are strongly activated during bladder inflammation.

As already mentioned, the functional distinction of visceral afferents as low or high threshold is based on responses to mechanical stimulation. However, the frequently changing composition of luminal contents and the importance of ischemia and inflammation as triggers of visceral pain clearly highlight the importance of chemical stimuli in visceral sensation and pain. Yet, relatively little is known about the differential contribution of visceral afferent pathways to chemonociception. Considering the acidic environment of the stomach, protons play a potentially important role as triggers of discomfort and pain in gastoesophageal reflux and dyspepsia. Acidic solutions can activate vagal and spinal sensory neurons. Consistent with

these results, obtained in dissociated cells, vagal afferents respond to luminal acidification of esophagus or stomach (Fig. 1).

Using c-fos expression as a surrogate marker for neuronal activation, intragastric administration of noxious acidic solutions appeared to selectively activate vagal rather than spinal afferent pathways. Consistent with these findings, vagotomy, but not splanchnic nerve resection blunted responses to infusion of acid into the stomach in rats. These findings suggest that, different from responses to mechanical stimulation, vagal afferents may contribute to chemonociception.

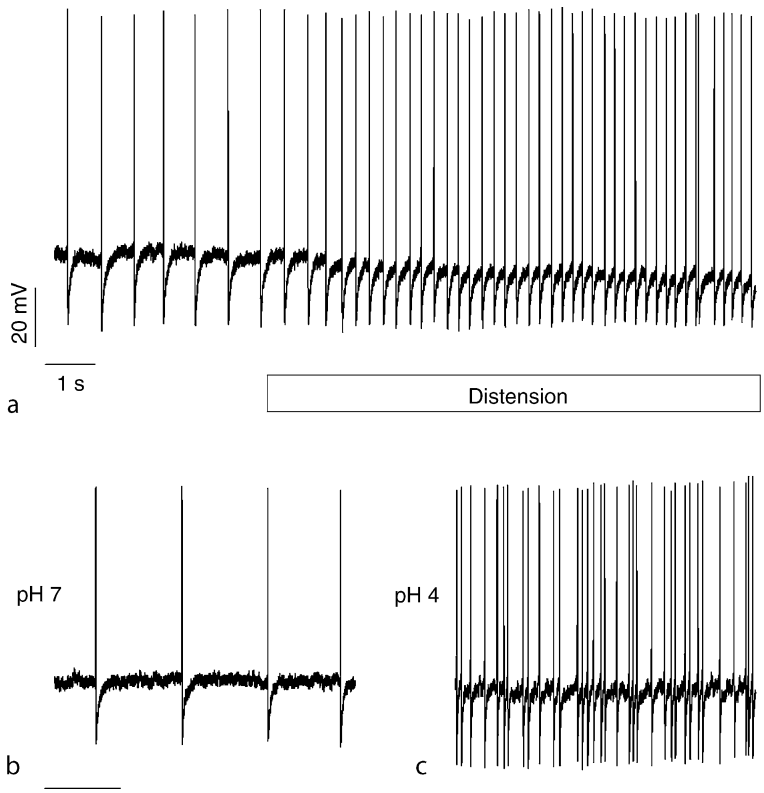
Finally, "silent" nociceptors have been proposed to play a role in triggering painful sensations. By definition, such silent nociceptors are not activated by typical experimental paradigms used to examine sensory neurons. However, exposure to inflammatory mediators or noxious chemicals can acutely alter their properties, making them responsive to mechanical stimuli. Very little is known about the presence and functional relevance of such silent afferents in the gastrointestinal tract. Interestingly, activation of previously silent afferents have been described in the vagus after luminal exposure to bile, again raising questions about a possible role of vagal input in nociception. However, the paucity of studies does not allow conclusions about the relative contribution of this class of afferents to visceral pain.

## Structure of Primary Sensory Nerve Endings

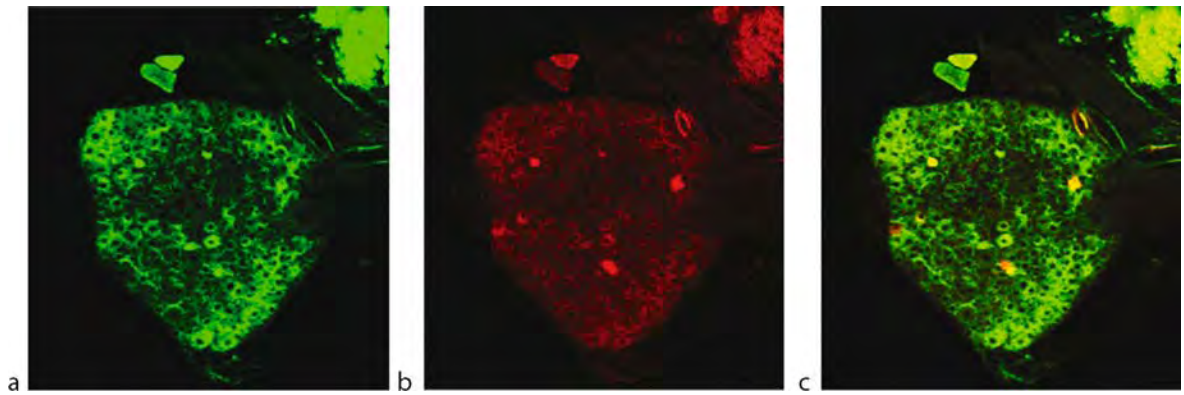
Visceral afferents often dichotomize extensively in the periphery with several sensory terminations that can span a wide region within a target organ. Anatomical and physiological experiments have demonstrated that a single neuron can project to several receptive fields within the target organ (Fig. 2).

Experiments with retrograde tracers injected into different organs even suggest that a single neuron may innervate two anatomically distinct structures, such as urinary bladder and distal colon or esophagus and heart. However, functional evidence of the existence of neurons projecting to two organs is still lacking. Nonetheless, these findings provide a potential explanation for the poor spatial discrimination of visceral afferent input.

Relatively little is known about structure-function relationship of visceral afferent terminals. Free nerve endings extend toward the epithelium, where they may form some varicosities and can be found in close proximity with specialized epithelial cells that can



**Visceral Pain. Figure 1** The tracings show intracellular recordings from a nodose neuron innervating the stomach. Gastric distension (a) identified the neuron as mechanosensitive. The baseline activity of this neuron (b) increases significantly after lowering the luminal pH to 4 (c).



**Visceral Pain. Figure 2** Gastric sensory neurons in the nodose ganglion were identified by injection of different retrograde labels into the fundus and pylorus of the mouse stomach. The differential uptake of labels identifies neurons projecting to fundus (a) or pylorus (b). The merged image (c) shows neurons innervating both areas.

release chemical mediators upon stimulation. These neuro-epithelial interactions have been best characterized in the gastrointestinal tract and urinary bladder. Within the gut, enteroendocrine cells store vesicles containing serotonin and/or a variety of neuropeptides. Luminal stimuli trigger the release of these signaling molecules, which in turn activate nerve endings within the vicinity. Similarly specialized cells have also been documented in the airways and may contribute to chemosensation. In the urinary bladder, distension or chemical stimuli cause release of ATP from epithelial cells, activating primary afferents through interaction with purinergic receptors. In areas covered by squamous epithelium, free nerve endings even project into the epithelial layer itself. Considering the role of such free endings as cutaneous nociceptors, it is likely that these fibers contribute to pain sensation.

In addition to such free endings, some structural specializations of visceral sensory nerve terminals have been identified. Vagal afferents innervating the gastrointestinal tract form intraganglionic laminar endings (IGLE), a branching network of nerve fibers surrounding enteric neurons within the myenteric ganglia, a component of the enteric nervous system. Based on their structure and proximity to punctate receptive fields of mechanosensitive vagal afferents, these IGLEs likely function as mechanosensitive endings and are activated by stretch. Similar structures have recently been described in the distal rectum, which is innervated by spinal afferents. A second structural specialization, intramuscular arrays (IMA), has been described in vagal afferents projecting to the proximal gastrointestinal tract. These branching fibers run parallel to smooth muscle cells. They are more restricted in their distribution and appear to cluster close to sphincteric regions in the foregut, suggesting a role as tension receptors. Currently available information suggests that these receptors are activated by low intensity stimuli. Thus, it is unclear whether they contribute to the sensation of pain. Recently, varicose branch points or endings have been described in mesenteric and serosal afferents that are only activated by high intensity punctate stimuli. While these results suggest a potential contribution to nociception, additional studies with more physiological stimuli are needed to determine the relevance of these findings.

## Functional Characterization of Primary Afferents

Different receptor types have been described based on functional characteristics. Within the gastrointestinal tract, some afferent fibers respond to low intensity mucosal stimulation, another group is activated by stretch, and a third group only responds to intense punctate stimuli. Considering these physiologic properties and the preferential location of their receptive fields, these afferents are often referred to as mucosal, muscular and serosal, respectively, although anatomical confirmation of such a restricted localization is still missing. The very low threshold of mucosal afferents argues against a role nociception. While muscular afferents also have low thresholds for activation, they encode stretch over a wide range of stimulus intensities and may thus contribute to pain or discomfort. The high threshold of serosal afferents has been interpreted as an indication of their role as nociceptors. However, the lack of responses to stretch, an important trigger for pain in hollow viscera, argues against such serosal afferents as the sole or even primary source of nociceptive input. Perhaps more importantly, it is difficult to relate the response to high intensity punctate stimuli used experimentally to physiologically meaningful events in the hollow viscera.

Independent of their different responses to different mechanical stimuli, most visceral afferents can also be activated by chemical and/or mechanical stimuli (Fig. 1). Thus, visceral afferents are polymodal

(►polymodal afferents), a characteristic they share with a subset of cutaneous nociceptors. This property may explain the poor discriminatory power of visceral input. For example, distension of the distal esophagus may trigger a sensation of heartburn. Similarly, while most individuals describe gastric distension with terms such as fullness, it may lead to epigastric burning or nausea in some persons.

## Neurochemical Properties of Visceral Sensory Neurons

Studies of cutaneous innervation suggest that neurons can be differentiated based on the expression of surface markers, ion channels or neuropeptides by using immunohistochemical techniques. Based on their neurochemical properties, many investigators distinguish two classes of neurons with presumed nociceptive function. Small peptidergic neurons, characterized by the presence of calcitonin gene related peptide (CGRP) or substance P as neurotransmitters, typically express the high affinity receptor for nerve growth factor (NGF) and the non-selective vanilloid receptor TRPV1. Hereditary disorders affecting this population of neurons or experimental destruction of these cells significantly alters responses to noxious stimuli. A second group of cells does not contain neuropeptides, but typically releases ATP as their transmitter and binds the plant lectin isolectin B4 (IB4). All of these ►neurochemical markers can be found in visceral sensory neurons. Yet, the utility of CGRP, TRPV1, IB4 or other surrogate markers used to identify nociceptive neurons is questionable for the innervation of the viscera. About 70–80% of spinal neurons projecting to the viscera are peptidergic. However, physiologic experiments reveal that only 20–30% of visceral afferents have high thresholds for mechanical stimuli. Similarly, TRPV1 and IB4 labels the majority of vagal afferents, which do not play a role in pain responses to acute mechanical stimulation (Fig. 3).

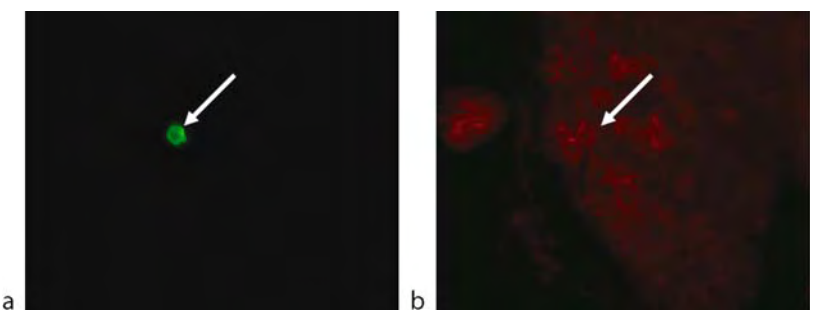
Additional studies are needed to identify neurochemcial characteristics that distinguish different subgroups of visceral sensory neurons and aid in the detection of nociceptive neurons.

## Physiological Properties of Visceral Sensory Neurons

Electrophysiological studies performed in vivo and in vitro demonstrate that most visceral afferent neurons exhibit little or no spontaneous activity. Most visceral sensory neurons possess unmyelinated (C-fibers) or thinly myelinated axons (Aδ fibers) with slow conduction velocities. Thus, based on conduction velocity, visceral afferents resemble cutaneous nociceptors. About 50–60% of vagal and spinal sensory neurons projecting to the viscera generate action potentials with a distinct hump during the falling phase – a property often attributed to the expression of tetrodotoxin (TTX) resistant voltage-dependent sodium channels (Fig. 4) (see Gold essay: Voltage-gated channels and pain).

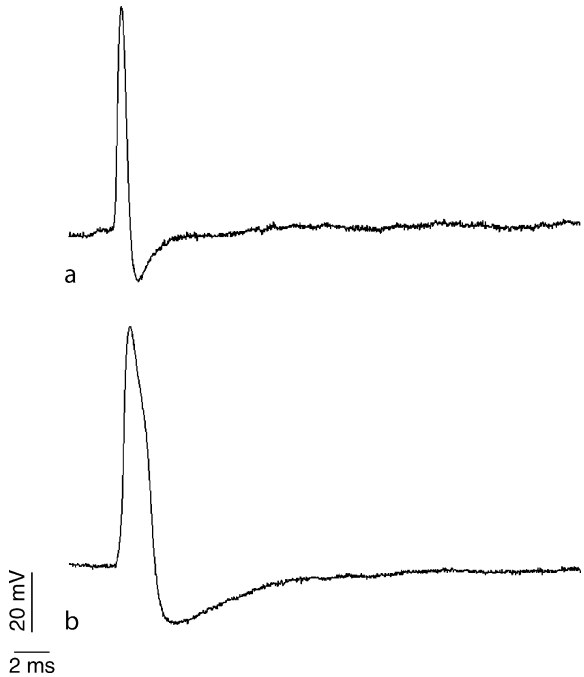
This interpretation is consistent with the presence of TTX-resistant spikes in more than half of the visceral sensory neurons studied in vitro, which again is similar to findings obtained in recordings from cutaneous nociceptors. However, the majority of visceral afferent fibers can be activated by low intensity stimuli, which do not trigger aversive responses or pain, demonstrating again the limited utility of applying commonly used criteria defining nociceptive neurons to the visceral innervation.

A series of studies has demonstrated the importance of purinergic receptors in normal visceral function. As mentioned above, bladder distension triggers ATP release from the epithelium and triggers micturition through activation of P2X receptors. While initially thought to be important in regulating visceral function, the P2X family of ligand-gated ion channels play an important role in pain. Considering the role of P2X receptors in urinary bladder function, several studies have examined the contribution of purinergic signaling in visceral sensation and pain. While only a small fraction of cutaneous neurons express P2X receptors, the majority of bladder afferents and about one third of gastrointestinal afferents innervating stomach, small intestine or colon respond to P2X receptor agonists. Visceral inflammation is associated with an increased ATP release from the epithelium, suggesting a potential contribution of enhanced purinergic signaling in



**Visceral Pain. Figure 3** Gastric mechanosensory neuron was directly labeled by intracellular injection of neurobiotin (a). The same neuron (arrow) also expresses TRPV1 immunoreactivity (b).

V



**Visceral Pain. Figure 4** The tracings show action potentials from nodose neurons innervating the stomach. The action potential shape differs significantly between the two tracings with panel B showing a broader spike with distinct hump during the falling phase.

visceral hypersensitivity. Finally, a selective P2X receptor antagonist blunted the behavioral changes in response to intraperitoneal injection of acetic acid. Thus, current evidence supports the importance of purinergic signaling in normal visceral function and a potential role in the development of visceral pain.

Considering the role of protons during ischemia, inflammation and the high proton concentration within the proximal gastrointestinal tract, many studies investigated mechanisms of acid-sensation in visceral sensory neurons. Essentially all visceral sensory neurons studied respond to protons through activation of different acid sensitive ion channels. The fraction of responsive neurons and the properties of acid-sensitive ion currents recorded in visceral sensory neurons differs from unlabeled dorsal root ganglion neurons, most of which likely innervate skin, muscle or joint structures. Several different ion channels have been proposed to contribute to these proton-gated currents. Considering their homology with mechanosensory channels in helminthes, members of the family of acid sensitive ion channels (ASICs) may function as molecular sensors for chemical (acid) and mechanical stimuli. Functional and immunohistochemical studies demonstrate that most visceral sensory neurons express different ASICs. The properties of acid-sensitive currents differ significantly between groups of visceral sensory neurons, pointing at distinct physiological roles. For example, higher proton concentrations are required to activate transient inward currents in nodose ganglion (vagal) compared to dorsal root ganglion neurons innervating the stomach. Data on the importance of these channels in visceral sensation are just emerging and show a complex picture: Loss of ASIC1 is associated with in increase in responses to mechanical stimulation of gastro-esophageal and colonic afferents. Within the gastrointestinal tract, loss of ASIC2 increased responses of gastric mucosal, but decreased those of muscular afferents. ASIC3 knockout mice showed an impaired visceromotor response to colonic distension and decreased activation of tension receptors in stomach and colon. As ASICs form heteromultimers, changes in the molecular makeup of these channel complexes may explain the disparate effects of selective gene knockouts. Thus, current data support an important role for ASICs in visceral mechanosensation.

Members of the TRP (transient receptor potential) family of ion channels, a group of non-selective cation channels first identified in drosophila, play a role in osmosensory and mechanosensory function in C. elegans neurons. Several members of this family have been identified in mammalian neurons, where they are activated by temperature, protons and/or a variety of algogenic substances, such as capsaicin or mustard oil. Most studies addressing the role of these channels in visceral sensation focused on TRPV1, the capsaicin receptor. However, other members of this channel family are also expressed in visceral sensory neurons. About 70–80% of neurons projecting to stomach, small bowel or colon respond to capsaicin, a pungent vanilloid that activates the TRPV1 receptor, which can also be activated by protons. These data are in line with results using immunohistochemical techniques to examine the expression of TRPV1 in visceral sensory neurons described above. Several recent studies suggest that TRPV1 channels are involved in visceral mechanosensation with knockout mice showing blunted responses to mechanical stimulation of bladder, jejunum and colon. Interestingly, the satiety factor oleoylethanolamide activates TRPV1 channels in vagal neurons and decreases food intake in mice.

TRPV1 and other members of the TRP family may play an important role in the plasticity of primary afferent neurons. Chemicals released during inflammatory processes, such as serotonin, bradykinin, nerve growth factor, proteases or ATP, alter the function of TRPV1 receptors. In colon sensory neurons, serotonin shifts the temperature-activation function of TRPV1 to lower temperatures, leading to inward currents and action potential activation around the normal body temperature, a mechanism that may contribute to sensitization of visceral afferents during inflammation.

In addition, inflammation alters the expression of this ion channel, thereby further increasing excitability.

### Peripheral Sensitization and Visceral Pain

Similar to nociceptors, primary afferents innervating the viscera exhibit significant functional plasticity. Different stimulus modalities may interact and acutely sensitize neurons to concomitant or subsequent stimulation. For example, prior administration of heated or acidic solution into esophagus or stomach sensitizes these organs to subsequent distending stimuli. In addition, inflammation or exogenous application of inflammatory mediators or cytokines can alter the physiological properties of visceral sensory neurons, increasing responses to different stimuli. These enhanced responses are due to changes in the expression and/or function of ion channels involved in signal transduction (e.g. TRPV1, members of the ASIC family and purinergic receptors described above) and channels determining excitability (e.g. voltage-sensitive sodium channels, transient potassium current). Mediators and mechanisms of ▶peripheral sensitization largely resemble those described for skin or other organs. Considering the role of growth factors in neuronal development and function, many studies have investigated their potential contribution to visceral hypersensitivity. Nerve growth factor (NGF) has been studied most extensively. NGF levels increase during visceral inflammation associated with enhanced responses to visceral stimulation. Neutralization of NGF through antibodies blunts the development of visceral hypersensitivity while transient NGF overexpression through viral gene transfer mimics the effect of inflammation.

Despite these similarities, differences exist between cutaneous and visceral afferents. Prior studies demonstrate that only the subgroup of cutaneous afferents thought to contribute to nociception sensitize in response to inflammatory mediators. In contrast, essentially all visceral afferents can sensitize, thus suggesting that they all may contribute to enhanced input to the central nervous system in pathologic states that may result in the sensation of pain. Consistent with these considerations, patients with dyspeptic symptoms due to hypersensitivity not only complain about increased pain intensity during gastric distension, but also report greater sensations of bloating, nausea or fullness during stimulation, arguing against a selective modulation of nociceptors alone in human disease.

Studies of patients with chronic pancreatitis provide important support for the clinical significance of peripheral sensitization in visceral pain. Pain is a typical characteristic of this often debilitating disease and at times leads to surgical interventions, including total resection of the organ. Detailed investigations of tissue samples obtained during such operations demonstrate significant alterations of peripheral nerves. In patients with pancreatitis, large neuroma-like nerve bundles surrounded by inflammatory cells are seen. In addition, the expression of neuropeptides, their receptors and growth factors and their receptors is increased in chronic pancreatitis. Thus, pain correlates with structural and functional changes of peripheral nerves that are consistent with findings obtained in animal experiments of human disease.

### Central Pathways of Visceral Sensory Input

Central terminations of primary afferents arborize extensively within the central nervous system and may synapse with many second order neurons. Within the spinal cord, these central processes may extend over several segments in the rostro-caudal axis and even cross the midline. The wide distribution of visceral afferent input is yet another factor for the poor spatial discrimination of visceral sensation. Visceral afferents primarily project to the superficial spinal laminae (laminae I and II), the area around the central canal (lamina X) and the deeper lateral spinal grey (lamina V). Stimulation of primary afferents leads to excitatory synaptic input in all second and most higher order spinal neurons. Vagal afferents project directly into the brain stem with most central terminations ending in the nucleus of the solitary tract, which shows some organotypic organization. Most second order neurons within the central nervous system encode visceral input over a wide range of intensities (wide dynamic range neurons). A small number of spinal neurons is only activated by mechanical stimulation in the noxious range, suggesting a potential role in nociception.

Essentially all second order neurons within the spinal cord also receive converging input from other viscera as well as somatic structures. This viscero-somatic and viscero-visceral convergence explains the referral of painful visceral sensation to other, often distant body regions. Typical examples are the pain in the left shoulder and left arm during myocardial ischemia and the right-sided back and shoulder pain in biliary disorders. Such referral due to convergent input appears to be unidirectional in humans, meaning visceral stimuli trigger a somatic sensation rather than somatic stimuli causing a perception of visceral changes. While no correlate has been described in humans, recent studies using experimental models of human disease suggest that skin or muscle injury can indeed trigger visceral hypersensitivity in animals.

Glutamate is the primary fast transmitter released from afferent neurons in spinal cord and brain stem. Several ionotropic and metabotropic glutamate receptors have been identified in the spinal cord and the nucleus of the solitary tract, where they play an important role in mediating excitatory synaptic potentials and modulating synaptic signal transmission through pre- and postsynaptic mechanisms. Experiments in animals and human

volunteers clearly demonstrated the importance of glutamate receptors, as inhibitors of NMDA and non-NMDA receptors block visceral sensation and pain. The high fraction of peptidergic neurons innervating the viscera suggests a special role of peptide release in visceral sensation and pain. Most studies have focused on substance P and neurokinin (NK) receptors, which are activated by substance P. Consistent with a role for substance P, noxious colorectal distension triggered internalization of NK1 receptors, which is increased in animals with colonic hypersensitivity. Neurokinin receptor antagonists and substance P or neurokinin receptor knockout mice show altered responses to visceral or cutaneous pain. However, despite these encouraging preclinical findings, testing neurokinin 1 receptor antagonists in humans has not shown convincing analgesic effects.

## Cortical Representation of Visceral Pain

The development of non-invasive techniques such as positron emission tomography or functional magnetic resonance imaging (see Tracey essay: Pain Imaging) allows detailed investigations of human brain activity in response to different visceral stimuli. Most studies focused on hollow organ distension as a mechanical stimulus that may be perceived as painful but does not cause injury. Consistent with bilateral organ innervation, stimulation of esophagus, stomach, colorectum or bladder activate both cerebral hemispheres. Painful stimuli typically activate several cortical and cerebellar structures, often referred to as the pain matrix. These include the insula, the cingulate cortex and, in many studies, the prefrontal cortices. In contrast to cutaneous pain, visceral pain does not consistently activate the primary sensory cortex. In addition, visceral stimulation preferentially activates the perigenual portion of the anterior cingulate cortex, which is not as clearly associated with other experimental pain states. This region has been implicated in the regulation of affect, thus providing a possible structural basis for the observation that visceral pain elicits stronger emotional response compared to noxious cutaneous stimulation.

## Descending Modulation of Visceral Pain

Cortical and lower centers within the brain do not only receive and process input, they also modulate signaling in the spinal cord through descending pathways, which can facilitate or inhibit transmission (see Mason essay: Descending modulation of nociception). Cortical structures, primarily the anterior cingulate cortex, project via the periaqueductal grey to brainstem structures, primarily the rostrolateral ventral medulla, which sends processes to the spinal dorsal horn. In experimental animals, electrical or chemical stimulation of these areas significantly alters responses to noxious stimulation. Current evidence suggests that this inhibitory influence, mediated in part by opioid receptors, predominates under physiological conditions and may contribute to the development of chronic pain in several disorders, including functional visceral pain syndromes.

## Central Sensitization and Visceral Pain

Increased sensitivity to noxious stimuli (hyperalgesia) is a hallmark of many structural and functional disorders affecting the viscera. Repetitive stimulation using a single stimulus modality (e.g. distension) or sequential administration of two different stimulus modalities (e.g. luminal acid administration followed by electrical stimulation of the esophagus) leads to a decrease in pain threshold and a parallel increase in the area of cutaneous pain referral, clearly proving involvement of central rather than peripheral mechanisms. Most experiments focus on the effects of visceral hyperalgesia on cutaneous referral patterns. However, several recent studies suggest that at least in animals, cross-sensitization can be bidirectional with sensitization of cutaneous or muscular afferents triggering visceral hypersensitivity in organs with sensory innervation converging to the same segment of the spinal cord. Administration of ketamine blocks the development of hyperalgesia, suggesting a role for NMDA receptors in the development of ►central sensitization, which is consistent with the known importance of NMDA receptors in synaptic plasticity (see Sandkühler essay: Synaptic long-term potentiation (LTP) in pain pathways).

Interestingly, acute sensitization through luminal acid exposure of the duodenum also lowers thresholds to esophageal stimulation. This effect on two distant organs with limited overlap in sensory innervation cannot be explained through spinal mechanisms. Additional evidence supports the importance of supraspinal sites in regulating visceral sensory function. Epidemiological studies have demonstrated the frequent coexistence of disorders characterized by chronic pain. For example, the majority of patients with irritable bowel syndrome suffer from other disorders characterized by chronic pain or discomfort without underlying structural or biochemical changes. The common association with mood disorders and a high prevalence of early childhood abuse or stressful life events in this patient population indicate that psychological factors contribute to the pathogenesis of these disorders. Such situations have been mimicked experimentally through maternal separation, water avoidance stress or neonatal colonic injury, which trigger visceral hypersensitivity in susceptible rodent strains. Current evidence suggests that decreased inhibitory modulation of afferent input plays an important role in mediating visceral hypersensitivity. Using heterotopic stimulation, several groups have shown differences in processing of painful stimuli between healthy controls and patients suffering from chronic pain syndromes. This paradigm

relies on intermittent application of painful stimuli during ongoing presence of an unpleasant stimulus at a second, distant site (hence heterotopic stimulation). While normal volunteers rate the intensity of visceral stimuli lower in the presence of the heterotopic stimulus, patients with irritable bowel syndrome rank the visceral stimulus similarly under the two experimental conditions. As the intensity of the visceral stimulus is equal for both groups and both conditions, differences in perception have been attributed to differences in descending modulation.

## Clinical Manifestations of Visceral Pain

Pain is a complex sensory and emotional experience that typically triggers responses to protect the organism from impending harm. While visceral pain clearly meets this definition, it nonetheless is distinct from pain caused by a noxious cutaneous stimulus. The source is not visible, and withdrawal from or removal of the source of potential injury are not possible. Under normal conditions, visceral sensory input rarely reaches the level of conscious perception. However, the ascending sensory information reaches brain structures and contributes to the regulation of organ function. Thus, visceral input that triggers pain also triggers changes in autonomic function, which further exacerbate its unpleasant or subjectively threatening impact. For example, dyspnea often accompanies cardiac pain; nausea is commonly associated with gastrointestinal pain; patients with cystitis typically complain about significant urgency. Verbal descriptors reflect this difference as healthy volunteers use more terms of unpleasantness in response to visceral compared to similarly intense cutaneous stimuli.

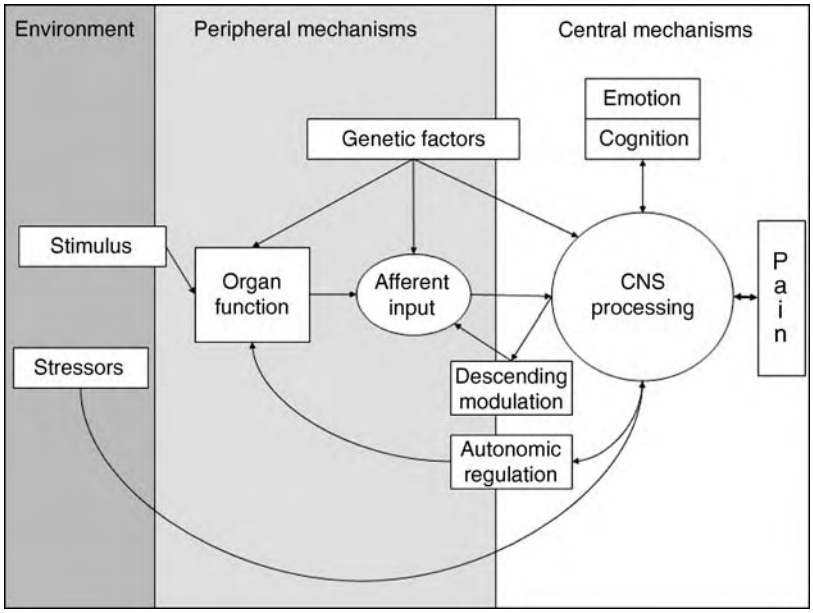
While acute visceral pain correlates quite well with abnormal function or potential injury, most chronic visceral pain syndromes are characterized by the defining pain and an association with other symptoms, indicating altered visceral function, but no identifiable structural or biochemical abnormalities. They are characterized by discomfort or pain in response to innocuous stimuli and as such represent a state of visceral hypersensitivity (Table 2) They often coexist in one individual or are associated with other chronic pain states, such headaches, low back pain or fibromyalgia and/or mood disorders. Finally, brain imaging studies all show increased comparable activation of areas associated with processing of visceral pain and affect, consistent with patient reports about discomfort and pain.

Many different mechanisms have been implicated in their pathophysiology. Current evidence suggests that both peripheral and central sensitization contribute to the pathogenesis of these disorders. Up to one third of individuals suffering from irritable bowel syndrome or functional dyspepsia recall an acute illness, such as infectious gastroenteritis, prior to the onset of their chronic disorder. Current evidence suggests that an acute episode of gastroenteritis increases the relative risk about sevenfold for development of irritable bowel syndrome. Thus, acute inflammation presumably sensitizes primary afferents, which has been shown repeatedly in animal experiments, and likely causes central sensitization as well, with both processes contributing to the development of hypersensitivity that persists after resolution of the initial injury/inflammation. While conventional investigations do no show overt inflammation, several subtle changes have been identified. Interestingly, increased mast cell numbers have been found in the mucosa of patients with irritable bowel syndrome and interstitial cystitis. These mast cells are often seen in close proximity to nerves. Mast cell stimulation can activate the release of several mediators, such as histamine or tryptase, which may directly activate primary afferent neurons. The potential importance of such a mechanism is supported by experiments that measured mediator release from colonic biopsies, showing higher levels for prostaglandin, tryptase and histamine release in patients with irritable bowel syndrome compared to healthy controls.

Yet, peripheral mechanisms are clearly not sufficient to explain the chronic course that characterizes many of these visceral pain syndromes. Preexisting psychiatric disorders, primarily anxiety, are an important predictor for the development of functional dyspepsia or irritable bowel syndrome after an episode of acute gastroenteritis, suggesting an important role of psychological mechanisms. Several conceptual models have been proposed to explain the development and frequent coexistence of these functional pain syndromes. Biological models are based on the assumption that an inciting peripheral event, such as an acute gastroenteritis, sensitizes peripheral afferent pathways which secondarily alter central processing, leading to persistent symptoms after apparently complete

**Visceral Pain. Table 2** Common visceral pain syndromes

| Syndrome | Pain location | Associated symptoms |
|---|---|---|
| Functional dyspepsia | Epigastrium | Postprandial fullness<br>Bloating<br>Nausea |
| Irritable bowel syndrome | Lower abdomen | Diarrhea and/or constipation<br>Bloating |
| Interstitial cystitis | Suprapubic area | Dysuria<br>Increase micturition frequency |
| Chronic Pelvic Pain | Sacral/pelvic | Sexual dysfunction |



**Visceral Pain. Figure 5** Conceptual model summarizing factors contributing to the development of visceral pain syndromes.

resolution of the initially triggering event. This model integrates psychological and environmental factors as important modulators that affect sensory processing in the brain (Fig. 5).

An alternative, exclusively psychological model invokes a primarily central mechanism, hypervigilance, with focused attention on visceral input. Stress and cognitive factors clearly play a key role in both models, which is consistent with reported exacerbations during or after stressful life events. Activation of the hypothalamic-pituitary adrenal axis with increased cortisol levels have been identified in patients with chronic visceral pain syndromes. Psychological of pharmacological interventions have successfully targeted these modulating or triggering factors. For example, antagonists of the corticotropin releasing factor receptor 1 alleviate symptoms in patients with irritable bowel syndrome.

## Summary

Experimental and clinical data clearly demonstrate that visceral pain has unique characteristics. Generally, visceral pain is triggered by stimuli that do not cause tissue injury. Conversely, truly noxious stimuli may not be perceived as painful. Despite their complex innervation with two anatomically and functionally distinct afferent pathways, the innervation density of visceral structures is low. This relatively sparse innervation and the polymodal nature of visceral afferent neurons likely contribute to the limited ability to accurately identify visceral stimuli. While vague and poorly localized at the site of origin, visceral pain is typically referred to distant structures (referral pain). Most visceral input is not consciously perceived, but provides feedback for autonomic regulation of organ function. However, essentially all visceral afferents can sensitize in response to injury or inflammation. Thus, the enhanced activity of such low threshold visceral afferents may directly or indirectly (i.e. through secondary changes in organ function) contribute to unpleasantness or even pain perceived during disease states. Central processing of visceral input and pain involves structures that are important in affective responses, providing a basis for the higher emotional valence of visceral sensation and pain. The perception of painful stimuli is altered by stressors, affective and cognitive factors all of which are important causes for the development and potential targets for the treatment of chronic visceral pain syndromes.

## Visceral Referred Pain

### Definition

Pain resulting from noxious stimulation of a visceral organ that is referred to somatic structures innervated by the same spinal segments as the diseased organ, is referred to proximal and axial body areas but generally not distal limbs, and is generally felt as a deep, but not superficial or cutaneous pain.

►Referred Pain
►Viscero-Somatic Reflex

## Visceral Reflexes

►Visceral Afferents

## Visceral Sensation

►Visceral Afferents

## Visceral Stimuli

### Definition

Stimuli applied to the gastrointestinal track including mechanical pressure, chemical and thermal stimuli. They are characterized by poor localization, tonic increases in muscle tone and autonomic responses including alterations in respiration, heart rate and blood pressure.

## Viscero-cardiovascular Reflexes

►Cardiovascular Reflexes

## Viscero-Somatic Reflex

Robert D. Foreman
Department of Physiology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA

### Definition

Viscero-somatic reflex or reflexes usually occur when a diseased visceral organ initiates the transmission of information in afferent nerves (Fig. 1).

This information is relayed and expressed in somatic structures after making synaptic connections

in the spinal cord. The status of neuronal activity within the spinal cord, depending on a variety of stressors, may contribute to the somatic symptoms. These viscero-somatic reflexes commonly affect somatic structures, particularly muscle, in the same segment that receives afferent input from the diseased visceral structure, but can affect somatic areas that are distant from the diseased structure. "Referred pain" is a form of a viscero-somatic reflex. The cardiac-somatic motor reflex will be used in this essay as a prototype of a viscero-somatic reflex.

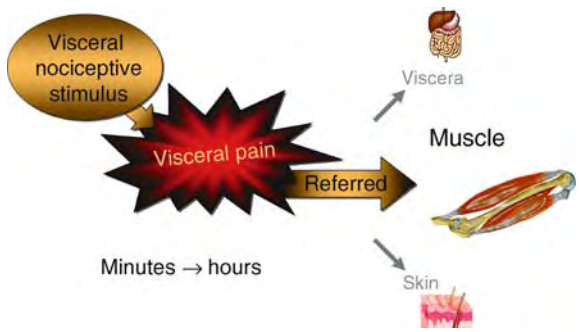
## Characteristics

### Quantitative Description

Referred pain is a classic symptom of diseased visceral organs. Angina pectoris resulting from cardiac disease will be used to describe the role of a viscero-somatic reflex. Muscle contractions produced during activation of cardiac afferent fibers by injecting noxious chemicals into the pericardial sac can be another source of cardiac pain [1,2]. In this model of muscle-related referred pain (►Visceral referred pain), visceral evoked muscle contractions increase muscle afferent activity, which converges on neurons also receiving input from cardiac afferent fibers, to generate angina-like referred pain. Episodes of angina pectoris resulting from ischemic episodes often cause a deep, muscular-like, incapacitating pain [3] in patients with infarcted hearts. In addition to the muscle pain, patients also exhibit increased tone of the upper thoracic ►paraspinal muscle [4].

### Lower Level Processes

Noxious chemical stimulation of the heart (►Noxious (Algogenic) Chemical Stimulation of the Heart) activated cardiac afferent fibers. A description of the visceral afferent fibers is given in an accompanying essay of this Encyclopedia.



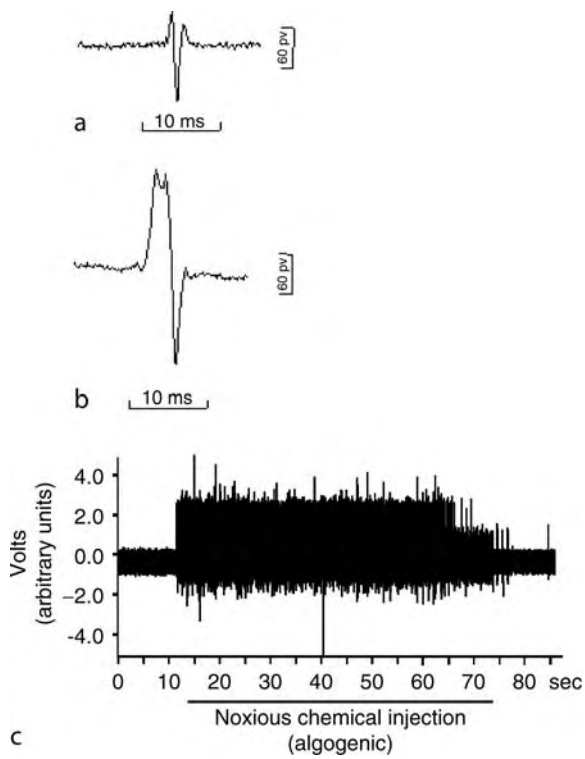
**Viscero-Somatic Reflex. Figure 1** A schematic figure describing the events that occur when a visceral nociceptive stimulus elicits referred pain to the somatic structures, particularly muscle. The events can occur from minutes to hours. This figure represents a form of viscero-somatic reflexes or motor reflexes.

Single unit potentials and compound motor action potentials were the most common motor unit discharge patterns identified from EMG records that were evoked by noxious chemical stimulation of cardiac afferent fibers. Most of the single-unit patterns lasted >75 s, with amplitudes that were <150 μV in response to noxious stimulation of the heart (Fig. 2a and c).

The EMG records also contained many compound motor action potentials; each compound potential is the sum of multiple single-unit potentials. These discharges represent the process of motor recruitment, and are described as the complex pattern (Fig. 2b). Most of the complex patterns lasted <75 s, and the amplitudes of the potentials were >150 μV.

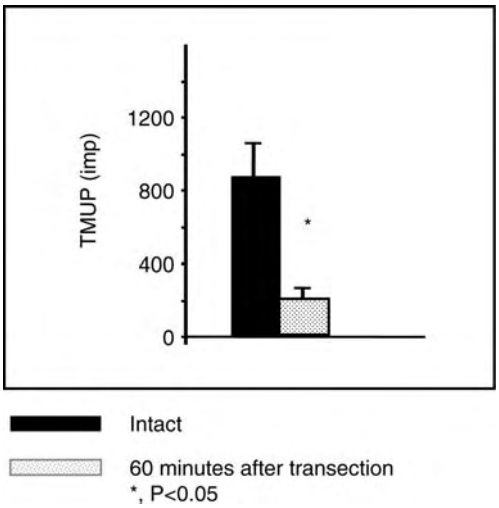
### Process Regulation

The prototype for the process regulation of the viscero-somatic reflex was to examine muscle responses to noxious chemical stimulation of the heart. The regulation was determined by generating ►spasm-like electromyography (EMG) activities in response to noxious



**Viscero-Somatic Reflex. Figure 2** Chemical-evoked EMG waveforms and discharge patterns. (a) Waveform of a single-unit potential. (b) Waveform of a compound motor action potential from a complex pattern. (c) Raw tracing of EMG activities when algogenic chemicals were injected into the pericardial sac to activate cardiac afferent fibers. The bar underneath the seconds indicates the time that the chemicals remained in the pericardial sac (Adapted from [1,2]).

chemical activation of afferent fibers innervating the heart [1,2]. The afferent pathways of the cardiac-motor reflexes were identified, and their functions were described as they related to cardiac ►nociception. The paraspinal muscles (spinotrapezius) were chosen to measure EMG activities because of the increased tonicity of the upper cervical and thoracic paraspinal muscles that have been palpated in cardiac patients [4]. Information transmitted via the sympathetic and the vagal afferent fibers contributed to changes in EMG activities (Figs. 3 and 4).



**Viscero-Somatic Reflex. Figure 3** Effects of left sympathetic chain transection on algogenic mixture-evoked EMG activities. The solid bar is the total motor unit potentials (TUMP) that were generated when algogenic chemicals were injected in the pericardial sac for 60 sec. The hatched bar represents the TUMP that were produced by the intrapericardial injections of the chemicals 60 minutes after transecting the left thoracic sympathetic chain (Adapted from [2]).

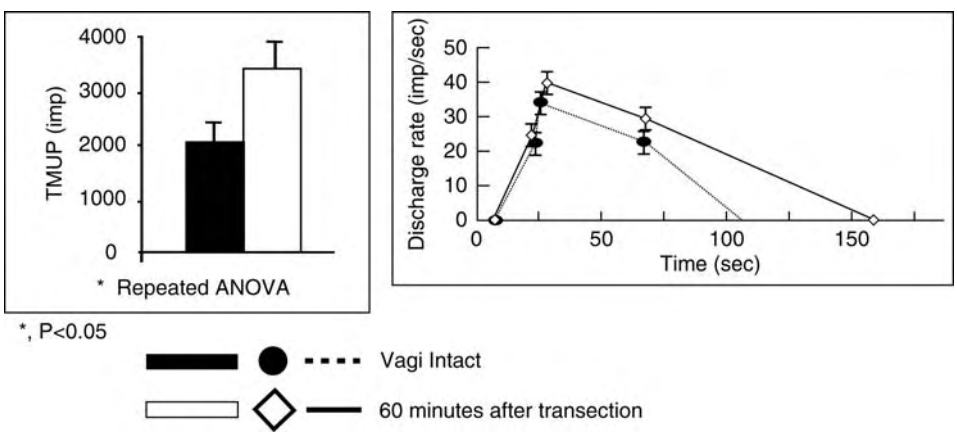
## Differentiation of the Afferent Pathways

### *Sympathetic Cardiac Afferent Fibers*

Injections of noxious chemicals into the pericardial sac activated cardiac sympathetic afferent fibers that significantly increased the total motor unit potentials, latency of response, peak rate of discharge and duration of the response of the paraspinal (spinotrapezius) EMG activities (Fig. 3). However, transections of sympathetic afferent fibers in the sympathetic chain significantly reduced the total motor unit potentials (Fig. 3). In addition, electrical stimulation of the left sympathetic chain excited afferent fibers that always evoked EMG activities.

### *Vagal Cardiac Afferent Fibers*

Electrical stimulation of either the left or right vagal afferent fibers did not generate any EMG activities; however, stimulation with the same parameters of either of these vagus nerves suppressed the EMG activities, when they were evoked by injecting the noxious chemicals into the pericardial sac. However, noxious chemical stimulation of the cardiac afferent fibers significantly increased the total motor unit potentials, the peak response and the duration of the response of the evoked EMG activities after performing bilateral vagal transection (Fig. 4).



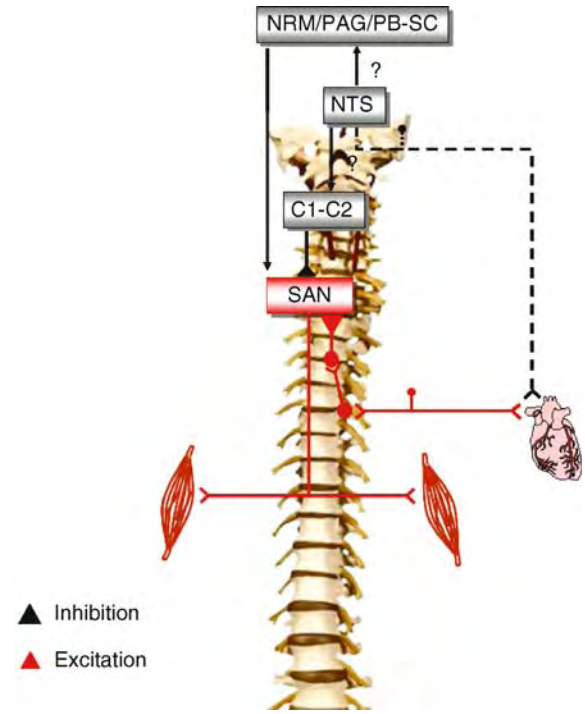
**Viscero-Somatic Reflex. Figure 4** Algogenic mixture-evoked EMG activities before and after bilateral cervical vagal transection. Left Panel: The solid bar represents the total motor unit potentials (TUMP) produced by the intrapericardial injections of algogenic chemicals for 60 sec. The open bar is the TUMP to intrapericardial injections after bilateral vagotomy. Right Panel: The discharge rate of the EMG activities in response to intrapericardial injections of algogenic chemicals for 60 sec. before vagotomy is represented by the dashed line and filled circles. The discharge rate after vagotomy is represented by the solid line and open diamonds. (Adapted from [2]).

### *Persistence of the Evoked Response of EMG Activities*

The EMG activities often persisted even after the noxious chemicals were withdrawn and the heart was repeatedly flushed with saline. Sensitization of peripheral and central mechanisms might play a role that contributes to protracted motor discharges.

## Function

Muscle contractions generated by noxious chemical stimulation of cardiac receptors have characteristics resembling muscle spasms. The amplitude of motor unit potentials and duration of the motor recruitment of the cardiac-evoked EMG activities have many similarities to EMG activities recorded from ischemic, fatigued, and painful muscles [5]. The similarities lead to the suggestion that the increased EMG activity evoked by algogenic chemicals is a type of reflexive muscle spasm. Clinical studies also provide evidence that support the transition from muscle contraction to muscle pain. The intensity and duration of the pain is dependent on the activity being transmitted in sympathetic and vagal afferent fibers during noxious chemical stimulation of their receptors in the heart (Fig. 5).



**Viscero-Somatic Reflex. Figure 5** Summary diagram of the functional pathways of the cardiac-spinotrapezius motor reflexes. The solid red line represents the excitation of the sympathetic afferent fibers from the heart. These afferents synapse on interneurons in the spinal cord that excite the motoneurons of the spinal accessory nerve (SAN). The black dashed line represents the vagal afferent fibers that originate from the heart and terminate in the nucleus tractus solitarius (NTS). The information from the NTS may inhibit the activity of the motoneurons in the SAN via descending modulation from the nucleus raphe magnus (NRM) and/or the parabrachial-subcoerelus (PB-SC) nuclei. The output from the NTS may also activate neurons in the upper cervical spinal segments (C1-C2) that, in turn, inhibit the activity of motoneurons in the SAN. The question marks in the circuits are included because the details of these pathways and their effects have not been described.

## Sympathetic Cardiac Afferent Fibers in Cardiac-Motor Reflexes

The functional relevance resulting from activation of sympathetic cardiac afferent fibers to evoke spinotrapezius contractions might be a type of primitive reflex. This reflex is similar to contractions of the rectus abdominus activated by electrical stimulation of lower thoracic sympathetic afferent fibers [6], which was suggested as a type of protective reflex. Therefore, the heart may be protected when the chest wall tightens around the cardiac region during a cardiac insult.

Sympathetic cardiac afferent fibers might also play a critical role in the generation of ►muscle hyperalgesia; since sympathectomies in humans result in pain relief (see [7]). Evoked muscle contractions during ischemic episodes would provide the necessary nociceptive input to muscle afferents to induce angina-like referred pain.

## Vagal Cardiac Afferent Fibers in the Cardiac-Motor Reflexes

Activation of vagal cardiac afferent fibers could modulate the intensity of cardiac pain. Intense excitation of sympathetic cardiac afferent fibers and/or decreased activity in the vagal cardiac afferent fibers can generate spasm-like muscle contractions. Inhibition of spasm-like muscle contractions by vagal afferent stimulation indicated that information transmitted by vagal cardiac afferent fibers could play an important anti-nociceptive role in muscle hyperalgesia. During an ischemic episode, pain of muscle spasms could function as a warning about a dysfunctional heart. However, if vagal attenuation (modulation) of muscle contractions were not present in the cardiac-motor reflexes, patients might experience intense pain. Thus, instead of a warning signal, the intense pain could exacerbate symptoms, thereby creating a vicious cycle that might result in chronic muscle pain. Consequently, excitation of vagal afferents might be a means to treat clinical pain with a muscular origin.

The interaction of these two afferent pathways, in addition to the convergence-projection theory onto the ►spinothalamic tract cells [7], could potentially explain cardiac referred pain. Furthermore, this mechanism might also be responsible for the increased paraspinal muscle tone found in patients with chronic cardiac diseases [4].

Ultimately, maintenance of cardiac afferent balance between the information transmitted in the sympathetic and in the vagal afferent fibers could be a useful strategy for treating the muscular component of cardiac pain. Thus, another benefit gained from the inhibition of the muscle spasms by vagal afferent stimulation might be maintenance of homeostasis. It is possible that vagal inhibition of motor reflexes might prevent excessive metabolic demand by the skeletal muscles. Consequently, the workload to the heart is decreased, thereby improving cardiac function and achieving homeostasis. In fact, therapeutic successes of vagal afferent stimulation for attenuation of cardiac pain and prevention of ischemia episodes [8] has been documented. The insights into the muscular mechanism of cardiac pain might improve efficacy of treatments in cardiac patients.

### Pathology

The myofascial ►trigger point is a pathological condition that is proposed to be the result of reflexive muscle spasms [9]. Trigger points are hyperirritable loci of skeletal muscle that are very sensitive to mechanical manipulation. Clinically, mechanical pressure applied to these regions can lead to referred pain and tenderness. EMG recording of the trigger points at rest reveal intermittent, variable high-amplitude (>100 μV) spike potentials and consistently present, lower-amplitude (<60 μV) spike potentials (see [9]). The EMG recordings from trigger points at rest are similar to the single-unit and complex patterns elicited by noxious chemical stimulation of the cardiac afferent fibers, leading to the suggestion that EMG activation in the paraspinal muscle evoked by noxious stimulation of the heart might have a hyperalgesic component.

There is also the proposition that muscle hyperalgesia is generated by noxious stimulation of visceral afferent fibers. Clinically, muscle pain and rigidity accompany many non-cardiac cases of visceral-evoked contractions. In addition, many patients also report severe non-localized tenderness in the abdominal area. Also, several animal studies also demonstrate visceral-evoked responses showing concurrence between EMG activities and muscle hyperalgesia in other regions of the body, resulting from stimulation of visceral organs such as the esophagus, uterus, ureter, urinary bladder and colon.

### Therapy

Patients with refractory angina pectoris are unresponsive to conventional treatments such as optimal anti-anginal pharmacological therapy and are not candidates for revascularization. However, human studies have shown that ►spinal cord stimulation can be used effectively to treat this pain [10]. The Gate-control theory is the most commonly accepted explanation for describing the pain relief experienced in these patients. The basis of this theory is that spinal cord stimulation activates large fibers in the dorsal column, which in turn activate inhibitory interneurons that modulate the processing of spinothalamic tract cells activated by the small fiber input resulting from noxious stimulation of the heart [7]. However, based on the viscero-somatic reflex that produces muscle contraction and leads to muscle pain and hyperalgesia, an alternative or additional explanation is that spinal cord stimulation activates spinal inhibitory interneurons that suppress visceromotor reflexes. Thus, spinal cord stimulation may provide a "calming" influence on noxious sympathetic afferent input at the spinal cord level, and reestablish the balance between the sympathetic and parasympathetic cardiac afferents fibers. This rebalancing would alleviate the skeletal muscle component of refractory angina pectoris.

## Viscero-Visceral Reflex

### Definition

A viscero-visceral reflex is a reflex in which stimulation of visceral receptors results in activation of visceral

motor phenomena. It is convenient to think of such reflexes as purely neurological phenomena, analogous to somatic reflexes such as the so-called "deep tendon reflexes." However, in normal homeostasis, humoral factors may also contribute to the afferent and efferent limbs of the reflex. Viscero-visceral reflexes play an important role in coordinating the activities of the various organs of the digestive system. For example, with stomach emptying, humoral and neural reflexes stimulate emptying of the gall bladder in order to assist digestion and absorption in the small intestine. Viscero-visceral reflexes also occur between different organ systems, for example, between the urogenital and digestive systems. Otherwise inconspicuous viscero-visceral reflexes may become pronounced when freed from descending inhibition, as for example in spinalized animals, and may become pathological in some situations, an example of which would be hypertensive incidents induced by bladder filling in patients with high spinal cord injuries.

# Vision

Uwe. Windhorst
Göttingen, Germany

## Synonyms

Seeing

## Definition

Vision emcompasses a range of organismic capabilities from the primordial detection of electromagnetic radiation to the sensation of the dynamic structure of the external world by means of such radiation within a limited bandwidth. In highly developed animals and humans that live in a complex environment, vision involves representational, attentional and memory processes as well as motor actions performed by large parts of the central nervous system.

## Introduction

Early on in evolution, organisms – even unicellular organisms – have developed a sense for light [1], maybe as early as for chemical stimuli. This attests not only to the significance of vision for the orientation and action of living beings in their specific environmental niche, but also to the long time span that evolution has had to develop visual systems, based on only eight known types of optical systems [2] and a larger variety of neurals systems.

What is the purpose of vision? A rash answer might be to provide a description of the external world as faithful as could possibly be. This answer would go astray. Unicellular organisms do not need such a description, quite apart from the fact that they would be unable to produce it. They should be content with the possibility of discriminating brightness from darkness to synchronize biochemical processes with the ►circadian cycle. This capacity has been preserved throughout evolution up to the most sophisticated organisms including humans. Other organisms have developed specialized visual capacities adjusted to specific environmental requirements. To cope with, and move in, the complex niche of tree canopies, primates and man's ancestors had to develop a visual system with exquisite spatio-temporal information-processing capacities: excellent object Computational vision, depth (Binocular vision) and motion processing perception at high resolution, perfected by ►color perception (Color processing; Retinal color vision in primates).

Vision enables not only perception of the world (Visual perception), but also provides part of the sensory control of movement. Many visual sub-systems controlling motor outputs have evolved as partially independent input–output modules. Thus, many behaviors of vertebrates, from catching prey to avoiding obstacles, depend on specialized pathways from the visual receptors (Photoreceptors) to the motor nuclei (Visual pathways for perception and action; Visuomotor integration).

What is it that the primate visual system must achieve? In order to arrive at an answer, imagine a monkey moving through the tree canopies, jumping from one tree branch to the next. The requirements to be fulfilled can be briefly summarized as follows:

- *Representation of the three-dimensional (3D) external world in space and time*; this requires:
  - *Figure-ground discrimination*: isolation, identification and recognition of objects. Objects may be characterized in terms of *intrinsic properties* (attributes of each object per se) and *relational properties* (properties that objects possess due to their relation to other objects). Objects must thus be characterized as to:
  - *Form (shape), texture*, etc., involving discrimination of boundaries (Form perception; Visual object representation).
  - *Color* (Color processing; Retinal color vision in primates).
  - *Spatial arrangement* (direction and distance (depth); Binocular vision).
  - *Motion* (Visual motion processing).
  - *Memory*: Recognition is impossible without attending to the object (Visual attention), associating it

with previous instances of its occurrence or that of similar objects stored in memory.
  - *Perception of self-motion* through the 3D world, which creates image shifts across the retina and must be distinguished from object motion (Optic flow).
- *Integration of visual information* with that of other ►sensory systems (e.g., ►audition, ►tactile sensation, ►proprioception; Multimodal integration).
- *Provision of inputs for evaluation and decision systems*; evaluation involves labeling the object(s) with affective and emotional cues, which greatly influence decisions for action.
- *Provision of inputs for visually guided motor actions including ►eye movements* (Active vision; ►Eye-hand coordination; Visuo-motor integration; Visual space representation for action; Visual space representation for reaching).
- *Provision of inputs for fast motor responses*: Some actions cannot await the outcome of long evaluation and decision processes, but must be initiated fast for escape or defense.
- *Selection by attention*: The recognition of complex spatio-temporal patterns is computationally very demanding and cannot, therefore, be performed with maximal resolution across the entire ►visual field. Parts of the visual world and specific objects of immediate interest must be selected by directed attention (Visual attention).

This synopsis will concentrate on visual processes in primates.

## Statistics of Visual Images

The problems involved in perceiving a plastic, moving, and potentially colorful external world are immense. On the other hand, the task is aided by the world's regularity. The world to be represented is not like a noisy random-dot display as generated by a computer. Rather, it is ordered and structured due to the evolutionary processes creating long-range spatial and temporal correlations among its parts. This structure corresponds to information that – if available to a seeing organism – could help it reduce the uncertainty about the world. Neural representations of such regularities thus correspond to some "pre-knowledge" about the world contained in its statistical structures. This pre-knowledge may be acquired by evolutionary and ontogenetic experience and learning and should be embodied in the dynamic structures and behaviors of nerve cells and their connections [3] (Experience with natural images as a basis for vision). Indeed, all learning may be said to be an internalization of environmental regularities, driven by the statistically regular occurrence of reinforcement following particular sensory stimuli or self-initiated actions. In this sense, environmental redundancy is exploited rather than suppressed [4] (►Retinal lateral interactions; Visual cortical and subcortical receptive fields; Sensory systems).

## Optical Projection, Adjustment to Target Distance, and Pupil Control

The very first representation serving as the input to central visual information processing is the 2D image on the retina, which is an inverse projection of the 3D external world through the eye's optical apparatus. Already here, the mapping is influenced and modulated by eye movements, adjustment to target distance (Accommodation of the lens; ►Vergence eye movements; Accommodation-vergence interactions) and changes in pupil width (Neural regulation of the pupil ►pupillary light reflexes), which are results of CNS actions.

## Neuroanatomical Overview

Before indulging in a deeper discussion of functions, a gross overview of primate visual structures and pathways is here given.

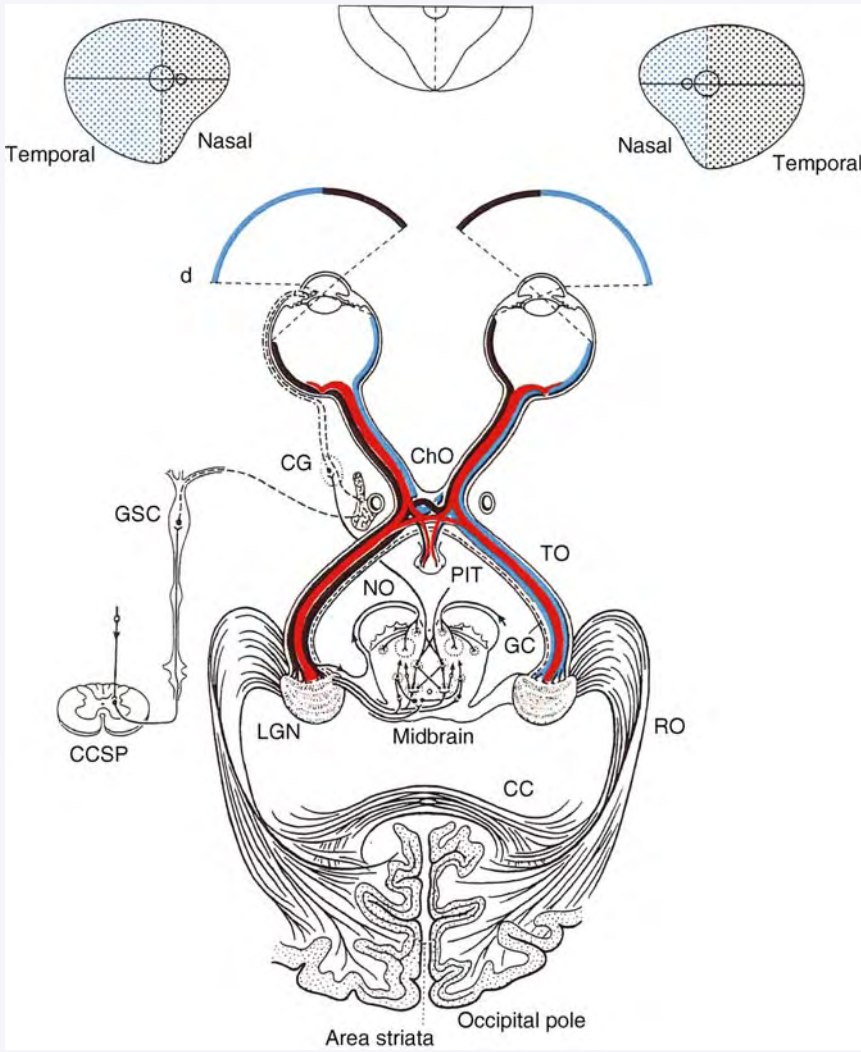
### Anatomy of the Early Visual System

A schematic section through the pathway from the retinas to the primary visual cortex (striate cortex, area V1, ►Brodmann's area 17 [5] and brainstem structures is presented in Fig. 1.

### Retina

Rather than a simple visual projection screen, the retina is a protrusion of the brain and an information-processing device of the same complexity as the cerebral neocortex [6–8], which makes the retina similarly susceptible to degenerative processes (Inherited retinal degenerations). While the post-retinal anatomy differs substantially among vertebrates, retinal anatomy does not, but is remarkably conserved from fish to primates [9]. The mammalian retina contains of the order of 80 cell types, distinct in terms of morphology, physiology, spatial distribution and synaptic organization [6–8].

There are three (nuclear) layers of cells: outer photoreceptors, intermediate cells and inner ganglion cells (Inherited retinal degenerations). Rod photoreceptors and multiple cone photoreceptors (Photoreceptors; Retinal color vision in primates) connect to at least ten types of ►retinal bipolar cells (Photoreceptors; Retinal bipolar cells) that in turn connect to more than a dozen types of ganglion cell (Retinal ganglion cells) and a greater number of amacrine cell types (Retinal direction selectivity and starburst amacrine cells). Connections are in part characterized by specialized, structurally complex "ribbon" synapses releasing glutamate (Retinal ribbon synapses). This vertical connectivity establishes parallel functional channels, between which extensive and varied lateral interactions



**Vision. Figure 1** Visual pathways from the retina, looked at from above, in humans. (a) Binocular visual field. (b) and (c) Visual fields of the left and right eye, respectively. (d) Visual pathways from the retina via the lateral geniculate nucleus to the primary visual cortex (also called striate cortex because of the stripe of ►Gennari). Note that the retina also projects to the brainstem, particularly via the K and, to some extent, via the M system, whereas in the primate P retinal ganglion cells do not project to the superior colliculus, which is therefore color-blind. Abbreviations: CC, corpus callosum; CCSP, centrum cervico-spinale (C8-Th2, involved in pupillary regulation); CG, ganglion ciliare; ChO, optic chiasm; GSC, ganglion cervicale superius; LGN, lateral geniculate nucleus; NO, nervus oculomotorius; PIT, pituitary gland; RO, radiatio optica (Gratiolet); TO, tractus opticus (Modified from Windhorst U (1996) Central processing of vision. In: Greger R, Windhorst U (Eds) *Comprehensive Human Physiology. From Cellular Mechanisms to Integration*. Springer, Berlin Heidelberg New York, pp 789–828).

take place, however (►Retinal lateral interactions; Retinal direction selectivity and starburst amacrine cells), providing for complex network processing. The complexity is also evidenced by the fact that, whereas each human eye contains of the order of 100 million photoreceptors, only about 1.5 million retinal ganglion cells project to the higher centers. This convergence necessitates profound data compression, which to accomplish poses problems as to an efficient code (►Retinal lateral interactions; Sensory systems).

## Ganglion Cell Projections

Retinal ganglion cells of each eye send their axons to the ►blind spot (a natural ►scotoma) where they form the optic nerve (Fig. 1). The two optic nerves merge to form the optic chiasm that in turn gives rise to the two optic tracts. In the optic chiasm, the ganglion cell axons from both eyes re-arrange as shown in Fig. 1. This ensures that information from the left visual hemi-fields separated by the vertical meridians is conveyed to the right hemisphere, and vice versa.

As seen in Fig. 1, ganglion cells also project to the midbrain ►superior colliculus and other brainstem structures, which are involved in accommodation of the pupils and control of eye movements. In addition, the superior colliculus projects to the ►pontine nuclei, which in turn project to the cerebellum; this pathway may be involved in the visual guidance of movements [10].

## Lateral Geniculate Nucleus

The lateral geniculate nucleus (LGN) of the ►thalamus is the first synaptic station for ganglion cell axons in the pathway toward the primary visual cortex (Geniculo-striate pathways). Optic nerve fibers from the ipsilateral eye terminate in layers 2, 3 and 5, and fibers from the contralateral eye in layers 1, 4 and 6. These layers are organized in topographical register (►retinotopy) with the retina and are stacked upon each other so that overlying cells in different layers receive ganglion cell inputs from corresponding retinal loci. Moreover, the LGN is differentiated as to the size of the principal (projection) cells (Geniculo-striate pathway; Visual processing streams in primates):

- Large neurons (*magnocellular: M*) lie in the lower two layers.
- Small cells (*parvocellular: P*) occupy the upper four layers.
- Very small neurons (*koniocellular: K*) lie in three pairs of specialized layers.

These different classes of geniculate cell are fed differentially by inputs from distinct sets of retinal ganglion cells and in turn project differentially to specific layers of the primary visual cortex (Geniculo-striate pathway; ►Striate cortex functions).

*Modulation of Lateral Geniculate Nucleus Neurons*. Retinal inputs provide a minority of the synapses on LGN neurons, the majority coming from the ►hypothalamus, brainstem ►parabrachial nuclei, the ►raphé nuclei, ►thalamus and the visual cortex (Geniculo-striate pathway; Striate cortex functions). The inputs from brainstem regions might modulate signal transmission through the LGN during different states of wakefulness and sleep [11].

*Geniculo-Cortical Projections* (Geniculo-striate pathway; Striate cortex functions). The axons of LGN cells travel through the radiatio optica (Fig. 1) to the primary visual cortex. Beside this major target, a small projection also targets visual areas other than area V1, so-called pre-striate or extra-striate areas (Extrastriate visual areas), including cortical areas V2, V3/V3a, V4, MT (V5). This might account for phenomena such as ►*blindsight* and residual motion perception after destruction of area V1. These areas receive visual information also via another pathway circumventing the LGN and involving the pulvinar (Visual role of the pulvinar) and/or the superior colliculus (cf. Fig. 1).

The geniculate projection to area V1 is ordered topographically (retinotopopically), as is the retino-geniculate one, creating a retinotopic map of the visual field on the primary visual cortex (Striate cortex functions). Similar retinotopic maps are seen in higher visual areas, but with decreasing precision, due in part to the increasing ►receptive field size [12].

## Primary and Secondary Visual Cortices

Although there are direct projections from LGN to ►extrastriate visual cortex bypassing the primary visual cortex [13], the latter receives the major LGN input, such that the different LGN cell classes project differentially to the six different layers and ►*blob* and *interblob* regions (Geniculo-striate pathway; Striate cortex functions), which in turn project differentially to further visual areas (areas V2 to V5 (MT) and the superior colliculus; Extrastriate visual areas).

As outlined above (see Fig. 1), each primary visual cortex receives inputs from both eyes. These two topographical projections must somehow be put in register, which on a large scale indeed occurs. Nonetheless, the geniculo-cortical fibers originating from different eye-specific LGN layers are kept fairly separate in area V1, with afferents related to the two eyes ending in different, interdigitating, vertical slabs of cortex called *ocular dominance columns* (Geniculo-striate pathway; Striate cortex functions).

An important link between area V1 and temporal and parietal areas is area V2. Unlike area V1, area V2 is not organized according to ocular dominance. But like area V1, area V2 is neurochemically differentiated into regions of different cytochrome-oxidase (CO) staining: thin and thick stripes of rich CO staining separated by pale "interstripes" of low CO density (Striate cortex functions; Extrastriate visual areas).

## Further Visual Areas and Cortico-Cortical Projections

Visual cortex of primates is parceled into a large number of distinct cortical areas [12,14] (Extrastriate visual areas), whose neuron populations are selective for various stimulus features [15]. While many of these areas are primarily involved in visual functions, others are also implicated in functions like multisensory integration (Multimodal integration) and visually guided ►motor control (Visuomotor integration; Visual space representation for action; Visual space representation for reaching). The connectivity within and between these areas is immensely complex, including many reciprocal connections (►Visual cortex – neurons and local circuits; Extrastriate visual areas, Neocortical circuits: Computation in 3D).

## Initiating Analysis in the Retina

The principal task of visual processing is to make inferences about the 3D world from its 2D projection

onto the two retinas [16]. The retinal image can be described as an intensity distribution that is a function of several physical variables: 2D position, wavelength, and time. Since the mosaic of photoreceptors samples the image as a collection of pixels, this initial fragmented representation must be integrated again into coherent neural representations. This process starts right in the retina, followed by other transformations at subsequent processing stages.

## Photoreceptors

The *duplicity theory of vision* is based on the existence of two broad classes of light receptors, rods and cones, accounting for colorless scotopic (night) vision and photopic (day) vision (Photoreceptors). These two systems are not completely independent, however, since signals generated in rods are also fed, via ►gap junctions and other pathways, into cone pathways, thus establishing 2–3 different rod pathways to ganglion cells (Retinal ganglion cells).

At the very start, vision requires the transduction of electromagnetic radiation into an electrical membrane potential change (Membrane biophysics). This transduction is initiated by ►photopigments, rhodopsin in rods and slightly different pigments in cones. Vertebrate photoreceptors hyperpolarize in response to light absorption, involving a cascade of intermediate steps (Phototransduction). This hyperpolarizing response to adequate sensory stimulation is unusual (Sensory systems) and creates a problem because the output of retinal ganglion cells must be in the form of sequences of ►action potentials. The hyperpolarizating response to light must therefore be converted into depolarization somewhere in the retinal network.

*Spectral Sensitivity of Cones.* Color perception is found throughout the animal kingdom, from insects to mammals, and may therefore be rightly assumed to convey a large evolutionary advantage to its possessors. But the mechanisms involved vary widely among species. Animals of some phyla can express as many as four ►opsins. Other animals seem to have lost this richness. Some nocturnal animals, such as the owl moneky, have only one cone photoreceptor. Most non-primate mammals, New-World monkeys and some humans have two types of cone. Old-World monkeys and normal humans are trichromatic having three types of cone, a long-wavelength (L-) cone, a middle-wavelength (M-) and a short-wavelenth (S-) cone. The spectral sensitivity functions of the different cones are broad and overlap widely, having the far-reaching implication that a particular wavelength cannot be determined by an individual cone, but only by comparison between signals from cones of different sensitivity [6,17] (Retinal color vision in primates; Color processing).

*Intrinsically Photosensitive Ganglion Cells*. Some specialized ganglion cells in mammals also operate as photoreceptors, project to the ►suprachiasmatic nucleus and ►pretectum, help synchronize the ►circadian rhythm, and contribute to the ►pupillary light reflex and other reactions (Retinal ganglion cells). But they also project to the LGN and may thus contribute to perception; since they do not adapt to ambient light, they could assist in perception of absolute brightness [17].

## Ganglion Cell Outputs

The complex connections between retinal neurons create new representations of the visual image as evident from responses of ganglion cells. Primates possess more than a dozen types of ganglion cell that receive different patterns of inputs from cones and intercalated interneurons and project to different cells in the lateral geniculate nucleus (Retinal ganglion cells; Visual processing streams in primates). In primates, *midget ganglion cells* (also called *P cells* because they project to the small cells in LGN) and *small bistratified ganglion cells* have antagonistic ►center-surround organization of their receptive fields (Visual cortical and subcortical receptive fields) and are involved in the red-green and blue-yellow chromatic channels, respectively (Color processing). Midget ganglion cells are also sensitive to non-chromatic stimuli and responsible for *contrast* and *high spatial acuity*. Another important feature of spatio-temporal retinal processing is the sensitivity of some ganglion cell types to moving stimuli. Primate *parasol cells* (also called *M cells* because they project to large cells in the LGN) are sensitive to fast moving or low-contrast stimuli and are thought to serve as "novelty detectors" underlying an alarm system and to contribute to global form perception and depth perception. *Direction-selective ganglion cells* may contribute to the discrimination between object and self-motion (Retinal ganglion cells; Visual processing streams in primates). Direction-selectivity may result from several mechanisms including network properties involving amacrine cells and individual intrinsic cell properties (Retinal direction selectivity and starburst amacrine cells). There are other unusual cells, in particular in non-primate mammals, such as cells "suppressed-by-contrast" and "local edge detectors." Correlations between morphology and response patterns suggest that there may be around a dozen afferent signal channels [13,17].

## Lateral Geniculate Nucleus

Cells in the LGN have response properties similar to retinal ganglion cells. Thus, M cells generally exhibit high contrast-sensitivity, with little, albeit existent, sensitivity to different isoluminant colors without specificity. By contrast, most P cells are very sensitive to differences in wavelength and little to luminance contrast [16,18]. LGN cells are subject to modulating effects of feedback connections and afferents from the

brainstem that are not yet well understood (see above). As for retinal ganglion cells, the receptive fields of most LGN cells are mostly organized in circular center-surround arrangements (Geniculo-striate pathway; Visual cortical and subcortical receptive fields), which also applies to their responses to color.

## Form, Color, Motion, Depth and Distance

The information coded in the discharges of LGN cells is about tiny aspects of the outer world rather than more global issues of importance. What happens with this pre-processed information?

### "What", "Where" and "How"

An influential hypothesis propounds that different aspects of the external visual world are processed through different processing streams, in non-human primates (Extrastriate visual cortex; Visual processing streams in primates) and humans [12]. The so-called *ventral processing stream* extends from area V1 into inferior temporal areas, with further connections to ►prefrontal cortex and ►limbic areas. It is mainly concerned with *intrinsic object qualities* such as shape (form), size, brightness, texture, and color, whereby it is also called "what" channel. Its major function is assumed to be the identification and recognition of objects, with short- to long-term memory being of utmost importance. The *dorsal processing stream* extends from area V1 into superior temporal and parietal areas, with connections into the frontal cortex (below). It has been assumed to be mainly concerned with *relational object properties*, such as location, depth and motion (the "where" or "spatial vision" channel). A somewhat different, albeit not incompatible, view has emphasized the role of the dorsal stream in visually guided motor actions (whence it is also called the "how" pathway [19]; Visual pathways for perception and action). This strict functional segregation has been disputed, however (Extrastriate visual cortex). In fact, shape is also processed in the dorsal stream and needs to be since motor actions on objects require information on the latter's shape [12,15] (Visual space representation for action). In any case, if different aspects of the world are processed in different areas, they must be bound together in some way (Binding problem). These major processing streams are complemented by sub-cortical visual pathways involving the pulvinar and/or the inferior and superior colliculus (Visual role of the pulvinar).

### Human Brain Lesions

In humans, the concepts of different processing streams involving functionally specialized cortical areas are in part based on functional brain imaging studies [12] and in part on clinical deficits following localized brain lesions (Visual neuropsychology). Impressive syndromes include blindsight, ►agnosia of form and object, ►prosopagnosia, ►achromatopsia and ►color agnosia, ►asynthesia, ►Balint's syndrome, ►hemispatial neglect, ►visuospatial disorientation, ►depth perception disorders, and motion perception disorders (►akinetopsia). Although these syndromes generally favor the idea of functional specialization (Visual perception), the interdependence of object properties requires communication between the pathways. Consequently, there are many anatomical connections between temporal and parietal areas, and neurons in these areas show intermixed sensitivities to object features (Extrastriate visual cortex).

### Form

When we intend to reach for and grasp a cup of tea, obviously we first need to recognize and identify the cup as a distinct and known entity. Humans are astonishingly good and fast at recognizing objects. There are several hypotheses as to how objects might be represented neurally (Visual object representation) and how the nervous system might accomplish this feat [12]. Generally, the identification and recognition of objects requires the visual system to solve the following problems (cf. Form perception):

- *Figure-ground separation*. The first problem is to distinguish objects from the background, thereby isolating and individualizing them. This in turn requires:
  - *Contour detection*: Object borders must be detected as localized and oriented features. Border contours are defined by discontinuities not only in luminance and color, but also in texture, disparity, and motion.
  - *Feature classification* as to whether they arise from an individual object or the interaction between different objects.
  - *Feature grouping*: The features intrinsic to an object must be grouped together to define the object's outline.
- *Discrimination of invariant and changeable object properties*: Neural object representations must be such as to allow object recognition independent of [20] (Face processing in different brain areas; Computational vision):
  - *Variations in size* due to varying distance.
  - *Variations in lighting conditions and contrast* due, e.g., to changing illumination.
  - *Variations in spatial frequency* due, e.g., to blurring (changes in spatial resolution).
  - *Variations in position* on the retina (translation of non-fixated objects).
  - *Variations in angle of view* due to object rotations.
- *Association with memory representations of objects*: *Per definitionem*, "re-cognition" implies linking perceived objects with memorized objects.

One influential hypothesis posits that object recognition is performed in the ventral processing stream in a

hierarchical series of steps involving several functionally specialized cortical areas. Object recognition would start in the primary visual cortex with the detection and representation of local stimulus features and thence proceed into the inferotemporal (IT) cortex by a succession of integrative processes putting the simple features together into more abstract holistic representations [12,15,16] (computational vision). In the following brief overview, we shall concentrate on primate research.

### Form Processing in the Primary Visual Cortex

Neurons in the monkey primary visual cortex are characteristically sensitive to simple features [15].

#### Contour Detection

Most cortical cells in primary visual cortex (area V1) respond weakly or not at all to diffuse light, but strongly to stationary or moving lines, contrast borders, slits of light etc., of various orientations and forms, which provides the main basis for the detection of object shape [1,15] (Striate cortex functions). In addition to tiny center-surround cells in layer IV C, area V1 has neurons with new types of receptive fields, some important ones being (Visual cortical and subcortical receptive fields):

- ►*Simple cells* with non-circular receptive fields, whose main characteristic is a specific spatial orientation. Clusters of cells with about the same orientation are concentrated within *orientation columns*, and the orientations change systematically along the length of ocular dominance slabs (Striate cortex functions).
- ►*Complex cells* are the commonest cells and share orientation-specificity with simple cells.
- ►*End-stopped cells*. For the simple cells discussed above, it does not matter whether the optimally oriented light bar or edge exceeds the limits of their receptive field, but there are others for which it does. That is, if the bar or edge exceeds a certain limit in one or both directions, the cell's response declines from its optimum. These so-called "end-stopped" simple cells would allow for the detection of corners, sudden breaks in lines or curvatures, and are also sensitive to the direction of motion in two dimensions [1,15].

#### Classical Receptive Fields and their Surrounds

The area V1 cells described above appear well suited to detect stationary or moving edges and contrasts. However, this is not enough because objects have extended borders and surfaces captured therein. The visual system must therefore integrate the information on local features over larger spatial expanses so as to define boundaries and surfaces belonging to distinct objects (Form perception; Perceptual filling-in). A first indication of such integrative processes is the modulation of receptive fields by their surrounds.

Receptive fields in area V1 are neither rigid nor time-invariant. Rather, their properties change over largely varying time scales, depending on spatial and temporal context (Contextual influences in visual processing), state of arousal and attention (Visual attention), on expectations (below) and on previous experiences [21,22]. The receptive fields defined above are therefore now referred to as ►classical receptive fields ('CRF'). Modulations by the surround may be exerted on [22]:

- *Orientation specificity.* The responses of area V1 neurons to oriented line segments placed in their CRF can be suppressed by a texture of line segments surrounding the CRF. These effects have been interpreted as providing possible substrates for perceptual "pop-out," the segregation of borders between textures and the detection of the location and direction of changes in contour orientation, such as junctions or corners [21].
- *Directional motion selectivity.* Perception of motion (Visual motion processing) and certain ►motion aftereffects possibly result from contextual surround effects [22].
- *Receptive field size* may change depending on events in the surround [22].

The responses of cells in area V1 are modulated by brightness of surfaces well outside the CRF [21]. Such effects may contribute to perceptual phenomena such as ►*lightness constancy* [23] and ►*color constancy* (below; Color processing). Also, the perception of *relative depth* of objects and their 3D shape requires integration of signals from cortical areas representing disparate points on the retina (below).

### Form Processing in the Ventral Processing Stream

Still, local contour elements must be put together into more or less coherent lines that delineate at least larger parts of objects (Form perception). Some of these processes follow, at a psychophysical level, Gestalt laws (Gestalt psychology).

*Contour Saliency.* In natural scenes, short contour segments do not occur at random, but are correlated to define elongated lines of object borders that are often nearly straight over limited ranges. One way of representing these lines could be to interconnect neurons that represent frequently occurring short contour elements of appropriate location and orientation. Contours composed of similarly oriented, collinear features are more readily visible than ones made up of segments with large orientation differences, giving rise to *contour saliency* [21].

*Illusory (Anomalous or Subjective) Contours.* In addition to real contours based on, e.g., luminance gradients, we are able to perceive illusory contours. Neurons that respond to illusory contours have been

found in areas V1 and V2 of the macaque monkey. Since many of such illusory contours are produced as if by occlusion by an interposed object, these neurons could contribute to ►figure-ground organization [15] (Form perception; Contextual influences in visual processing).

►*Contour (or Boundary) Completion*. If near objects partially occlude far objects, these are segmented into image fragments. However, these fragments can be grouped together to create a representation of the partially occluded object (Form perception; Contextual influences in visual processing).

►*Border Ownership* (Form perception). To recognize partial occlusion requires that the visual system, firstly, distinguish between the "true" boundaries of a surface and those created by an intervening surface and, secondly, determine whether separate image patches should be grouped together into a single surface. An essential step here appears to be the determination of border ownership, and that may be helped by the illusory contours. Border ownership is coded by subsets of neurons in areas V2 and V4. They encode not only local contrast borders, but also the side (object) to which the border belongs [15].

*Kinetic contours* emerge from the differences in direction or speed of motion of two abutting textures; neurons in areas V2 and V4 might contribute to their detection [15].

*Surface Filling-In*. Objects are not just defined by the boundaries delineating them, but also by the surfaces within the boundaries. How are these surfaces *filled* in terms of brightness, color, depth etc.? When a portion of the visual field is masked by a gray area, with the boundaries kept constant, the pattern and color of the surrounding area spills into the mask (Form perception; Perceptual filling-in). Neurons in area V1 respond when their CRFs are positioned in the mask. In area V3, the cell responses develop with a time course corresponding to the perceptual fill-in phenomenon. Again, long-range intracortical connections and their dynamic modulation may underlie these phenomena [21].

### Neurons Responsive to Complex Features

Proceeding from area V4 into infero-temporal (IT) cortex, neurons become increasingly selective for complex stimulus characteristics [15,24] (for cortical areas named below see ►Extrastriate visual cortex). In area V4 and ►PIT, they may be selective for single characteristics, such as stimulus size, orientation in the plane and color, and for moderately complex patterns, such as line intersections, e.g., an "X" or T junctions, and curvatures. Populations of curvature-selective V4 neurons may encode complete shapes as aggregates of curved boundary fragments. In posterior IT, neurons appear to integrate multiple contour elements as coded in area V4. In areas ►CIT and ►AIT, "elaborate" cells respond to ever more complex features, such as star-shaped stimuli or combinations of features, such as a circular brown stippled area with a bar extending to the right. These features are not complex enough to completely specify natural objects. This implies that any individual object (shape with texture and color, often moving at some spatial depth) can only be represented by the coordinated activity of several to many cell populations, except in the case of faces (below). Far out in ►area TE of the ventral pathway, neurons are selective for 2D shape defining the external contour of an object, irrespective of the cues (motion, texture, luminance or disparity differences) [15].

Three-dimensional object shape may be inferred or derived from a number of cues, including two-dimensional ones, but stereoscopic vision based on the slightly different aspects delivered by the two eyes would be much more powerful for 3D shape description (Binocular vision; see below). In fact, a large proportion of macaque IT neurons are selective for 3D shape. Thus, IT cortex processes not only 2D but also 3D shape information and may thus complete shape representation by a stereoscopic mechanism [25]. 3D-selective cells are concentrated in the lower bank of the ►superior temporal sulcus (STS) [26]. This area receives input from the ►intraparietal cortex (IPS) of the dorsal processing stream, containing neurons responsive to disparity-defined orientation in depth.

Increasingly complex object representations and invariances have been modeled successfully (Computational vision).

### Invariances

Objects known to a viewer are identified by reproducible, invariant constellations of features, which may still appear differently under varying circumstances, i.e., change with size, position (retinal place), orientation, viewing angle, illumination etc. The task of the perceptual system is to recognize the object despite its changing appearance. This requires the capability to extract the invariant features from the changeable ones. Thus, if the IT pathway is involved in object recognition and identification, it should contain neurons that can abstract from certain properties such as size, orientation, retinal position, color and viewing angle (Face processing in different brain areas; Computational vision).

- *Invariance to object translation.* Neurons in IT have large receptive fields and might thus fulfill the prerequisite for invariance to object translation in the visual field.
- *Orientation constancy.* Only about 3% of elaborate cells display *orientation constancy* (responding equally to presentations of effective stimuli at all angles) or *size constancy* over a quite a large range [24].

V

- *Size constancy* denotes the capacity of monkeys and humans to accurately judge the size of objects up to a distance of 30 m. It requires that object size be scaled with distance, for which an estimate of distance is required (see below). A constancy intimately associated with size constancy is *speed constancy* (constancy of the distance traveled by a moving object per unit time), which must also take into account distance. In fact, viewing distance modulates neuronal responses also in the ventral processing stream leading up to inferotemporal cortex [27].
- *View invariance.* There are also neurons responding selectively to one or more familiar objects irrespective of the viewing angle (Face processing in different brain regions).

These invariances resemble those seen in some face- and hand-specific cells (Face processing in different brain areas; Computational vision). An intriguing instance of invariance, namely *color constancy* (Color processing), is mentioned below.

### Object Categorization

Object recognition (Visual object representation) is not enough to deal with the world. Different objects have different implications for the observer. This has put an evolutionary pressure on being capable to perceptually categorize objects [28]. For example, it is of paramount importance to distinguish between edible and non-edible objects, living and non-living objects, dangerous and harmless objects, etc. In advanced animals, most categories are learned. Characteristic of perceptual categorization is that objects in different categories are regarded as distinct despite their potential similarity (apple vs. billiard ball), while dissimilar objects in the same category (apple vs. banana) are treated alike. In macaque monkeys trained to categorize cats and dogs, neuronal activity in the lateral prefrontal cortex reflects these categories and category boundaries [29]. In human patients, category-specific cell responses occur in the ►hippocampus, ►amygdala and ►entorhinal cortex, all of which receive convergent input from temporal neocortical regions specialized for processing complex visual stimuli (Face processing in different brain areas).

### Recognition of Biologically Important Objects

Recognition of complex visual patterns such as biological bodies, faces, hands, limbs and other known objects is an essential, and perhaps the most highly developed, skill of the visual system, and is of obvious evolutionary significance.

Quite a proportion of cells in the monkey IT cortex, in particular in areas AIT and ►STPa, are selectively responsive to objects, biological bodies, heads, faces, hands, and limbs [20,24]. However, face-sensitive cells (Face processing in different brain areas; Computational vision), and probably also neurons that "learn" to become acquainted with specific objects, are distributed more widely over cortical and limbic structures.

## Color

Color sensitivity is not absolutely necessary for object recognition, as evidenced by color-deficient animals and humans who manage quite well in the world. Nonetheless, color helps to discriminate objects from each other (Color processing; Striate cortex functions). For all its usefulness, however, color perception comes along with a number of problems. The foremost are:

- *Color constancy*: Invariance of color perception against changes in ambient illumination [30]. While changes in ambient illumination change the spectrum of wavelength reflected from a surface, the perceived color associated with that surface should not change. This is a context-dependent phenomenon (Color processing).
- *Color contrast*. In contrast to color constancy, which generates similar percepts despite dissimilar spectral returns from the target, similar spectral returns may generate dissimilar color percepts, again as a function of context.
- *Color assimilation*. While in color constancy and contrast the color percepts generated by the targets are shifted away from those of their surrounds, highly repetitive spatial patterns make the apparent colors of the patterned elements assimilate with each other.

These well-known psychophysical phenomena have been explained by the idea that they are generated by past experience with the statistical organization of spectral returns from the natural visual environment [31] (Experience with natural images as a basis for vision).

### Color Coding in Subcortical Pathways

As mentioned above, a single cone photoreceptor cannot distinguish between a change in wavelength and intensity of light [6,17] (Retinal color vision in primates; Color processing). This implies that the signals from different cones need to be recoded, as in fact occurs in the antagonistic center-surround organization of the receptive fields of *midget ganglion cells* (also called *P cells* because they project to the small cells in LGN) and *small bistratified ganglion cells*, which are involved in the red-green and blue-yellow chromatic channels, respectively. But there are more cells and channels carrying chromatic signals [17]. Recoding continues in the primary visual cortex and beyond.

### Color Coding in Visual Cortex

While LGN receptive fields show some similarity to those of retinal ganglion cells, those of area V1 cells are

rather dissimilar and indicate another major recoding [17] (Color processing;). Color appears to be a quality altogether different from shape. However, color coding and edge and orientation coding are multiplexed rather than separated in monkey visual areas V1 and V2, indicating that cortical processing does not separate form and color information in different feature maps [32]. Area V1 cells show a variety of color preferences with varying receptive field structures. Area 2 contains color-sensitive neurons with their sensitivity depending on surrounding context [17]. In area V4 (an important gateway to the inferotemporal cortex involved in form processing), color can be combined with texture and other shape information to facilitate object recognition. Area 4 thus contains many color-processing neurons, among which neurons exhibiting color constancy are of great importance. While some area V4 cells are selective for the stimulus form independent of color, others show conjoint sensitivity to both form and color. As well, cells in infero-temporal cortex appear to code conjointly for both color and shape.

## Depth and Distance

Acting in a 3D world requires an excellent representation of the spatio-temporal arrangement of objects and their relations to the body. Arms and hands, working under close visual guidance (Eye-hand coordination; Active vision), have been of paramount importance for the rise of the human intellect and culture, especially for the production and use of tools (Visual space representation for action). The hand and binocular stereopsis have developed together. Depth perception is based on monocular and binocular cues.

### Monocular Vision

Even in monocular vision, a number of cues enable some guess as to the distance of objects [1]:

- *Static (pictorial) cues*
  - *Relative size* of objects known from experience.
  - *Perspective*. Roads and railway tracks narrow into the distance.
  - *Texture gradient*. Texture elements of a regularly textured pattern narrow down with increasing distance.
  - *Shadows*.
  - *Brightness*. Brighter objects appear closer.
  - *Color* (*chromostereopsis*). Highly saturated red and blue patches in a plane may appear to have different distances.
  - *Haziness*. Far objects appear hazier and less clear than near objects.
  - *Occlusion (interposition)* (see above).
- *Motion cues*
  - ►*Motion parallax*.
  - *Optic flow*.

### Stereopsis

Depth perception based on binocular vision is much more vivid than that derived from monocular cues [33] (Binocular vision). The two retinal images of 3D objects differ in both horizontal and vertical dimensions, giving rise to *horizontal and vertical disparities*. Vertical disparity occurs because objects on either side of the vertical meridian are closer to one eye than the other and thus span different angles in the two eyes. The patterns of these disparities across the visual field depend on the 3D world structure, gaze angle, viewing distance and eye alignment. Disparity-based stereopsis poses a number of new problems [34]:

- *Binocular matching*: In order to compute disparities, corresponding features in the two retinal images must be selected and identified correctly.
- *Disparity detection*: The retinal disparities must be detected by neural mechanisms based on signals from both eyes.
- *Binocular fusion:* The two images of the two eyes must be *fused* into a single percept.
- *Depth constancy:* Since the magnitude of horizontal disparity depends on viewing distance and alone is insufficient to compute stereopsis reliably, additional information about distance and angle of gaze is required.

#### The Binocular Correspondence Problem

In order to compute disparity, corresponding features in the two images must be selected and identified correctly (Binocular vision). How this is done, is one of the fundamental problems in stereoptic research.

#### Disparity-Selective Cells

Required for disparity detection and evaluation are binocular cells with receptive fields in both retinae. In monkey cortex, cells with non-circular receptive fields, simple and complex cells, receive inputs from both eyes. In fact, nearly all cells in the foveal region of areas V1 and V2, and most cells in higher-order areas are binocular. Disparity detectors have been found in areas V1, V2, V3, V3A, VP, V5 (MT), ►MST and IT of monkeys and in the superior colliculus of cats and opossums [33–37].

In foveal cortex, there are several categories of cells responding in various ways to horizontal disparities, each class responding to stimuli appearing in depth farther, at, or nearer than the binocular fixation point (Binocular vision). Exactly how disparity-sensitivity comes about is not yet completely understood [34].

In humans, the dorsal processing stream contains areas responsive to 3D cues [12]. In monkeys, the caudal part of the lateral bank of the intraparietal sulcus (►area CIP) contains neurons that are responsive to binocular disparity and tuned to the *axis orientation* of

long and thin stimuli in 3D space. Other neurons prefer broad and flat stimuli and are tuned to the *surface orientation* in depth. Such neuron sensitivities may be functionally important for grasping and object manipulation (Visual space representation for action).

Disparity-sensitive neurons are also found in the inferotemporal (IT) cortex of the ventral processing stream. A proportion of neurons concentrated in area TEs is sensitive to 3D shape defined by disparity (e.g., curved surfaces) with properties suggesting that at this level the 'stereo correspondence problem' is solved. These representations are also invariant to fronto-parallel position and size [15].

### Binocular Rivalry

When two different images are presented to the two eyes, they are not perceived superimposed, but compete for perceptual dominance so that perception is disintegrated into complex sequences of patchworks from the two images. It is not clear yet where in the brain rivalry occurs and how it is organized (►Binocular rivalry).

## Motion

Objects move relative to each other and to an observer, and the observer himself moves his eyes or the head or the entire body in the environment (self-motion). To detect, analyze, categorize and evaluate these various motions is of utmost survival value (Visual motion processing). Motion analysis is a complex biological process. For higher animals, such as many mammals including primates, a number of problems must be solved:

- *Detection of motions of retinal image elements* (Retinal direction selectivity and starburst amacrine cells).
- *Deduction of object motion from image-element motions* despite the restricted size of receptive fields, which causes the ►aperture problem (Visual motion processing).
- *Integration of object and motion information*, requiring the convergence of signals from the ventral and dorsal processing streams.
- *Distinction of retinal image changes resulting from object motions or from movements of the eyes, head and/or whole body movements (self-motion)*, or both; this may require integrating information from other (non-retinal) signals about eye, head and/or body movements.
- *Provision of appropriate outputs* to:
  - *Evaluation systems* (dangerous or not?).
  - *Decision systems*.
  - *Motor systems* (oculomotor and somato-motor).

### The Motion Correspondence Problem

At the origin of motion perception must be mechanisms for motion detection (Visual motion processing). Here appears a problem similar to the correspondence problem in binocular depth estimation, translated into the temporal domain. The visual system must identify and determine the spatio-temporal displacements of those features in the dynamic retinal image, which originate from the same moving objects. This is known as the ►*motion correspondence problem*. For help in a solution, the human visual system exploits local, cross-cue matching constraints [38].

### Motion and Direction Sensitivity

Motion and direction sensitivity is particularly prevalent in areas and neurons in the dorsal processing stream from primary visual cortex through area V5 (MT) and ►area MST [12,15]. Area MT (V5) – by also being sensitive to pattern direction, speed gradients and disparity and having large antagonistic surrounds – appears to play a prominent role in segmenting motion from its background and possibly in computing structure from motion and depth cues [15,35] (Visual motion processing). Signals from area MT (V5) are transmitted to ►area MSTd (dorsal MST) involved in assessment of self-motion via optic flow analysis, to ►area MSTv (ventral MST) involved in the analysis of visual trajectories, smooth ►pursuit eye movements and arm trajectories, and to ►area FST (floor of the superior temporal visual area), from which might originate an action-related pathway [15]. Many neurons in area MSTd respond to movement in depth, rotary movement in space and optic flow (Visual space representation for action).

### Object Motion

The problem of recovering coherent object motion from the motion of retinal image features has no unique solution. For example, when two objects move past each other, some moving retinal features belong to one or the other object, but other features arise from changing overlap (corners at points of overlap). The distinction requires, firstly, the classification of the moving features as arising from one or the other source and, secondly, the grouping of those features belonging to any individual object. Interpretation of object motion is thus secondary to *feature classification* [39,40]. Another principal problem for the visual system is to deduce the direction of object motion from the direction of object contours (Visual motion processing). There is evidence that area MT contains neurons performing this integration. The ►anterior superior temporal polysensory area (STPa) contains motion-sensitive neurons that selectively respond to movements of external objects, but not to retinal motion resulting from the observer's own motion. These cells then compute object motion relative to the observer, which suggests that some (retinal, vestibular, somatosensory) reference signals are used to discriminate between object and self-motion [41].

### Biological Motion Recognition

Human subjects are extremely good at perceiving and interpreting ►biological motion from impoverished displays of small light sources attached to points of articulations, e.g., shoulders, elbows, wrists, knees, ankles etc. They can even distinguish movement patterns such as dancing, running, walking, as well as identity, gender, facial expression etc. And they are fast at it, responding to exposure durations of 100–200 ms [12,42].

The biological correlates of these perceptual capabilities may be found in neurons in the macaque temporal cortex, which are selectively sensitive to particular body movements, e.g., walking. The inferotemporal (IT) cortex and the anterior superior temporal polysensory area (STPa) contain form-sensitive cells that respond preferentially to four characteristic views: the face (Face processing in different brain areas), the left, the right and the back view of head and body. Also, in area STPa, form-independent neurons discriminate between motions in Cartesian directions: toward, away, left, right, up and down. There are, then, neurons that conjointly react to specific body motions, such as a left-profile view walking to the observer's left, etc. Whole-brain functional MRI of *humans* suggests that, whereas face and form stimuli activate primarily the ventral processing system and motion stimuli primarily the dorsal processing system, recognition of biological motion stimuli may activate both systems as well as their confluence in the superior temporal sulcus (STS) [43].

### Perception of Self-Motion

Eye or head movements and self-motion induce changes in retinal image. The image changes resulting from self-motion are briefly referred to as *optic flow*. Due to the motion parallax, self-motion and depth perception are intimately related. The analysis of optic flow is important for stabilizing stance and locomotion (walking speed), for perceiving the 3D scene and object motion, for computation of the time to contact in impending collision, for stabilizing the visual world by eye movements, for orientation, for visually guided navigation in the 3D world and path integration. A predominant role in optic flow analysis has the dorsal processing stream leading up to area MT and medial superior temporal area (MST) (Optic flow).

## Attention and Expectation

The recognition of complex spatio-temporal displays is very demanding and surpasses the computational capacities of the brain. The many objects in a visual scene thus compete for neural representation (Visual attention). Moreover, much of the sensory, especially visual, information impinging on the nervous system is not immediately relevant behaviorally. These problems require mechanisms ensuring

- *Selection of relevant pieces of information*; involving
  - *Facilitation* of needed information.
  - *Suppression* of unneeded information.
- *Localization of this information and directional processes* toward this locus.
- *Eye movements* toward selected objects (if needed) to focus and regard them at high spatial resolution.

These processes require complex and flexible mechanisms engaging widely distributed networks at cortical and sub-cortical levels, which have also been modeled by ►neural network approaches (Computational vision). Attention thus modulates visual signal processing by way of ►top-down influences as distinct from stimulus-driven ►bottom-up processes (Visual attention).

The biological significance of a visual (or other) sensory stimulus is greatly influenced by whether it is novel or expected. There are many examples of cell responses to stimuli being modulated by expectation. For instance, cells in macaque area V3a respond strongly to the motion of an oriented bar when the monkey is maintaining steady fixation, but they respond much more weakly when the monkey induces the same retinal stimulus by moving his eyes with the bar fixed in space [44]. Also, there are neurons in area STPa that respond to any moving object except when the object is the monkey's own hand moving into the cell's receptive field [45]. This indicates that, for some neurons, a stimulus can produce a response when the motion is unpredictable or unexpected, but fails to do so when the motion is predictable from the monkey's own behavior. Such anticipatory influences on sensory processing may be generated by an ►internal model of the motor system (Motor control) and explain why you cannot tickle yourself [46].

## Toward Action

Adaptive goal-directed behavior depends on the successful integration of multifarious sub-functions, sensory and motor. In visually highly developed animals such as primates, vision plays a predominant role in guiding many motor activities. To do so, eye movements must be closely coordinated with other body movements (Active vision), which involves some partially specialized areas in posterior parietal cortex and connected areas in the frontal lobe. Similarly, visually guided goal-directed arm and hand movements such as reaching, grasping and object manipulation involve specific parietal and frontal areas (Visual space representation for action; Visual space representation for reaching). Conversely, movements change visual inputs, closing the loop (Visuo-motor integration).

In order to direct a movement toward a visual and/or other sensorily defined target, visual spatial information must be combined with auditory, tactile and proprioceptive spatial information. For example, for directing

gaze (eye plus head) toward a visible target, it is necessary to determine the location of the target relative to the body, which in turn requires the combination of information on retinal image location and eye and head position. Hence, multimodal information from different senses must be combined (Multimodal integration). What is more, the different types of information are encoded in different frames of references, necessitating coordinate transformations (Sensory systems; Motor control).

## Concluding Remarks

In the history of philosophy and science, vision has always occupied a preeminent stand, not only since Plato's cave allegory. Over the past several centuries, wide strides have been made in unraveling the mysteries of vision by the use of a huge number of approaches. While considerable advances have been achieved in our understanding of the neuroanatomical and neurophysiological bases of the visual system in many organism, the major challenge of bridging the gaps toward comprehending the nature and generation of visual perception rermains and will do so for some time to come.

### Acknowlegment

Dedicated to the outstanding scientist, academic teacher and friend Rainer F. Greger (3.1.1946–16.12.2007).

## Definition

Brain mechanisms for object and face recognition

## Characteristics

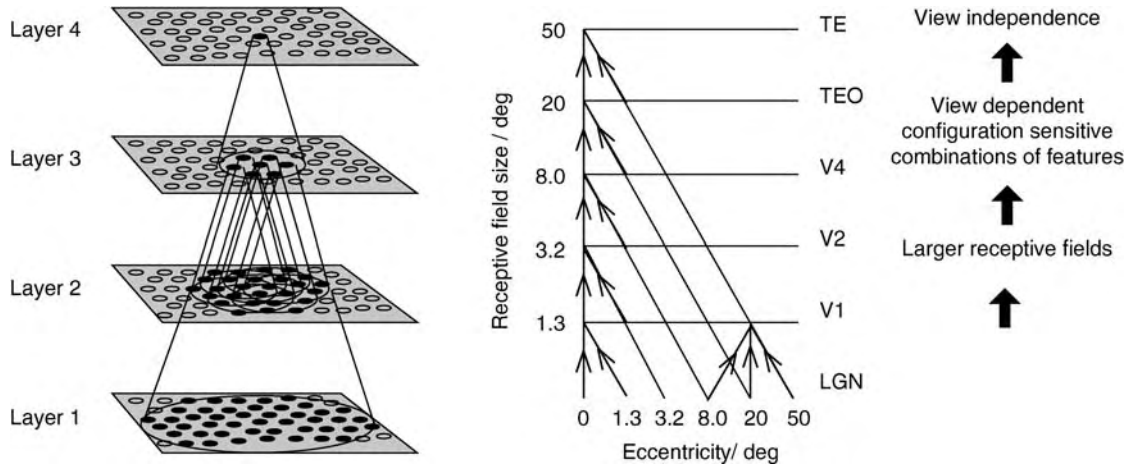
Cortical visual processing for object recognition is considered to be organized as a set of hierarchically connected cortical regions consisting at least of areas V1, areasV2, areasV4, ►posterior inferior temporal cortex (TEO), and ►anterior inferior temporal cortex (TE) as shown in Fig. 1 [1].

There is convergence from each small part of a region to the succeeding region (or layer in the hierarchy) in such a way that the ►receptive field sizes of neurons (e.g. 1° near the fovea in area V1) become larger by a factor of approximately 2.5 with each succeeding stage (see Fig. 1). Such zones of convergence would overlap continuously with each other. This connectivity would be part of the architecture by which translation-invariant representations are computed.

Each layer is considered to act partly as a set of local self-organizing competitive neuronal networks with overlapping inputs as shown in Fig. 1b. These competitive nets operate by a single set of forward inputs leading to (typically non-linear, e.g. sigmoid) activation of output neurons; of competition between the output neurons mediated by a set of feedback inhibitory interneurons which receive from many of the principal (in the cortex, pyramidal) cells in the net and project back (via inhibitory interneurons) to many of the principal cells which serves to decrease the firing rates of the less active neurons relative to the rates of the more active neurons; and then of synaptic modification by a modified ►Hebb rule, such that synapses to strongly activated output neurons from active input axons strengthen, and from inactive input axons weaken [1].

Translation-, size- and view-invariance could be computed in such a system by utilizing competitive learning operating across short time scales to detect regularities in inputs when real objects are transforming in the physical world [1–3]. The hypothesis is that because objects have continuous properties in space and time in the world, an object at one place on the retina might activate feature analyzers at the next stage of cortical processing, and when the object was translated to a nearby position, because this would occur in a short period (e.g. 0.5 s), the membrane of the postsynaptic neuron would still be in its "Hebb-modifiable" state (caused for example by $Ca^{2+}$ entry as a result of the voltage-dependent activation of ►NMDA receptors, or by continuing firing of the neuron implemented by recurrent collateral connections forming a short-term memory), and the presynaptic afferents activated with the object in its new position would thus become strengthened on the still-activated postsynaptic neuron. Other invariances, for example size, spatial frequency, rotation, and view invariance, could be learned by similar mechanisms to those just described [1–3]. It is suggested that the process takes place at each stage of the multiple-layer cortical processing hierarchy, so that invariances are learned first over small regions of space, and then over successively larger regions. This limits the size of the connection space within which correlations must be sought.

Increasing complexity of representations could also be built in such a multiple layer feature hierarchy by similar competitive learning mechanisms. Evidence consistent with this suggestion that neurons are responding to combinations of a few variables represented at the preceding stage of cortical processing is that some neurons in areas V2 and V4 respond to end-stopped lines, to combinations of lines, or to more complex



**Vision – Computational Approaches. Figure 1** Schematic diagram showing convergence achieved by the forward projections in the visual system, and the types of representation that may be built by competitive networks operating at each stage of the system from the primary visual cortex (area V1), through the secondary visual cortex (area V2), to area V4, then to the posterior inferior temporal cortex (TEO), and then to the anterior inferior temporal visual cortex (area TE) (see text). LGN - lateral geniculate nucleus. *Right*: as it occurs in the brain. *Left*: as implemented in VisNet. Convergence through the network is designed to provide fourth layer neurons with information from across the entire input retina.

features; in posterior inferior temporal cortex to stimuli which may require two or more simple features to be present; and in the temporal cortical face processing areas to images that require the presence of several features in a face (such as eyes, hair, and mouth) in order to respond [1]. It is an important part of this suggestion that the relative spatial location of the features would be inherent in the features which were being combined [3]. For example, cells might not respond to the combination of an edge and a small circle unless they were in the correct spatial relation to each other. Further combinations of such neurons at the next stage would include sufficient local spatial information so that an arbitrary spatial arrangement of the same features would not activate the same neuron, and this is the proposed, and limited, solution which this mechanism would provide for the feature-►binding problem. It is suggested that view-independent representations could be formed by the same type of computation, operating to combine a limited set of views of objects [3].

In this biologically plausible scheme, the representation would be suitable for recognition of an object, and for linking associative memories to objects, but would be less good for making actions in 3D-space to particular parts of, or inside, objects, as the 3D coordinates of each part of the object would not be explicitly available. It is therefore proposed that visual fixation is used to locate in foveal vision part of an object to which movements must be made, and that local disparity and other measurements of depth then provide sufficient information for the motor system to make actions relative to the small part of space in which a local, view-dependent, representation of depth would be provided [1,3].

To test and clarify these hypotheses, a network (VisNet) with the architecture shown in Fig. 1b has been simulated. It can perform object, including face, recognition in a biologically plausible way, and after training shows for example translation- and view-invariance [1–3].

The synaptic learning rule used can be summarized as follows:

$$\delta w_{ij} = k.m_i.r'_j$$

and

$$m_i^t = (1-\eta)r_i^{(t)} + \eta m_i^{(t-1)}$$

where $r'_j$ is the $j$th input to the neuron, $r_i$ is the output of the $i$th neuron, $w_{ij}$ is the $j$th weight on the $i$th neuron, $\eta$ governs the relative influence of the trace and the new input (typically 0.4–0.6), and $m_i^{(t)}$ represents the value of the $i$th cell's memory trace at time t. In the simulation the neuronal learning was bounded by normalization of each cell's dendritic weight vector, as in standard competitive learning [1].

To train the network to produce a translation-invariant representation, one stimulus was placed successively in a sequence of nine positions across the input, then the next stimulus was placed successively in the same sequence of nine positions across the input, and so on through the set of stimuli. The idea was to enable the network to learn whatever was common at each stage of the network about

a stimulus shown in different positions. To train on view-invariance, different views of the same object were shown in succession, then different views of the next object were shown in succession, and so on. It has been shown that the network can learn to form neurons in the last layer of the network that respond to one of a set of simple shapes (such as "T, L and +") with translation-invariance, or to a set of 5–8 faces with translation-, view-, or size-invariance, provided that the trace learning rule (and not a simple Hebb rule) is used.

Further developments include analysis of more powerful learning rules; a solution to the feature-binding problem by the use of neurons that self-organize to represent feature combinations with the relative positions of the features part of what is required for a neuron to respond; operation of the system in a cluttered environment; generalization from trained to untrained views of objects; a new training algorithm named continuous transformation learning [3]; the incorporation of top-down connections so that attentional effects can be simulated [4] (see Fig. 2); and a unifying theory of how invariant representations of optic flow produced by rotating or looming objects could be produced in the dorsal visual system [3].

Related feature hierarchy approaches to invariant object recognition include investigations of Fukushima in 1991 and Riesenhuber, Poggio and colleagues [5] (though they did not have self-organizing learning rules), and investigations that performed function optimization to generate neurons in the later layers that were orthogonal and showed temporal continuity when trained on visual scenes [6].

## A Biased Competition Model of Object and Spatial Attentional Effects on the Representations in the Visual System

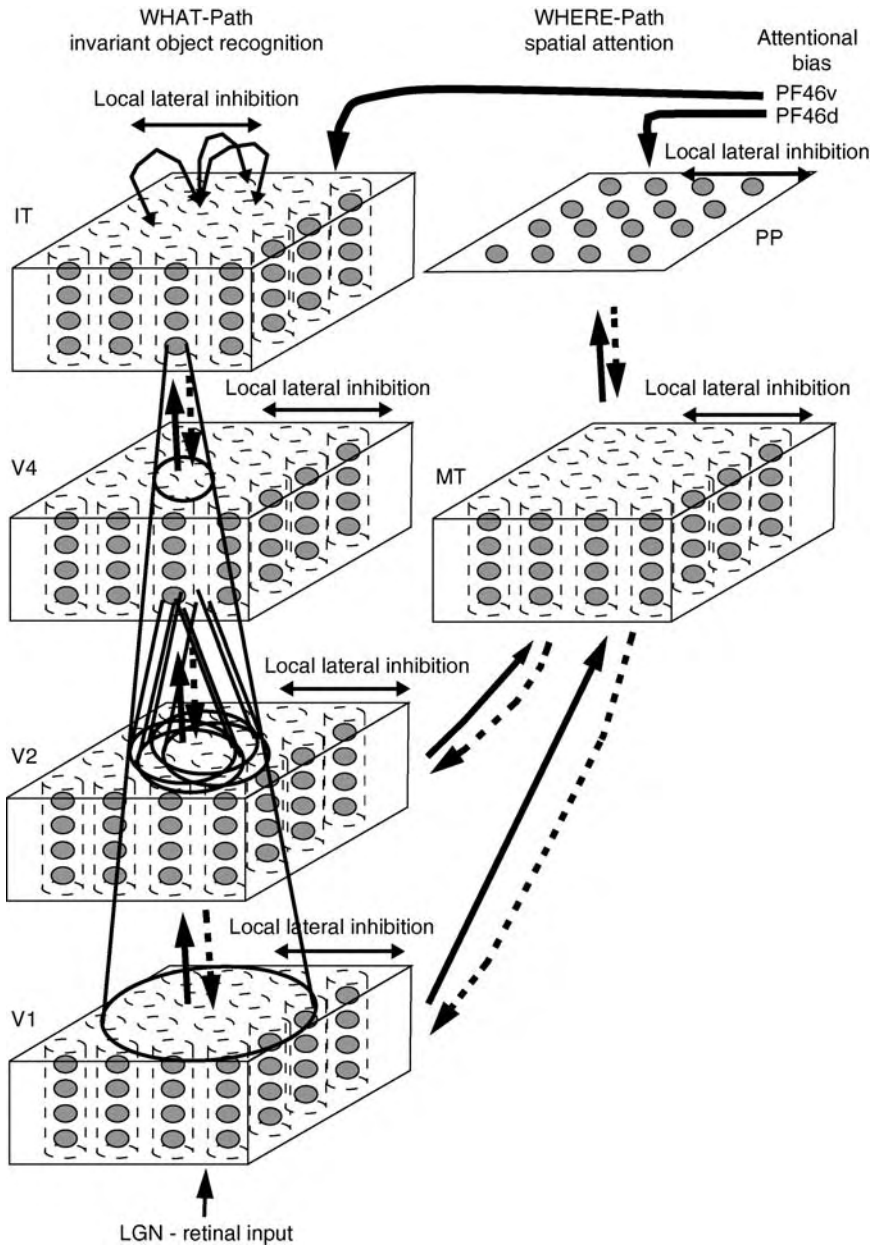
Visual attention (►Visual attention) exerts ►top-down influences on the processing of sensory information in the visual cortex, and therefore is intrinsically associated with inter-cortical neural interactions. Thus, elucidating the neural basis of visual attention is an excellent paradigm for understanding the basic mechanisms of inter-cortical neurodynamics. Recent cognitive neuroscience developments allow a more direct study of the neural mechanisms underlying attention in humans and primates. In particular, the work of Chelazzi, Miller, Duncan and Desimone in 1993 has led to a promising account of attention termed the biased competition hypothesis [7]. According to this hypothesis, ►attentional selection operates in parallel by biasing an underlying competitive interaction between multiple stimuli in the visual field toward one stimulus or another, so that behaviorally relevant stimuli are processed in the cortex while irrelevant stimuli are filtered out. Thus, attending to a stimulus at a particular location or with a particular feature biases the underlying neural competition in a certain brain area in favour of neurons that respond to the location, or the features, of the attended stimulus.

Neurodynamical models for biased competition have been proposed and successfully applied in the context of attention and ►working memory. In the context of attention, Usher and Niebur introduced in 1996 an early model of biased competition. Deco and Zihl in 2001 extended Usher and Niebur's model to simulate the psychophysics of visual attention by ►visual search experiments in humans. Their neurodynamical formulation is a large-scale hierarchical model of the visual cortex whose global dynamics is based on biased competition mechanisms at the neural level. Attention then appears as an emergent effect related to the dynamical evolution of the whole network. This large-scale formulation has been able to simulate and explain in a unifying framework visual attention in a variety of tasks and at different cognitive neuroscience experimental measurement levels, including single-cells, ►fMRI, psychophysics, and neuropsychology [1,8].

For example, Deco and Rolls [9] extended previous concepts of the role of biased competition in attention by providing the first analysis at the integrate-and-fire neuronal level, which allows the neuronal non-linearities in the system to be explicitly modeled, in order to investigate realistically the processes that underlie the apparent gain modulation effect of top-down attentional control. In the ►integrate-and-fire model, the competition is implemented realistically by the effects of the excitatory neurons on the inhibitory neurons, and their return inhibitory synaptic connections. This was also the first integrate-and-fire analysis of top-down attentional influences in vision that explicitly models the interaction of several different brain areas. Part of the originality of the model is that in the form in which it can account for attentional effects in areas V2 and V4 in the context of biased competition, the model with the same parameters effectively makes predictions which show that the "contrast gain" effects in area MT can be accounted for by the same model (see [9] and references therein). These detailed and quantitative analyses of neuronal dynamical systems are an important step towards understanding the operation of complex processes such as top-down attention, which necessarily involve the interaction of several brain areas.

## Extending Perceptual Models to Cognitive Processing

In addition to biased competition, there is also *cooperation* between neurons, where global representations find their neural correlate in assemblies of co-activated neurons. Co-activation is achieved by stronger than average mutual connections between the members of each assembly. Reverberatory communication between the members of the assembly then leads to persistent activation of the member neurons and gives



**Vision – Computational Approaches. Figure 2** Cortical architecture for hierarchical and attention-based visual perception. The system is essentially composed of five modules structured such that they resemble the two known main visual paths of the mammalian visual cortex. Information from the retino-geniculo-striate pathway enters the visual cortex through area V1 in the occipital lobe and proceeds into two processing streams. The occipital-temporal stream leads ventrally through areas V2-V4 and IT (inferior temporal visual cortex), and is mainly concerned with object recognition. The occipito-parietal stream leads dorsally into PP (posterior parietal complex), and is responsible for maintaining a spatial map of an object's location. The solid lines with arrows between levels show the forward connections, and the dashed lines the top-down back-projections. Short-term memory systems in the prefrontal cortex (PF46) apply top-down attentional bias to the object or spatial processing streams (after [4]).

rise to a representation extended in time. In this way, the theoretical and computational framework of *biased competition and cooperation* offers a unifying principle for neurocognitive modeling of higher neocortical functions [8]. Cognitive behavior requires complex context-dependent processing of information that emerges from the links between attentional perceptual processes, working memory and reward-based evaluation of the performed actions. Indeed, *cognitive flexibility* requires coordination between associative

cortical areas that implement working memory, attention, expected rewards, and the alteration of behavior if reinforcers are not obtained as expected.

In this framework one can show how an attentional state held in short-term memory in the prefrontal cortex can by top-down processing influence ventral and dorsal stream cortical visual areas (►Extrastriate visual cortex); using biased competition to account for many aspects of visual attention. Furthermore, in the context of *working memory and reward processing*, one can model in a unifying form attentional and memory effects in the prefrontal cortex, integrating single-cell and fMRI data, and different paradigms in the framework of biased competition, including the following. (i) Visual Working memory, in the context of the "What" and "Where" paradigm and the Context-Dependent Delayed Match to Sample task (including modeling of single neuron responses, of fMRI signals, and of the effects of pharmacological manipulations which are relevant for clinical diagnosis) [8,9]. (ii) ►Attentional Filtering, which represents a particularly strong attentional effect, in which the context gates sensory input in an all-or-none fashion. Moreover, attentional filtering might be part of a neural correlate of ►inattentional blindness, which is the inability of humans to recover any information from unattended sensory stimuli. Inattentional blindness is thought to be part of an important cognitive mechanism, namely that of focusing or "concentrating" on a task to be performed [10]. (iii) ►Selective Working Memory, which allows the formation of working memory, where task-relevant information is maintained in mind over a delay period while task-irrelevant information is filtered out through an attentional mechanism. (iv) Task-Switching in the Wisconsin card-sorting task. Earlier models involving semi-realistic neural networks focused on the existence of "rule coding clusters" and on perseverative errors. The current model improves the biophysical realism in order to generate predictions for functional MRI studies, and for lesion effects. The fMRI signal during task-switching was predicted in an implicit condition (where subjects had to detect a change in task by trial and error), and in an explicit condition (where subjects were informed about the change). Comparison with the actual fMRI data showed a close almost quantitative agreement with experimental data (Stemme, Deco, Busch and Schneider, 2005).

The models also directly address how ►bottom-up processes and top-down processes interact in visual cognition, and show how some apparently serial processes reflect the operation of interacting parallel distributed systems. It is also possible to show how within the prefrontal cortex attentional bias can influence the mapping of sensory inputs to motor outputs, and thus play an important role in decision making [8]. Furthermore, the absence of expected *rewards* can switch the attentional bias signal, and thus rapidly and flexibly alter cognitive performance [8].

## Visual Action Space

►Visual Space Representation for Reaching

## Visual Acuity, Hyperacuity

V

### Definition

Visual acuity is the ability to perceive fine detail, usually measured as the minimal size and distance of two points, or of a set of alternating black and white lines (grating), required to see them separately. Visual acuity is commonly given in minutes of visual angle, e. g. human grating acuity is 1′, cat grating acuity is

~10′. Acuity depends on the peak density and receptive field size of the smallest ganglion cell type in the area centralis/fovea. Hyperacuity refers to conditions where performance is better than at the two-point separation. Examples are Vernier acuity = the detection of an alignment offset between two lines (10″ in man, 1′ in cat), and stereo acuity = depth discrimination by the use of the two eyes

## Visual Attention

Stephanie A. McMains, Sabine Kastner
Department of Psychology, Princeton Neuroscience Institute, Center for the Study of Brain, Mind and Behavior, Princeton University, Princeton, NJ, USA

### Definition

The term "visual attention" refers to a set of cognitive operations that mediate the selection of relevant and the filtering out of irrelevant information from cluttered visual scenes.

### Characteristics

In everyday life, visual scenes typically contain more items than can be processed at any one time due to the limited processing capacity of the visual system. "Visual attention" refers to the cognitive operations that allow us to efficiently deal with this capacity problem by selecting relevant information and by filtering out irrelevant information. Attention is a highly flexible mechanism that can operate on regions of space, particular features of an object, or on entire objects. Attention can also be directed either overtly or covertly. For instance, if a barking dog ran up to you, you would not only direct your attention towards it, but would also look directly at it, deploying overt attention. On the other hand, if you are driving a car, you might need to attend to an approaching pedestrian while still looking at the road, thereby deploying covert attention. In most laboratory settings, experiments investigate one particular type of attention, such as covert attention to a spatial location, but in everyday life, all forms of attention interact dynamically.

The two most common behavioral paradigms employed to study visual attention are the ►spatial cueing paradigm that probes attention to a single location or stimulus, and the ►visual search task that probes attention in the presence of distracters. In this chapter, we will outline the neural basis that underlies attentional operations in these two tasks, as they have been studied in humans using functional brain imaging and in non-human primates using electrophysiological techniques.

### Neural Basis of Single Stimulus Detection

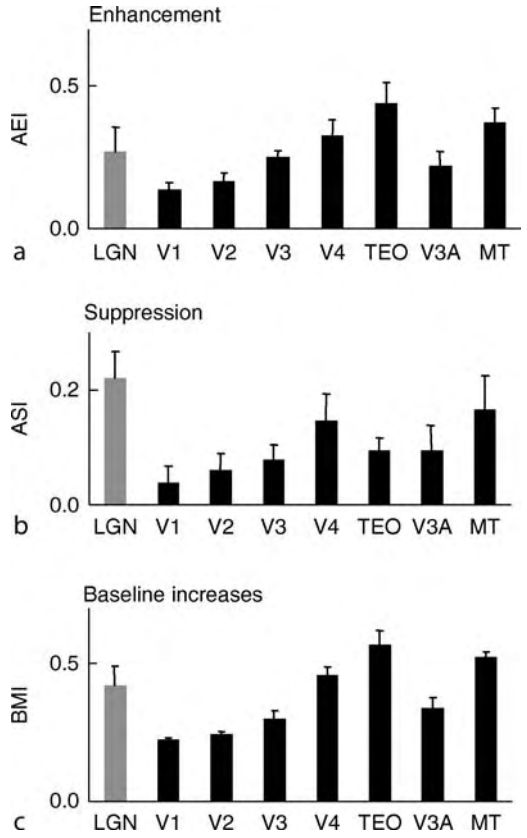
The spatial cueing paradigm was invented by Michael Posner and is often simply referred to as the "►Posner paradigm." In this paradigm, subjects look at a central fixation point and are given a brief cue instructing them to attend to a particular peripheral location. The cue can either be symbolic such as an arrow at fixation pointing to the target location, thereby indicating it abstractly, or physical such as a brief stimulus flashed at the target location. A symbolic cue requires subjects to deploy their attention endogenously, based on internal representations, while physical cues at the target location draw exogenous attention, a quick stimulus-driven orienting of attention to a salient stimulus. After a variable delay, a visual stimulus is presented briefly, which subjects are required to detect. On most trials, known as valid trials, the target appears at the cued (i.e. attended) location. On the rest of the trials, known as invalid trials, the target appears at an uncued (i.e. unattended) location. The typically observed response difference in detecting stimuli on valid and invalid trials is thought to reflect the effects of attention on selected locations in space. Attending to a location improves the accuracy and speed of reporting a target at that location and can increase perceptual sensitivity for target discrimination.

Attentional effects during Posner type cueing tasks have been investigated both in single-cell recording studies in monkeys and in neuroimaging studies in humans. In a typical physiology experiment, a stimulus is presented within a neuron's receptive field (RF; ►Visual cortical and subcortical receptive fields), while the animal is either cued to covertly attend to the stimulus in the RF or to a different location in the visual field. Neural responses are enhanced when the animal attends to the stimulus in the RF as compared to when it attends away from the RF [1]. In general, attention effects are larger on "effective" stimuli that elicit a strong response when placed in the RF compared

to "non-effective" stimuli that elicit a small response. Attentional response enhancement has been observed in several areas in the macaque visual system including ►areas V1, V2, V4, MT, ►inferior temporal (IT) cortex and the ►lateral intraparietal (LIP) area (►Extrastriate visual cortex). Interestingly, attentional modulation of more advanced processing stages occurs earlier (after about 150 ms in IT cortex relative to stimulus onset) than that of early stages (after about 230 ms in area V1).

In a typical human experiment, instead of placing a single stimulus within a RF, identical stimuli are placed at corresponding locations to the right and left of a central fixation point, with one stimulus in each visual hemifield. Subjects are then cued to covertly attend to either the right or left visual field. When subjects attend to the cued stimulus, responses in visual cortex are enhanced (as early as 80–130 ms after stimulus onset) in the ►retinotopic representation of the attended stimulus compared to when subjects are cued to attend elsewhere in the visual field [2] (Fig. 1a). These results indicate that attention biases processing in favor of stimuli at the attended location at the expense of those at unattended locations (Fig. 1b). Such attentional response enhancement has been observed throughout the visual system, including subcortical processing stages such as the ►lateral geniculate nucleus (LGN) and cortical stages such as ►areas V1, V2, V3, V4, V3A, and MT (Fig. 1a). In cortex, the magnitude of attentional modulation increases from ►primary visual cortex (Brodmann's area 17, striate cortex, area V1) to more advanced processing stages. Together with the latency differences of attention effects observed in monkey physiology this finding supports the idea that attention operates through top-down signals that are transmitted via corticocortical feedback connections, thereby reversing the visual processing hierarchy. However, this notion has recently been challenged by findings of larger attentional modulation in the LGN than in area V1 (Fig. 1). The greater LGN modulation may be due to additional feedback input from sources other than area V1 such as the ►reticular nucleus of the thalamus (TRN). Importantly, these findings suggest that attentional modulation in the visual system may be organized in more complex ways than by simply reversing the visual processing hierarchy.

Attentional enhancement has also been investigated during the cue period, when subjects are covertly attending to a spatial location prior to the onset of the target stimulus, in the absence of visual stimulation. Physiology and functional brain imaging studies [3] have revealed increased neural signals at the cued location (Fig. 1c). This attentional modulation in the absence of visual stimuli is termed a baseline increase and is thought to reflect a top-down bias of neural signals in favor of the attended location.



**Visual Attention. Figure 1** Attentional response modulation in the lateral geniculate nucleus (LGN) and in visual cortex. Checkerboard stimuli that reversed contrast at 7.5 Hz were presented in alternation either to the left or right visual hemifield. Subjects either detected luminance changes within the checkerboard stimuli or ignored the peripheral stimuli and performed a letter counting task at fixation. Attention effects were quantified by defining several indices: (a) attentional enhancement index (AEI), which reflects the amount of attentional enhancement observed when subjects attended to the peripheral stimuli, (b) attentional suppression index (ASI), which reflects the amount of suppression observed for the peripheral stimuli when subjects performed an attention task at fixation, and (c) baseline modulation index (BMI), which reflects cue period activity observed when subjects were attending to a peripheral target location in expectation of the stimulus onset (for index definitions, see O'Connor et al., 2002). For all indices, larger values indicate larger effects of attention. In visual cortex, attention effects increased from early to later processing stages. Attention effects in the LGN were larger than in area V1. Averaged index values from four subjects. Vertical bars indicate S.E.M. across subjects. (From O'Connor et al., 2002.)

In addition to biasing processing in favor of a spatial location, attention can also bias processing in favor of a particular stimulus attribute (►Feature-based attention) or in favor of an entire object (►Object-based attention).

V

In experiments investigating feature-based attention, stimuli are typically composed of multiple stimulus features (e.g. colored shapes moving in different directions), and subjects are cued to attend to a particular feature dimension (e.g. the color red) while ignoring the other dimensions. In monkey studies, neural responses increased, when the feature in the RF matched the cued feature regardless of where the animal was attending. Feature-based attention effects have been observed in area V4 for several feature dimensions including color, luminance, orientation, and direction of motion [4]. In human neuroimaging studies, where activity is measured at the level of entire areas within neural networks, researchers have taken advantage of the functional specialization of visual cortex (►Visual perception) in studying feature-based attention. In one such study, Corbetta and colleagues investigated attention to shape, color, or speed and observed enhanced activity in visual regions specialized for processing the attended feature, including enhanced activity in the posterior ►fusiform gyrus for attention to shape, area V4 for attention to color, and area MT for attention to motion.

Object-based attention signals have been investigated in human studies, in which subjects attend to a particular feature of an object, while signals evoked by the unattended features of the attended object are measured. In one such study, Kanwisher and colleagues used stimuli that consisted of overlapping images of houses and faces [5]. On any given trial, one of those images moved. Subjects attended to and performed a task on either the house, the face, or the motion, resulting in increased activity in regions specialized for processing the attended feature or object, that is, the ►fusiform face area, ►parahippocampal place area, or MT, respectively. Interestingly, activity also spread to the unattended feature of the attended stimulus. For instance, when the face stimuli were moving, and subjects attended to the faces, increased activity was observed in MT as compared to when subjects attended to stationary house stimuli. Thus, attentional biasing signals appear to spread to the unattended features of the attended object, resulting in enhanced signals in regions specialized for processing the unattended feature. These studies demonstrate that processing can be biased in favor of an attended object, with all features of the attended object receiving some amount of enhanced processing.

Taken together, the studies reviewed thus far provide converging evidence that attention biases processing in visual cortex towards a particular location, feature, or object by increasing the activity of neural populations that represent the attended aspect of the visual scene. However, many of the studies summarized thus far have only considered attention effects on a single stimulus or object while typical scenes contain several objects, of which one is chosen for further processing. The attentional operations involved in such a selection process are studied in the visual search paradigm.

## Neural Basis of Visual Search

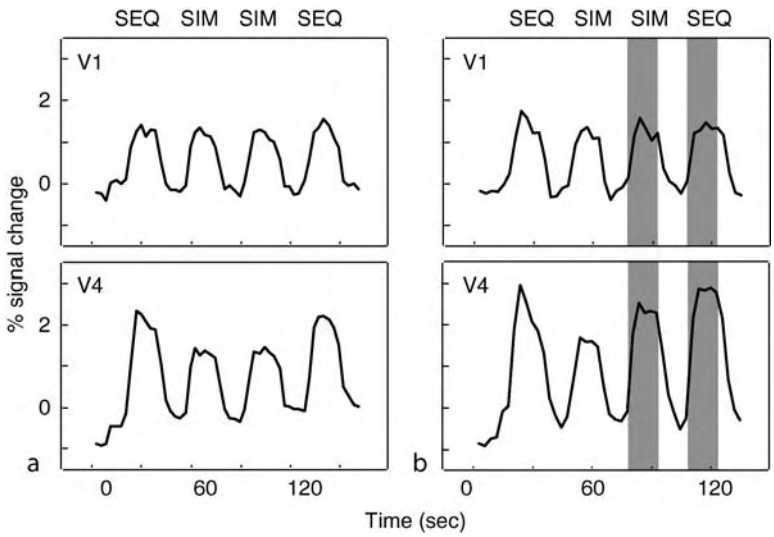
In a typical visual search task, subjects are given an array of stimuli (e.g. circles of different colors) and asked to report if a particular target stimulus (e.g. a red circle) is present in the array. Many factors affect the difficulty of this task. Anne Treisman and her colleagues have suggested that one important factor is how many features the target shares with other elements in the array. If the target (e.g. red circle) has a unique feature, such as being a different color from the distracters (e.g. green circles), the search is completed relatively quickly regardless of the number of elements in the array. This phenomenon is known as "pop-out" or efficient search. For other search arrays, where the target is defined by a conjunction of features (e.g. red horizontal line) that are shared by the distracters (e.g. red and green horizontal and vertical lines), search time increases as a function of the number of elements in the array. This is known as inefficient search, and each additional element in the array is thought to add about 50 ms to the time required to identify the target. Visual search type tasks are more similar to our everyday experience, where we typically face cluttered scenes with many objects that exceed our processing capacity. Due to limited processing capacity, multiple stimuli compete for processing resources in the nervous system. For instance, imagine you are watching your favorite TV program. This is much easier to do when alone in a room than when in a room full of rowdy children. The addition of sensory input interferes with your processing of the TV program. The neural substrate of competitive interactions among multiple sensory inputs in the visual domain is a mutual suppression of activity evoked by stimuli in nearby locations. In physiology studies, such suppressive interactions have been observed by comparing neural responses to stimuli presented alone in a neuron's RF to those evoked by the same stimulus when presented together with a second stimulus within the RF [1]. The response to the two stimuli presented together has been shown to be a weighted average of the responses to each individual stimulus. For instance, if a single effective stimulus elicits a high firing rate and a single non-effective stimulus elicits a low firing rate, the response to the two stimuli presented together will be somewhere in between the firing rates of the individual stimuli. Competitive interactions among multiple stimuli have been found in several areas of macaque visual cortex including areas V2, V4, MT, ►Cerebro-Cortical Area (MST), and IT.

Competitive interactions have also been reported in human visual cortex using a design in which four

stimuli were presented in nearby locations in the periphery of the visual field, while subjects performed a task at fixation [3]. The peripheral stimuli were either presented simultaneously, allowing neural competition to occur, or sequentially, resulting in less competition for neural resources as the stimuli were not present in the visual field at the same time. Activity was reduced in the simultaneous relative to the sequential condition, suggesting that the stimuli interacted in a mutually suppressive way (Fig. 2a). These suppressive interactions were smallest in area V1 and increased in magnitude toward ventral extrastriate areas V4 and ►Cerebro-Cortical Area (TEO) (Fig. 2a). This increase in magnitude of suppression effects across visual areas suggests that competitive interactions were scaled to the RF size of the neurons, given that only neurons in area V4 and TEO have large enough RFs to encompass all four stimuli. This idea was tested directly in a second study in which the separation among the stimuli was increased. When the stimuli were moved further apart, suppressive effects weakened in areas V2 and V4 while remaining unchanged in TEO. Taken together, these monkey and human studies have begun to provide a neural basis for competition among multiple stimuli in cluttered visual displays.

According to the ►biased competition theory of attention, competition among multiple stimuli can be biased by both bottom-up (stimulus-driven) and top-down (cognitive) factors. To probe bottom-up factors the four stimuli in the sequential/simultaneous paradigm described above were presented in a "pop-out" array, in which one stimulus differed in color and orientation from the others. Such an array results in an efficient search when probed in a visual search task. Competitive interactions among the four stimuli in the pop out array were eliminated, suggesting that competition was biased in favor of the salient "pop-out" stimulus.

Top-down attentional influences on competition have been studied in physiology studies, in which monkeys were instructed to attend to one of two stimuli present in the RF. Remarkably, neural responses to the attended stimulus were as large as if the stimulus was presented alone suggesting that attention operates by counteracting the suppressive influences of the second (distracter) stimulus [1]. Similarly, in humans, activity has been found to be greater for simultaneously presented (i.e. competing) stimuli when subjects attend to a stimulus in the presence of distracters (Fig. 2b). Taken together, these monkey and human studies suggest that attention may enhance processing of attended stimuli and counteract suppressive influences of distracters at intermediate stages of visual cortex. This may be an important mechanism by which unwanted information is filtered out effectively from cluttered visual scenes.



**Visual Attention. Figure 2** Competitive interactions and attentional modulation in visual cortex. (a) Suppressive interactions in areas V1 and V4. Simultaneously presented stimuli evoked less activity than sequentially presented stimuli in area V4, but not in area V1, suggesting that suppressive interactions were scaled to the RF size of neurons in visual cortex. (b) Attentional modulation of suppressive interactions. The suppression effect in area V4 was replicated in the unattended condition of this experiment, when the subjects' attention was directed away from the stimulus display (*unshaded time series*). Spatially directed attention (shaded time series) increased responses to simultaneously presented stimuli to a larger degree than to sequentially presented ones in area V4. (Adapted from Kastner et al., 1998.)

Feature-based attention mechanisms have also been investigated in the presence of distracters. The observation that neural responses to a selected feature increases regardless of where the animal attends has led to the hypothesis that feature-based attention may operate globally throughout the visual field. If one considers a visual search task where subjects are looking for a red circle in an array of colored shapes, it will certainly be advantageous from a computational point of view to increase neural responses to any red items, thereby marking the candidate target stimuli and restricting the remaining search to the subset of red shapes to ultimately find the circle. This is opposed to space- and object-based attention, which are both inherently tied to a spatial location. This hypothesis has been tested in physiology studies, in which the effects of feature-based attention on unattended stimuli were systematically investigated [6]. Two moving dot patterns were presented in different locations of the visual field. The direction of motion of each stimulus was varied independently while one stimulus was attended and the other one was ignored. Neural responses to the ignored stimulus were investigated while two factors were varied, the similarity of the attended motion direction in relation to the unattended neuron's directional tuning function (i.e. whether the attended direction constitutes an effective or non-effective stimulus for the unattended RF), and the similarity between the attended direction of motion and the direction of motion presented to the unattended RF. Enhancement of responses evoked by the unattended stimulus depended on both factors. Feature-based attentional enhancement was greatest when the motion direction of the stimulus in the unattended RF was effective and also when it matched the attended direction.

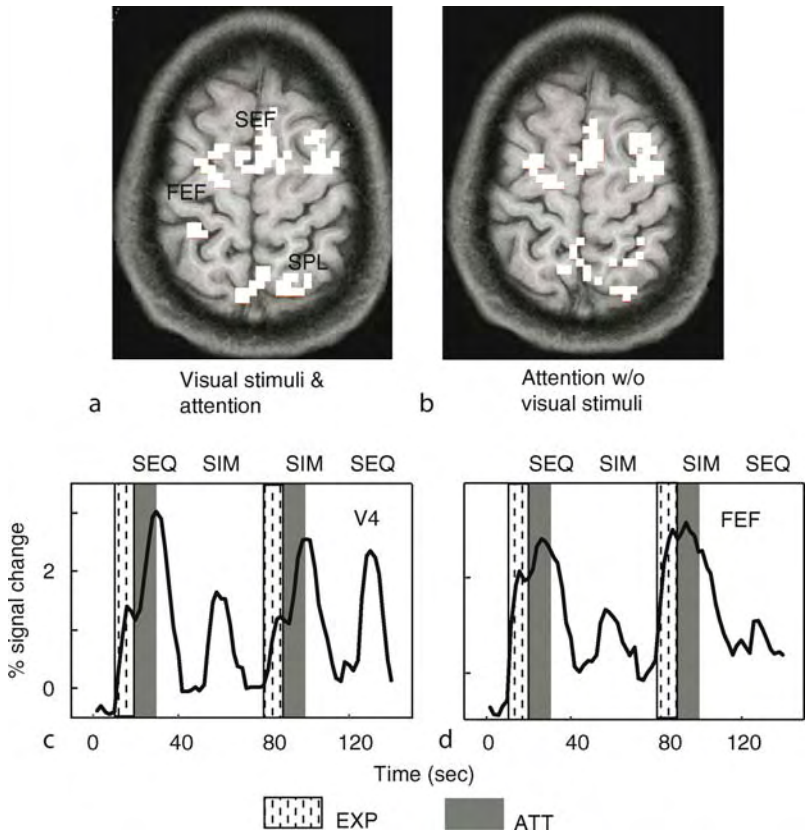
A similar effect has been observed in humans in an experimental design with two stimuli, one presented in each visual hemifield [7]. The attended stimulus consisted of two overlapping dot patterns, one moving upward and the other moving downward. The stimulus in the unattended hemifield always moved in the same direction (e.g. downward). ►fMRI signals were measured in the retinotopic representation of the unattended stimulus while subjects alternated between attending to the same direction as the distracter (i.e. downward) or to the opposite direction (i.e. upward). As in the physiology studies, signals evoked by the distracter stimulus were greater in areas V1, V2, V3, V3A, V4, and MT when it matched the attended direction. Taken together, these results suggest a feature-based attention mechanism that operates globally and biases processing throughout the visual field by enhancing the population response to attended features. This type of global attention mechanism might be important in guiding spatial attention to regions of the visual field that contain behaviorally relevant stimuli.

## Attentional Control Mechanisms in Frontal and Parietal Cortex

Converging evidence from patient, functional brain imaging, and physiology studies suggests that there is a distributed network of brain regions crucial for the control of attentional biasing signals that operate in visual cortex, as reviewed in the previous sections. It has long been known from the patient literature that unilateral brain lesions to regions of the ►parietal lobe, ►frontal lobe, ►anterior cingulate gyrus, ►basal ganglia, or pulvinar (►Visual role of the pulvinar) can result in an impairment in spatially directing attention to the contralateral hemifield, often referred to as ►visuospatial hemineglect. Patients suffering from neglect will ignore the visual hemifield contralateral to the side of the lesion, often failing to read from one side of a book, or ignoring food on one side of a plate. In less severe cases the deficit only becomes apparent when the patient is confronted with competing stimuli, such as in ►visual extinction. When visual extinction occurs, patients are able to orient attention to an object presented to their impaired visual hemifield in isolation, but not when a competing object is presented simultaneously in the normal hemifield. When two stimuli are presented simultaneously, one in each hemifield, patients will only detect the one presented to the intact side.

In human neuroimaging studies, a network consisting of the ►superior parietal lobe (SPL), ►frontal eye fields (FEF), and ►supplementary eye fields (SEF) (extending into the anterior cingulate cortex) has been found to be activated in tasks that involve spatial-, feature-, and object-based attention suggesting that it constitutes a general attention network (Fig. 3a) [8]. This network of brain areas heavily overlaps with that involved in oculomotor processing and thus appears to be recruited for both overt and covert attention [9].

Researchers have attempted to disambiguate regions involved with attentional operations, or "sources" that generate attentional biasing signals (i.e. the fronto-parietal network), from "sites" that receive the biasing signals via feedback connections resulting in modulation of ongoing processing in visual cortex. One such study in humans contrasted activations observed while subjects directed attention to a blank peripheral location in anticipation of the onset of a visual stimulus (expectation period) with activations following the onset of the peripheral stimulus while subjects detected the occurrence of a target stimulus [3]. During the expectation period, the same fronto-parietal network was activated as during the selection of relevant information, consisting of the SPL, FEF, and SEF (Fig. 3b). Importantly, there was no further increase in activity evoked by the attended stimulus presentations, rather there was sustained activity throughout the expectation period and the attended stimulus presentation (Fig. 3d). This is different from the activity in visual cortex, which increased during the



**Visual Attention. Figure 3** A fronto-parietal network for spatial attention. Axial slice through frontal and parietal cortex. (a) When the subject directed attention to a peripheral target location and performed a discrimination task, a distributed fronto-parietal network was activated including the SEF, the FEF and the SPL. (b) The same network of frontal and parietal areas was activated when the subject directed attention to the peripheral target location in expectation of the stimulus onset. (c) Time series of fMRI signals in area V4. Directing attention to a peripheral target location in the absence of visual stimulation led to an increase of baseline activity (*textured blocks*), which was followed by a further increase after the onset of the stimuli (*gray shaded blocks*). Baseline increases were found in both striate and extrastriate visual cortex. (d) Time series of fMRI signals in FEF. Directing attention to the peripheral target location in the absence of visual stimulation led to a stronger increase in baseline activity than in visual cortex; the further increase of activity after the onset of the stimuli was not significant. (Adapted from Kastner et al., 1999.)

expectation period but was also followed by an additional increase in activity during stimulus presentation (Fig. 3c). These findings suggest that activity in fronto-parietal cortex reflects the attentional operations of the task itself and not visual processing, implying that these regions are the sources of top-down biasing signals. This notion has been strongly supported by physiology studies in monkeys, in which subthreshold stimulation of eye movement representations within FEF resulted in spatial attention-like modulation of activity in retinotopically corresponding sites in area V4 [10]. Together, these studies indicate that the fronto-parietal network is the source of top-down attention signals that bias competition by facilitating neural processing of selected information and by filtering out suppressive influences of distracting information.

As reviewed in this chapter, visual attention comprises complex and flexible mechanisms that engage a widely distributed network of brain regions ranging from subcortical nuclei to high-level regions in frontal cortex. All of these areas cooperate to mediate the selection of relevant stimuli from the environment for further processing based on the cognitive demands of the behavioral context.

## Definition

This essay describes the neuronal elements and the basic circuits they form in the ►primary visual cortex. The primary visual cortex is a clearly defined area of the ►neocortex that receives input from the ►retina relayed by the visual ►thalamus and contains a complete representation of visual space. It has served as the key example for studies of the circuits and functions of neocortex.

## Characteristics

### The Structure of Visual Cortex

The visual cortex is one of numerous areas of the neocortex that contribute to high-level perceptual, motor, and cognitive functions. There are about $10^{11}$ neurons in the Central Nervous System (CNS), of which $10^{10}$ comprise the neocortex. Over 50% of the non-human primate neocortex is involved in visual processing, compared to about 11% for somatosensory, 8% for motor, and 3% for auditory processing. The visual processing takes place in many different areas of neocortex and they are connected together in a hierarchy. The primary visual cortex, which receives the earliest visual input, comprises less than 10% of the cortex ($10^8$ neurons in primates, and $10^{(6-7)}$ neurons in rat and cat). The primary visual cortex, also called ►visual area 1 (V1), ►striate cortex, or ►area 17, is the best-studied cortical area and so has been the primary source of knowledge of cortical neurons and circuits. As with the rest of the neocortex, the visual cortex is composed of six distinct layers. Its overall thickness is about 1.5 mm, which is about the average thickness of the neocortex across all mammals despite the wide range of brain size across species. The density of synapses ($\sim 10^8$ synapses/mm$^3$) is also remarkably constant across species. On the other hand, the density of neurons varies with cortical region, and histological layer. Sensory cortical areas, such as the visual cortex, have the densest neuronal packing (100,000 neurons/mm$^3$ in cat visual cortex, for example). On average, neurons receive the same number of synapses as they give, which is about 5,000 synapses. The axons that interlink cortical neurons in their local circuits extend only a few millimeters, but they are highly branched. If joined together, the nerve fibers contained within one cubic millimeter of neocortex would form a 4-km long thread. This is a vivid indication of the extreme degree of connectivity amongst the local cortical neurons.

Based on regional histological differences of the cortical layers, the primate neocortex can be divided into about 100 different areas, some of which correspond to functionally distinct areas. The cell densities in these various areas may differ significantly from the averages referred to above, with primary visual cortex. All regions of cortex are composed of the same basic types of neurons, which are found in approximately the same proportions throughout the neocortex.

### Synaptic Types

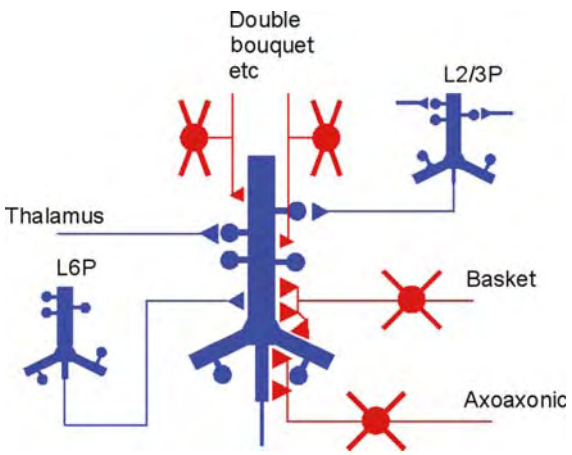
As in many other regions of the brain, the neocortex has two basic functional types of ►synapses, excitatory and

inhibitory. These functional types correlate with distinct morphological types: asymmetric and symmetric. There is a very useful correlation between the morphology of the synapses, and their function. The asymmetric synapses excite their postsynaptic targets, while the symmetric synapses inhibit their targets. The two types of synapse are named for the presence of electron dense specializations on their ►postsynaptic membrane, but their ►neurotransmitter-containing vesicles also have distinctive morphologies. The most obvious distinction is that the electron dense structures lining the pre- and postsynaptic membranes are of equal thickness for inhibitory synapses ("symmetric" synapses), but for excitatory synapses the thicknesses are "asymmetric," being much thicker on the postsynaptic side than the presynaptic. Symmetric synapses also usually have pleomorphic synaptic vesicles, while for asymmetric synapses the vesicles are spherical.

## Neuronal Types

There are no universally agreed criteria for classifying cortical neurons, but like synapses they come in two basic types, with many subdivisions (Fig. 1).

These two classes have physiological correlates: the spiny neurons of neocortex are excitatory, while the smooth neurons are inhibitory. The "spiny" cells are so-named, because their dendrites bear thousand of club-like protrusions called "►spine", which are a few microns in length. The smooth neurons are so-named, because they lack dendritic spines. Different types of spiny neurons are classified according to their shape of their dendritic tree and the layer in which their cell body is located, while the smooth neurons are classified, not on the basis of dendritic morphology, but on the basis of their axonal morphology. Spiny neurons have about $10^3$–$10^4$ spines per neuron. Spines are the major location where synapses are formed and each spine receives only one excitatory synapse. In addition to the excitatory synapse, about 8% of spines receive also an inhibitory synapse. Why some cells have spines and others do not, is not known. The role of the spine itself remains mysterious. One possibility is that spines offer some electrical advantage in controlling the effect of the spine synapse on the input to the post-synaptic neuron. Another possibility is that spines provide a local chemical environment that is isolated from the trunk dendrite and able to support specific metabolically mediated long-term changes in synaptic efficacy. Yet another is that the spines provide a motile "leash" that enables the postsynaptic neuron to select actively amongst the possible presynaptic input synapses in the vicinity of the spine.



**Visual Cortex: Neurons and Local Circuits. Figure 1**
Schematic of excitatory and inhibitory cortical neurons and their synaptic targets. In the center is a pyramidal cell (*blue*) with typical club-like spines, which form excitatory synapses with thalamic axons arising from the dorsal lateral geniculate nucleus (dLGN) and other pyramidal cells of layers 2/3 (L2/3P). The layer 6 pyramidal cells (L6P) form excitatory synapses. The pyramidal cell shown to be inhibited by axo-axonic or "chandelier" cells, by basket cells and by double-bouquets cells, each of which forms synapses on different parts of the pyramidal cell, including the initial segment of the pyramidal cell's axon.

## Spiny Neurons

Spiny neurons can be broadly subdivided into two groups: the ►spiny stellate cells, named for their radially symmetrical dendrites that give them a star-like appearance, and the ►pyramidal cells, which are characterized by one apical dendrite, which is much thicker than the basal dendrites (4–8 μm diameter, compared to 1–1.5 μm for the basal dendrites) and extends upward to the surface of the cortex. In the primary sensory areas such as the primary visual cortex, spiny stellate cells are the main cell type in layer 4, which is the major target layer of input from the thalamus. The axons of spiny stellate cells project horizontally within layer 4 and upward into the more superficial layers. Only rarely do they project out of their own cortical area. However, in the remaining layers the spiny neurons are represented exclusively by the pyramidal cells, which comprise 70–80% of all cortical neurons.

Pyramidal cells each have about 8 basal dendrites, dispersed radially about the soma and one apical dendrite, which gives rise to oblique branch dendrites close to the soma. Although the apical dendrite is a very prominent feature, it contributes only about 10% of the total dendritic length of the pyramidal cell. The overall length of basal dendrites, measured from soma to their tips, is 150–200 μm. The length of the apical dendrite depends on the cortical depth of the soma. Some layer 5 (L5) pyramidal cells have apical dendrites of over 1.0 mm. The pyramidal cells found in the superficial

layers of cortex (layers 2 and 3) have apical dendrites that ramify in the top of layer 2 and in layer 1. The local arborization of their axon is either in the superficial layers, or in layer 5 and 6.

In general the axons of the deep pyramidal cells arborize in the superficial layers or in the deep layers, only rarely in both. Many have axons that project out of the cortical area. The pyramidal cells of layer 5 can also be divided into two classes on the basis of the morphology of their dendrites. One class has thick apical dendrites that branch in top layer 2 and layer 1, and the others have thin apical dendrites that end in the superficial layers without further branching. Layer 5 is the only layer of visual cortex that projects to nuclei involved in motor control. A major target of the layer 5 cells is the ►superior colliculus, which is part of the system that drives ►saccadic eye movements. The apical dendrites of L6 pyramidal neurons ramify in layer 4, and the single thin apical trunk ends in the superficial layers. Their axons mainly in layer 4, but unusually, the majority of synapses made by layer 6 pyramidal cells are with dendritic shafts of other spiny neurons, not with their spines. Many layer 6 pyramidal cells also project back to the dorsal ►lateral geniculate nucleus (dLGN).

Spiny neurons make most of their synapses onto the spines and shafts of other spiny cells. 85% of the contacts are onto spines, and 14% onto shafts. Less than 50% of the postsynaptic shafts are ►GABA-ergic. 1% of the synapses are made with the cell bodies of GABA-ergic neurons. Overall, 80–90% of pyramidal cell synapses are made onto spiny cells, which are usually other pyramidal cells, and the remainder are made with smooth cells. Each pyramidal neuron usually forms only 1–5 synapses with a single target cell.

## Smooth Neurons

The smooth neurons comprise between 15–20% of cortical neurons. They are called "smooth" merely to indicate that they have very few, if any, spines. The smooth neurons have varicose, multipolar dendrites and are rather irregular in appearance. Smooth cells contain GABA and they make symmetrical synapses with their targets. Not all the symmetrical synapses of the cortex are made by synaptic boutons that contain GABA. Immunocytochemical studies have shown that some symmetrical synapses are formed by boutons that contain ►acetylcholine, ►noradrenalin, ►dopamine, ►serotonin, or ►neuroactive peptides. However, the vast majority (99%) of symmetrical synapses are formed by GABA-ergic synaptic boutons. The symmetrical synapses account for 16% of all synapses in the primary visual cortex.

Although smooth neurons only constitute a minority of cortical neurons, they seem to have more variety in their morphological appearance. The total number of different varieties is not certain, but each layer seems to possess its characteristic types. Layer 1, which is sparsely populated with neurons, contains only GABA-ergic neurons, which include the large horizontal ►Cajal-Retzius cell, which contain the protein "reelin," which is important for the control of neuronal migration. Many other types are found in all the other layers and include ►basket cells, ►chandelier cells (or "axo-axonic" cells), ►double-bouquet cells, ►neuroglia form cells and ►Martinotti cells. The exact proportions and connectivity of each cell type is not known. Each GABA-ergic neuron contains one of three different $Ca^{2+}$-binding proteins. The basket cells and chandelier cells contain a $Ca^{2+}$-binding protein called parvalbumin, while the double-bouquet cells contain calretinin, or calbindin. The parvalbumin-containing neurons form synapses on the proximal portions of their target neurons (cell body, axon initial segment, and proximal dendrites), while the calbindin- and calretinin-containing neurons form synapses on the distal parts of the dendritic tree of their targets. Experimentally, the basket cells are encountered most frequently, so most is known about them. Their axons ramify within the layer of its cell body. The superficial and deep basket cell axons may extend 1–1.5 mm, but the clutch cell axonal arborization is restricted to only about 0.3–0.5 mm. Each basket cell contacts about 300 target cells, making roughly ten synapses with each target. Each pyramidal cell receives input from about 10–30 basket cells.

We suspect that the different smooth cell types and the different distributions of synapses on their target neurons reflect different functions, but this has not yet been established. It is possible, for example, that different types of smooth cells effect either local, or inter-areal operations; or that some mediate different dynamics of inhibition. One celebrated case that begs a linkage between connectivity and function is that of the chandelier (axo-axonic) cell. These cells are located mainly in superficial layers and their axons terminate exclusively on the initial segment of pyramidal cells, mainly in the superficial layers. The initial segment is a thickening at the beginning of the axon that is thought to be the locus of action potential initiation, and is an attractive site for possible inhibitory control. However, the action of such inhibition is unknown.

## Inputs to Visual Cortex

### *Subcortical Inputs*

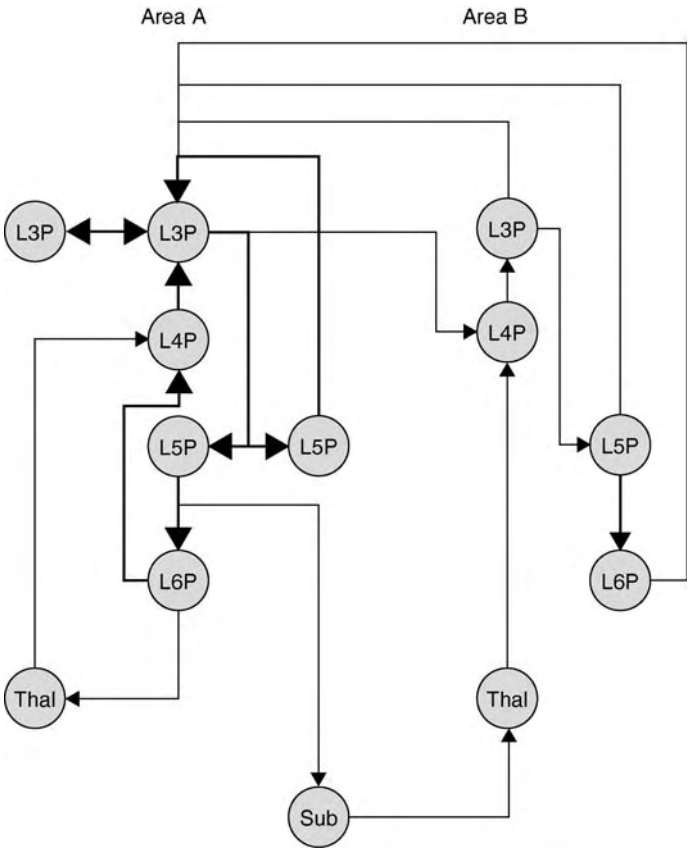
The local circuits in visual cortex receive their input from the dorsal lateral geniculate nucleus (dLGN) of the thalamus, which is the major nucleus for processing retinal information before passing it on to the primary visual cortex. In primates there are about $10^6$ neurons in the dLGN that project to the $10^8$–$10^9$ cells of V1. The input ratio of 1:1,000 gives some indication of the active role that the cortical circuitry must play in the

interpretation of the input data. Layer 4 is the principal target layer of the dLGN input (Fig. 2), but all other layers also receive an input from the dLGN. The dLGN is divided into eye-specific sublayers and this segregation of left and right eye is maintained in the distribution of dLGN axon terminals in layers 4 and 6, where they form patchy domains of terminals about 0.5 mm wide.

The left and right eye columns are reminiscent of zebra stripes when looked at from above and this pattern is known as "►ocular dominance columns."

The dLGN synapses are excitatory (glutamate is the neurotransmitter) and they activate both spiny and smooth cells. However, even in layer 4 the dLGN provides less than 10% of the total number of excitatory synapses. The arbor of a single dLGN terminal forms 1,000–10,000 boutons and each bouton forms on average more than one synapse. However, any particular cortical cell receives only a few synapses from a single dLGN relay cell, so each relay cell may form synapses with several thousand cortical cells. Thus, the contribution from one relay cell to a particular cortical cell is very small, and provides only a fraction of a percent of its total excitatory synaptic input.

In addition to the dLGN, which provides the major sensory input, about 20 other subcortical structures project to the neocortex. The monoaminergic systems are the best studied of these and include the dopamine-positive fibers arising from the rostral mesencephalon, the noradrenalin fibers originating from the ►locus coeruleus, and the serotonin fibers that originate from the mesencephalic ►raphé nuclei. The monoaminergic projections are thought to be facultative in the processes



**Visual Cortex: Neurons and Local Circuits. Figure 2** Graph showing the dominant interactions between significant excitatory cell types in neocortex, and their sub-cortical and interareal relations. The nodes of the graph are organized approximately spatially; vertical corresponds to the layers of cortex, and horizontal to the lateral extent. *Linking arrows* show the direction of excitatory transmission. *Lines in bold* indicate the relations between excitatory neurons in a local patch of neocortex *Thin lines* indicate excitatory connections to and from subcortical structures and other cortical areas. Each node is labeled for its cell type. For cortical cells the number after "L" refers to the layer in which the cell body is located and P indicates that it is an excitatory neuron (generally of pyramidal morphology). "Thal" denotes the dorsal lateral geniculate nucleus of the thalamus, and "Sub" indicates target structures such as the superior colliculus.

of ►cortical plasticity. However, the dopaminergic neurons, which are thought to provide an error signal during ►trial-and-error learning, project mainly to the prefrontal cortex and not to the primary visual cortex.

### Outputs from Visual Cortex

Of the $10^{10}$ cells in cortex, only about $10^{(7–8)}$ project to extra-cortical targets. This means that over 99% of cortical cells are involved only in intracortical circuits. The inter-areal projections are exclusively axons of spiny cells. The targets of these projections are always both spiny and smooth cells. None of the projections in cortex that have been studied so far terminate exclusively on excitatory or inhibitory targets. However, the ratio of excitatory to inhibitory terminations may vary and so the balance of excitation and inhibition could be an important aspect of each projection.

Superficial pyramidal cells tend to project to other cortical areas, whereas deep pyramidal cells tend to project both to other cortical areas and subcortically (Fig. 2). The extent of the subcortical projections is quite large in some contexts. For example, the projections from the L6 pyramidal cells to the LGN are ten times more numerous than the geniculocortical projections themselves. The purpose of this arrangement is still not known.

Although most pyramidal cells project outside their cortical area, they have extensive collaterals that project within their local area and they make about 80% of their synaptic contacts within a few dendritic diameters (1–2 mm) of their cell body. Thus, the major component of cortical processing seems to be local. Where projections between cortical areas occur, they are usually associated with a reciprocal connection from their target area. Usually the forward projections arise from the pyramidal cells of the superficial layers and terminate in the middle layers of the target area, whereas the backward projections arise in layers 3 and 5 of the target area and terminate outside the middle layers – in layer 1 and 2 and layer 5 and 6 of the target area.

### Organization of Neuronal Types in Circuits

There are two features of cortical neurons that simplify the analysis of cortical circuits. One is that the dendritic and axonal projections of the different types of neurons are laminar specific. The second is that the different types of neurons make stereotyped synaptic connections with each other. For example, all spiny cells make 85% of their connections with other spiny cells. When a layer 5 pyramidal cell axon is observed to form most of its synaptic boutons in layer 6, then it is safe to assume that its major connection is to the pyramidal cells of layer 6. By defining the principal layers to which the different spiny cell axons project and assuming that they connect mainly to the neurons located in the target layers, a possible basic circuit of the cortex emerges (Fig. 2).

In this basic circuit, the thalamic input arrives in layer 4. The excitatory cells in layer 4 project to the superficial layers. The superficial pyramidal neurons project to layer 5, which in turn project to layer 6, and the loop is closed by a projection from layer 6 to the input layer 4 (Fig. 2). This circuit infers only the connections of the spiny, excitatory neurons. The spiny neurons as a class provide most of the inter-laminar connections within a cortical area, whereas the axons of smooth neurons principally arborize locally within their layer of origin. The cardinal feature of the circuits of the necortex is that they form rich excitatory and inhibitory connections with each other. These are referred to as "recurrent" circuits.

Overall, the spiny cells provide the basic framework of long distance excitation in both the vertical and lateral dimensions, which is then shaped by local inhibitory neurons. In the visual cortex this sequence of processing was thought to be the mechanism by which the ►receptive fields are elaborated from simple to complex. The interlaminar connections are also the means whereby common properties are transmitted to a radial "column" of cells. This "columnar" organization of functional properties is the means whereby common functional attributes can be represented by all the neurons in a given patch of cortex. In the visual cortex there are many common properties shared by all the neurons in a radial column that extends from layer 1 to layer 6, including common position in their representation of visual space, orientation of the stimulus, and their eye preference. These local circuits between and within the 6 layers of the visual cortex provide the major processing required to correctly interpret the enormous amount of information relayed from the retina by the dLGN every second. While we understand more about the elements that make up the visual cortex than any other area, we are still some way from understanding the general principles by which visual cortex processes its inputs.

## Synonyms

Center-surround receptive fields; Simple receptive fields; Complex receptive fields

## Definition

The term ►receptive field refers to the region of visual space where changes in luminance influence the activity of a single neuron. Receptive fields of different types of cells in the visual pathway have different substructures. For example, receptive fields with a center-surround structure are common in the ►retina and ►lateral geniculate nucleus of the ►thalamus whereas most cells in the ►primary visual cortex have either simple or ►complex receptive fields.

## Characteristics

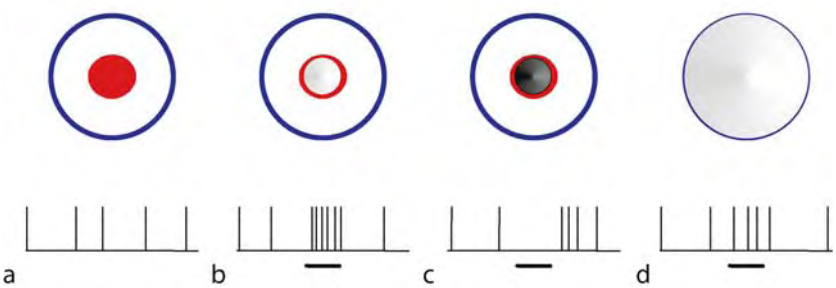
### Subcortical Receptive Fields

#### *The Retinal Receptive Field*

Although we see the world as a seamless whole, our perception is based on the contribution of many cells, each encoding only a small area of visual space. An individual neuron's window on the world is called its "receptive field." This term was coined by Hartline to explain his observations of how single retinal ganglion cells (►Retinal ganglion cell) in the frog's retina respond to light [1]. Hartline described the receptive field as the retinal region where a change in luminance either reduced or increased a neuron's activity. Later, Kuffler, recorded from ganglion cells in the mammalian retina and found that their receptive fields had a stereotyped substructure [2]. The entire field covered a roughly circular patch that was divided into two concentric subregions; a disk shaped "center" and an annular "surround" (Fig. 1a). The border between the center and surround was defined by preference for stimulus ►contrast. A spot of light shone in an On subregion evoked excitation at short latency (Fig. 1b). If the dark spot was flashed in same place, however, firing rate increased only after the stimulus was removed (Fig. 1c). Thus, On responses are driven by increases in luminance and Off responses by decreases in luminance. Based on such response patterns, Kuffler divided ganglion cells into two classes, ►On center cells and ►Off center cells.

#### *Antagonism Between the Center and Surround Retinal Receptive Field*

Kuffler also found that the center and surround had an antagonistic influence on each other (►Center-surround antagonism). This mutual suppression results from push-pull responses to stimuli of the reverse contrast within each subregion; that is, where bright stimuli excite, dark stimuli inhibit. How does the geometry of the receptive field combine with push-pull to influence neural responses? As mentioned above, a small bright spot confined to an On center evokes robust excitation. If that bright spot is presented along with a dark annulus in the surround, then that bull's-eye stimulus elicits even greater excitation. But, if the both the On center and Off surround are filled by a large bright stimulus, the level of excitation induced is less than that driven by illumination of the center alone, (Fig. 1d). Ganglion



**Visual Cortical and Subcortical Receptive Fields. Figure 1** Neural responses of cells with center-surround receptive fields. Panels (a–d) represent responses of a single On center retinal ganglion cell or thalamic relay cell to different types of visual stimulation; the On center is represented by a red disk and the surround by a blue circle. In ambient lighting, the cell fires spontaneously (a). A bright spot falling in the center is excitatory; stimulus position is indicated by the shaded disk in the receptive field and stimulus duration is symbolized by the horizontal bar at bottom (b). A dark stimulus at the same position suppresses firing (c). Stimulation of the center and surround with bright light evokes weaker excitation than illumination of the center alone (d).

cells with Off centers and On surrounds behave in a commensurate fashion.

### Functions of the Retinal Receptive Field

Not long after Kuffler's work was published, it became clear that structure of the retinal receptive field was well suited to perform specific tasks in visual processing. The concentric placement of On and Off subregions made single cells sensitive to local changes in stimulus ►contrast (as if each cell were a spot detector). The antagonistic relationship between subregions enhanced this sensitivity and served another function too. Specifically, Barlow and colleagues suggested that subfield antagonism reduces redundancy in the visual signal transmitted downstream to the thalamus and cortex [3] (►Sensory senses). This reduction is analogous to image compression in computer vision. The importance of this concept has gained importance over time as it has become clear that natural images, like those of the landscapes or social gatherings we see daily, are themselves highly redundant (►Experience with natural images as a basis for vision). That is, natural images contain significant spatial correlations – neighboring points in the image often have similar luminance values [4] (►Vision). Subfield antagonism reduces the number of spikes that are required to convey information about redundant segments of the visual scene. Last, apart from its role in visual processing *per se*, subfield antagonism helps to conserve energy by limiting the number of spikes required to encode images – spikes, after all, are metabolically expensive.

### Similarities and Differences in the Receptive Fields of Different Retinal Ganglion Cells

There are many types of ganglion cells, with the greatest diversity found in primates (►Retinal ganglion cells; ►Visual processing streams in primates). Cells in each class form a layer in the retina and are arranged as an anatomical mosaic such that their receptive fields tile all of visual space. Even though ganglion cells all have receptive fields with a center-surround structure, for some the border between center and surround is defined by sensitivity to different wavelengths rather than intensities of light. In other words, some types of ganglion cells have subregions divided by preference for stimulus color rather than contrast. Another difference among the receptive fields of different ganglion cells is size. Some classes of ganglion cells have receptive fields that are relatively small (e.g. X cells in the cat or P cells in the monkey) or large (e.g. Y cells in the cat or M cells in the monkey) at any given position in the retina. Cells with the smallest fields confer the finest degree of spatial acuity; that is, they are tuned to the highest spatial frequencies [5]. Despite such differences among classes of ganglion cells, the structure of the retinal receptive field can be generalized. It is often characterized mathematically as the difference of two Gaussians, one a narrow function representing the center and the other a wide function symbolizing the surround [5].

### The Structure of Receptive Fields in the Lateral Geniculate Nucleus of the Thalamus

Retinal ganglion cells project to the lateral geniculate neurons of the thalamus. Relay cells in the lateral geniculate nucleus reprise the center-surround structure of their presynaptic partners [6]. Yet, this does not mean that the thalamic fields are direct copies of those in retina. A single relay cell might receive inputs from multiple ganglion cells, hence remixing the spatial information sent from retina. The subregions that build thalamic receptive fields also are mutually antagonistic and have a push-pull arrangement of excitation and suppression. This pattern is not simply fed forward from the eye, however; it is generated *de novo* by local inhibitory circuits.

## Receptive Fields in the Primary Visual Cortex

### Simple Receptive Fields

Hubel and Wiesel joined the Kuffler laboratory and made the first recordings from the primary visual cortex. They found a population of cortical neurons that they named ►simple cells because of striking similarities with relay cells [6]. Like receptive fields in the thalamus, simple receptive fields were divided into On and Off subregions that had an antagonistic influence on each other. Unlike the subcortical concentric pattern, however, the On and Off subregions were elongated and lay side by side. What made this discovery so exciting was that the new geometric arrangement correlated with the emergence of neural sensitivity to stimulus ►orientation. In the thalamus, a ►contour of any orientation drives cells vigorously, provided the stimulus covers a much larger fraction of the center than the surround. This is not the case for simple cells. These neurons respond briskly to a stimulus aligned with the long axis of a sign-matched subregion; for example, a bright bar flashed over an On subfield elicits a strong discharge. But as the bar is tilted farther and farther away from the preferred angle, it evokes fewer and fewer spikes.

Thus, as in the retina and thalamus, the structure of this new type of cortical receptive field has the potential to explain how neural response properties are generated. In the retina and thalamus, neural receptive fields confer sensitivity to highly localized boundaries in light intensity. This local selectivity is pooled by cortical neurons for the detection of spatially extended contrast borders, e.g. edges, of various orientations. The ability to detect oriented contours is widely viewed as an essential step in parsing the visual scene into its meaningful components. Moreover, in the spirit of Barlow, theoretical studies show that the simple

receptive field is ideal for efficiently encoding natural images [4].

### Circuits Build the Simple Receptive Fields

By marking recording sites with electrolytic lesions, Hubel and Wiesel linked the simple receptive field to cortical layers 4 and 6, the regions where thalamic afferents terminate. Combining this anatomical result with their physiological observations, they proposed a model of how cortical receptive fields were built. The essence of the idea is that convergent input from On and Off center relay cells, whose receptive fields are aligned in visual space, build the On and Off subregions of the cortical fields (Fig. 2a, left) (see also ►Geniculostriate pathway; ►Striate cortex functions). This feedforward circuit for the simple receptive field has received substantial experimental support [7]. Also, the circuit has been expanded to include inhibitory simple cells that complete a push-pull profile within subregions [7] (Fig. 2a, right). Although simple receptive fields vary in terms of the number, length and width of component subregions, they have a stereotyped shape and are often represented in computational models as 2D Gabor functions (sinusoidally modulated Gaussian functions) [8].

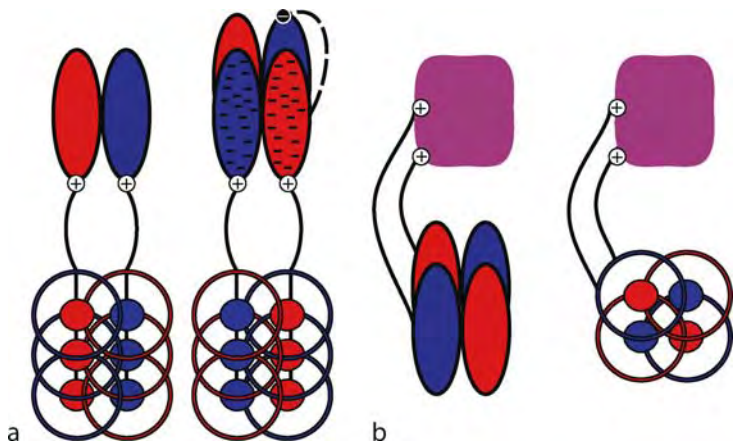
### Complex Receptive Fields

A second type of cortical receptive field is called complex. This category was originally defined by exclusion to encompass all receptive fields that lacked spatially opponent and mutually antagonistic subregions [6]. Most ►complex cells that Hubel and Wiesel reported were tuned for stimulus angle and were excited by bright or dark bars placed anywhere within the receptive field (there are exception to these rules; a fraction of complex cells respond only to stimuli of one contrast while others are not oriented). Hubel and Wiesel originally believed that all complex receptive fields were generated hierarchically by convergent input from simple cells that had the same orientation preference but different arrangements of On and Off subregions (Fig. 2b, left). It later became clear that a minority of complex cells receive direct input from lateral geniculate relay cells (Fig. 2b, right). Presumably there are also complex receptive fields that are constructed by input from other complex cells. Complex cells are found in all six cortical laminae, with stereotypic differences in response properties in each layer [7].

The idea of the hierarchically constructed complex receptive field was formalized with the "energy model" [9]. The model builds complex receptive fields by squaring and summing the responses of Gabor filters that represent simple cells. These Gabor filters have similar spatial frequencies (the simulated subfields are of equal width) and orientation but are arranged in quadrature so that the "On" and "Off" subregions overlap.

### Mapping Cortical Receptive Fields

Different techniques are required to map simple vs. complex receptive fields [10]. Simple receptive fields can be mapped easily with stimuli like visual noise. One of the first noise patterns used was sparse noise – small, dark or bright rectangles flashed individually in random order [8]. The power of modern computers has made the use of complicated noise patterns, like those with a Gaussian distribution of luminances, common as well.



**Visual Cortical and Subcortical Receptive Fields. Figure 2** Hypothesized wiring diagrams for cortical receptive fields. Convergent input from thalamic relay cells with aligned On (*red*) and Off centers (*blue*) provide excitation to On and Off subregions of the simple receptive field; conventions as in Fig. 1 (a, *left*). Local inhibitory simple cells, labeled with minus signs, mediate suppression evoked by stimuli the non-preferred contrast (a, *right*). Complex receptive fields built by convergent input from co-oriented simple cells whose receptive fields overlap and have similar shapes but the reverse placement of On and Off subregions (b, *left*). Convergent input from On and Off relay cells with overlapping receptive fields form some complex fields (b, *right*).

Simple receptive fields can easily be reconstructed from the responses to such stimuli with the method of ►spike-triggered averaging. This technique defines the receptive field as the average of all stimuli that appear a short time before each spike occurs. Spike-triggered averaging, however, is not appropriate for characterizing complex receptive fields. For example, the average of all stimuli that evoke spikes for cells in which On and Off responses spatially overlap would approach zero. Thus, sophisticated methods such as spike-triggered covariance, which recover second- and higher-order aspects of the stimuli that drive spikes, are required [10].

An important message to take home from the description of complex cells is that their receptive fields alone do not provide sufficient information to predict the neural response to a given stimulus. Nor does the structure of the complex receptive field necessarily provide information about underlying circuitry. Thus, the idea of the receptive field as defined by Hartline becomes less powerful at higher levels of cortical integration. At these later stages of processing, the term receptive field is often stretched to include the best mathematical model that can be made to predict a given cell's response to visual signals. Last, Hartline defined the receptive field as spatial construct, but most modern descriptions include a temporal dimension as well.

### *Alternative Definitions of Simple and Complex Cells and Consideration of Species Differences*

There is a separate criterion used to separate simple from complex cells that is not based on receptive field structure *per se*, but on the linearity of response to sinusoidal gratings. The test for linearity comes from an important approach to visual processing based on spatial and temporal frequency analyses [5]. Linear responses were once thought to be restricted to cells whose receptive fields had separate On and Off subregions, i.e. simple cells. But complex cells that respond exclusively, or much more strongly, to dark stimuli than to bright ones also respond to gratings in a roughly linear manner. Indeed linear responses are found in all cortical layers, suggesting that different types of circuit operate in this fashion. Understanding how such circuits are built might help explain ►orientation selectivity in higher species, which develops fully at intracortical stages of processing rather than at the thalamocortical level as in cat. In particular, it is not clear if simple cells provide the sole route to orientation selectivity in primates. Along this line of thought, the circuitry underlying the receptive fields described here has been delineated in the cat, whose cortex has been studied more intensively than that of any other animal. Future research is required to understand the circuits that build receptive fields in primates.

Last, not all authors classify simple and complex cells based on the types of receptive fields that Hubel and Wiesel described, nor on measurements of the linearity of response. Thus, when reading the literature, it is useful to read each group of authors' own criteria for categorizing receptive fields.

# Visual Cortical Processing Streams

## Definition

Visual cortical processing streams denote sequences of cortical visual areas involved in processing different aspects of the environment. The dorsal cortical pathway is dominated by input from parasol retinal ganglion cells, projects through cortical areas including MT, MST, LIP and VIP, and is thought to be crucial for motion and localization analysis. The ventral cortical pathway is dominated by input from midget retinal ganglion cells, projects through cortical areas including V4 and inferotemporal cortex (IT), and is thought to be crucial for color and form analysis.

## Visual Dependence/Independence

### Definition

Subjects whose verticality perception (and spatial orientation) is/is not influenced by background visual stimuli (e.g. static frames or rotating disks).

►Verticality Perception

## Visual Extinction

### Definition

►Visual Attention

## Visual Field

### Definition

The visual field (synonym for field of view) is the total area in which objects can be seen. Visual fields are typically measured in terms of angular co-ordinates centered on the direction of gaze. One might therefore characterize a normal visual field (in humans) for one eye as extending about 60° upward, 75° downward, 60° laterally toward the nose and 100° laterally toward the temple. Visual fields are measured using a device called a perimeter.

## Visual Field Defects

### Definition

Various pathologies can cause visual field defects, that is, areas of blindness. These pathologies can affect the retina, areas of the brain involved in visual processing or the neural tracts that link these areas.

### Definition

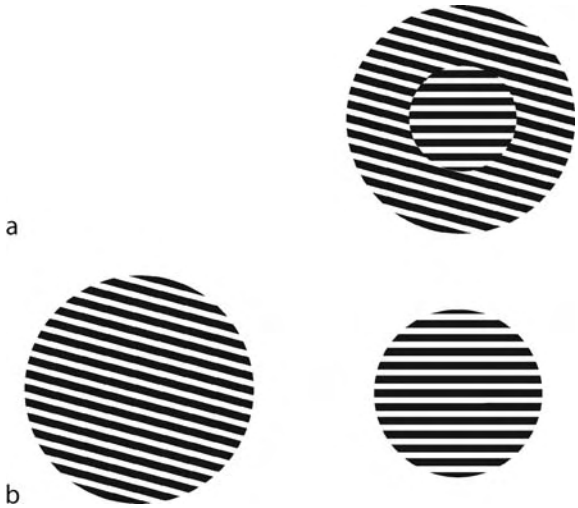
Unfortunately, there is no generally agreed definition of visual illusions [1] and, as a result, some visual phenomena are classed as illusions by some authors but not by others. For example, similar effects often occur both when all parts of a stimulus are displayed simultaneously (often called "►illusion") and also when certain parts are presented successively (often called "►aftereffect"). In Fig. 1a, the surrounding grating tilted down on the right makes the surrounded horizontal grating appear tilted up on the right (the "tilt illusion"). The same tilt misperception occurs in Fig. 1b if one adapts to (stares steadily at) the grating on the left for 30 s and then looks at the horizontal grating on the right (the "tilt aftereffect"). Some authors classify aftereffects as illusions.

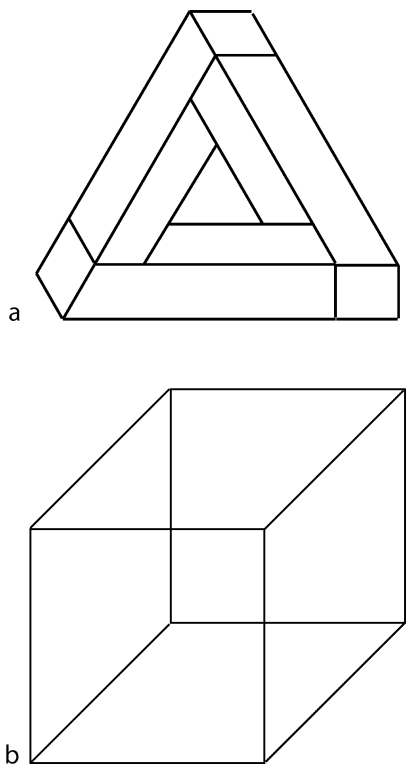
The definition of illusion adopted here is: A visual illusion occurs when there is a discrepancy between a physical stimulus and the perception of that stimulus, despite the normal functioning of the visual system. With this definition, an aftereffect is not an illusion because ►adaptation causes the visual system to be modified temporarily so that it is not functioning normally. So the effect in Fig. 1b is not strictly an

illusion but the effect in Fig. 1a is an illusion, because it occurs without adaptation.

Several authors [e.g., 2] regard Penrose's impossible triangle (Fig. 2a) and the Necker cube (Fig. 2b) as illusions but with my definition of illusions they are not.



**Visual Illusions. Figure 1** Tilt illusion (a) and tilt aftereffect (b). For details see text.



**Visual Illusions. Figure 2** Penrose's impossible triangle (a) and Necker cube (b). For details see text.

Each corner of the triangle looks like a proper corner in depth when viewed locally but no such three-cornered global triangle could exist in depth. However, there is no sense in which there is a discrepancy between the physical display and the perception. Similarly, the Necker cube perceptually fluctuates in depth so that it appears sometimes as being viewed from above, sometimes from below, but neither of these bistable percepts is a discrepancy between the stimulus and the percept. It is simply that the minimal depth information in the drawing is consistent – not discrepant – with either view.

## Characteristics

### A functional Approach to Illusions

It is clear from the above that the term "illusion" is a difficult one and it has even been suggested that the term is no longer useful [1]. One reason for this is that there is often "a discrepancy between a physical stimulus and the perception of that stimulus, despite the normal functioning of the visual system" due to nothing other than the design limits of the visual system. For example, metamerism, the fact that a mixture of three primary spectral lights can be used to match a monochromatic light is a mistaken perception because the two stimuli are physically different yet look the same. However, this "discrepancy" is more usefully viewed as the result of normal human ►trichromacy. Although human observers would make fewer mistakes in the domain of color vision if they had more than three cone types, it is likely that having just three types provides sufficient disambiguation of sensory signals to achieve most of what needs to be achieved in operating in the world, most of the time.

Beginning with Helmholtz, there is a strong tradition of viewing the visual system as sets of mechanisms that are designed to interpret incoming sensory data and that use inference, knowledge of constraints and other "tricks" to compensate for the limitations in the sensory input so as to optimally recover properties of the world [2]. Recently, there has been a strong revival of this conceptual approach using Bayesian theory (see below).

### Illusions in the History of Psychology

In his book entitled *The Psychology of Visual Illusion* [3], Robinson notes that "a large proportion of all that is in this book was described by Helmholtz (1856) in his *Handbuch*" [4]. Between 1856 and the present it is possible to identify four broad phases in the scientific study of illusions: the early approach to ►geometrical illusions; illusions used as exemplars to promote general theories of perception ("Schools" of Psychology); the "feature detector" approach based upon the explosion of knowledge of visual neurophysiology; and current modelling approaches.

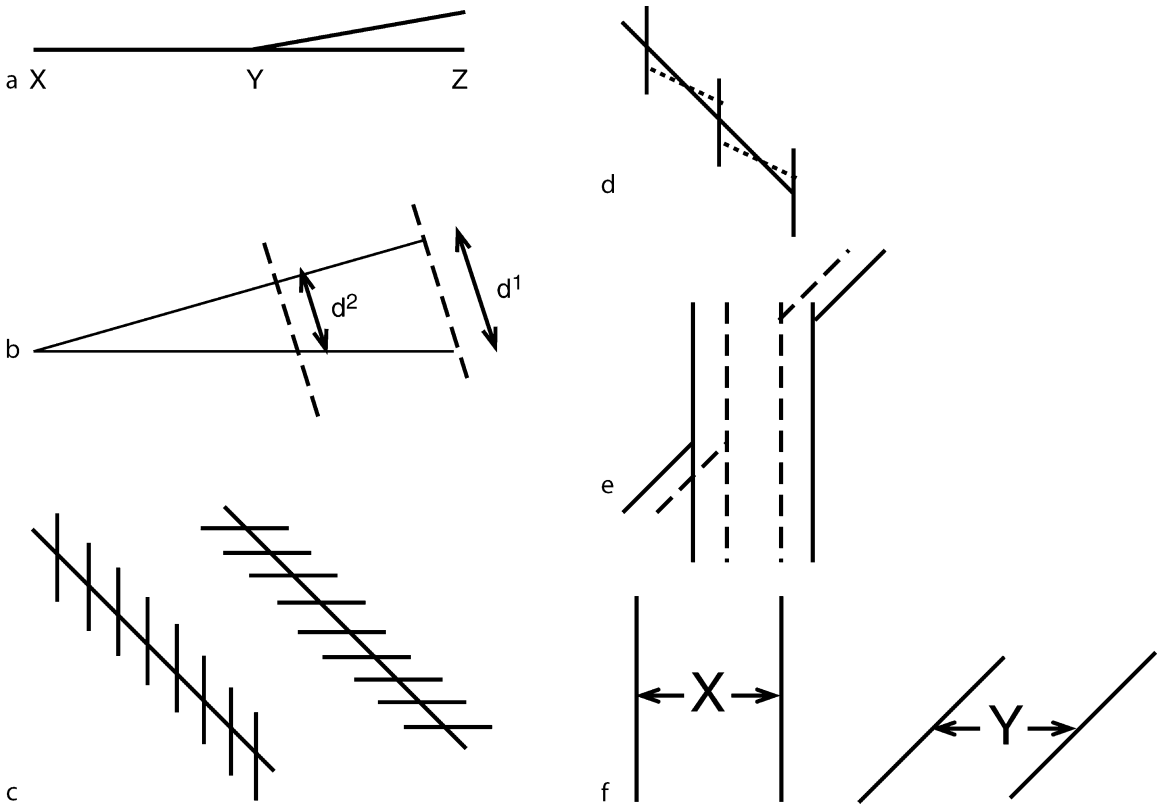
### The Early Approach to Geometrical Illusions

First, for many years around the turn of the twentieth century, illusions were studied by many as curiosities and as primary targets for explanation in their own right. Emphasis was on how many different illusions, mainly those evident in geometrical drawings, could be explained in terms of the same principles. A favorite way of attacking this question was to attempt to show that one illusion could be explained in terms of another and a master of this method was Judd [5]. Fig. 3 demonstrates a Euclidean *tour de force* that actually reveals nothing at all about the mechanisms underlying the illusions and also tells us nothing about visual processes. Thus, in Fig. 3a, the acute angle arm, YZ, looks shorter than the obtuse angle arm, XY. Therefore, in Fig. 3b, the true distance between the acute angle arms, d1, appears to lie closer to the vertex, at $d^2$. Because $d^1$ is a longer distance than $d^2$ acute angles look larger than they are. This in turn accounts for the Zöllner illusion (Fig. 3c) in which the long parallel lines appear to diverge at the top, because the acute angle segments (dotted) appear expanded.

However, the dotted oblique lines in Fig. 3d are shorter than the solid oblique segments so the distance between vertical parallels will be underestimated. This "explains" the Poggendorff illusion in which oblique and truly collinear transverse test segments appear noncollinear (Fig. 3e): because the parallels appear (dashed parallels) closer than they really are the perceived transversals must appear misaligned and, in addition, Judd predicted and found (Fig. 3f) that the distance, Y, between oblique parallels appears shorter than that, X, between vertical parallels. It should be noted that many of Judd's "explanations" have been shown to be false.

### Schools of Thought in Psychology

The second phase of the study of illusions, in the first half of the twentieth century, saw the rise of the "schools" of perception psychology: the ►Gestalt movement, ►Transactional Functionalism and the ►Direct Perception movement, propagated by James Gibson. In all three of these movements, the initial question was "Why do things look as they do?" and as has been pointed out, to ask such a general question of all perceptual phenomena simply guarantees an answer so broad as to be meaningless, because the answer cannot contain principles or processes that apply to



**Visual Illusions. Figure 3** (a–f) Various geometrical illusions. (c) Zöllner illusion. (d) Poggendorf illusion. For more details see text.

only a subset of perceptual phenomena [6]. Nevertheless, illusions were used by the Gestaltists to argue that all perception is due to innate brain organizing processes so that, for example, a coin that is tilted and so is elliptical on the retina appears circular, as it really is, because innate brain processes make shapes as "good" as possible. The Transactionalists built a distorted, nonrectangular room that looked like a normal room through a peephole. Consequently, although two people in the room looked equidistant from the observer, the one who was actually much closer looked huge and the other, much further away, looked like a dwarf. The Transactionalists wanted to assert that all perception is determined by past experience and argued that experience dictates the normal room percept and also allows the illusory percept of different sized people. Interestingly, although these theorists never addressed the illusions presented by the other group, it is clear that past experience could "explain" the circular appearance of the coin; and brain forces that made objects as "good" as possible could "explain" the room's looking normal and rectangular. Gibson ignored illusions altogether, arguing that perception is a "function of stimulation" and, since illusions are by definition not a function of stimulation they are not perception either.

### The "Feature Detector" Approach to Illusions

In the third phase of the study of illusions, interest in the classic geometrical illusions (e.g., Fig. 3) waned; rarely were illusions studied for their own sake; and illusions were not (usually) used to bolster general theories of perception. Rather, with the explosion of knowledge of neurophysiology and new imaging methods such as ►fMRI, researchers have used the knowledge of visual mechanisms in nonhumans to predict visual illusions that would be expected to occur if humans had the same machinery; and they use newly discovered illusions to infer the presence of underlying neural mechanisms that can be searched for in the brains of non-human animals. This more modern approach to the study of illusions dates back to at least 1963, when a study of adaptation in rabbit retina by Barlow and Hill [see 2] led to this comment regarding the ►motion aftereffect (but the comment equally applies to illusions): "Finally, it is interesting to ask if the argument can be used in reverse. If after-effects are due to the imbalance of maintained activity of units [i.e., neurones] specifically excited by features of the inspection [i.e., inducing] figures, *can one deduce the nature of the units which analyse sensory data from the nature of the after-effects which are so readily produced?*" [my italics] (p. 1374). Although many physically different stimuli can produce the same output from a single unit or neuron so that no one such cell can literally be a "detector" of anything, the fact that visual neurones exhibited narrow ►tuning curves to various parameters of a stimulus (e.g., orientation, motion direction, color, etc.) often led to the misleading use of the term "feature detectors" to describe these neurones. Explanations of illusions (and aftereffects) were then sought in terms of interactions between populations of neurones that are selectively tuned to the features of the ►inducing and test stimuli. The general notion was that illusions were perceptual mistakes that arose as unfortunate by-products of normal perceptual processes.

### Modeling Mechanisms and Processes in Vision

Vision scientists often use conceptual models to help explain and understand the mechanisms of vision. This entails explicit mathematical descriptions of brain processes that are hypothesized to occur under particular experimental conditions, using the constraints of known neurophysiology and ►psychophysics: ►computational modelling. This contemporary approach often tends not to regard illusions as regrettable side effects of normal vision but rather as manifestations of the visual system's "best guess" as to the state of the world, given the available noisy sensory data. This more functional approach, which has its origin in Helmholtz's notion of "unconscious inference" [4], has recently been revived in Bayesian models of visual perception. Proponents of this approach consider that the visual system performs some form of Bayesian inference to derive a perception from sensory data, using prior probabilities and likelihood calculations. Models based on this idea have been used to describe various visual subsystems, including motion perception, with very impressive fits to a variety of data sets [7].

Whether an illusion is experienced or not or what kind of illusion occurs with a particular visual stimulus can depend entirely upon the task given to the observer [8]. The Bayesian idea that perception, including perceptual error, does not arise from direct experience of sensory events but rather from likelihoods calculated from those sensory events, has been shown to predict that exactly the same visual stimulus may induce an illusion or may not, depending upon the task [9]. When observers are asked to judge whether dots are drifting to the left or right of a marker, neurones tuned to the marker direction are not very helpful because their response to the marker direction and slightly different directions is almost the same. Neurones tuned to directions somewhat different from the marker direction are more useful, because the slope of their tuning curve means that differences in their responses to the marker direction and a slightly different direction are much larger. Hence, the optimum strategy is to more heavily weight responses of neurones tuned to directions away from the marker direction and this results in a repulsion illusion for such a fine discrimination. But when the task is to judge whether the dots are moving toward or away from the marker, a very coarse discrimination, the

best strategy is to weight most heavily the responses of neurones tuned precisely to the marker direction and in that case an attraction illusion occurs. The occurrence of illusions has sometimes been taken to indicate that there are two spaces, the physical and the psychological. But as Morgan (1979) noted, there is only one physical space on which we perform operations or tasks, and it is no surprise that physically different operations can produce physically different outcomes [see 8].

### Why Study Visual Illusions?

Neuropsychologists often learn about the normal working of the brain from case studies of patients with localized brain damage that causes the brain to behave abnormally. In the same way, in order to understand the mechanisms that underlie normal, and usually correct, perception, it is often helpful to investigate instances in which erroneous perceptions occur. It is particularly theoretically useful when one factor, A, (whether an experimental manipulation or neural damage) affects process 1 but not process 2 while another factor, B, affects process 2 but not process 1. This ►double dissociation allows the conclusion that 1 and 2 are different processes and have different determinants. By way of example, the tilt illusion can be measured as a function of the angle between the central, horizontal test stimulus in Fig. 1a and the surrounding inducing stimulus. When the angle is small (e.g., 15°) the test appears repelled in orientation from the inducer. When the angle is large (e.g., 75°) the test is perceptually attracted to the inducing orientation. It has been shown that one set of experimental manipulations reduces repulsion effects without any effect on attraction effects; whereas other manipulanda eradicate attraction effects without affecting repulsion effects, a double dissociation indicative of different mechanisms [10]. Indeed, the evidence suggests that repulsion effects occur early in the visual system in ►striate cortex (area V1) but that attraction effects occur in ►extrastriate cortex, in V2 or higher [10,11]. Illusions such as the tilt illusion can be used to probe normal visual mechanisms in another way, by probing levels of processing in the human visual system. For example, oriented stimuli can be defined by ►first-order cues (luminance and color) or ►second-order cues (disparity, texture, motion, etc.). Because the tilt illusion occurs when the inducing and test stimuli are defined by the same or by different cues [11], the illusion can be said to be cue invariant to some extent, which in turn implies that it may occur at a cue invariant level of the visual system. More recently, it has been shown that the repulsion tilt illusion is reduced significantly when the inducing stimulus is second-order while the test stimulus is first-order; but that the attraction tilt illusion is unaffected by that manipulation [12]. This is consistent with the idea that first- and second-order processing mechanisms are initially separate but combine after a nonlinearity, with repulsion effects generated prior to the nonlinearity but attraction effects generated after the nonlinearity [12]. These results are also consistent with other evidence for separate mechanisms underlying repulsion and attraction tilt illusions [10,11,13]. For excellent demonstrations and explanations of optical illusions go to http://www.michaelbach.de/ot/.

## Visual Memory

V

### Definition

Visual memory refers to the ability to recall pictures, scenes, words, or other information that is presented visually. Visual memories can last for a short amount of time, as in visual iconic memories or afterimages, or for many years, as in the type of learned long-term memory that enables us to visually imagine and recognize events that have occurred years or even decades ago.

# Visual Motion Processing

Colin W. G. Clifford
School of Psychology, University of Sydney, Sydney, NSW, Australia

## Synonyms

Motion processing; Motion vision

## Definition

Various factors contribute to changes in the pattern of light incident on our retinas, such as our movement through the world, our eye and head movements, and the motion of objects in the world around us. Visual motion processing refers to the sensory analysis of retinal image motion and its interpretation in terms of these factors.

## Characteristics

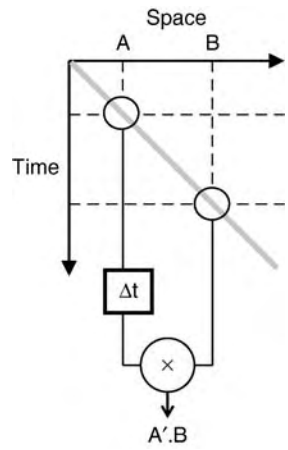
### Motion Detection

Physically, motion is change in position over time. Computationally, a processing scheme for detecting the direction of image motion must satisfy several requirements [1]. Temporal change in the image signal at a single location on the retina contains no information about the direction of image motion. Instead, the dynamic image signal must be sampled at multiple locations or spatial phases. These samples must then be processed asymmetrically in time and combined. Consider, for example, the delay-and-compare scheme for motion processing [2] illustrated in Fig. 1.

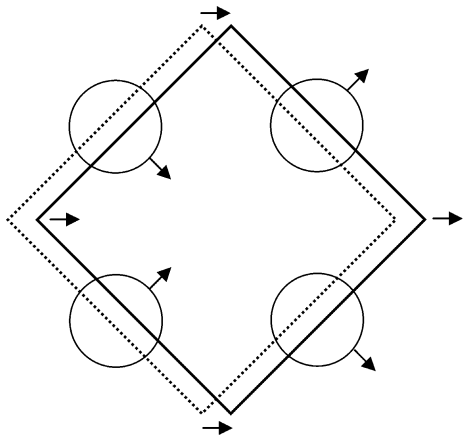
Two samples of the retinal image are taken from nearby spatial locations. Temporal asymmetry is implemented in the form of a delay between samples, introducing ►direction selectivity into the scheme. The resulting signals are then multiplied together (a quadratic non-linearity). In a final stage of ►motion opponency, signals from motion detectors selective for opposite directions of motion are subtracted to produce a signal whose sign conveys the direction of image motion.

### Direction Processing

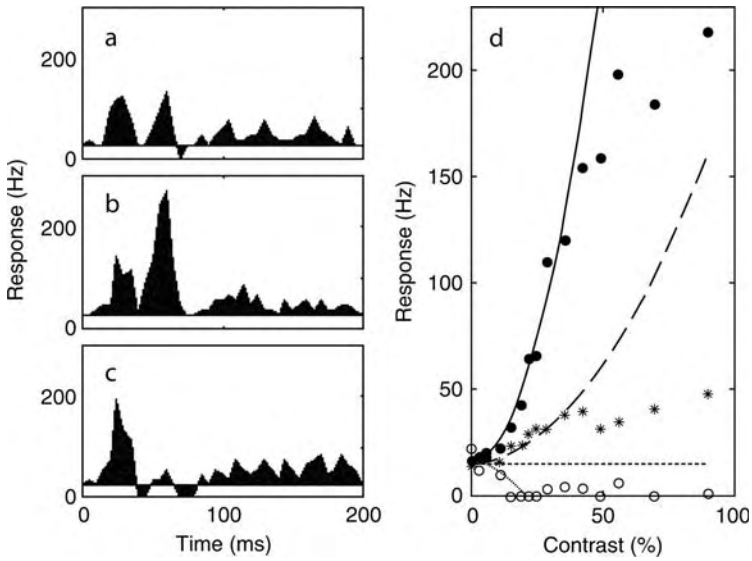
Elementary motion detectors are sensitive to motion between the spatial locations at which they sample the retinal image but not to motion along the perpendicular axis. In other words, each elementary motion detector is only sensitive to motion along one spatial dimension in the two-dimensional retinal image. Recovery of two-dimensional retinal motion requires the combination of responses from a population of detectors sensitive to different axes of motion. Even then, the structure of the retinal image may be such that two-dimensional motion cannot be recovered unambiguously. Specifically, if the



**Visual Motion Processing. Figure 1** Schematic of elementary motion detector. The trajectory of an object moving at a constant velocity is oriented in space-time (*grey line*). To detect this motion we need to take signals from at least two points in space and combine them asymmetrically in time. The simplest "delay and compare" mechanism is a direct multiplication of two signals: the correlation detector [2]. When the stimulus moves from Position A to Position B at the appropriate speed, signals from the two receptors reach the comparison stage at the same time. When the stimulus moves in the opposite direction, from Position B to Position A, the non-delayed signal from one receptor reaches the comparison stage long before the delayed signal from the other receptor.



**Visual Motion Processing. Figure 2** The aperture problem. Neurons early in the visual processing hierarchy have small receptive fields. It is as though each neuron is "viewing" the world through a small aperture. Consequently, the region of the retinal image which they sample can often be essentially one-dimensional in structure (e.g. an edge). In this case, only the component of motion perpendicular to the edge can be recovered unambiguously. Only in regions of the image with two-dimensional structure (e.g. corners) can motion be recovered locally.



**Visual Motion Processing. Figure 3** Response to motion of neurons in the nucleus of the optic tract. (a) Two flashes of a wide-field sinusoidal grating with no phase shift between presentations produce responses similar in size. (b) When phase shifts by quarter of a cycle between presentations, corresponding to ►apparent motion in the preferred direction, the magnitude of the second response is increased. (c) When apparent motion is in the anti-preferred direction, the second response is smaller than the first (motion opponency) [4]. (d) Response of a different neuron to no motion (*stars*); apparent motion in the preferred direction (*filled circles*); apparent motion in the anti-preferred direction (*open circles*) as a function of grating contrast. The curves are the best-fitting quadratic functions for contrasts up to 25% [3].

region of the image sampled by the population of detectors is spatially one-dimensional (e.g. an edge) then only the component of motion perpendicular to the spatial structure can be recovered locally. This is the essence of the ►aperture problem (Fig. 2), whose solution requires integration of motion information from disparate regions of an object.

## Sub-Cortical Motion Processing

In the sub-cortical mammalian brain, direction selectivity is most clearly evident in the ►nucleus of the optic tract (NOT) and the ►accessory optic system (AOS). The NOT and AOS are connected to the motor system that controls stabilizing eye movements such as ►optokinetic nystagmus. Most cells respond in a highly direction-selective and motion-opponent manner to movement across large regions of the visual field such as the ►optic flow produced by self-motion. Their directional properties probably originate in the retina but in certain species there is an additional cortical input. The essential non-linearity in the motion detectors is quadratic [3], characteristic of a multiplication of signals (Fig. 3).

## Cortical Motion Processing

In the primate brain, significant direction selectivity is evident in ►primary visual cortex (V1) but motion opponency does not emerge until the ►MT complex [5]. Ascending the visual motion processing hierarchy from V1 to the MT complex reveals an increase in receptive field size and the emergence of neurons able to integrate local motions into a coherent interpretation of object motion or patterns of optic flow [6,7]. Patterns of activity in the MT complex and in other extrastriate visual areas have also been shown to correlate with the perception of three-dimensional ►structure-from-motion [8]. Micro-stimulation of MT has been shown to bias reports of perceived direction [9], indicating that the processing of motion in the MT complex is causally linked to motion perception and not simply involved in oculomotor control. Indeed, bilateral damage to the MT complex in a human subject has been reported to produce a selective deficit in motion perception while leaving other aspects of vision largely unimpaired [10].

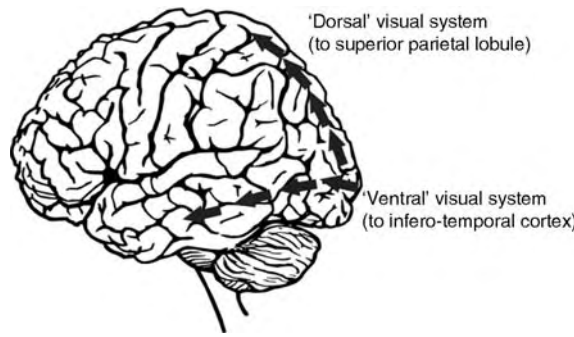
## Definition

Visual neuropsychology is the field of enquiry devoted to elucidating links between the anatomy and physiological functioning of cerebro-cortical structures and the ►visual perception and cognition as well as visually-mediated behaviors to which they give rise through experimentation in healthy and brain damaged humans.

## Characteristics

Visual neuropsychology is the sub-discipline of neuropsychology dedicated to understanding how visual information is processed by cerebro-cortical and subcortical mechanisms and how that information gives rise to perception, cognition, and other behaviors. The discipline has grown in conjunction with knowledge of the anatomical connections and tuning properties of visual cortical neurons in ►occipital cortex and extra-occipital cortex. In particular, the discovery of streams of processing arising within the ►primary visual cortex (Brodmann's area 17; striate cortex; ►area V1) and extending into other cortical areas (see Fig. 1) (►Visual processing streams in primates; Extrastriate visual cortex), and the elucidation of the contribution of those processing streams to visual behaviors through scientific and clinical observations forms the basis of visual neuropsychology. Thus, visual neuropsychologists explore cortical functioning using psychophysical and neuroimagining techniques in healthy and brain-damaged humans to understand the nature of visually mediated behaviors.

Interestingly, while visual perceptions seem coherent and unitary, striking clinical dissociations illustrate that each stream can to some extent operate independently of the other (►Visual perception). Behavioral dissociations manifest as processing difficulties in one domain in the relative absence of difficulties in another, so suggesting independence of the two domains. An example of a single-dissociation within visual neuropsychology has been the observation of a patient who has impaired motion perception (►Motion blindness or



**Visual Neuropsychology. Figure 1** The so-called "where" pathway runs dorso-medially from visual area V1 through visual cortical ►areas V2, the ►V3/V3a complex, the ►superior temporal sulcus (►STS) or ►middle temporal sulcus (MT) to ►posterior parietal cortex (►PPC). It encodes primarily spatial- and timing-related information, and is also heavily implicated in visuo-motor processing. Damage along this pathway can result in a number of deficits, the most striking of which is ►spatial neglect, akinetopsia, or optic ataxia (see below). The second pathway runs from area V1 ventro-laterally through areas V2, V3, V4 and to the ►inferior temporal cortex (►IT). It processes information relating to the color and shape of objects within the visual array and for that reason commonly is referred to as the "what" pathway (see for example [1]). Damage along this pathway can result in a number of deficits; the best studied are ►visual agnosia and prosopagnosia (see below).

►akinetopsia) but almost normal form perception (see for example [2]). Double dissociations occur when two single dissociations with complementary deficit/ability profiles due to comparable size of brain damage are observed. Thus, while clinical participants are more heterogeneous in terms of their neural functioning than healthy participants, case studies illuminate sometimes unpredicted relationships between visual processes. Indeed neuropsychological case observations have often provided first clues on functional specialization within the human brain. It now seems clear, then, that visual perception and cognition as well as visually-mediated behaviors arise from simultaneous and largely parallel processing in both streams (►Visual perception).

## Akinetopsia

Akinetopsia or motion blindness is defined as a selective impairment in perceiving the direction and speed of visual motion stimuli (►Visual motion processing), while other aspects of the visual scene such as color and form are perceived normally. The most clear and comprehensive demonstration of akinetopsia has been provided by Zihl and colleagues [2] who described a patient suffering from extensive and bilateral brain damage at the occipito-temporo-parietal junction. While the patient was unable to discriminate objects in motion the ability to perceive static form and color was normal. Interestingly, auditory motion perception and the perception of static and biological forms defined by visual motion stimuli are normal or much less impaired. Patients with severe motion blindness may also suffer from illusory visual motion perceptions suggesting that ►area MT±/V5 is also relevant for conscious motion perception.

Brain damage, from tumors, trauma, or stroke, may lead also to more complex forms of motion blindness such as a selective deficit in the detection and discrimination of forms defined by visual motion stimuli (►Form-from-motion (FfM) blindness). Double dissociations between motion blindness and FfM blindness also have been observed [3]. FfM blindness seems to arise due to damage to at least three distinct posterior processing areas: Severe FfM blindness without akinetopsia is due to damage in, usually, the right hemisphere ventral occipito-temporal cortex, whereas FfM blindness with akinetopsia is due to damage to either or both area MT+/V5 and the ►lateral occipital complex (►LOC), an area that is highly active during object perception and object recognition [4] (►Visual object representation).

Finally, the perception of ►biological motion (BM) (►Biological motion processing) stimuli may also be impaired by focal brain damage. BM blindness seems to be associated with parietal and temporal lobe damage. Patients with BM blindness often have normal visual motion perception but often suffer also FfM blindness. Neuroimaging work in healthy subjects has shown that a distributed network of brain areas is involved in BM perception including the superior temporal sulcus, the lateral occipital complex, MT+/V5, and the ►fusiform gyrus. A remarkable aspect of BM is that, along with motion direction and speed information, it conveys also a large range of socially relevant information. Accordingly, it seems that left frontal brain damage may impair the perception of personality traits and that damage to right ►somatosensory cortex may impair the perception of emotions as conveyed by BM stimuli.

## Balint's Syndrome

Named after Hungarian physician Rudolf Balint and sometimes referred to as ►Balint-Holmes syndrome in honor of the later contributor Gordon Holmes, the syndrome is classically defined as an acquired, triple-symptom complex. The original patient described by Balint exhibited a range of symptoms including firstly ►optic ataxia or misreaching for objects under conditions of visual guidance. Behaviors associated with this symptom include, for example, lighting the middle rather than the end of one's cigarette, or misreaching for a door-handle. Based on Balint's observations that when assessed independently his patient's elementary visual and motor capabilities appeared intact, the deficit was defined as being specific to visuo-motor integration (►Visuomotor integration). The second symptom, termed psychic paralysis of gaze by Balint but now more commonly known as ►optic apraxia, relates to the occurrence of sticky visual fixations. Such ►spasms occur in spite of intact extraocular function (and thus unrestricted eye rotations), and manifest as an inability to voluntarily shift one's gaze from one object within the visual scene to another. The third and final symptom reported by Balint was spatial disorder of attention (►Visual attention), now more commonly referred to as ►simultanagnosia. In this case, a patient's ability to recognize individual objects is compromised when those objects are presented simultaneously within the visual scene.

In the case of Balint's original patient and those reported subsequently, attempts have been made to map the neuroanatomical underpinnings of the triple-symptom complex. Whilst some lack of consensus remains about the neural structures giving rise to the syndrome, most reports implicate involvement of bilateral posterior parietal cortex: post-mortem results of Balint's and others' patients, and more recent neuroimaging studies support the contention that damage to bilateral occipito-parietal cortex underlies the syndrome. Certainly that analysis is consistent with the role in visually guided behaviors of the so-called visual dorsal processing stream (which includes occipito-parietal cortex). Indeed, convergent evidence related to visuo-temporal processing capabilities – attributed directly to

dorsal stream processing - has recently been reported. As predicted by models of normal dorsal stream processing, such capabilities are disrupted in patients exhibiting ►Balint's syndrome.

The cortical damage on which Balint's syndrome onset appears to be based arises via a number of etiological mechanisms. These include trauma through accident, stroke, and the development of cortical tumors. High levels of co-occurrence have also been observed in patients exhibiting posterior cortical atrophy (►Posterior cortical atrophy) and degenerative diseases such as Alzheimers (►Alzheimer's). Perhaps unsurprisingly those same diseases lead also to akinetopsia. Consistent with the aetiology of those diseases, incidence of the syndrome is observed almost exclusively in adults, although at least one case study involving a child has been reported [5]. The most effective treatment strategies are multi-contextual and involve first raising awareness of their functional deficits in sufferers, and then teaching them to anticipate conditions under which deficits manifest. That process usually depends upon patients being taught functionally adaptive and compensatory techniques.

Problems disambiguating Balint's syndrome from disorders such as visual ►neglect (see below), along with the scarcity of classical triple-symptom presentations has led to recent re-conceptualizations of the syndrome. That is, the symptoms may not be sufficiently autonomous to satisfy Benton's criteria for an independent syndrome. Rather, attention is now focused on understanding the three symptoms individually rather than considering them as a consistent constellation of signs.

## Optic Ataxia

Considered the typical visuo-motor deficit, optic ataxia (OA) was first described by Rudolf Balint as one of a constellation of symptoms associated with what later came to be known as Balint's syndrome (see above). Classic definitions of the disorder focus on pronounced deficits reaching for objects under conditions of visual guidance. That is, patients are deficient in their capacity both to reach for and grasp objects represented in visual space despite preservation of visual, motor, and musculo-skeletal processing capacity. For example, and as originally described by Balint, patients can search with their knife outside a plate for food positioned in plain view on the plate. Based on its frequent occurrence in the absence of the other symptoms of Balint's syndrome, OA has emerged as an independent neuropsychological disorder.

More recent reviews of the disorder cite three key characteristics. The first is the pronounced deficit in the control of direction of arm and hand movements made under visual guidance, particularly for objects located in *peripheral* visual space. The second is the specifically *visuo*-motor aspect of the disorder: equivalent motor tasks performed under ►proprioceptive guidance, for example, can be performed without deficit. The third characteristic is the specificity of the deficit for *immediate* visuo-motor functions. Tasks involving delayed behavioral responses are performed with higher levels of accuracy than those performed "online".

Neural accounts of the disorder emphasize the key role played by the action-oriented visual dorsal processing stream: Patients typically exhibit symptoms after extensive damage to posterior parietal cortex. Specific sub-areas involved likely include the ►superior parietal lobule, ►intraparietal sulcus, and ►occipito-parietal sulcus in various combinations. OA manifests as a consequence of both bilateral and unilateral parietal damage. In the latter cases, hemispheric asymmetrics are observed: damage to unilateral cortex results in misreaching via both hands to objects presented in contralesional visual space (the so-called *field* effect), or misreaching to either visual field of the contralesional hand (the so-called *hand* effect).

## Prosopagnosia

Also known as *face blindness* or *facial agnosia*, ►prosopagnosia is a disorder in which sufferers are unable to recognize previously familiar human faces (►Face processing in different brain areas). This is the case in spite of preserved ability to recognize objects (►Visual object representation) more generally and to make fine visual discriminations.

Historically multiple examples of patients presenting with such patterns of impairment were reported in the eighteenth Century (for an historical overview see [6]). However the term prosopagnosia itself was not coined until 1947. At that time, German neurologist Joachim Bodamer published a report identifying the existence of a number of patients deficient in the ability to discriminate between familiar individuals on the basis of visual inspection of their facial features. For example, Bodamer described one of his patients as manifesting a severe deficit in ability to discriminate friends, family or himself on that basis, whilst the ability to perform the same task on the basis of cues such as individual speech or gait patterns was retained.

Neural correlates of prosopagnosia have been identified primarily on the basis of lesion analysis. Such analyses most commonly implicate bilateral damage to the inferomedial part of the temporo-occipital region, specifically the fusiform gyrus and ►lingual gyrus. Less commonly unilateral, right-hemisphere damage to the same region gives rise to the disorder [7]. Based on those findings and in acknowledgement of its key role in vision-based face recognition, the right mid-fusiform gyrus is now commonly referred to as the ►fusiform face area or FFA [8].

Acquired prosopagnosia arises usually from stroke damage, brain injury, or from diseases such as Alzheimer's and Parkinson's disease (►Parkinson's disease). However, less common congenital presentations have also been reported. The patterns of cortical disruption on which the disorder is based also commonly give rise to additional vision-based deficits including bilateral upper visual field deficits, ►achromatopsia or left ►hemiachromatopsia and ►topographagnosia (for a review see [6]).

Neurocognitive accounts of the disorder vary. The co-occurrence of prosopagnosia with deficits in performing general object recognition (►Visual object agnosia) has been presented as evidence that the disorder is domain-general. That is, prosopagnosia represents one specific manifestation of more general object recognition deficits. That account is weakened by the existence of facial/object recognition double dissociations: Complementary to face-specific deficits of the type described by Bodamer and others, the existence of patients with deficits in object recognition but not in face-recognition have been reported. In an example reported by Moscovitch and colleagues [9] patient CK was shown to be poor at recognizing non-face objects and at reading, but not deficient in terms of his capacity to recognize faces.

Initial diagnosis of the disorder is commonly based upon self-report and a simple clinical test in which one familiar individual, dressed in a similar fashion to several others amongst whom he or she stands, must be identified on the basis solely of visual inspection. An inability to perform that task, combined with tests demonstrating the face-specificity of the deficit while excluding the existence of general intellectual impairment or poor visual processing, form the basis for confirmation of the initial diagnosis. Once diagnosed, treatment options are limited. Most commonly, the debilitating social and functional aspects of the disorder are addressed through training in the implementation of compensatory strategies. These include using alternative perceptual cues such as the gait, speech patterns, and isolated (rather than global) facial features to identify individuals, and cognitive strategies such as keeping lists of the individuals likely to be present at particular times of day and in particular locations.

## Spatial Neglect

►Neglect (also known as spatial, unilateral or hemi-spatial neglect) is a syndrome characterized by the tendency to act as if half of the world does not exist. Typically it manifests across sensory domains (vision, touch, audition, even smell) despite normal processing, at least peripherally, in each. Neglect arises typically from unilateral damage to inferior parietal or superior temporal cortex, often as a result of an infarction of the right middle cerebral artery. Involvement of ►prefrontal and premotor cortex, along with ►thalamus and ►basal ganglia, has also been implicated. While the syndrome occasionally manifests as a function of damage to left hemisphere, it arises more commonly, and with more severe and enduring symptoms from damage to right hemisphere.

The behavioral correlates of neglect can be mapped across three conceptual, patient-referent spatial areas: personal, peri-personal (within reaching distance), and extra-personal space (within sensory processing distance). Examples of behaviors related to personal space include the application of make-up only to the ipsi-lesional side of one's face, and the dressing of only the ipsi-lesional side of one's body. Symptomatic behaviors in peri-personal space include inattention to contra-lesional text and pictures presented in books, and lack of awareness of the presence of food positioned contra-lesionally on one's plate. Finally, behaviors associated with extra-personal space include a tendency to ignore people and objects in the contra-lesional hemifield and a failure to navigate routes or spaces that require contra-lesional turns or deviations.

Contemporary theories of the cognitive correlates of neglect focus on disruption to processes mediating mechanisms of spatial attention (►Visual attention). Such disruptions can occur in the absence of patient awareness (►Anosognosia) and can temporarily be ameliorated by the deliberate re-focusing of attention to a target within the neglected space. Similarly, the severity of neglect is spatially heterogeneous, becoming more severe as a function of distance into contra-lesional space. Thus, neglect must be differentiated from functional deficits associated with sensory (e.g. ►Hemianopia) or motor impairment, both of which are less influenced by attentional strategies. Interestingly, and in a further contrast to sensory and motor deficits, neglect can manifest in tasks requiring recall (►memory) and ►mental imagery. Memory deficits particularly are interesting: Patients may be unable to describe, from memory, that part of a familiar scene corresponding to neglected space. However, if asked to adopt a different perspective, one that moves features that previously fell into neglected space into ipsi-lesional space, those features can be recalled.

Diagnostically the most reliable tools are simple pencil-and-paper tests. On drawing-from-memory or copying tasks neglect patients will omit details from the neglected side of the object to be recalled or copied. On line-bisection tasks requiring participants to mark the mid-point of a horizontal line neglect patients typically indicate their perceived midpoint far to the right of the actual midpoint (and normal subjects on the same task typically mark a little to the left of the actual midpoint, so-called ►pseudo-neglect). Similarly, on line- and other types of cancellation tasks neglect

patients will delete only targets in their non-neglected hemi-field.

Amelioration of neglect can be achieved by ►optokinetic stimulation and ►caloric stimulation, but improvements are temporary. Similarly transient improvements are associated with the application of vibration to the neck. The only reliable and medium-to-long-term treatment for neglect seems to be achieved by using ►prism adaptation [10]. In the absence of an effective treatment for neglect most patients undergo rehabilitative therapies that focus on the development of cognitive strategies to overcome inattention to objects within the neglected hemifield.

# Visual Object Recognition

►Visual Object Representation

# Visual Object Representation

Charles E. Connor
Krieger Mind/Brain Institute and Department of Neuroscience, Johns Hopkins University, Baltimore, MD, USA

## Synonyms

Visual shape representation; Visual form representation; Visual object recognition

## Definition

Visual object representation is the process of encoding object information in ►visual cortex for purposes of object identification, discrimination, evaluation, and ►memory storage.

## Characteristics

### Computational Difficulty

Object vision is so computationally difficult that even the best computer vision systems achieve only rudimentary performance compared to humans. The difficulty lies in the enormous complexity and variability of visual object information. The representation of an object on a ►retina or camera is an isomorphic pattern of response rates or pixel values. This pattern is extremely complex (on the order of a million pixel-like signals for human vision) and hopelessly variable – the same object can produce a virtual infinity of retinal images depending on its position, orientation, lighting, partial occlusion, and plastic deformation. Object information at this level is therefore highly implicit, i.e., extensive analysis would be required to extract useful information such as object identity. The visual system must transform this complex, implicit, variable input into an explicit, compact, stable representation of useful object information. This transformed representation is then accessible to other brain structures for storage and association in memory, decision-making, behavioral guidance, and conscious awareness.

The brain is so adept at this transformation process that it is transparent to us – it seems trivial to look around a room and recognize all the objects in it. Yet, this is one of the most computationally intensive tasks the brain performs, and it depends on continuous processing in a dedicated series of brain regions that make up the ventral visual pathway (see the entry on ►Visual Processing Streams in Primates). The final stages of this pathway in ventral occipitotemporal cortex carry the transformed neural representation underlying our remarkable abilities to recognize and understand objects. The nature of this representation is unknown, but experimental results support several theoretical ideas that could help explain the extraordinary power of human object vision.

## Structural Representation

One dominant theory is that visual objects are represented as spatial configurations of common geometric parts. This representation would be carried by the ensemble activity of neurons tuned for various part shapes and positions [1]. A ►structural representation of this kind could be relatively simple and compact, facilitating transmission, storage, and association of object information. It could also be relatively stable across changes in object position, size, and orientation, if the spatial ►reference frame were defined by the object itself. It would provide explicit geometric information useful for evaluating the properties and functionalities of objects and guiding physical interactions with objects (►Visual space representation for action). Perhaps most importantly, structural representation has the combinatorial power to encode the limitless space of real-world objects, in a way somewhat analogous to encoding millions of words with different combinations of just 26 letters. Structural representation may be reflected in the way we verbally describe objects as spatial arrangements of parts. ("A teapot is round, with a C-shaped handle on one side, an S-shaped spout on the other side, and a disc-shaped lid on top.")

The theory of structural representation is supported by psychophysical studies showing human perceptual sensitivity to part information and neurophysiological studies of visual responses in ventral pathway cortex of nonhuman primates. Neurons in higher level ventral pathway cortex of macaque monkeys respond selectively to simple object components and neurons with similar component sensitivity are grouped into columns [2]. Component shape is encoded in terms of geometric derivatives. Neurons are tuned for contour orientation (a first-order derivative), contour curvature (second order), contour spirality (third-order) and surface curvature [3–5]. Derivative coding is much more compact than the original retinal representation, because real-world object boundaries are relatively smooth, and thus large shape fragments encompassing many retinal receptors can be summarized by a few neurons signaling overall orientation and curvature.

Component position is represented in an object-centered reference frame. Higher level ventral pathway neurons are finely tuned for position relative to object center-of-mass, and only broadly tuned for retinotopic position [6]. This makes for a representation that is much more stable across changes in object position on the retina. Tuning for component shape and component position is simultaneous – a given neuron might respond to concave boundary fragments, oriented toward the right, positioned above object center. At intermediate processing stages, neurons represent individual, local shape components. At higher processing stages, neurons represent combinations of components [6], a trend that may lead to neurons selective for global shapes of familiar, ecologically important objects.

## Exemplar-based Representation

A very different coding scheme may be necessary for extremely complex shape patterns, especially faces (►Face processing), which are processed in specialized brain regions (see entries on ►Extrastriate Visual Cortex and ►Visual Cortical Areas). Humans are remarkably sensitive to the fine structural differences that distinguish individual faces. The highly composite nature of facial shape might make a structural description unwieldy. Instead, composite shape differences can be efficiently represented in terms of similarities to exemplars. Detailed local shape correspondences with exemplars can be implicitly summed across entire objects to generate an explicit signal for overall similarity. The pattern of similarities to multiple exemplars can uniquely define an individual object [7]. In the case of faces, exemplar coding may be organized around the "average" face, learned across a lifetime of exposure. Psychophysical, imaging, and neurophysiological evidence suggests that neurons are tuned along similarity dimensions with an origin (lowest response point) near the morphological average across large numbers of human face photographs. Neural coding with respect to the average face would explain why caricatures are easier to recognize than veridical photographs. ►Exemplar-based representation may be reflected in the way we verbally describe faces in terms of well-known individuals ("He looks like a cross between Al Pacino and Dustin Hoffman") and averages across groups ("She looks Asian, female, middle-aged").

## Categorical Representation

Structural and exemplar-based coding depend directly on object geometry inferred from retinal images. However, much of our knowledge about object identity and meaning transcends geometry and depends instead on learned categorical relationships between geometrically dissimilar shapes. Representation of such relationships is bound to depend on ►medial temporal lobe structures like the ►hippocampus, which make extensive reciprocal connections with higher level visual cortex. Neurons in human hippocampus have been shown to respond selectively to both photographs and typewritten names of the same celebrities [8], clearly reflecting learned associations between geometrically unrelated objects. Animal experiments indicate that such arbitrary neural response relationships can be established by repeated exposure to stimulus pairs in close spatiotemporal proximity and by learning task-related associations between stimuli [9]. Categorical associations can also be important for making fine distinctions between geometrically similar objects, and neurons in ►prefrontal cortex have been shown to represent sharp task-defined boundaries

between highly similar images of quadrupedal animals [10]. Finally, categorical learning provides an alternative to explicit processing of object geometry for achieving stability across image changes, especially changes in orientation or viewpoint. The relationship between different views of the same object could be learned from their close spatiotemporal proximity during normal experience.

# Visual Pathways for Perception and Action

David A. Westwood
School of Health and Human Performance, Dalhousie University, Halifax, NS, Canada

## Definition

The study of vision has traditionally been guided by the goal of understanding the representations – neural or otherwise – that underlie one's perception of the visual world. Of course, vision is not merely a system for generating a representation of the surrounding environment; it also plays a key role in guiding the organism's interactions with that environment. In other words, vision must be considered as both a perceptual and a sensorimotor system. Many models of human cognition assume that the sensorimotor aspects of visual function are intrinsically linked to the representational aspects of vision. According to this perspective, the visual control of movement proceeds from visual afference to perceptual representation to response selection and execution. In contrast to this intuitively appealing idea, however, considerable evidence has amassed in recent years which suggests that the situation is not quite so simple. This evidence comes from a number of converging methodologies, including ►neuroanatomy, ►neuropsychology, ►psychophysics, and a variety of neurophysiological techniques including non-human primate electrophysiology, functional magnetic resonance imaging (►fMRI), and ►transcranial magnetic stimulation (TMS). One broad interpretation of the existing evidence is that there are separate systems in the central nervous system for the visual control of action, and for visual ►perception [1]. These systems have different operating characteristics, and work together in the control of goal-directed behavior. Although the action and perception systems may map onto the ►dorsal and ventral streams of cortical vision, respectively, there is likely not a simple relationship between structure and function.

## Characteristics

### Neuroanatomy of the Visual System

The visual system is in fact many distinct systems. The ►retinal ganglion cells leaving the ►retina are organized into subcortical (tectopulvinar; ►Visual Role of the Pulvinar) and cortical (geniculostriate; ►The geniculo-Striate Pathway) pathways. Afferent fibers in the tectopulvinar pathway make connections in the ►optic tectum of the midbrain, including the ►superior colliculus, before projecting to the pulvinar nucleus of the ►thalamus and then the ►parietal cortex. The superior colliculus and parietal cortex are known to play important roles in the visual control of eye, head, and limb movements, leading to the conclusion that the tectopulvinar pathway is primarily a sensorimotor system. Afferent fibers in the geniculostriate system project to the ►lateral geniculate nucleus of the thalamus before terminating in the ►striate cortex of the ►occipital lobe (area ►V1). From V1, neurons project to the adjacent extrastriate region (area ►V2), which then gives rise to two streams of projections. The so-called ►dorsal stream includes ►V5 (also known as the motion-sensitive region, ►MT), ►V3a, ►PO, and a variety of distinct regions in the parietal cortex [e.g., ►VIP, ►LIP, ►MIP, AIP (►Area AIP)]. The so-called ►ventral stream consists of areas ►V3 and ►V4, and various regions of the ►inferior temporal cortex. It has

been suggested that the dorsal stream is actually two distinct streams, one consisting of neurons in the ►superior parietal lobule and the second consisting of neurons in the ►inferior parietal lobule. Whereas the tectopulvinar pathway is primarily a sensorimotor system, the geniculostriate pathway and the subsequent cortical streams mediate a variety of high-level visual functions such as conscious awareness, object recognition (►Visual object representation), spatial orientation, form perception, and sensorimotor integration.

Considerable efforts have been made to understand the functions of the dorsal and ►ventral visual streams, given their prominence in the cortical visual system. Based on a series of elegant lesion studies with macaque monkeys, Ungerleider and Mishkin [2] proposed that the dorsal stream is responsible for spatial perception, whereas the ventral stream is responsible for object perception. A more recent interpretation advanced by Goodale and Milner suggests that the dorsal stream is a sensorimotor system that is responsible for the visual transformations necessary for the control of skilled movement, whereas the ventral stream is a perceptual system that is responsible for interpreting current visual input using long-term representations stored in memory. A complete exposition of this model and its supporting evidence can be found in [1]. Some of the key evidence will be reviewed here.

## Evidence from Human Neuropsychology

### *Cortical Blindness ("Blindsight")*

►Blindsight is a disorder occurring from damage to the ►primary visual cortex, in which phenomenal visual awareness is lost but some visual functions are spared. Some of the earliest reports of blindsight indicated that patients could point to targets in the affected region of space with reasonable accuracy despite reporting no awareness of the target's location. Although it is not entirely clear which visual pathways underlie the preserved visual functions in blindsight, it has been suggested that the tectopulvinar (i.e., subcortical) pathway, with its projections to the superior colliculus and ►posterior parietal cortex, may mediate some of the residual sensorimotor abilities. Independent of the neural substrates associated with blindsight, the fact that patients can point with reasonable accuracy to targets they claim not to perceive argues strongly for some independence between the visual pathways for perception and action.

### *Visual Form Agnosia*

In 1991, David Milner, Melvyn Goodale and their colleagues published two papers describing the case of a woman, known as D.F., who presented with a ►visual agnosia subsequent to an anoxic episode. At the time of these initial reports, CT images indicated extensive damage to brain regions near the junction of the occipital and temporal lobes. More recent high-resolution MR images confirmed that the primary site of injury was a region of cortex called the lateral occipital complex (►LOC), which resides at the junction of the occipital and temporal lobes. As reported by Milner and Goodale, D.F. was quite unable to identify common objects depicted by black and white line drawings, although her performance improved with grey-scale and colored drawings in which diagnostic color and/or texture cues were available. Thus, D.F.'s visual agnosia was relatively selective for the form, or shape, of objects. Indeed, D.F. performed poorly when asked to indicate the orientation of a high-contrast slot either by rotating a hand-held manipulandum or by comparing the orientations of two slots. Despite her inability to perceive the orientation of the slot, however, D.F. was quite good at orienting a small wooden card when she reached out and attempted to insert the card into the slot as though mailing a letter. The card was oriented appropriately early in the unfolding movement, well before physical contact with the slot could have provided feedback. Clearly, D.F.'s lack of form perception had no impact on her ability to use form information to control her action, suggesting a separation between the visual pathways mediating perception and action. Goodale et al. proposed that D.F.'s preserved visuomotor abilities are attributable to her intact dorsal stream, whereas her poor form perception is likely due to the lesion in the ventral stream.

### *Optic Ataxia*

►Optic ataxia is a visuomotor disorder characterized by an inability to transform visual information into appropriate actions despite relatively intact visual and motor abilities. Because optic ataxia is typically associated with bilateral damage to the posterior parietal cortex, a major constituent of the ►dorsal visual stream, this disorder has often been held up as a counterpoint to D.F.'s ►visual form agnosia, which occurred following a lesion in the ventral stream. Indeed, Goodale and colleagues directly compared D.F., a visual form agnosic, and R.V., an optic ataxic, in a motor task and a perceptual task using irregular shaped, unfamiliar objects. In the perceptual task, the patients were asked to make same-different judgments about pairs of shapes, and in the motor task, the patients were asked to reach out and grasp the objects. In the judgment task, R.V. performed on par with age-matched controls, whereas D.F. performed well below chance. In the ►grasping task, D.F. showed good grip placement on the object's surfaces, aligning her index finger and thumb such that they spanned the object's geometric centre of mass, whereas R.V. often selected unstable grip points. The results of the study thus provide a compelling ►double dissociation suggesting that the dorsal stream is responsible for the visual control of

action whereas the ventral stream is responsible for visual perception. In recent years, the notion that optic ataxia is a global disorder of visuomotor control or integration has been challenged, since the observed deficits are typically only seen for targets located in the peripheral visual fields, or when target information must be updated in response to a change in eye position. Nevertheless, the observed visuomotor deficits in optic ataxia are not accompanied by similar deficits in visual perception, supporting the independence of the pathways mediating perception and action.

## Evidence from Psychophysics

### *Pictorial Illusions Affect Perception More Than Action*

Although the evidence from human neuropsychology provides compelling support for the distinction between the visual pathways for perception and action, it is wise to question the external validity of a model of visual function that is based heavily on evidence gleaned from patients with brain lesions. In 1995, Salvatore Aglioti and colleagues published a paper on participants with no visual or neurological conditions, in which they claimed to find different effects of a ►pictorial illusion (the well-known ►Ebbinghaus illusion or ►Tichener Circles figure) in perceptual and motor tasks. The perceptual effects of the illusion were measured by having participants choose to pick up one of two target disks depending on which one was judged to be larger. One disk was surrounded by an annulus of much smaller circles and the other was surround by an annulus of much larger circles. In trials where the two disks were physically identical, participants' decisions confirmed the existence of a perceptual illusion: the disk surrounded by smaller circles was judged to be larger than the disk surrounded by larger circles. In contrast to this perceptual judgment, however, the size of the maximum grip aperture (i.e., the separation between the index finger and thumb) used to pick up the chosen disk was unaffected by the sizes of the circles in the surrounding annulus. The sizes of the target disks were then adjusted within the small- and large-circle annuli so that participants consistently judged them to be of similar sizes. In this case, the physical difference in disk sizes was accurately reflected in the size of the grip aperture used for grasping. Aglioti et al.'s observations are broadly consistent with the notion that perception and action are mediated by distinct visual systems that have different operating characteristics. This study generated a tremendous amount of interest in pictorial illusions and their effects on a variety of perceptual and motor tasks [3].

Although there is some disagreement about whether or not the visual illusion paradigm provides convincing support for the independence of visual perception and visually guided action, there are some consistent themes that have emerged from the paradigm that mirror similar themes in the neuropsychological literature [3]. For example, the apparent independence of action and perception disappears when the tasks are performed after the target stimulus has been removed from view and thus require memory. In the illusion paradigm, one finds that grasping actions, for example, are much more sensitive to a pictorial illusion when the target is removed from view as compared to when it remains visible. In a similar vein, one finds that the visual form agnosic patient, D.F., performs very poorly when grasping a target object that has been removed from view, as compared to her quite good performance when the target remains visible. Together, these observations converge on the idea that there is a dedicated visuomotor system that operates separately from visual perception, but only when current vision of the target stimulus is available. When interacting with remembered objects, it appears that visual perception is in fact used to guide the action.

### *Rapid updating of Limb Movements in Response to Undetected Changes in the Visual Array*

In 1986, Goodale and colleagues carried out a study in which participants reached out to touch a small visual target that occasionally changed position during the course of a concurrent saccadic eye movement. During a ►saccade, there is a transient reduction in perceptual sensitivity to changes in the visual array. This phenomenon is known as ►saccadic suppression. Consistent with this phenomenon, participants in the study were unaware that the target had changed position. Nevertheless, the ending points of the reaching movements reflected the updated position of the target, indicating that information about the perturbation was available to the sensorimotor system. Recent studies on the updating of reaching movements in response to changes in target features suggest that this form of on-line visuomotor control is analogous to an "automatic pilot", in the sense that the updating is rapid and resistant to countermanding intentions. The on-line control system appears to be located in the posterior parietal cortex, since the system breaks down in cases of damage to the posterior parietal cortex, or when brief magnetic pulses are used to temporarily interfere with neural activity in posterior parietal cortex [4]. Using ►PET imaging, Desmurget and colleagues [5] found increased metabolic activity in posterior parietal cortex when participants reached to a target that changed position during the movement as compared to trials where the target remained stationary, providing support for a parietal locus of on-line visuomotor control.

## Evidence from Neurophysiology

The evidence presented above arguably represents the strongest support for the hypothesis that separate systems exist in the human visual system for perception

and the control of action. However, a large body of evidence has accumulated in the past decade that provides indirect support for this hypothesis, by localizing the neural substrates associated with a variety of sensorimotor and perceptual functions and by characterizing the neural processing that places in those regions.

In the extensive non-human primate literature, ►single-unit recording (►Extracellular recording) studies have identified distinct neural populations in parietal cortex where neural activity is correlated with the performance of specific sensorimotor tasks like saccadic eye movements, head movements, reaching movements, and grasping movements (for a recent review, see [6]). The causal connection between these brain areas and the implicated sensorimotor task has been probed in some cases in permanent or reversible inactivation studies. This literature supports the notion that there are distinct populations of neurons in the dorsal stream that contribute to the visuomotor transformations that underlie control of body movements. In a similar vein, single-unit recording studies implicate a variety of distinct neural populations in extrastriate regions in the processing of various low-level visual features associated with perceptual analysis, such as color, shape, depth, orientation, and motion (for a recent review, see [7]). There are also populations of neurons in the inferior temporal cortex where complex visual stimuli, involving conjunctions of a variety of low-level visual features, elicit preferential responding (for a recent review, see [8]). This line of evidence points to a role for neurons in the ventral stream in perceptual analysis of the surrounding environment.

In humans, there has been an explosion of interest in generating functional maps of ►cerebral cortex using functional MRI. Although a comprehensive review of this literature is not possible here, the human fMRI data tends to be broadly supportive of the work described above from non-human primates. That is, distinct neural regions appear to be preferentially activated in posterior parietal cortex for various sensorimotor tasks, such as saccades, head movements, reaching movements, and grasping movements (for a recent review, see [9]). Likewise, regions in the occipital and temporal cortices are preferentially activated by low-level visual features, and conjunctions of visual features (for a recent review, see [8]). In a very recent study, [10] present fMRI evidence suggesting a double-dissociation between the analysis of 3D object shape for action and perception, with the anterior intraparietal region (AIP) showing selective activation for grasping, and the lateral occipital complex (LOC) showing selectivity for shape discrimination.

With the advent of transcranial magnetic stimulation (TMS), the causal connection between brain regions and task performance can now be explored. A few studies have used TMS to disrupt activity in regions of posterior parietal cortex, and have found significant disruptions to the on-line control of reaching movements [4], and a break-down in the temporal coordination between the ►kinematics of hand and eye movements. In the future, TMS studies will surely provide important insights into the functional organization of the cortical visual pathways, and will contribute to the understanding of how perceptual and sensorimotor systems interact.

## Concluding Remarks

Vision is used for perceptual and ►sensorimotor functions, so that organisms can both understand and interact with their environment. Despite the intuitive notion that perception guides action, converging evidence from diverse methodologies suggests that perception and action are mediated by distinct visual systems that have different operating characteristics. This organizational structure reflects the different ways that afferent information needs to be organized and transformed for guiding movements versus interpreting objects and their spatial relationships.

## Definition

General neural strategies for constructing the perceived visual world.

## Characteristics

### The Primary Visual Cortex and the Hierarchical Processing of the Visual Scene

One simple fact of enormous significance separates our present-day view of the visual brain and of vision as a process from the view held until the 1960s. That fact lies in the extent of the visual cortex as it was conceived in the 1960s and as we know it today. Up to the 1960s, it was commonly believed that there is a single visual area, ►cerebro-cortical area V1 (Brodmann's area 17; primary visual cortex), co-localized with a cortical zone of distinct architecture – the ►striate cortex – which occupies a fraction of the cerebral cortex. Connected with the ►retinas through a subcortical station (the ►lateral geniculate nucleus, LGN), area V1 was long imagined to be the sole visual perceptive centre, with cells in its different layers analyzing the features of the visual environment in increasingly complex ways, in hierarchical fashion. There might, to be sure, be other areas somehow involved with vision, but their involvement was thought to be of an associative kind – involving activities such as ►learning and memory. Since the late 1960s, the extent of cerebral cortex recognized to be devoted directly to vision has increased dramatically, so that we now consider something perhaps in the region of one fifth of the entire cortex to be directly visual. This dramatic upward revision of the extent of visual cortex is not the result of redefining the boundaries of area V1, but rather the realization that there are many more visual areas besides it. The actual number remains uncertain, some putting it as high as 36 while others considering a dozen or so to be more realistic. Whatever the actual number, the principle of the multiplicity of visual areas is now beyond doubt.

### The Principle of Parallelism

But what do all these visual areas do? Do they continue the process of hierarchical analysis previously thought to reside in area V1? A simple anatomical finding that was later confirmed by functional studies suggested that visual processing is organized in an entirely different way than thought previously. The visual areas are not connected serially, starting from area V1. Instead area V1 has several reciprocal, parallel connections with the other visual areas, although serial connections incorporating hierarchical stages are a feature of each of the parallel pathways. In these parallel pathways emanating from it, area V1 sends different types of signals to each of the other visual areas, e.g. color information to area V4 (►Color Processing), and motion information to area V5 (MT) (►Visual Motion Processing). This anatomical fact alone ushers in the important principle of parallelism or parallel processing in vision, as indeed in other cortical operations.

### Functional Specialization in the Visual Brain

The consequence of this parallelism is of enormous interest. For it suggests that different visual areas outside area V1 receive signals in parallel and process them simultaneously and independently. It would be difficult to suppose that they process the same signals. In fact, direct physiological recordings from single cells in the macaque monkey brain supplemented later by human brain imaging experiments, and fortified by the results of clinical studies, show that there is a functional specialization in the visual brain, with different visual areas processing different visual attributes. Perhaps the easiest way to demonstrate this is to show the difference in the processing of color and motion. The former is processed in area V4 (►Cerebro-cortical area V4) while the latter in area V5 (►Cerebro-cortical area V5). These are not the only two specializations in the visual brain, far from it. But, for the purposes of this article, consideration of these two attributes helps to illustrate admirably a cardinal factor in the operations of the visual brain, namely the principle of functional specialization.

### Feature Independence in the Visual Scene

Why there should be a functional specialization in the visual brain is a moot point. There are two major candidates. The first is inherent in our visual world. Different visual attributes, such as color, or motion or depth (►Binocular Vision), or a particular expression on a face (►Face Processing in Different Brain Areas), occur haphazardly and unpredictably and with temporal independence of one another. If, for example, a bus moving to the right was always red, then the presence of a bus could be determined from its color, or form (►Form Perception), or direction of motion alone; there would be no need for these different attributes to be registered independently. But a bus can be stationary or move to the left, and could be any color. Equally red could be a property of many different objects. We refer to the unpredictable and independent occurrence of attributes as the principle of feature independence.

### The Temporal Requirements for Processing Form and Color

Another factor that may be important is that the temporal requirements for generating different visual attributes are themselves different. To determine the color of a surface, the brain has to compare the wavelength composition of the light coming from it and from surrounding points simultaneously in time, whereas to determine the presence, direction and speed of motion, it has to integrate signals from at least two points successively in time. Thus, the functional processing requirements as well as the temporal requirements of the two are different. Immanuel Kant had argued that time is a given a priori, a sort of inherited organizing principle that categorizes (visual) experiences. If this is indeed so, then the conclusion seems inescapable that the same temporal a priori cannot be applied to the generation of different visual experiences. Implied in this is the belief that the two different, specialized areas, have inherently different inherited wiring mechanisms and temporal dynamics.

### The Asynchronous Perception of the Visual World

That the generation of different visual experiences entails different temporal requirements and therefore that activity in different, specialized, visual areas reaches a perceptual endpoint at different times is exemplified by the principle of temporal asynchrony, which simply states that different visual attributes are perceived at different times. The basis for this lies in psychophysical observations in which subjects are asked to pair two different attributes, for example two colors with two directions of motion. These experiments have shown that we perceive color about 80–100 ms before we perceive motion. Nor is the temporal asynchrony confined to color and motion alone. For example, we also perceive color and orientation with a difference of about 40 ms. Many variations of these experiments leave little doubt that different attributes of the visual world are not perceived in precise temporal registration. There have been different interpretations of why this should be so. But the one that is to date the more compelling, because backed-up by the more convincing experiments, is that it is due to differences in processing time for the different attributes of the visual scene.

### The Mis-Binding of Attributes Over Brief Periods of Time

One consequence is that, because we see different attributes at different times, we mis-bind them over brief time windows (<100 ms), in the sense that we pair the color presented at time t with the motion that occurred at time δt-1. The strong implication of this finding is that the brain does not have a centre that waits for the results of processing in different areas to reach an end-point before binding them (►Binding Problem). Instead, it binds what has been processed and is therefore perceptually available. This in turn implies that, up to a significant degree, processing sites such as areas V4 and V5 are also perceptual sites, activity in them becoming perceptually explicit without the mandatory involvement of higher areas such as the ►frontal lobe or ►parietal lobe. It is however unlikely that they can act in complete isolation, but which other areas or cortical systems may be involved in bringing their processings to perceptual fruition remains unknown.

### Processing Sites may Also be Perceptual Sites

That a processing site is also a perceptual site is shown by experiments, which have used combined psychophysical and imaging approaches. In these, stimuli belonging to distinct ►visual categories (for example, faces and houses) are presented in such a way that they are either consciously perceived or not. Imaging experiments show that, whether perceived or not, a house stimulus activates the area of the brain specialized for object detection (►Visual Object Representation), while a face stimulus activates the part of the brain specialized for detection of faces (►Face Processing in Different Brain Areas). The difference is that, when consciously perceived, the activity in the respective areas is more intense. It is still not clear whether the change from the processing to the perceptual stage involves an increase in the activity of cells that are already engaged or whether new cells are recruited to render what has been processed perceptually, and therefore consciously, explicit. Similar experiments lead to a generally accepted principle that the conversion from a processing stage to a perceptual state depends upon a change in strength of activation.

### Conscious Visual Perception without V1

The picture that has emerged therefore is that each of these areas has considerable autonomy, in the sense that activity in one of the specialized areas is independent of that in others to a surprising extent. This of course should have become evident from an examination of the clinical literature, which shows that damage to distinct visual centers can lead to distinct forms of perceptual loss, confined to the attribute for which the area is specialized, without affecting other attributes. Prominent among these syndromes are those of ►achromatopsia (color imperception resulting from damage to area V4), ►akinetopsia (motion imperception resulting from damage to area V5) and ►prosopagnosia (failure to identify faces, resulting from damage to another specialized area, lying in front of area V4). It also becomes evident from examining clinical evidence which shows that when visual area V5 is disconnected

from area V1 (with which it is reciprocally connected and from which it normally receives its visual input) but has a secondary visual input that reaches it without passing through area V1, the subject can still experience visual motion consciously though crudely (►Riddoch Syndrome). The relative autonomy of these areas is also shown by experiments that study brain activity in more natural settings. It turns out that each area has a highly characteristic activity time course. This is the logical consequence of each area's distinct processing architecture, and the specialization in distinct features such as color and motion that can vary independently over time in our environment. It is thus possible to delineate cortical areas simply based on their distinct temporal activity fingerprint. Modern methods can thus reveal the brain's organization based on its chronoarchitecture.

### The Distribution of Visual Consciousness in Space and in Time

There is a relentless and ineluctable logic to this succession of findings, leading to conclusions that seem also inescapable. If we become aware of different attributes of the visual world because of activity in different specialized areas, it follows that visual consciousness is distributed in space. If we become aware of different attributes at different times, it follows that visual consciousness is distributed in time. From this it follows that there is no unified visual consciousness, but instead that there are many visual consciousnesses that are distributed in time and space (theory of micro-consciousness). Actual experiments lead ineluctably to this conclusion, even if the conclusion itself is not radically different from what Kant, after his philosophical speculations, enunciated in his book, *The Critique of Pure Reason*: "All presentations have a necessary reference to a possible empirical consciousness [micro-consciousness]. For if they did not have this reference, and becoming conscious of them were entirely impossible, then this would be tantamount to saying that they do not exit at all. But all empirical consciousness has a necessary reference to a transcendental consciousness (a consciousness that precedes all particular experience), viz., the consciousness of myself as original apperception" (original emphasis).

# Visual Pigments

►Photopigments

# Visual Probe Trials

## Definition

At the beginning of a trial, a visual target is presented, and the subject (human or monkey) is required to fixate it. After a delay period, a second target is presented, but the fixation target remains on. To perform the trial correctly, the subject must maintain fixation on the original target. This task is commonly used with monkeys, to allow the experimenter to measure visual receptive fields.

►Visual Receptive Field

# Visual Processing Streams in Primates

William H. Merigan
University of Rochester Eye Institute and Center for Visual Sciences, University of Rochester, Rochester, NY, USA

## Synonyms

Primate visual pathway; Parallel visual processing streams

## Definition

Like all known ►visual systems, the primate (human and monkey) visual system consists of several parallel visual pathways, each originating in the ►retina and projecting to a variety of brain locations, and each covering the entire visual field. The separate pathways originate in the approximately 14 ►retinal ganglion cell types in the primate.

## Characteristics

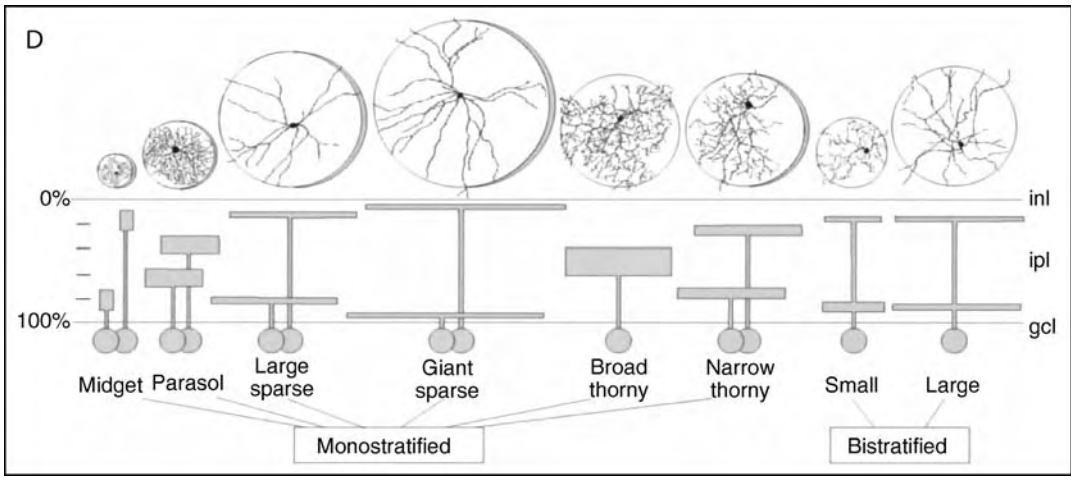
### Organization of the Retinal Ganglion Cell Classes

All visual systems contain numerous specialized ganglion cell types, in the primate visual system there are at least 14 ganglion cell types [1] (Fig. 1).

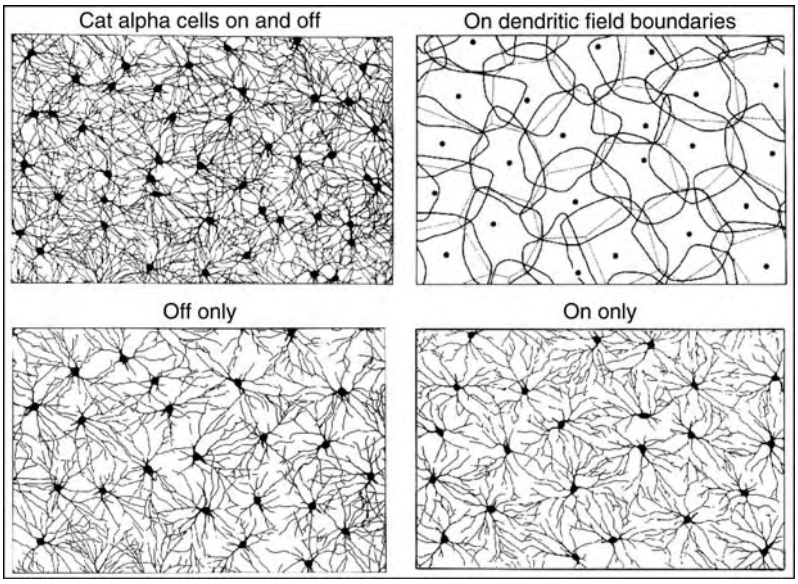
Each of these cell types has unique anatomy and physiology suggesting specialized roles in visual processing. Individual retinal ganglion cells have irregularly shaped ►dendritic fields (►Dendritic field of retinal ganglion cell) and ►receptive fields (►Receptive field of retinal ganglion cell), whose size is inversely proportional to the number of cells, but for each class of ganglion cell all of the dendritic/receptive fields are juxtaposed such that they cover the entire visual field. This is illustrated in Fig. 1 for two retinal ganglion cell classes in the cat (On and Off alpha cells) [2] (Fig. 2).

## Does Each Retinal Ganglion Cell Class Have an Independent Role in Visual Processing?

Independence is suggested both by the unique anatomy and physiology of ganglion cell types described above and the fact that each cell type covers the entire retina. Thus, it is conceivable that each could function independently



**Visual Processing Streams in Primates. Figure 1** Illustration of 13 retinal ganglion cell types in the macaque retina. Dendritic fields are illustrated at the top and the branching level of dendrites in the inner plexiform layer are shown by the horizontal bars that are placed in the correct depth (0–100%). From Dacey et al. [1].



**Visual Processing Streams in Primates. Figure 2** Illustration of ganglion cell coverage of he retina from the cat. Two types of retinal ganglion cells, On and Off Alpha cell, each provide complete coverage of the retina. From Peichl and Wassle [2].

to mediate some aspects of visual processing. However, it is more likely that most aspects of visual processing involve multiple ganglion cell types.

## What is Known About the Most Prominent Retinal Ganglion Cell Types?

### *Midget Ganglion Cells*

These are the most numerous retinal ganglion cells, constituting approximately 80% of total ganglion cells. As described above, dendritic/receptive field size is inversely proportional to the number of cells, thus these cells have the smallest dendritic/receptive fields. This is also the most studied type of ganglion cell having been shown to mediate ►visual acuity, ►color vision and many aspects of ►contrast sensitivity [3]. In some publications these cells are labeled ►P cells, because they project to the ►parvocellular layers of the ►lateral geniculate nucleus [4].

### *Parasol Ganglion Cells*

These are the second most numerous retinal ganglion cells, making up approximately 10% of all retinal ganglion cells. Dendritic/receptive fields of these cells are larger than those of midget cells, but smaller than those of most other retinal ganglion cell classes, which are less numerous. The function of these cells are also well studied, and they have been found critical to visual sensitivity for fast moving or low contrast stimuli [5]. These cells have been termed ►M cells because they project to ►magnocellular layer of the lateral geniculate nucleus.

### *Blue-Yellow Cells*

Blue-yellow cells are the third most numerous retinal ganglion cell type, making up about 5% of all retinal ganglion cells. Receptive/dendritic field sizes are approximately the same size as those of parasol cells. These cells, also called small bistratified, receive input from ►blue cones and appear to mediate blue-yellow visual perception.

### *Melanopsin-Containing Cells*

Relatively recently discovered, there appear to be two classes of these cells, each of which seems to cover the entire retina. One class projects to ►suprachiasmatic nucleus and mediates ►diurnal rythyms and the other projects to the ►pretectum and plays a role in pupillary control. In addition, both types also project to the lateral geniculate nucleus, suggesting additional roles in vision [6].

## Other Sparse, Large Dendritic/Receptive Field Cell Classes

The anatomy, physiology and visual function of the other classes of retinal ganglion cells including broad and narrow thorny cells, large bistratified cells and other cells are not well understood at present.

## Dorsal and Ventral Visual Processing Streams

It has been proposed (cite Ungerleider and Mishkin) that the different retinal ganglion cell types give rise to two functionally specialized ►retino-geniculo-cortical pathways.

The ►ventral cortical pathway is dominated by input from midget retinal ganglion cells, projects through cortical areas including area ►V4 and ►inferotemporal cortex (IT), and is thought to be crucial for color and form analysis.

The ►dorsal cortical pathway is dominated by input from parasol retinal ganglion cells, projects through areas including ►MT, ►MST, ►LIP and ►VIP, and is thought to be crucial for motion and localization analysis.

## Summary of the Known Role of the Different Retinal Ganglion Cell Classes

Although particular ganglion cell types appear to mediate the visual functions they are specialized for (e.g. midget cells mediate acuity; blue-yellow cells mediate blue-yellow color perception) it is likely that the visual system combines information from individual cell types when possible.

## Visual Receptive Field

### Definition

The term receptive field refers to the region of visual space where changes in luminance influence the activity of a single neuron. Also known as the classical receptive field (CRF). For structures such as the retina, lateral geniculate nucleus (LGN) and primary visual cortex, visual receptive fields (RFs) are measured in degrees of visual angle, and organized by their position on the retina (retinotopic). Receptive fields of different types of cells in the visual pathway have different substructures. For example, receptive fields with a center-surround structure are common in the retina and lateral geniculate nucleus of the thalamus whereas most cells in the primary visual cortex have either simple or complex receptive fields. The term may also be used to cover other restrictive properties of the response of a cell, i.e., a direction-selective receptive field, which responds only to motion within the receptive field in some particular direction. Similar concepts exist for other sensory modalities.

## Visual Role of the Pulvinar

Kenneth L. Grieve[1,2], Casto Rivadulla[2], Javier Cudeiro[2]
[1]Faculty of Life Sciences, University of Manchester, Manchester, UK
[2]Neurociences and Motor Control Group (Neurocom), Department of Medicine-INEF-Galicia, University de A Coruña, Campus de Oza, A Coruña, Spain

### Synonyms

Higher thalamic sensory processing; Cortico-thalamic interactions in higher thalamus

### Definition

The "Visual Role of the ►Pulvinar" refers to the dominant sensory input to the largest thalamic nucleus in the primate. However, the structure of the Pulvinar comprises several sub-nuclei and reciprocally links lower brain structures, such as the ►superior colliculus, to almost the entire ►cerebral cortex. It is involved with many ►sensory systems, particularly in the phenomena of ►arousal, ►attention and salience.

### Characteristics

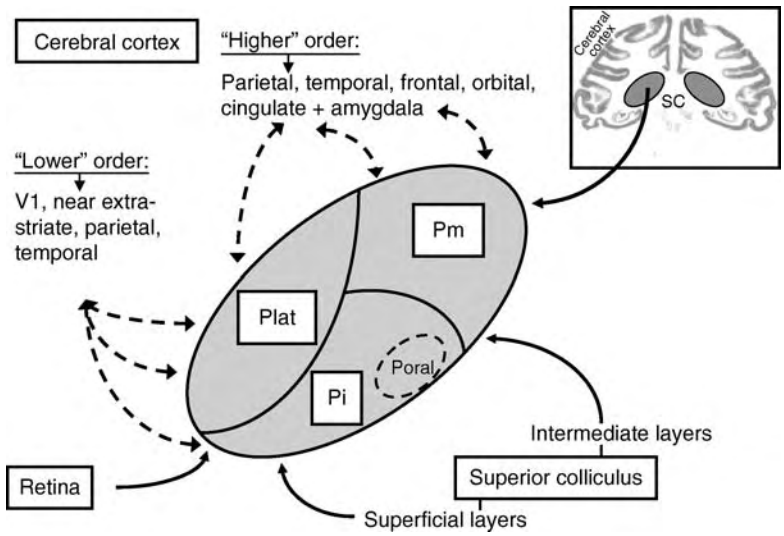
#### Connections of the Pulvinar Nuclei

The Pulvinar is a large dorsal thalamic cellular mass comprising four major sub-nuclei which occupy ~25% of the ►thalamus in higher primates (reviewed in [1]). On anatomical grounds the Pulvinar was traditionally divided into Inferior, Lateral, Medial and Oral (or Anterior) nuclei; see Fig. 1. Of these the Oral Pulvinar is considered mainly somatosensory in function and will not be dealt with in detail here. Much as its better known cousin, the ►dorsal Lateral Geniculate Nucleus (dLGN), nestles over its input from the optic tract, the Pulvinar nucleus forms a cushion-like structure over the fibers forming the brachium of the Superior Colliculus (SC, which provides a significant input, see below). Unlike the dLGN, the Pulvinar nucleus is less cell dense and does not appear obviously internally structured or laminated. It required anatomical studies, coupled with histochemistry (for substances as diverse as ►calbindin, ►AChE and ►SMI32; recently reviewed in [2]) to reveal the internal organization of the nucleus.

In terms of "vision," the Pulvinar receives a small input directly from the ►retina, and from the superficial layers of the SC – these are focused on the Inferior and Lateral divisions, located laterally in the nucleus.

The Pulvinar is typical of a 2° sensory thalamic structure – it receives input from sub-cortical structures and is reciprocally connected to the cerebral cortex (a 1° structure would be dLGN, with major input from the periphery). In the case of the Pulvinar this connectivity with cerebral cortex is extremely widespread, from ►primary visual cortex (V1) on the ►occipital pole, up to and including ►parietal, ►temporal, ►frontal and even ►cingulate cortices, as well as the amygdala. These connections are organized within the Pulvinar in a lateral to medial direction, with those areas dealing with "lower" sensory function, primary visual cortex and near extra-striate (V2 to MT (V5)) being more medially located than the "higher" sensory areas (temporal, parietal and above). These therefore associate directly with visual inputs from the retina and SC – see Fig. 1.

Indeed, the sub-cortical connections themselves also mirror this organization, such that the deeper layers of the SC (more motor than the superficial



**Visual Role of the Pulvinar. Figure 1** Inset shows the relative position of the Pulvinar in the posterior thalamus – note that at this relatively posterior level the Pulvinar occupies almost the whole of thalamic space (modified from an image from BrainMaps.org). Main figure: of the four Pulvinar nuclei, the Oral, or Anterior Pulvinar is not visual, but deals with somatosensation, and would not normally be found at the same AP level as the main mass. The structure is divided roughly equally into three subnuclei – Inferior, Lateral and Medial. The homologous structure in lower animals is the Lateral Posterior thalamic group. *Arrows* indicate anatomical connections known to exist between structures listed, showing the topography of these connections across the Pulvinar from lateral to medial: from "early" visual structures to "higher-order" cortical and associated structures. *Pi* Inferior Pulvinar; *Plat* Lateral Pulvinar; *Pm* Medial Pulvinar. Near-extrastriate include these cortical fields like V2, V4 etc, which surround V1, but whose names may vary from species to species. Note that this is an over simplification – there may be as many as 8–10 possible subdivisions of the Pulvinar and nomenclature is not fixed but varies from publication to publication.

visual layers) contact the more medial regions of the Pulvinar [3].

Like other thalamic nuclei, the Pulvinar also receives powerful modulatory inputs from the ►brainstem and other brain regions involved in arousal and ►sleep/wake.

Divisions within the Pulvinar have been defined anatomically. However, they are also identifiable by virtue of the maps of visual space which are represented by the ►visual receptive fields of the individual cells within the nucleus. Thus contralateral visual space is represented several times across the medio-lateral extent of the nucleus.

Cells within the Pulvinar are of two major types – the more common "relay" cells, which are excitatory and project to the cerebral cortex, and intrinsic inhibitory interneurones, which project locally within the nucleus, and may be restricted within sub-nuclei – this is a common feature of thalamic processing in most (but not all) thalamic nuclei.

Thus the Pulvinar has the capacity to carry out significant, possibly high level, visual processing and sits in a unique position, whereby information from very diverse cortical sources may be processed in a central location, prior to "redistribution" to a wide cortical receiving network.

## "Higher" Thalamus

The Pulvinar is often regarded as a higher thalamic nucleus – basic visual functions are first carried out by the network which includes the dLGN and cortical area V1, before higher cortical regions (and associated thalamic nuclei) then add subsequent processing (the hierarchical model, but see below). Visual cortical areas send axons to the pulvinar regions with which they communicate in ►retinotopic order and, as noted above, this is reflected in the physiological organization of the pulvinar. Cortical cells providing input to thalamus (this is a general statement which applies to the pulvinar) come in two different types – driver and modulators – these appear to sub-serve different functions – driver provide a main source of activation, while modulators alter on-going activity [4]. Anatomically, driver activity appears to come from ►cortical layer V cells, and modulator from layer VI. While specific sensory nuclei, like the dLGN, receive only modulatory inputs, higher nuclei, like the pulvinar receive both types from each of the cortical areas with which it communicates (with the possible exception of V1 which sends only driver type). The nature of the visual inputs to Pulvinar nuclei has not been studied in depth at the single cell level.

Visual Pulvinar cells have visual receptive fields – these can range from simple concentric types to oriented

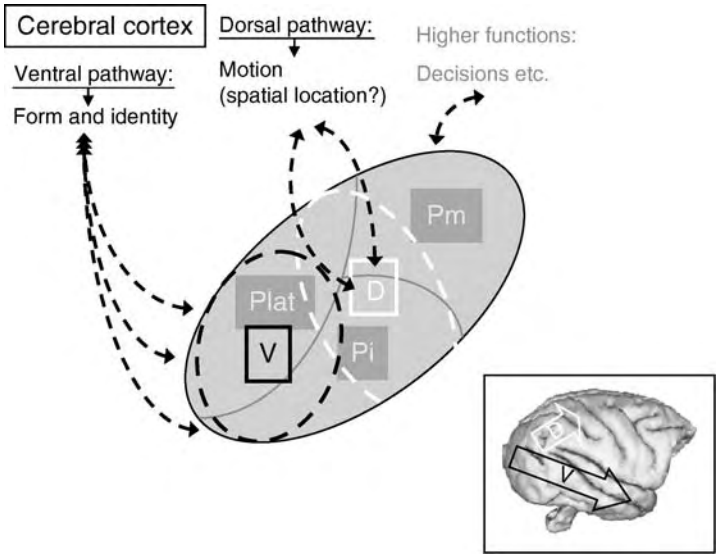
or binocular, or even color specific, but these are mixed throughout the region, perhaps signaling the diversity of inputs, or some level of organization as yet not known. It is known that some cells in Inferior and Lateral Pulvinar have responses which include modulation from "non-visual" sources such as eye-position – responses typical of some higher cortical areas e.g. parietal/frontal [5]. Key to an understanding of pulvinar function, visual responses are modulated by attention, or ►visual salience – which can result in increased activity – selecting a salient cue – or decreased – for the suppression of non-salient cues [1]. At the "higher" end, in the medial pulvinar, receptive fields are even more diverse and difficult to quantify, again representing the more abstract nature of their inputs. We may regard these as non-visual, in the sense that processing has gone beyond the strictly sensory.

Cells projecting from pulvinar to cortex may be organized at a finer level than the main subdivisions suggest – for example, cells projecting to neighboring, but separate, parietal cortical areas are found in sheets (laminae?) within lateral and medial pulvinar [6]. However, the influence of pulvinar cells on recipient cortical cells is largely unknown.

## Sensory Integration for Attention and Arousal

The visual pulvinar cannot be properly described without placing it in the context of the nucleus as a whole, and the organization of the visual primate brain. Separation of visual information through the primate brain into two functionally distinct streams has been widely accepted for many years – the ►Dorsal Stream carries information about spatial location, and motion, from V1 to parietal cortex and beyond, and the ►Ventral Stream carries information about form and color, etc, from V1 to the temporal cortices (including, for example, face recognition cells). Very recently, Kaas and co-workers [2] have suggested that the Pulvinar may also be organized in this way, such that the more lateral component (parts of the Inferior and Lateral divisions, as defined before) form part of Ventral stream, and the more medial Inferior and part of the Lateral form part of the Dorsal pathway, in particular related to the motion sensitive areas such as MT and MST – see Fig. 2. However, this appealing suggestion falls short of a complete picture, as these authors have not accounted for the major part of the Dorsal stream which involves parietal areas encoding eye-position etc. It is tempting to speculate that the more medial components of the Lateral and parts of the Medial Pulvinar may form this other component, as these are the very areas containing cells with eye position information (see above, and Fig. 2).

Information from other senses are clearly utilized by the higher regions of the pulvinar; for example it is notable that cells may respond not only to vision, but eye movements, and, further, head or even arm movements. Although not strictly "visual," it is important to note that these movements (actions) are based upon the visual knowledge of the relative positions of the objects



**Visual Role of the Pulvinar. Figure 2** As for Fig. 1, the Pulvinar nucleus is shown as a coronal section. Here we illustrate current thoughts on the relationship of Pulvinar with basic visual function: regions of pulvinar, which cross traditional anatomical/connectional borders, are "associated" with the two main cortical processing streams, which are illustrated in the inset (modified from an image from BrainMaps.org). Thus, parts of Inferior and Lateral Pulvinar contribute to the Ventral "What" pathway, while the remainder of the inferior and parts of the Lateral and Medial Pulvinar contribute to the Dorsal "Where" pathway – see text for more detail.

of interest and this combination of vision and action is key to our interaction with the space around us [3].

Whether or not we regard the pulvinar as "following" the now accepted two visual pathway model, the key element in its function is the major descending cortical input (driver and modulator), with reciprocating connections back to cortex. These loops may constitute a mechanism as important for central processing, (here for vision, but in more medial pulvinar involving other senses), as the loops created between directly linked cortical areas (for example the massive reciprocal connections between V1 and V2, or V1 and MT(V5)). They provide a part of the alternative view to the traditional hierarchical model of cortical function, in which activity may ascend and descend cortical areas with equal strength, acting continuously. Thus pulvinar may act as a component in a series of integrated loops-within-loops allowing cortico-cortical interactions to achieve appropriate levels of excitation to "pick" sensory stimuli of relevance, without producing saturating or damaging levels of excitation, or uncontrolled oscillation, a hypothesis first put forward by Crick and Koch (the "No-strong-loops" hypothesis [7]).

### Clinical Note

Much of our current understanding of the overall role of the Pulvinar has come from clinical studies of brain damage in humans. While animal lesion studies can give significant insight in many cases, work on the Pulvinar is sparse and not very revealing, particularly because of the ability of animals to recover function soon after lesioning. In humans, damage to thalamic areas following ►stroke is quite common. However, the exact region of damage is less easy to ascertain than in precise animal lesion studies, and may often include several sub-regions. Nevertheless, human studies support the view that the Pulvinar (as a whole) is involved with attention and, for example, the selection of appropriate targets from within a field of distractors (picking a face from the crowd!) [8]. At a higher, perhaps more abstract level, damage to the most medial components of the Pulvinar can alter our visual recognition of fear-inducing stimuli [9]. However, most excitingly very recent imaging studies have utilized strategies to reveal internal organization of the human Pulvinar which confirms that the visual organization can be examined on a level equivalent that of animal studies, and promises that future studies may complete the link between the single cell-level studies in monkeys and cognitive studies in humans [10].

## Synonyms

Visual space perception for action

## Definition

Visual space representation refers to the perception of position, movement and orientation in 3D space as well as 3D shape of visual objects.

## Characteristics

### Introduction

We live in a three-dimensional world. In order to act in the real world, we need an internal representation of the 3D space around us. Where in the brain do we have the neural representation of the 3D world? Since Ungerleider and Mishkin proposed the idea of "two visual pathways" in 1982, it has been generally accepted that the dorsal cortical visual pathway projecting into the posterior ►parietal cortex is concerned with "space vision," i.e., perception of the position and movement of visual objects in space, whereas the ventral cortical visual pathway projecting into the ►inferotemporal cortex is concerned with "object vision," i.e., identification of objects by their shape and color (►Visual processing streams in primates). There are two important areas for the early processing of space vision in the dorsal pathways [1]. One is ►V5/MT for visual motion, and the other is ►V3A for ►binocular disparity or ►stereopsis. Area V5/MT projects to area ►MST [2] and area V3A projects to area ►CIP [3,4] (LOP defined by Van Essen's group) of the ►parietal association cortex. MST represents movement of objects in space and CIP represents 3D orientation of axis and surface of visual objects.

In early studies of single unit activity of the posterior parietal association cortex in conscious behaving monkeys, V.B. Mountcastle's group found several classes of neurons related to ►eye movements of ►smooth pursuit, ►saccade, and fixation as well as those related to the hand movements of reaching and grasping. Initially, they were considered to be related to the motor command or visual attention (►Visual attention). Later, it became clear that many of them were related to the perception of spatial positions or movements of visual targets [5,6]. Moreover, in the anterior bank of caudal ►STS (MST and its vicinity), purely visual neurons sensitive to visual motion in space such as the ►depth-movement-sensitive (DMS) neurons [6] and the ►rotation-sensitive (RS) neurons [7] were recorded. In area CIP in the lateral bank of the caudal intraparietal sulcus, a group of disparity-sensitive neurons that represent the axis orientation [6] and surface orientation [3,4] of objects in space were recorded. Sakata et al. [6] proposed that the parietal association cortex is primarily concerned with the visual space perception, by representing motion, position, and orientation of visual objects in space. In recent studies of area ►AIP of the inferior parietal lobule (►IPL), Murata et al. [8] found a group of ►hand manipulation task-related neurons that were visual dominant and selective for the 3D shape and orientation of the target object. Motor dominant and visual-motor neurons were also recorded in AIP, which may play an important role in the visual guidance of hand actions.

In this essay, we briefly describe a variety of parietal visual neurons that represent various aspects of space vision. The parietal association cortex is primarily concerned with the perception of the physical environment, representing three-dimensional movement, position, orientation, and structure in the egocentric frame of reference. Space vision is action-oriented, and its information is used to guide hand actions through the parieto-frontal interconnections.

### *Representation of Visual Movement in Space by MST Neurons*

MST (medial superior temporal) area in macaque monkeys is anatomically defined as a forward cortico-cortical projection from the neighboring V5/MT area [2]. Two distinct areas of projection from V5/MT were demonstrated by tritium-labeled proline injection [2], and these may correspond to the MSTl and MSTd areas defined by R. H. Wurtz's group in relation to pursuit eye movement. Unlike V5/MT, MST neurons have large receptive fields and no retinotopic organization. The appropriate stimulus for MST neurons is not a simple linear movement of the retinal image. Many MST neurons respond to more complicated stimuli such as movement in depth [6], rotary movement in space [7], and optical flow (►Optic Flow), as studied in the MSTd by Wurtz's group.

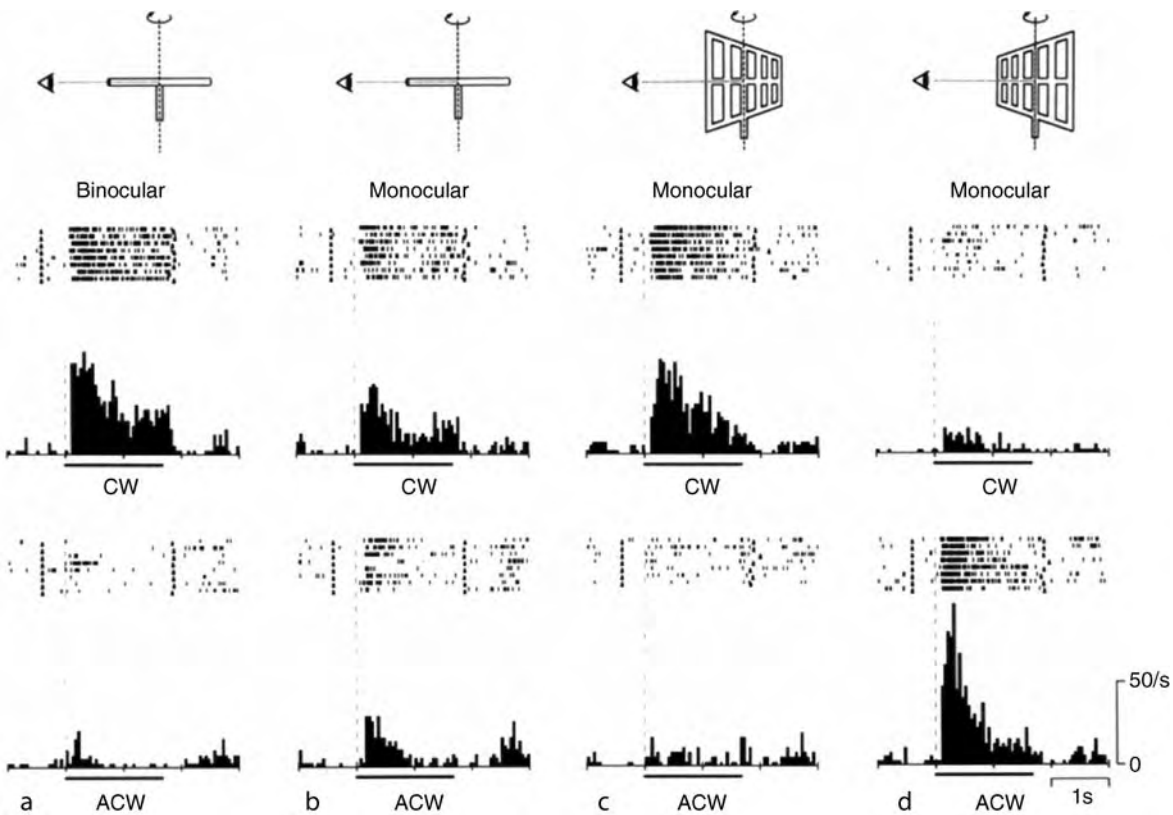
*Depth-movement-sensitive neurons*: A group of MST neurons that respond to approaching or receding movement of the visual stimulus better than to the fronto-parallel movement were designated as depth-movement-sensitive (DMS) neurons [6]. Most DMS neurons respond to size changes as well as to disparity changes of the stimulus. The majority of DMS neurons respond to a combination of these two stimuli better than to either one of these stimuli alone.

*Rotation sensitive (RS) neurons*: RS neurons respond significantly better to rotary movement than to linear translational movement of the same stimulus. These neurons were found in the anterior bank of the caudal superior temporal sulcus that turned out to be MST and its vicinity. An extensive study of these neurons was published later [7]. RS neurons respond well to the rotation of a luminous bar or a spot and are likely related to the perception of rotations of individual objects. Moreover, the majority of RS neurons respond better to depth rotation than to rotation in the fronto-parallel plane [5]. An example of a depth RS neuron responding to the Ames window is shown in Fig. 1. RS neurons may play an important role in guiding turning, swinging, and revolving actions.

### Neural Representation of Spatial Position in Area LIP and 7a

The posterior parietal cortex is the most likely area of the brain involved in the perception of position in egocentric space, as lesions in this area in humans cause visual disorientation in which the judgment of distance is severely disturbed.

*Visual fixation neurons of ►LIP and 7A*: In early studies of parietal neurons in alert monkeys, visual fixation (VF) neurons were found to be activated during fixation on a static target in a certain position [5]. Most of the VF neurons are selective for the fixation direction (gaze direction) and increase their activity monotonically with increasing orbital eccentricity. Many are also selective for the distance of the fixation point. The majority of depth-selective VF neurons prefer a nearby target, and their activity increases gradually as the distance of the target from the eye decreases with increasing angle of convergence and degree of accommodation. There is psychophysical evidence by C. Hofsten to indicate that a change in the angle of convergence changes the distance estimation. It was found that the visual stimulus in the fovea was necessary to activate at least some of the VF neurons



**Visual Space Representation for Action. Figure 1** Responses of depth RS neuron to rotation of Ames window (a trapezoid 21 cm in height, with a long edge of 25 cm and short edge of 14 cm), compared with those to a regular bar. (a) Response to rotation of a bar under binocular viewing conditions. (b) Response to rotation of a bar under monocular viewing conditions. (c), (d) Response to rotation of a trapezoidal (window-shaped) plate (around the axis parallel to the base) under monocular viewing conditions, with the longer edge moving in front of (c) or behind (d) the axis. The range of rotation was half a turn (180°), and the viewing distance was 150 cm for all conditions. Note a reversal of preferred direction of rotation in D. Stimuli were rotated in the sagitto-horizontal plane, although diagrams are drawn on the horizontal plane for simplicity (Adapted from [7]).

[5]. Since many VF neurons stopped their discharges when the LED spot for fixation was turned off, they likely represent the spatial position of the visual target in the egocentric frame of reference.

Recent discovery of eye position neurons in the ►somatosensory cortex (SI) by M. E. Goldberg's group support the view that VF neurons receive ►proprioceptive signals from the extraocular muscles via SI to represent the eye position to be combined with the visual signal of the target in the fovea. This position signal is necessary to guide reaching of the hand to the target.

### Area CIP and the Representation of 3D Surface Orientation by the Integration of Multiple Depth Cues

In the caudal part of the lateral bank of the intraparietal sulcus, we identified a distinct visual area that contains neurons selective to the orientation of an object in depth [6], which was later designated as area CIP (caudal intraparietal) [3,4]. This area appears to be included in the dorsal visual pathway, as it receives strong input from the neighboring V3A, which has been reported by S. M. Zeki's group to contain neurons sensitive to binocular disparity and its neurons are organized in a columnar fashion according to binocular disparity (near/far). The majority of CIP neurons are sensitive to binocular disparity, and the receptive field size of the neurons is normally more than 15° in diameter, often extending to quarter or half of the visual field. The visual properties of these neurons are tested using real objects as well as binocular computer graphics. Many CIP neurons show rough selectivity to the shape of the visual object, either to an elongated object or a flat plate-like object, and show strong selectivity to the 3D orientation of the preferred object. Orientation-selective neurons with selectivity to the elongated object were designated as ►axis-orientation-selective (AOS) neurons, and those selective to the flat plate-like object were designated as ►surface-orientation-selective (SOS) neurons.

In further experiments, the properties of the SOS neurons were extensively tested using binocular computer graphics. First, their preference to the 3D surface orientation was tested for depth invariance, by changing the depth of the object from "in front of" to "behind" the fixation spot [3]. Most of the SOS neurons tested showed strong depth invariance, preserving the 3D orientation-selectivity regardless of the change in depth of the object relative to the fixation spot. In contrast, the disparity-sensitive neurons in the occipital cortex are known to be tuned to a specific disparity (near, far or zero) as studied by G. F. Poggio's group. It is likely that the disparity gradients across a cluster of V3A neurons are integrated in the SOS neurons in order to represent depth-invariant 3D orientation. Second, the SOS neurons were tested for their sensitivity to monocular depth cues, such as linear perspective and texture gradients [4]. The majority of SOS neurons show a selective response to the surface orientation defined by a monocular depth cue alone. In almost all the SOS neurons showing sensitivity to both binocular and monocular depth cues, the selectivity is the same for the surface orientation defined by the binocular cue alone in the random-dot stereogram (RDS) and that defined by the monocular cue alone (Fig. 2). This result suggests that the binocular and monocular depth cues are integrated in the SOS neurons in order to construct a cue-invariant general representation of surface orientation. SOS and AOS neurons are necessary to adjust the orientation of the hand to the orientation of the object to be grasped or the slot to be inserted.

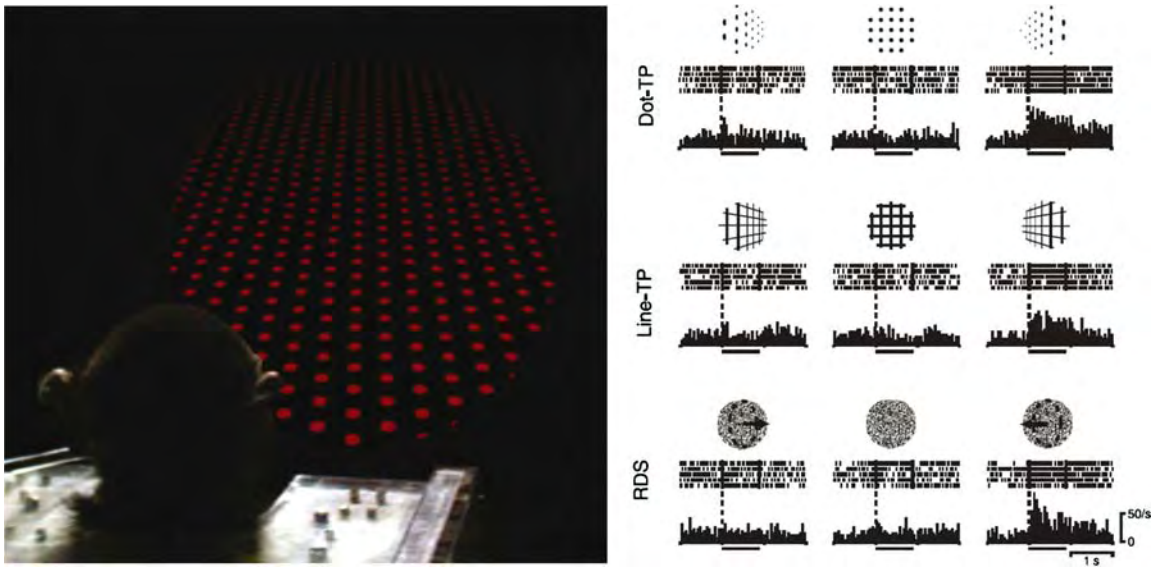
### Linking Space Vision to the Control of Hand Actions

The parietal association cortex and ►premotor areas have several parallel inter-connections with each other that may play an important role in linking space perception to the control of hand and arm movements. The dorsal visual pathway is separated into two channels: the dorso-dorsal pathway and the ventro-dorsal pathway as suggested by G. Rizzolatti's group. In the dorso-dorsal pathway, ►V6A defined by Galletti et al. [9] in the ►superior parietal lobule (SPL) on the anterior bank of the parieto-occipital sulcus has strong reciprocal connections with the dorsal premotor cortex (►F2 and ►F7). V6A neurons are mainly related to reaching [9], although they may also be related to grasping. They may also be related to eye-hand coordination, as indicated by R. Caminiti's group. V6A and ►MIP overlap the ►parietal reach region (PRR), as defined by R.A. Andersen's group. Some of the visual neurons in V6A encode the craniotopic (head-centered) frame of reference that is suitable for controlling reaching movements [4]. There is an intense anatomical connection between V6A and LIP as demonstrated by G. Rizzolatti's group. This connection may provide a spatial position signal from VF neurons to V6A for the control of reaching.

The ventro-dorsal pathway projects to the anterior intraparietal (AIP) area and area ►PFG/PF of the inferior parietal lobule (IPL). These areas have reciprocal connections with the ►ventral premotor cortex (F5), as studied by G. Rizzolatti's group. They found ►mirror neurons in the PFG/PF, similar to the ones they found in F5, whereas AIP was related to visual guidance of grasping [8].

### Hand Manipulation Task-Related Neurons in AIP

AIP neurons are activated during a hand-manipulation task in which monkeys are required to grasp and pull various objects [8]. In order to separate the visual response from the movement-related activity, the activity of AIP neurons was compared under three conditions: movement in light and in darkness, and fixation on an object in light. Thus, the task-related



**Visual Space Representation for Action. Figure 2** *Left*: photograph of a monkey facing a computer display showing a surface orientation defined by texture gradients. *Right*: activity of a representative SOS neuron showing sensitivity to both monocular and binocular cues. This neuron showed selectivity to a surface tilted 45° clockwise around the Y-axis regardless of the type of the depth cue, such as texture gradients in a dot texture pattern (Dot-TP, *top row*), those in a line texture pattern (Line-TP, *middle row*), or binocular disparity gradients in a random-dot stereogram (RDS, *bottom row*) (Adapted from [4]).

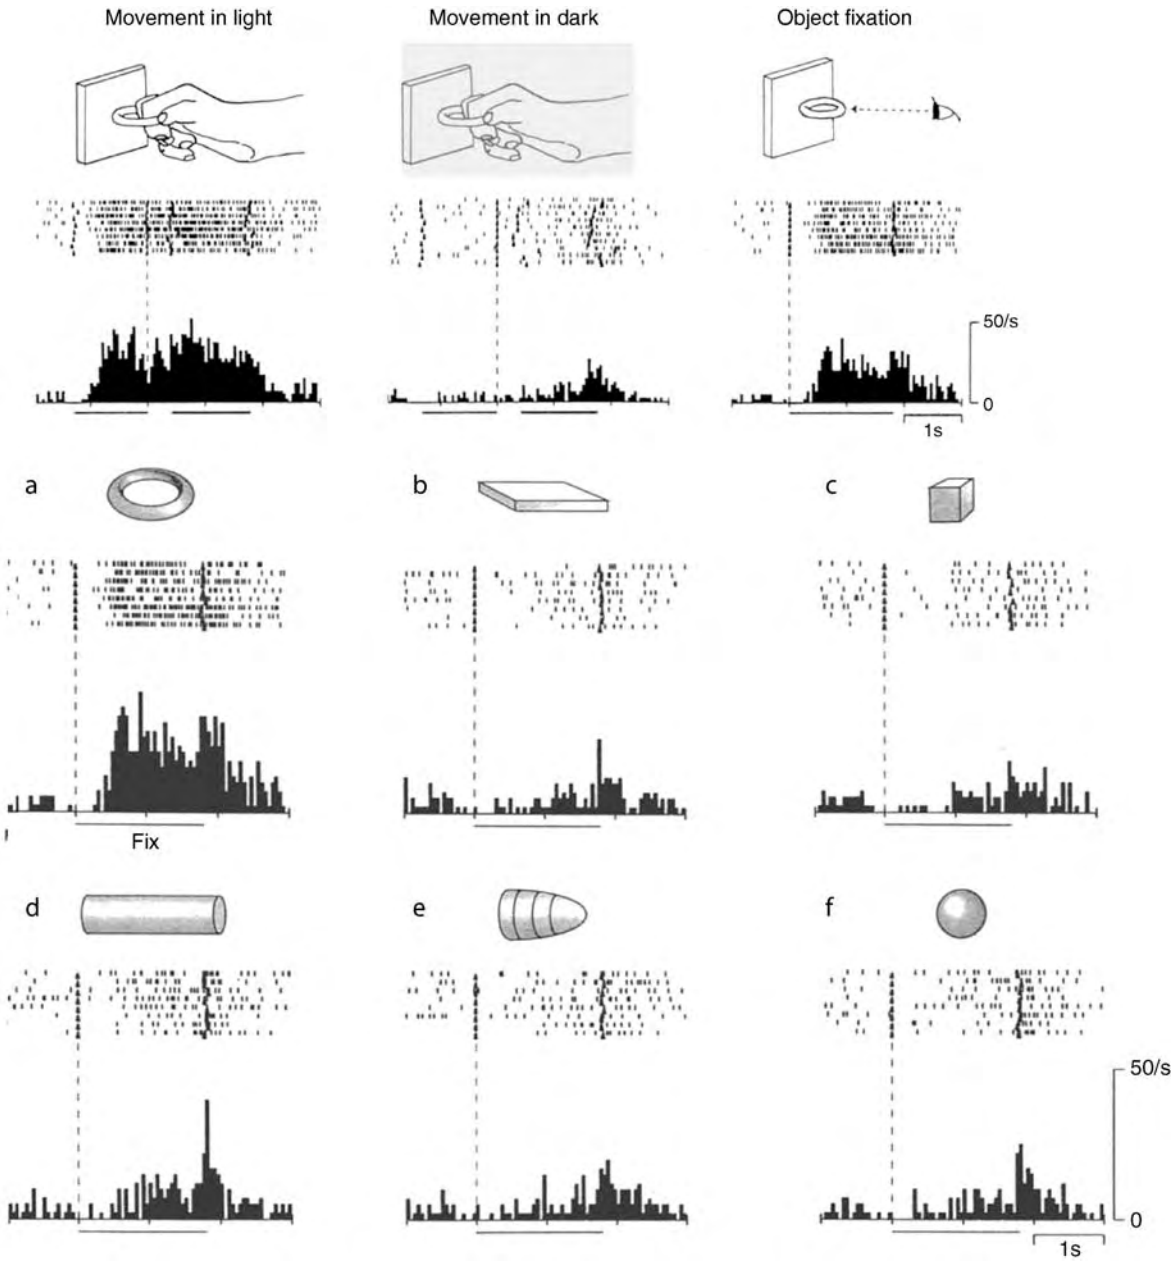
neurons could be classified into three different types; motor-dominant, visual-motor, and visual-dominant neurons. Motor-dominant neurons fire during manipulation both in light and in darkness with the same intensity. Visual-dominant neurons respond only in the light. Some of them (object type) are activated during object fixation. Visual-motor neurons reduce their responses during manipulation in darkness and some of them (object type) respond during object fixation. Figure 3 shows an example of object-type visual-dominant neurons. This typical neuron showed a highly selective response to the view of a ring among six 3D objects with elementary shapes, suggesting that it represented the 3D shape of the objects. Motor-dominant neurons are likely to be activated by the efference copy of the motor command. Since AIP has a strong reciprocal connection with F5, the efference copy most likely comes from F5.

### *Role of F5 Neurons in Visual Guidance of Grasping*

In the ventral premotor cortex (F5), neuron activity shows selectivity for the type of hand movement, such as precision grip, finger prehension, and whole hand grasping [10]. The functional properties of F5 neurons were studied in collaboration with Rizzolatti's group using the same hand manipulation task apparatus as used for the AIP neurons. A group of hand-manipulation-related neurons in F5 is activated partially when the monkey fixated on the objects to be grasped, just as in the visual-motor neurons in area AIP. The other group of grasping neurons does not show any visual response, just like the motor-dominant neurons in AIP. The major difference is that no neurons similar to the visual dominant neurons of AIP were found in F5. These results suggest that F5 is closer to the output motor system than the AIP is. Indeed it is well known that the premotor areas including F5 send projections to the ►primary motor cortex (F1). F5 likely receives visual information about objects, such as 3D-shape, orientation and size from AIP.

## Conclusion

The parietal association cortex is the site of visual space perception. In MST, (i) depth-movement-sensitive (DMS) neurons integrate size changes and disparity changes in order to represent movements in depth; and (ii) rotation-sensitive (RS) neurons, including depth RS neurons, represent rotary movements in space. In CIP, (i) axis-orientation-selective (AOS) neurons and (ii) surface-orientation-selective (SOS) neurons represent the 3D orientation of elongated and flat objects in space, respectively. The early finding that ►visual fixation (VF) neurons in LIP and 7A represent spatial positions of objects in a head-centered frame of reference was supported by a more recent finding of eye position neurons in S1. VF neurons may contribute to the control of reaching through the reciprocal connection of LIP to V6A. In AIP, hand-manipulation task-related neurons are categorized into motor-dominant, visual-motor, and object-type visual-dominant neurons representing the



**Visual Space Representation for Action. Figure 3** Example of visual-dominant neuron which responded very selectively to the ring. The *upper panel* shows activity during manipulation of the object in light and in darkness, and during fixation on the objects. The *lower panel* shows the selectivity of the neuron during fixation on six different objects (Adapted from [8]).

V

3D shapes of objects for grasping. AIP neurons likely contribute to the ►preshaping of the hand through the reciprocal connection of the AIP and F5.

# Visual Space Representation for Reaching

Alexandra Battaglia-Mayer,
Roberto Caminiti
Department of Human Physiology and Pharmacology, SAPIENZA, University of Rome, Rome, Italy

## Synonyms

Visuo-motor space; Visual action space

## Definition

Visual space for ►reaching refers to the ►peri-personal space within which arm movement is made to bring the hand on objects that have been localized by using visual information.

## Characteristics

### Behavioral Characteristics of Arm Reaching to Visual Targets

Visually-guided reaching consists of a coordinated eye-hand action, often also accompanied by a movement of the head, toward objects identified through visual information (for a review, see [1]). When the visual target to reach is in the periphery of the ►visual field, the hand movement is usually preceded by a fast (800°/s) ►saccade that brings the target onto the ►fovea. If target eccentricity exceeds 10° of visual angle, eye movement is accompanied by concomitant head movement. The command to move the head, the eye, and the arm is addressed almost simultaneously to these different effectors, as indicated by the onset of their respective ►electromyographic activity. However, the different inertia allows the eye to move first, followed by the head and then by the arm. Since the speed of the saccade brings the eye to the target before the hand moves from its starting position, the initial motor command is composed by using peripheral visual information, while foveal vision might be used for control of hand movement in its final stage. Accuracy of reaching is maximal when vision of hand is allowed and it is deteriorated whenever eye or head movements are prevented.

### Coordinate Transformations

In the visual space for reaching, the direction of the target is mapped in ►retinotopic coordinates, whereas its distance is derived by combining ►retinal disparity and fixation distance information, such as the ►vergence angle of the two eyes, ►accommodation, and ►vertical disparity. The vergence angle has a crucial importance, since in the peri-personal space its range of maximal efficiency roughly coincides with the arm length. This view is supported by the observation that in early postnatal development arm reaching develops at the same time as binocular control. It is believed that this information, together with that about hand position in space, is used to specify the desired movement trajectory, which is based on the computation of the difference between the target and the hand location, an entity referred to as "►motor error." In the field of view, the position of the hand can be encoded in visual coordinates, while outside the visual field or in the dark, ►proprioceptive information and corollary signal of the motor command contribute to its determination. The combination of information concerning target and hand position requires the transformation of the end-point of reaching from retinal to ►egocentric coordinates, a process to which eye position can contribute essential information, provided that target depth is recovered mainly from binocular (►vergence) cues. Therefore, a combination between eye and hand information is believed to occur into a common egocentric (binocular) frame of reference. Various psychophysical studies have outlined the cascade of sensorimotor transformations necessary to remap target location from initial retinotopic coordinates into binocular viewer-centered frame, to body- and hand-centered frames. A modern view is that the ►coordinate frame used to encode arm reaching to visual targets is hybrid and context-dependent, since it can vary depending on the current sensory information, task demands, geometry of the visual space, and cognitive context (for a review, see [1]). Forward models of movement control state that an estimate of

the sensory consequence of an upcoming or planned movement is used to compute the difference between the motor command and its state, thus contributing essential information to the computation of the "motor error."

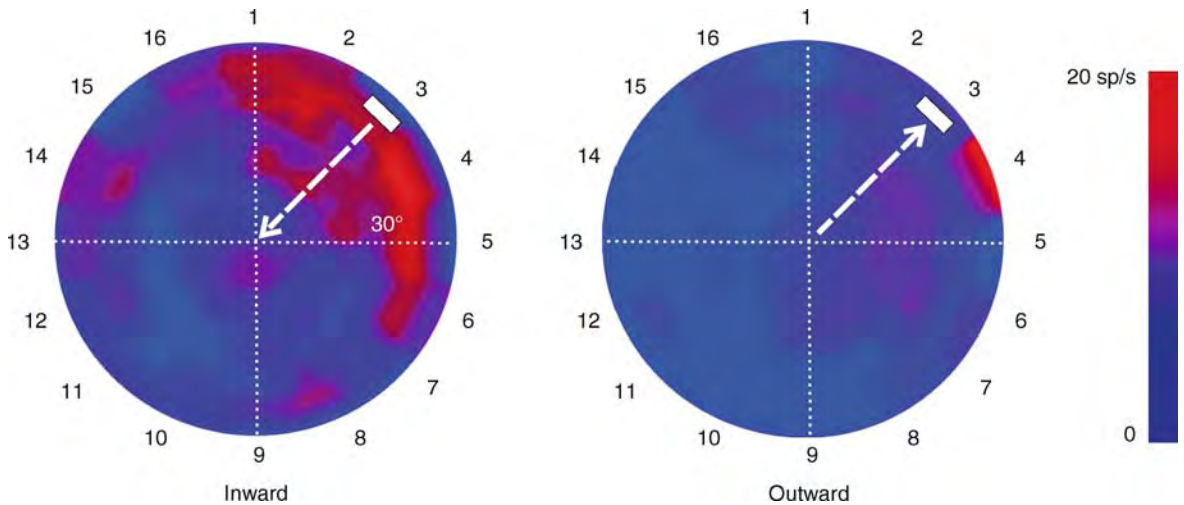
## Central Representation of the Visual Space for Reaching

The visual space for reaching is represented in a variety of parieto-frontal cortical areas, which form the so-called ►*visual dorsal stream* [2], a cortical pathway that originates from visual cortical areas and through ►Posterior Parietal Cortex (►PPC) processes information about spatial properties of objects and of the visual scene where they are located ("where" information). This type of information is then conveyed, through cortico-cortical projections, to ►premotor and ►motor cortex that are the output-regions of the parieto-frontal network to address messages to the spinal cord. From this perspective the dorsal stream can be considered a distributed system essential for composition of motor commands of eye-hand signals necessary for the visuomotor operations of daily life. The cortical areas of the parieto-occipital (PO) junctions are believed to play a crucial role, since they receive visual inputs from different ►extrastriate cortical areas and project to ►premotor cortex in the ►frontal lobe [1–4].

►Parieto-occipital (PO) cortex contains a coarse representation of the visual field, with a wider representation of visual periphery, as compared to other visual areas. PO neurons have large and often bilateral ►receptive fields, and are sensitive to the orientation and direction of motion of visual stimuli (Fig. 1).

These neurons are also influenced by optic flow fields (►Optic flow), and this property is an important source of optic flow information to motor cortex, via frontal premotor areas. In fact, optic flow modulates also the activity of motor cortical cells that, among the different flow motions, are particularly sensitive to expansion-like flow fields. In fact, "expansion" is the type of motion that influences the retina when a subject moves toward an object (or when the object approaches the subject), therefore this type of optic flow provides information about the subject-object relative movement direction, in other words about the interaction between ego-motion and object motion (see chapter on ►Vestibular-Visual Interaction). Posterior parietal cells sensitive to optic flow do not display "opponent vector organization," a feature of parietal visual neurons that can be important in processing the radial motion of objects moving toward or away from the fovea [5]. Thus, encoding object motion in the visual space representation of parietal cortex might reside on separate parallel mechanisms, segregated in different populations of neurons, one based on optic flow information and related to global motion, another on opponent vector organization, mostly devoted to local motion analysis.

As with the majority of parietal neurons, the activity of PO cells is often influenced by the angle of ►gaze



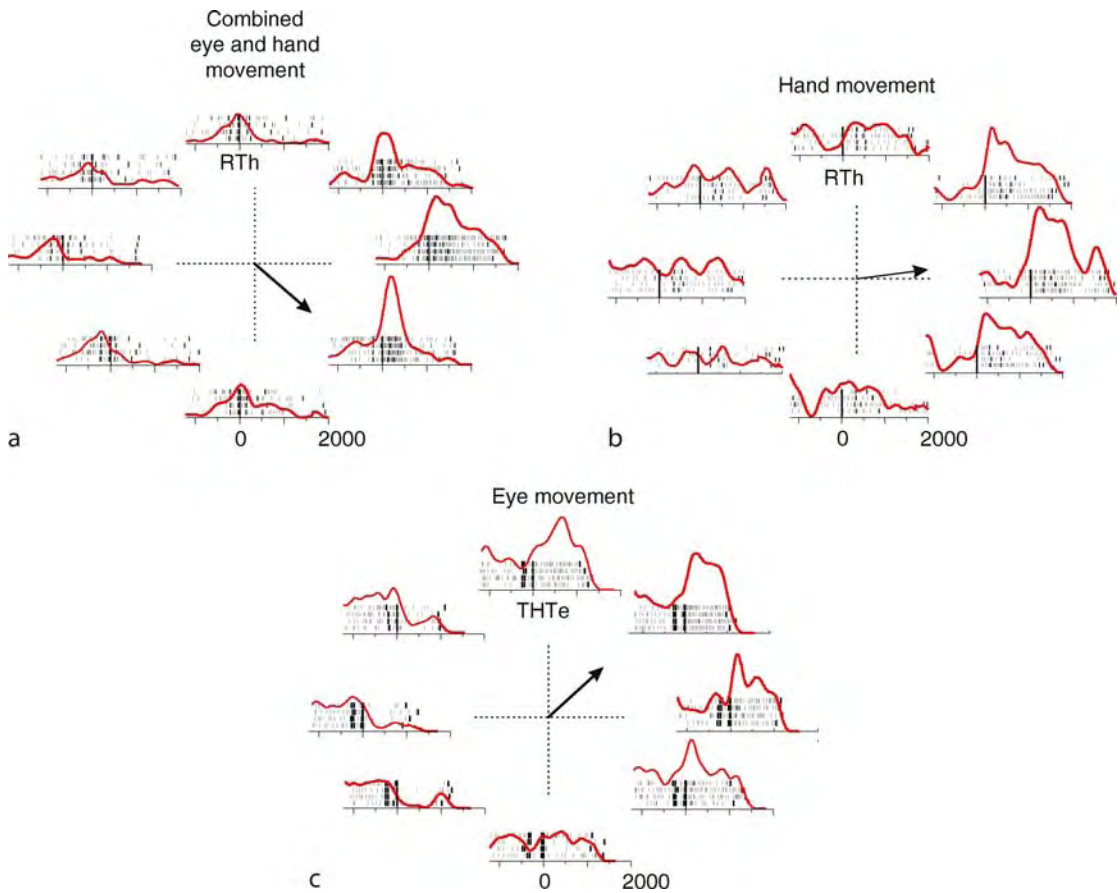
**Visual Space Representation for Reaching. Figure 1** Visual response features of a parietal cell in the form of color contour maps of the visual field, observed during a visual stimulation task during which the monkey was fixating in the center of the workspace and a white bar was moved in 16 directions inward (IN) and outward from the fovea (0°). Notice the difference of the cell response for different stimulus motion direction. Horizontal and vertical meridians of the visual fields are shown by white dotted lines, the numbers indicate the direction of stimulus motion. The color calibration bar is in spikes/s.

[6], a signal that is essential for the transformation of the position of a visual target from retinal to head-centered coordinates.

Neurophysiological studies have shown a gain modulation of eye vergence on the disparity-tuning of neurons in the ►Lateral intraparietal area (LIP, area 7) of monkeys performing saccadic eye movement to targets in 3D space [7]. This study provides evidence for an egocentric coding of 3D target distance in parietal cortex. Interestingly, LIP projects to the ►anterior intraparietal area (AIP), a region cortico-cortically connected to ventral premotor (►Area F5) cortex, and involved in the control of visually-guided hand movement (for reviews, see [8]). Therefore, information about target distance and its update is available to the network controlling not only eye, but also hand movement.

## General Properties of Reach-related Neurons in the Parieto-Frontal System

The activity of reach neurons in both frontal and parietal cortex varies in a broad fashion with arm movement direction and position (Fig. 2a and b), and encoding of movement direction resides in a ►population code (for a review, see [1]). In addition, reaching neurons across the parieto-frontal system are influenced by the visuo-spatial signal concerning target location, as well as by the eye position and movement direction (Fig. 2c). In both frontal and parietal cortices, neural modulation occurs at all stages of reaching, i.e. during preparation, execution of eye-hand movements, as well as during static holding of hand and/or eye in space [1,9,10]. In conclusion, the essential characteristic of parietal reach neurons consists in their combinatorial nature,



**Visual Space Representation for Reaching. Figure 2** Neural activity in the form of raster displays and spike density functions (*red curve*) of three parietal cells studied in the *Reaching Task* (a), where both eye and hand moved toward a peripheral target, the *Reaching-Fixation Task* (b), where only the hand moved to the target, while the eyes were fixating the center of the workspace, and the *Eye Movement Task* (c), where only the eye moved toward the visual target. For each movement direction four replications are displayed. Action potentials are indicated by grey strokes, while thick black markers define behavioral epochs. The neural activity is aligned (*black vertical line*) to the hand reaction-time (RTh) epoch (a, b), and to the end of eye movement when the eye stays on the peripheral target (THTe; c). In the centre of each panel, the black arrow indicates the preferred direction. (modified from Battaglia-Mayer et al. (2005) Cereb Cortex 15:514–525).

with different eye and hand signals influencing neural activity with different strength, depending on the task demands.

The coexistence of a variety of signals is not specific to the parietal cortex, but might be regarded as a general feature of all nodes of the parieto-frontal system, where different signals are combined and distributed all over the network in a gradient-like fashion. However, the different cortical regions might be functionally distinguished on the basis of the strength with which a given signal influences neuronal activity, together with their cortico-cortical connections.

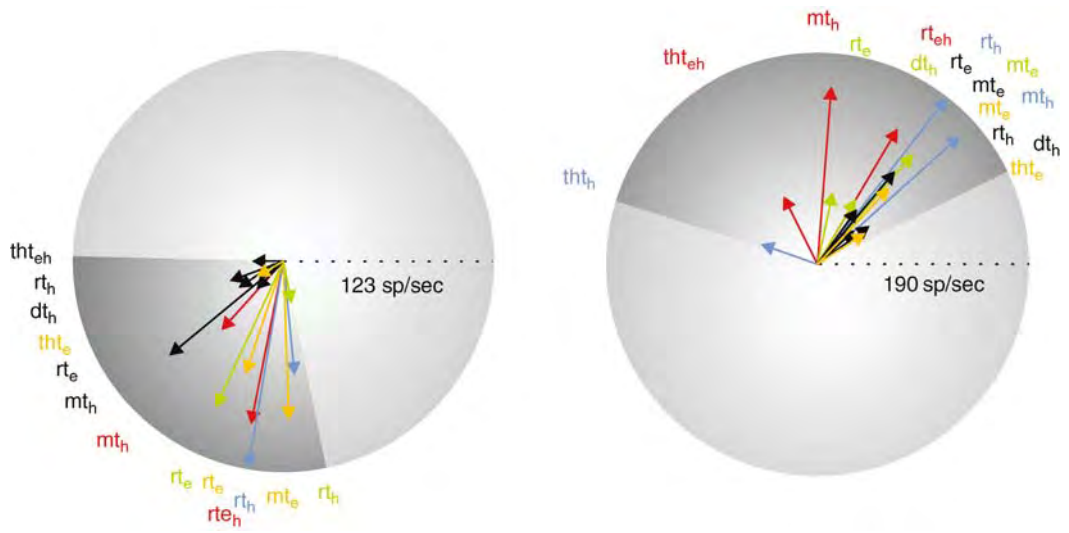
This graded influence takes different forms and can be shown both at single cell level, as well as by the overall distribution of reaching-related signals across parietal and frontal cortex. This distribution, together with the pattern of reciprocal association connections among these areas, determines the architecture of the parieto-frontal network.

In the ►superior parietal lobule (SPL) cells, the ►preferred directions of individual eye and hand signals obtained from different epochs of different visuomotor tasks, cluster within a restricted part of space, the *global tuning field* [1,4] (GTF; Fig. 3), an ideal visuomotor frame to dynamically combine eye and hand signals on the basis of their spatial tuning, therefore a possible substrate for eye-hand coordination, in its different forms (for a review, see [4]).

In the ►inferior parietal lobule (IPL) (►Area 7a), three main classes of combinatorial reach neurons have been identified: hand-dominant, whose neural activity is mostly correlated to hand signals, eye-dominant, whose activity is mostly modulated by eye signals, and eye-hand cells, with neural activity equally determined by eye and hand information. At the population level, the distribution of the eye-hand preferred directions computed during different epochs of different tasks is highly skewed (Fig. 4) toward the contralateral space [4]. IPL neuronal activity is more intensely modulated during the hand movement to the fixation point, therefore in an ecologically relevant form of visuomotor behavior.

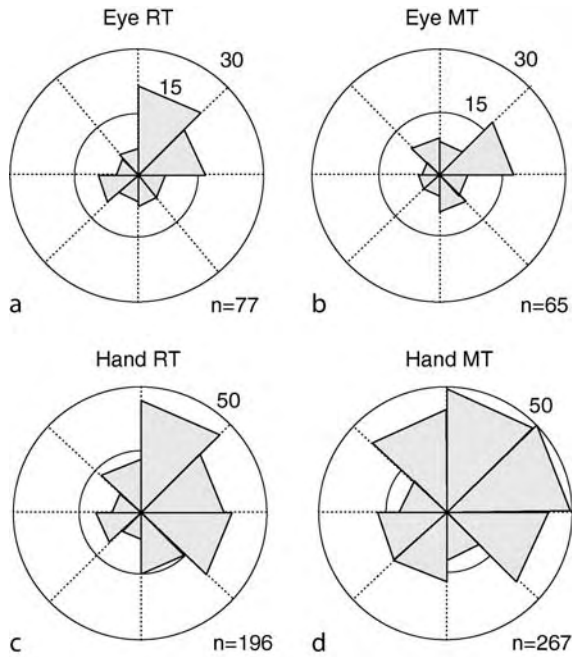
## The Functional Architecture of the Parieto-Frontal Network Underlying Reaching

When the distribution of hand and eye information in the parietal and frontal cortex is confronted with the organization of cortico-cortical connections, a distributed system emerges, characterized by a gradient-like architecture ([9]; for a recent review, see [4]), where parietal and frontal areas are reciprocally connected (Fig. 5). At the caudal and rostral nodes of the network, respectively in the parieto-occipital cortex (►Area



**Visual Space Representation for Reaching. Figure 3** The two circles refer to two typical parietal cells, displaying the orientation of their preferred direction (PD) vectors in different task epochs. Macaque monkeys made arm and/or eye movements from a central origin in eight different directions. PDs (*colored arrows*) of cell activity were computed during different epochs of different tasks: a Reaching task to foveal (*red*), or to extrafoveal targets (*blue*) targets, an eye movement task (*yellow*), and a Delay Reaching task, performed both under light conditions (*light green*) and in total darkness (*black*). The length of each PD vector is proportional to the mean cell's firing rate (sp/s) in a particular epoch, and the radius of the circle is normalized to the maximum discharge rate. For each cell, PD vectors cluster within a restricted part of the workspace, referred to *global tuning field*. The acronyms *rt*, *mt*, *dt*, *tht* indicate reaction-time, movement-time, delay-time, target holding time, respectively; subscripts *e* and *h* stand for eye and hand, respectively. Each acronym is color-coded (see above), depending on the behavioral task (modified from Battaglia-Mayer et al., 2006).

V



**Visual Space Representation for Reaching.**
**Figure 4** Rose diagrams indicating the distribution of preferred directions across the population of directionally-tuned cells recorded in the Inferior Parietal Lobule (*left hemisphere*), obtained during eye reaction time (RT, a) and eye movement time (MT, b) of visually guided saccades and hand reaction time (c) and hand movement time (d) of reaching movement to visual targets. The number (n) of preferred directions included in each distribution is displayed in each plot. Numbers on the circle indicate the scale of the rose diagrams. All distributions show a significantly difference from uniformity and are clearly skewed toward the right hemifield, that is contralateral to the recording hemisphere (modified from Battaglia-Mayer et al. (2005) *Cereb Cortex* 15:514–525).

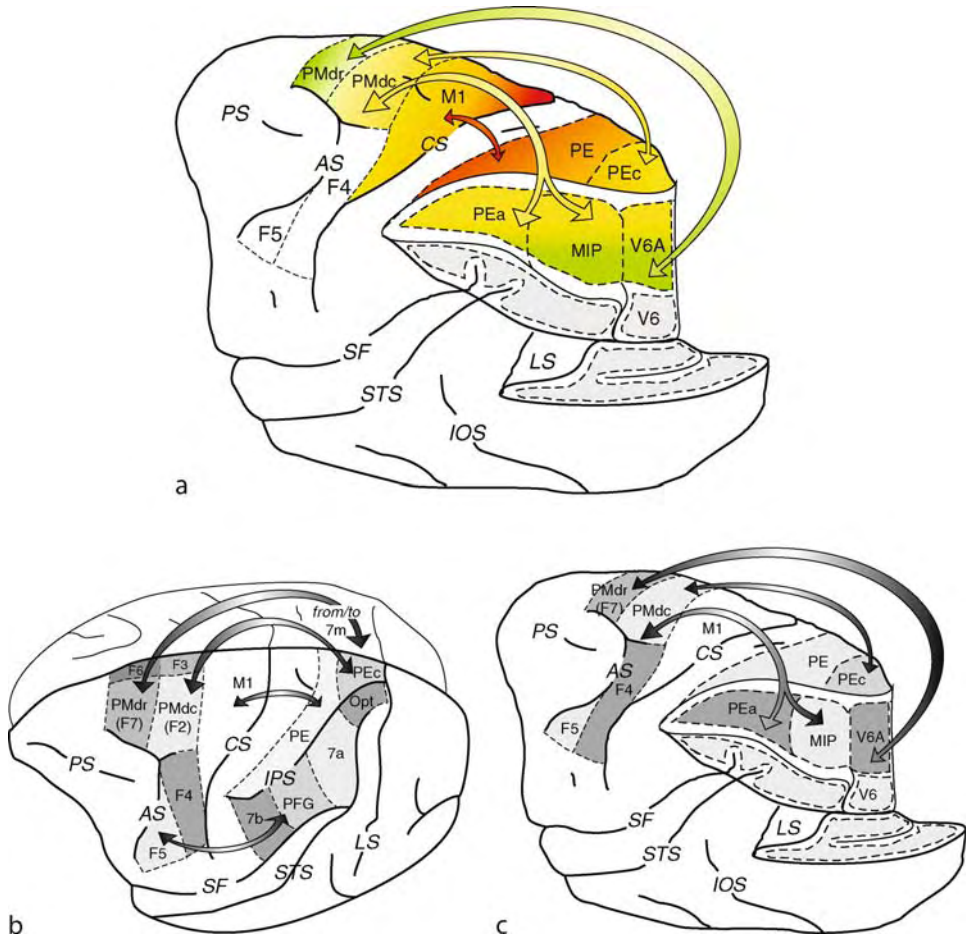
V6A, ►Area 7m, ►Area PEc) and in the rostral part of dorsal premotor cortex (►PMdr; ►Area 6), eye signals predominate on hand information (Fig. 5a, green shaded regions). At intermediate parietal (►Area MIP, Area PEc, ►Area PEa, ►Area 5) and frontal (border between rostral, PMdr, and caudal, ►PMdc, premotor cortex) levels, eye and hand signals coexist, although their strength relationships may differ depending on the specific sub-region considered (Fig. 5a, yellow shaded regions). Finally, in the rostralmost part of the parietal cortex (►Area PE) and in the caudalmost part of the frontal cortex (PMdc; ►primary motor cortex, MI), hand information dominates on eye signals (Fig. 5a, red shaded regions). The gradient-architecture also characterizes the functional organization of other cortical networks, such as that including motor cortex (►Area 4); ►pre-supplementary motor cortex (►pre-SMA, antero-mesial part of area 6), and ►SMA (postero-mesial part of area 6). Frontal and parietal regions displaying a similar activity-type are cortico-cortically connected (Fig. 5b and c). Throughout the network, all these reach-related signals are directional in nature.

Another gradient concerns the type of information treated in the network. Moving from caudal to rostral in SPL, a transition from signals concerning preparation to those about movement execution and sensory feedback occurs; the opposite has been described in the frontal cortex. Eye and/or hand position information are to a large extent ubiquitous at most rostro-caudal locations of parietal and frontal cortex. This is an essential feature of the network, since the gain modulation exerted by eye position on visual parietal neurons (for a review, see [10]) favors the transformation of target location from retinal to ►body-centered coordinates, while hand position signals are essential for computing hand movement trajectory [1] across the network.

Concerning the temporal relationships between neural activity and reaching movement in the parieto-frontal system, in both the SPL and IPL, neural activity in most cells leads arm movement onset (Fig. 6), while other cells discharge around or during movement. The same is true in dorsal premotor and motor cortex, to which SPL projects via cortico-cortical connections. In posterior parietal cortex, most SPL cells fire before the saccade that brings the eye to the target, while in IPL they mainly fire at the end of the saccade, thus encoding an eye-position signal. The comparison of the onset time of cell activity relative to different behavioral events leading to arm reach in parietal (SPL) and frontal (dorsal premotor and motor) cortex shows a simultaneous recruitment of cells relative to the presentation of the visual target [9]. Instead, at the visual go-signal and at the beginning of arm movement, frontal cortical activity leads parietal activity, suggesting that the latter is mostly related to ►coordinate transformation and control of reach, the former to planning and execution of movement. Therefore, the same visual signal can recruit different populations of cells at different times, depending on whether it instructs the animal on the future direction of arm movement, or to make such a movement.

## The Visuomotor Disorders after Lesion of Posterior Parietal Cortex in Humans

*Superior parietal lesions*. A common consequence of lesion of PPC (in particular right SPL) is ►optic ataxia (OA) [4]. This deficit consists of a failure to properly reach targets under visual guidance. In addition, OA patients are unable to make fast on-line corrections of hand movement trajectory. Optic ataxia occurs during reaching or grasping for real targets, but not when pantomiming hand grasping movement of memorized objects, thus showing its context-dependency.

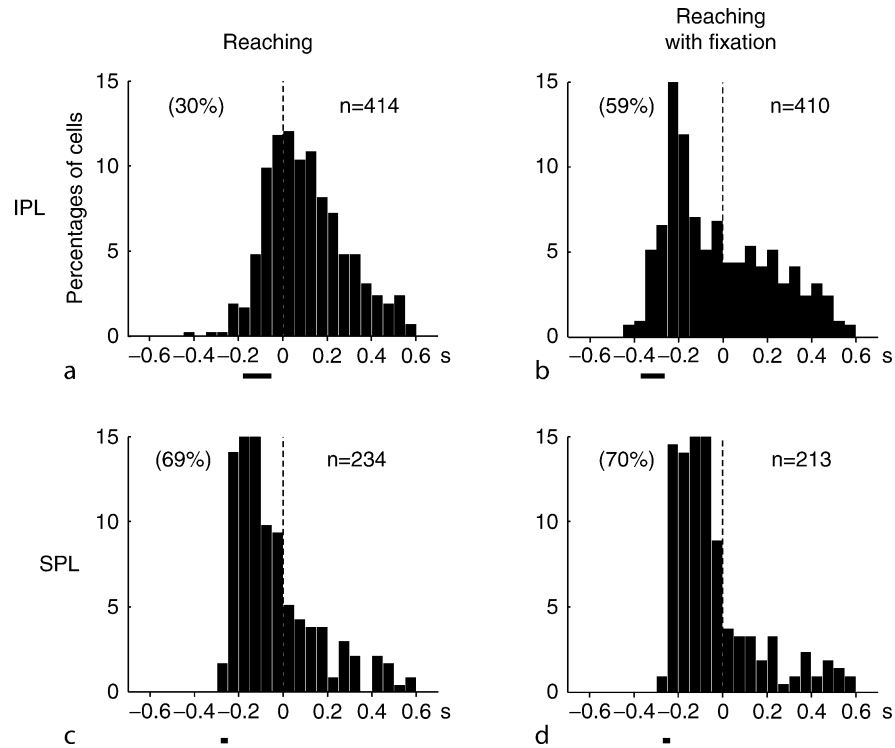


**Visual Space Representation for Reaching. Figure 5** (a) Gradient-like architecture of the fronto-parietal system. Lateral view of the monkey's brain (left hemisphere) where parts of the parietal and occipital lobes have been removed to show the location of the areas buried in the medial bank of the intraparietal sulcus and in the rostral bank of the parieto-occipital sulcus. The color code indicates the distribution of the main types of visuomotor signals processed in the network. Green areas refer to regions were eye signals predominate, red areas depict the predominance of hand related signals, while the yellow areas indicates the regions where eye and hand signals coexist in rather uniform fashion (see text for details). The arrows indicates the main cortico-cortical connections and are color coded (same as above) according to the type of information flow. (b,c) Main ipsilateral connections (*arrows*) between the parietal and the frontal areas involved in reaching.

The functional properties of neurons in PPC and their connections with premotor and motor cortex via association fibers offer the basis for an interpretation of OA from a neurophysiological perspective: (i) SPL neurons are influenced by different signals concerning localization of visual target, eye and hand position and movement direction; the key feature of SPL neurons is the *global tuning field,* characterized by the invariance of the cell's preferred directions across different eye-hand visuo-motor tasks; (ii) parietal neurons encode both hand movement direction and tangential velocity and modulate their activity in a way that predicts changes of hand movement trajectory; (iii) SPL neurons project to and receive from premotor and motor cortices, thus forming a parieto-frontal network with recurrent dynamics.

In conclusion, the disorders of reaching and of its on-line control in OA patients can be interpreted as a consequence of the breakdown of the combinatorial mechanisms of SPL neurons, and of the collapse of the parietal frontal cross-talk, therefore as a cortico-cortical ►disconnection syndrome.

*Inferior parietal lesions.* Parietal patients with lesion in the right IPL suffer from ►hemispatial neglect, which, beyond the well-known attention and spatial disorders, also includes movement disorders, such as ►directional hypokinesia (DH). This is characterized by a lengthening of the hand reaction-time for leftward



**Visual Space Representation for Reaching. Figure 6** Frequency distributions of onset-time of cell activity relative to hand movement to visual targets with *(Reaching)* and without *(Reaching with Fixation)* prior eye movement. (a–b) Data from area 7a (IPL). (c–d) Data from areas V6A and PEc (SPL). Vertical interrupted lines indicate the beginning of hand movement. Percent in brackets indicate the proportion of cells firing before the onset of hand movement. Thick horizontal bars below the *x*-axes refer to the mean of the begin of reaction time ± SD (from Battaglia-Mayer A, Mascaro M, Caminiti R (2007) *Cereb Cortex* 17:1350–1363).

movement to targets mainly, but not exclusively, located in the contralateral space (for a review, see [4]). In visual search tasks, probably because of a failure in updating the motor command on the basis of past movements, the hand recursively moves among the same targets, all located in the right part of space, and so does the eye. Saccade reaction-time is elongated, and saccades tend to be ►hypometric, while the eye trajectory displays a "staircase" shape. In this context it is worth stressing that a main spatial property of IPL reach-related neurons is the anisotropy of the representation of the motor space, since the distribution of these cells' preferred directions during reaction and movement-time mostly points toward the contralateral space (see above). The loss of this representation after IPL lesion can explain the difficulty of movement toward the contralateral space, typical of DH in patients with hemispatial neglect.

## Conclusions

The modern analysis of the dynamic properties of population neurons and of their emergent properties in the parietal-frontal network, together with the study of their cortico-cortical connections, represents a powerful tool to understand the eye-hand visuomotor operations underlying reaching, as well as their disorders in patients suffering from PPC lesions.

### Synonyms

Visual-vestibular integration

### Definition

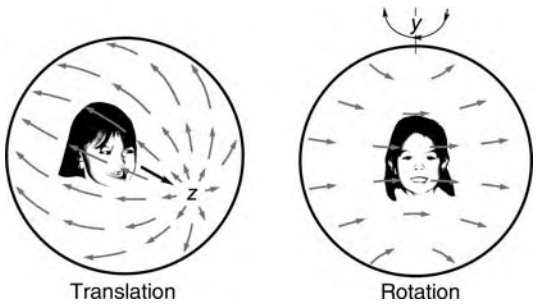
Visual-vestibular interaction refers to the combining of sensory signals from the vestibular apparatus with visual information from the retina to assist in the control of posture, locomotion and eye movements.

### Characteristics

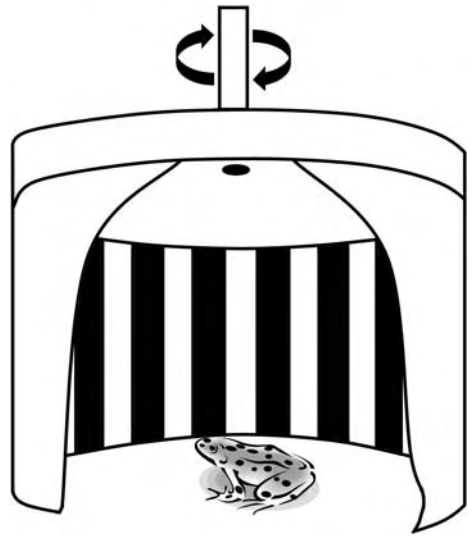
#### Optic Flow During Self-Motion

The vestibular system responds to motion of the head in space, but other sensory systems also provide information about self-motion, including the visual system. Because the world consists of stationary objects and surfaces, self-motion through the environment induces patterns of motion across the entire retina, known as ►optic flow [1]. Optic flow provides a rich source of proprioceptive information and can be used for several behaviors including determination of heading, control of posture and locomotion, perception of self-motion and navigation [2]. Figure 1 shows an illustration of the optic flow resulting from forward translation (*left*) and rotation about the vertical axis (*right*).

The arrows represent local image motion in the optic flowfield, as projected onto a sphere surrounding an observer. From self-translation, the optic flowfield consists of a radial focus of expansion in the direction of self-motion. During self-rotation, there is circular flow about the axis of rotation, but opposite to the direction of head rotation. These examples are very much-simplified versions of the optic flowfield. This is especially the case for self-translation, as there is also a velocity gradient, from zero at the focus of expansion to maximal along the equator of the sphere. Moreover, during self-translation near objects move faster in



**Visual-Vestibular Interaction. Figure 1** Schematic illustrations of optic flow that occurs during self-translation (*left*) and self-rotation (*right*). The *grey arrows* indicate the direction of local motion within the flowfield as projected onto a sphere surrounding the observer. For forward self-translation, out of the page along the vector indicated by the *black arrow* toward point *z*, there is a radial focus of expansion in the direction of translation, and backward planar motion along the equator of this sphere. For rightward rotation about the vertical axis (*y*), there is circular motion along the axis of rotation (i.e. directly above and below the head) and leftward planar motion along the equator.



**Visual-Vestibular Interaction. Figure 2** An optokinetic drum. The cylinder is enclosed, but the front has been cut away to reveal the stripes inside.

the flowfield than do far objects. Finally, the structure of local motion in the flowfield during self-translation changes depending on the point of fixation [3].

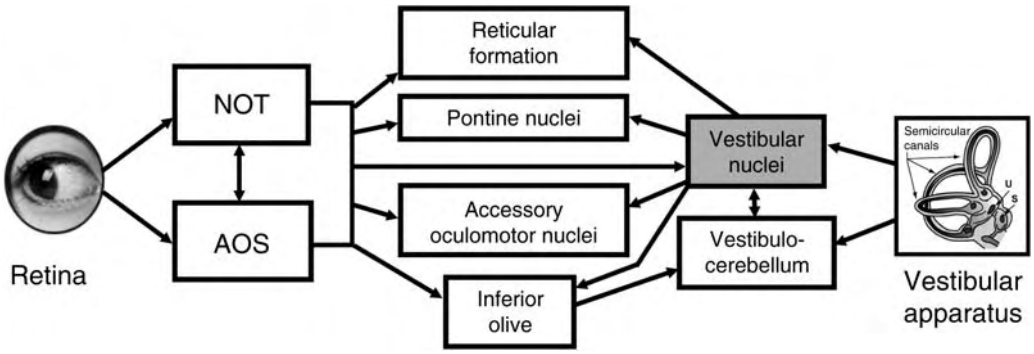
## Optokinetic Responses

The use of visual information for postural stabilization is easily demonstrated by observing two people standing on one foot, one individual with eyes open and the other with eyes closed; the latter will begin to stumble whereas the former can maintain posture. The individual with eyes open can maintain posture by minimizing optic flow, a process referred to as an optomotor or ►optokinetic response. Optokinetic responses work with spinal and vestibular reflexes to maintain posture and gaze. The easiest way to demonstrate optokinetic responses is with an optokinetic drum (Fig. 2).

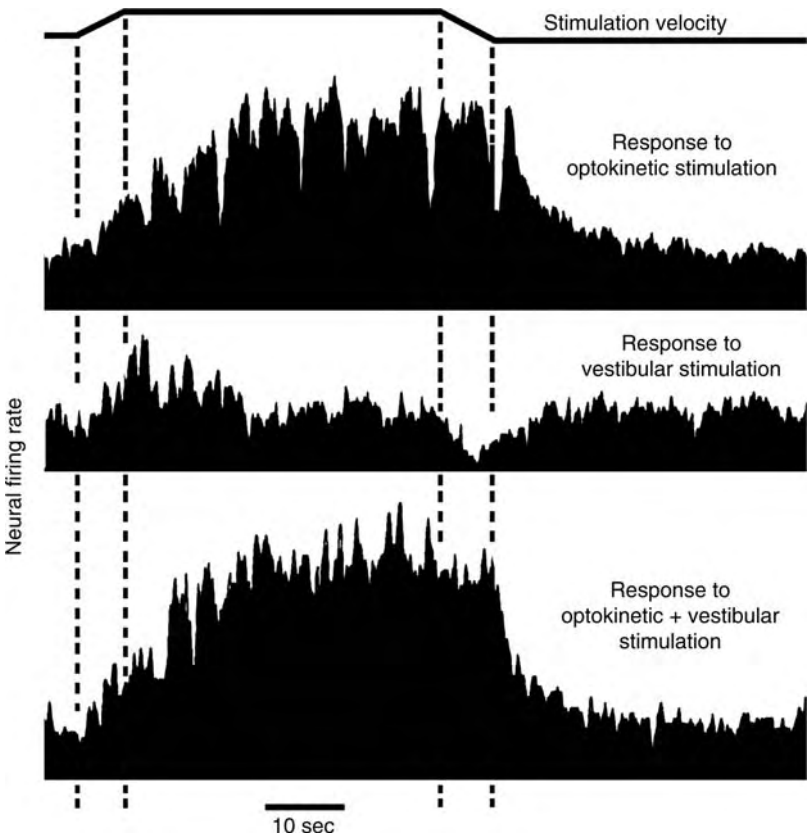
This device consists of vertical black and white stripes on the inside of a rotating cylinder. If an animal is placed inside the center of the cylinder, but with the head fixed, an oscillating horizontal eye movement known as ►optokinetic nystagmus (OKN) will result. OKN consists of two phases, a slow phase in which the eyes move slowly in the direction of visual motion and a fast phase in which saccades bring the eyes back to a central position. If the head is free but the trunk is fixed, a nystagmic head movement results; this is known as the optocollic response (OCR). During the slow phase of OKN, the attempt is to match eye velocity with the velocity of the visual motion, i.e. the optokinetic responses function to stabilize the retinal image and work with the vestibuloocular reflex (VOR) in this regard. In fact, the OKN can support gaze stabilization when the VOR is non-optimal. The gain of the VOR is low for slow head movement, but increases with faster stimulation. In contrast, the gain of the OKN is very high for slow visual motion, but declines with increasing speed. Moreover, the VOR starts at movement onset, but the vestibular signal habituates exponentially during a head movement and is absent during constant velocity. The OKN builds up rather slowly (see below) and continues to respond even during constant velocity. Thus, the OKN and VOR have somewhat complementary roles to contribute to gaze stabilization throughout the head movement.

The slow phase of OKN builds up slowly until it reaches a steady state and if the lights are turned off, the eye movements persist, decaying over the course of a few seconds. This is known as optokinetic afternystagmus (OKAN). The build-up to the steady state and OKAN is accomplished by the "velocity-storage mechanism" and is reflected in the activity of vestibular nucleus neurons (see Fig. 4 below).

In frontally eyed mammals, the build-up to the steady state is quicker and the slow phase of OKN is said to consist of "direct" and "indirect" components. These are also known as the "early" and "delayed" components of OKN and the early/direct component is also referred to as the ocular following response [3]. The indirect component refers to the gradual build-up of slow phase due to the velocity storage mechanism. The "direct" component occurs soon after the onset of visual motion and allows for a quicker build-up to a steady state. OKN persists at high velocities (100–200°/s).



**Visual-Vestibular Interaction. Figure 3** A simplified schematic of the projections of the nucleus of the optic tract (*NOT*), the accessory optic system (*AOS*) and the vestibular apparatus. Although the projections are much more extensive [5], sites of visual-vestibular interaction in the brainstem are indicated. The primary vestibular projection is to the vestibular nuclei and vestibulocerebellum, which also receive input from the AOS and NOT. When considering secondary vestibular targets, the sites of visual-vestibular interaction are numerous.



**Visual-Vestibular Interaction. Figure 4** Responses of a neuron from the vestibular nucleus of the goldfish to visual and vestibular stimulation. The stimulus velocity profile is shown at the *top*. The *top* peri-stimulus time histogram shows the response of the neuron to leftward rotation of the optokinetic drum. The *middle* histogram shows the response to rotation of the animal to the right in darkness. The *bottom* trace shows the response of the neuron to rotation of the animal to the right in the light. Adapted from [6].

V

## Vection

In addition to eliciting optokinetic responses, optic flow also elicits the perceptual state known as ►vection [4]. Vection is the illusory percept of self-motion that results when one is presented with optic flow stimuli. This is often exploited by the entertainment industry. For example, in the original *Star Wars* movie, the character Luke Skywalker is in the cockpit of a spacecraft, which

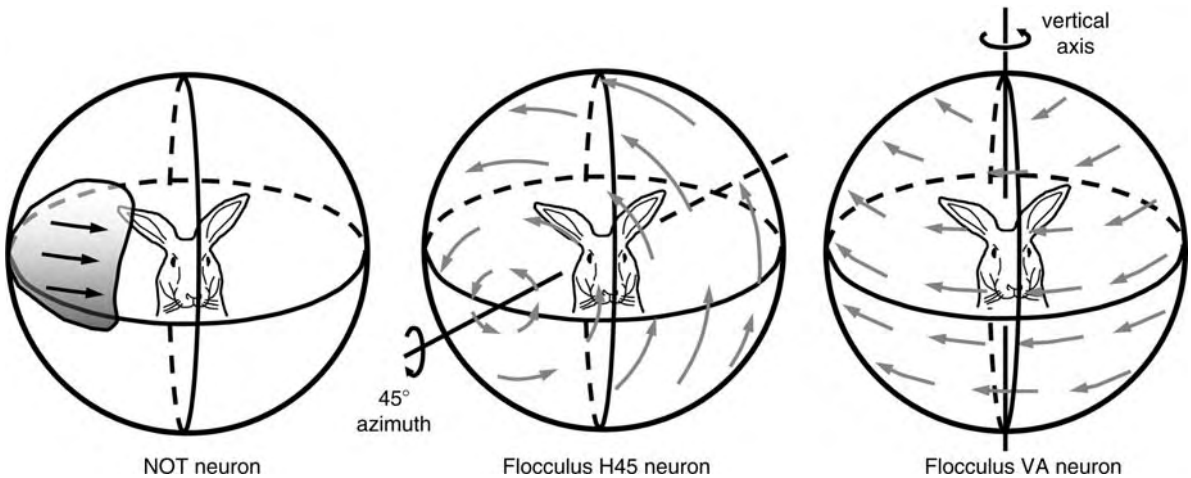
descends into a trench along the surface of the Deathstar. When the point of view is from the cockpit, the audience is exposed to a flowfield resulting from forward translation (Fig. 1). Members of the audience may then experience the feeling that the visual stimuli are stationary, but they themselves are in the spacecraft moving forward across the surface of the Deathstar. The illusory percept of self-translation is known as linear vection. In the laboratory, vection can be easily demonstrated and quantitatively measured using an optokinetic drum. If placed inside the drum depicted in Fig. 2, an observer initially reports that the drum is spinning around them. However, as the drum continues to spin, after a period of about 30 s, they report that the drum is stationary, but they are rotating in the direction opposite that of the drum. The illusory percept of self-rotation is known as circular vection. Generally, larger stimuli are more effective in eliciting vection. When the visual stimuli consist of foreground and background, it is the perceived background that drives vection. Radial motion is most effective for eliciting linear vection, but laminar flow with kinetic occlusion will support linear vection.

## Neural Substrates

In mammals, retinal-recipient subcortical nuclei that convey visual information related to self-motion include the nuclei of the ►accessory optic system (AOS) and the nucleus of the optic tract (NOT) in the pretectum [5]. In most mammals, the AOS consists of four nuclei, the medial, lateral and dorsal terminal nuclei (MTN, LTN, DTN) and the interstitial nucleus of the superior fasciculus. Critically, lesions to the AOS and NOT abolish optokinetic responses and stimulation elicits nystagmic eye movements. Neurons in these pathways have large receptive fields (see Fig. 5, *left*) and respond best to large moving stimuli that are rich in visual texture (e.g. checkerboards or random dot patterns). Generally speaking, the MTN and LTN are associated with vertical motion whereas the NOT and DTN are associated with horizontal motion. The AOS and pretectum project to many structures that are involved in motor and oculomotor control, including structures that receive vestibular input (Fig. 3). Efferents of the AOS and the pretectum include the accessory oculomotor nuclei, several pontine nuclei, the vestibular nuclei and parts of the inferior olive that project to the vestibulocerebellum. In some species there are direct projections from the AOS and pretectum to the vestibulocerebellum.

Visual-vestibular integration at the neural level was first shown in recordings from vestibular nucleus neurons [6]. Figure 4 shows the response of a neuron in the vestibular nuclei of an anesthetized goldfish to optokinetic and vestibular stimulation.

The top trace shows the response to rotation of the visual surround in the leftward direction. Note the slow build-up of the response, which mirrors the gradual build-up of the indirect OKN. Also the response of the neuron decays slowly after the cessation of visual stimulation, which mirrors OKAN. The middle trace shows the response of the same neuron to body rotation to the right, in darkness. Note the relatively quick response at the onset of the vestibular stimulation, but



**Visual-Vestibular Interaction. Figure 5** Optokinetic receptive fields. On the *left*, the receptive field of a neuron from the nucleus of the optic tract (*NOT*) is shown. They are large (average 60°) and most prefer forward (i.e. temporal-to-nasal) motion. In the flocculus, Purkinje cells have panoramic visual receptive field and prefer rotational optic flow about either the vertical axis (VA neurons; *middle*) or a horizontal axis oriented 45° from the midline (H45 neurons).

the decline during the constant velocity portion of the stimulation. This neuron responded more to visual than to vestibular stimulation, but the relative magnitude of the responses to visual vs. vestibular stimulation is quite variable. The bottom trace shows the response of the neuron to rightward rotation of the animal in the light, which provides concomitant visual and vestibular stimulation. The response appears as a linear combination of the responses to the two inputs. Neurons responsive to patterns of optic flow and vestibular stimulation have also been found in parietal and occipito-temporal areas of the cerebral cortex. For example, in primates, neurons in the medial superior temporal area respond to patterns of translational and rotational optic flow, and vestibular stimulation [1].

The efferent pathway of the AOS and pretectum that has been most thoroughly studied is that from the inferior olive to the vestibulocerebellum [7]. The vestibulocerebellum consists of the flocculus, nodulus and ventral uvula. The congruence of visual and vestibular processing is best demonstrated with reference to the responses of flocculus Purkinje cells. In the inferior olive and the vestibulocerebellum, the visual information from the AOS and pretectum is integrated so that the Purkinje cells have panoramic receptive fields and respond best to patterns of optic flow resulting from either self-translation or self-rotation [8,9]. As shown in Fig. 5, flocculus Purkinje cells respond best to rotational optokinetic stimulation about one of two axes, either the vertical axis (VA neurons) or a horizontal axis oriented 45° to the midline (H45 neurons).

This means that floccular Purkinje cells respond best to optic flow resulting from a head rotation that maximally stimulates either the horizontal semicircular canals (VA neurons) or the ipsilateral anterior/contralateral posterior canal pair (H45 neurons). The system is evolutionarily highly conserved as demonstrated by essentially identical response properties in rabbits and pigeons [8,9].

The flocculus has been shown to be critical for the adaptation of the VOR. The gain of the VOR can be changed by rotating an animal inside an optokinetic drum that is not stationary, but moving at the same speed in the opposite direction. The compensatory eye movement required for this circumstance is twice that of normal conditions. After prolonged adaptation with this stimulation, subsequent rotation of the animal in the dark will reveal that the gain of VOR has increased, i.e. the aberrant optokinetic information given is somehow responsible for adjusting the gain of the VOR so that effective gaze stabilization can be maintained. Lesions to the flocculus prevent the adaptive change in the VOR. The synaptic mechanism of adaptive recalibration of the VOR involves long-term depression (LTD) but the site(s) of this learning is a topic of debate [10].

Visual-vestibular integration also occurs in the nodulus and ventral uvula of the vestibulocerebellum. In mammals, some Purkinje cells respond to optic flow patterns, whereas others respond best to vestibular stimulation originating in the otolith organs [7]. In birds it has been shown that Purkinje cells respond best to patterns of optic flow resulting from self-translation along either the vertical axis or a horizontal axis oriented 45° to the midline, i.e. a common reference frame is used for processing optic flow resulting from self-translation and self-rotation [8]. A precise role for the ventral uvula and nodulus has yet to be determined, although they are involved in controlling posture and eye movements.

## Synonyms

Visuomotor transformation; Visuomotor interaction

## Definition

Visuomotor integration is the coordination of neuronal activity between visual-related and motor-related parts of the brain in order to influence behavior and perception.

## Characteristics

### Vision and Movement

Vision guides movement, and movement affects vision. To facilitate the coordination between vision and movement, reciprocal interactions are needed between brain areas involved in visual and motor processing. The use of visual information to influence movement processing, and movement information to influence visual processing, is termed visuomotor integration.

For primates, vision is the primary sense. It drives behaviors as diverse as looking around a scene and moving through the world. Visual information arrives from the ►retina, is interpreted by a network of ►visual processing areas in the brain (Fig. 1, yellow arrows), and is sent to subcortical areas that cause movement generation (red arrows). In turn, movements may influence visual input, and so information about actions is fed back to visual processing areas to close the loop (Fig. 1, grey arrows).

Visuomotor integration varies in its details depending on the behavioral context and the effector used, e.g., eye or hand. There are four general aspects of visuomotor integration, however. First, visuomotor integration is relatively slow. Vision is useful for planning movements but sluggish for online control, and the time from visual input to motor output is surprisingly long and variable. Second, visuomotor integration is spatially organized. The retina is a finely grained two-dimensional map, and central brain regions recapitulate this map. Third, visuomotor integration is adaptive. The relationship between visual input and motor output is continuously monitored and adjusted as necessary. Fourth, visuomotor integration is bidirectional. Not only are visual signals transformed to motor commands, but motor commands are fed back to aid visual processing. Here we review these four components of visuomotor integration.

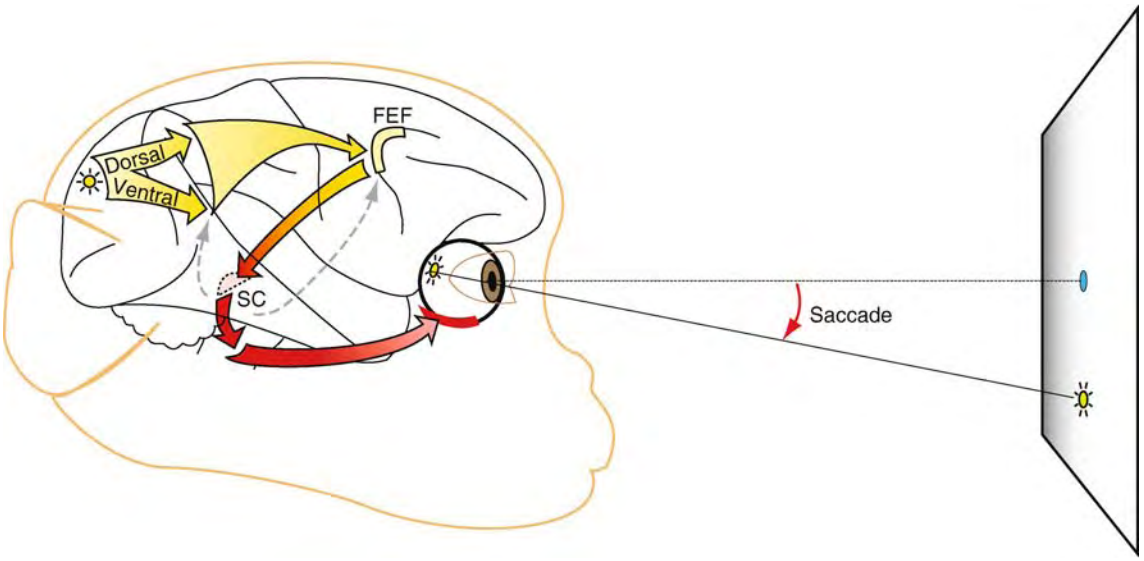
### Visuomotor Integration is Relatively Slow

A good way to begin analyzing a system is to consider its input. Characteristics of the input limit the possible ways that the system may produce an output. Visual information is the input to visuomotor transformations, and vision is one of our slower senses. Vision helps to initiate movements but may be too slow for the real-time control of movements.

After visual information is transduced by ►photoreceptors, approximately 70 ms elapses before it reaches central areas for visuomotor integration. Added to this afferent lag are further delays related to planning. The final reaction times of visuomotor acts are typically around 200 ms. These afferent lags and reaction times are about 50 ms longer than analogous delays for auditory inputs and 20 ms longer than for skin receptor inputs.

At the output of visuomotor transformation, many movements take less than 70 ms to complete. Hence the movements terminate before visual feedback can provide information about movement progress. Brief movements, therefore, can be triggered but not continuously controlled by visual signals. Such movements must be ►ballistic (open-loop) or controlled by non-visual feedback.

An example of a short-duration movement that is triggered but not controlled by vision is the ►*saccade*, a rapid eye movement that relocates the fovea to a new part of the scene. To minimize time in flight (when vision is blurred on the retina), and maximize time during fixation (when vision is optimal), saccades have high velocity and short duration. For most naturally occurring saccades (<15° amplitude), the duration is



**Visuomotor Integration. Figure 1** Neuronal circuits for visuomotor integration in the primate brain. Illustrated as an example circuit is the core network for ►saccade generation. While a monkey foveates one stimulus (*blue dot*), another suddenly appears (*yellow dot*). The goal is to make a saccade to the new stimulus. An image of the yellow stimulus is projected onto the retina and encoded in ►primary visual cortex (*far left*; the pathway from retina to visual cortex is omitted for clarity). The location of the visual stimulus is processed by a ►dorsal pathway, the identity of the stimulus by a ►ventral pathway, and the processed information is sent to visuomotor areas such as the ►FEF (*yellow arrows*). From there, signals are sent to the ►SC and other brainstem areas to cause eye muscle contraction (*red arrows*). Feedback information about saccades is sent to cerebral cortex to close the loop (*grey arrows*). Modified from [1].

less than 50 ms. Such movements, therefore, are too fast for visual feedback. Even for large, long duration saccades, visual feedback is blurred by the fast eye motion. The low-level saccade generating circuitry (in the ►pons and ►midbrain) controls saccadic progress not with visual feedback, but with internal estimates of the eye's instantaneous state [2].

Certain eye movements, such as ►smooth pursuit, are slower and may use vision for control. The function of smooth pursuit is to keep the eyes foveated on a moving object such as a bird in flight. Smooth pursuit can persist for several seconds, so visual feedback is able to influence the ongoing movement. Continual visual input is compared with predictions of the input, and if there is a mismatch, pursuit velocity is adjusted.

As note above, visual sluggishness has two main components: initial, afferent lag and subsequent planning-related lags. The planning stage seems to begin in ►parietal and frontal cortex, after basic visual scene analyses are performed by ►occipital cortex. Cortex is only a few synapses above the oculomotor muscles. It is intriguing, therefore, that the time from the start of parietal/frontal cortex activation to the start of the movement is long (~100 ms) and variable. The delay is used for cortical computations that select the next movement as a function of past, present, and predicted future visual inputs [3,4].

## Visuomotor Integration is Spatially Organized

Visual information reaches about one third of the primate ►cerebral cortex and much of the brainstem. Many of these brain areas are laid out in a visually ordered ►topographic manner. We focus on two of the areas as examples of the spatial aspects of visuomotor integration. These are the ►frontal eye field (FEF) in frontal cortex, and the intermediate layers of the ►superior colliculus (SC), in the midbrain (Fig. 1). Both the FEF and intermediate SC contain neurons that are active for incoming visual stimuli as well as outgoing eye movement commands; moreover, electrical stimulation of each area evokes saccades and inactivation of each area impairs saccades. Thus, the FEF and the SC are implicated in using visual information to guide the execution of saccades. Visually guided skeletal movements, such as moving one's hand, depend on comparable areas of the cortex and brainstem, as well as the spinal cord.

Spatial orderliness begins in the two-dimensional sheet of the retina. Visual stimuli produce a pattern of activity on the retina that reflects the layout of stimuli in the real world. The pattern is recapitulated throughout the visual system with high fidelity. This maintenance of spatial relationships is due to connections that form repeated topographies. For the purpose of visual analysis, ►topographic maps facilitate form discrimination and other

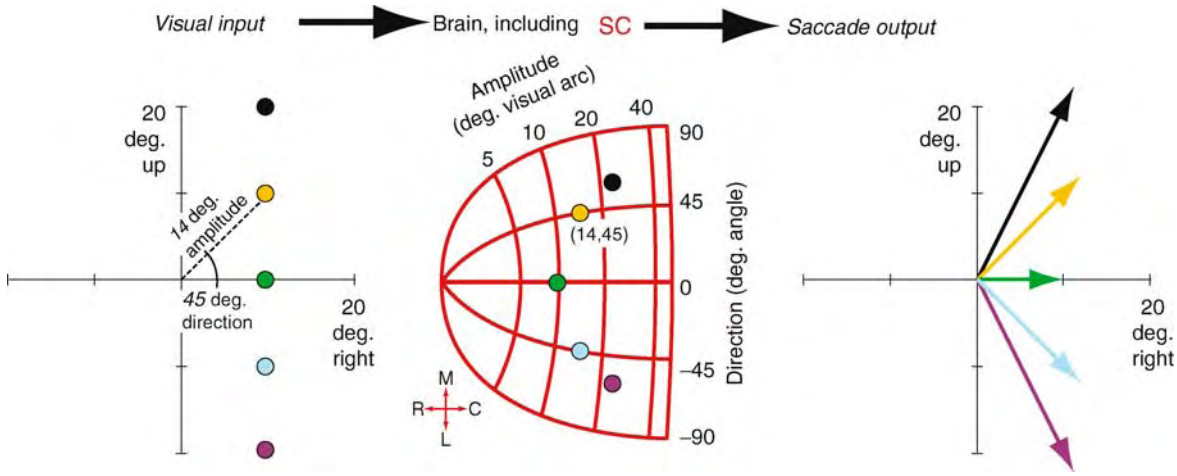
spatial evaluations. For the purpose of visuomotor integration, the maps offer an efficient link between the ►visual field and the motor workspace.

The FEF and SC contain neurons that are active for visual input (so-called visual neurons), saccade generation (movement neurons), or both (visuomovement neurons) [5,6]. Neurons with visual responses fire for stimuli falling within a certain retinal zone called the receptive field. Neurons with saccade-related activity fire for saccades having a certain range of vectors (amplitudes and directions) that delimits the movement field. Visual and movement neurons are arrayed together such that neighboring neurons have similar receptive fields and movement fields. For visuomovement neurons, which have both a receptive field and a movement field, the two fields are coincident. Across the FEF and SC, receptive fields and movement fields vary systematically. In an elegant fashion, therefore, evolution and development have interlinked the visual and motor maps. This spatial organization plays a vital role in transforming visual input to eye movement output.

To see why the overlap of visual and motor maps is beneficial, consider a simple example. Imagine you are looking straight ahead and see something in the upper-right portion of your peripheral vision, for example a yellow dot (Fig. 2, left). The dot will activate a discrete portion of your retinas and then a corresponding location on the FEF and SC visual maps (for the SC map, the location is shown with a yellow dot in Fig. 2, middle). Each visual map is spatially integrated with a coincident movement map, and therefore locations on each map encode not only a visual stimulus but also the vector of saccade needed to foveate the stimulus (Fig. 2, right, yellow arrow). All locations in contralateral space are represented in each FEF and SC map (other colored dots and arrows in Fig. 2).

Although visuomotor maps in FEF and SC are similar, there are some notable differences between them. Pure visual-related neurons are common in the FEF but rare in the SC intermediate layers. Overall, FEF neurons seem to play more of a role in representing visual targets for saccades, while SC neurons seem more related to saccadic dynamics such as instantaneous motor error and velocity. Also, the SC map is more finely elaborated in terms of movement vectors. In both the SC and FEF, saccadic amplitude is well organized, but in the SC saccadic direction is laid out explicitly too, in a mapping orthogonal to amplitude (Fig. 2). In the FEF there may be some directional organization, but it seems patchy [5].

The differences between the FEF and SC maps suggest that the former is more visual and the latter more motor in nature. This is not to say, however, that visuomotor transformations proceed in a leap from visual FEF to motor SC, or between any two structures. The differences between FEF and SC are a matter of degree, and visuomotor transformations are best characterized as gradual [7]. Neuronal activity slowly loses its dependence on vision and gains a tight relation to movement as it proceeds from area to area. Below the SC, spatial codes of saccadic vectors are transformed into temporal codes that



**Visuomotor Integration. Figure 2** Visuomotor transformation using a ►topographic map. *Left*: Visual stimuli (*dots*) in the right visual field. The *yellow dot* appears ~14° from the fovea at an angle of 45° up from horizontal. *Middle*: Stimuli in the right visual field are encoded on the left SC visuomotor map, shown schematically. The rostral (R) to caudal (C) dimension represents increasing amplitudes of distance from the fovea. The lateral (L) to medial (M) dimension represents increasing angles relative to horizontal. The *yellow dot* in the visual field is encoded by neurons at site (14, 45) on the SC map. Other visual stimuli are encoded by corresponding sites. *Right*: The neuronal output of the SC map causes saccades. Neurons driven by the *yellow dot* cause a saccade of 14° amplitude angled 45° up from horizontal (*yellow arrow*). Neurons elsewhere on the map generate other saccadic vectors (*other arrows*). Modified from [6].

precisely coordinate the contractions of oculomotor muscles.

In the skeletal motor system, movement topographies are present as well. However, the spatial relations between visual input and skeletal movements (e.g., arm movements) are more complex and variable than those between vision and eye movements. The ultimate control region for skeletal motor execution seems to be ►primary motor cortex, which contains neurons with visual (and other sensory) inputs arranged in a body map. How the spatiotemporal transformation occurs from this map to the alpha-►motoneurons of the spinal cord is the focus of much physiology and modeling.

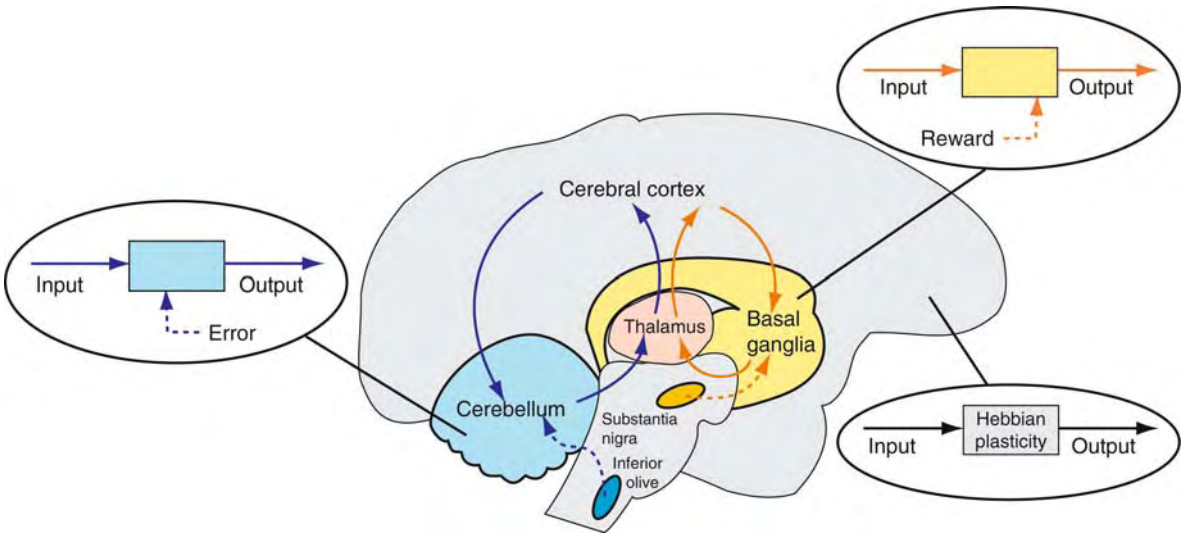
## Visuomotor Integration is Adaptive

Visuomotor integration must be able to change as our body and surroundings change. From infancy to adulthood the relation of the retinas to the rest of the body is altered extensively, and yet visually guided movements must stay accurate. Even in adults, injury can alter visual input, motor output, or the relation between the two. The environment changes too, requiring behaviors to adapt accordingly.

►Adaptation can be quick, as shown by donning prism glasses; within only a few dozen trials, eye and reaching movements are re-calibrated to adjust for the altered visual input. Once a visuomotor relation is adapted, the new behavior can persist for life.

While steady-state visuomotor integration mostly involves the cerebral cortex, brainstem, and spinal cord, plasticity in visuomotor integration relies on two extensive subcortical networks: the ►cerebellum and the ►basal ganglia [8,9]. The cerebellum (Fig. 3, left) is most critical for short-term adaptation as in the prism glasses example. Error signals that represent unexpected differences between visual input and motor output reach the cerebellum via ►climbing fibers from the ►inferior olive. These error signals have a strong, long-lasting effect on cerebellar activity. This altered cerebellar activity is relayed through ►thalamus to modify visuomotor transformations in the cerebral cortex.

The basal ganglia play a broader role in adaptation. Rather than micro-managing movements on a millisecond time scale as the cerebellum, the basal ganglia seem to help select which movement is appropriate given the context of the situation. This context may change to require a different motor response for the same visual input. Context-dependent adaptation in basal ganglia depends on occurrence of reward (Fig. 3, upper right). Reward is reported by dopaminergic neurons in the substantia nigra and other brainstem regions that feed back to the input nodes of the basal ganglia. The feedback alters basal ganglia activity, and as with the cerebellum, the altered neuronal activity is relayed by thalamus to influence visuomotor transformation in the cerebral cortex.



**Visuomotor Integration. Figure 3** Circuits for visuomotor adaptation. A silhouette of the monkey brain is shown with the critical subcortical networks for adaptation superimposed. *Left*: The cerebellar loop receives visual information from cerebral cortex and other areas and relays the information back to cortex through ►thalamus. The feedback to cortex is modified, however, by error signals provided by the inferior olive. *Upper right*: The basal ganglia loop is similar, but its signals are modified by reward, for example from the ►substantia nigra (pars compacta). *Lower right*: Many neurons in the cerebral cortex also have the capacity to adapt through intrinsic, Hebbian, processes, so that input-output (visual-saccade) relationships may change with ►long-term potentiation or depression. Modified from [8].

Finally, it should be noted that many neurons have an intrinsic capacity for input-output plasticity. Any neuron may be involved in adaptation as long as its action potential output can be modified for a given pattern of afferent input, for example via ►Hebbian synaptic plasticity. Some adaptation mechanisms may be resident in cerebral cortex, therefore, and independent of basal ganglia and cerebellum (Fig. 3, lower right).

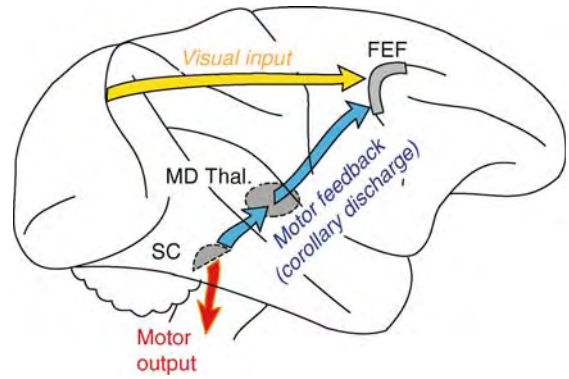
## Visuomotor Integration is Bidirectional

Every movement that we make causes spurious changes to our sensory input. A major problem for the brain is to disregard the sensory artifacts of self-movement while maintaining sensitivity to sensory changes caused by external objects. One way that the brain solves this problem is by copying the outgoing motor command and sending this copy back to visual areas to provide information about the upcoming movement. Such copies of motor commands are called ►corollary discharge or ►efference copy [1].

Just as saccades have proven a good model for studying visual-to-motor processes, they have been equally important for understanding motor-to-visual processes. Saccades permit rapid relocation of the fovea, but an attendant visual artifact is the sudden displacement of the entire scene across the retina. If we were to perceive the visual world as actually detected by the retinas, we would see the world jumping from place to place every time we make a saccade. Yet we enjoy a percept of visual stability. To complicate things further, some objects in the visual scene move on their own, and the brain must distinguish those movements from the saccade-induced visual artifacts. Corollary discharge is crucial for the joint processes of stabilizing our visual percept across saccades and distinguishing real object motion from saccade-induced motion.

Where does the corollary discharge originate, and where does it travel to influence vision? One corollary discharge pathway ascends from the SC to the FEF via a thalamic relay node (Fig. 4). When the SC issues a movement command to lower saccade-generating circuits, it sends a corollary discharge of the command to the FEF (blue arrows). The corollary discharge encodes information about saccadic timing, size, and direction, allowing the FEF to prepare for the imminent eye movement and its visual consequences.

Within the FEF, corollary discharge interacts with visual input arriving from earlier visual areas (Fig. 4, yellow arrow). One result is that some visual neurons suddenly sample a new part of the visual field just before the eyes begin to move [10]. Such shifting receptive fields allow neurons to analyze the same region of absolute visual space (in ►world-centered coordinates) before and after each saccade. Hence this mechanism may help to stabilize our percept of the visual scene across saccades.



**Visuomotor Integration. Figure 4** Example circuit for motor-to-visual feedback. As in Fig. 1, visual input is sent to the FEF (*yellow arrow*) and motor output descends from the SC (*red arrow*). In addition, a copy of the motor output ascends as feedback through mediodorsal thalamus (MD Thal.) to the FEF (*blue arrow*). Such feedback is known as corollary discharge. As discussed in the text, corollary discharge interacts with visual input at single FEF neurons to cause shifting receptive fields. The general function of corollary discharge is to help the visual system interpret whether changes in visual input represent trivial artifacts of self-movement or real changes in the external environment. Modified from [1].

Smooth pursuit is another example of a behavior that requires an ongoing, internal estimate of movement progress. As noted above, visual feedback is used by the smooth pursuit system to monitor accuracy and control the movement in real time. But the actual control process requires the visual input to be compared with a prediction, and that prediction requires an internal estimate of the ongoing eye movement. This estimate could be provided by corollary discharge or by ►proprioception, i.e., the sense of muscle position.

## Summary

Visuomotor integration is the coordination of sensation with action. Distributed cortical-subcortical circuits transform visual input to motor output in a manner that is spatially precise but relatively slow. The circuits, and their attendant visuomotor processes, change as needed. Because movements influence visual input, corollary discharge of movements closes the loop. The basic principles of visuomotor integration as established for eye movements are likely to hold for skeletomotor movements as well.

## Visuospatial Attention

### Definition

Visuospatial attention refers to mechanisms by which a particular spatial location in the visual field is selected for further processing. The processing of stimuli appearing at the attended spatial location will be enhanced, while stimuli appearing at neighboring regions will be suppressed. Visuospatial attention can be directed either overtly or covertly. During overt attention, attention is linked to the eye gaze direction. During covert attention, the oculomotor and attention systems operate independently, allowing attention to be deployed throughout the visual field while the eye gaze remains fixed. Visuospatial attention can be deployed prior to stimulus onset, biasing processing in favor of any upcoming stimuli presented at the attended location.

►Visual Attention

## Visuospatial Disorientation

### Definition

Some brain-damaged patients can identify objects, but have problems in visually locating them or their distance. These patients also cannot look at named objects or cannot navigate correctly so as to avoid bumping into them. The damage is typically in the occipital-parietal area on both sides. Visuo-spatial disorientation occasionally concurs with ►simultanagnosia, both of which are components of ►Balint's syndrome. Focal parietal lesions may lead to impairment of the perception of horizontal and vertical axes, of length and distance estimation, orientation discrimination and position matching.

## Vocalization Afterdischarges (VADs)

### Definition

Animal vocalizations that occur after a noxious stimulus that are considered to be a direct index of the unpleasantness associated with the sensations evoked by the noxious stimulus. VADs are mediated by brain structures involved in mediating pain unpleasantness in humans (medial thalamus, anterior cingulate cortex, amygdala) and suppressed by drug treatments that reduce pain unpleasantness in humans. VADs are distinguished from vocalizations that occur during noxious stimulation. These latter vocalizations are mediated by brainstem mechanisms and exhibit different spectrographic characteristics than VADs.

## Voigt Element

### Definition

Voigt element is a spring in parallel with a dashpot. The spring exhibits linear elastic behavior (the force required to extend it is proportional to the extension), and the dashpot exhibits linear viscous behavior (the force required to extend it is proportional to the speed of the extension). Used to model the viscoelastic behavior of inorganic and organic materials, including for example eye muscles and orbital tissue.

►Eye Orbital Mechanics

## Volition

### Definition

The power to will to do something or the willing of something. Willing is sometimes understood as the mental action of deciding or choosing to do something, sometimes as trying to do something, and sometimes as the combination of deciding or choosing to do something and trying to do it. Wishing and wanting to do something are less closely connected to action. We do not always decide, choose, or try to do things that we wish or want to do. When we recognize that we wish or want to do something, we may reflect on whether to do it and decide not to do it. We may even try to prevent ourselves from doing it.

**Definition**

Members of this superfamily of transmembrane proteins bearing highly selective aqueous pores are activated and inactivated by changes in the plasma membrane potential. The family comprises several subclasses of channels (e.g., $Na^+$, $K^+$, $Ca^{2+}$, cyclic nucleotide-regulated channels). The channels display a conserved core structure consisting of six transmembrane segments and an ion-conducting pore loop between S5 and S6. In most channels the S4 segment is positively charged and serves as voltage sensor. All members of the family are tetrameric.

## Synonyms

Voltage-dependent ion channels; Voltage-sensitive ion channels; Pain and voltage-gated ion channels

## Definition

►Voltage-gated ion channels are channels in cell membranes that when open are permeable to ions in solution where the opening and closing of the channel, referred to as gating, is controlled by membrane potential [1]. These channels are generally described in reference to the ion(s) ($Na^+$, $K^+$, $Ca^{2+}$, etc.) for which they are most permeable. Voltage-gated ion channels involved in the perception of pain are located on neurons critical for the transmission and modulation of noxious, or potentially tissue damaging stimuli.

## Characteristics

### Structure of Voltage-Gated Ion Channels

The focus of this section is on channels with intrinsic voltage sensitivity. Ion channels with intrinsic voltage sensitivity encompass large and diverse protein families, but all members share several common features [2]. These include a protein structure composed of four repeat domains of six membrane-spanning regions (S1-S6). The voltage-sensor is composed of specific amino acid residues in S4 [1]. The channel pore with residues that serve as a "►selectivity filter" for specific ions is lined by the linker between S5 and S6. Additional membrane-spanning regions are present on some channels, such as the voltage- and $Ca^{2+}$-gated big conductance $K^+$ (BK) channel. The α-subunit of voltage-gated $Na^+$ and $Ca^{2+}$ channels constitutes a single protein encompassing all 4 domains. Therefore, diversity in the properties of these channels reflects, in part, diversity in α-subunits [3]. Voltage-gated $K^+$, BK and hyperpolarization and cyclic nucleotide (HCN) gated channels are composed of four distinct subunits that may be from the same gene (homomers) or from different genes (heteromers). Therefore, the diversity of these channels not only reflects properties of the α subunit, but the combination of α subunits that comprise the channel.

The superfamily of voltage-gated ion channels includes family members such as the ►inward rectifying $K^+$ channels ($K_{ir}$) and the ►two-pore $K^+$ channels ($K_{2P}$) composed of segments with homology to the S5-pore loop-S6 sequence of the prototypical voltage-gated ion channel, but lack intrinsic voltage-sensitivity conferred by the S4 segment [2]. The superfamily also includes transient receptor potential (►TRP) channels and ►cyclic nucleotide gated (CNG) ion channels with subunit homology that encompasses the entire S1-S6 segments of the prototypical voltage-gated ion channel, although the "voltage-sensor" has been largely uncoupled from the channel gating process, resulting in channels that are gated by stimuli other than voltage [2]. Finally, there are ion channels such as members of the $K_{ir}$ family and *N*-methyl-D-aspartate (►NMDA)-type glutamate gated channels that do not have intrinsic voltage sensitivity, but have voltage-dependent properties. The voltage-dependence of these channels is conferred by a voltage-dependent block of the channel by other molecules such as polyamines or $Mg^{2+}$ and are relieved with the appropriate change in membrane potential. None of these channels will be discussed further here.

### Gating of Voltage-Gated Ion Channels

The state (open, closed and/or inactivated) of a voltage-gated ion channel is controlled by membrane potential, or voltage. "Steady-state" is often used to describe the fraction of channels residing in any given state at a specific membrane potential. The rate at which channels transition between states, referred to as a channel's kinetic properties, may or may not be voltage-dependent [2]. Furthermore, for any given channel, some transitions, such as those associated with ►activation or the ►recovery from inactivation, may be voltage-dependent, while other transitions, such as those associated with ►inactivation and ►deactivation, may not be. At a single channel level, voltage-dependent transitions between states are not absolute, but rather reflect changes in channel open probability such that the probability of the channel being open is very low when it is in the "closed" state and considerably higher, but rarely equal to one, when it is in the "open" state. The voltage-dependence and rates at which channels transition between states, referred to as channel biophysical properties, are determined by intrinsic properties of the α-subunits, the interaction between α-subunits and accessory subunits or other proteins, the phosphorylation state of the channel

and, in the case of BK channels, the concentration of intracellular $Ca^{2+}$ [2]. The biophysical properties of a channel, in addition to the channel density and relative distribution in a membrane, determine its function. The biophysical properties, density and relative distribution of channels are dynamically regulated [4].

## Transmission of Noxious Stimuli

A series of events are necessary for noxious or potential tissue damaging stimuli to ultimately result in the perception of pain. The stimulus energy must be ►transduced (►sensory transduction) into an electrical signal in a nociceptor, usually its terminal, resulting in a ►generator potential. The generator potential must be of sufficient magnitude to produce an ►action potential. The action potential must be successfully propagated to the central terminals of nociceptive afferents. Depolarization of central terminals must be of sufficient magnitude and duration to enable the $Ca^{2+}$ influx necessary for transmitter release [4]. The ►synaptic potential (postsynaptic potential) evoked in the second order dorsal horn neuron must of sufficient magnitude to generate an action potential in that dorsal horn neuron. This series of processes must be repeated to enable the dorsal horn neuron to transmit the neural signal to, for example, the thalamus and neurons in the thalamus to subsequently transmit the neural signal to a number of critical sites in the cerebral cortex.

## Voltage Gated ion Channels Critical for the Transmission of Noxious Stimuli

Different classes and types of voltage-gated channels are critical for action potential initiation, propagation and transmitter release [5]. ►Voltage-gated $Na^+$ channels underlie the rapid membrane depolarization associated with the upstroke of the action potential. ►Voltage-gated $K^+$ channels contribute to the repolarization of the membrane during the falling phase of the action potential. These channels also contribute to the increase in membrane conductance that occurs following an action potential (►after-hyperpolarization), and therefore may influence the timing between action potentials. ►Voltage-gated $Ca^{2+}$ channels mediate $Ca^{2+}$ influx in neuron terminals that is necessary for transmitter release. The relative density of channel types, their distribution and biophysical properties determine critical aspects of neuronal excitability, including ►action potential threshold, maximum firing frequency, action potential burst duration (also known as ►adaptation or ►accommodation), and action potential ►conduction velocity.

## Channels Mediating Pain in Response to Tissue Injury

Following tissue injury, there are changes in the biophysical properties, density and distribution of voltage-gated ion channels that contribute to on-going pain and increased sensitivity of the injured tissue [5]. These changes reflect rapid events that involve protein-protein interactions, such as those underlying channel phosphorylation, as well as slower events that may reflect changes in channel ►trafficking (transport and membrane localization similar to ►receptor trafficking) and/or gene ►transcription and ►translation (RNA). Inflammatory mediators and ►trophic factors such as prostaglandin E2, tumor necrosis factor α and nerve growth factor (NGF) play important roles in the acute regulation of ion channels (see ►Inflammatory pain). Appropriate access to trophic factors such as NGF and glial-derived neurotrophic factor (GDNF) play important roles in the regulation of ion channel expression [5]. The specific pattern of changes in voltage-gated ion channels depends on a number of factors including: (i) type of injury (i.e. neuropathic versus inflammatory), (ii) time following injury (i.e. acute versus chronic), (iii) site of injury (i.e. cutaneous versus visceral), (iv) past history of the injured subject and injured tissue, (v) sex and (vi) age [4]. In general, an increase in inward current (i.e. $Na^+$ and $Ca^{2+}$ channels) and/or a decrease in outward current (i.e. $K^+$ channels) will result in an increase in nociceptor excitability and therefore pain.

*Voltage-gated $Na^+$channels ($Na_V$)*: Of the nine voltage-gated $Na^+$ channel α-subunits known to generate functional channels [6], four may play particularly important roles in pain: $Na_V1.3$, $Na_V1.7$, $Na_V1.8$ and $Na_V1.9$ [7].

$Na_V1.3$ expression is increased in peripheral neurons following peripheral nerve injury or inflammation. This channel may contribute to an increase in the rate of ►recovery from inactivation, and inhibiting its expression (knock-down) may attenuate nerve injury-induced hypersensitivity [7]. $Na_V1.3$ in the spinal cord and thalamus may also contribute to ongoing pain following spinal cord injury [8].

Expression of $Na_V1.7$ is restricted to the peripheral nervous system and neurendocrine tissue and is preferentially expressed in nociceptive afferents. Channel expression is increased following peripheral inflammation. Mutant (knockout) mice deficient in $Na_V1.7$ fail to develop an appropriate level of inflammatory hypersensitivity. Humans with a loss of function mutation in $Na_V1.7$ are insensitive to noxious stimulation. Two gain-of-function mutations have been associated with two distinct human pain syndromes [9].

Expression of $Na_V1.8$ is generally restricted to sensory neurons where it is preferentially expressed in nociceptive afferents. A host of inflammatory mediators that produce hypersensitivity increase channel function while mediators that attenuate inflammatory hypersensitivity attenuate channel function. Knock-down or selective block of the channel attenuates both inflammation and nerve injury-induced hypersensitivity.

While the $Na_V1.8$ knockout mouse only demonstrates a decrease in mechanical sensitivity with little decrease in hypersensitivity associated with inflammation or nerve injury, compensatory changes have been documented [5].

$Na_V1.9$ is present in nociceptive afferents and inflammatory mediators increase channel function. The $Na_V1.9$ knockout mouse has an attenuated response to inflammation [5].

*Voltage-gated $Ca^{2+}$ channels ($Ca_V$)*: Voltage-gated $Ca^{2+}$ channels are described in terms of their threshold for activation (high threshold versus low threshold) or what was originally thought to be their function: ►L-type ($Ca_V1.1$–$Ca_V1.4$) in heart, ►N-type ($Ca_V2.2$) in neurons, ►P/Q-type ($Ca_V2.1$) in purkinje neurons [10]. High threshold channels are critical for transmitter release and are, therefore, a primary target for both endogenous (i.e. enkephalins) and exogenous (i.e. morphine) analgesic drugs (e.g. opioids). The N-type channels appear to be particularly important for transmitter release in the spinal cord because of the analgesic efficacy of selective N-type channel blockers after spinal administration. High threshold channels may be inhibited by the inflammatory mediator prostaglandin $E_2$, although the functional consequences of this inhibition remain to be determined. Similarly, nerve injury is associated with a decrease in both high threshold and low threshold voltage-gated $Ca^{2+}$ currents, but it is also unclear whether these changes contribute to the hypersensitivity associated with nerve injury [5]. Peripheral nerve injury is associated with a dramatic increase in the α2δ- $Ca^{2+}$ channel subunit complex. This subunit is a binding site for drugs such as gabapentin, and may confer therapeutic efficacy by enabling block of $Ca^{2+}$ channels. Low threshold (►T-type, $Ca_V3.1$–$Ca_V3.3$) channels may play an important role in establishing the excitability of peripheral nerve terminals, and manipulations that produce an increase in channel function may be associated with an increase in nociceptive sensitivity [5].

*Voltage-gated $K^+$ channels (Kv)*: Voltage-gated $K^+$ channels are generally described in terms of properties of the current (i.e. inactivating versus non-inactivating) or their pharmacological sensitivity (i.e. 4-aminopyradine (4-AP)-versus tetraethyamonium (TEA)-sensitive). These channels play a critical role in regulating the excitability of sensory neurons as pharmacological block of these channels results in a dramatic increase in excitability [5]. Tissue injury-induced increases in afferent excitability have been shown to be associated with decreases in 4-AP-sensitive and/or TEA-sensitive $K^+$ currents. Because of the complexity of this channel family, the specific subunits responsible for the changes in excitability have yet to be identified in most cases. However, Kv4.2 does appear to play a major role in regulating the excitability of dorsal horn neurons and block of this channel suggests a significant role in inflammatory hyperalgesia.

*HCN channels*: The contribution of HCN channels to pain associated with tissue injury has not been studied extensively. However, there is evidence that following nerve injury there is an increase in HCN channel function that may contribute to spontaneous activity in nociceptive afferents and therefore on-going pain [5].

## Synonyms

Neuropathic pain; Inflammatory pain; Painful neuropathies

## Definition

Normal pain or nociception is an adaptive process that is necessary for the survival of the species because it alerts the individual to harmful conditions which can be life-threatening. Signals for painful or noxious stimuli, for example hot surfaces, are first detected by specialized high-threshold sensory neurons called nociceptors. Pathological pain, for example ►neuropathic pain, is caused by lesion or disease of the somatosensory system and which persists even after the physical aspects of injury have healed.

## Characteristics

### General Features of Voltage-Gated Sodium ($Na^+$) Channels

►Voltage-gated sodium ($Na^+$) channels underlie the generation and propagation of electric impulses along excitable membranes of cells such as neurons and myocytes (►Action potential; ►Action potential propagation), and ►sodium ($Na^+$) channelopathies underlie several inherited human disorders that affect neuronal function, skeletal and cardiac muscle contraction [1–4]. We will review in this essay recent data from human patients with gain-of-function or loss-of-function mutations in $Na_v1.7$, which confirm this channel's key role in pain states and identify it as a novel target for drug development to treat pain.

Sodium ($Na^+$) channels are heteromultimeric structures containing a single large pore-forming α-subunit and smaller auxiliary β-subunits [5]. While the α-subunit alone is necessary and sufficient to form a functional channel, β-subunits and an array of cytosolic molecules regulate trafficking and channel density at the cell membrane [3] (►Cell membrane – components and functions). Nine α-subunits ($Na_v1.1$-$Na_v1.9$) and four β-subunits (β1– β4) have been identified in mammals with specific spatial and temporal expression patterns, and several of their cognates have been found in lower vertebrates [5].

The α-subunits of $Na^+$ channels are large polypeptides (200–260 kDa), which are organized into four domains (DI-DIV), each consisting of six transmembrane segments connected by intra- and extra-cellular linkers (Fig. 1) [5].

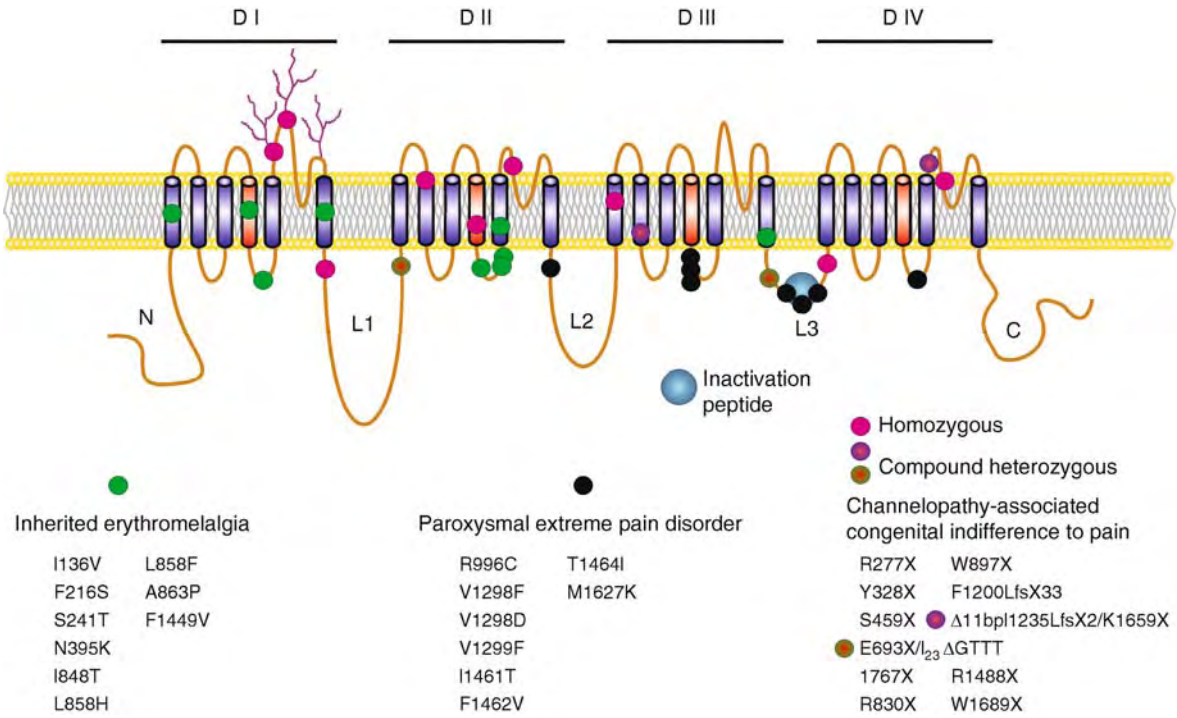
The β-subunits are much smaller (33–36 kDa) and belong to the immunoglobulin superfamily of proteins (►Immunoglobulin), each with a single transmembrane segment and a larger extra-cellular domain that has the characteristic immunoglobulin fold [5]. Many of the $Na^+$ channels produce currents with distinct biophysical and pharmacological features [6] that invariably impact the electrogenic profile of neurons or muscle cells in which they are present (►Action potential).

Among the neuronal channels, recent studies indicate that a mutant phenotype depends on the complement of $Na^+$ channels in the neuron in which the mutant channel is expressed (as will be discussed in a later section). Gain-of-function mutations in ►voltage-gated $Na^+$ channels are often dominantly inherited [2,4] whereas loss-of-function mutations are either dominant as in ►epilepsy [4], or recessive as in ►congenital indifference to pain [2]. Recently, $Na_v1.7$ has become the focus of intense investigation for its role in acquired and inherited ►neuropathic pain symptoms.

### Tissue Distribution of $Na_v1.7$

Robust $Na_v1.7$ expression has been reported in a majority of functionally identified ►nociceptive neurons and in ►sympathetic neurons of the peripheral nervous system (PNS) (Fig. 2) [2]. Evidence for the expression of $Na_v1.7$ in central nervous system (CNS) neurons has been controversial because of inconsistent findings. A global knock out of $Na_v1.7$ has been shown to be lethal in new-born mice [7]. Surprisingly, however, humans with ►nonsense mutations of $Na_v1.7$ survive with no apparent cognitive or motor deficits but with impaired smell and complete indifference to pain [2]. One explanation for the lethality in transgenic mice is that the inability to smell due to the loss of $Na_v1.7$ leads to starvation in affected mice.

Immunohistochemical studies (Fig. 2) have shown that $Na_v1.7$ is uniformly distributed within the cell bodies of small-diameter ►dorsal-root ganglion (DRG) neurons and along the unmyelinated ►C-fibers within the sciatic nerve. $Na_v1.7$ has also been found within nerve endings of DRG neurons in culture [2], an observation that suggests a similar accumulation at nerve endings *in vivo*. The presence of $Na_v1.7$ at nerve endings and its enabling biophysical properties would be consistent with a role of amplifying the typically weak ►generator potentials [6]. Since the reagents used in these immunohistochemical studies cannot distinguish between cytoplasmic and plasma membrane-bound channels, future



**Voltage-gated Sodium Channels: Multiple Roles in the Pathophysiology of Pain. Figure 1** Schematic of voltage-gated sodium channel showing locations of the known mutations in Nav1.7-related inherited pain disorders. Inherited erythromelalgia (green symbols) and paroxysmal extreme pain disorder (PEPD, black symbols) mutations are gain-of-function and inherited as a dominant trait. Channelopathy-associated congenital indifference to pain (CIP) is caused by loss-of-function mutations which are inherited as a recessive trait. Homozygous channelopathy-associated CIP mutations carry the same nonsense mutation on both alleles of *SCN9A* (solid magenta), whereas two pairs of compound heterozygous mutations (blue-magenta and red-green) carry different mutations which produce non-functional channels on the two alleles. Reproduced with permission from [2].

studies using $Na_v1.7$-specific reagents that can bind to the extra-cellular regions of the channel are needed for unequivocal demonstration of the presence of this channel at the plasma membrane.

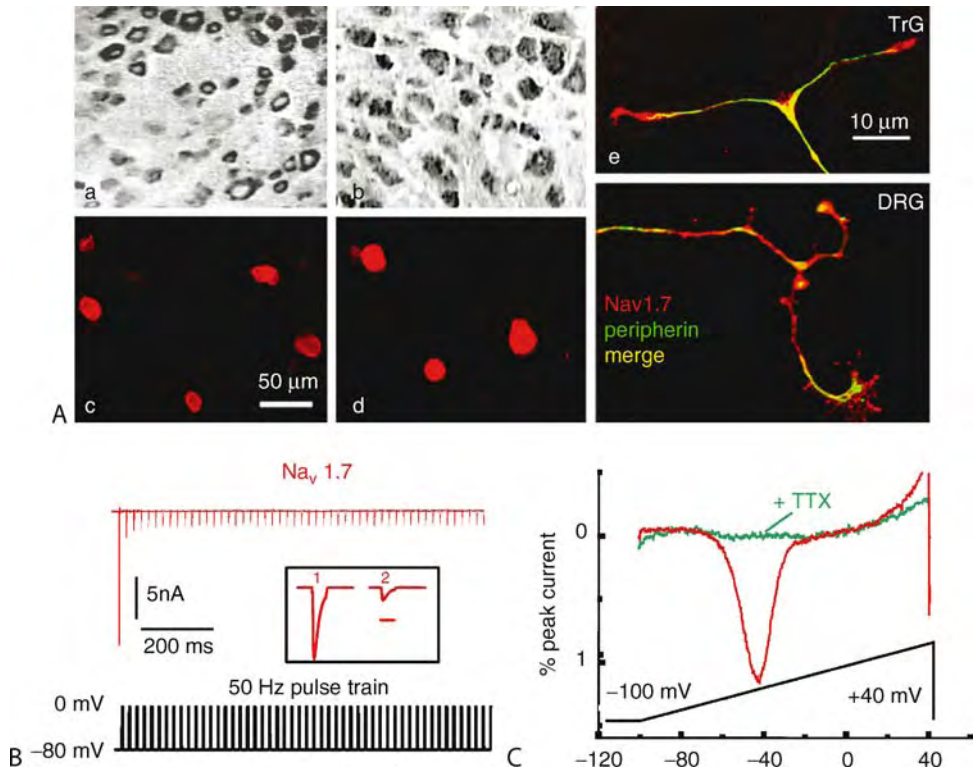
## Role of $Na_v1.7$ in Painful Neuropathies

There is substantial evidence for a critical role of $Na^+$ channels in acquired and inherited painful ►neuropathies, and clinical evidence that $Na^+$ channel blockers produce partial relief from neuropathic pain. A direct and central role of $Na_v1.7$ in painful disorders in humans has been confirmed by the identification and analysis of gain-of-function and loss-of-function mutations in this channel [1,2]. Genetic studies have identified gain-of-function ►missense mutations within ►SCN9A, the $Na^+$ channel gene that encodes $Na_v1.7$, in patients with inherited ►erythromelalgia (IEM) (see below). A different set of gain-of-function missense mutations has been identified in $Na_v1.7$ in patients with ►paroxysmal extreme pain disorder (PEPD) (see below), previously referred to as familial rectal pain [8]. Recently, loss-of-function mutations in $Na_v1.7$ have been identified in individuals with congenital and complete inability to experience pain [9]. These studies provide a complementary picture for the role of this channel in pain signaling.

## Inherited Erythromelalgia

Erythromelalgia or "burning feet syndrome," first described by S. Weir Mitchel in the late nineteenth century, is characterized by episodes of excruciating pain in the extremities and associated skin redness. Inherited erythromelalgia (IEM) (also known as ►erythermalgia) can start early in life with a mean age of onset of 3 years and typically affect feet and hands, whereas symptoms of adult-onset IEM typically start in mid-life [2]. While early- and juvenile-onset IEM have been linked to mutations in $Na_v1.7$ (Fig. 1), the genetic cause for adult-onset IEM remains to be identified [2].

Pain episodes in $Na_v1.7$-related, early-onset IEM are triggered by mild warmth or exercise, and are accompanied by erythema and mild swelling in the hands and feet, and sometimes in the ears or face [2]. The frequency and severity of symptoms increase with age. Patients with $Na_v1.7$-related IEM do not suffer



**Voltage-gated Sodium Channels: Multiple Roles in the Pathophysiology of Pain. Figure 2** $Na_v1.7$ is expressed in DRG and SCG neurons, accumulates at neurite tips, and possesses distinct biophysical characteristics consistent with its role in nociception. (a) Immunostaining of $Na_v1.7$ channels in DRG and SCG neurons *in vivo* and in cultured neurons. (Aa,Ab) $Na_v1.7$ channels are present in adult rat DRG and SCG neurons *in vivo*, and (Ac, Ad) in cultured DRG and SCG neurons from P2 rat pups. (Ae, Af) $Na_v1.7$ protein is present in neuritic extensions of small trigeminal (TrG) and dorsal root ganglion (DRG) which give rise to peripherin-positive unmyelinated C-fibers, and accumulates at the tips of these neurites. (b) Trains of 50 Hz stimulation show that sodium channel $Na_v1.7$, expressed in HEK 293 cells, recovers slowly from fast-inactivation and is unable to follow and sustain high frequency firing. (f) Using ramp stimulation to mimic small graded subthreshold potentials, $Na_v1.7$ produces a TTX-sensitive ramp current. Aa–Ad are adapted from [Rush AM, Dib-Hajj SD, Liu S, Cummins TR, Black JA, Waxman SG (2006) Proc Natl Acad Sci U S A 103:8245–8250]; Ae–Af, are adapted with permission from [2]; B and C are adapted from [Cummins TR, Howe JR, Waxman SG (1998) J Neurosci 18:9607–9619].

from sensory (other than somatosensory pain), motor or cognitive abnormalities. However, their degraded quality of life and lack of effective drugs for treatment has led to several cases of suicide. Except for skin redness in the affected extremities, patients with early-onset IEM do not report other ►autonomic abnormalities such as orthostatic hypotension or gastrointestinal symptoms. The erythema in affected areas might be caused by a combination of the release of vasodilating peptides, ►substance P and ►calcitonin-gene related peptide, by hyperactive C-fibers, and impaired cutaneous vasoconstriction caused by hypoexcitable sympathetic neurons [2]. In the absence of effective drugs for all forms of erythromelalgia, patients find partial relief from cooling their affected extremities while avoiding environmental conditions that can precipitate attacks.

## Paroxysmal Extreme Pain Disorder

Several cases of paroxysmal extreme pain disorder (PEPD) have been linked to mutations in $Na_v1.7$ [8] that are distinct from those in IEM (Fig. 1); however, almost half of the reported cases of PEPD do not carry mutations in this channel. The severe pain in PEPD patients along with redness in the lower body can start in infancy (and possibly *in utero*), and is induced by defecation or probing of the perianal areas, and, unlike cases of IEM, is accompanied sometimes by tonic non-epileptic seizures, syncopes, bradycardia and occasionally asystole [10]. It remains to be determined if the nonepileptic seizures, syncope, bradycardia and asystole are caused by autonomic neuron dysfunction which might be induced by $Na_v1.7$ mutant channels in sympathetic neurons. Pain progresses with age to

ocular and maxillary/mandibular areas and is triggered by cold, eating or emotional state [10]. Pain episodes can last seconds to minutes (and hours in extreme cases), and gradually subside over minutes. When tolerated, the anti-convulsant $Na^+$ channel blocker carbamazepine has been effective in relieving the symptoms, while other drugs including other anti-epileptics are not effective [10]. It is remarkable that these patients do not complain from pain in their extremities or show reddened feet as in patients with IEM, nor do patients with IEM suffer from rectal, ocular or mandibular pain as in PEPD patients.

## Congenital Indifference to Pain

$Na_v1.7$-related congenital inability to experience pain is a very rare, autosomal recessive trait [9]. These patients do not produce functional $Na_v1.7$ channels and do not experience pain from normally painful acts such as inserting sharp objects in their hands or after bone fracture, tongue and lip biting, or walking on hot surfaces (burning coal). However, except for deficits in their ability to smell and feel pain, these patients suffer no other sensory, motor or cognitive deficits. Heterozygous parents are asymptomatic suggesting that loss of functional $Na_v1.7$ on one allele does not lead to ►haploinsufficiency. Because many of the patients in these studies are young or adolescent, it remains to be seen what changes in pain perception might come with age, and if these changes represent learned behavior or physiological changes along the pain information axis.

## Molecular Pathophysiology

The role of $Na_v1.7$ in pathophysiology of pain in inherited neuropathies has been inferred from the effect of individual mutations on the ►gating properties of mutant channels, and in specific cases by studying the effect of mutant channel expression on firing properties of DRG neurons. The ability to study the biophysical properties of $Na_v1.7$ in a mammalian cell line [2] has facilitated the characterization of almost a dozen mutations by whole-cell patch clamp (see ►Intracellular recording) analysis to determine changes in intrinsic channel properties, for example ►activation and ►steady-state inactivation. Importantly, the establishment of transfection of primary neurons by ►electroporation has enabled the elucidation of physiological aspects of neuronal hyperexcitability of sensory neurons, which underlies neuropathic pain.

$Na_v1.7$ produces a fast activating and inactivating current, which is sensitive to nanomolar concentrations of ►tetrodotoxin (TTX-S), but unlike other TTX-S channels, $Na_v1.7$ channels are slow to recover from fast inactivation (►reprime) and produce a current in response to small slow depolarizations (ramp stimulus) (Fig. 2) [2,6]. The ability of $Na_v1.7$ to produce a ramp current close to the resting membrane potential (►Membrane potential – basics) of DRG neurons suggests that it might act at earlier stages of electrogenesis as a "threshold" channel, amplifying weak stimuli such as generator potentials, and thus setting the gain in nociceptors [6]. While experimental evidence has begun to explain how gain-of-function mutations of $Na_v1.7$ render DRG neurons hyperexcitable in painful neuropathies (see below), it is less understood why the lack of functional $Na_v1.7$ in patients with congenital indifference to pain completely abrogates the pain response [9].

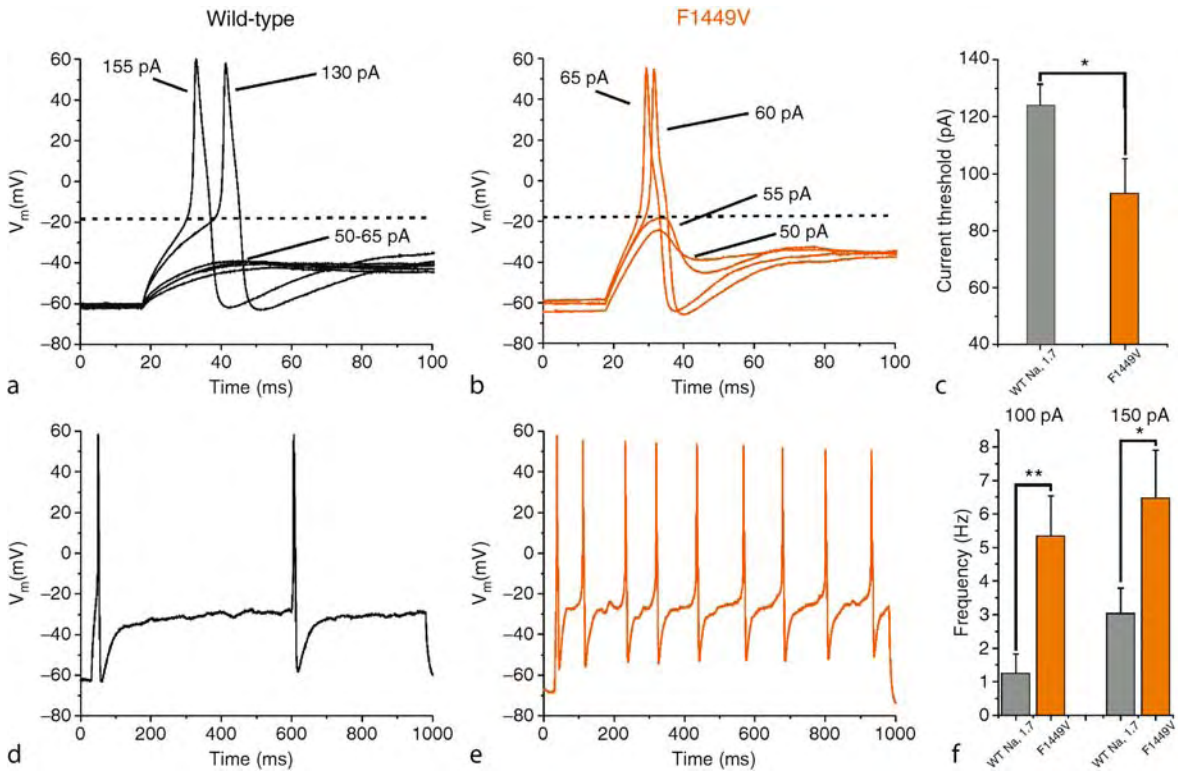
To date, eight IEM mutations [2] and three PEPD mutations [8] in $Na_v1.7$ have been characterized by whole-cell voltage-clamp (see ►Intracellular recording) studies. All of the IEM mutations lower the threshold for activation of $Na_v1.7$, thus allowing the channel to open in response to a weaker stimulus compared to wild-type channels. The three PEPD mutations do not affect the voltage-dependence of activation, but shift the voltage-dependence of fast-inactivation in a positive direction ensuring that more channels will be available to open at more depolarized potentials compared to normal DRG neurons [8]. Changes in threshold of channel activation (►Sodium ($Na^+$) Channel Activation) or the fraction of the total channels available to open at depolarized potentials can contribute to DRG neuron hyperexcitability by lowering the threshold for single action potentials or sustaining repetitive firing (as will be discussed below) (see ►Action potential).

The location of PEPD mutations in $Na_v1.7$ (Fig. 1) [8] within the fast-inactivation peptide in L3 and its putative receptor site in the S4-S5 linkers in domains III and IV, is consistent with the impaired channel fast-inactivation (►Sodium ($Na^+$) channel fast-inactivation) [5].

The structure-function effect of the mutations in $Na_v1.7$ from IEM patients is less clear. Except for the mutation in the S4 of domain I (DI/S4) where an effect on activation might be expected *a priori* because S4 segments act as the ►voltage-sensors of the channel, the other mutations clearly bias the open state of the channel through unknown mechanism(s).

The expression of three mutant $Na_v1.7$ mutations A863P, L858H and F1449V but not wild-type channels in DRG neurons lowers the threshold for single action potential and increases the number of spikes produced by a sustained stimulus (Fig. 3) [2], both hallmarks of neuronal hyperexcitability.

The majority of current underlying the depolarizing phase of action potential in nociceptive DRG neurons is carried by the $Na^+$ channel $Na_v1.8$, a tetrodotoxin-resistant (TTX-R) channel which is present in sensory but not sympathetic neurons, and the biophysical properties of $Na_v1.7$ suggest that it might not contribute significantly to this current [6]. Thus, the activation of mutant $Na_v1.7$ channels at more hyperpolarized



**Voltage-gated Sodium Channels: Multiple Roles in the Pathophysiology of Pain. Figure 3** Effect of the F1449V mutation on electrogenesis in small DRG neurons. (a): Representative traces from a small (<30 mm) DRG neuron expressing wild-type $Na_v1.7$, showing subthreshold responses to 50–65 pA current injections and subsequent all-or-none action potentials evoked by injections of 130 pA (current threshold for this neuron) and 155 pA. (b): In contrast, in a cell expressing the F1449V erythromelalgia mutation, action potentials were evoked by a 60 pA current injection, demonstrating a lower current threshold for action potential generation. The voltage for takeoff of the all-or-none action potential (dotted line) was similar for the neurons in panels a and b. (c): There is a significant (*$p < 0.05$) reduction in current threshold in cells expressing F1449V compared to cells expressing wild-type $Na_v1.7$. (d) Shows the firing of a neuron expressing wild type $Na_v1.7$ (same neuron as in *A*), which responded to a 950 ms stimulation of 150 pA with two action potentials. In contrast, (e) shows that, in a neuron expressing the mutant channel F1449V (same cell as in *b*), an identical 150 pA depolarizing stimulus evoked high-frequency firing. (f) There is a significant increase in the frequency of firing in response to 100 pA and 150 pA stimuli (950 ms) following expression of F1449V in comparison to wild-type $Na_v1.7$. Reproduced with permission from [Dib-Hajj SD, Rush AM, Cummins TR, Hisama FM, Novella S, Tyrrell L, Marshall L, Waxman SG (2005) Brain 128:1847–1854].

voltages compared to wild-type channels would be expected to reduce the threshold stimulus required to generate an all-or-none action potential without altering the voltage at which the action potential is elicited, presumably the voltage at which $Na_v1.8$ channels are activated. Indeed, the threshold voltage for a single action potentials in DRG neurons transfected with wild-type or mutant $Na_v1.7$ channels is around −20 mV, the voltage at which $Na_v1.8$ activates [6].

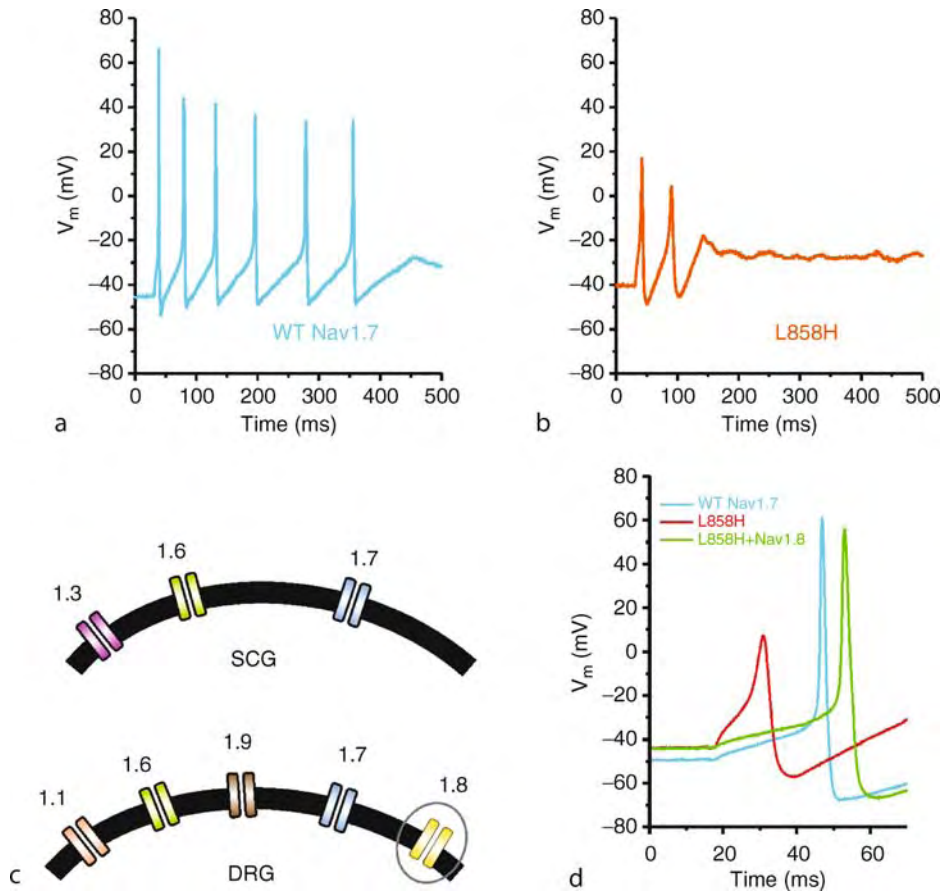
The shift in voltage-dependence of activation as in the case of all known IEM mutations, steady-state inactivation as in the case of PEPD mutations, or both as in the case of IEM mutations A863P and F1449V, are predicted to increase the number of channels that are constitutively "open" within the voltage range that is defined by the overlap between activation and inactivation curves (window current). The larger window current is predicted to cause a depolarizing shift in the resting membrane potential of neurons. Indeed, both L858H and A863P mutant $Na_v1.7$ channels have been shown to cause a 5 mV depolarizing shift in resting membrane potential of DRG neurons [2]. Depolarization of the resting membrane potential brings DRG neurons closer to activation threshold for $Na_v1.8$ channels and thus enhances the chances that these neurons will fire in response to a stimulus.

The depolarization of the resting membrane potential of neurons expressing mutant $Na_v1.7$ could also cause a resting inhibition of the other TTX-S channels, including the mutant channel itself, which have a

hyperpolarized activation and inactivation compared to $Na_v1.8$ [6]. Thus, it is predicted that neurons, which do not normally produce $Na_v1.8$ channels, will become hypoexcitable. Indeed, the L858H $Na_v1.7$ mutant channels, which render DRG neurons hyperexcitable, cause SCG neurons to become hypoexcitable (Fig. 4) [2]. The role of $Na_v1.8$ channels in neuronal hyperexcitability is supported by its ability to rescue firing properties of SCG neurons when it is co-expressed with the L858H mutant $Na_v1.7$ channel (Fig. 4).

## Dysregulation of $Na_v1.7$ in Acquired Pain States

$Na_v1.7$ has been shown to be a major contributor to inflammation-induced pain (►Inflammatory pain) in animal models. Following inflammation of the hind paw in rats, $Na_v1.7$ levels in DRG neurons are elevated, with a concomitant increase in the amplitude of TTX-S current in these neurons [2]. A contribution of $Na_v1.7$ to inflammatory pain is further supported by the finding that antisense-mediated knock-down of $Na_v1.7$ levels in primary afferents reduces inflammation-induced thermal hyperalgesia (►Hyperalgesia and allodynia) in mice. Importantly, a direct role of $Na_v1.7$ in inflammatory pain has been confirmed in studies using $Na_v1.7$ knock-out mice, which show almost no signs of inflammation-induced pain [7]. Thus, $Na_v1.7$ appears to play an important role in inflammation-induced pain.



**Voltage-gated Sodium Channels: Multiple Roles in the Pathophysiology of Pain. Figure 4** L858H mutation decreases firing frequency in SCG neurons and phenotype is rescued by the co-expression of $Na_v1.8$. (a) Representative SCG neuron expressing WT $Na_v1.7$ fires 6 action potentials in response to a 950 ms input of 40 pA from RMP (∼ −45 mV). (b) Representative SCG neuron expressing L858H fires only 2 action potentials, with reduced overshoot, in response to a 100 pA current injection from RMP (∼ −40 mV). (c) Schematic representation of the cell membrane of SCG and DRG neurons showing the different complement of voltage-gated sodium channels that are present in the two different neurons. (d) Action potential overshoot in SCG neurons transfected with the L858H erythromelalgia mutant channel (red trace) was significantly reduced compared to that in neurons transfected with wild type $Na_v1.7$ (blue trace). The action potential overshoot was restored to wild type levels when $Na_v1.8$ was co-expressed with L858H (green trace). Adapted with permission from [Rush AM, Dib-Hajj SD, Liu S, Cummins TR, Black JA, Waxman SG (2006) Proc Natl Acad Sci USA 103:8245–8250].

### Summary
The elucidation of the role of $Na_v1.7$ in different forms of inherited painful neuropathies has not only identified a potential target for treatment but also provides hope for future mechanism-based diagnosis of such disorders. The lack of cognitive, motor and sensory deficits in humans lacking functional $Na_v1.7$ suggests that $Na_v1.7$-specific blockers might be free from significant side effects. While generic $Na^+$ channel blockers have been effective in treatment of some cases of neuropathic pain, their usefulness in a clinical setting is tempered by their undesirable side effects. While the contribution of $Na_v1.7$ channels to pain states in acquired and inherited neuropathies is only now beginning to be revealed, the pursuit of small molecule blockers of $Na_v1.7$ for pharmaceutical applications is in full vigor.

## Voluntary Movement

Martha Flanders
Department of Neuroscience, University of Minnesota, Minneapolis, MN, USA

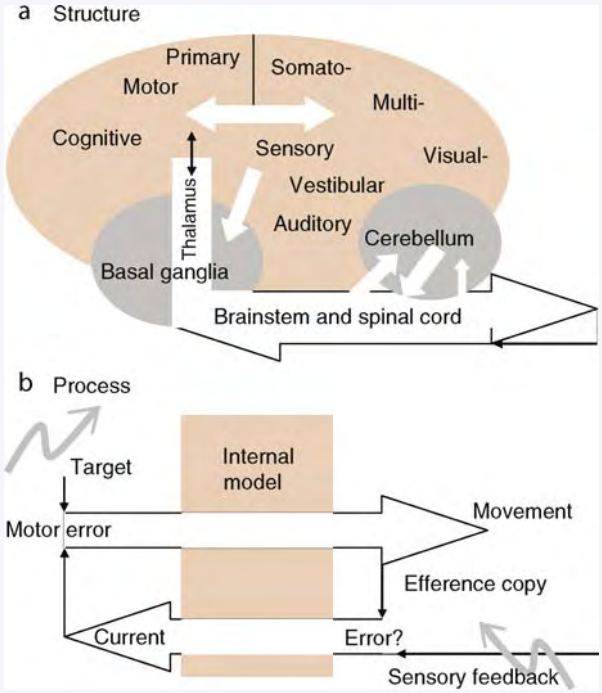
### Introduction
Voluntary movement is the expression of thought through action. Virtually all areas of the central nervous system are involved in this process. The main flow of information may begin in cognitive cortical areas in the frontal lobe, or in sensory cortical areas in the occipital, parietal and temporal lobes. Ultimately, information flows from motor areas in the frontal lobe through the brainstem and spinal cord to the motoneurons. The ►basal ganglia and ►cerebellum have reciprocal connections with most of the structures listed above, and therefore play a supporting role.

One approach to understanding the neural control of voluntary movement is to consider the function of each of the structures involved (Fig. 1a).

For example, the primary motor cortex is generally regarded as the main cortical area for providing descending motor command signals to motoneurons. However, the exact functions of other brain structures remain open for debate. Since diseases of the basal ganglia and cerebellum are relatively common, numerous functions have been proposed for these structures (e.g., movement initiation, error correction, etc.). One emerging perspective is that the basal ganglia and cerebellum do not have discrete roles in motor control and instead work via their interconnections with other subcortical and cerebral cortical structures (see 1–3).

A different approach to the study of voluntary movement is to consider the movement goals, strategies and algorithms for implementation, without direct reference to the neuroanatomy. Theoretical and computational studies have been aimed at providing a quantitative description of movement characteristics in order to gain insight to the neural code. Furthermore, flow chart models like the one shown in Fig. 1b have become increasingly sophisticated by incorporating hypothetical processes such as the use of efference copy.

Hopefully, future studies will merge this functional approach with the more anatomical approach by establishing the exact neural mechanisms for implementing the key algorithms that are essential to sensorimotor integration.



**Voluntary Movement. Figure 1** (a) Schematic diagram of the main central nervous system structures involved in voluntary movement. Cognitive and motor cortical areas are in the frontal lobe; sensory and association areas are in the occipital, parietal and temporal lobes. The basal ganglia and cerebellum get input from the brainstem and spinal cord, and are interconnected with the cerebral cortex through the thalamus. (b) Schematic flow chart of the types of processing that must occur in the control of voluntary movement. Information about target location is combined with information about current location to form a motor error input command to the internal model. The output is the motor command to produce a movement. An efference copy of this command, representing the expected result of the movement, can be compared to sensory feedback, representing the actual result. The efference copy can also by used to update the representation of the current location. If the central nervous system can extrapolate in time, the information in the sensory input (gray, smoothly curved arrows), it would make up for delays due to synaptic transmission and axonal conduction.

## Structures Involved in Voluntary Movement

The ultimate output of the motor system is the activation of a ►motor unit (defined as a single motoneuron and the group of the muscle fibers contacted by its axon). Researchers have documented several consistent aspects to the patterns of motor unit activation used for voluntary hand and arm movement:

1. As muscle force is increased, small motor units tend to be recruited prior to large motor units (the ►size principle, 4).
2. Neighboring motor units within the same muscle can be preferentially selected for different movements (such as arm movements in different directions, 5).
3. The motor system does not exert independent control of each motor unit or of each muscle, instead groups of motor units across different muscles show covariation in their recruitment patterns (see ►muscle synergies).
4. There is often inhibition of motor units with a mechanical action antagonistic to that of the excited motor units (a classical phenomenon in motor control physiology known as ►reciprocal inhibition).

The brain controls voluntary arm and hand movements by sending descending motor commands to the pattern generating circuitry in the spinal cord. The primary motor cortex is the cerebral cortical structure most directly responsible for activating this circuitry and thereby controlling motor unit selection and recruitment. Although premotor cortical areas also provide direct projections to motoneurons (see ►motor cortex – output properties and organization), and somatosensory cortical areas also contribute to the corticospinal tract, the primary motor cortex provides the most powerful projection to the spinal cord for the control of voluntary

hand and arm movements. There is a complex mapping of hand and arm representations across the surface of the cerebral cortex; it has been characterized as patchy and redundant (see ►motor cortex – hand movements and plasticity). This pattern may be consonant with the number of different types of voluntary movements that are possible and the inherent plasticity of the hand motor control system [6].

The basal ganglia play a modulatory role in shaping the output of the cerebral cortex. Because the basal ganglia are organized into loops that run from cortex through striatum through pallidum through thalamus back to cortex, they are positioned to assist with the facilitation, shaping, and learning of movement. While modern investigations have revealed that the basal ganglia also influence cognition and emotion, their participation in motor control has received the greatest attention and may be their most important function (see ►basal ganglia – motor function of). Deficits seen in humans with ►Parkinson's disease (degeneration of dopamine pathways from substantia nigra to striatum) suggest that in healthy humans, the basal ganglia have a role in integrating the activities of the many, diverse cortical and sub-cortical regions that are engaged in implementing and adapting ongoing motor behavior.

The cerebellum is an intriguing and somewhat mysterious structure (see ►cerebellum – motor function of ). It is a key structure for processing sensory information from the ►vestibular system, and for the control of ►eye movement. It is also important for voluntary limb movement. An exquisite feature of voluntary movement is its flexibility and adaptability, and the cerebellum, in conjunction with other sensory and motor structures, is thought to play an important role in ►motor learning. Due to its interconnections with the cerebral cortex and its involvement in motor learning, theorists have speculated that the cerebellum is the site of (or at least an important part of) the so-called ►internal model, a functional construct which will be described in detail in the following section.

## Processing Algorithms for Voluntary Movement

Due to the complexity of the sensorimotor system, it may be useful to analyze its function without direct consideration of the specific anatomical structures involved. A class of voluntary movements that has been used extensively for this purpose is point-to-point ►reaching movements. In a reaching movement, the arm begins at rest with the hand in a specific initial location. A visual target appears and the hand must then be moved, in one simple motion, to stop at the specified final location. Observations about the characteristics of such movements have given rise to various ►motor control models, which generally provide a description of the sensorimotor transformation by proposing that the goal is to optimize a particular characteristic, like the smoothness of the hand trajectory or the amount of muscle activation [7–10]. These models have provided valuable accounts of the types of kinematic (position and movement-based) and kinetic (force-based) parameters that are used by the control system.

Studies of reaching movements have also provided solid evidence for the simplest aspect of the flow chart shown in Fig. 1b. The simplest part of this model is the transformation from a visually presented goal (labeled "target"), through the "INTERNAL MODEL," to the output command to contract arm motor units (labeled "movement"). This aspect of the internal model is called the inverse model because the visual target is specified in terms of its position or velocity (kinematic parameters) and the output is in terms of muscle force or change in force (kinetic parameters). Because the laws of physics generally describe the cause and effect transformation of force to movement (i.e., force equals mass times acceleration), the sensorimotor transformation of a kinematic goal to a muscle force is considered to be backwards or "inverse." This neural mapping must take into account the mechanical characteristics of the arm and any object held in the hand, or else the reaching movement would miss its target. Numerous investigations (e.g., 11) have provided evidence that the brain can learn a new internal model within a few trials, even when the model must account for unusual patterns of elastic or viscous resistance to arm movement (rather than the more common situation where one learns to interact with a new object with unexpected inertial characteristics).

The goal of moving the hand from an initial location to a final location can be called a "motor error," defined as the difference between the current and the target locations. Electrophysiological studies have shown that frontal and parietal cortical areas represent this motor error in terms of the direction or velocity of a reaching movement, not just the final target position (e.g., 12,13). Furthermore, the proper pattern of motor unit recruitment depends on both the initial and the final arm positions, as well as the other mechanical aspects of the arm and hand held object. Therefore the internal model must take into account the arm's initial position as well as its final target position.

In studies of reaching from a stationary hand, head and body position to a stationary target, it is possible to regard the sensorimotor transformation as open-loop or feedforward (i.e., occurring without additional information about the hand or target location). However if the body moves (as in stepping while reaching) or the target moves (as in tracking or drawing), the hand and target locations must be updated (see ►movement sequences). Models to describe such processes are more speculative than the initial proposal of a feedforward transformation through the inverse model.

Several lines of indirect evidence indicate that the sensorimotor system may contain a real-time estimate of the current arm and hand position during the course of a reaching, tracking, or drawing movement [14,15]. This may be accomplished by creating an "efference copy" (Fig. 1b) within the cerebral cortex, of the motor commands sent to the spinal cord (see also 16). It has been hypothesized that the efference copy information, which is in terms of muscle forces, goes back through the internal model in the opposite (forward) direction (right to left in Fig. 1b) in order to quickly produce an estimate of current hand position (the expected result of the current motor command).

If this is true, it is possible for the sensorimotor system to make an ongoing comparison of the target location and the current hand location (the "motor error" in Fig. 1b) during the course of a fast reaching movement. However, to use this mechanism for tracking a moving target, the representation of current hand position should be compared with a representation of current target location, which would need to be extrapolated from previously sensed target motion to make up for visual sensory processing delays. This hypothetical predictive extrapolation is indicated by a gray, smoothly curved arrow in Fig. 1b.

The initial motivation for proposing a quick efference copy feedback loop was the fact that sensory feedback may be subject to processing delays of as much as 100–200 ms. This is due to the numerous synaptic delays in the visual pathway, and also due to long axonal conduction times in the somatosensory system. If the current hand location was simply sensed using visual or somatosensory input, this sensory feedback information would arrive at the internal model too late to be used during an ongoing movement. However, as mentioned above, recent research on ►smooth pursuit eye movement has begun to provide evidence that smooth, natural target trajectories can be extrapolated (see ►eye-hand coordination). For example, a target velocity sensed on the retina could potentially be transformed to a representation of the most likely future target location via processing in motion sensitive cortical areas [17].

It is not known whether the somatosensory cortical areas can perform a similar function, i.e., extrapolating a smoothly changing, familiar input to make up for the sensory delay. If so, it could make up for the time delay in tactile and proprioceptive feedback (as suggested by the gray smoothly curved feedback arrow in Fig. 1b). This would serve to produce an additional, somatosensory-based input to the forward model, which, along with the efference copy, would update current arm position (see Fig. 1b). Furthermore, it would provide the basis for a haptic comparison of the expected and actual somatosensory consequences of a hand movement ("error?" in Fig. 1b). This may be the mechanism that forms the basis of haptic perception.

## Conclusions and Future Directions

In voluntary movement, collections of motor units are selected and recruited based on an ongoing evaluation of neural representations of current and target states. The transformation from goal to motor command must be processed using memories: the internal model and hypothetical mechanisms for sensory extrapolation are essentially memories developed through experience. Most prior research on this process has employed arm movements to visual targets, but one can think of more general examples as well:

Imagine a woman driving while singing along with the singer of a familiar song on the car radio. The driver's voice is the immediate result of a complex sequence of motor unit activations and aspects of these patterns have become "hard wired," genetically and through prior use of the pattern generating circuitry. The driver's song does not lag the radio's song by the amount of time that it takes to process the radio's auditory information. This suggests that the radio's auditory cues are filtered through the memories ingrained in the driver's brain, to make up for the sensory delay. The driver is constantly listening to the radio but she can lead the voice on the radio and she can even finish the song after the radio goes off.

Common experiences such as this indicate the types of processes that must occur in sensory and motor areas (e.g., flexible patterns of motor unit recruitment and sensory extrapolation based on learning). The structures involved in some of these functions have been revealed mainly through cases of human brain lesions and disease, and studies using functional brain imaging in humans and electrophysiological recordings in animals. However, few studies have specified the neurophysiological basis of complex algorithms such as the use of efference copy and the recollection of memories. Thus there are many open questions for future research.

►Vomeronasal Organ (Jacobson's Organ)

## Vomeronasal Organ (Jacobson's Organ)

### Definition

The nose of most vertebrates contains an additional anatomically distinct chemosensory system, the accessory olfactory system or vomeronasal organ (VNO) or Jacobson's organ. The peripheral organ is a cigar-shaped, blind-ended sac or tube located in the most ventral part of the nasal septum. It contains the vomeronasal epithelium where vomeronasal receptors neurons are located. The sensory neurons within the VNO detect distinct scents containing chemical compounds which are often, but not always, large non-volatile molecules. The VNO is used in the detection of pheromones and detects other odorous compounds in addition. The VNO has been postulated to be involved in responses to pheromones, molecules produced and emitted by members of the same species. Pheromones have been defined to elicit a reproducible reaction and implicated in mating, courtship, sexual and other behaviors. They can also interact with the endocrine system. Pheromones are mostly present in bodily secretions such as urine, sweat and seminal fluid. The axons of pheromone sensory neurons in the VNO project to the accessory olfactory bulb, from which they relay to the amygdala and hypothalamus, structures associated with reproductive behavior, mood, memory and neuroendocrine responses. In mammals, two additional families of G-protein coupled receptors V1R and V2R receptors, unrelated to the family of olfactory receptors, have been identified in the vomeronasal organ and they are differentially expressed in two different populations of vomeronasal sensory neurons. In the apical part of the VNO, neurons express receptors of the V1R family which couple to a Gi-type of G-protein, whereas those in the basal part of the VNO express the V2R receptors which couple to Go-proteins. V1R receptors number about 140 and are of the same general type of proteins as the olfactory receptors. V2R receptors on the other hand possess a long extracellular N-terminal loop. They are estimated to be about hundred in rodents. The signal transduction mechanism in the vomeronasal neurons is not completely understood, but recent physiological and biochemical

evidence implicates phospholipase $C\beta_2$, $IP_3$ and DAG as important second messenger components which induce a calcium increase and the activation of a transient receptor potential (TRPC2) channel. So far, none of the V2R class of receptors could be functionally expressed and characterized. In the case of the V1R receptor, for one of the family member in mouse activating ligands have been identified.

### Synonyms

VOR motor learning

## Definition

The vestibulo-ocular reflex or VOR is a feed forward, short limb reflex to compensate head movement with an equal, but opposite eye movement, thus stabilizing the eyes within the orbits to ensure ocular fixation upon a visual target. There are also visually driven eye movements to keep the visual target on the fovea of the retina, the region with the highest visual acuity. Visually driven reflexes require the image of the visual target to travel via the retina to the visual cortex for processing before a motor command can be sent to the brainstem to move the eyes. Due to this long pathway and concomitant processing time, these visually driven processes are by nature relatively slow. By contrast, the VOR is a three-neuron arc in its shortest pathway and thus produces motor commands relatively rapidly. Visually driven and vestibularly driven oculomotor reflexes work in concert to ensure that the eyes always accurately track the visual target within the bandwidth of naturally occurring head and target motion. In analogy to VOR control, the eyes are akin to a gyroscope in the orbit always remaining stable, focused upon the viewed target despite head movement. The gain of this VOR reflex, defined as eye velocity/head velocity, is nominally one in the light, i.e. the eyes are always stable within the orbit during head movement.

The VOR is a plastic or adaptive reflex. Change due to aging, disease or other causes that might reduce the magnitude of the input signal concerning head velocity arising within the vestibular labyrinth, or reduce the magnitude of the output or eye velocity caused by the extra ocular eye muscles, can reduce the VOR gain. If gain reduction occurs, the visual image will no longer be stable upon the fovea during head movement. By a process called motor learning, the VOR gain can be again recalibrated to a value of one. Although the VOR is recalibrated in the light, the actual eye movements produced by the vestibular system are measured in the dark in the absence of vision. Gain of the reflex in the dark is generally slightly less than one.

## Characteristics

### Quantitative Description

In the laboratory, VOR gain change or motor learning can be achieved by prolonged, conflicting visual-vestibular stimulation to increase or decrease the output of the reflex. Motor learning causes changes in the efficacy of synaptic transmission through multiple, specific information pathways, and these can be quantified as changes in neuronal sensitivity to specific stimuli [1–5]. Physiological recording shows that synaptic plasticity is likely to occur in many elements of the circuitry and in many pathways; e.g. a plastic site located at the GABAergic synapses between Purkinje cells and ►flocculus target neurons (FTNs) in the vestibular nuclei has been identified [1]. The effect of VOR motor learning upon the sensitivities of FTNs can also be compared with results taken from floccular Purkinje cells [1,5–11]. Model simulations indicate that VOR motor memories are stored as plastic changes at multiple synapses carrying both sensory and motor information located both in the cerebellum and brainstem. Thus, changes at a single site (e.g. FTN or cerebellum) are not sufficient to account for the learned behavior. This hypothesis is further supported by studies showing that behavior in lesioned animals results from different mechanisms than those observed in the intact animal (►Flocculus hypothesis). Thus, simple measurement of VOR gain following cerebellar lesion does not adequately evaluate the role of the lesioned structure in VOR memory storage.

### Structural Regulation

In the laboratory, the VOR gain can be artificially recalibrated by the wearing of magnifying lenses such as reading glasses to raise the gain, or telescopes to lower the gain. In primates, including humans, the gain can thus be changed from values of about 0.2 to 2. Importantly, removal of the cerebellar flocculus precludes further change in VOR gain. Thus, an intact flocculus is necessary for adaptive VOR gain modification.

## VOR Gain

### Definition

The gain of the vestibuloocular reflex (VOR) is used in experimental and clinical settings to give a quantitative measure of the effectiveness of the VOR. It is defined as the ratio of the amplitude of slow phase eye and head movement.

►Vestibulo-ocular Reflexes

## VOR Phase

### Definition

The phase of the vestibulo-ocular reflex (VOR) is used in experimental and clinical settings to quantify the time delay between eye and head movement onset of the VOR. Phase values are often expressed in degrees or radians. This is because sine wave stimulation is often used to test the VOR.

►Vestibulo-ocular Reflexes

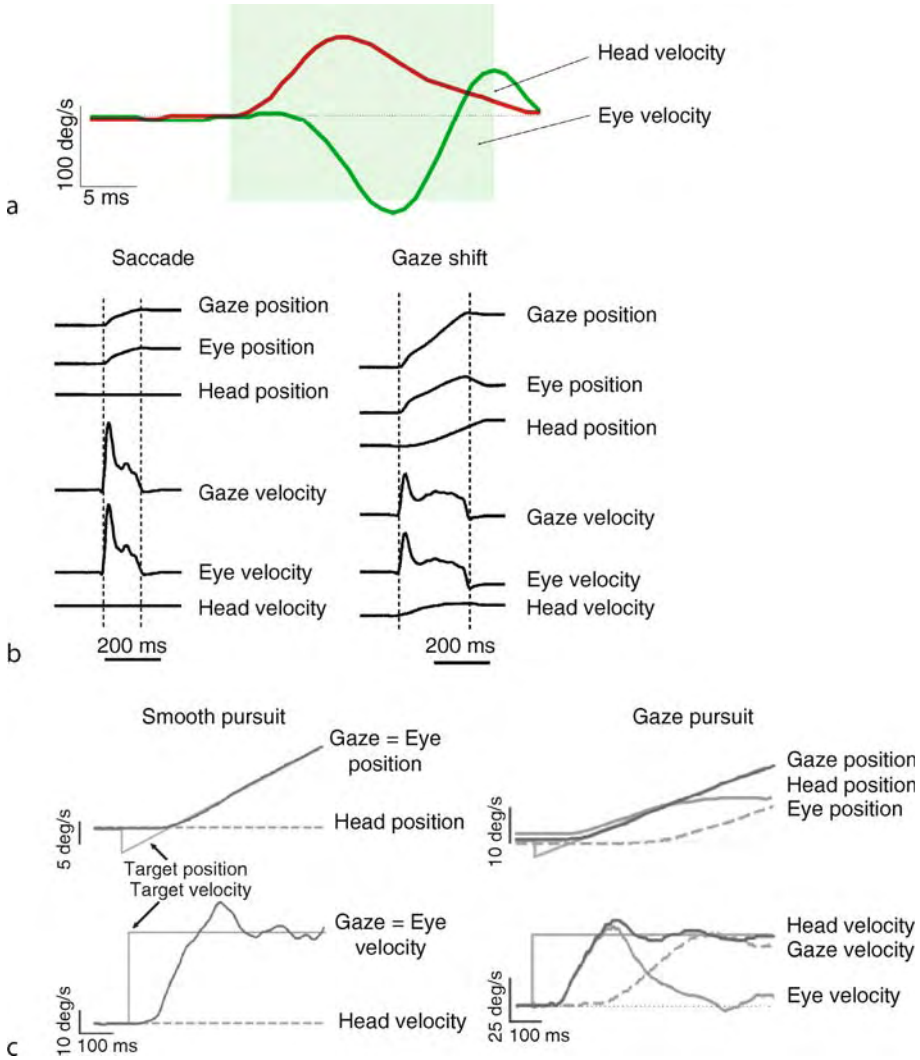
## VOR Suppression

Kathleen E. Cullen
Department of Physiology, Aerospace Medical Research Unit, McGill University, Montreal, QC, Canada

### Definition

The vestibulo-ocular reflex (VOR) is classically associated with stabilizing the visual world on the retina by producing an eye movement of equal and opposite amplitude to the motion of the head. Indeed, the VOR effectively stabilizes the visual axis in space for the wide range of head motions that are generated during daily activities such as walking and running. The most direct pathway that mediates the VOR consists of only three neurons; vestibular afferents, which project to interneurons in the vestibular nuclei, which in turn project to extraocular motoneurons. The efficiency of this direct three neuron arc is reflected in its fast response time (Fig. 1a). Compensatory eye movements lag head movements by as little as 5–6 ms in the primate [1].

While a fully operational VOR is crucial for minimizing retinal slip during our every day activities, it is counterproductive during natural orienting behaviors in which the head movements are made to redirect our fovea or axis of visual gaze to a particular object in our visual field. Specifically, when the head is immobilized, saccadic and smooth pursuit eye movements are made to voluntarily redirect the axis of gaze in space. Saccadic eye movements function to rapidly redirect the fovea to a new object of interest (Fig. 1b, *left panel*). Smooth pursuit eye movements function to keep a slowly moving visual object on the fovea (Fig. 1c, *left panel*). Under natural conditions, where the head is not restrained, head movements are commonly generated in combination with saccadic and smooth pursuit eye movements to redirect gaze. These coordinated eye-head movements are termed rapid ►gaze shifts (Fig. 1b, *right panel*) and eye-head pursuit (Fig. 1c, *right panel*), respectively. A fully operational VOR would be counterproductive during both behaviors, because a fully functional VOR would produce an eye movement command in a direction opposite to that of the intended shift of the axis of gaze. This essay considers the results of behavioral and neurophysiological investigations that have advanced our understanding of how the VOR is suppressed during gaze shifts, when the behavioral goal is to redirect rather than stabilize gaze.



**VOR Suppression. Figure 1** (a) The minimal latency of the VOR is ~5 ms. (b) Gaze shifts made with the head-restrained (*left panel*) and head unrestrained (*right panel*). (c) Pursuit response to a step-ramp target trajectory made with the head-restrained (*left panel*) and head unrestrained (*right panel*).

## Characteristics

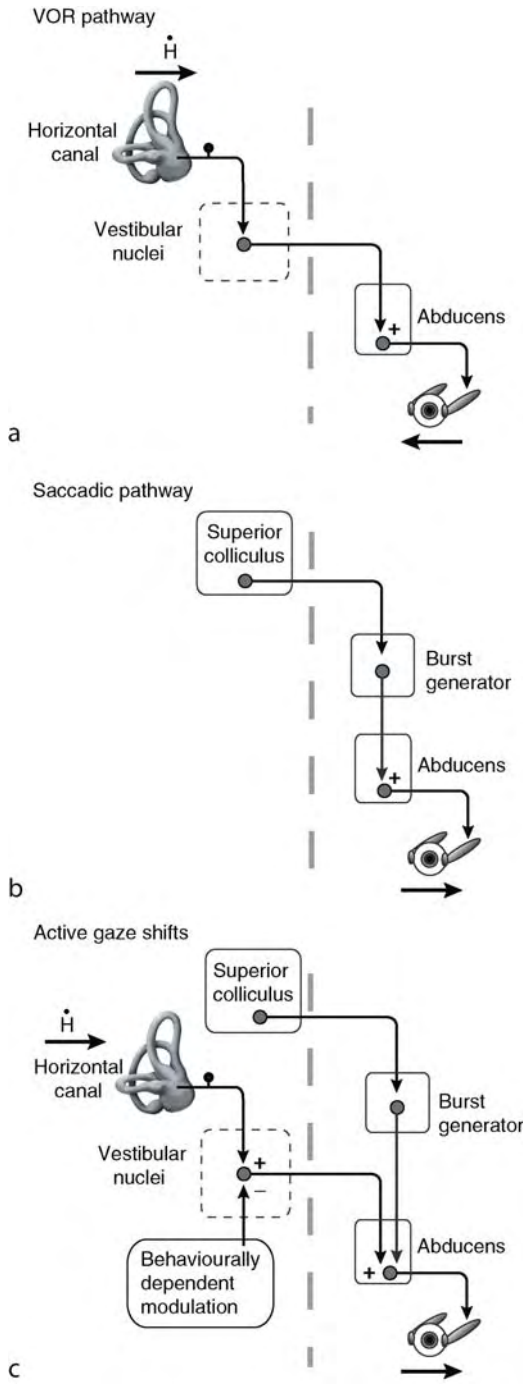
### The VOR During Gaze Shifts

#### *Behavioral Studies*

When the head is not restrained, a combination of rapid eye and head movements (gaze shift) is commonly used to redirect the visual axis to a new target in space. Bizzi and colleagues [2] originally proposed that the VOR remains functional during gaze shifts, such that it eliminates the head's contribution to the change in gaze. In this schema, termed "the ►linear summation hypothesis", the actual eye movement generated at the level of the extraocular motoneurons reflects the summation of two signals: an intact VOR from vestibular pathways (i.e. a compensatory eye movement signal (Fig. 2a)), and a separate oculocentric saccadic eye movement signal from the brainstem 'burst generator (Fig. 2b), which counters the VOR and redirects the axis of gaze. The conceptual simplicity of this proposal (Fig. 2c) has made it an attractive model of gaze shift generation.

Over the past three decades, substantial evidence has accumulated indicating that the linear summation hypothesis is generally not valid during gaze shifts (see discussion in [3]). In order to probe the status of the VOR during gaze shifts, perturbations as diverse as electromagnetic clutches to brake the head, torque motors or hammers to "bump" the head, as well as whole-body rotations have been employed. The

V



**VOR Suppression. Figure 2** The primary inputs to the abducens motor nucleus that mediate (a) the VOR and (b) Saccadic eye movements. (c) Interactions between these pathways during a rightward gaze shift.

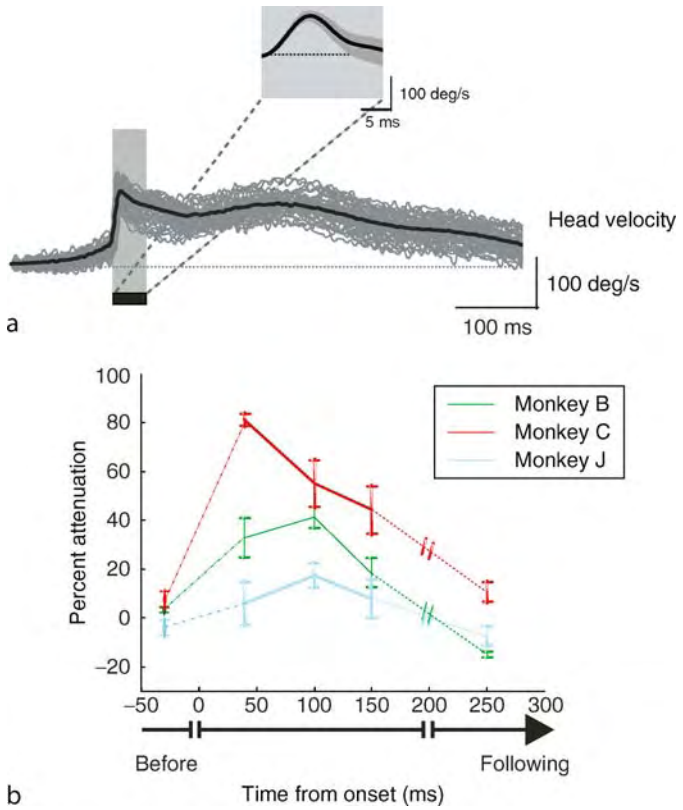
results of most studies have shown that transmission through the VOR pathways is modulated in a behaviorally dependent manner during gaze shifts (Fig. 2c). There is common agreement that the VOR is completely turned off during large gaze shifts and is significantly suppressed during smaller gaze shifts. For gaze shifts less than 50 degrees, VOR gain (defined as: change in eye velocity/change in head velocity caused by a perturbation) decreases as a function of increasing gaze shift amplitude. Thus, the head movements generated during gaze shifts contribute to changing the axis of gaze in space, since the contribution of the head movement to gaze is not completely cancelled out (i.e. VOR gain $\neq -1$). As a result, several models have been proposed to explain how eye and head movements are coordinated to produce accurate gaze shifts.

Until recently, the exact time course of the suppression during gaze shifts had been a matter of controversy (see discussion in [3]). It was initially proposed that the VOR was rapidly switched from an "on" to an "off" state during gaze shifts and then back on at gaze shift end. This was furthered by the suggestion that VOR gain decreases exponentially (Tc = ~50 ms) from the onset of the gaze shift, and returns to a value greater than unity immediately after a gaze shift. However, the temporal resolution of the method used in this latter study was limited. More recently, discrete transient perturbations have been used to more directly probe the time course of VOR attenuation during gaze shifts (Fig. 3a; [3]. This approach has shown that VOR suppression is maximal early in the gaze shift and progressively recovers to reach normal values near gaze shift end (Fig. 3b). High variability across subjects, however, precludes establishing a unifying description of the absolute level and time course of VOR suppression during gaze shifts.

### Neural Correlates

A neural correlate for the suppression of the VOR during gaze shifts has recently been identified (reviewed in [4]). Prior investigations in head-restrained monkeys have revealed that there are several classes of vestibular nuclei neurons, which discharge in relation to horizontal passive whole-body rotation and/or eye movements. ►Type I position-vestibular-pause (PVP) neurons are thought to constitute most of the intermediate leg of the direct VOR pathway; PVP neurons receive a strong monosynaptic connection from the ipsilateral vestibular afferents and, in turn, project directly to contralateral extraocular motoneurons (Fig. 4a).

Type I PVP neurons derive their name from the signals they carry during head-restrained oculomotor and vestibular paradigms: (i) their firing rates increase when the eyes move to more contralaterally directed ►positions, (ii) during slow phase ►vestibular nystagmus, these neurons are sensitive to ipsilateral head rotations (i.e. a type I response), and (iii) their discharges cease (►pause) for ipsilaterally directed



**VOR Suppression. Figure 3** (a) Head trajectories that were experimentally perturbed (vertical shaded grey bar and inset) during gaze shifts. (b) VOR gain in response increases over time from gaze shift onset ultimately reaching unity at gaze shift end. Error bars represent standard errors.

saccades and vestibular quick phases (for more detail see Essay on PVP Neurons). While these neurons are robustly modulated in response to passive head rotations, their responses to head velocity are dramatically attenuated during gaze shifts. As shown in the inset of Fig. 4a, neuronal responses are much less than those predicted by the same neuron's response during passive whole body rotation (pVOR model; heavy line). Note, that the gaze shift interval is denoted by the two vertical dashed lines.

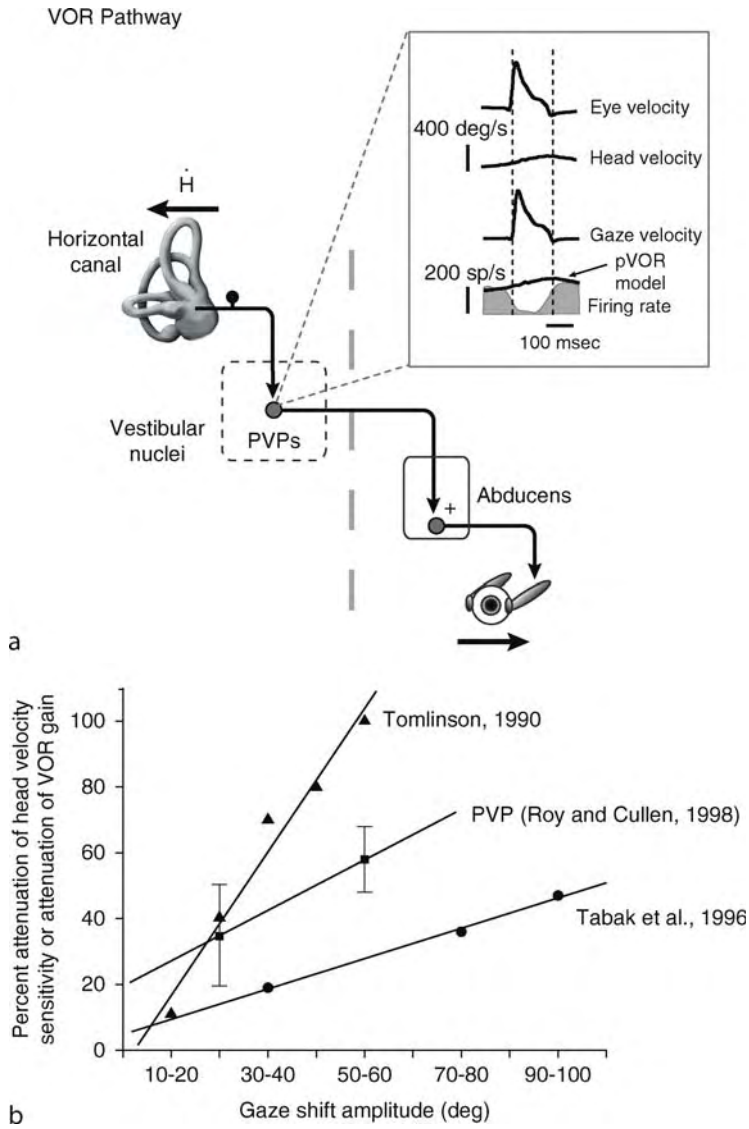
The head-velocity information encoded by type I PVP neurons is increasingly attenuated as a function of gaze shift amplitude. This neurophysiological trend (Fig. 4b) mirrors the results of the prior behavioral studies which were discussed above. In Fig. 4b, results from two of these prior studies have been superimposed on PVP neuron data for comparison (see [5]). These findings provide strong support for the proposal that the amplitude-dependent reduction of the responses of PVP neurons underlies the amplitude-dependent decrease in behavioral VOR gain observed during gaze shifts (see: [5]).

The attenuation of PVP responses during gaze shifts can be accounted for by a known mechanism, namely projections from the brainstem saccade generator to the vestibular nuclei (Fig. 5; reviewed in [5]). During saccades, vestibular quick phases and gaze shifts, brainstem burst neurons (BNs) become active as denoted by the "gate". As a result, BNs provide an inhibitory input related to eye velocity (E′) and head velocity ($H'_{BN}$) to type I PVP neurons during gaze shifts via their projections to type II neurons in the vestibular nuclei. (*Note:* type II vestibular nuclei neurons are activated in response to contralateral head rotations). In contrast, the head velocity sensitivity of PVP neurons recovers immediately following the end of a gaze shift once gaze is stable, even when the head is still moving (see inset: Fig. 4a). This observation is also consistent with the mechanism illustrated in Fig. 5, since the brainstem saccade generator is not active during this interval.

## The VOR During Eye-Head Pursuit

### *Behavioral Studies*

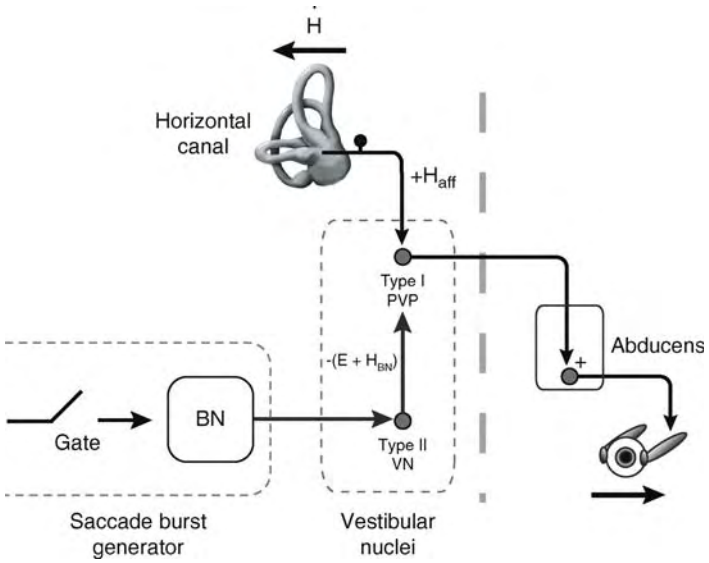
Head-restrained primates generate continuous eye movements, termed smooth pursuit, to shift gaze to follow a moving visual target of interest. When the head



**VOR Suppression. Figure 4** (a) The three-neuron arc that mediates the horizontal VOR and responses of PVP neurons during gaze shifts (inset). (b) Comparison of the percent attenuation of PVP (*filled square*) head velocity sensitivity during gaze shifts and the percent attenuation of the VOR gain as measured in behavioral experiments.

is not restrained, a combination of head and eye motion (eye-head pursuit) is commonly used. Bizzi and colleagues proposed that the linear summation hypothesis could also be applied to eye-head pursuit see discussion in [4]. In this schema, the eye movements generated reflect the summation of two opposing signals (Fig. 6c): a VOR (Fig. 6a), which cancels out the contribution of head motion to gaze and an ocular pursuit signal of cerebellar origin (Fig. 6b). In support of linear summation, several subsequent studies demonstrated that the frequency response of head-restrained smooth pursuit and head-unrestrained eye-head pursuit are generally comparable.

An intact VOR would be counterproductive during eye-head pursuit for the same reason it would be counterproductive during gaze shifts. As shown in Fig. 6c, a fully functional VOR would generate an eye movement command in the direction opposite to that of the ongoing tracking. To date there is much accumulated evidence indicating that the VOR is not only cancelled by a smooth pursuit signal (i.e. the schema proposed in Fig. 6c), but that the gain of the



**VOR Suppression. Figure 5** The brainstem mechanism that underlies the reduction in VOR gain during gaze shifts.

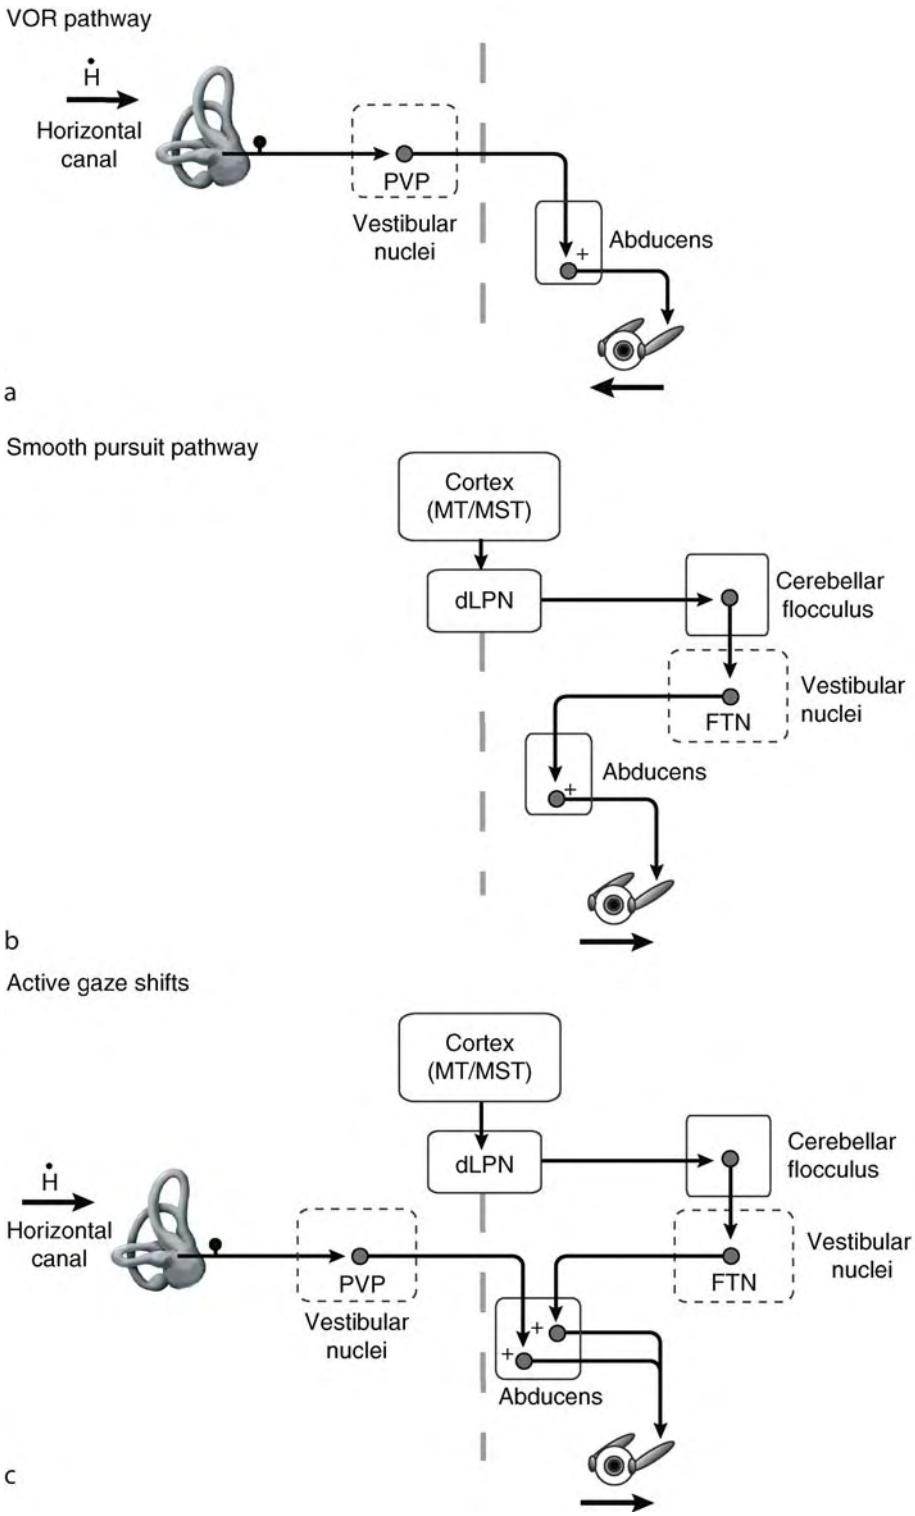
VOR pathway itself is partially suppressed during combined eye-head tracking [6]. Firm evidence for this non-visual or parametric adjustment of VOR gain was found by applying transient perturbations to the head while subjects voluntarily cancelled their VOR by tracking a head stationary target. In monkeys and humans, suppression of the evoked VOR is observed at very short (i.e. < 30 ms) latencies (Fig. 7b) in this condition versus when the same perturbation is applied while the animal is stationary (>90 ms Fig. 7a; [7,8]). This indicates that during VOR cancellation, the efficacy of the VOR is suppressed by a mechanism that does not depend on visual feedback or smooth pursuit (Fig. 7c).

The idea that a parametric adjustment of transmission in the VOR pathways contributes to VOR cancellation is consistent with the findings of many investigations (reviewed in [7]). First, it has long been known that humans can decrease the gain of their VOR by simply imagining a target that moved with their heads (e.g. [6]). This result shows that the VOR can be suppressed by non-visual inputs. Moreover, humans are better able to suppress their VOR during passive, pseudorandom vestibular stimulation than they are able to pursue a visual target that is moved pseudorandomly at similar velocities, and their ability to cancel torsional VOR is better than their ability to generate torsional smooth pursuit. Finally, there is some clinical evidence showing that the ability to generate smooth pursuit eye movements and to cancel the VOR are not always equally affected by CNS lesions.

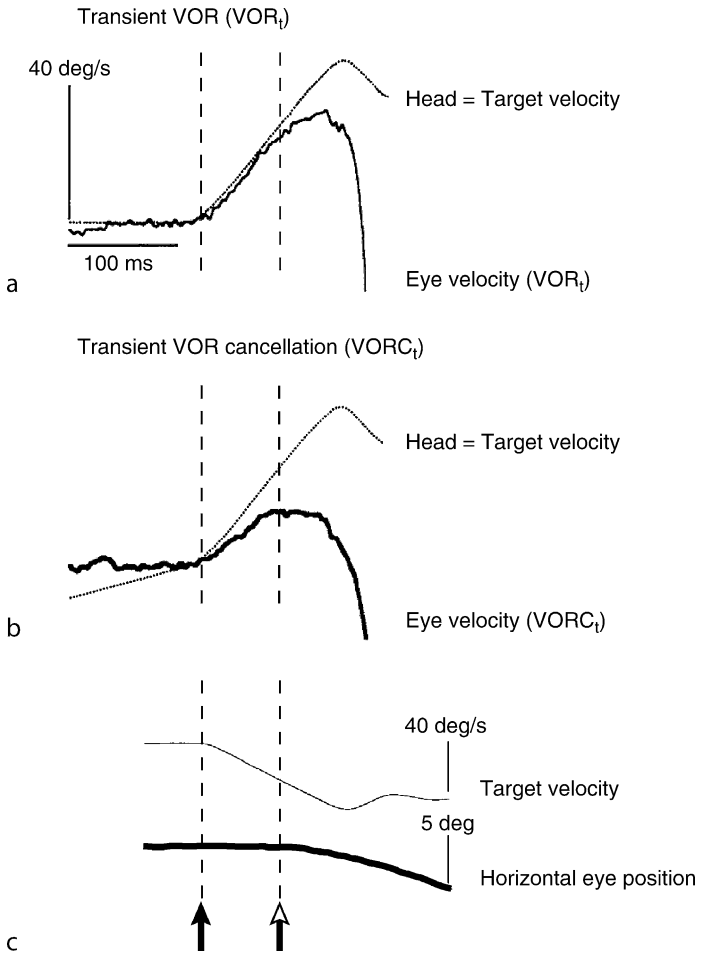
The question then arises: what is the advantage of having a non-pursuit related mechanism to negate the VOR during eye-head tracking? It appears that parametric suppression of the VOR operates to extend the accuracy of eye-head tracking movements beyond what would be possible by the pursuit system alone. Although gaze accuracy is comparable during eye-head pursuit and pursuit in the head-restrained condition when target motion is predictable, pursuit of faster unpredictable moving targets can be improved when primates are free to move their heads.

### Neural Correlates

Electrophysiological studies have provided insights into the mechanisms that suppress the VOR during eye-head pursuit. The attenuation of the head-velocity sensitivity of PVP neurons underlies parametric (i.e. non-visual) suppression of the VOR during eye-head tracking. The head velocity modulation of the direct VOR pathways (i.e. PVP neurons) is attenuated by 30% during cancellation of the VOR. This reduction in head-velocity sensitivity occurs at latencies that are too short to be mediated by smooth pursuit pathways (Fig. 8a; [9]). The relative attenuation of the response of PVP neurons is directly comparable to the amount of suppression of VOR that can be attributed to the non-visual mechanism (bottom: Fig. 7b; [9]). During combined eye-head pursuit, the velocity modulation of the direct VOR pathways is likewise attenuated by 30%. Thus, parametric adjustments of



**VOR Suppression. Figure 6** The primary premotor inputs to the abducens motor nucleus that mediate the (a) VOR and (b) smooth pursuit eye movements. (c) Interactions between these pathways during combined eye-head tracking. Abbreviations: dLPN: (►Dorsal lateral pontine nuclei), MT/MST, (►Middle temporal area and middle superior temporal area (MT/MST).



**VOR Suppression. Figure 7** (a, b) An unpredictable step in head acceleration was applied in two conditions: (a) the subject was initially stationary and fixating a stationary target (VORt) and (b) the subject was initially canceling its VOR (VORCt). (c) When the visual target is accelerated in a similar manner, the latency of the smooth pursuit eye movement (dotted line) is comparable to latency of VOR suppression in b.

transmission in the direct VOR pathway are observed during cancellation of the VOR as well as during the active head movements made during coordinated eye-head pursuit.

In contrast, pursuit related cancellation of the VOR is mediated by a different group of premotor neurons in the vestibular nuclei and nucleus prepositus. These neurons receive a pursuit-related command from the cerebellar flocculus, and also project to the abducens nucleus. During head-restrained pursuit and eye-head pursuit, these cells carry a gaze velocity signal (reviewed in [8]). Moreover, when the head is perturbed during eye-head tracking, the longer latency responses of these cells are consistent with smooth pursuit delays [10]. Thus, during eye-head tracking, the smooth pursuit inputs mediated via these neurons function in parallel with the attenuation in the gain of the direct VOR pathways (i.e. PVP neurons) to cancel the VOR at the level of abducens motor neurons. The specific premotor pathways that mediate parametric and pursuit-dependent cancellation are shown schematically in Fig. 8b.

# VOR - Rotatory

## Definition

Compensatory eye movements subsequent to head or body rotations mediated by the vestibulo-ocular reflex (VOR).

►Vestibulo-ocular Reflexes
►Vestibulo-oculomotor connections
►Vestibulo-oculomotor System: Functional Aspects

## VOR - Tilt VOR

### Definition

Compensatory eye movements subsequent to head or body rotations about the naso-occipital axis, i.e., lateral tilt, mediated by the vestibulo-ocular reflex (VOR). The reflex can be dynamic, i.e., during oscillatory movements, or sustained, i.e., during static tilt. In the latter case, eye position is maintained by otolith input.

## Wake-on Cells

### Definition

This group of neurons begins to discharge seconds before the onset of wakefulness and remains very active until 5–8 s before the end of wakefulness. During wakefulness, discharge rates of these cells (8–20 spikes/s) are much higher than those of REM-off cells. The neurotransmitter identity of these neurons is not definitive but based on their location it is most likely that these cells contain the neurotransmitter acetylcholine (Ach) and/or glutamate.

## Wake-REM-on Cells

### Definition

This group of neurons displays higher discharge rates during REM sleep and waking than during NREM sleep. The majority of this type of cell is located within the pedunculopontine tegmentum (PPT) and laterodorsal tegmentum (LDT). The neurotransmitter identity of these neurons is not definitive but based on their location it is most likely that these cells contain the neurotransmitter acetylcholine (ACh).

►Acetylcholine

►Rapid Eye Movement (REM) Sleep

## Wake-sleep Cycle

►Sleep-Wake Cycle

## Waking

### Definition

Waking is the physiological state that alternates with sleep, with the periodicity of the alternating rhythm being controlled by the circadian clock located in the suprachiasmatic nucleus of the hypothalamus. Wakefulness is maintained by the reticular activating system, and the electroencephalogram (EEG) is characterized by low-voltage, fast frequency activity, with alpha rhythm (8–12 Hz) emerging during relaxed wakefulness and eyes closed.

Wakefulness features mental activation associated with muscle tone, maintenance of posture, and full capability for behavioral, perceptual, cognitive, and emotional interaction with the environment.

## Weber Syndrome

### Definition
The Weber syndrome results from unilateral ventral lesion (infarction) of the midbrain and is characterized

by ipsilateral ►paresis of adductive and vertical eye movements and of pupillary dilation, and by paresis of contralateral face, arm and leg.

## Weigert Stain

### Definition

The Weigert stain involves the treatment of nervous tissue with potassium dichromate to preserve myelin lipids. The lipids are then stained with the use of hematoxylin, providing a useful technique for visualizing fiber pathways. The pathways appear black due to the staining of myelin sheaths.

## Werdnig-Hoffmann Disease (Spinal Muscular Atrophy, SMA)

### Definition

Common recessive autosomal disease characterized by degeneration of lower ►motoneurons caused by mutations of the "Survival of Motor Neuron 1" (SMN1) gene. Patients present with muscle ►paralysis and ►muscle atrophy, greater in the proximal muscles, leading to scoliosis and limited upper extremity function. Spinal Muscular Atrophy Type I (SMA I) is a frequent disorder and without treatment death occurs by 2 years. Death is caused by severe and progressive restrictive lung disease.

## Wernicke-Korsakoff Syndrome/ Encephalopathy

### Definition

Serious consequence of alcoholism and ►thiamine (vitamin B1) deficiency. Certain characteristic signs of this disease, notably ►ophthalmoplegia, ►nystagmus, and ►ataxia, respond rapidly to the administration of thiamine but to no other vitamin. Wernicke's syndrome may be accompanied by an acute global confusional state that may also respond to thiamine. Left untreated, Wernicke's syndrome frequently leads to a chronic disorder in which ►learning and ►memory are strongly impaired. This so-called Korsakoff's psychosis is characterized by ►confabulation, and is less likely to be reversible once established.

►Ataxia
►Confabulations
►Nystagmus

## Wernicke's Aphasia

### Definition

Wernicke's aphasia is primarily a deficit in language comprehension resulting from lesions of Wernicke's area (Brodmann's area 22: posterior part of the left temporal lobe) and often of left superior temporal areas (Brodmann's areas 39 and 40) and area 37. With extensive lesions, auditory and visual inputs are disturbed. Patients may speak at normal rate and melody, but excessively (logorrhea) and without meaning (empty speech), and may use the wrong words (paraphasia) or produce new words (neologisms). They also are disabled as to reading and writing.

## Wernicke's Area

### Definition

Auditory comprehension center

►Wernicke's Aphasia

## Western Blot

### Definition

Western Blot is a technique used to identify proteins in a sample. Gel electrophoresis separates the proteins in the sample on the basis of size. Proteins are transferred to a membrane where they are probed with a primary antibody specific to the target protein, followed by secondary antibody detection of the primary antibody.

## Wheatgerm Agglutinin Conjugated with Horseradish Peroxidase (WGA-HRP)

### Definition

Wheatgerm-agglutinin conjugated with horseradish peroxidase is a neural tracer that is transported both from the cell body to axon terminals (the orthograde directions) and axon terminals to the cell body (retrograde directions). Wheatgerm agglutinin is much more strongly transported than HRP so that WGA-HRP can be used in much lower concentrations than HRP (1% vs 20% is typical). HRP is conjugated to the wheatgerm agglutinin so that WGA-HRP can be visualized with the wide variety of familiar chemical reaction for revealing HRP.

## Whiplash-associated Disorders (WAD)

### Definition

WADs result from fast whip-like neck movements induced mainly by rear- and front-end or lateral impacts during motor vehicle collisions, producing abrupt accelerations and decelerations of the head relative to the body with compressions or torsions of the cervical spine. These cause bone or soft-tissue injuries, which may lead to acute and chronic pain and dysfunctions of various sorts, such as local mechanical ►hyperalgesia, sensory and motor deficits, muscle fatigue, stiffness, temporo-mandibular dysfunctions, cognitive impairments of memory and concentration, distress, depression, anxiety and sleep disturbances.

## Whitten Effect

### Definition

The presence of a male will induce estrous in females made anestrous by injections of estradiol, group housing or constant light.

## Work

### Definition

A quantity of energy passed from one system to another. Usually refers, when used without qualification, to mechanical work. Mechanical work is calculated as the time integral of force in the mechanical linkage between the systems with respect to distance moved by the linkage. The common formulation force x distance only applies when the force is constant. Also work can describe the transfer of electrical or osmotic work.

►Energy/Energetics

## Working Memory

### Definition

A capacity of short-term storage of information used in complex cognitive activities such as reasoning, problem solving and language by maintaining information in an active state during processing.

►Emotional Learning/Memory
►Memory and Dementia

## Worm

►Serial Analysis of Gene Expression

## Writer's Cramp

### Definition

Writer's cramp is a task-specific focal upper limb dystonia characterized by abnormally contracting muscles causing cramping in the hand and fingers while writing. The dystonia causes abnormal posturing of the wrist and fingers while writing. The most common posture is flexion and ulnar deviation of the wrist, and a tight grip of the pen with the thumb and index finger. The first line of treatment is botulinum toxin injection into target muscles which are thought to be overactive.

►Botulinum Toxin

## Wulst

### Definition

German for "bulge" Refers to a bulge-like structure in the anterior forebrain, demarcated by the vallecula, which houses a large blood vessel.

## Xenografting

### Definition

Synonym: xenotransplantation. Transplantation of tissues and organ pieces from an animal to a person, or to another animal of a different species.

## Xerostomia

### Definition

Xerostomia is sensation of dryness; with or without hyposalivation (usually defined as measured resting secretion ≤0.1 ml/min or stimulated secretion ≤0.7 ml/min of whole saliva).

►Salivary Secretion Control

## X-Linked Disease

### Definition

The two sex chromosomes are X and Y. Males are characterized by an XY pair, and females are characterized by an XX pair. X-linked disease is a genetic disease caused by a mutation of a gene on the X-chromosome. Males will be affected, because they have only the one X-chromosome located mutant allele. Females show much less prevalence of disease, because to be affected they would need to receive a mutant allele from both parents.

For example, a disease such as Duchenne muscular dystrophy (DMD) is inherited, because the responsible mutated dystrophin gene is carried on the X chromosome. As males have only one X chromosome, the characteristics represented by its genes are typically expressed, whereas in females with two X chromosomes they are not. DMD is therefore considered an X-linked recessive genetic disease.

►Duchenne Muscular Dystrophy

## Yaw

### Definition

Turn about the vertical axis.

## Yeast 2-Hybrid

### Definition

Yeast 2-hybrid is a technique used to identify proteinprotein interactions, based on the idea that if two proteins interact a reporter gene is activated. This approach is often used to identify unknown interactors (prey) of a known protein (bait). The yeast GAL-4 gene is split into DNA binding and activating domains, and each used separately to tag the bait protein and the prey proteins. The GAL-4 protein is only functional when the split domains come in close contact with one another, because the proteins they tag interact. These DNA sequences are subcloned into vectors and used to transform yeast, which contain the reporter gene. Yeast that turn color are then isolated and used to identify the prey protein that interacts with the bait.

## Yoked Muscles

### Definition

Muscles that always contract together, i.e., are "yoked."

## Young's Modulus

### Definition

The Young's Modulus of a material is defined by the slope of the stress-strain curve.

►Measurement Techniques

## Zeitgeber

### Definition

The word "zeitgeber" is derived from the German words for time (Zeit) and giver (Geber). It refers to a stimulus that conveys environmental time information to a biological clock. An environmental signal is said to be a zeitgeber when it can be shown to re-set the timing of a biological rhythm. In the case of a circadian (daily) rhythm, the strongest zeitgeber is typically light, which is detected primarily via specialized non-visual photoreceptors.

In addition to light, any signal that is structured with a reliable 24 h periodicity could, in theory, be utilized by biological systems to gather time information concerning the environment. Even the low amplitude oscillations in temperature that occur in vertebrates will synchronize daily cellular rhythms and social cues can act as (weak) zeitgebers.

►Chronobiology
►Circadian Rhythm

## Zeitgeber Time

### Definition

Zeitgeber time (ZT) refers to experimental time, specifically within an experiment concerning chronobiology.

In such an experiment, a zeitgeber is delivered at least once per cycle to synchronize a free-running circadian rhythm to the cycle. Under the formalism of ZT, each full cycle is divided into 24 equal "hours" (even if an experimental day of more or less than 24 actual hours is used). The 0 and 24 h time points correspond to lights-on or experimental dawn. This means that, in an experiment with a cycle of 12 h of light and 12 h of darkness, ZT0 corresponds to lightson, or 6 h after the mid-point of the dark period. An alternative convention, External Time (ExT), is the same as ZT except that the 0 and 24 h time points correspond to midnight, as for our local clock time.

►Chronobiology
►Circadian Rhythm
