Homogenous Transformation is a commonly used technique for simultaneously specifying translations and rotations between coordinate systems in threedimensional motion analysis.

►Motion Analysis

## Homolog

### Definition

A gene that has the same origin and function in at least two species.

## Homologous

### Definition

Inherited from a common ancestor (with phyletic continuity), but not necessarily similar in function (e.g., the limbs of horses and sea lions, used for walking in one case, and swimming in the other case; another example are the wings of birds and bats which are both homologous and analogous, since they were both derived from forelimbs and are used for flying).

## Homologous Recombination

### Definition

Homologous recombination also known as DNA crossover, homologous recombination occurs in meiosis when homologous pairs of sister chromatids align.

Homologous recombination occurs between two homologous stretches of DNA and involves exchange of the DNA between sister chromatids. This naturally occurring process is taken advantage of by researchers when constructing a knockout transgenic animal, whereby one allele of a gene is replaced with an engineered DNA construct without affecting other loci in the genome. To perform homologous recombination in ES cells, the DNA sequence of the gene to be replaced needs to be known.

## Homologue

### Definition

Structures of the same evolutionary origin, which are not necessarily similar in function.

## Homology

### Definition

Structures are proposed to be homologous in different animals whenever it is thought that the same structures were present in their common ancestor, being not necessary a functional similarity.

►Evolution of the Amygdala: Tetrapods

## Homonymous Hemianopia

### Definition

Homonymous hemianopia is hemianopia which affects vision in both eyes in the same way. Hemianopia caused by damage to areas of the brain in which signals from

both eyes are combined (e.g. primary visual cortex) is homonymous, whereas damage to earlier monocular structures (e.g. the optic nerve) only affects vision in a single eye.

►Optic Nerve
►Primary Visual Cortex

## Homosynaptic Depression

### Definition

Reduction of transmitter release produced by prior activation of the same presynaptic terminals. Reflects a depletion of available neurotransmitter stores.

## Homosynaptic Long-term Potentiation (LTP)

### Definition

Homosynaptic LTP is that the enhancement in the amplitude of the excitatory postsynaptic potential (EPSP) is confined to the stimulated pathway and is thus input specific.

►Synaptic Plasticity

## Homotypic Fasciculation

### Definition

The fasciculation, or bundling, of neuronal processes with a common property. Commonly used to refer to the sorting of olfactory sensory neuron axons in the outer nerve layer of the olfactory bulb, where fibers from cells expressing the same olfactory receptor join into bundles for the first time.

►Olfactory Bulb
►Olfactory Nerve
►Olfactory Receptor

## Honey Bee

### Definition

Insect of the order hymenoptera that lives in colonies. The honey bee is a model system for learning and memory.

## Hopfield Model

►Associative Memory

## Hopocretin/Orexin

### Definition

See before.

►Neuroendocrinology of Tumors

## Horizontal Cells

### Definition

One of the lateral interneurons in the vertebrate retina, interacting with photoreceptors and bipolar cells in the outer plexiform layer (synaptic layer).

►Inherited Retinal Degenerations

## Horizontal Fissure (of Cerebellum)

### Synonyms

►Fissura horizontalis (cerebelli)

**Definition**
The horizontal fissure is a large cerebellar groove running transversely across the semilunar lobule. It separates the superior semilunar lobule from the inferior semilunar lobule.

►Cerebellum

## Horizontal-Gaze-Velocity Purkinje Cells

**Definition**
Purkinje cells found in the floccular lobe and in the oculomotor vermis that encode the velocity of horizontal gaze in their discharge

►Cerebellum – Role in Eye Movements
►Purkinje Cell, Neuron

## Horizontal Saccade Generator

**Definition**
►Brainstem Burst Generator

►Saccade, Saccadic Eye Movement

## Hormonal Secretion Regulated by the Autonomic Nerves

**Definition**
Both sympathetic and parasympathetic nerves regulate secretion of some hormones. Hormones secreted in response to stimulation by sympathetic nerves include catecholamines from the adrenal medulla, glucagon from the pancreas and renin from the kidney. Stimulation by sympathetic nerves inhibits insulin secretion from the pancreas. Hormones secreted in response to stimulation by parasympathetic nerves include gastrins from the stomach and insulin from the pancreas.

Secretion of these various hormones can be elicited by either direct stimulation of the central nervous system, or by visceral and somatic afferent stimulation whereby autonomic nerves serve as the efferent limbs of the respective reflex arcs.

►Autonomic regulation of endocrine system
►Parasympathetic Pathways
►Sympathetic Pathways

## Hormone

**Definition**
Molecule that is transported in the blood, reaches a specific target organ, where it binds to specific receptors and may influence metabolism, development, or behavior.

## Horner's Syndrome

**Definition**
Horner's syndrome is characterized by miosis (contracted pupil), anisocoria (difference in pupil sizes on both sides), ptosis (drooping eyelid) and enophthalmos (retraction of eye into its socket) and results from interruption of the oculo-s►ympathetic pathway, the clinical features being classified into central, preganglionic, and postganglionic types according to the anatomic location of the underlying pathologic process.

►Sympathetic Pathways

## Horseradish Peroxidase (HRP)

**Definition**
An enzyme used for tracing connections between different regions of the central nervous system, as well as the structure of cell bodies, dendrites and axons of single neurons. When delivered in small quantities to the extracellular space by iontophoresis or by pressure ejection, it is taken up by synaptic terminals and

H

transported retrogradely to cell bodies. Neurons projecting to the site of injection are made visible by applying a histochemical procedure based on the transfer of oxygen to a chromogene, a substance that changes color on oxidation.

►Microiontophoresis and Micropressure Ejection

## Household Proteins

### Definition

Proteins synthesized inside the cell necessary for upheaval of the cellular functions, structure and integrity.

## HOW-Response Element

### Definition

An RNA nucleotide sequence to which the RNA binding protein HOW binds.

## Hox Gene-related Respiratory Control Disturbance

Jean Champagnat
UPR CNRS 2216 Neurobiologie Génétique et Intégrative, FRC CNRS Institut de Neurobiologie Alfred Fessard, Gif sur Yvette, France

### Synonyms

Breathing abnormalities after altered expression of genes orchestrating rhombomere formation

### Definition

Although an altered gene expression in the brain is a normal component of physiological adaptive responses, such as the acclimatization to altitude, most of our knowledge on mechanisms that may link gene function and breathing patterns result from observations in transgenic mice, in which the respiratory behavior is studied after gene inactivation.

Transgenic models point to a major implication of ►developmental genes essential at all developmental steps from early specifications in the neural tube to the function of respiratory rhythm generators and controllers. During development, the assembly of neural circuits that encode animal behavior, results from several mechanisms contributing to generate distinct neuronal cell types in appropriate number and position. ►Regionalization of the neural tube controls proliferation and specifications of progenitors, until they exit from the cell cycle, at precise location according to antero-posterior and dorso-ventral axis of the neural tube. ►Neurogenesis refers to a variety of processes by which neuronal types differentiate, migrate and form nuclei to eventually produce neuronal populations and their synaptic interconnections. Once activity starts in primordial neurons, neuronal circuitry is refined in a use-dependent manner and the size of neuronal populations depends on the activity of ►neurotrophic factors interacting with apoptotic processes.

In all vertebrates, regionalization of the brainstem (rhombencephalon) along the antero-posterior axis, leads the partitioning of the neuroepithelium into a series of cellular compartments, called rhombomeres (r1-r8) [6]. ►Rhombomeres are polyclonal developmental compartments containing all types of progenitors that are required to produce the large variety of cellular elements forming neuronal circuits and reflex arches at a given level of the neural tube. Strong regulatory constraints couple ►*Hox* gene expression to the progression of hindbrain regionalization. Therefore, the chromosomal organization of ►Hox genes into four clusters is highly conserved in vertebrates. The formation of territories patterned by *Hox* genes is accompanied by a sequential activation of these genes from 3′ to 5′ in the clusters. As a result, early structures are given an anterior identity with 3′*Hox* genes (►anterior group Hox genes) as key determinants, while progressively later structures start expressing more 5′ Hox genes and acquire a more posterior identity. The most 3′ *Hox* genes, *Hoxa1* and *Hoxb1* are expressed up to the rhombomeric r3/r4 boundary and they are directly repressed in r3 by ►Krox20, a ►zinc-finger transcription factor also known as *Egr-2*. The *Krox20/Hox* signaling is required for the proper development of r3, r4 and of the boundary between r3 r4 [2,3,6].

### Characteristics

#### Structures

►Respiratory control refers to the activity of the hindbrain respiratory neuronal network generating and

modulating the breathing behavior. Peripheral sensory receptors such as chemoreceptors in the carotid body or stretch receptors in the lungs initiate the reflex control of this network. Within the hindbrain, central respiratory neuronal groups have been located with the help of electrophysiological studies on hindbrain preparations isolated *ex vivo*. The antero-posterior organization of the mature network conforms to the rhombomeric pattern of embryos [2,3] in register with location of branchio-motor nuclei (the vagal glossopharyngeal deriving from r6-r7, the facial from r4, the trigeminal from r2r3 [6]). Caudally, at the vagal glossopharyngeal level (called "post-otic" because it is caudal to the otic vesicle), the inspiratory rhythm is generated in the ►pre-Bötzinger complex (pre-BötC), and persists in coronal brainstem slices of newborn rodents, isolated *ex vivo* [4,9,10]. Stimulation of the rhythm by CO2 results from the specific responsiveness of different structures, among which the ►retro-trapezoid nucleus [8]. At the facial (pre-otic) level, another rhythm generator, called the **para-facial respiratory group** (pFRG [6 and refs herein]), has been delineated by activity-dependent imaging. In the hindbrain isolated *ex vivo*, permanent rhythm generation requires a balanced interaction between the pFRG and the pre-BötC, which can be disrupted by potent pre-BötC depressants such as opioïds [2,6]. At the trigeminal level, pontine controls of the rhythm include noradrenergic neurons of the A5 group exerting a depressant effect upon the more caudal respiratory groups. The most rostral hindbrain, close to the hindbrain/midbrain boundary contains the **pontine respiratory group** as well as several structures controlling breathing including cholinergic pediculo-pontine tegmental neurons [5,7].

## Processes

### *Pontine Controls of Breathing*

Regionalization of the hindbrain starts at E 7.5 in mice. Retinoic acid (RA) at this stage is known to affect the spread of *Hox* and *Gbx2* expression domains into the anterior hindbrain, followed by a retraction, leaving behind an abnormal gene expression pattern. RA treatment at E7.5 with low (subteratogenic) doses was found convenient in mice to further investigate the importance of this stage for the breathing behavior [5]. This induced pontine abnormalities associated with an hyperpnoeic episodic breathing, a clinical trait widely reported in pre-term neonates, in patients with Joubert syndrome, and in adults (Cheyne-Stokes respiration) with congestive heart failure and brainstem infarction. Respiratory and anatomical anomalies of treated mice resembled several traits reported in the Joubert syndrome, a genetically heterogeneous syndrome, with three known loci, on 9q34.3 (JBTS1), 11p11-q12 (CORS2/JBTS2, and JBTS3, on chromosome 6q23.2-q23.3. Defects might involve the pontine respiratory group [5,7] as well as the cholinergic control of breathing by the pediculo-pontine tegmentum. Impairment of this latter cholinergic control is known to induce an abnormal breathing pattern in adult mice, as seen by homozygous inactivation of the gene encoding the enzyme acetylcholinesterase. In these mice, although the pontine control [7] is altered and the breathing pattern significantly modified, rhythm generation appears normal and no abnormal apneas and lethality were seen in neonates.

### *Parafacial Rhythm Generators: Induction Requires Krox20 and Hoxa1*

Investigation of the respiratory behavior of *Krox20*$^{-/-}$ and *Hoxa1*$^{-/-}$ mutants has established links between the transient rhombomere-related expression of these genes and deletions, neoformations and reconfiguration of the respiratory rhythm generator at the facial level [2,3,6]. Inactivation of *Krox20* and elimination of r4 in *Hoxa1* null mutants lead to neonatal apneas and death due to central respiratory deficits [2,3]. The *Hoxa1*$^{-/-}$ neonates show profound hypoplasia in the ventral pons including the facial branchiomotor nucleus (r4-derived) and of the underlying adjacent area where the pFRG is located. These mutants revealed the "anti-apneic" function of the pFRG at birth. In contrast to *Hoxa1*and *Krox20* null mice, homozygous *kreisler* mice lacking r5, show no life-threatening apneic respiratory patterns, but rather a hypoplasia of the ventral reticular formation causing an abnormal rostral positioning of the (vagal) ambiguus nucleus [3]. Therefore, r4 and r5 greatly differ with respect to their respiratory fates, and lethality in Hoxa1 mutants involves the elimination of parafacial structures originating from r4 rather than from r5. In vivo and *in vitro* analysis show that the caudal medulla including the pre-BötC is not affected by the *Krox20*$^{-/-}$ and *Hoxa1*$^{-/-}$ mutations. These observations are important to understand neonatal apneic syndromes [2,4]. They give insights into the crucial role of *Krox20*/*Hoxa1* on early phenotypic choices that affect parafacial neuronal progeny [3], leaving the pre-BötC functionally active. Therefore, in both *Krox20*$^{-/-}$ and *Hoxa1*$^{-/-}$ mutants, administration of opioïd antagonists to alleviate pre-BötC depression effectively improved survival at birth [2].

### *Central Chemosensitivity in the Retro-Trapezoid Nucleus*

In embryos and neonates, the paired-like ►homeobox transcription factor, Phox2b [8 and refs herein], provide the best documented case of matching gene expression with function in the autonomic reflex arc during development. Mutations of the human homolog PHOX2B have been identified in patients with congenital hypoventilation syndrome, CCHS, a rare

congenital syndrome which is characterized by a decreased sensitivity to hypercapnia and hypoxia, frequently associated with anomalies of the autonomic nervous system.

The majority of Phox2b dependent neuronal precursors, irrespective of their neurotransmitter phenotype, or of any aspect of their cellular phenotype or developmental history, are fated to partake in the medullary reflex circuits of the visceral nervous system. The homozygous inactivation of *Phox2b* affects glossopharyngeal and vagal afferents, the second order neurons of the nucleus tractus solitarius as well as vagal and glossopharyngeal motor nuclei. Recently, one of the central CO2-sensitive structure of the ventral medulla, the retro-trapezoid nucleus has been found to selectively express *Phox2b* thereby identifying a potential site of altered chemosensitivity in *Phox-2b* deficient animal models and human disease [8]. Interestingly, this *Phox2b*-expressing site appears anatomically and developmentally different from the *Krox20*-dependent pFRG oscillator, so that CO2 chemosensitivity of the animal is preserved in $Krox20^{-/-}$ mutants. Altogether, these results suggest that breathing abnormalities in CCHS might result from abnormal chemosensitivity and are probably distinct from neonatal apneas and sudden infant death resulting from the impairment of the pFRG control [2,4,8].

### Control of pre-Bötzinger Complex function

The pre-BötC neural network contains rhythmic neurons connected by glutamatergic synapses, some of them exhibiting pacemaker burst-generating properties [4,9,10]. Embryological experiments confirm that the post-otic territory (r6-r8, caudal to the otic vesicle) from which the pre-BötC develop, is endowed with a selective capacity to generate a respiratory-like rhythm [1]. In these experiments, pre-otic (r3r4), post-otic (r6r8) and spinal segments of the mouse neural tube were isolated and grafted into the same position in stage-matched chick hosts (heterospecific grafting, [1]). Three days later, cranial nerves exiting the graft and the host indicate that the rhythm is generated in post-otic segments, but not in more anterior (pre-otic) and more posterior (spinal) territories. These experiments suggest that a selective developmental program enforcing rhythm generation is already set at end segmental stages in post-otic segments [1]. In adults, the destruction of neurons expressing the NK1 receptor in the pre-BötC leading to ataxic respiration and sleep apneas supports the view that the pre-BötC plays a primary role in respiratory rhythmogenesis in adults [4].

Immunohistochemical, electrophysiological and calcium imaging studies on transverse slices of the brainstem showed that the pre-BötC is anatomically and functionally defined in the mouse embryo at E15 [9]. Recent results provide insights on the possible mechanisms that turn on pre-BötC activity at this stage. Rhythm generation depends on glutamatergic transmission through AMPA/kainate receptors, as in older preparations [9,10]. Glutamate excitatory transmission is dependent on the release from glutamate-filled presynaptic vesicles loaded by three members of the solute carrier family, Slc17a6–8, that function as vesicular transporters (VGLUTs). VGLUT2 (Slc17a6) was found to be required for the function of the respiratory neuronal network [10]. While VGLUT1 is dispensable for life, *Vglut2* null mutant pups die immediately after birth due to complete loss of rhythm generation in the pre-Bötzinger complex. Observations in embryos at the stage when the pre-BötC activity normally emerges shows that in these mutants respiratory rhythm is not turned on, although burst-generating mechanisms and non-glutamatergic transmission are available. The entire set of pre-BötC characteristics being differentiated at E15, functional VGLUT2 glutamatergic synapses underlying neuronal synchronization seems to constitute the rate limiting step for establishment of the pre-BötC as a rhythm generator [4,9,10].

## Conclusion

### The Dual Oscillator Hypothesis

There is emerging evidence that the pre-BötTC and the pFRG are distinct and play a critical role in generating respiratory rhythm [2,4]. Ablation of the pre-BötC in adult rats resulted in a progressive, increasingly sever disruption of the respiratory pattern initially during sleep and then also during wakefulness. Therefore, sleep-disordered breathing and apneas may result from the loss of pre-BötC neurons in elderly humans and patients with neurodegenerative disease [4]. Studies in neonatal $Krox20^{-/-}$ and $Hoxa1^{-/-}$ rodents show that apneas can also be induced by disrupting the development of the pFRG. In an attempt to improve survival, administration of naloxone to block opioid receptors in the pre-BötC definitely suppressed the occurrence of apneas and all animals survived past 18h of age [2]. These observations revealed a post-natal stage of development after which the breathing rhythm looses post-natal irregularity in wild type and apneas are no more detrimental to survival after the elimination of the pFRG in mutants. Therefore, the novel hypothesis on a dual respiratory rhythm generation in restricted sites of the hindbrain [2,4], has important implications in respiratory pathology, with the pFRG playing a major role to prevent sudden infant death while the pre-BötC becomes prevalent with age to alleviate sleep apneas in adults. In summary, on the one hand, neonatal and mature respiratory rhythm generators are likely to play a vital anti-apneic role to control respiratory frequency [2,3,4,9,10]. On the other hand, mutations of the respiratory neuronal network outside these

rhythm generators, for example in the Pons, may cause significant respiratory abnormalities, although frequency and apneas are not dramatically affected [5,7].

## Hox Genes

### Definition

Hox genes are genes that encode a class of DNA binding proteins that regulate DNA transcription, which contain an essentially invariant short sequence of nucleotides called the homeobox.

►Homeotic Genes/Hox Genes

## H-reflex (Hoffmann Reflex)

### Definition

An H-reflex (also called a "Hoffmann reflex") is the earliest response of a muscle to stimulation of large afferent fibers in the muscle nerve. If the nerve stimulation also excites large efferent fibers, the H-reflex is typically preceded by an M wave (or M response), which reflects excitation of the muscle by these efferents. An H-reflex and the preceding M wave are usually detected and measured electromyographically.

An H-reflex is produced by an entirely spinal pathway consisting mainly of group Ia afferents from the muscle spindles, their excitatory synapses on the muscle's motoneurons, and the motoneurons. Oligosynaptic (i.e., di- and tri-synaptic) excitatory and/or inhibitory inputs to the motoneurons from group I or II afferents may also contribute. Because it is largely monosynaptic, the latency of an H-reflex depends mainly on the lengths and conduction velocities of the afferent and efferent axons in the peripheral nerve. The H-reflex is often considered to be the electrical analog of the "tendon reflex," since it involves the same afferents and spinal pathways and is elicited by direct stimulation of the nerve rather than by muscle stretch.

At the same time, it may differ from the tendon reflex in the contributions of different group I and large group II afferents, in the relative importance of monosynaptic and disynaptic inputs to the motoneurons, and in the synchrony of these inputs.

## Human Circadian Timing System

Michel A. Hofman
Netherlands Institute for Neuroscience, Amsterdam, The Netherlands

### The Biological Clock in Mammals

Many organisms experience oscillations in biological processes within a period of around 24 h. These circadian rhythms (circa = around; dies = day) enable organisms to anticipate periodic changes in the environment and are consequently important adaptive

mechanisms. In mammals, these circadian cycles are regulated by an endogenous clock, the central component of which resides in the ►suprachiasmatic nucleus (SCN) of the hypothalamus [1]. The pacemaker of the SCN oscillates with a near 24-h period and is entrained to the daily light-dark cycle. Destruction of the SCN results in the complete absence of a regular sleep/wake rhythm. Consistent with its role in circadian timing, investigations in rodents and non-human primates furthermore suggest that the SCN is the locus of the brain's endogenous calendar, enabling organisms to anticipate seasonal environmental changes [3].

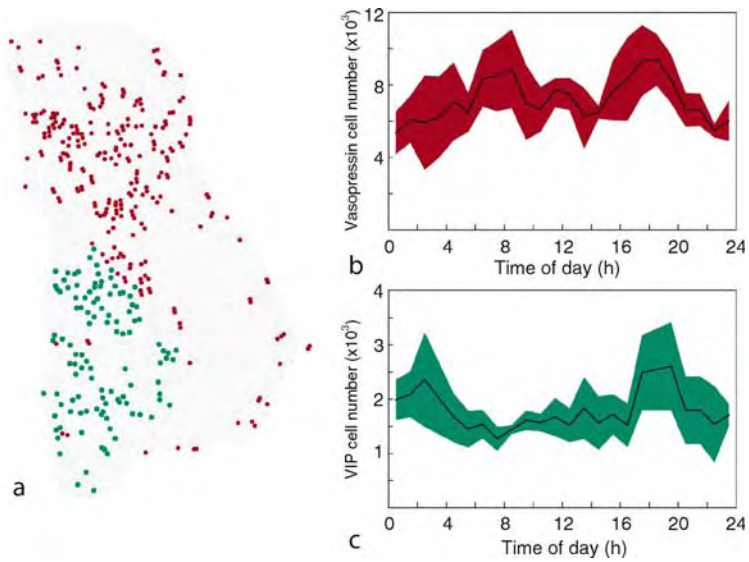
## Organization of the Human SCN

### Neural Organization

The human SCN is a distinct group of neurons in the basal part of the anterior hypothalamus, just dorsal to the optic chiasm on either side of the third ventricle. The bilateral SCN in humans is about 1 $mm^3$ in volume and contains close to 100,000 neurons in total [5,9]. Based on differences in morphology, afferent inputs and output projections, the SCN can be divided into a dorsomedial part or shell and a ventrolateral part or core (Fig. 1). The core receives primary and secondary visual afferents and predominantly contains neurons producing vasoactive intestinal polypeptide (VIP), gastrin-releasing peptide, neurotensin, neuropeptide-Y, substance-P and calbindin. The shell largely surrounds the core and receives input mainly from nonphotic sources and is composed predominantly of neurons containing arginine-vasopressin (AVP). Many neurons in both regions of the SCN contain γ-aminobutyric acid (GABA). A similar topographic organization of SCN efferent projections was found, indicating that the nature of the signal conveyed to areas receiving core or shell projections varies as a function of the subdivision from which the innervation is derived.

### Molecular Organization

Circadian clocks arise from the expression and temporally regulated activity of specific genes and gene products. Individual SCN neurons express self-sustained circadian oscillations driven by autoregulatory transcription-translation feedback loops [1]. The period of this process is approximately 24 h, giving rise to the ►circadian rhythm. At least six genes have now been identified as putative components of the mammalian clock: *Per1, Per2, Cry1, Cry2, Clock* and *Bmal1*. Additional genes potentially involved in output pathways from and input pathways to the circadian clock have been identified. Oscillations of mRNA transcripts of these ►clock genes have been an important element of the study of biological clocks. These clock genes are expressed in a circadian manner, with peak values at different times. Expression profiles for a specific gene may also differ among subdivisions of the SCN. Similar



**Human Circadian Timing System. Figure 1** (a) Distribution of vasopressin (AVP) (*red dots*) and vasoactive intestinal polypeptide (VIP) (*green dots*) neurons in the human suprachiasmatic nucleus (SCN). Note that the populations of AVP and VIP neurons are located in the shell and core of the SCN, respectively. (b) Circadian cycle of the AVP-expressing neurons and (c) the VIP-expressing neurons in the human SCN. The original data sets were subjected to a simple scatterplot smoothing procedure and are represented by mean ± SEM values. Note that both cycles have an asymmetrical, bimodal waveform and that the ►neuropeptides do not reach their peaks and troughs at exactly the same time of the 24-h light-dark cycle. Reproduced from [2], with permission.

phase differences that are observed at the molecular level exist at the level of electrical activity rhythms in the SCN.

### Functional Organization

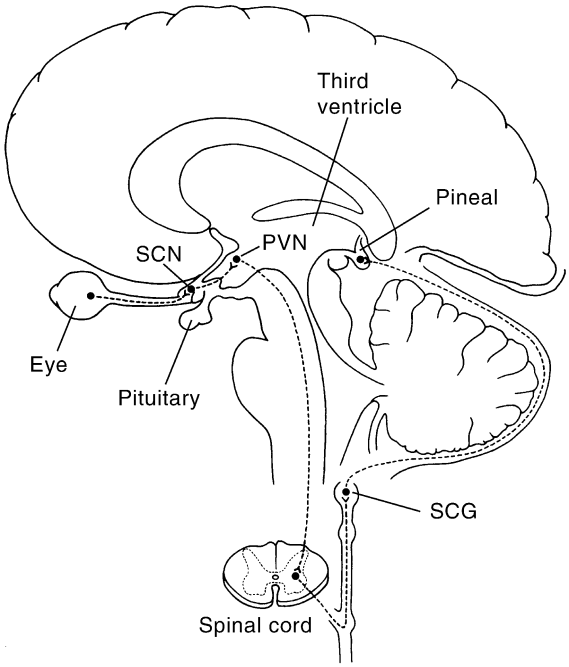
Classically, the expression of circadian rhythms is thought to have three fundamental components: input pathways that transmit environmental cues to the circadian clock, the clock itself, which generates and coordinates the biological rhythm(s), and output pathways that transmit the clock's information regarding phase and periodicity to the rest of the brain and body [6,7]. The biological clock is synchronized to the environmental light-dark cycle by photic information from the retina to the SCN via the retino-hypothalamic tract (RHT) and via the intergeniculate leaflet of the lateral geniculate complex via the geniculo-hypothalamic tract (GHT). These afferent fibers predominantly terminate in the ventral part of the SCN, where they make synaptic contacts with VIP neurons. The VIP subdivision of the SCN is therefore thought to play a prominent role in the mediation of photic information to the circadian timing system.

In the past decade, several studies have been conducted to determine whether variations in light intensity and photoperiod affect the morphology and neuronal activity of the mammalian SCN, by studying brains obtained at autopsy [2,3,5]. The AVP- and VIP-expressing neurons in the human SCN, for example, were found to exhibit distinct circadian rhythms with an asymmetrical, bimodal waveform (Fig. 1). The AVP cycle has a peak in the early morning, a lower plateau during the day, a second peak in the late afternoon, and a decline beginning in the early evening, leading to a nadir around midnight. The VIP cycle shows a peak in the middle of the night, a lower plateau beginning in the late night lasting for about 12 h, and a second peak in the late afternoon, followed by a sharp decline in the early evening. The demonstration of two significantly different, but temporally linked, output profiles suggest that the SCN contains more than one oscillator.

## The SCN-Pineal Complex

### Circadian Timing

The ►pineal gland is a central structure in the circadian timing system and the major source of the hormone ►melatonin [8]. The pineal is innervated by a neural multi-synaptic pathway originating in the SCN (Fig. 2). Disruption of any portion of this pathway from the SCN to the pineal gland abolishes melatonin rhythmicity. In all species studied to date, there is a day/night variation in pineal melatonin production, with peak concentrations occurring during the dark phase [4]. The circadian clock and its output rhythms are synchronized to the 24 h light/dark cycle by ocular light which is transmitted from the retina primarily via the retinohypothalamic tract (RHT) to the SCN. Although functions of this hormone in humans are mainly based on correlative observations, there is some evidence that melatonin stabilizes and strengthens coupling of circadian rhythms, especially of core temperature and sleep-wake rhythms [10].



**Human Circadian Timing System. Figure 2** Diagram of the human brain (mid-sagittal section) showing the neural pathways of the circadian timing system by which photic information reaches the SCN and the pineal gland. *SCN* suprachiasmatic nucleus; *PVN* paraventricular nucleus; *SCG* superior cervical ganglion. Reproduced from [4], with permission.

### Seasonal Timing

In recent years it has also become clear that in mammals the SCN and the pineal gland are the principal neural structures involved in the regulation of annual cycles [3,4]. In fact, many of the functions that exhibit seasonal cycles in mammals, such as sexual behavior, energy metabolism, food intake, and hibernation, are regulated by this timing system in the brain. Photoperiodic information has been shown to be the strongest synchronizer of seasonal functions in most species. These findings strongly suggest that the endocrine activity of the mammalian pineal is under neural control, and receives a major input from the SCN. This means that in addition to its role as a circadian pacemaker, the SCN may also be involved in the seasonal timing of a number of physiological and behavioral processes by regulation of the photoperiod-dependent changes in melatonin secretion.

## Circadian Clock and Aging

### Suprachiasmatic Nucleus and Aging

With advancing age the circadian timing system is progressively disturbed, both in humans and other mammals, as is clearly demonstrated by a reduced amplitude and period length of circadian rhythms and an increased tendency towards internal desynchronization [5,10]. In humans, age-related changes have been described for hormonal rhythms, body core temperature, sleep-wakefulness, and several other behavioral cycles. A reduction in the amplitude of the circadian sleep-wake cycle was found in long-term registrations of activity patterns in young and elderly men, and even more so in patients with Alzheimer's disease (AD). It appears that aging not only affects the amplitude but also the frequency of circadian rhythms, particularly in dementia. The increase in time spent in both wakefulness during the night and daytime naps, a characteristic pattern in many elderly people, is a symptom of disruption of circadian sleep rhythms similar to the one found following experimental SCN lesions. In fact, disorders of the circadian timing system during aging may first be manifested as sleep-wake pathologies [10].

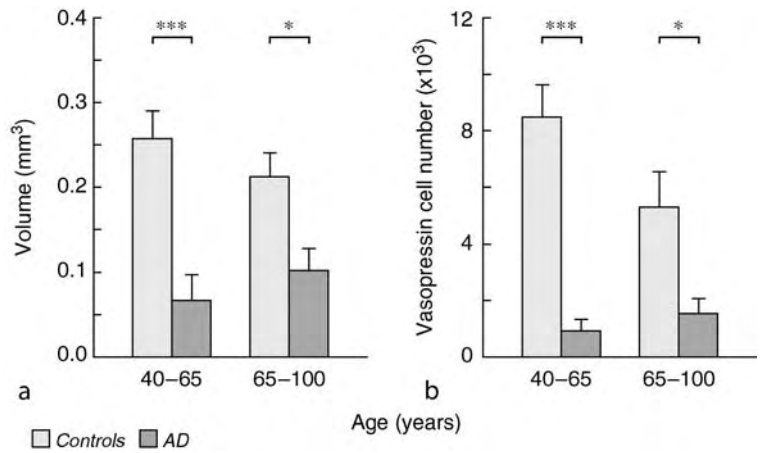
The many lines of evidence of age-related decrements in circadian time-keeping in human beings and the observed neuronal degeneration of the SCN in senescence and Alzheimer patients strongly suggest an organic deterioration of the circadian oscillator. The disruption of circadian rhythms and the increased incidence of disturbed sleep in humans during aging are paralleled by age-related alterations in the neural organization of the SCN, a decreased photic input to the clock, and, in the SCN of demented patients, also with a dramatic decrease in peptide synthesis (Fig. 3).

The immunocytochemical data showing decreased activity of the SCN in Alzheimer's disease have been confirmed by *in situ* hybridization [9]. The total amount of AVP mRNA in the SCN of AD patients was three times lower than in age- and sex-matched controls. In addition, the AVP mRNA-expressing neurons in the SCN showed a marked day–night difference in controls under 80 years of age. The amount of AVP mRNA was more than three times higher during the day than at night, whereas no clear diurnal rhythm of AVP mRNA was observed in AD patients. These data support the idea that damage to the SCN is the underlying anatomical substrate for the clinically often-observed disturbances in circadian rhythmicity in Alzheimer's disease.

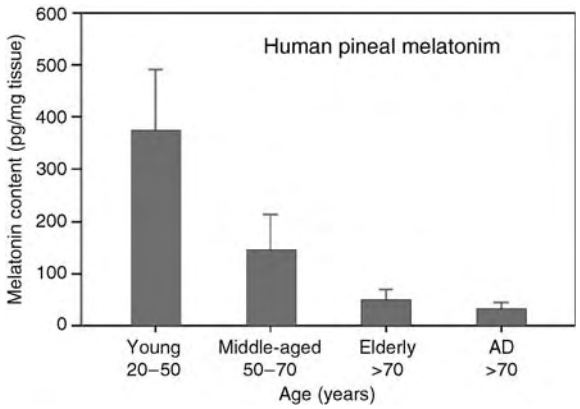
Immunocytochemical studies, furthermore, provide evidence that degenerative alterations in the human SCN occur at a later phase in life than the reported functional changes in circadian organization [5]. More frequent and prolonged awakenings and shorter sleep periods have already been found in 50- to 60-year-old subjects, whereas a reduction in SCN volume and number of AVP-expressing neurons are only present from the age of 80 years onwards. Thus, the observed loss of AVP-expressing neurons in the SCN of very old people may only be a relatively late correlate of functional changes in the biological clock appearing much earlier.

### Pineal Melatonin and Aging

Reduced melatonin concentrations during aging, especially nocturnal levels, have been reported in plasma,



**Human Circadian Timing System. Figure 3** Effect of aging and ►Alzheimer's disease (AD) on the human suprachiasmatic nucleus (SCN). In Alzheimer patients, both presenile (<65 years of age) and senile (>65 years of age), the volume of the SCN (a) and the number of arginine vasopressin (AVP)-expressing neurons in the SCN (b) are significantly decreased compared to age-matched controls. Note that in presenile Alzheimer patients the number of AVP-expressing neurons is only 10% of that of controls of comparable age. Reproduced from [9], with permission.



**Human Circadian Timing System. Figure 4** Effect of aging and Alzheimer's disease (AD) on the night-time melatonin level in the human pineal gland. Note the dramatic decline of the nocturnal melatonin production in middle-aged subjects compared to that of young subjects and the further decline after the age of 70 years.

cerebro-spinal fluid (CSF) and in urine [8,10]. Studies of the major urinary metabolite of melatonin, 6-sulfatoxymelatonin show that age related decrease in melatonin production occurs even as early as 20–30 years of age. A decline of the nocturnal serum melatonin peak was only significant at the age of 60 and further declined from 70 years of age onwards. Even within a fairly narrow age range (40–69 years) a significant effect of age was found on the daily excretion of urinary 6-sulfatoxymelatonin in 160 women.

Melatonin content in the human pineal has also been found to be reduced with age (Fig. 4). Besides the age-related decline of melatonin production, age-related changes in the timing of the melatonin rhythm have also been reported. Moreover, older subjects enter sleep and awake earlier relative to their nightly melatonin secretory episode, which indicates that aging is also associated with a change in the internal phase relationship between the sleep–wake cycle and the output of the circadian pacemaker. These findings suggest that degeneration of the SCN-pineal complex could well be the neural substrate for the disrupted circadian rhythms, which have been reported in elderly subjects, demented patients and in depression.

In patients who lack serum melatonin rhythms, clinical symptoms of delirium and sleep-wake disturbance were frequently but not always found. In AD patients with disturbed sleep-wake rhythms a higher degree of irregularities in melatonin secretion have been observed. The finding that the daily variations in pineal melatonin and 5-methoxytryptophol content disappeared in AD patients may be linked with the clinical observations of sleep disorders and sundowning in these patients [10].

In conclusion, the age-related functional changes in circadian organization in humans may be associated with subtle degenerative alterations in the SCN and other parts of the clock, leading to disruptions of the circadian system. Recent studies suggest that this may happen relatively early in life, well before any dramatic neuronal atrophy of the biological clock becomes manifest.

### Definition

Humoral Immunity denotes that aspect of immunity that is mediated by secreted antibodies, produced in the cells of the B lymphocyte lineage or plasma cells (B cells).

## Huntington's Disease (HD)

### Definition

Autosomal dominant, progressive neurodegenerative disorder caused by degeneration of cells in the brain, particularly in a specific pathway of the ►striatum, due to a mutant protein called huntingtin. Its main symptoms are ►chorea and ►dystonia, dis-coordination, later followed by ►athetosis, dementia and behavioral problems. Although the symptoms can become manifest at any time, their onset is often in middle age. The precise pathophysiological mechanisms are not yet well understood. In animal models, signs of Huntington's disease can be reproduced by excitatoxic cell death within the striatum induced by ibotenic and quinolinic acid, most successfully in association with ►dopamine agonists. The striatal ►GABA/►enkephalin neurons giving rise to the 'indirect pathway' perish at an early stage. According to the traditional model of HD, this would result in increased activity of neurons in ►globus pallidus externus (►GPe) and, hence, increased inhibition of the ►subthalamic nucleus (►STN), ►globus pallidus internus (►GPi) and ►substantia nigra pars reticularis (SNr), which would release the ►thalamus and subsequently the ►cerebral cortex from inhibition, giving rise to choreiform movement disorders similar to those often seen in ►hemiballism. Drug-induced dyskinesias may result from similar reductions of activity in STN and GPi. At later stages of HD, the striatal neurons containing GABA and ►substance.

► P may be affected as well, resulting in ►rigidity and ►akinetic symptoms. Huntington patients suffer from a number of psychic disorders, which need not go in parallel with the somatic symptoms. Disorders of affect, motivation and cognition are frequent, also hallucinations. The above model for hyperkinetic disorders has some problems. First, GPe lesions do not appear to reduce drug-induced dyskinesias. Second, if reduction in ►basal ganglia output alone were responsible, further reduction by lesions of the GPi/SNr should worsen the dyskinesias. However, ►pallidotomy ameliorates hemiballism, drug-induced dyskinesias and dystonia, and hyperkinetic disorders can be treated with ►thalamotomy. There must thus be explanations beyond the simple average-firing-rate model.

►Athetosis
►Basal Ganglia
►Chorea
►Dystonia

## Hybrots

►Computer-Neural Hybrids

## Hydrencepalus

### Definition

Infant born without a forebrain, but still able to suckle, smile, cry, move eyes, arms and legs similar to normal newborns.

## Hydrocephalus

### Definition

"Waterhead" resulting from accumulation of ►cerebrospinal fluid in the cerebral ventricles (hydrocephalus internus) or at the brain's surface below the subarachnoidal space (hydrocephalus externus). When the circulation or absorption of cerebrospinal fluid is blocked, or excessive fluid is produced, the volume of fluid in the brain becomes higher than normal. The accumulation of fluid puts pressure on the brain, forcing it against the skull and damaging or destroying the tissues. The symptoms vary depending on the cause of the obstruction, the person's age when the problem develops, and the extent of brain tissue damage caused by the swelling.

►Cerebrospinal Fluid (CSF)

## Hydropathy

### Definition

The hydrophilicity or water solubility characteristics of a short sequence of amino acids within a protein. For membrane proteins, the variations in hydropathy in the amino acid sequence are used to predict those parts of the protein that will lie within the membrane bilayer itself (which is composed of oil-like hydrophobic domains) and those that will interact with the aqueous solutions on either side of the membrane bilayer. For example, a leucine or valine-rich sequence would tend to form transmembrane structures, whereas sequences enriched in charged residues (e.g. aspartate, glutamate, lysine, etc.) will tend to project into the aqueous solutions on either side of the membrane. Such predictions are made using computer programs that incorporate empirically determined hydropathy values (e.g. the Hopp and Woods, or Kyte and Doolittle indices).

# Hyperalgesia and Allodynia

Fernando Cervero
Anesthesia Research Unit (Faculty of Medicine), Faculty of Dentistry and McGill Centre for Research on Pain, McGill University, QC, Canada

## Synonyms

Pain hypersensitivity; Touch-evoked pain; Increased sensitivity to pain

## Definition

The following are the definitions proposed by the International Association for the Study of Pain (IASP):

- ►Hyperalgesia: An increased response to a stimulus which is normally painful.
- ►Allodynia: Pain due to a stimulus which does not normally provoke pain.

## Characteristics

### The Dynamics of Pain Sensation: Pain and Hyperalgesia

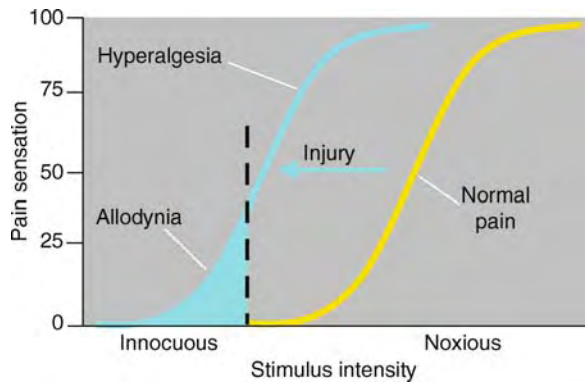
Pain is a normal sensation that protects us from impending damage and helps us to heal once the damage is done. Like all other sensations pain has a sensory threshold and an encoding range (Fig. 1), but unlike most other sensations the stimuli that cause pain are not defined by the appropriate form of energy (mechanical, chemical, photic, thermal), but by their ability to cause pain. Stimuli that do not evoke pain are called innocuous and those that evoke pain are called noxious, regardless of their type of energy. Another unique property of pain is that the application of a prolonged and constant noxious stimulus does not lead to sensory adaptation – as is the case with all the other sensations – but, on the contrary, to sensory enhancement. Therefore, a prolonged noxious stimulus shifts the psychophysical curve of pain not towards the right – which would produce a higher threshold and reduced responses – but towards the left, thus resulting in a lowering of the pain threshold and the generation of enhanced pain sensitivity known as hyperalgesia (Fig. 1).

Under laboratory conditions it is possible to generate hyperalgesic sensations by the application of a stimulus of constant intensity that activates peripheral ►nociceptors [2]. In real life, hyperalgesia is a direct consequence of tissue injury and inflammation and the component of the normal sensory repertoire that demonstrates the dynamic nature of pain sensation. Hyperalgesic sensations can also appear in the absence of tissue injury or inflammation when there is a dysfunction of the peripheral or the central nervous system. In this case hyperalgesic sensations are abnormal and an expression of a pathological sensory process known as ►neuropathic pain [►see Neuropathic pain essay and ►Central pain]. However, in all cases, normal or abnormal, the most significant sensory aspects of a hyperalgesic state are the enhancement of pain sensitivity and the lowering of the pain threshold.

### The Taxonomy of Hyperalgesia

There is some confusion as to the precise meaning of the word hyperalgesia and of its related terms. The expression hyperalgesia is often used to qualify all aspects of enhanced sensitivity to pain and therefore we talk about "hyperalgesic states," meaning "pain hypersensitivity states," in very general terms. However, the International Association for the Study of Pain (IASP) has restricted the meaning of the word hyperalgesia to an increased sensitivity to stimuli that are normally painful and has proposed the word "allodynia" to describe those pain sensations that are caused by stimuli that are normally not painful, such as the pain evoked by light touch of sunburned skin [3]. In this way, hyperalgesia defines augmented pain sensitivity and allodynia a change in the quality of the sensations evoked by normally non-painful stimuli (see Fig. 1). The key difference is whether the originating stimulus is normally painful (hyperalgesia) or normally non-painful (allodynia).

Before the IASP proposed this taxonomy and coined the new word allodynia, all forms of increased sensitivity to pain were known as hyperalgesia. From these earlier times comes a subdivision of hyperalgesia that not only has survived to our days, but has also



**Hyperalgesia and Allodynia. Figure 1** Diagram that represents the changes in pain sensation induced by injury and the psychophysical definitions of hyperalgesia and allodynia. The normal relationship between stimulus intensity and pain sensation is represented by the yellow curve. The vertical dotted line indicates the normal pain threshold. Injury provokes a leftward shift in the curve as a consequence of which innocuous stimuli can evoke pain (allodynia) and stimuli that normally evoke pain produced increased pain sensations (hyperalgesia). From [1].

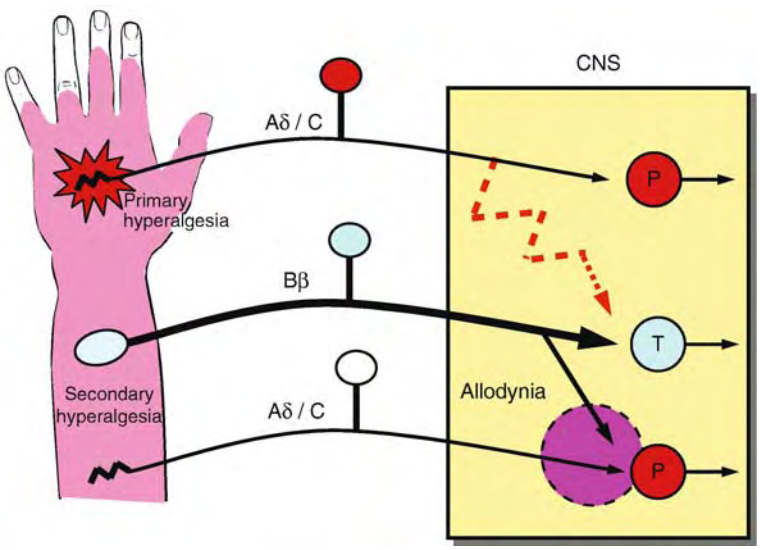
provided the contemporary basis for a mechanism-based distinction between different hyperalgesic states. Hardy and colleagues [4] carried out extensive psychophysical studies (psychophysics) in human volunteers and concluded that there were two kinds of hyperalgesia: primary and secondary. Primary hyperalgesia is an increased sensitivity to pain at the site of injury and secondary hyperalgesia is an increased sensitivity to pain at locations adjacent or even remote from the site of injury. For instance a burn to the hand will produce not only an enhanced pain sensitivity of the hand (primary hyperalgesia), but also increased tenderness and pain sensitivity of large portions of the forearm or even the arm (secondary hyperalgesia). When the primary lesion is in an internal organ, the area of secondary hyperalgesia may be remote, like the enhanced pain sensitivity of the left arm during cardiac ischemia. In these cases, secondary hyperalgesia is called referred hyperalgesia.

The distinction between primary and secondary hyperalgesia is not just based on location of the sensation. There is also an important mechanistic component to this division based on the facts that primary hyperalgesia is due to peripheral alterations of the sensory endings at the site of injury or inflammation and secondary hyperalgesia is the result of a change in the sensory processing by the central nervous system of afferent signals from an otherwise normal periphery.

## Mechanisms of Primary Hyperalgesia: Nociceptor Sensitization

It has been known for a long time that the functional properties of peripheral ►nociceptors change following injury or inflammation of the territory that they innervate [5]. This property, known as ►sensitization, results in nociceptors becoming more excitable to subsequent stimulation following a period of intense activation. Their threshold is lowered and their responses are enhanced, showing a characteristic leftward shift in their stimulus-response function that matches the leftward shift of behavioral hyperalgesia. In some cases, injury or inflammation can bring into action populations of nociceptors that were previously unresponsive (the so-called "silent" nociceptors). This is regarded as an extreme form of nociceptor sensitization.

Sensitization of nociceptors is believed to be the mechanism responsible for primary hyperalgesia (Fig. 2). The process of sensitization is not fully understood, but it involves the release of inflammatory mediators and tissue factors from the nociceptor terminals themselves or adjacent cells – such as mast cells – by the originating injury or inflammatory process. The consequence of nociceptor hyperexcitability at the injury site is a lowering of the pain threshold and an enhancement of pain responses evoked from the injured area, that is, primary hyperalgesia.

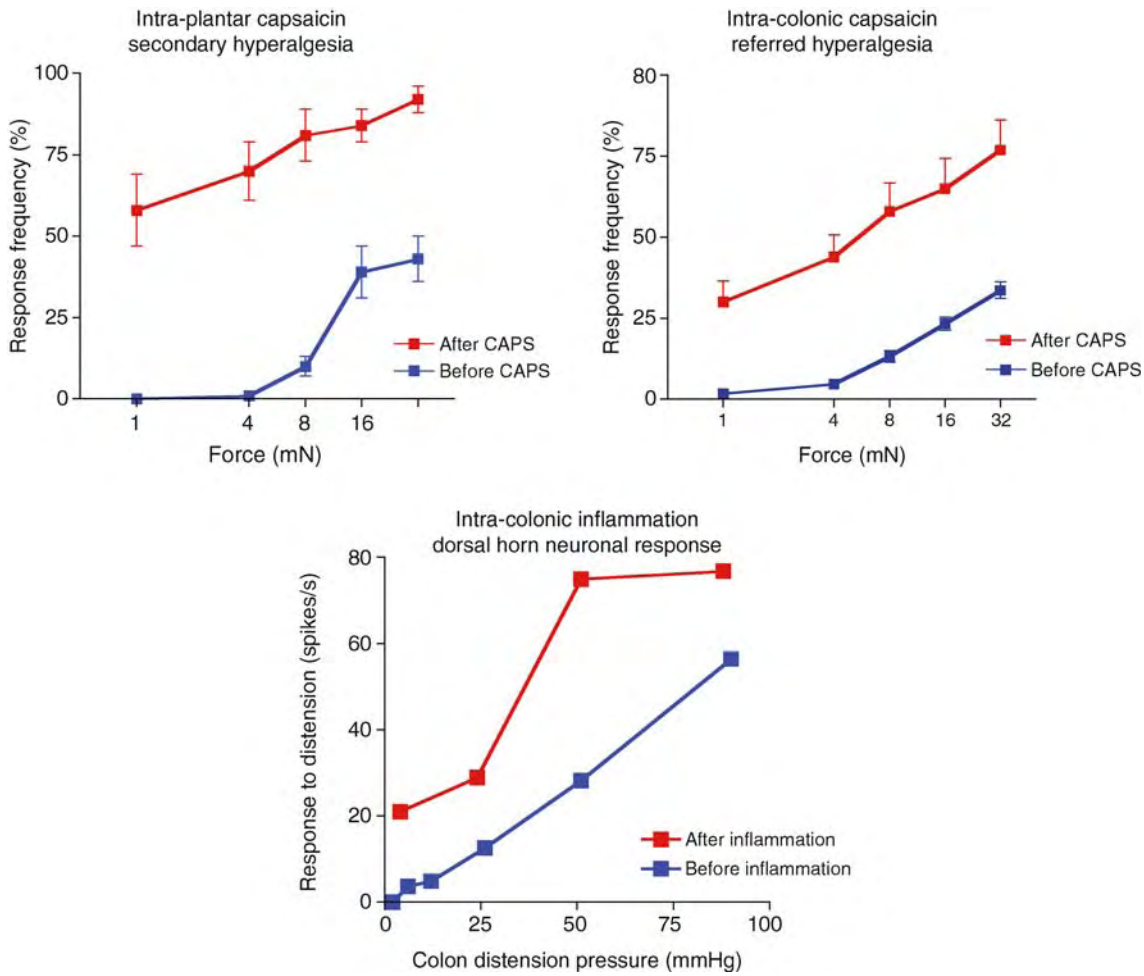


**Hyperalgesia and Allodynia. Figure 2** Diagram representing the basic neural organization of the peripheral and central mechanisms of primary and secondary hyperalgesia. The diagram shows the afferent input to the spinal cord (Aβ, Aδ and C fibers) and their projection to spinal cord nociceptive (P) and tactile (T) neurons. Primary hyperalgesia (red star) is due to the sensitization of peripheral nociceptors by injury. Secondary hyperalgesia (pink area) is caused by a central alteration in the processing of the tactile and nociceptive inputs. This alteration is induced by the increased afferent barrage form sensitized nociceptors (indicated by the dotted-line red arrow).

## Mechanisms of Secondary Hyperalgesia: Central Sensitization

The fact that secondary hyperalgesia is felt in areas of the body distinct, or even remote, from the actual site of injury indicates that this form of hyperalgesia is more likely to be mediated by a central nervous system mechanism than by a peripheral alteration. We now know that the impulses generated in nociceptors at the site of injury or inflammation evoke central changes that in turn produce secondary hyperalgesia [7,8]. These changes are triggered by the impulses arriving from nociceptors at the injury site and maintained by the enhanced spontaneous activity of these nociceptors due to their sensitization (Fig. 2). This process has been called "central sensitization" by analogy to the peripheral sensitization observed at the site of injury, and involves an increase in the excitability of second order neurons in the spinal cord and supraspinal nuclei and a switch in the sensory consequences of the activation of low threshold afferent fibers from touch to pain.

There is considerable evidence showing that intense or persistent activity in peripheral nociceptors leads to increases in responsiveness of dorsal horn neurons (see references in [1]). This enhancement of the excitability of spinal cord neurons matches the characteristic leftward shift of the pain curve observed in human and experimental animals in areas of secondary hyperalgesia (see Fig. 3) and it is conceivable that one



**Hyperalgesia and Allodynia. Figure 3** Three graphs with original data showing the characteristic leftward shifts that underlie hyperalgesic states. The two graphs at the top are from behavioral studies in awake mice in which the mechanical sensitivity of an area remote to the test site was tested before (blue curves) and after (red curves) the intradermal injection of capsaicin (left curve, test site adjacent to the paw) or the intracolonic installation of capsaicin (right graph, test site in the abdominal wall). The bottom graph is from an electrophysiological study in an anaesthetized rat in which the responses of a dorsal horn neurone to colonic distension were recorded before (blue curve) and after (red curve) inflaming the colon by instillation of acetic acid. Data from the author's laboratory.

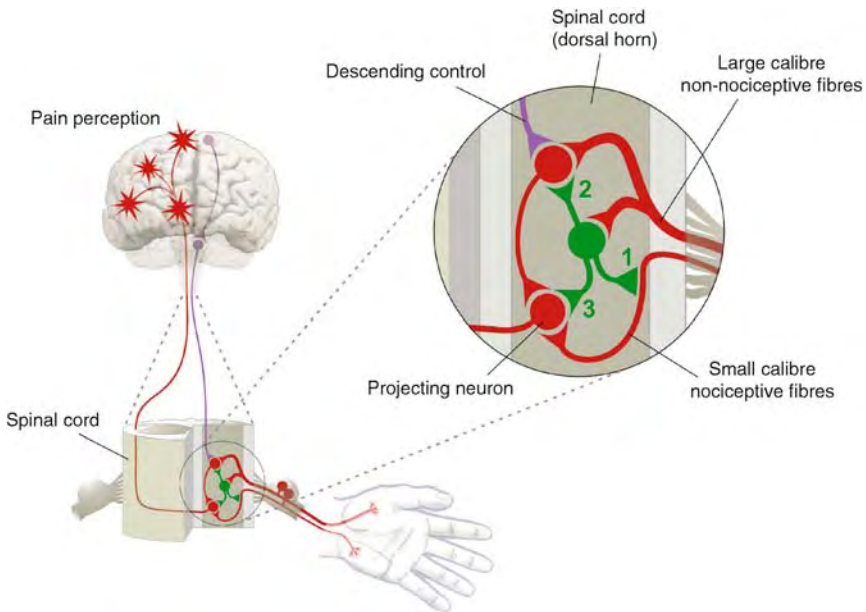
process leads to the other. Therefore, the idea of a central sensitization process has been widely accepted as a possible neural mechanism for the generation of hyperalgesic states.

Many molecular candidates have been put forward as mediators of central sensitization, including neurotransmitters such as glutamate and neuropeptides such as Substance P. However, there are also many aspects of this process that remain unknown, including the link between the increase in excitability observed in spinal cord neurons following a noxious stimulus and the specific sensory changes observed in secondary hyperalgesic states. Moreover, the precise meaning of "central sensitization" is not clear, as this expression has been used to qualify most forms of increased excitability in central neurons or of enhanced pain responsiveness in humans and experimental animals. The cellular processes that underlie these changes in excitability are due to alterations of synaptic excitability identical to those of ►Long term potentiation ([9]; also see ►Synaptic long-term potentiation (LTP) in pain pathways), which is also observed in other regions of the nervous system unrelated to pain processing. It is possible that "central sensitization" is an expression of synaptic plasticity in the central nervous system rather than a specifically pain-related phenomenon.

## Mechanisms of Allodynia: Touch-Evoked Pain

The characteristic features of secondary hyperalgesia include not only an increase in the magnitude of the pain sensations evoked from this zone, but also a change in the modality of the sensation evoked by ►low threshold mechanoreceptors from touch to pain [2,7]. This process is known as touch-evoked pain or tactile allodynia. In areas of secondary hyperalgesia, touch-evoked pain is mediated by impulses in low-threshold mechanoreceptors connected to large myelinated afferent fibers. This shows that pain can be produced in normal individuals by the activation of low-threshold mechanoreceptors, albeit under the special circumstances of having sustained a previous injury. Touch-evoked pain can appear very shortly after the activation of nociceptors from the primary area and can also disappear very quickly if the activity of these nociceptors is reduced or blocked. The process is dynamic, reversible and not dependent on the formation of new anatomical connections between the tactile and the nociceptive systems.

Whereas the increased sensitivity to pain in areas of secondary hyperalgesia could be explained by an enhanced excitability of the nociceptive system (see Fig. 3), the switch from touch to pain in the central actions of low-threshold mechanoreceptors requires



**Hyperalgesia and Allodynia. Figure 4** Spinal cord mechanisms that can cause hyperalgesia by facilitating low threshold input to nociceptive neurons. The enlarged diagram on the right illustrates three potential mechanisms by which input from large afferents may be conveyed to nociceptive neurons causing allodynia. (i) Exaggerated Primary Afferent Depolarization that can reach firing threshold and produce action potentials in the nociceptive afferent terminal evoked by impulses in the low threshold afferent; (ii) Disinhibition of polysynaptic pathways to nociceptive neurons that can unmask subliminal input to these neurons from low threshold afferents and (iii) Direct relay of low threshold input to nociceptive neurons via a reversal of the action of GABA/glycine such that low threshold afferents that would normally cause inhibition of the relay cell can now cause an excitation of this neuron. From [6].

alternative explanations. Several hypotheses have been put forward to address this remarkable switch and some are illustrated in Fig. 4. All of them are based on the reversal of the actions of the inhibitory neurotransmitters GABA and glycine such that they become excitatory and facilitate the low threshold input to nociceptive neurons [6].

One proposed mechanisms is based on the ►Primary afferent depolarization of the terminals of nociceptive afferents induced by activity in low threshold sensory fibers. This is known to be mediated by a GABA-ergic current that is normally depolarizing because of the higher than normal concentration of chloride ions in primary afferent terminals. If these depolarizations were intense enough to evoke action potentials, this would provide an excitatory pathway for low threshold sensory fibers to activate nociceptive afferents and therefore the nociceptive pathway.

Another proposed mechanism is based on disinhibition of a polysynaptic pathway from low threshold afferents to nociceptive neurons. Under normal conditions these pathways are inhibited by local GABA-ergic interneurons, but release of this inhibition can unmask existing low threshold afferent input to the nociceptive system.

Finally, a mechanism has also been proposed based on the complete reversal of the actions of GABA or glycine on spinal cord neurons from inhibition to excitation [10]. This would be made possible by an increase in the intracellular concentration of chloride ions in these neurons produced by an inhibition of the co-transporter responsible for reducing internal chloride. Under these circumstances, GABA and glycine become excitatory by inducing cell depolarizations rather than hyperpolarizations and the normally inhibitory actions of low threshold afferents on nociceptive neurons become excitatory.

# Hyperbaric Oxygen Treatment

## Definition

Treatment by 100% oxygen under increased pressure. Normal atmospheric pressure is defined as 1 atmosphere (1 ATA). Hyperbaric oxygen is supplied usually at a pressure of 2 ATA or more.

# Hypercoagulable State

## Definition

The propensity to develop blood clots due to an abnormality in the coagulation system.

The main tests for hypercoagulable states include prothrombin time and INR, partial thromboplastin time, thrombin time, fibrinogen levels, antiphospholipid antibody levels, protein C, protein S and antithrombin III, APC (activated protein C) resistance, factor V Leiden and prothrombin mutation. Other than persistent abnormalities of antiphospholipid antibodies, all these other problems are almost exclusively associated with an increased risk of venous, not arterial, thrombosis.

►Stroke

# Hyperelasticity

## Definition

A material model of an elastic body for which the elastic constitutive function for the stress tensor can be

obtained as the derivative of a single scalar function of the deformation gradient. This scalar function is sometimes called the strain-energy function or the stored energy function.

►Mechanics

## Hypergeusia

### Definition

Hypergeusia is used to describe the abnormal enhancement of the sense of taste, also referred to as gustatory hyperesthesia. Hypergeusia may occur in a generalized form or be specific to a single or limited number of tastants.

►Gustation

## Hyperkalemic Periodic Paralysis

### Definition

Autosomal dominant disease of early onset, resulting from a point mutation of the skeletal muscle ►$Na^+$ channel (Nav1.4) gene on chromosome 17 and characterized by periodic attacks of flaccid muscle weakness and areflexia (loss of tendon reflexes), and intermittent ►myotonia, although (despite its name) not necessarily associated with hyperkalemia during the attacks, while $K^+$ administration may typically provoke attacks of muscle weakness. In some patients, muscle weakness is aggravated by cold and exercise.

►Tendon Reflex

## Hyperkinesia

### Definition

Abnormally increased motor activity, such as that seen drug-induced dyskinesia or the chorea seen in Huntington's disease. Hyperkinetic movement disorders include Huntington disease, tardive dyskinesia, essential tremor, restless limb syndrome, neuroleptic-induced akathisia, myoclonus, and tic disorders (such as Tourette's syndrome).

►Essential Tremor
►Huntington's Disease
►Myoclonus
►Restless Legs Syndrome
►Tardive Dyskinesia
►Tourette's Syndrome

## Hyperlipidemia

### Definition

Defined as a low-density lipoprotein (LDL) cholesterol level of 160 mg/dl or higher and is associated with an increased risk of stroke. High levels of high-density lipoprotein (HDL) cholesterol reduce the risk of stroke.

►Stroke

## Hypermetria

### Definition

A type of dysmetira, characterized by overshooting an intended target during the trajectory movement of a limb towards that target, usually seen in cerebellar disorders.

## Hyperoxia

### Definition

Higher than normal oxygen levels.

## Hyperpolarization

### Definition

Hyperpolarization is the change in membrane potential to a more negative, less excitable potential.

►Action Potential
►Membrane Potential: Basics

## Hyperpolarization-activated Cyclic Nucleotide-gated Channels

►Cyclic Nucleotide-Regulated Cation Channels

## Hyperreflexia

### Definition

Enhancement of tendon reflexes above normal level.

►Tendon Reflex

## Hypersomnia

### Definition

An increased propensity to fall asleep or a subjective feeling of excessive sleepiness; this is a symptom of a variety of sleep disorders and other medical conditions.

►Sleep – Developmental Changes

## Hypertelorism

### Definition

Abnormally large distance between two organs such as the eyes.

►Endocrine Disorders of Development and Growth

## Hypertension

### Definition

Is defined as a blood pressure of 140/90 mmHg or higher for an extended period of time. It is the most important modifiable risk factor for stroke.

►Stroke

## Hyperthyroidism

### Definition

A clinical syndrome resulting from excess of thyroid hormone. Among its features are heat intolerance, restlessness, tachycardia, increased perspiration, weight loss and increased appetite.

►Hypothalamus-Pituitary-Thyroid Axis

## Hypertonia

### Definition

Increased muscle tone detected by the examiner during passive range of motion. Rigidity (seen in Parkinson disease) is one form of hypertonia and it should be differentiated from spasticity, paratonia, pain-related guarding of the joints in arthritic patients, or even a cogwheel phenomenon seen in essential tremor.

Spasticity is velocity-dependent (clasp-knife) hypertonia and is associated with upper motor neuron signs such as pathologic hyperreflexia, Babinski signs, and pyramidal distribution weakness. Paratonic hypertonia (paratonia), seen in dementia, is characterized by a resistance to passive movement that is proportional to the force applied by the examiner.

Joint pain in the setting of arthritis can lead to local muscle spasm and guarding and cause increased tone.

The cogwheel phenomenon is typically part of Parkinson disease, but may also be seen in severe essential tremor as a result of coarse tremor interrupting passive movement, especially if the patient fails to completely relax.

►Babinski Reflex
►Clasp-knife Phenomenon
►Essential Tremor
►Parkinson Disease
►Spasticity

## Hypertrophy

### Definition

Volume increase in a cell, due to increased protein synthesis and increased assembly of myofibrils in striated muscle cells.

►Sarcomere Structural Proteins

# Hypochondriasis

## Definition

Hypochondriasis objective groundless and constant worry about healthiness and life. The hypochondriac person is preoccupied with fears of having a serious disease, which persists despite medical reassurance to the contrary.

►Personality Disorder

# Hypocretin

## Definition

Hypocretins, also called orexins, are the common names given to a pair of highly excitatory neuropeptide hormones from the lateral hypothalamus.

# Hypocretin/Orexin

Antoine Adamantidis, Luis de Lecea
Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, CA, USA

## Synonyms

Hypocretin-1, 2/Orexin-A, B

## Definition

The hypocretins (Hcrts) are neuroexcitatory peptides produced in approximately ~3200 neurons in the mouse brain (~6700 and 50,000–80,000 in the rat and human brain, respectively), restricted to the perifornical area of the lateral hypothalamus (LH) [1,2]. Hcrts were independently discovered in the late 1990s by two groups and thus have two names [1,2]. The name "hypocretin" is due to sequence similarities with various members of the incretin family and its hypothalamic localization [1]. The name "►orexin" comes from the orexigenic effect observed after intracerebroventricular administration the peptide in rat [2]. These two names designate the same peptide system and the terms are used interchangeably in the literature.

## Characteristics

### Peptide Structure

Hcrts are processed from the same 130 amino acids precursor. Hcrt-1 (33 residues; EPLPDCCRQKTCSCRLYELLHGAGNHAAGILTL-amide) and Hcrt-2 (28 residues; RPGPPGLQGRLQRLLQANGNHAAGILTM-amide) both contain an identical 13 amino-acid sequence in the C-terminal region, suggesting that the peptides have related structures and functions [1]. This region of Hcrt-2 contains a seven-amino-acid match with secretin. Hcrt-1 contains two intra-chain disulfide bonds. Human Hcrt-1 is identical to the rodent peptide, whereas human Hcrt-2 differs from rodent Hcrt-2 at two residues. The non-amidated forms of the peptides are not electrophysiologically active.

### Neuroanatomy of the Hcrt System

Hcrt neurons are multipolar or fusiform in shape, with 2–5 primary dendrites that are either smooth or sparsely invested with dendritic spines. Hcrt mRNA and Hcrt immunoreactivity are located in the perifornical area of the hypothalamus (►Perifornical area/lateral hypothalamus) [1]. In mammals, the projections of Hcrt-containing neurons are widely distributed within the central nervous system (CNS), including arousal centers of the CNS, cortex, hippocampus, amygdala, nucleus accumbens, and the hypothalamus itself. In addition to central expression in the lateral hypothalamus (LH), there are several reports of Hcrt and receptor expression in the periphery, including the enteric nervous system, pancreas, kidney, stomach and ileum. Hcrt expression has also been detected in the human retina, anterior pituitary, and adrenal gland.

The hypocretin peptides bind to two G-protein coupled receptors with differential affinities. Hypocretin receptor-1 (Hcrtr1, also referred to as OX1R), binds Hcrt-1 with high affinity and Hcrt-2 with 100–1,000-fold lower affinity. A related GPCR, Hypocretin receptor-2 (Hcrtr2/OX2R), shares 64% identity with Hcrtr1. These two receptors are highly conserved (95%) across species [2]. The mRNAs that encode the two hypocretin receptors, both are enriched in the brain but have different and complementary distributions [3]. The expression of Hcrt receptors is largely consistent with Hcrt axon innervation patterns and are found in the ►locus coeruleus (LC), amygdala, and ►brainstem noradrenergic groups. Hcrtr2 is predominantly expressed in regions such as the septum, hypothalamus, and much of the brainstem. The Hcrt receptors are also widely expressed in the periphery, especially in endocrine tissues including the pituitary, adrenal gland, testis, gastrointestinal tract, pancreas, and pineal gland.

Both Hcrt-1 and Hcrt-2 act through a family of GTP-binding proteins (Gq) that activate protein kinase C (PKC) and mobilization of intracellular calcium. Gq-activated signaling cascades result in phosphorylation

of $Ca^{2+}$ channels, which can increase $Ca^{2+}$ conductance and neuronal excitability. In some instances, Hcrtr2 has been associated with activation of $G_i$ and inhibition of adenylyl cyclase.

## Input and Output

The LH receives inputs from multiple, diverse neuron populations of the brain. Among those are the descending projections from the limbic forebrain, subsets of the hypothalamus itself (for example, arcuate nucleus, dorso-median hypothalamus, ►paraventricular nuclei), and subcortical and thalamic areas. Ascending projections come from the brainstem cholinergic nuclei, the reticular formation, the midbrain ►raphe nuclei, and periaqueductal gray.

Hcrt neurons in the LH are highly interconnected with a network of glutamatergic, GABAergic, dopaminergic, and cholinergic neurons [3]. Several extracellular signaling molecules exert excitatory effects on Hcrt neurons, including ►glutamate, ghrelin, glucagon-like peptide 1, CRF, ATP, noradrenaline and charbachol (acethycholine agonist), cholecystokinin, neurotension, vasopressin, and oxytocin. A subpopulation of Hcrt cells were found to be excited by ACh. Other molecules, including GABA (through GABAa, b), glucose, ►serotonin (5-HT1a), noradrenaline (alpha 2), dopamine, NPY, leptin, acethylcholine (muscarinic receptor; 6% of the cells) and adenosine (A1) have been found to inhibit Hcrt neurons. Accordingly, proteins detected in Hcrt neurons include dynorphin, GABAa receptor epsilon subunit, 5-HT1a receptor, μ-opioid receptor, pancreatic polypeptide Y4 receptor, adenosine $A_{1,2}$ receptor, leptin receptor, transcription factor STAT-3, and the neuronal pentraxin Narp, involved in clustering of ionotropic glutamate receptors.

## Functional Implications

The Hcrt system is a target of arousal ascending brainstem projections and descending forebrain structures, which in turn, projects back to these nuclei. Thus, they are in an ideal position to integrate peripheral inputs, such as metabolic and other homeostatic afferents, and modulate behavior outputs, such as arousal and ►goal-oriented behaviors.

### *Arousal*

Concomitant discoveries of the link between ►narcolepsy and the Hcrt system established the role of Hcrts in arousal [3]. Continuous analysis of the behavior of mice with the Hcrt gene deleted (Hcrt knockout (KO) mice) revealed periods of ataxia, which were especially frequent during the dark/active period. EEG recordings showed that these episodes were not related to epilepsy, that the mice displayed abrupt behavioral arrests, reminiscent of cataplexy-like attacks, and that their EEGs showed episodes of direct transition from wakefulness to ►REM sleep, all hallmarks of narcolepsy. Similar observations were made in rats in which the hypocretin neurons of the lateral hypothalamus were inactivated by saporin targeting, although in this model, cataplexy was not observed.

Studies of mice deficient for hypocretin receptors support a role for the hypocretin system in arousal. Hcrtr2 KO mice have a milder narcoleptic phenotype than the Hcrt KO animals, and double Hcrtr1 and Hcrtr2 mutant animals recapitulate the full Hcrt KO phenotype, suggesting that signaling through both receptors contributes to normal arousal, although the contribution of Hcrtr2 appears greater than that of Hcrtr1. Dogs with deficient Hcrtr2 displayed a similar phenotype.

Transgenic rats and mice depleted of Hcrt neurons (animals generated by expressing a mutant form of ataxin 3 in these cells) show a narcolepsy-like phenotype as well as reduced locomotor activity upon fasting [3], strongly suggesting that the Hcrt system is an important component of the brain circuit necessary to maintain arousal. Consistent with this hypothesis, data from recent studies demonstrate an increase of Hcrt neuron firing rate during robust locomotor activity during periods of wakefulness, as well as sleep-to-wake ►transitions during REM sleep [4,5]. Interestingly, Mochizuki and collaborators demonstrated that the behavioral state instability (e.g. fragmented wakefulness) of Hcrt KO animals is not a consequence of abnormal sleep homeostasis, poor circadian control, or defective fundamental arousal systems. Selective photostimulation of Channelrhodospin-2-expressing Hcrt neurons using ►optogenetic tools *in vivo* increase the probability of sleep-to-wake transitions [6].

Altogether, these studies establish a causal link between the activation of the Hcrt system and the maintenance of arousal. Hcrt concentrations in the cerebral spinal fluid (CSF) are tightly regulated in healthy human whereas most of the patients with narcolepsy with cataplexy show neither Hcrt-producing neurons nor detectable Hcrt level [7,8]. Patients with other neurological diseases have normal Hcrt levels in the CSF A single patient with a non-HLA-linked narcolepsy carries a mutation within the hypocretin gene itself. These findings leave no doubt as to the central role of the Hcrt system in narcolepsy and arousal. Because most cases are sporadic, mutations in the Hcrt gene or those for its receptors can account for no more than a small subset of human narcolepsies. The HLA association, loss of neurons with signs of gliosis, and age of disease onset are consistent with autoimmune destruction of the Hcrt neurons accounting for the majority of narcolepsy, although a non-immune-mediated degenerative process has not been ruled out. The cause of Hcrt neuron loss is an active area of narcolepsy research.

### Goal-Oriented Behaviors

Goal-oriented behaviors can be elicited by natural (food, thirst, sex) or artificial (drugs of abuse) clues. Onset of these behaviors requires an appropriate balance between sleep- and wake-promoting circuits of the brain, which set up an arousal threshold. Hcrt-producing neurons play a key role in setting up this threshold, and activate circuits involved in motivation for consummatory behaviors.

Intracerebroventricular administration of either Hcrt-1 or Hcrt-2 increases short-term food consumption in rats, sheep and goldfish. Furthermore, rats that have been deprived of food for 48 h show increased concentrations of hypocretin mRNA and peptides in the hypothalamus. The Hcrt system also influences and is influenced by primary energy homeostasis circuits. For example, Hcrt neurons are sensitive to glucose, leptin, triglyceride and carbon dioxide concentrations [3]. However, other findings suggest that the Hcrt are not critical players in food intake behavior, but rather play roles in increasing arousal and motivation levels that allow feeding to take place. Continuous administration of Hcrt-1 for 7 days in rats does not significantly alter daily food intake, body weight, blood glucose, total cholesterol, or free fatty acid levels, suggesting that many of Hcrt's effects may be limited to short-term, immediate stimulation of feeding behavior consequent to the increased duration of wakefulness. In addition, Hcrt KO mice show modest differences in food intake and Hcrt-ataxin 3 mice, which would be expected to be lean, show obesity and hypolocomotion phenotypes, an effect dependent on diet and genetic background. Also, during fasting, Hcrt-1 accumulation in the CSF does not exceed concentrations observed during the waking period. These data suggest that some of the food-uptake effects may result from heightened arousal during food craving and/or food intake as opposed to feeding pressure.

Infusion of Hcrt-1 in the brain ventricles elevates intra-cranial self stimulation (ICSS) thresholds indicating that the peptide decreases brain reward function in a similar way as stress [9]. Hcrt neurons, which express the μ-opioid receptor, are highly responsive to morphine and their activation is linked to preferences for cues associated with drug and food reward and also naltrexone-precipitated withdrawal [10]. Interestingly, Hcrt neurons are strongly activated by copulatory behavior in male rats. Expression of Hcrt mRNA increases after precipitated withdrawal. Hcrt KO mice exhibit dramatically attenuated morphine withdrawal symptoms. Moreover, Hcrt reinstates extinguished drug-seeking behavior, an effect prevented by blockade of the Hcrt-1 systems. Accordingly, a Hcrt-1 receptor antagonist blocks footshock-induced reinstatement of previously extinguished cocaine-seeking behavior leading to the conclusion that the Hcrt system is an important component of stress-mediated drug seeking behavior [9].

Finally, Hcrt neurons are activated in male mice hypothalamus during copulatory behavior and Hcrt-1 infusion in the medial preoptic area potentiates male sexual behavior in rats. Since Hcrt-1 downregulates the firing rate of downstream dopaminergic neurons in the ventral tegmental area, these data suggest that the Hcrt system may act in a steroid-sensitive manner to facilitate motivation toward natural rewards, such as food or sex, via activation of the mesolimbic dopaminergic system.

### Summary

Anatomical and electrophysiological data suggest that the Hcrt neuronal system integrates complex information about circadian, limbic and metabolic variables. This information is transmitted into a coherent behavioral output that excites arousal centers depending on the physiological demand. Together, the data gathered thus far indicate that the Hcrt peptides provide an alarm signal and stability to arousal centers.

### Definition

►Ageusia

## Hypoglossal Nerve (XII)

### Synonyms

N. hypoglossus (N.XII)

### Definition

Hypoglossal nerve (XII) is a purely somatomotor nerve and innervates the tongue muscles. It has important functions in speaking, drinking, eating and swallowing. Skull: hypoglossal canal.

►Nerves

## Hypokalemic Periodic Paralysis

### Definition

Autosomal dominant in 2/3 of cases (more males than females) and sporadic in 1/3, usually begins at early age (below 25) and is characterized by episodic attacks of weakness predominantly in proximal limb muscles (especially in the morning after night rest or after hard exercise and work), low serum $K^+$ concentration during attacks and elicibility of attacks by glucose and insulin administration. The pathophysiology is not well understood.

## Hypokinesia

### Definition

Associated with bradykinesia, it refers to abnormally reduced mobility such as that seen in Parkinson disease.

►Parkinson Disease

## Hypometabolism

### Definition

State of reduced metabolism, used by animals to reduce energy expenditure during phases of inactivity (torpor), e.g., in hibernation or daily torpor.

►Hibernation

## Hypometria

### Definition

A type of dysmetria, characterized by undershooting an intended target during the trajectory movement of a limb towards that target, usually seen in cerebellar disorders.

►Cerebellar Functions

## Hypomyelination

### Definition
Reduced levels of myelin detected in different mutants.

## Hyponatremia

The electrolyte disturbance in humans when the sodium concentration in the plasma falls below 135 mmol/L.

►Neuroendocrinology of Psychiatric Disorders

## Hypophysis

### Synonyms
Pituitary gland

### Definition
The hypophysis consists of the hypothalamic neurohypophysis (posterior lobe of the hypophysis) and the adenohypophysis (anterior lobe of the hypophysis) arising on the pharyngeal roof (Rathke's pouch). The hypophysis is the “hormone center” of the body and has close connections with the hypothalamus. With its effector hormones and glandotropic hormones, it controls the autonomic processes and hormone glands of the body.

►Diencephalon

## Hypoplasia

### Definition
Incomplete development of organs or organ systems

►Endocrine Disorders of Development and Growth

## Hyporeflexia

### Definition
Reduction of reflexes.

## Hyposmia

### Definition
Hyposmia is a diminution in the sense of olfaction. The etiologies for hyposmia are much the same as those for anosmia (complete loss of the sense of smell).

Physical obstruction of the nasal cavities, due to inflammation (rhinitis), polyps and/or a deviated septum, may reduce olfactory acuity.

Olfactory dysfunction may also result from direct lesion of the olfactory system. Damage of the olfactory epithelium, for example due to a chemical burn or infection, may cause hyposmia or even anosmia. One of the most frequent causes of olfactory loss is head trauma, resulting in section of the olfactory nerves passing through the cribiform plate. Intracranial tumors have also been described to affect olfaction.

►Smell Disorders

## Hypothalamic Clock

### Definition
The primary circadian "clock" of the brain in mammals is located in the suprachiasmatic nucleus (SCN), a paired group of cells located on top of the optic chiasm that regulates e.g., sleep/wake rhythm.

►Neuroendocrinology of Psychiatric Disorders

## Hypothalamic Paraventricular Nucleus (PVN)

### Definition
The hypothalamic paraventricular nucleus is located in the vicinity of the third ventricle and is composed of

several functionally distinct subnuclei that affect both endocrine and autonomic responses. Specific sets of PVN neurons contain peptides involved in anterior and posterior pituitary regulation, and other neurons are involved in autonomic control.

## Hypothalamic-Pituitary Gland Axis

### Definition

The nervous part of the neuroendocrine system (hypothalamic-pituitary-adrenal axis), controlling reactions to stress and vital functions in regulating body homeostasis, immune reactivity and energy usage.

►Hypothalamo-Pituitary-Adrenal (HPA) Axis, Stress and Depression

## Hypothalamic-preoptic Area

### Definition

A region of the forebrain that includes both the hypothalamus and cells rostral to (in front of) the hypothalamus.

## Hypothalamo-neurohypophysial System

Dick F. Swaab[1], Paul J. Lucassen[2]
[1]Netherlands Institute for Neuroscience, Amsterdam, The Netherlands
[2]Centre for Neuroscience, Swammerdam Institute of Life Sciences,, University of Amsterdam, The Netherlands

### Definition

The hypothalamo-neurohypophysial system (HNS) consists of the *supraoptic* and *paraventricular nuclei* (SON and PVN) and their axons that run towards the neurohypophysis. There, vasopressin and oxytocin are released into the blood circulation from where these neurohormones act on peripheral organs.

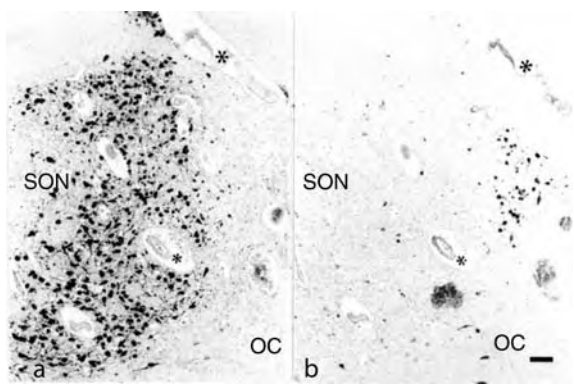
### Characteristics

The HNS represents the classic example of a neuroendocrine system, i.e. of hormone producing neurons. Vasopressin acts as an antidiuretic hormone on the kidney and regulates free water clearance by V2-type vasopressin receptors and the subsequent formation of aquaporin-2 water channels in the renal collecting duct. In women, oxytocin is involved in labor and lactation by its actions on the uterus and mammary gland respectively [1].

### Quantitative Description

Hypophysectomy causes an average loss of 80% of the large neurons from both the SON and PVN, showing that most large SON and PVN neurons project to the neurohypophysis. The SON is subdivided into three parts. The largest part, the *dorsolateral SON*, has a volume of 3 $mm^3$ and contains 53,000 neurons, 90% of which contain vasopressin and 10% oxytocin (Fig. 1).

The *dorsomedial and ventromedial SON* together contain another 23,000 neurons. The PVN has a volume of 6 $mm^3$ and consists of about 56,000 neurons of which some 25,000 contain oxytocin and 21,000 express vasopressin. Clusters of magnocellular neurosecretory neurons are further found in between the PVN and SON and are generally referred to as



**Hypothalamo-neurohypophysial System.**
**Figure 1** Consecutive sections of a 49-year-old female control stained for vasopressin and oxytocin. (a) dorsolateral supraoptic nucleus (*SON*) stained with an antiglycopeptide (Boris Y-2) against the vasopressin precursor and (b) oxytocin (0–1-V, purified). Note that the relatively small oxytocin cell population is clearly separated from the vasopressin cell population. *Asterisk* indicates a blood vessel that is present in both consecutive sections: *OC* = optic chiasm. *Bar* = 100 mm. (From Evans et al., 1996; Fig. 1, with permission.)

"*accessory nuclei*". They contain more oxytocinergic than vasopressinergic neurons [1].

## Description of the Process (Fig. 2)

The nonapeptides vasopressin and oxytocin are synthesized in the hypothalamus as part of a large precursor that includes a neurophysin moiety for both peptides and a C-terminal glycoprotein for the vasopressin precursor only. The *oxytocin and vasopressin receptors* form a subfamily of G-protein coupled receptors. The vasopressin V1 receptor, formerly known as V1a, is expressed in the liver, blood vessels, smooth muscle cells and many other peripheral tissues. The V2 receptor is selectively expressed in the kidney and the brain of newborn rats, while the V3 receptor (formerly known as V1b) is more abundantly expressed in the majority of the anterior pituitary corticotropin cells, in multiple brain regions and in a number of peripheral tissues, including kidney, thymus, heart, lung, spleen, uterus and breast.

Vasopressin is released from the neurohypophysis during osmotic stimulation, hypotension or hypovolemia. The hypothalamus integrates signals from *osmoreceptors* that are probably located in the SON, from the organum vasculosum lamina terminalis, the subfornical organ and from stretch or baro-receptors in the carotid sinus and aortic arch of the vascular tree. Aquaporin-4 expressing astrocytes in the SON, PVN and the subfornical organ are also presumed to play a key role in osmoreception. In humans, 90% of the circulating vasopressin is bound to platelets. Men have higher vasopressin levels than women [2] and the posterior lobe of the pituitary is larger in boys than in girls. These sex differences are consistent with the higher metabolic activity in vasopressin neurons in the SON in young men as compared to women. In postmenopausal women activation of neurosecretory vasopressin neurons occurs.

During normal delivery, stretching of the lower birth canal triggers the neurohormonal *"Ferguson" reflex*, leading to rapid secretion of oxytocin by the pituitary gland, which results in strong expulsive uterine contractions. This would explain why, following epidurals, more arrests of the descent during the second stage of labor and more forceps deliveries are required. Indeed, oxytocin treatment during the second stage of labor with epidural analgesia reduces the need for forceps. Oxytocin is also involved in heart rate regulation by neuroendocrine and central mechanisms and oxytocin receptors are indeed present in all heart compartments and in the vasculature. In addition, oxytocin is synthesized in the heart and in large vessels like the aorta and vena cava. Finally, oxytocin induces contractions of smooth muscle cells both in men and women and may thus facilitate transport of eggs as well as sperm. During aging, the HNS is activated, especially in women [1,3,4].

## Higher Processes: Central Release (Fig. 3)

Vasopressin and oxytocin are not only released into the bloodstream, but also transported through nerve fibers from the PVN to other brain areas where they act as neurotransmitters or neuromodulators and influence central processes. The central vasopressinergic fibers are involved in blood pressure and temperature regulation, regulation of osmolality and corticosteroid secretion. As such, they may influence cognition, aggression, paternal behavior and social attachment.

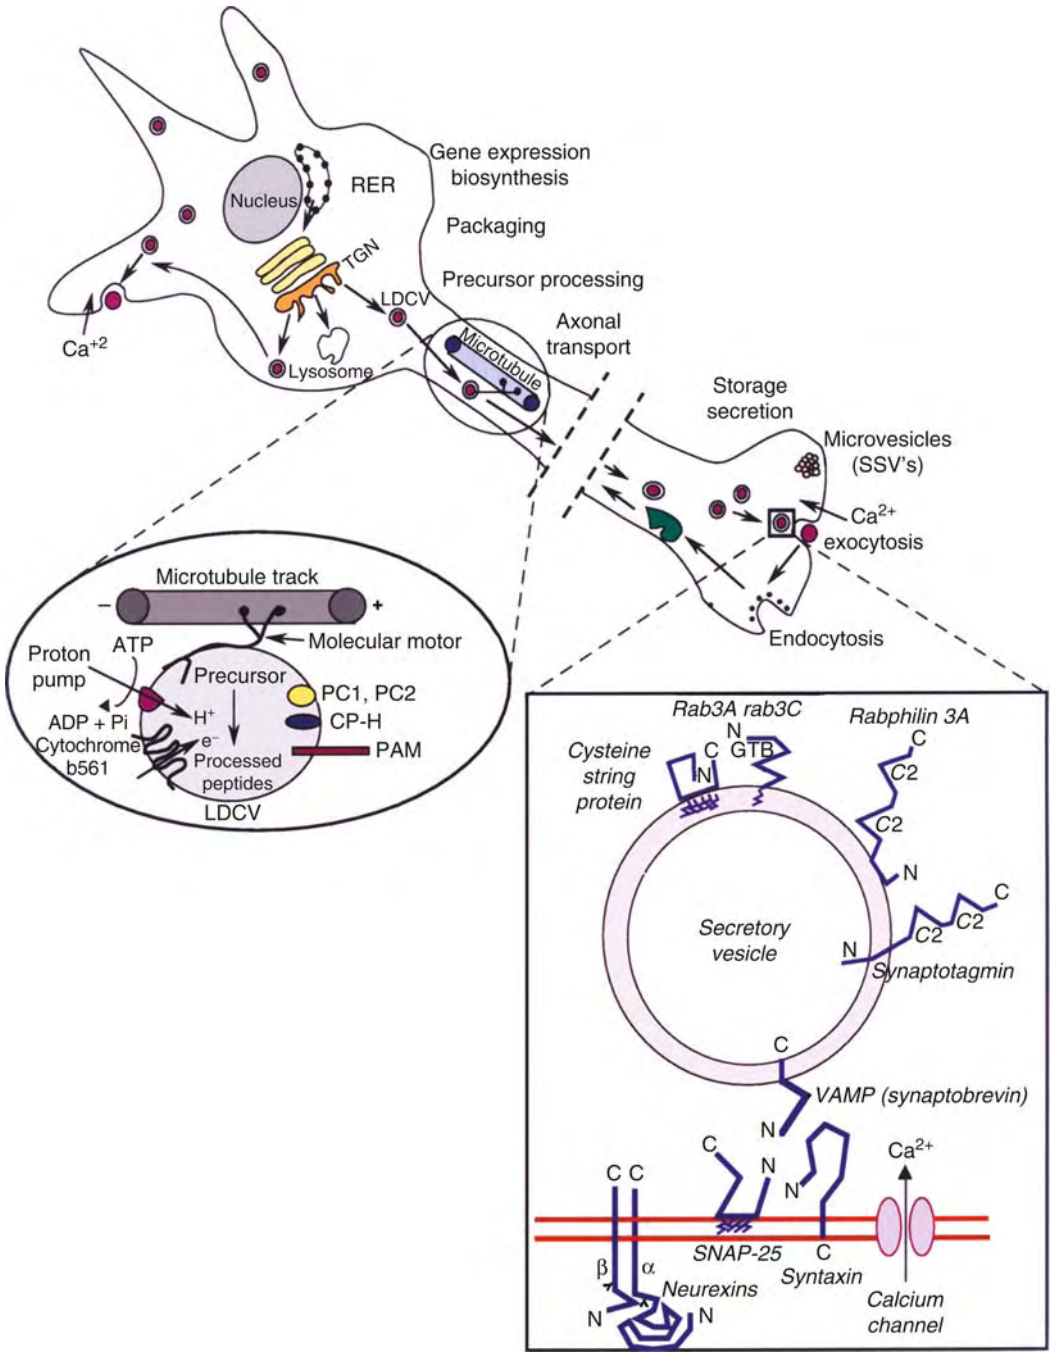
Oxytocinergic central pathways are involved in reproduction, cognition, tolerance, adaptation and the regulation of cardiovascular and respiratory functions. Oxytocin neurons from the PVN innervating the brainstem nuclei are involved in blood pressure and heart rate regulation. Centrally released oxytocin would also give rise to sedation, e.g., during lactation. Oxytocin further induces a decline in cortisol, which may be essential for the formation of social bonds. Brain oxytocin modulates a range of social behaviors, from parental care to mate guarding, while it also has central effects on food intake as oxytocin neurons are considered putative satiety neurons for the control of eating behavior [1,5].

### *Oxytocin, Vasopressin and Reproductive Behavior*

Oxytocin and vasopressin are involved in affiliation, including pair bonding, parental care and territorial aggression in monogamous animals, maternal behavior and other aspects of reproductive behavior. In men, the oxytocin cells of the PVN are involved in penile erections. In addition, oxytocin may reduce *maternal aggression* in the period shortly after birth when lactating females are more aggressive anyway. In women, basal levels of oxytocin during lactation are associated with a desire to please, give and interact socially. Oxytocin released during labor and lactation may influence human maternal responsiveness and perhaps attachment. One minute after orgasm, oxytocin levels are increased in women. In men, oxytocin may also be involved in sexual arousal and ejaculation. In agreement with this, oxytocin levels are known to rise during sexual arousal and peak during orgasm in men [1].

### *Vasopressin, Oxytocin and Osmotic Regulation in Pregnancy*

Probably the most important factor contributing to the variation in plasma levels of vasopressin in pregnancy is the in vivo activity of cystyl aminopeptidase (CAP), an enzyme also called vasopressinase or oxytocinase. It degrades vasopressin or oxytocin very rapidly. Oxytocin plasma levels rise during delivery. The vasopressin levels in fetal cord blood are extremely high after delivery supporting the idea of an active role of the fetus in its own delivery [1].



**Hypothalamo-neurohypophysial System. Figure 2** A neurosecretory cell shown schematically. Gene expression, protein biosynthesis, and packaging of the protein into large dense core vesicles (*LDCVs*) in the cell body, where the nucleus, rough endoplasmic reticulum (*RER*) and Golgi apparatus are located. Enzymatic processing of the precursor proteins into the biologically active peptides occurs primarily in the LDCVs (see *inset*), often during the process of anterograde axonal transport of the LDCVs to the nerve terminals on microtubule tracks in the axon. Upon their arrival at the nerve terminal, the LDCVs are usually stored in preparation for secretion. Conduction of a nerve impulse (action potential) down the axon and its arrival in the nerve terminal causes an influx of calcium ions through calcium channels. The increased calcium ion concentration then causes a cascade of molecular events (see *inset*) that leads to neurosecretion (exocytosis). Reuptake of the excess LDCV membrane after exocytosis is performed by endocytosis, but this membrane is not recycled locally and instead is retrogradely transported to the cell body for reuse or degradation in lysosomes. *TGN* trans-Golgi network; *SSV* small secretory vesicles; *PC1* or *PC2* prohormone convertase 1 or 2 respectively; *CP-H* carboxypeptidase H; *PAM* peptiylglycine a-amidating monooxygenase. ### *Vasopressin Secretion in Various Disorders*

Activation of the HNS has been reported in depression [6,2]. Chronic alcohol consumption is toxic to hypothalamic SON and PVN neurons in a concentration and time dependent manner. Glucocorticoids have a suppressive effect on the expression of processed vasopressin, whereas the precursor of vasopressin itself is not decreased by these steroids, indicating a processing disturbance [7,8]. Consistent with this, in glucocorticoid deficient Addison patients, vasopressin levels are indeed increased. The vasopressin gene promotor further contains a glucocorticoid response element. In this way, glucocorticoids inhibit vasopressin promotor activity, which explains part of the nonosmotic increase in vasopressin secretion occurring with glucocorticoid deficiency. In stroke patients, the increased vasopressin level is related to the size of the lesion. In pain and smoking, large rises in vasopressin levels, even up to several hundred-fold increases, have been reported. Surgery also increases vasopressin levels, which may at least in part relate to the stress of the operation [1].

### *Vasopressin Administration in Various Disorders*

DDAVP (1-desamine-8 D-arginine vasopressin = desmopressin) is used to treat central diabetes insipidus, while it has been also been used in children for prophylaxis of bleeding, e.g. in adenotonsillectomy and to stop bleeding in mild *hemophilia*, type I von Willebrand's disease, in hemophilia B and in patients with various functional defects of their platelets.

Vasopressin has been used for the treatment of refractory hypotension after cardiopulmonary bypass and may sometimes provide a dramatic improvement in hemodynamic conditions. For the same reason, vasopressin infusion at 0.01–0.04 U/min is often given and appears beneficial in patients with *septic shock* and *vasodilatory shock* as it increases urinary output while vascular resistance decreases [1].

In conclusion, the HNS and its main hormonal output form a dynamic and essential neuroendocrine system integrating various diverse central and peripheral homeostatic functions.

## Definition

Stress systems are activated whenever a discrepancy occurs between an organism's expectations and the reality it encounters, particularly when it involves a threat to the organism's homeostasis.

## Characteristics

The hypothalamo-pituitary-adrenal (HPA) axis consists of several interconnected centers in the brain and body that together orchestrate the hormonal response to stress and that is aimed to restore homeostasis.

### Description of the Process

Stress-induced activation of the HPA system triggers the production of corticotropin-releasing hormone (CRH) in parvocellular neurons of the hypothalamic paraventricular nucleus (PVN). This in turn induces adrenocorticotropic hormone (ACTH) release from the pituitary which causes glucocorticoid hormone (GC) release from the adrenal cortex into the blood. Glucocorticoids exert a wide range of biological effects on the brain and body. Their plasma levels are carefully kept within physiological limits through GC-mediated feedback inhibition at specific steroid receptors in the pituitary and PVN.

Stress represents an old and essential alarm system for any individual organism. Stress occurs whenever an organism encounters or anticipates a potential threat to its homeostasis, arising from outside or from within the organism. Such threats can derive from a lack of information, loss of control, unpredictability or uncertainty when faced with e.g. predator threat, but also when confronted with physical perturbations of its internal homeostasis, like food or water shortage, blood loss, injury or inflammation, or a serious disease. Also

psychosocial demands, or the social hierarchy within a given group can produce profound stress signals [1].

Whenever a stressor is perceived, various brain systems are activated that will coordinate a stress response by triggering various adaptive molecular, physiological and psychological processes aimed to restore homeostasis and thereby re-establish a functional steady-state. In mammals, the stress response is mediated by the limbic-hypothalamo-pituitary-adrenal (HPA) system, a classic neuroendocrine circuit in which limbic and hypothalamic brain structures integrate emotional, cognitive, neuroendocrine and autonomic inputs together determining magnitude and duration of the behavioral, neural and hormonal stress responses. Together with other neuro-hormonal components, stress-induced HPA axis activation (CRH) in paraventricular nucleus (PVN) (Fig. 1) and ACTH release from the pituitary which causes glucocorticoid (GC) release (cortisol in primates, corticosterone in rodents) from the adrenal cortex into the blood [1].

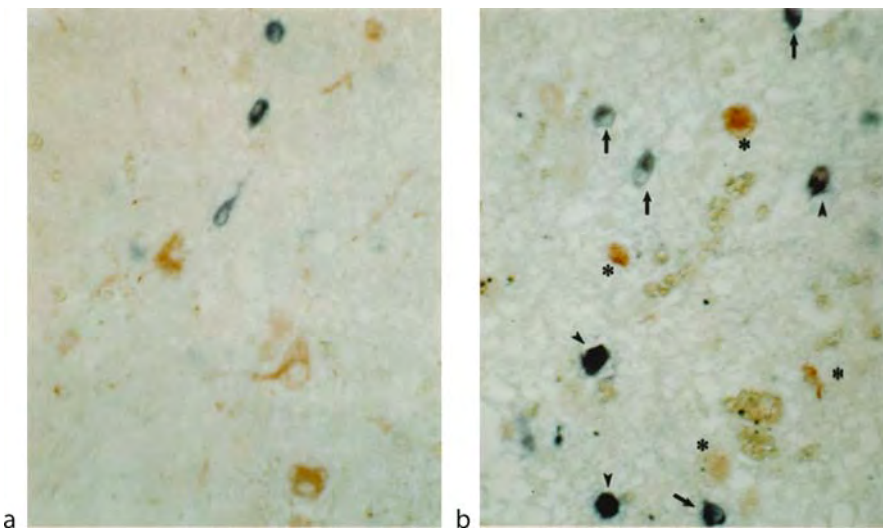
GCs exert a wide range of biological effects by influencing glucose, fat and mineral metabolism, cognition and the immune system. Their plasma levels are carefully kept within physiological limits through GC-mediated feedback inhibition at specific steroid receptors in the pituitary and PVN. Also the hippocampus, that contains high densities of glucocorticoid (GR) and mineralocorticoid (MR) receptors in rat, is sensitive to GC action. Upon GC binding to MR or GR, the activated steroid hormone receptor translocates from the cytoplasm to the nucleus, where gene transcription and electrophysiological properties of the cell can be altered [1]. Steroid action to target tissues is further influenced by a.o., steroid converting enzymes and various co-activator/co-repressors. Amongst other brain areas, the hippocampus is thought to exert an (indirect) tonic inhibitory control on HPA system activity, and is important in emotional processing and in key aspects of learning and memory [1].

## HPA Changes, Stress and the Hippocampus

Even though the acute stress response itself is considered harmless, prolonged hyperactivity of the HPA system, as occurs after chronic stress, can result in maladaptation and alterations in HPA setpoint or feedback sensitivity. This can cause prolonged (over) exposure of the brain and body that may predispose to pathology and can affect hypothalamic and hippocampal function and hippocampal structure [1,2,3].

In rodents and man, GC excess is generally associated with deleterious functional changes in e.g. hippocampal excitability, longterm potentiation and learning. GCs can also affect structural hippocampal parameters, comprising initial, and still reversible atrophy of the CA3 dendritic tree as well as reversible remodeling of synaptic terminal structures. In later stages, the hippocampus as a whole shrinks, followed by an increased vulnerability to metabolic insults and even neuronal loss of CA3 neurons has been reported, that can extend into other hippocampal regions if severe stress persists [2,4,7].

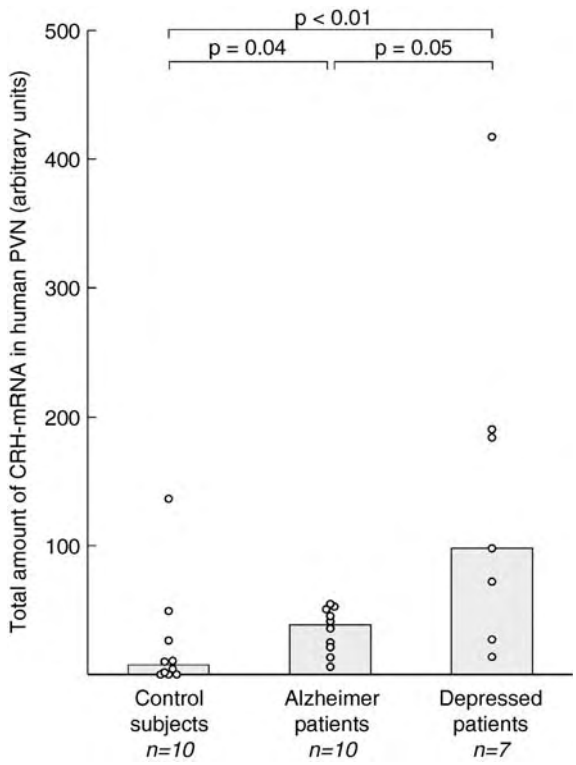
Effects of chronic stress are assumed to be largely GR-mediated. However, chronic stress may also alter the function of the mineralocorticoid receptor (MR) that is implicated in tonic inhibitory control of the HPA axis and e.g. suppresses adrenalectomy-induced hippocampal apoptosis and modulates adult neurogenesis



**Hypothalamo-Pituitary-Adrenal Axis, Stress and Depression. Figure 1** Immunocytochemical double staining for CRH (*blue*), vasopressin (*red*) and CRH/AVP co-expression (*purple*) in the PVN of a young (a) and old (b) subject indicates HPA axis activation. A similar activation is found in depression.

in the hippocampal dentate gyrus subregion [1,7,8]. In view of its proposed inhibitory role in HPA activity control, neuronal loss in the hippocampus as initially reported in stressed rodents and primates, was expected to disinhibit the HPA axis, that could cause a positive feedforward cascade of increasing glucocorticoid levels over time. This could be causally involved in an age-related accumulation of hippocampal damage in disorders like Alzheimer's disease and major depression, where reductions in hippocampal volume were found parallel to elevated basal GC plasma levels. Given other reports on correlations between hippocampal volume changes, cognitive impairment and HPA changes, the glucocorticoid cascade concept of stress and hippocampal damage was proposed, that has later been adapted [2,4,7,8].

Regarding the possibility of steroid-induced hippocampal damage, however, no neuropathology or major structural changes could be found in the hippocampus of depressed or synthetic steroid-treated subjects, consistent with observations on the recovery of hippocampal volume following treatment of the tumor in Cushing's disease e.g. [3,5,7]. However, cell death may have occurred earlier in time while also almost all patients studied received antidepressant therapy. From many antidepressant drugs, it is known they can influence adult neurogenesis and apoptosis and hence may preserve hippocampal structure [7,8].



**Hypothalamo-Pituitary-Adrenal Axis, Stress and Depression. Figure 2** In situ hybridization revealed significant increases in CRH mRNA expression in the PVN of Alzheimer and depressed patients.

## The HPA Axis and Major Depression

Numerous clinical and preclinical studies indicate that HPA axis hyperactivity is implicated in the pathogenesis of major depression. Although also the serotonin system and other factors are involved, HPA feedback abnormalities occur in many depressed patients often resembling a subset of the changes seen in chronically stressed animals [1,4,6,9]. Patients suffering from major depression frequently show psychomotor retardation, changed circadian activity patterns, appetite disturbances, weight changes and a loss of libido. HPA hyperactivity is reflected by the increased plasma ACTH and cortisol levels, elevated plasma and salivary cortisol and cortisone levels, increased urinary free cortisol excretion and increases in CRH and vasopressin co-expression in PVN neurons. Both patients with a major and bipolar depression show a much stronger CRH neuron activation than aged controls or Alzheimer's disease patients [4,9] (Figs. 1 and 2).

In addition to a hypothalamic hyperdrive, various other measures point to a primary role for the HPA-axis in depression [1,3,4,9]. First, a well-known side effect of glucocorticoid treatment is depression while atypical depression often occurs in Cushing patients, especially when their disease duration is long [1,5]. Moreover, decreased GR function, an enhanced adrenal response to ACTH as well as hypertrophy of the adrenal and pituitary are common in depressed patients. In addition to significant reductions in hippocampal volume [3,7], many patients with depression are dexamethasone non-suppressor. The elevated cortisol response in the test also correlates with a higher risk for relapse than in individuals who had a depression but subsequently showed a normal cortisol response. Studies in high-risk probands of depressed patients have further shown that abnormalities in HPA axis function already exist prior to the onset of the clinical symptoms, suggesting that HPA abnormalities can in fact precipitate depressive episodes [1,10]. Hence, treatment aimed directly at interfering with the HPA axis may prove beneficial. Following (pharmaco)therapy, normalization of the HPA axis indeed decreases relapse probability, while studies in depressed patients treated with steroid synthesis blockers or GR-antagonist also support this concept [1].

It should be noted that not every depressed individual suffers from a hyperactive HPA axis and that considerable individual variability exists. Increased basal plasma cortisol levels are present in over 25% of the subjects with major depression, while on average more than 50% show non-suppression of cortisol to dexamethasone. Most depressed patients are not

hypercortisolemic when studied cross-sectionally; yet, clinically significant episodes of excessive exposure to glucocorticoids could have been present already. In addition, part of such differences may be attributed to methodological aspects like sampling over the circadian cycle, and whether or not patients had been admitted to psychiatric wards or were living at home when tested. Subjects with psychotic major depression even have higher cortisol levels than otherwise depressed subjects, which may contribute to the variability in cortisol levels.

An important argument for a hypothalamic hyperdrive as initial event is that symptoms resembling depression, e.g. a decreased food intake, decreased sexual activity, disturbed sleep and motor behavior and increased anxiety, can all be induced in experimental animals by intracerebroventricular injection of CRH. In addition, antidepressant drugs attenuate the synthesis and CSF concentrations of CRH. Lastly, a transgenic mouse model with an overproduction of CRH appeared to have increased anxiogenic and depressive like behavior, whereas a mouse with a genetic deletion of the CRH-1 receptor has indeed reduced anxiety-like behavior. An interesting new compound in depression research is urocortin, a CRH-related peptide that also exerts anxiogenic-like properties in experimental animals. The recent development of selective small molecule CRH1 receptor antagonists, blocking CRH effects, suggests these compounds could be effective in the treatment of mood and anxiety disorders. Taken together, hyperactivity of those CRH neurons that project into the brain, may be activated in depression [1,4].

An alternative possibility involves changes during early development lasting into adulthood. Although the set point of HPA-axis activity is programmed by genotype, it can be readjusted by early life stressors like bereavement, child abuse, and early maternal separation that also form risk factors for depression, anxiety disorder, or both [1].

Another hypothesis focuses on glucocorticoids as causative agents, secondary to a disturbed local corticosteroid signaling due to changes in GR level or sensitivity. Transgenic mice with a defective GR indeed show symptoms resembling those seen in depression. Although little is known about GR levels in human brain, glucocorticoid receptor antagonists could become promising candidates for additive treatment of stress related forms of depression [1].

# Hypothalamo-pituitary-gonadal Axis

## Definition

Homeostatic feedback system involved in the coordination of sex hormone release. Includes hypothalamic centers, the pituitary and the gonads, i.e. the testis in males and the ovaries in females.

►Neuroendocrinology of Psychiatric Disorders

# Hypothalamus

Qian Gao, Tamas Horvath
Section of Comparative Medicine, Department of Ob/Gyn & Reproductive Sciences and Neurobiology, Yale University School of Medicine, New Haven, CT, USA

## Definition

Hypothalamus is from the Greek ὑποθαλαμος, which means "under the thalamus." As the name indicates, the

hypothalamus is located ventromedially in the brain, immediately beneath the thalamus. It is a small neuronal structure about the size of an almond comprising mostly grey matter and accounting for about 1/300 of total brain weight in humans. It forms part of the walls and floor of the third ventricle and is found in all mammalian brains.

## Characteristics

### Anatomy

The hypothalamus is divided in the rostrocaudal dimension into more or less arbitrarily designated anterior, middle (tuberal) and posterior regions. Each of these is further split into medial and lateral areas (Table 1). The region approximately between the optic chiasm and anterior commissure contains the preoptic area, which is generally regarded as the rostralmost part of the hypothalamus, and the anterior part of the hypothalamus proper. The mammillary bodies form the posterior end of the hypothalamus. Between the anterior and posterior hypothalamus, a tuberal part contains ventromedial, dorsomedial, lateral and dorsal territories. The hypothalamus extends downward to connect to the pituitary gland (also known as the *hypophysis*), a key endocrine organ controlled by the hypothalamus (Fig. 1).

The hypothalamus is composed of numerous nuclei (Table 1), each of which contains distinct neuron subpopulations and has distinct functions. Only a few examples will be given here. The anterior portion of the hypothalamus including the preoptic area is important in control of estrus cycle in females and fertility in both sexes. It also contains thermosensitive neurons important for regulation of ►thyrotropin-releasing hormone (TRH) secretion. At the base of the anterior hypothalamus, the suprachiasmatic nucleus is critical to maintaining the circadian rhythm, while at the dorsalmost extent of this region, the paraventricular nucleus is involved in feeding and metabolism. The ventromedial hypothalamus, together with the arcuate nucleus, a long cigar like structure localized to the very base of the hypothalamus (Fig. 2), is known as a satiety center that inhibits food intake and increases energy expenditure upon accumulation of bodily energy stores. The lateral posterior hypothalamus is crucial in feeding and sleep-arousal behavior.

Some hypothalamic nuclei are sexually dimorphic with differences in gross neuroanatomy and function between males and females. Notable among these is the sexually dimorphic nucleus within the preoptic area, which presents only in males. The importance of these differences is not fully understood, but can be recognized by phenotypic differences between males and females. For instance, the secretion pattern of growth hormone is sexually dimorphic, and this contributes to the tendency in many species for adult males to be larger than females.

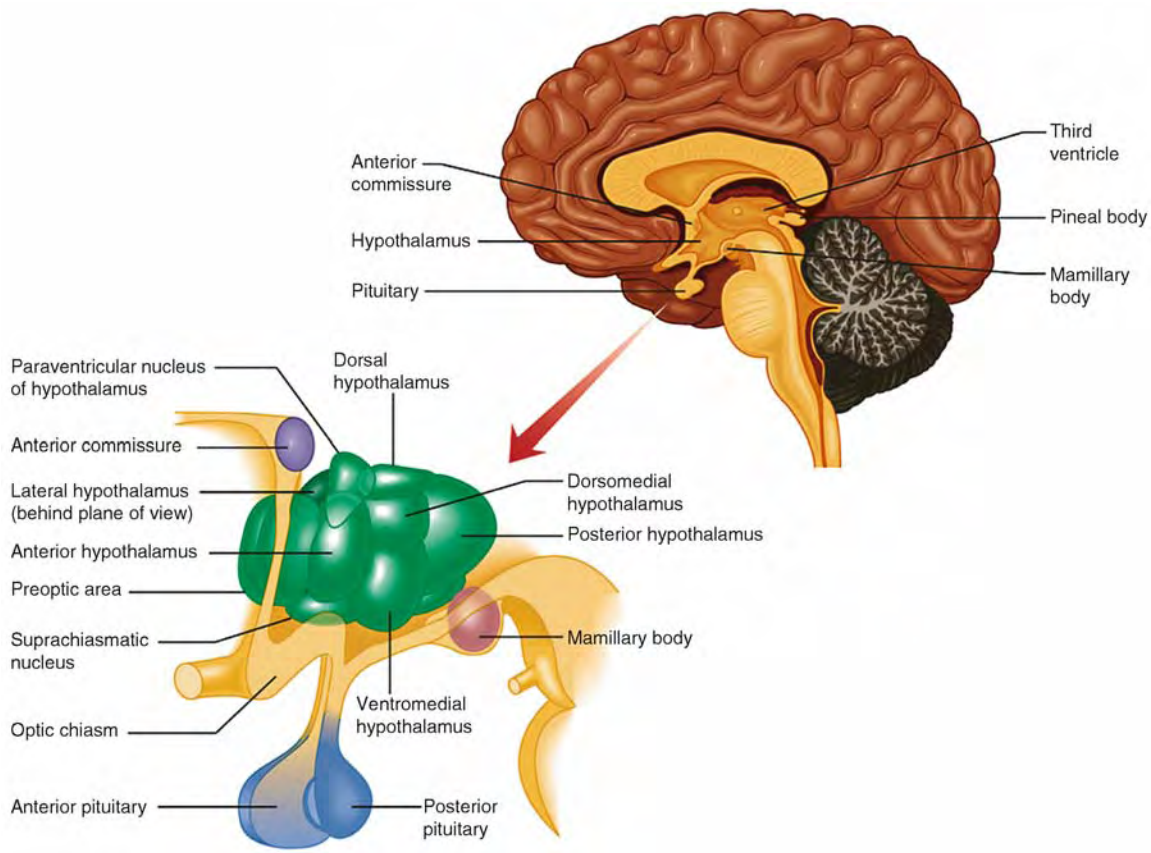
An effect of aging on the anatomy of the hypothalamus is an interesting, under studied phenomenon and its significance is not well understood. Nonetheless, it is observed that in female mice both the supraoptic nucleus (SON) and paraventricular nucleus (PVN) lose approximately one-third of insulin-like growth factor-1 receptor (IGF-1R) immunoreactive cells during normal aging. In contrast, senescent mice raised in a condition of caloric restriction (CR) lost more non-IGF-1R immunoreactive cells as compared to controls, but maintained similar counts of IGF-1R immunoreactive cells. Consequently, in comparison to normally aging mice senescent CR mice exhibited a higher percentage of IGF-1R immunoreactive cells along with an increased hypothalamic sensitivity to IGF-1 [1].

### Functions

The central function of the hypothalamus is to regulate bodily homeostasis. Thus, the hypothalamus contains neuronal circuits that control, e.g. long-term energy balance (fat stores), glucose utilization, water-salt balance, sleep-wake cycle, body temperature and blood pressure. Furthermore, the hypothalamus links the central nervous system to the endocrine system, autonomic nervous system and peripheral tissues.

**Hypothalamus. Table 1** Hypothalamic nuclei

| Region | Medial area | Lateral area |
|---|---|---|
| Anterior | Medial preoptic mucleus | |
| | Supraoptic nucleus | Lateral preoptic nucleus |
| | Paraventricular nucleus | Lateral nucleus |
| | Anterior hypothalamic nucleus | Part of supraoptic nucleus |
| | Suprachiasmatic nucleus | |
| Tuberal | Dorsomedial nucleus | |
| | Ventromedial nucleus | Lateral nucleus |
| | Arcuate nucleus | Lateral tuberal nuclei |
| Posterior | Mammillary nuclei (part of mammillary bodies) Posterior nucleus | Lateral nucleus |



**Hypothalamus. Figure 1** Digrammaticrepresentations of the human hypothalamus in relation to the rest of the brain (*upper right*) and enlarged (*lower left*). A variety of landmarks and hypothalamic nuclei are labeled. Reproduced with permission from a drawing by Edward I. Pollak; http://mywebpages.comcast.net/epollak/PSY255_pix/PSY255_pix.htm.

The hypothalamus exerts these control functions by detecting peripheral cues, such as hormones, nutrients and salts and integrating them with various central and peripheral neuronal inputs, which also contain information about existing body conditions. In turn, the hypothalamus sends hormonal and neuronal outputs to the brain and peripheral tissues to adjust corresponding behavior and physiology. For example, hypothalamus regions implicated in the regulation of long-term energy homeostasis, the arcuate nucleus and ventromedial hypothalamus, by definition, need to "know" the amount of pre-existing body energy stores (fat) in order to determine the amount of energy intake and expenditure. This is accomplished by hypothalamic detection of the level of circulating adipohormone ►leptin, which is secreted by adipocytes (fat cells) in proportion to the total amount fat tissue.

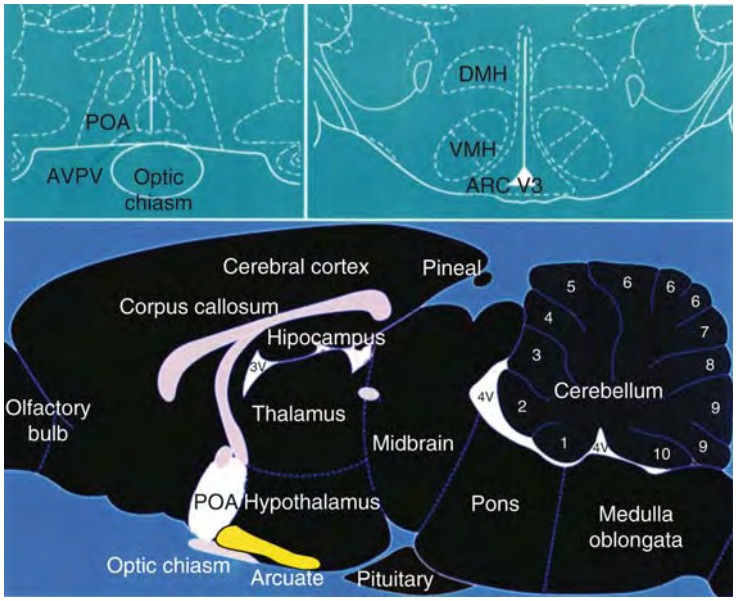
The anatomical characteristics of the hypothalamus sustain such functions in the sense that neurons within the hypothalamus are, in part, anatomically placed in close proximity to fenestrated capillaries, giving them access to various humoral signals that are unavailable to other regions of the brain. Thus, the subfornical organ (SFO), organum vasculosum of the lamina terminalis (OVLT), area postrema and the median eminance, so-called ►circumventricular organs, are in intimate contact with both blood and CSF and project widely within the hypothalamus and other brain sites. The neurohypophysis and the median eminence, on the other hand, are the sites of neurosecretion. All of these structures are densely vascularized.

The hypothalamus is also broadly connected with many parts of the CNS, including the reticular formation and autonomic effector sites in the brainstem, the limbic forebrain, including particularly the amygdala, septum and diagonal band of Broca, and the olfactory bulbs and cerebral cortex.

## Regulatory Inputs

### *Peripheral hormones and nutrients*

Hypothalamic neurons are directly targeted by peripheral hormones and nutrients, including leptin, ►ghrelin,



**Hypothalamus. Figure 2** Diagrams illustrating aspects of the rat hypothalamus in relation to the rest of the brain (*bottom*) and in a rostral (*upper left*) and more caudal (*upper right*) frontal section. The arcuate nucleus is shown in yellow. Abbreviations: *Arc* - arcuate nucleus; *AVPV* anteroventral periventricular nucleus; *DMH* dorsomedial hypothalamic nucleus; *POA* preoptic area; *Sp Co* spinal cord; *V3, 3V* third ventricle; *VMH* ventromedial hypothalamic nucleus; *4V* fourth ventricle.

angiotensin, insulin, pituitary hormones, steroids (including gonadal steroids and corticosteroids), cytokines, glucose and long chain fatty acids.

### *Neuronal projections*

The hypothalamus is responsive to day length and photoperiod for generating circadian and seasonal rhythms, olfactory stimuli, including those elicited by pheromones, which arouse sexual behaviors, and somatic (autonomic) inputs arising from the heart, stomach, reproductive system relayed through the brainstem, via structures such as the ►nucleus of the solitary tract, locus coeruleus, and ventrolateral medulla. For example, ►oxytocin secretion occurs in response to suckling and vasopressin secretion in response to cardiovascular stimuli arising from chemoreceptors in the carotid sinus and aortic arch. The hypothalamus suppresses feeding in response to visceral signals elicited by gastric distension, which are conducted to the hypothalamus mainly via spinal pathways that relay in the brainstem.

## Regulatory Outputs

### *Hormones*

Neurohormones produced in the hypothalamus, known as releasing hormones (Table 2), have the major function of stimulating the secretion of hormones by cells located in the adenohypophysis, or anterior pituitary gland (Table 3). Releasing hormones consist of simple amino acid chains (peptides) ranging in size from only three amino acids (thyrotropin-releasing hormone) to 44 amino acids (►growth hormone-releasing hormone). Releasing hormones are secreted into the hypophysial-portal system in the median eminence of the hypothalamus from which they are carried in the blood stream to the adenohypophysis. Certain other hormones, such as oxytocin and vasopressin (►antidiuretic hormone) are released by the terminations of axons of neurons that project from the hypothalamus proper to a fenestrated capillary bed in the posterior pituitary (Table 3).

## Neuronal Projections

### *Projections to areas caudal to the hypothalamus*

The hypothalamus sends descending signals through the medial forebrain bundle, mammillotegmental tract and dorsal longitudinal fasciculus (DLF). The descending fibers of the DLF originate in the hypothalamus, traverse the brain stem periaqueductal gray matter along the base of the fourth ventricle and continue into the spinal cord to synapse with preganglionic automomic neurons.

### *Projections to areas rostral to the hypothalamus*

These projections are carried by the medial forebrain bundle, mammillothalamic tract, fornix and stria terminalis, which contains fibers projecting from hypothalamus to the amygdala.

**Hypothalamus. Table 2** Hypothalamic hormones

| Name | Other names | Abbreviations | Location | Function |
|---|---|---|---|---|
| Corticotropin-releasing hormone | Corticotropin-releasing factor, Corticoliberin | CRH, CRF | parvocellular neuroendocrine neurons in the paraventricular nucleus | with vasopressin, stimulates anterior pituitary to secrete ACTH |
| ►Gonadotropin-releasing hormone | Luteinising-hormone releasing hormone | GnRH, LHRH | neuroendocrine neurons in the medial preoptic and arcuate nuclei | stimulates anterior pituitary to secrete LH and FSH |
| Growth hormone-releasing hormone | Growth-hormone-releasing factor, somatocrinin | GHRH, GHRF, GRF | arcuate nucleus neuroendocrine neurons | stimulates anterior pituitary to secrete growth hormone |
| Thyrotropin-releasing hormone | Thyrotropin-releasing factor, Thyroliberin, Protirelin | TRH, TRF | parvocellular neuroendocrine neurons in the paraventricular and anterior hypothalamic nuclei | stimulates anterior pituitary to secrete TSH |
| Somatostatin | Growth hormone-inhibiting hormone, Somatotropin release-inhibiting factor | SS, GHIH, SRIF | neuroendocrine neurons of the periventricular nucleus | inhibits secretion of growth hormone from the anterior pituitary |
| Vasopressin | Arginine vasopressin, Antidiuretic hormone, Argipressin | AVP, ADH | parvocellular neuroendocrine neurons in the [supraoptic nucleus\|supraoptic] and paraventricular nuclei | with Corticotropin-releasing hormone, stimulates anterior pituitary to secrete ACTH |
| Oxytocin | | | supraoptic nucleus | facilitates parturition (childbirth) |

**Hypothalamus. Table 3** Pituitary hormones

| | Hormone | Major target organ(s) | Major physiologic effects |
|---|---|---|---|
| Anterior Pituitary | ►Growth hormone | Liver, adipose tissue | Promotes growth (indirectly), control of protein, lipid and carbohydrate metabolism |
| | ►Thyroid-stimulating hormone | Thyroid gland | Stimulates secretion of thyroid hormones |
| | ►Adrenocorticotropic hormone | Adrenal gland (cortex) | Stimulates secretion of glucocorticoids |
| | ►Prolactin | Mammary gland | Milk production |
| Posteroir Pituitary | ►Luteinizing hormone | Ovary and testis | Control of reproductive function |
| | ►Follicle-stimulating hormone | Ovary and testis | Control of reproductive function |
| | ►Antidiuretic hormone | Kidney | Conservation of body water |
| | ►Oxytocin | Ovary and testis | Stimulates milk ejection and uterine contractions |

## Pathology

Defects of the hypothalamus often result in severe dysfunction of homeostasis and various endocrine disorders. For example, patients with pituitary tumors (adenomas) that damage certain part of the hypothalamus, rapidly gain body weight (obesity) [2]. A hamartoma (a benign tumor) located in the hypothalamus may produce excessive amounts of GHRH, leading to acromegaly. Excessive secretion of ►corticotropin-releasing hormone (CRH) leads to excessive stimulation of the adrenal cortex, resulting in Cushing's syndrome. On the other hand, reduced release of hypothalamic hormones could also result in corresponding defects. For example, a congenital deficiency of GnRH is associated with hypogonadism, in which the functional activity of the gonads is decreased and sexual development is inhibited. A deficiency of GHRH could cause abnormally small stature (dwarfism). Furthermore, because of the close

H

position of optic chiasm to the hypothalamus and pituitary gland, pressure from expanding tumors or inflammations in the hypothalamus or pituitary gland may cause severe visual defects or blindness.

## Hypothalamus, Lateral

### Definition

the part of hypothalamus merging with no distinct boundaries with the preoptic region rostrally and the ventral tegmental area caudally and bounded medially by the mammillo-thalamic tract and fornix and laterally by the medial edge of the internal capsule. The medial forebrain bundle, which contains most of the afferent and efferent fibers connecting the lateral hypothalamus with other brain structures, is located eccentrically within the lateral hypothalamus throughout its rostro-caudal extent. Lateral hypothalamic tissue organization is reticular formation-like and projections extend from it rostrally into the forebrain and cortex, caudally far into the brainstem and medial-ward into the medial hypothalamus. The complex functional organization of the lateral hypothalamus is concerned with arousal, control of the autonomics and probably in coordination with the medial hypothalamus, the synthesis of defensive, ingestive and reproductive behaviors.

## Hypothalamus, Medial

### Definition

the part of the hypothalamus lying between the lateral and periventricular zones. Extending from the medial preoptic area rostrally to the mammillary region caudally, the medial hypothalamus comprises a somewhat undifferentiated hypothalamic gray substance within which are found more obviously differentiated structures such as the ventromedial and dorsomedial hypothalamic nuclei. The medial hypothalamus is thought to play a role in the initiation of copulatory, aggressive and appetitive behaviors, probably in coordination with the lateral hypothalamus and to contribute to the coordination of neuroendocrine responses via its relations with the periventricular hypothalamic zone.

## Hypothalamus-Pituitary-Thyroid Axis

Eric Fliers
Dept of Endocrinology and Metabolism, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands

### Synonyms

Thyroid axis

### Definition

The serum concentrations of the thyroid hormones thyroxin (T4) and the biologically active diiodothyronine (T3) are kept between narrow margins. This is accomplished by a negative feedback system consisting of (i) the thyroid gland, which synthesizes thyroid hormones and secretes T4 and T3 into the circulation and (ii) the anterior pituitary gland, which produces thyroid-stimulating hormone (TSH or thyrotropin), the secretion of which is inhibited by thyroid hormone. TSH stimulates the synthesis and release of thyroid hormone in the thyroid gland. The set point for serum concentrations of thyroid hormones is determined by thyrotropin-releasing hormone (TRH), produced in the paraventricular nucleus (PVN) of the ►hypothalamus, which stimulates TSH release from the pituitary. The synthesis and release of TRH is inhibited by thyroid hormone. These components represent a classical example of a negative endocrine feedback system, generally referred to as the hypothalamus-pituitary-thyroid axis (HPT axis) or the thyroid axis.

### Characteristics

#### Description

TRH was the first hypothalamic hormone to be isolated and structurally characterized in the 1960s. This was followed by the immunocytochemical identification of

TRH neurons in the paraventricular nucleus (PVN) of the rat hypothalamus in the 1970s and 1980s and a key role for these neurons in the neuroendocrine regulation of thyroid hormone was gradually revealed. There appeared to be an inverse relationship between serum thyroid hormone levels and TRH mRNA expression in the PVN during experimentally induced hypo- and hyper-thyroidism [1] confirming a pivotal role for these neurons in this classical endocrine negative feedback loop. The rat PVN consists of magnocellular neurons containing, e.g. vasopressin and oxytocin in its lateral portions and of a parvocellular part in its more medial portions. TRH neurons in the medial and periventricular parvocellular subdivisions of the PVN project to the median eminence, which explains observations in experimental models of ►hypothyroidism showing increased TRH mRNA only in these subdivisions of the PVN (for review see [2]). These so-called hypophysiotropic TRH neurons project to the median eminence (ME) and terminate in its external zone, where TRH is released into the portal capillaries for transport to the anterior pituitary and regulation of TSH release. Hypophysiotropic TRH neurons in the PVN receive monosynaptic projections from leptin responsive neurons in the arcuate nucleus (ARC) containing either alpha-melanocyte stimulating hormone ($\alpha$-MSH) and cocaine and amphetamine regulated transcript (CART) or neuropeptide Y (NPY) and agouti-related protein (AGRP). These projections play a key role in the leptin mediated resetting of the thyroid axis during food deprivation, resulting in reduced TRH mRNA expression in the PVN, which contributes to lower serum concentrations of thyroid hormone in the fasting state [2].

In the 1990s TRH containing neurons and fibers were reported throughout the human hypothalamus, including some TRH neurons in the hypothalamic gray. The majority of TRH neurons reside in the dorsocaudal portion of the human PVN, with only a small number of magnocellular neurons expressing TRH. Both the suprachiasmatic nucleus (SCN), which is the circadian pacemaker of the brain acting as a biological clock and the sexually dimorphic nucleus (SDN) of the human hypothalamus contain a small number of bipolar TRH cells [3]. The exact efferent projections of hypothalamic TRH containing neurons in the human brain are unknown, but dense TRH fiber networks, e.g., in the tuberomammillary nucleus (TMN) and perifornical area suggest an important role for non-hypophysiotropic TRH neurons in the human brain as demonstrated earlier in the rat. The thyroid hormone receptor (TR) isoforms $\alpha$1, $\alpha$2, $\beta$1 and $\beta$2 are expressed by TRH cells in both the rat and the human PVN. Additional TR expression is present in the ARC of the rat and in the infundibular nucleus (IFN) of the human hypothalamus, which is the human homologue of the rat ARC [2,4].

Although the thyroid gland mainly secretes T4, most thyroid hormone actions are mediated via binding of the biologically active thyroid hormone T3 to its receptor. The biological activity of thyroid hormone in target cells is therefore determined in part by the intracellular concentration of T3, which depends on the activity of the iodothyronine deiodinases. In the brain, type 2 deiodinase (D2) is responsible for deiodination of T4 into T3, whereas type 3 deiodinase (D3) inactivates thyroid hormone by converting T3 into the biologically inactive diiodothyronine (T2) and T4 into reverse T3 (rT3). In the human hypothalamus, prominent D2 immunoreactivity is present in cells throughout the ependymal layer of the third ventricle, in glial cells within the IFN/ME region and in blood vessel walls. This distribution pattern of D2 immunostaining is in agreement with studies in rats, where electron microscopy studies have identified D2 immunoreactive cells as astrocytes, including ►tanycytes [2,4]. The distribution of hypothalamic D3 expression clearly differs from that of D2, showing intensely staining neurons in the human IFN and PVN. In contrast to D2, D3 is expressed exclusively in neurons showing a strong distribution overlap with TR, suggesting that D3 is expressed in T3-responsive neurons [5]. *MCT8* has recently been identified as a thyroid hormone transporter with a crucial role in thyroid hormone metabolism in the CNS, providing cells expressing deiodinases with thyroid hormone. The functional importance of *MCT8* became evident from observations in patients with severe psychomotor retardation who carry mutations or deletions in the *MCT8* gene [6]. Since TRH neurons in the human PVN express *MCT8* [5] and patients carrying *MCT8* mutations have unusual combinations of serum TSH, T3 and T4 [6], this protein is probably an important element in human HPT axis regulation.

The concept of thyroid hormone feedback at the level of the hypothalamus has traditionally focused on direct effects of thyroid hormone on TRH neurons. Taking into account more recent studies reporting hypothalamic D2, *MCT8* and TR expression, T4 may be taken up locally within the PVN from the circulation. Feedback following thyroid hormone uptake from the CSF represents an alternative possibility. In this model, thyroid hormone is taken up from the CSF in the third ventricle and transported by tanycytes to neurons in the arcuate nucleus that project to TRH cells in the PVN. Finally, thyroid hormone may have direct access from the circulation to the ARC or IFN in view of the absence of the blood-brain barrier in this part of the mediobasal hypothalamus. TR$\beta$2 is predominantly expressed in rat ARC neurons that may be able to sense T3 produced by glial cells expressing D2. NPY, POMC and AGRP containing neurons from the ARC project to TRH neurons in the rat PVN. If indeed thyroid hormone

may act via the vascular compartment-IFN/ARC-PVN route remains hypothetical at this stage.

In the human anterior pituitary, folliculostellate (FS) cells show prominent D2 and *MCT8* immunoreactivity, while granular (hormone producing) cells express TR and D3 [7]. FS cells have long cytoplasmic processes and are able to modulate anterior pituitary hormone secretion by endocrine cells. Both TR$\alpha$2 and TR$\beta$2 co-localize with TSH. The overlap between TRs and D3 expression suggests that thyroid hormone action and degradation may occur in the same hormone secreting cells, while T4 conversion to T3 occurs in a subset of FS cells that may be stimulated by TSH via TSH-R binding. This fits very well with the ultra short feedback loop regulation of TSH as proposed earlier [8]. However, earlier studies in rat anterior pituitary have reported D2 expression in thyrotrophs. The apparent difference in D2 expressing cell types between human and rat anterior pituitary suggests an interspecies difference, although at this time fatal illness in the patients studied cannot be completely ruled out as a confounding factor for the anatomical distribution of D2 expression observed in human specimens.

## Function

During ►hyperthyroidism, elevated serum T4 and T3 concentrations exert negative feedback action at the level of the PVN and the anterior pituitary, leading to suppressed serum TSH, which may even become undetectable. During hypothyroidism, the reverse situation is present with lower serum T4 inducing elevated serum TSH. Thus, serum TSH is frequently used in the clinical setting to detect and monitor (even slight) changes in thyroid function. In some clinical situations, however, the thyroid set point regulation is clearly different and not consistent with negative feedback regulation. Highly prevalent examples are ►critical illness and ►major depression.

During critical illness, serum T3 levels decrease without giving rise to higher TSH levels, a phenomenon known as nonthyroidal illness (NTI) or the low T3 syndrome [9]. The magnitude of the drop in serum T3 within 24 h after the onset of a severe physical stress such as surgery or trauma reflects the severity of the stressor. The acute changes in the thyroid axis have been interpreted teleologically as an attempt to reduce energy expenditure. In patients treated in intensive care units (ICU) for prolonged periods, a dramatic decrease in TSH pulsatility occurs. Specifically, a loss of TSH pulse amplitude occurs in this setting in direct relation to low serum levels of thyroid hormone. Continuous iv administration of TRH, in particular when administered together with the GH secretagogue GHRP-2, to ICU patients with prolonged critical illness restores TSH pulsatility as well as physiological levels of thyroid hormones [10]. Whether this partial restoration of the neuroendocrine features of critically ill patients is beneficial is unknown at present. The pathogenesis of NTI is incompletely understood but the paradoxically low TSH in the setting of decreased serum T3 points to a hypothalamic factor. In patients whose serum concentrations of TSH, T3 and T4 were assessed in a serum sample taken <24 h before in hospital death, a positive correlation was reported between total TRH mRNA hybridization signal in the PVN on the one hand and serum TSH and T3 on the other hand [11]. In addition, patients who die after severe illness have less than half the concentrations of tissue T3 in the hypothalamus and pituitary seen in patients who die acutely from trauma. The combination of low hypothalamic T3 and low TRH expression in the PVN implies a major change in hypothalamic thyroid feedback regulation during critical illness and suggests that the drop in thyroid hormone production in chronic severe illness has – at least in part – a hypothalamic origin [4].

Major depressive disorder has been associated with changes both in the HPT axis and the hypothalamic-pituitary-adrenal (HPA) axis. In the HPT axis a decrease in serum TSH, a blunted TSH response to TRH and an increase in serum free T4 (FT4) have been reported in inpatients by various authors as well as an increased prevalence of subclinical hypothyroidism and thyroid peroxidase (TPO) antibodies. Hypercortisolism in depression has been reported in many studies as reflected by elevated mean 24 h serum cortisol concentrations and increased 24 h urinary excretion of free cortisol. In view of the often blunted TSH response to TRH and the absent nocturnal TSH surge reported in depression, alterations in hypothalamic TRH expression may be involved in the pathogenesis of HPT axis changes in major depression. This was supported by one study comparing TRH mRNA expression in the PVN of patients with a long history of depression to age and sex matched controls by quantitative in situ hybridization, revealing a strong decrease in TRH mRNA expression in depression. That this decrease may be the result of hypercortisolism was supported by a subsequent study in glucocorticoid versus non-glucocorticoid treated patients showing decreased TRH mRNA expression in the glucocorticoid-treated group (for review see [4]).

## Hypothyroidism

### Definition

A clinical syndrome resulting from shortage of thyroid hormone, mostly as a consequence of thyroid gland failure. Among its features are depressed mood, decreased energy, weight gain, slowness and constipation.

►Hypothalamus-Pituitary-Thyroid Axis

## Hypotonia

### Definition

Abnormally reduced muscle tone seen in the acute phase of spinal cord injury, on in disorders of the peripheral motor system, such as lower motor neuron disease, peripheral nerve disease, neuromuscular junction disorders, or myopathy.

## Hypoxemia

### Definition

A condition in which there is an inadequate supply of oxygen in the blood.

## Hypoxia

### Definition

Lower than normal oxygen levels.

## Hypoxia-inducible Factor-1α (HIF-1α)

### Definition

A transcription factor involved with hypoxia signaling and oxygen sensing. This transcription factor can be involved with neuroinflammation and a variety of other inflammatory disorders.

►HIF-1 and Neuroinflammation

## Hysteria

Heinz Boeker
University Hospital of Psychiatry Zurich, Hospital for Affective Disorders and General Psychiatry Zurich East, Zurich, Switzerland

### Synonyms

Hysterical neurosis; Histrionic personality disorder; Conversion disorder; Dissociation

## Definition

The concept of hysteria or conversion disorder, firmly anchored in psychoanalytic theory, postulates the emergence of physical symptoms as an unconscious attempt to resolve painful psychic conflicts. By adopting the role of a sick person unconsciously, the conflict remains and the symptoms are perpetuated.

## Characteristics

### History/Background

Descriptions of hysteria were included in ancient Greek medical texts. At that time, the disorder was thought to result from movement of the uterus from its normal position (hence the name of the condition). In the second century AD, Galen rejected the idea that the uterus had been displaced and suggested instead that the condition was caused by an undue retention of uterine secretions. Various forms of uterine pathology were generally thought to cause hysteria until the seventeenth century, when the English physician, Thomas Willis (1621–1675) suggested that hysteria was caused by a disorder of the brain. By the nineteenth century, the importance of predisposing constitutional and organic causes of this brain disorder was recognized, and it was accepted that strong emotion was the usual provoking cause.

Charcot, a French neurologist in the late nineteenth century, believed that hysteria was caused by a functional disorder of the brain which led to caused symptoms also rendering patients susceptible to hypnosis so that new symptoms could be detected by suggestion. Charcot's ideas were developed further by Pierre Janet, who proposed that the disorder in hysteria was a tendency to dissociate, that is to lose the normal integration between various parts of mental functioning, together with a restriction of personal awareness, so that the person became unaware of certain aspects of psychological functioning, which would otherwise be within his awareness [1]. Freud and his colleague Breuer studied patients with hysteria and reported their findings in a paper "On the psychical mechanisms of hysterical phenomena" [2]. In a subsequent monograph, *Studies in Hysteria* [3], Breuer and Freud suggested that hysteria was caused by emotionally charged ideas which had become lodged in the unconscious of the patient at some previous time, and which were excluded from conscious awareness by a process which the authors called repression. They summarized this idea in the phrase "hysterics suffer mainly from reminiscences" [2, p. 7]. Freud suggested that the repressed ideas were usually sexual.

After Janet, a wider view of the emotionally charged ideas that could cause hysteria was supported by findings from the First World War, when hysteria was observed as a response to the stressful experience of battle.

The terms "dissociation" and "désaggregation" ("disaggregation") were coined by Pierre Janet [4,5]. Janet viewed the mental life of the individual as an aggregate of mental elements, which he described as "psychological automatisms." Under normal circumstances, psychological automatisms are unified in nominal consciousness and are accessible to voluntary control. Under traumatic, stressful conditions, however, single automatisms may become split off – dissociated – from the rest of consciousness and exert their effects autonomously. Genetically transmitted temperamental traits as well as early experiences, together with the individual's present physical condition define the capacity of a person for the mental integration of new information in general, and of traumatic experiences in particular.

Janet's model of dissociation is essentially based on the idea of a constitutional pre-disposition to dissociation ("dégénerancance"). The individual's premorbid vulnerability to dissociative disorders thus plays a decisive role. A dissociation, which is to be understood as passive, by no means requires an intense external trauma for it to be released. Rather, reactivity to exaggerate emotions, inherent in the individual's personality, often exerts a traumatogenic effect and leads to the generation of a psychopathological disorder.

The original position of Freud and Breuer [3] is still very close to that of Janet. They too viewed traumatic exposure during a sensitive developmental phase and a pre-disposition to dissociative psychopathology as decisive. Like Janet, they also recognized the importance of autosuggestion, used as a defense against traumatic experiences, in the pathogenesis of dissociative syndromes, as well as the special role of hypnotic techniques in the treatment of this unique class of disorders.

A major shift of emphasis took place with the conception of the dissociative disorders. The predominant idea was initially that of external events leading to traumatic excitation beyond the individual's objective ability to cope and thus to a feeling of psychophysical helplessness. Later, Freud increasingly identified the strong influence of unconscious phantasies and the attribution of meaning to "traumatic situations." What was originally thought of as an external, traumatic situation came to be viewed as an intra-psychic situation of danger, for which the ego can prepare itself in advance with controlled amounts of signal anxiety, and to which it can react with specific defense mechanisms, such as repression. While developing these ideas, Freud in no way denied the existence and clinical relevance of real trauma. Yet this concept of repression and defense neurosis became the leading paradigm of dynamic psychiatry in the following years and consigned Janet's concept of dissociation to obscurity for many decades thereafter [7].

Kretschmer (1960) [6] proposed an interpretation of the observation of hysterical disorders in wartime. He suggested that the symptoms resulted from an innate biological mechanism counteracting highly stressful experiences. He believed that hysterical symptoms could develop in psychologically stable people as a result of this "reflex" mechanism, and could subside rapidly when the stress receded.

Hilgard [8], making use of the newly developed concepts of cognitive psychology, proposed a neo-dissociative theory that had many points of contact with the psychology of Janet. In his model of the "divided consciousness," the psyche is viewed as an organized system of mental structures controlling perceptual, cognitive and behavioral processes in different areas. These mental sub-systems bear a certain resemblance to Janet's psychological automatisms, but may also be thought of as comparable to the modules and cognitive units postulated in the cognitive theories of parallel information processing. According to Hilgard, the central executive system may become dysfunctional and cease to integrate and organize the individual control structures, resulting in a state of divided consciousness [9].

Two major problems with the concept of hysteria have detracted from its clinical value. The first is the difficulty in establishing the occurrence, relevance and timing of a "sufficient" psychological stressor. The second is how to distinguish "unconscious" motivation from feigning. Faced with these difficulties and the possibility of overlooking treatable neurological conditions, clinicians have opted for a diagnosis per exclusion, stating hysteria or conversion disorder only after detailed investigations have failed to find an alternative explanation for the symptoms [8].

## Classification

The two major systems of classification have adopted somewhat different ways of classifying the conditions formerly known as hysteria. In DSM-IV, two terms, conversion and dissociative disorder, are used. Conversion denotes cases in which physical symptoms are the principal manifestations of the disorder; whilst dissociative disorder denotes cases in which psychological symptoms are the principal manifestations. In ICD-10, both kinds of manifestation are called dissociative disorders (with the term conversion used as an alternative means of indicating the same meaning) (cf. Table 1).

In DSM-IV, conversion disorders (those with physical symptoms) are classified under the rubric "somatoform disorder" (a rubric for mental disorders with mainly physical symptoms), while dissociative disorders have a rubric of their own. In ICD-10, all these disorders are classified together under the rubric "dissociative disorder".

**Hysteria. Table 1** Classification of dissociative or conversion disorders

| ICD-10 | DSM-IV |
|---|---|
| **F4 Dissociative (conversion disorders)** | **Dissociative disorders** |
| Dissociative amnesia | Dissociative amnesia |
| Dissociative fugue | Dissociative fugue |
| Dissociative stupor | |
| Other dissociative disorder | |
| Ganser's syndrome | |
| Multiple personality disorder | Dissociative identity disorder (multiple personality disorder)<br>Depersonalization disorder |
| Trance and possession disorder | Dissociative disorder not otherwise specified |
| Dissociative motor disorder | Conversion disorder (without further sub-divisions) |
| Dissociative convulsions | |
| Dissociative anesthesia | |

In the modern psychiatric classification systems, the dominant characteristic of the diagnostic category of dissociative disorders is the partial or total loss of the integrative functions of consciousness, memory, personal identity and perception of the self and of the environment. These disorders were referred to in earlier diagnostic manuals as "hysterical neurosis of dissociative type".

The term "histrionic personality disorder" can replace the term "hysterical personality disorder" (Histrio was an actor in ancient Rome). The historical forerunner of histrionic personality disorders was hysterical neurosis, which was always considered inconsistent and multifaceted, with conversion symptoms and dissociative phenomena at the forefront, and all descriptions have dwelled on the variety and diversity of the disorder. The term "hysteria" was abandoned as a category, not only because of discrimination and labeling problems, but also because it could not be shown that hysterical symptoms, as originally postulated, occurred primarily in Oedipus conflicts.

The main characteristics of histrionic personality disorder are a strong need for attention and recognition, suggestibility and a tendency towards affective instability and superficiality. Histrionic personalities have a sense of atmosphere, but also tend to dramatize and to manifest falseness and coquetry. They are largely unable to maintain a consistent pursuit of goals and value-orientation and are therefore inconstant, especially in relationships with other people and partners. Their typical thinking has been called "impressionistic".

There is an increased tendency for identification and traits such as empathy, sensitivity and theatrical skills, which can be positive, but can also allow the individual to mimic a series of conditions. According to Nemiah [6], dissociation plays a central role where hysterical mechanisms of repression, denial and hyper-emotionality, identification and identity-shift can favor a "consciousness-impairing" effect.

The term "conversion" is derived from Freud's hypothesis that the somatic symptoms are a symbolic solution to an unconscious conflict enabling a reduction of anxiety and the exclusion of the conflict from conscious awareness (a process called primary gain). Current theories stress the importance of social factors and regard conversion symptoms as a mal-adaptive variance of normal processes which, in some circumstances, are culturally accepted or even encouraged (e.g., possession states). *Belle indifference*, an apparent lack of concern about the symptoms, was stressed in past accounts of the condition, but it is not an invariable feature.

In DSM-IV this category denotes symptoms or deficits involving voluntary motor or sensory functions.

Conversion disorder, as defined in DSM-IV, is much less common, with a reported prevalence of between 1% and 3% among patients referred to psychiatrists. However, short-lived conversion syndromes, such as difficulty in walking or sensory complaints, are seen regularly in emergency departments.

In DSM-IV, conversion disorder is sub-divided as follows:

- With motor symptoms or deficits (e.g., psychogenic paralysis, psychogenic disorder of gait, psychogenic tremor, psychogenic dysphonia and mutism and globus hystericus, a feeling of a lump in the throat)
- With sensory symptoms or deficits (e.g., dissociative anesthesia, paresthesia, hyperesthesia and pain, as well as deafness and blindness)
- With seizures and convulsions (the patient does not become unconscious, the pattern of movements does not show a regular and stereotype form of seizure, and there is no incontinence, cyanosis or injury and the tongue is not bitten; EEG findings are normal)

Assessment of conversion disorder depends on the patient's history and an examination to ascertain the characteristic features, and on great caution in excluding neurological and other physical causes.

The cause of the condition is very variable. It is probable that most episodes are transient, but a minority have a chronic cause; recurrence is common.

## Etiology and Pathogenesis

There are, in essence, two conceptual approaches to the understanding of the causes of dissociative conditions:

- A complex mode of reaction to an external trauma
- Certain primary personality attributes that can predispose an individual to the occurrence of dissociation

### Dissociation as a Reaction to Trauma

Many patients with dissociative disorders report having experienced a severe psychological trauma, mostly during their early development. The most serious traumas described include sexual and physical abuse, emotional neglect and deprivation. It must be kept in mind, however, that most of the data published on this topic were gathered retrospectively and may thus give a distorted picture of the reality. The researchers and therapists favoring the explanation of a true post-traumatic reaction are opposed by those preferring that of a genetically pre-disposed personality [9].

A problem in many studies is the lack of distinction between different types of trauma, i.e., unexpected, single-event trauma versus continued or repeated exposure to trauma, or the presence or absence of protective compensation in a traumatized child. The relationship between trauma and dissociation indeed seems to be a close one, but it should not be thought of as linear or monocausal. The inter-relatedness of trauma, memory and dissocation should always be analyzed on multiple levels, reflecting the dilemma of "historical" versus "narrative truth" [10].

### Trauma and the Neurobiology of Dissociation

In the context of adjustment to a traumatic event, two basic modes of reaction may be distinguished. An individual typically reacts to an external threat with an alarm reaction consisting of an elevation of sympathetic tone in preparation for a basic fight- or flight-response pattern. This hyperarousal continuum is brought about mainly by the centrally driven peripheral secretion of epinephrine and norepinephrine, by the secretion of adrenal corticotrophic hormone (ACTH) and cortisol by the hypothalamic-pituitary-adrenal (HPA) axis, and by activation of the immune system.

On the other hand, a dissociative continuum is associated with a basic response pattern of surrender. It seems to be activated preferentially when an organized fight- or flight-response appears unlikely to succeed, or when this type of response is not yet fully developed, as in children. There is initially a stress-response with secretion of catecholamins and corticoids. However, in dissociation but not in hyperarousal, there is also a strong vagal activation. Moreover, the mesolimbic and mesocortical dopaminergic systems play an important role and, by way of the central reward systems, exert a primary influence on affect modulation. Collateral connections to the endogenious opioid system lead to a change in the perception of noxious stimuli and also to a distortion of the sense of time, place and reality.

Both response patterns can be combined, to varying relative extents, in basic adaptive styles.

A neurobiological inter-relationship of dissociation disorder and PTSD (post-traumatic stress disorder) is suggested by the fact that peri-traumatic dissociative symptoms have a high predictive value for the later development of PTSD.

## Hysterical Conversion and Brain Function

Hysterical conversion disorders represent "functional" or unexplained neurological deficits such as paralysis or somatosensory losses not explained by organic lesions in the nervous system, but arising in the context of "psychogenic" stress or emotional conflicts. Several recent studies have used functional brain imaging techniques (such as EEG, fMRI, PET or SPECT) in the attempt to identify specific neural correlates associated with hysterical conversion symptoms. Functional neuroimaging has revealed selective decreases in the activity of frontal and sub-cortical circuits involved in motor control during hysterical paralysis, decreases in somato-sensory cortexes during hysterical anesthesia, or decreases in visual cortex during hysterical blindness [11]. Such changes are usually not accompanied by any significant changes in elementary stages of sensory or motor processing, as measured by evoked potentials, although some changes in later stages of integration (such as P300 responses) have been reported. On the other hand, several neuroimaging results have shown increased activation in limbic regions, such as cingulate or orbito-frontal cortex during conversion symptoms, effecting different sensory or motor modalities. Taken together, these data generally do not support previous proposals that hysteria might involve an exclusion of sensory motor representations from awareness through attentional processes. Rather, they seem to point to a modulation of such representations by primary affective or stress-related factors, perhaps involving primitive reflexive mechanisms of protection and alertness that are partly independent of conscious control, and mediated by dynamic modulatory interactions between limbic and sensori-motor networks.

A better understanding of the neuropsychobiological basis of hysterical conversion disorder might therefore be obtained through future imaging studies comparing different conversion symptoms and employing functional connectivity analysis. This could also provide new insights into the brain mechanisms of self-awareness.

## A Contemporary Re-conceptualization of Hysteria

Yarom (1997) [12] presented a matrix of hysteria, which is a contemporary re-reading of Freud's basic conceptualization. It integrated oedipal concepts (referring to unconscious conflicts in the triangular relationship between both parents and the child) with others borrowed from object-relation theories, self-psychology and the inter-subjective approach. In this way, the focus of the issues of gender and sexuality in hysteria has been continued without the original roots being lost. The focus is on the content, whereas the structure may vary. Within the first axis of the matrix, Yarom proposes identifying the conflict of gender and sexual identity as the unconscious and conscious solutions adopted by a hysteric to the question "Am I a man or a woman?" Repression and conversion are incorporated to constitute the second and third axes of the matrix. Several defense mechanisms (repression, denial, dissociation and phantasy) are shown to be employed in the context of gender and sexuality, and along a continuum of personality structures. In this context, the turning to the body, the conversion, still acts as an effective language, to which therapists should listen.

## Psychotherapy

There is a consensus among experts that treatments should be planned and provided largely on an individual basis. Psychotherapeutic strategies are generally preferred to biological approaches. In view of the importance of severe trauma in the etiology and pathogenesis of both the simple and, in particular, complex dissociative disorders, emphasis should be placed on avoiding the danger of inducing further trauma through therapeutic measures. The treatment of a comorbid psychiatric disorder is geared towards the therapeutic standard for that particular disorder. Syndrome-oriented, mainly psychopharmacological treatment of this psychiatric comorbidity may become a priority when psychiatric emergencies arise or when access to the patient is blocked by the comorbidity, so that the selected form of psychotherapy can not be performed.

For acute dissociative and conversion disorders seen in general practice or hospital casualty departments, treatment by reassurance and suggestion is usually appropriate, together with immediate efforts to resolve any stressful circumstances that provoked the reaction. The general approach is to focus on the elimination of factors reinforcing the symptoms. It should be explained to the patient that he/she has a disability (as in remembering or moving arms and legs) not caused by physical disease but by psychological factors.

Patients with dissociative and conversion disorders often appear to respond well to psychodynamic psychotherapy or to psychoanalysis. Psychoanalysts working with hysteric patients find themselves in unconscious communication with the patient. The psychoanalyst may experience in his/her reveries that he/she is moved by particular mental contents narrated by the patient, and when the psychoanalyst echoes them, the patient usually responds by producing further material. This collaboration is of enormous importance in the outcome of such analysis, as the patient is a creatively contributing psychic partner to the psychoanalyst.

By interpreting transfer and counter-transfer processes, the therapeutic relationship is supposed to deal

not only with the Oedipus conflict, but also with desires for attention and care.

## Hysterical Amnesia

### Definition

Hysterical amnesia to forget something due to unconscious intrapsychical processes. Forgetting is just about certain events or persons whereas other things are well remembered.

►Personality Disorder

## Hysterical Aphonia

### Definition

Hysterical aphonia lost of voice due to unconscious intrapsychical processes.

►Personality Disorder

## Hysterical Gait

### Definition

Bizarre gait seen with hysteria-conversion reaction. While walking the foot is usually dragged or pushed ahead, instead of lifted. Frequently the foot is held dorsiflexed and inverted.

►Personality Disorder

## Hysterical Neurosis

►Hysteria

## Hysterical Torticollis

### Definition

Torticollis, psychosomatic in aetiology.

►Personality Disorder

## Ia Inhibitory Interneuron

### Definition

Population of glycinergic spinal interneurons, which exert reciprocal inhibition between motoneurons of antagonistic muscles. The interneurons receive input from a number of different sensory modalities as well as descending motor tracts. One of the important sensory inputs is from muscle spindle group Ia afferents and elicitation of stretch reflexes is therefore coupled with reciprocal inhibition of the antagonist motoneurons.

However, it should be noted that the Ia afferent input is only one of many sensory inputs and that the naming of the interneurons is solely explained by the way they were originally discovered. A major descending input is from corticospinal tract fibers which branch to activate agonist motoneurons and Ia inhibitory interneurons projecting onto antagonist motoneurons in parallel.

This ensures that antagonist motoneurons are inhibited when agonist motoneurons are activated during voluntary movements. The Ia inhibitory interneurons are the only interneurons in the spinal cord to receive (recurrent) inhibition from Renshaw cells. This connection – and its supraspinal control – may help to ensure a larger flexibility in the activation of muscles working on a joint, and may for instance help to ensure co-activation of antagonistic muscles by decreasing reciprocal inhibition.

►Nf-κB – Potential Role in Adult Neural Stem Cells

## ICC

### Definition

►Interstitial Cell of Cajal

## Ice-Pick Headache

### Definition

A recurrent severe, stabbing headache lasting less than one second occurring on any part of the head.

►Headache

## Ictal Phenomena

### Definition

Emotional changes occurring during seizures (icti) in ►chronic temporal epilepsy and consisting of transient

auditory and visual hallucinations, delusions, paranoia, feelings of unreality and depersonalization and of déjà vu (already seen), anger, fear, and sexual feelings.

## Identified Neuron

### Definition

A neuron that can be documented to occur as either a single copy or a small number of copies, and that can be characterized by repeated study in the same region of the nervous system in different individuals of the same species. Commonly, identified neurons are given a name that represents either their first identified function, anatomical location or some relatively unique feature.

## Identity

### Definition

Identity is either a relation that everything entertains with itself (sameness) or it is the characteristic properties of something that distinguish it unambiguously from other things. These different senses of identity are expressed in the questions "Is the evening star identical with the morning star?" and "What are the identity conditions of propositional attitudes?".

►Information

## Ideomotor Apraxia

### Definition

►Apraxia

## Idiopathic

### Definition

Medical term to indicate that the etiology (i.e., cause) of a disease is unknown.

## Idiopathic Hypersomnia

### Definition

A condition of excessive sleepiness that is likely caused by abnormalities in the central nervous system arousal pathways. Unlike narcolepsy, another hypersomnia of central origin, little is known about the underlying mechanisms idiopathic hypersomnia. Sleep times are generally longer than in narcolepsy, and naps tend to be longer and less refreshing. Objective sleep propensity is high when measured on the multiple sleep latency test.

This is currently a diagnosis of exclusion when other causes of hypersomnia have been excluded.

►Sleep – Developmental Changes

## Idiopathic Inflammatory Demyelinating Diseases (IIDDs)

### Definition

IIDDs of the central nervous system are a heterogeneous group varying in their clinical course, regional distribution, and pathology, and containing ►acute disseminated encephalomyelitis, ►neuromyelitis optica, and classical ►multiple sclerosis, and characterized by several immunopathological patterns potentially implicating different inflammatory, ►demyelinating, and apoptotic mechanisms that suggest the involvement of diverse pathogenic effector mechanisms.

►Acute Disseminated Encephalomyelitis (ADEM)
►Multiple Sclerosis
►Neuromyelitis Optica (NMO or Devic's Disease)

## Idiopathic Parkinsonism

►Parkinson Disease

## Idiopathic Parkinson's disease

►Parkinson Disease

## Idiothetic Cues

**Definition**
Synonym for self-motion cues. Typically contrasted with "allothetic cues."

►Spatial Learning/Memory

## Idiothetic Information

**Definition**
Stimuli provided by the body like vestibular, proprioceptive and motor command efferent copy inputs.

►Spatial Memory

## IEM

**Definition**
Inherited erythromelalgia.

►Erythromelalgia

## IGRF

**Definition**
The international geomagnetic reference field (IGRF) is a series of mathematical models describing the Earth's main field and its secular variation. The IGRF is the product of a collaborative effort between magnetic field modelers, and the institutes involved in collecting and disseminating magnetic field data from satellites and from observatories and surveys around the world. See http://www.ngdc.noaa.gov/IAGA/vmod/igrf.html.

►Geomagnetic Field

## Iguanid (Type)

**Definition**
Referring to the family Iguanidae, large-bodied South-American lizards.

►Evolution of the Brain: At the Reptile-Bird Transition

## ILD (Interaural Level Difference)

**Definition**
The difference in the sound pressure level of the sound in the two ears.

►Acoustics
►Neuroethology of Sound Localization in Barn Owls

## Illusion

**Definition**
A visual illusion occurs when there is a discrepancy between a physical stimulus and the perception of that stimulus, despite the normal functioning of the visual system. Generally, illusions are measured as follows:

An observer judges a test stimulus in isolation (called a pretest trial or baseline measure) and then judges it again, but this time with the addition of an inducing stimulus (called a test trial). The illusion, that is, the effect of the inducing stimulus on the test stimulus, is defined as the algebraic difference between the test and pretest judgments. Because on the test trial the test and inducing stimuli are presented together, an illusion is a simultaneous effect. For example, to measure the tilt illusion, an observer could be asked to make an isolated circular test grating look vertical or horizontal (pretest trial) and then do it again when the test grating is surrounded by an inducing grating tilted 15° clockwise of the test grating (test trial). This would make the vertical or horizontal test grating appear tilted slightly counterclockwise so the observer would have to set it slightly clockwise to now make it look vertical or horizontal again.

►Visual Illusions

# Illusory Contour

## Definition

A contour that is seen in the absence of any physical edge in the image. Also referred to as the subjective contour. The perceived shape of an illusory contour is induced by special alignment of local stimulus elements called inducers as their shapes and layout suggest an implicit object in front occluding other objects behind.

In the Kanizsa square, a square-shaped illusory contour is induced by four "pacman"-shaped inducers arranged appropriately such that their notches coincide with the apices of an implicit square.

►Perceptual Filling-In
►Visual Illusions

# Illusory Memory

## Definition

Memory for details or entire events that never occurred.

►Memory Distortion

# Image

## Definition

The projection of light onto a plane.

# Image-Mental

## Synonyms

Imagery

## Definition

The term "mental image" in cognitive science denotes mental representations that represent information depictively. This can be understood in a stronger sense: that mental images actually are pictures; or in the weaker sense: that they function in the same way as pictures (are only picture-like). In both claims, mental (or internal) images are usually defined in analogy to external pictures by some kind of similarity relation, mostly by structure ►isomorphism. According to this relation, parts or properties of mental images represent parts or properties of objects, and the relations between the parts or properties of the mental images represent relations between parts or properties of the objects represented. This holds particularly for spatial relations.

The term "mental image" is regarded as an umbrella term. It is often used ambiguously to denote either ►phenomenal images (what one "sees with the mind's eye"), certain functional states of the mind or the neurophysiological correlates of those states. Within the research on mental imagery in cognitive science, two theoretical viewpoints are in contest: ►pictorialism and ►descriptionalism [1,2]. Pictorialists [3–6] defend a picture theory of mental images. They claim (i) that mental images consist of two components: the surface or phenomenal image and the underlying representations; (ii) that the underlying representational system contains at least two sorts of representations with distinct formats or data structures: propositional encodings related to language and picture-like encodings related to sensory input; and (iii) that mental images play an important causal role within information processing. Descriptionalists [7,8] state (i) that the representational system contains only propositional representations with a unified language-like format; (ii) that mental images are reducible to ►structural descriptions that represent properties and spatial relations in an explicit manner; and (iii) that mental images (in the phenomenal sense) are therefore epiphenomenal.

## Description of the Theory

The concept of mental imagery has its roots in antiquity. It played an important role in the theorizing of the British Empiricists and has gained, after a decline in behaviorism, novel attention within cognitive science since 1960. Mental images were then postulated to explain more adequately some distinct behavioral features various experiments had pointed out. A highly influential set of experiments on mental imagery and mental rotation in the context of problem solving and information processing was conducted by Roger Shepard and Nancy Metzler [6]. In a variety of different settings, subjects were shown alphanumerical items, letters or pairs of figures depicting three-dimensional

geometric object in different forms. In the latter case, subjects were asked whether the figures are congruent or not. The outcome was that subjects needed the more time for deciding the more the figures were rotated: reaction time and degree of rotation are significantly correlated in linear proportion.

These findings seemed to support the plausible assumption that in order to solve the kind of task described, subjects imagine and then rotate one of the figures so as to superimpose it on the other in order to decide about congruency. If internal images are like external images, longer reaction times are to be expected since rotating external pictures takes time. If, in contrast, we assume that our cognitive system does not function the way but, e.g., by inspecting descriptions with lists of properties, we have difficulties to explain the differences in the reaction times observed. This interpretation is confirmed by another set of experiments on image scanning conducted by Stephen M. Kosslyn. These experiments showed a similar correlation between the actual distance of two points on a map and the time taken to scan internally from one point to another [4].

A famous early example of using the concept mental image in the context of psychology of memory is Allan Paivio's dual coding theory [9]. According to this theory, information can be stored in two independent but interconnected systems: verbally and pictorially. A particular item will be memorized more easily if it is decoded dually, i.e., in both systems. That is, e.g., more likely in the case of concrete concepts than in the case of abstract concepts.

The most influential work on mental imagery comes from Kosslyn. His early theory, orientated towards the cathode-ray tube metaphor (CRT-metaphor) (►Cathode-ray tube (CRT) metaphor), includes a computer model [4]. Within this model, images can be generated on a display from more abstract underlying representations. That is, the model contains a surface display, a memory system, and computational mechanisms to generate, maintain, inspect, and transform mental images on the display. The display is conceived of as a ►visual buffer that functions as short term memory. It is necessary both for inspecting visual information coming from visual perception and for retrieving it as constructed by mental imagery. It also accounts for typical restrictions like image resolution that can be observed in human imagery and in computational models as well [3]. The visual buffer depends on long term memory. In order to generate a mental image, information from visual perception has to be interpreted and encoded in long term memory, both propositionally and pictorially. Whereas propositional encoding describes the relevant properties and relations explicitly, pictorial encoding is thought of as a pixel matrix that preserves visual information particularly of spatial relations in an implicit manner, not by explicit description. Generating a mental image therefore requires a top-down activation of both types of representations. Thus, mental images necessarily have propositional aspects as well. They include an interpretation although they can be regarded as ►analogue data structures.

Cognitivists like Zenon W. Pylyshyn [7,8] have criticized the pictorialist's view on mental imagery, focussing on the following questions: (i) In what sense can mental images be said to be picture-like; (ii) to what extent is mental imagery determined by the underlying propositional representations, and (iii) how is mental imagery linked to perception? Following these questions, three types of objections have been developed within cognitive science: (i) a conceptual, *a priori* critique of mental imagery, (ii) a methodologically orientated discussion on the architecture of cognitive science, and (iii) an empirical approach aiming mainly at the neurophysiological basis of mental imagery. *A priori* arguments were presented in the 1960s and 1970s prominently by Daniel C. Dennett and Jerry A. Fodor [1], the methodological discussion worked out by Pylyshyn took place mainly in the eighties [7], and the work on the neurophysiological questions summarized by Kosslyn [5] became increasingly prominent since 1990.

1. *A priori* arguments try to show that the concept of mental imagery is inconsistent and therefore useless in cognitive science. These arguments normally address a picture theory of mental imagery, which assumes that mental images are pictures in a literal sense. According to one of these arguments, put forward by Dennett, pictures are informative with respect to various details but mental images are not. The picture of a tiger reveals a determinate number of stripes but the corresponding mental image normally does not provide such information. According to Ned Block, that sort of argument is not successful because it commits the photographic fallacy [1]: descriptionalists neglect that different types of pictures, e.g., photographs and sketches of stick figures, depict differently. Mental images do not have to be like photographs. Additionally, mental images do not have to share all properties with pictures. Even the strong view – that mental images are pictures in a literal sense – is only committed to the claim that mental images share some important properties with pictures, namely, that they are spatial.

   Philosophers have developed a number of important arguments against the ►resemblance theory of pictures that are essential also for formulating a theory of mental images. Surprisingly, these arguments do not play any substantive role within the imagery debate. The most influential attack on the

resemblance theory has been undertaken by Nelson Goodman who claimed that resemblance is neither necessary nor sufficient for something to be a picture. The resemblance relation is symmetrical and reflexive while the depicting relation is not. Pictorialists, however, have an alternative: They can understand similarity in terms of structure isomorphism, a more sophisticated similarity criterion which may be combined with a causal theory that links perception with imagery.

2. Pylyshyn has put forward a different, methodological type of critique [7,8] that hinges mainly on the concept of ►cognitive penetrability. According to this line of reasoning, a mental process is cognitively penetrable if it depends on semantic interpretations and changes systematically when the interpretations vary. The concept of cognitive penetrability is meant to provide a criterion for distinguishing different levels of the cognitive architecture. Only those processes that depend on semantically interpreted representations like beliefs and desires are subject to cognitive rules whereas processes that are cognitive impenetrable belong to the neurophysiological level and are subject to neurobiological laws, only. Based on these considerations, Pylyshyn presents a dilemma: mental images are either defined by intrinsic properties of the underlying representational medium, as the pictorialists claim. In this case they are cognitively impenetrable and should not be considered as functional states that are to be explained within cognitive science. Or mental image including the process of generating, inspecting, or transforming them, are determined by tacit knowledge. Then they are cognitively penetrable and better thought of as ►structural descriptions. Pylyshyn does not deny that people experience imagistic representations. His claim is only that if these representations are subject to cognitive science they must be cognitively penetrable and, therefore, have a propositional character. Appealing to these representations as tacit knowledge in explaining the empirical evidence about imagery allows then for the possibility that an imitation of the use of external pictures is responsible for the observed effects of mental imagery.
3. Pictorialists are not committed to identifying a spatial medium (e.g. a mental canvass) for mental imagery but only to the weaker claim that mental images are picture-like. Accordingly, various attempts have been made to avoid the problems Pylyshyn's tacit-knowledge-argument poses by defining mental images functionally [2,10]. However, those pictorialists who take the analogy between internal and external images literally, as Kosslyn does, are forced to identify some physical properties of the representing medium that preserve at least the spatial relations. These accounts claim that mental imagery and perception share the same neurophysiological basis. The decisive feature of mental imagery can then be seen in its perceptual equivalence [3]. Perceptual equivalence means that similar neural mechanisms in the visual system are activated no matter whether an object is imagined or actually perceived. Within this framework, the difference between imagery and perception can be explained with respect to different sources of activation. Whereas imagery entails top-down activation of the visual buffer caused by memory, perception relies on bottom-up activation caused by sensory input. This claim includes a correlation of imagery processes with neural processes that are usually activated in visual perception. These patterns are retinotopically mapped, i.e., correspond to the retinal image [5]. It is generally agreed in cognitive neuroscience that three levels of perceptual representations can be distinguished. Empirical findings suggest that imagery is not to be identified with low level representations that are associated with the primary visual cortex but rather with intermediate level representations that are associated with regions in the extrastriate cortex. At the intermediate level, mental images are organized in units similar to Marr's 2.5-D sketches, but since mental images can be reinterpreted under special circumstances, descriptive, high level representations must be involved as well [10].

## Imitation

### Definition

A behavior whereby an individual observes and replicates another's [behavior].

►Imitation Learning

## Imitation Learning

Akichika Mikami
Primate Research Institute, Kyoto University, Inuyama, Japan

### Synonyms

Learning by imitation

### Definition

►Imitation learning is learning by imitation in which an individual observes an arbitrary behavior of a demonstrator and replicates that behavior.

### Characteristics

#### Imitation in Humans and Animals

Imitation is the copying of a novel behavior. Arbitrary or unusual activity by the demonstrator leads to the emittance of similar, previously unemitted behavior by the observer. The target behavior should not already be part of the observer's repertoire. However, ruling out the prior existence of a behavior is usually difficult. Then, imitation can be defined as a relatively large increase in the probability of the demonstrated response, relative to that of an appropriate group that controls for all of the already-noted non-imitative causes of such behavior.

Although the word "imitation" can often be used in a broader meaning including the mimicry, imprinting, discriminated following or observational conditioning, in a more conservative meaning, imitation has been considered as an advanced behavior and a cognitive process. According to this view, imitation includes understanding of the behavior of the demonstrator and ability to reproduce that behavior. Imitation itself is not necessary to cooperate with learning. However, its effect often remains in each individual for a long period of time and it can contribute to the acquisition of a new behavior. Imitation is an efficient way to learn something new. It allows us to pass the experience of one individual on to others and it works more efficiently than trial-and-error learning. Imitation is especially effective in learning motor skills, such as, performing athletic sports or playing musical instruments. Imitation is also effective in learning creative works such as painting or composing music. Thus, imitation can work as part of a learning process. Imitation learning is also a core topic of research in robotics. Imitation learning may be a powerful mechanism for reducing the complexity of search spaces for learning and offer an implicit means of training a machine.

Neonatal imitation has been reported in macaques, chimpanzees as well as in humans. Macaques imitate lip smacking and tongue protrusion from the first day of birth (Ferrari et al. 2006). This neonatal imitation disappeared within 7 days. They did not imitate hand gestures. Chimpanzees imitate tongue protrusion and other facial expressions within 2 months. Neonatal humans can also imitate various facial expressions from the first day of birth. It lasts for 2–3 months and then disappears. If true imitation can occur in newborns, it suggests that the mechanisms responsible for imitation are probably not cognitively based. Since the neonatal imitation starts very early in life and lasts for only a short period of time, it must be different from the true imitation of adulthood. At the same time, it must also be different to a simple reflex. Infants may have the ability to actively compare the visual information about the seen body movement with the proprioceptive feedback from their own movement in space. Neonatal imitation could be a sort of cross-modal matching.

Imitation of gestures in adult animals has been reported in chimpanzees, macaque monkeys, dolphins and a number of avian species. Chimpanzees can learn to respond correctly to the command "Do this" over some classes of behaviors. This was first demonstrated by Hayes and Hayes (1952) and was then replicated by Custance et al. (1995). More recently, Myowa-Yamakoshi and Matsuzawa [1] instructed the performance of 48 arbitrary actions consisting of different

bodily motor patterns and object directionality. Their chimpanzees could imitate 6% of them. For them, an object directed toward another external location was easier than a single object alone. Actions involving unfamiliar motor patterns were also more difficult for them to perform than those involving familiar motor patterns that were already present in the subject's repertoire. Thus, the chimpanzees could imitate, but could not imitate as well as humans. Macaque monkeys cannot imitate in natural conditions. However, imitation can be induced by joint attention. Kamashiro et al. [2] trained monkeys to follow the gaze or the pointing gesture of an experimenter. Then they showed the tongue-protrusion, manual actions such as nose-touching, hand-closing, cotton-separation, knob-touching or box-opening. Their monkeys could copy these actions from the experimenter. This result indicates that macaque monkeys have the potential ability to imitate.

## Neural Basis of Imitation

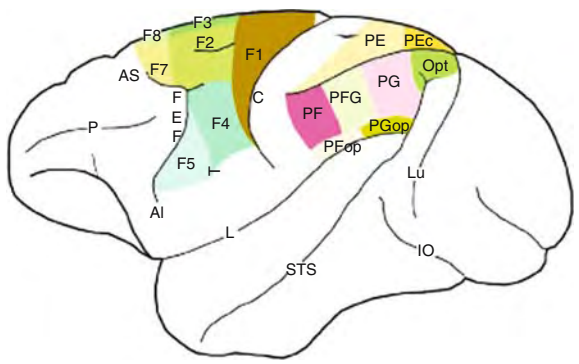
Brain areas involved in imitation have been explored in brain imaging studies. The observation of actions done by others activates a complex network including occipital, temporal, and parietal visual areas. Two cortical regions whose function is fundamentally or predominantly motor are also activated. Those two regions are the rostral part of the inferior parietal lobule (area PF and PFG) and the lower part of the precentral gyrus plus the posterior part of the inferior frontal gyrus (IFG). These regions probably form the core areas for imitation.

When two conditions, observation-only and observation-execution were tested, the fMRI activation was stronger during imitation trials than during the motor trials in four areas: the left pars opercularis of the IFG, the right anterior parietal region, the right parietal operculum, and the right superior temporal sulcus (STS) region (Iacononi et al. 1999, 2001). STS activation was highest when there was a matching between the action that was prepared and the action that was observed. Later experiments emphasized the importance of Broca's area when the action to be imitated had a specific goal (Grezes et al. 2003). In more complex imitation learning, musically naïve participants were scanned during observation of guitar chords played by a guitarist, pause after the observation and execution of the observed chords [3]. Event-related activation in observation-to-imitate condition was found in the inferior parietal lobule and the posterior part of the inferior frontal gyrus plus the adjacent premotor cortex. During pause, the middle frontal gyrus (area 46) plus structures, dorsal premotor cortex, superior parietal lobule, rostral mesial areas were activated. They suggested the contribution of the interaction between these areas.

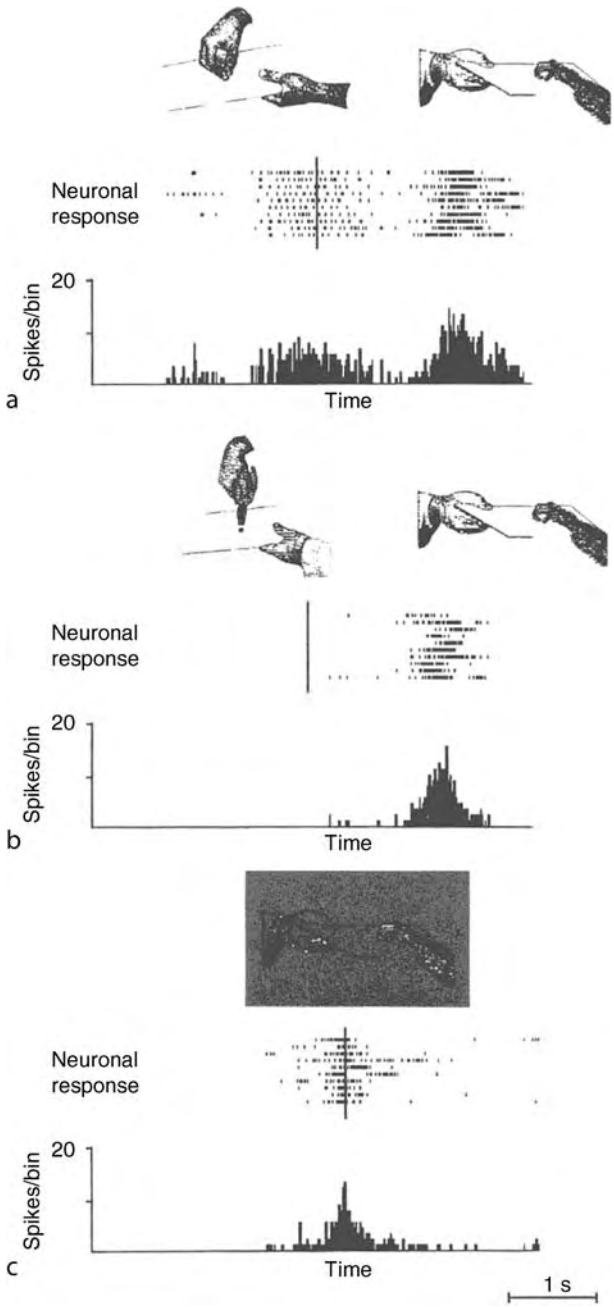
The neuronal basis of imitation learning is unknown. However, ►mirror neurons found in the premotor cortex (F5, Fig. 1) and in the inferior parietal cortex (PF/PFG, Fig. 1) are considered to be able to contribute to imitation. A mirror neuron is a neuron which fires both when an animal performs an action and when the animal observes the same action performed by another animal.

Thus, the neuron "mirrors" the behavior of another animal, as though the observer were itself performing the action [5] (Gallese et al. 1996, 2002, Fogassi et al. 1998). Fig. 2 shows an example of a mirror neuron. This neuron fired when the experimenter grasped a piece of food with his hand and when the subject grasped a piece of food. The neuron also fired when the subject grasped it in the dark, implying that the visual input is not necessary to activate this neuron.

To imitate someone's behavior, the observer needs to understand the act of the demonstrator. Since the mirror neurons are active during observation of the specific behavior, these neurons can contribute to the cognitive process of that behavior. Since these neurons are also active during the action of that behavior, they can bridge from the cognition of the behavior to the execution of that behavior. In general, a single neuron with multiple properties can contribute to integration of different kinds of information. In the case of a mirror neuron, two kinds of information, visual and motor, share the same single neuron. Thus, a neuron can integrate visual cognition of the motor act and the execution of that motor act. Although the true imitation is rare in macaque monkeys, the existence of mirror neurons in monkeys may indicate their potential ability to imitate. From these considerations, although there is no direct evidence that mirror neurons contribute to imitation,



**Imitation Learning. Figure 1** Lateral view of the monkey brain. The shaded area shows the anatomical location of the rostro-ventral premotor cortex (F5) and the inferior parietal lobule (PF/PFG) where mirror neurons were recorded. AI, inferior arcuate sulcus; AS, superior arcuate sulcus; C, central sulcus; L, lateral fissure; Lu, lunate sulcus; P, principal sulcus; IO, inferior-occipital sulcus; STS, superior temporal sulcus (modified from Fig. 1 [4]).



**Imitation Learning. Figure 2** Neuronal activities of a mirror neuron recorded in monkey F5. The behavioral situations are schematically represented in the upper part of each panel. In the lower part are shown a series of consecutive rasters and the peristimulus response histograms. a, the experimenter grasps a piece of food with his hand and moves it towards the monkey who, at the end of the trial, grasps it. The neuron discharges during grasping observation, ceases to fire when the food is moved and discharges again when the monkey grasps it. b, the experimenter grasps the food with a tool. Subsequent sequence of events as in a. The neuron response during action observation is absent. c, the monkey grasps food in the darkness. In a and b the rasters are aligned with the moment in which the food is grasped by the experimenter (vertical line across the rasters). In c the alignment is with the approximate beginning of the grasping movement (from Fig. 2 [1]).

mirror neurons can be candidate neurons to compose a neuronal circuit for imitation.

When the animal observed actions done by others, neurons in the superior temporal sulcus (STS) fired (Perrett et al., 1989, 1990). These neurons may also contribute to the generation of mirror neurons. Thus, the rostral portion of the ventral premotor cortex (F5), the inferior parietal lobule (PF/PFG) and STS can form a ►mirror neuron system in macaque monkeys. More recently, a brain-imaging study has revealed the activation in Area 45 and 46, in addition to F5, when monkeys were observing actions performed by others [6]. These areas may also be involved in imitation or ►intention learning.

There is no direct evidence for the existence of mirror neurons in humans. However, several brain areas activated during imitation are analogous to the areas where mirror neurons were recorded in monkeys. The brain areas activated during imitation in humans are often called the mirror neuron system. It has been suggested that mirror neurons might contribute to language acquisition. This idea is based on the fact that the area F5 of monkeys probably correspond to or overlaps with the Broca's area in humans. Imitation involves some degree of intentionality. The contribution of mirror neurons in ►intentional attunement has been also suggested. However, no plausible neural models have been put forward yet to describe how mirror neuron activity supports cognitive functions such as imitation learning, intention attunement or language acquisition. These topics are open for future research.

# Immediate Early Gene

## Definition

A gene whose expression can be triggered by specific kinds of inputs to cells and can, in turn, regulate expression of other genes. The genes that it regulates are not necessarily the same from one cell populations to another.

# Immune-based Therapy

## Definition

Treatment of acutely or chronically damaged tissue by harnessing an immune response, which facilitates the generation of a local response that supports cell survival and renewal and results in tissue regrowth.

# Immune Evasion

## Definition

Escape from immune surveillance.

►Immune Surveillance

# Immune Surveillance

## Definition

Ability of the immune system to maintain vigilance for any deviation from homeostasis.

# Immune System

## Definition

A set of organs or parts in the body serving a particular function, namely defense of the internal environment against hostile exogenous agents (invading microorganisms) or endogenous factors (of physiological origin). It consists of two arms: "innate" immunity (natural killer cells, basophils, phagocytic cells including macrophages) that fights invading hostile agents without needing to specifically recognize them, and "adaptive" immunity (T and B lymphocytes), whose defensive activity requires specific recognition of the hostile agent.

[2]Department of Pharmacology, Dartmouth-Hitchcock Medical Center, Lebanon, NH, USA

## Synonyms

Pain and immune system

## Definition

It has been gradually realized that although pain sensation, transmission and perception is mediated through a "wired" network of the nervous system; the immune system, the major host defense system in the body, is actively involved in every aspect of pain, including etiology, initiation and progression. Both traditional immune cells (circulating and tissue residing ►leukocytes) and nervous system resident glial cells (microglia, astrocytes and Schwann cells) are recognized as essential players in the pathophysiology of persistent pain states. In addition, it has become increasingly accepted that diseases of the immune system precipitate and enhance behavioral pain sensitivity (summarized in Fig. 1).

## Characteristics

### Immunological Disorders Associated with Pain Symptoms

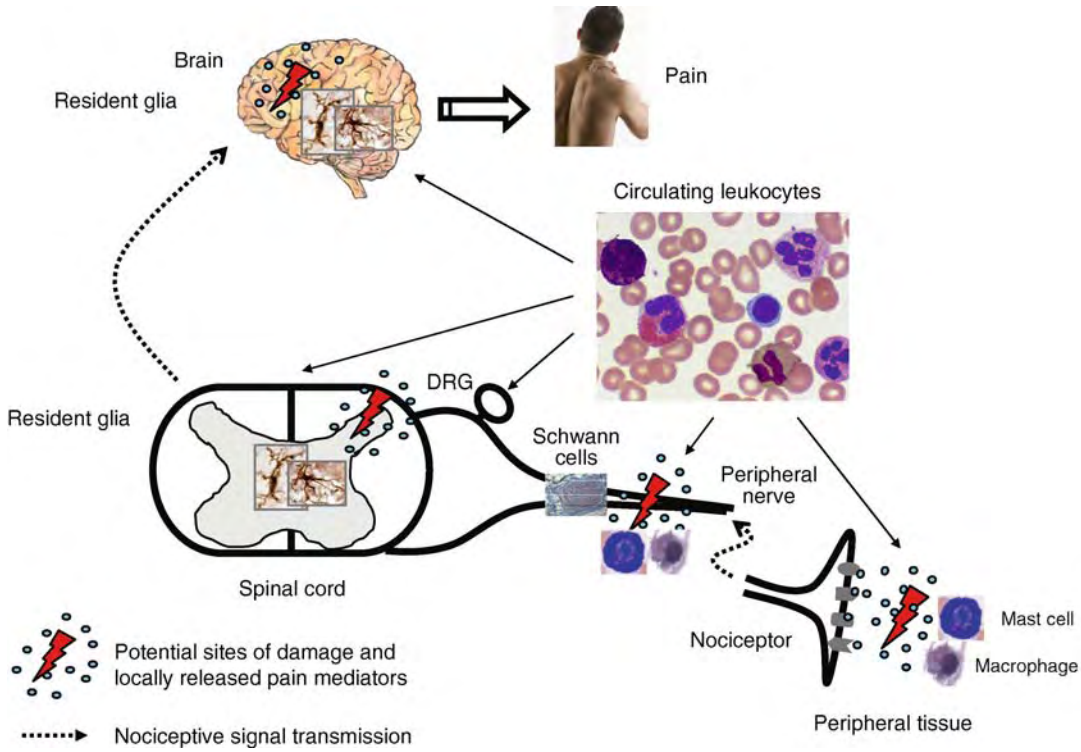
Immunological disorders are a significant cause of pathological pain. ►Autoimmune diseases are characterized by a dysregulation of an immune response that leads to the targeting of self components either in a specific tissue/organ or systemically. Autoimmune diseases often lead to inflammation and pain, and are the leading causes of disability among the elderly in the United States.

Rheumatoid arthritis (RA) is a chronic destructive disease, featuring persistent inflammation in the synovium of peripheral joints in a symmetric distribution. The subsequent cartilage damage and bone loss in joints is the hallmark of the disease. Although the etiology is still unknown, abnormal immune responses targeting the joint are believed to be the significant players in the pathogenesis of RA. Infiltrating leukocytes, particularly activated $CD4^+$ T lymphocytes, $CD8^+$ Tlymphocytes, B lymphocytes and ►macrophages are observed in the synovial membrane of the affected joints. Evidence indicates a key role of macrophage-produced proinflammatory cytokines such as tumor necrosis factor (TNF)-α and interleukin (IL)-1β in RA. These studies led to the concept and successful use of TNF-α-targeted treatments of RA in patients [1].

Multiple sclerosis (MS) is characterized as specific destruction of the CNS leading to demyelination and neurodegeneration. Pain is a common symptom in MS patients and moderate to severe pain may occur throughout the body. Due to the damage of pain processing systems in the CNS, it is often referred to as a central pain syndrome. The etiology of MS is still unknown, although a pathogenic mechanism of autoimmune responses targeting CNS myelin has been proposed and supported by animal models of MS and some clinical studies. Cytokines, including interferon (IFN)-γ, TNF-α, IL-23 and IL-17, are positively associated with disease activity, while IFN-β negatively modifies disease through its anti-inflammatory and/or immunosuppressive effects. Long-term IFN-β administration has become the routine treatment for patients with relapsing remitting MS to reduce the frequency of relapses.

Diabetes mellitus (DM) is a metabolic disorder and one of its subtypes is caused by autoimmune responses targeting the insulin producing β cells of the pancreas. Diabetic neuropathies include polyneuropathy, mononeuropathy and polyradiculopathy, with symmetric polyneuropathy the most common form. Symmetric polyneuropathy often presents as a sensory disorder that starts in the extremities and spreads proximally. Neuropathy can be either acute or chronic and can be painful. In most cases, pain subsides eventually with the progression to anesthetic neuropathy.

Painful neuropathies associated with viral infectious diseases are most prevalent in human immunodeficiency virus (HIV) and reactive human ►herpes virus infections. HIV is a RNA retrovirus that specifically targets $CD4^+$ cells, resulting in a decrease in peripheral $CD4^+$ T lymphocytes, decreased immunity, and the development of the acquired immunodeficiency syndrome (AIDS). HIV-associated neuropathies include



**Immune System and Pain. Figure 1** Overview of the immune system and pain processing. Pain is modulated via a neural/immune/glial network throughout the neuroaxis: nociceptors in the periphery, afferent nerves, sensory neurons in the DRG, and at the spinal cord and brain. Pain can be initiated by injury or disease localized at the peripheral tissue, nerve or in the CNS. Local resident immune cells (mast cells and macrophages surrounding the peripheral nerves or nerve terminals and glial cells in the nervous system), infiltrating leukocytes (both peripherally and centrally) and factors released by these cells can be actively involved in nociceptor activation, transmission to higher centers and perception.

HIV-associated distal symmetrical polyneuropathy (DSP), mononeuropathy and progressive polyradicularopathy. DSP is the most frequent neurological complication related to HIV infection and occurs in about one-third of patients with HIV infection. Similar to diabetic polyneuropathy, painful DSP is most prominent in the toes and soles of the feet in symmetrical distribution. DSP is often correlated with advanced stages of HIV infection, low $CD4^+$ T lymphocyte count and high plasma HIV loads. Anti-viral treatments, particularly dideoxynucleoside, have also been shown to be risk factors in DSP development.

Herpes simplex virus (HSV) and varicella-zoster virus (VZV) are human DNA herpes viruses that can be maintained in neurons after primary infection and cause recurrent infection upon reactivation. Both primary and recurrent HSV infections are related to painful mucosal and skin ulcerative lesions. Recurrent VZV infection, herpes zoster or shingles, involves localized skin lesions and severe pain along the distribution of affected nerves. A painful condition, known as postherpetic neuralgia, can last long after healing of the skin lesions. It is interesting to note that stress and immunosuppressants can induce viral reactivation, however the underlying mechanisms are unknown.

## Peripheral and CNS Immune Mechanisms of Pain

Immune cells involved in the pathophysiology of pain include leukocytes that act at peripheral or CNS sites such as the dorsal root ganglia (DRG), spinal cord and activated nervous system resident glia (i.e. Schwann cells, microglia and astrocytes). Immune factors released by these cells include but are not limited to cytokines (proinflammatory cytokines are particularly important in the development of pain) and chemokines.

### *Tissue Resident and Infiltrating Leukocytes*

The tissue leukocytes involved are mainly ►mast cells and leukocytes that have long been known to mediate allergic reactions. Mast cells can be activated by damaged peripheral nerve and non-nerve tissue, and quickly release substances stored in their cytoplasmic granules. Several of these substances, including histamine, proteases and cytokines, can sensitize nociceptors and activate sensory afferent neurons, as well as recruit circulating leukocytes into the injured

site [2]. Circulating leukocytes can penetrate blood vessels and enter into the site of tissue damage upon injury or disease, becoming infiltrating leukocytes. The major types of infiltrating leukocytes are ►neutrophils, macrophages and T lymphocytes. All of these have been identified as present in peripheral nerve and DRG following nerve injury. Studies depleting a subtype of leukocytes, or using mutant rodents that lack a particular leukocyte subset or the ability to recruit leukocytes into injured sites, highlight the critical roles of infiltrating leukocytes in pain genesis [2]. Interestingly, infiltrating leukocytes with either macrophage or T lymphocyte morphology have also been detected in the spinal cord following peripheral nerve injury [3]. Infiltrating leukocytes can either act independently by releasing cytokines, chemokines and reactive oxygen species (such as nitric oxide) or function through an interaction with CNS resident cells (microglia and astrocytes) to enhance pain sensitivity.

Neutrophils and macrophages are cells involved in the non-specific, first-line defense of innate immunity (►innate immune responses), while T lymphocytes are cells within the ►adaptive immunity arm and are capable of specific recognition. Microglia have been shown to express increased content of the major histocompatibility complex class II (MHC class II). This molecule is involved in specific ►antigen presentation to T lymphocytes in ►adaptive immune responses, in a rodent nerve transection-induced neuropathic pain model. Also, MHC class II knockout mice exhibit decreased pain-like behavior post-nerve injury. These results led to the postulation that self antigens may be liberated after nerve injury and these antigens can specifically activate the adaptive immune responses mediated by T lymphocytes.

### CNS Resident Immune and Glial Cells

CNS immune cells include microglia which are bone marrow and monocyte derived and are the intrinsic macrophages in the CNS. As the first cellular defense in the CNS, microglia respond to a tissue disturbance by migrating towards the site of injury, proliferating to amplify their capacity to respond, phagocytosing any dead cells and debris, expressing certain activation surface molecules, and releasing soluble factors such as cytokines and chemokines. Activated microglia have been observed in multiple animal models of neuropathic pain as well as in animal models of MS. Mediators including ATP, bradykinin, substance P and prostaglandins have been shown to be able to activate microglia [2]. Minocycline, a microglial-inhibiting agent, is effective in both preventing [4] and reducing existing [5] pain-like behaviors in rodents after peripheral nerve transection and spinal cord injury, respectively. These studies indicate a role of microglia in both pain initiation and maintenance. Microglia have been shown *in vitro* to release cytokines and chemokines and to interact with other effector cells via increased expression of some surface molecules such as MHC class II. Additionally, signaling through microglial receptors P2X4 and toll-like receptor 4 (TLR4) has been reported to be critical in the development of neuropathic pain and may be involved in the initial activation of microglia after nerve injury [6,7].

Astrocytes, derived neuro-ectodermally, play a role in maintaining CNS homeostasis and have been recognized to possess various immune features, including immune marker expression, antigen presentation, and production of cytokines and chemokines. Thus, astrocytes can be viewed as "immunocompetent cells." Increased glial fibrillary acidic protein (GFAP) expression due to a hypertrophic response of astrocytes (thought to be sign of astrocytic activation) is reported in multiple animal models of pain. Non-specific glial modulators such as fluorocitrate are effective in preventing and reversing existing pain behaviors accompanied by decreased spinal GFAP expression in rodent models of pain. However, because specific glial inhibitors are not currently available, it is difficult to determine the role of distinct glia in pain etiology. It has been suggested that astrocytes may be more involved in the maintenance of neuropathic pain since GFAP and S100B (another protein expressed by astrocytes) demonstrate a delayed but sustained spinal expression after nerve injury. Non-immune functions of astrocytes, such as neurotransmitter regulation through glutamate transporter regulation, have also been implicated in pain processing [8]. Schwann cells which provide the myelin sheath for axons in the peripheral nervous system have also been reported to exhibit immune functions, including the production of algesic factors (such as TNF-α and IL-1β). More recently, direct support of Schwann cell-producing TNF-α has been demonstrated in nerve injury-induced neuropathic pain [9].

### Proinflammatory Cytokines

IL-1β, TNFα and IL-6, produced by neutrophils, mast cells and macrophages, are critical mediators in acute and chronic inflammatory responses. They are also well-known algesic factors and can be detected at the site of injury of most painful disorders. Administration of these cytokines can produce pain-like behaviors, while neutralizing them can prevent or reduce these behaviors in animals. In addition to their role in active recruitment of circulating leukocytes, proinflammatory cytokines dose dependently affect the sensitivity of nociceptors in the periphery and interfere with pain processing in the CNS. Several mechanisms on how proinflammatory cytokines promote pain have been proposed: (i) Interaction with specific cytokine receptors expressed on nerve terminals and somata (such as receptors for IL-1 and TNFα), which induces a cascade of signaling events within the neuron and increases their excitability to noxious stimuli; (ii) Mediating production

of other algesic factors (e.g. prostaglandin $E_2$ ($PGE_2$) by IL-1β) that can act on their receptors on nerve terminals to further sensitize nociceptive responses; and (iii) Non-membrane receptor-mediated pathways have also been observed. For instance, IL-6/soluble IL-6 receptor complex has been shown to directly shift the activation threshold of nociceptors to noxious stimuli. A TNFα trimer can insert itself into the cell membrane and form a nonspecific cation channel, modifying sensory signal transduction. Other cytokines such as IFN-γ can contribute to the inflammatory responses and has also been implicated in T lymphocyte-mediated pain-like behaviors in rodents.

### *Chemokines*

Chemokines are chemotactic cytokines that are small secreted proteins which attract leukocytes into the site of tissue damage in a local inflammatory response. Strategies involving the use of chemokine receptor knockout mice and the administration of neutralizing antibodies confirm the involvement of chemokines in pain. Several chemokines, including monocyte chemoattractant protein-1 (MCP-1, CCL2), RANTES (regulated on activation, normal T cell expressed and secreted, CCL5) and fractalkine (CX3CL1), have been vigorously investigated for their roles in the pathophysiology of pain. Chemokines serve their functions in pain development, not only by recruiting leukocytes into the injury site, but also through several unique mechanisms [10]: (i) Sensory neurons in DRG express receptors for various chemokines, and ligation of these chemokine receptors can reduce DRG's threshold in responding to noxious stimuli resulting in hyperalgesia; (ii) The chemokine CCL3 can cross-sensitize the transient receptor potential vanilloid 1 (TRPV1) cation channel commonly expressed on nociceptive neurons and required for certain types of thermal hyperalgesia; and (iii) CNS-released fractalkine can bind to receptors expressed by microglia and enhance proinflammatory effects in the CNS.

In conclusion, peripheral and CNS immune responses are actively involved in every aspect of pain, including both acute and persistent pain as well as pain resulting from immunological disorders. Modulation can occur throughout the neuroaxis from peripheral nociceptors to sensory processing at all levels of the CNS. Targeting these specific immune responses and cell types may yield novel drug targets for the treatment of pathological pain conditions.

# Immunocytochemical Techniques

## Definition

This is a set of techniques for using antibodies to visualize the location and distribution of target molecules in cells or tissue. Typically these techniques consist of two steps. First, the cells or tissue are treated with a solution containing an antibody, called the primary, for the target molecule. These primary antibody molecules adhere specifically to the target molecule. Second, the cells or tissue are treated with a solution containing a fluorescent molecule, called the secondary, that adheres specifically to the antibody. Thus after both steps the target molecule is marked with a fluorescent molecule.

# Immunocytochemistry

## Definition

The techniques of using selective antibodies to visualize the distribution of a specific protein within cells.

# Immunoglobulin Superfamily Cell Adhesion Molecules

Yoshihiro Yoshihara
RIKEN Brain Science Institute, Wako, Saitama, Japan

## Definition

Cell surface molecules that contain one to several ►immunoglobulin-like domains (Ig-like domains) in their extracellular region and that play roles in various cell-cell interaction events such as recognition, adhesion and signal transduction. Ig superfamily cell adhesion molecules (IgCAMs) comprise one of the largest gene families in the genome of various animal species.

## Characteristics

### Structures

The Ig-like domain is composed of 70–110 amino acid residues and has a globular structure containing two β-sheets, each of which consists of 3–5 anti-parallel β-strands. A hallmark of typical Ig-like domains is the presence of two conserved cysteine residues forming a disulfide bond that stabilizes the overall domain structure [1,2].

Most IgCAMs are type I integral membrane proteins composed of an N-terminal signal peptide, an extracellular region with Ig-like domains, a single transmembrane segment and a C-terminal cytoplasmic region. The extracellular regions of IgCAMs are the principal site of trans- and cis-interactions with molecules on the target cell membrane or on the same cell surface, respectively. The cytoplasmic regions play crucial roles in intracellular signal transduction and association with cytoskeletal proteins. Several IgCAMs lack the transmembrane/cytoplasmic regions and are attached to plasma membrane through another type of linkage structure, a glycosylphosphatidylinositol (GPI)-anchor. The GPI-anchoring structure may offer several advantageous properties to cell recognition/adhesion molecules, such as restricted localization in a specialized membrane compartment called a lipid raft, higher lateral mobility in plasma membrane compared with transmembrane proteins and GPI-specific phospholipase D-mediated release into the extracellular space, resulting in either turning off the switch for cell-cell interactions or producing soluble forms which might function as signal-transducing ligands or dominant-negative molecules.

Neural IgSF molecules can be classified into four groups based on their domain organization (Fig. 1). Group I includes molecules whose extracellular regions consist exclusively of Ig-like domains. The smallest molecules in the group I are P0 and Thy-1 that possess only one Ig-like domain, while the largest one is ►telencephalin with nine tandemly arranged Ig-like domains. Group II includes molecules whose extracellular regions contain several Ig-like domains and fibronectin type III (FnIII) domains. Crystallographic studies revealed that the secondary structure of the FnIII domain is highly homologous to that of the Ig-like domain, having two opposing β-sheets with four and three antiparallel β-strands. Most of the IgCAMs belonging to group II are localized on axonal surfaces, as represented by L1, TAG-1, Robo and DCC. Group III consists of molecules that possess tyrosine kinase (TK) or tyrosine phosphatase (TP) domains in the cytoplasmic region. Hence the molecules belonging to group III are signal-transducing receptors for secretory ligands such as growth factors and neurotrophic factors. Group IV includes molecules whose extracellular regions contain Ig-like domains and other motifs such as a thrombospondin domain, a Sema domain, EGF-like repeats or a MAM domain.

## Functions

Neural IgCAMs play extremely diverse roles in various cell-cell interaction events in both the developing and mature brains. This review focuses on three important functions of IgCAMs, cell adhesion, axon guidance and dendritic development and synapse formation.

### Cell Adhesion

Many IgCAMs act as cell adhesion molecules. The mode of adhesion mediated by Ig-like domains is divalent and cation-independent, whereas other neural adhesion molecules such as cadherins and integrins require $Ca^{2+}$ or $Mg^{2+}$ for their adhesive functions. One of the representative structures in which IgCAMs play important roles as adhesion molecules can be seen at the sites of myelination of axons (Fig. 2a).

The compaction of myelin is mediated by P0, the smallest IgCAM as well as the most abundant structural protein of the peripheral myelin sheath of Schwann cells. A myelinated axon is compartmentalized into four segments, node, paranode, juxtaparanode and internode. Distinct sets of IgCAMs belonging to group II are involved in axon-myelin adhesion in these different segments, NrCAM and neurofascin-186 at the nodes, ►contactin and neurofascin-155 at the paranodes and TAG-1 at the juxtaparanodes. Perturbation of these IgCAM functions results in abnormal localization of ion channels and cytoplasmic adaptor molecules at the individual axon-myelin contact sites [3]. Other types of cell adhesion events mediated by IgCAMs in the nervous system include axon fasciculation and synapse stabilization.

### Axon Guidance

During development, newly generated neurons extend axons toward their target regions through a series of

(b) IgCAMs involved in axon guidance of commissural neurons in the spinal cord. (c) IgCAMs involved in dendritic morphogenesis and synapse formation.

events called chemoattraction and chemorepulsion and make synaptic connections with appropriate partner cells. In recent decades, a number of secreted factors and receptors that promote axon elongation and/or that guide axonal growth cones to correct target regions have been identified. In particular, the commissural neurons in the spinal cord provided a good model for studies of molecular mechanisms of axon guidance (Fig. 2b) [4]. Several IgCAMs are expressed in developing chick commissural neurons, including axonin-1 (TAG-1), NgCAM (L1), DCC and Robo. The commissural neurons located in the dorsal spinal cord project axons toward the ventral midline structure, the floor plate. The fasciculation of commissural axons is mediated by the interaction between NgCAM and axonin-1. The floor plate produces a chemoattractant, netrin-1, which acts on its receptor DCC expressed at the growth cones of commissural axons. The entry of commissural axons into the ventral midline structure is dependent on the interaction between axonin-1 on the axons and NrCAM on the floor plate. Once having crossed the midline, the commissural axons never recross the midline owing to a mechanism mediated by a chemorepellent, Slit, which is released from the floor plate and which acts on its receptor Robo on the growth cones of axons that have crossed. Thus, IgCAMs play different and important functions at multiple steps of commissural axon guidance. Other examples of IgCAM functions in axon guidance process have been reported for myelin-associated glycoprotein (MAG) as an

inhibitor of axon outgrowth acting on Nogo receptor [5], for Unc5H as a receptor on the trochlear motor axons for the chemorepellent netrin-1 [5], for Robo2 as an crucial molecule for olfactory axon guidance in zebrafish [7] and for TAG-1, DCC, Thy-1, OCAM, Robo and ►L1 as differentially expressed markers of mitral cell axons in the developing lateral olfactory tract [8].

### Dendritic Development and Synapse Formation

Not only in axon guidance, but also in dendritic development, IgCAMs play several important roles. In particular, several IgCAMs have been identified that function in processes of dendritic filopodium formation, spine maturation and synaptogenesis (Fig. 2c). Telencephalin (TLCN; ICAM-5) is the sole neuronal member belonging to the ICAM subgroup of the Ig superfamily. It is expressed specifically by spiny neurons within the most rostral brain segment, the telencephalon. In the telencephalic neurons, TLCN is selectively localized to the somatodendritic compartment and not to axons. During development, TLCN is abundantly present on the ►dendritic filopodia (precursors of spines), but is mostly excluded from mature spines. The over-expression of TLCN causes an increase in dendritic filopodia, while the loss of TLCN induces accelerated maturation of spiny synapses [9]. Therefore, TLCN regulates dendritic morphogenesis as a negative regulator of spine maturation. On the contrary, multiple IgCAMs function as positive regulators of synaptogenesis, including SynCAM, nectins and SALM2, together with cadherin family proteins [10]. The balance between positive and negative regulation of spine maturation by TLCN and SynCAM/nectins/SALM/cadherins respectively, may be important for the formation of appropriate synapses during the critical period of brain development.

## Immunogold Labeling

### Definition

This is a method for labeling target molecules in cells or tissue with gold molecules to make their location and distribution visible in electron microscopes.

## Immunohistochemistry

### Definition

It is a method allowing the detection of specific proteins in a tissue slice by using specific antibodies following several steps. First step consists of binding between a specific primary antibody and specific antigen. Second step requires a secondary antibody which binds to the previously formed antigen-antibody complex, this antibody is either enzyme- or fluorophore-conjuguated.

Third step concerns the enzyme-conjugated antibody where the enzyme forms a colored deposit at the site of antigen-antibody binding in the presence of substrate and chromogen.

## Immunomodulation, Brain Areas Involved

Danuta Wrona
Department of Animal Physiology, University of Gdansk, Gdansk, Poland

### Definition

Brain immunomodulation; Discrete brain area modulation of the immune response resulting in immunoenhancement or immunosuppression.

## Characteristics

### Bidirectional Neuroimmune Communications

Recent evidence has shown that there are bidirectional (Fig. 1) circuits between the central nervous system (CNS) and immune system [1]. The CNS can have far-reaching effects on the immune system after activating the hypothalamic-pituitary-adrenal (HPA) axis [2] and the sympathetic nervous system (SNS). Recent evidence has shown the importance of the acetylcholine-secreting neurons within the parasympathetic nervous system, which suppress acute inflammation and is termed *the inflammatory reflex* or *cholinergic anti-inflammatory pathway* [3]. The immune system, in turn, may communicate with the CNS through immune products, primarily cytokines leading to the direct activation of the CNS [2] or to the release of CNS-derived cytokines. Moreover, immune cells synthesize and secrete hormones, neurotransmitters and neuropeptides, similar to those released from the CNS, which react with the receptors in the common immune and central nervous systems. In addition, recent findings [4] indicate that the CNS responds to systemic bacterial infections with innate immune reactions without the pathogen's direct access to the brain.

### Brain Immunoregulation

In ►neuroimmunomodulation research, some investigators have taken a neuroanatomical approach, evaluating the role the CNS (brain) plays in modulation of immune reactivity. Studies utilizing ►brain lesions or ►brain stimulation suggest that specific regions of the brain may modulate immune activity (Fig. 1).

### The Hypothalamic Immunomodulation

It has been shown that the intact preoptic and anterior part of the hypothalamus (ah) and paraventricular nucleus of the hypothalamus (pvn) which represents an integral part of the neuro-endocrine circuit may be important for normal humoral and cell-mediated immune functions. Lesions of the ah usually evoked decreased immune function whereas stimulation of the ah increased it, which suggests the immunoenhancing effect of ah via endocrine and/or sympathetic activity systems. Moreover, pvn is proposed as an integrative center for immunomodulation.

### Emotion and Immunomodulation

Recently, it was shown that discrete brain areas related to emotionality influence the immune response. The positive or negative emotional state of the man or animal may influence immunological parameters via the limbic-hypothalamic circuits representing the neurophysiological background of emotionality. The structures of "the ►brain reward system" related to positive reinforcement such as the lateral hypothalamus (lh) and ventral tegmental area (vta) have a beneficial effect on immune response, including antiviral and antitumor cytotoxic activity of natural killer cells (NKCC) and the behavioral outcome of lh/vta stimulation may influence the immunoenhancing effect of these structures. In parallel with stereotaxic methods, it was demonstrated that lh is closely related to an increase of NK cell activity induced by electroacupuncture, which when delivered through lh enhances or restores the splenic NKCC suppressed by anterior hypothalamic area lesions in rats.

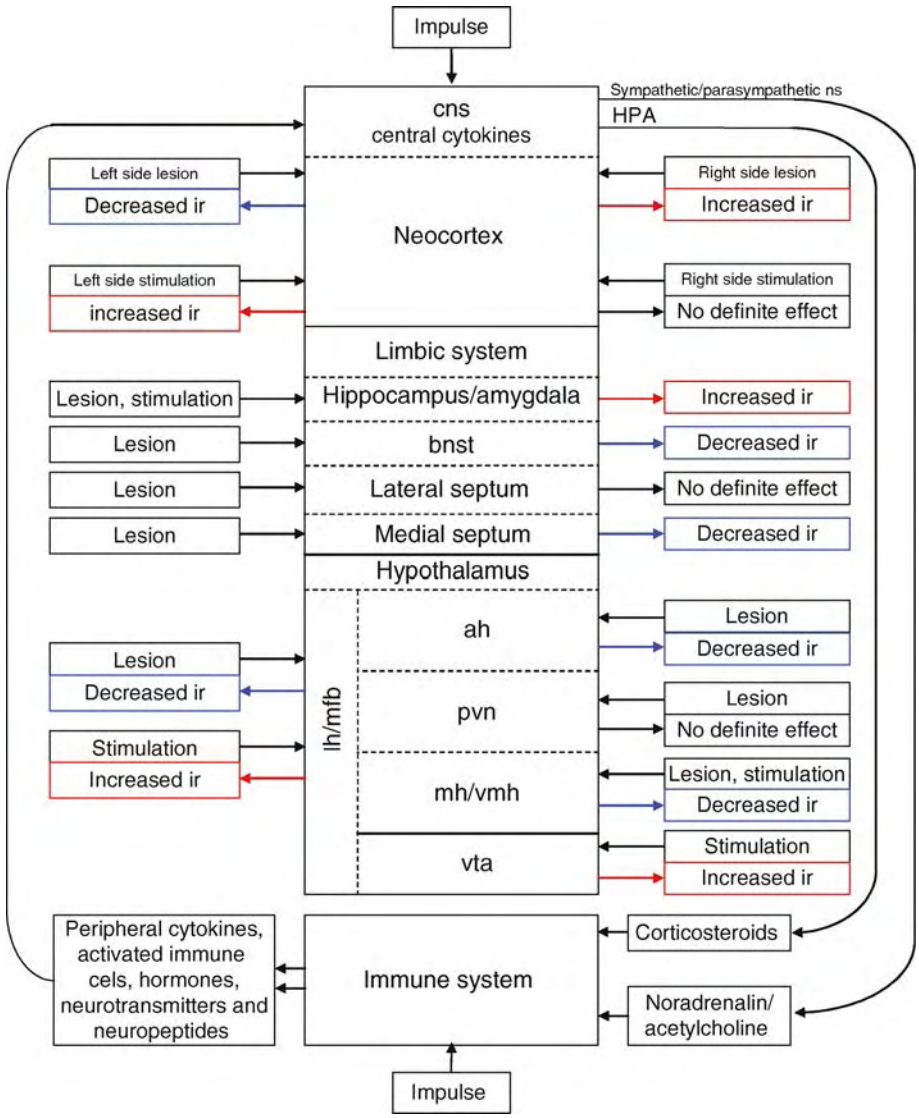
On the other hand, it was suggested that immune suppression, including decreased NKCC obtained from the stimulation of the midbrain dorsal part of the periaqueductal gray matter (pag) or ventromedial hypothalamic nucleus (vmh), is due primarily to the ►stimulation-bound aversive effect of stimulating these structures. Interestingly, how such behaviorally opposite structures like LH and VMH influence the immune system are polarized: stimulation of LH increases immune response while stimulation of VMH decreases it.

### Limbic System and Immunomodulation

Parts of the limbic system related to emotions are differently involved in modulating the immune function. Lesions within the amygdaloid complex and hippocampus have generally enhanced several immune parameters while lesions of either the medial septum or bed nucleus of stria terminalis regions (bnst) inhibited T-lymphocyte proliferation, and decreased the number of peripheral blood leukocytes, and peripheral blood NKCC. The limbic effects on the immune system were mediated through the neuroendocrine axis. Moreover, it is known that both striatal and mesolimbic dopaminergic pathways are asymmetrically involved in neuroimmunomodulation.

### Neocortex and Immunomodulation

Brain asymmetry in neuro-immunomodulation also concerns the cerebral cortex influence on immune responses. These data yield interesting correlations with handedness and the increased incidence of early dyslexia, together with the development of autoimmune diseases in left-handed individuals. It has been shown [5] that there is a direct neocortical influence on the migration of mature T cells from the thymus mediated by the sympathetic nervous system and, therefore, proposed that a cortically derived neurothymic circuit regulates thymic production of mature $CD4^+$ and $CD8^+$ T cells. In addition, it seems that neocortical-dependent functions, such as attitudes, hopes and spiritual resources, may neutralize the effects of extreme stress thereby shaping the immunological mechanisms involved in the maintenance of health.



**Immunomodulation, Brain Areas Involved. Figure 1** The scheme of bidirectional communication between the central nervous and immune systems including the results of stereotaxic method used to study the location of brain areas involved in immunoregulation. Stimulation or lesion (ablation) of various regions of the brain can, depending upon the region, inhibit or enhance immune responses. Cytokines, neurotransmitters, neuropeptides represent the signaling molecules relaying chemical information and depending on the stimulus either neurons or immune cells can be the initial source. The chemical information in turn can be received by both neurons and leukocytes since they share receptor repertoires. Abbreviations: *CNS*, central nervous system; *HPA*, hypothalamic-pituitary-adrenal axis; *IR*, immune response; *BNST*, bed nucleus of stria terminalis; *AH*, anterior hypothalamus; *PVN*, paraventricular nucleus of the hypothalamus; *MH/VMH*, medial hypothalamus/ventromedial nucleus of the hypothalamus; *LH/MFB*, lateral hypothalamus/medial forebrain bundle; *VTA*, ventral tegmental area; *red arrow and box*, immunoenhancing effect of lesion or stimulation; *blue arrow and box*, immunosuppressive effect of lesion or stimulation; *black arrow and box*, no definite effect of lesion or stimulation.

## Blood-Brain-Barrier, Circumventricular Organs and Immunomodulation

Cytokines are the major mediators in bidirectional interactions. Circulating cytokines could enter the brain through areas with a poorly developed blood-brain-barrier (BBB) or can be actively transported. The ►circumventricular organs (CVOs) which are not homogenous, but consist of distinct regions, are a likely route through which signals from the periphery area are transmitted into the CNS by afferent and efferent nerves or the translocation of substances. The concept of afferent nerve transmission is well

documented for vagus, which provides another pathway for communication between the immune and nervous systems [6]. As the barrier pathways, the vagal input, and the CVOs are all represented in the area postrema, this small anatomical area could play a significant role in neuro-immune communication [7].

### Conclusions

The mutual functional relationship between the CNS and immune systems has been intensively studied with the perspective of immunity pharmaceutically through the modulation of selective brain functions in clinical practice. The "immunoreactive" brain areas include the hypothalamic nuclei, "brain reward system", limbic structures, cortex, midbrain PAG, cerebellum, circumventricular organs and vagal complex. The brain structures related to positive reinforcement ("brain reward system"), positive attitudes and hopes (limbic structures and neocortex) have beneficial effects on immune response which may neutralize the effects of extreme stress and offer a new direction for therapy in immune disorders.

## Immunoregulation

### Definition

Regulation of immune-related functions.

## Impedance

►Muscular Stiffness

## Impedance Control

Theodore E. Milner
Department of Kinesiology and Physical Education, McGill University, Montreal, QC, Canada

### Definition

Impedance control is the ability of the central nervous system to modify the ►mechanical impedance of single joints independently of ►net torque or the mechanical impedance of multi-articulated body structures independently of the force which they produce [1]. Impedance control allows the central nervous system to vary the resistance to forces applied to the body, modulate energy exchange with the mechanical environment and stabilize the body.

### Description of the Theory

#### Muscle Impedance

The impedance of vertebrate limbs is fundamentally linked to the impedance of muscles. Although the ►inertia of a muscle is effectively an invariant property, its intrinsic stiffness and ►damping can be actively modified. Muscle stiffness arises from several sources, which include connective tissue (primarily collagen), structural proteins, contractile protein filaments and actomyosin ►crossbridges. Although the responses to imposed displacements are highly dependent on the characteristics of the displacements, they can be explained within the framework of crossbridge dynamics [2]. In general, an increase in muscle activation results in a relatively linear increase in muscle stiffness and damping for continuous, bi-directional stochastic displacements. This is also true for rapid step stretches that do not exceed short-range stiffness, i.e., that are not large enough to produce forcible crossbridge detachment. However, for larger amplitude stretches stiffness drops markedly. In addition, once the region of short-range stiffness has been exceeded, the muscle damping appears to dominate the impedance response until after the stretch stops. The final ►steady-state (static) stiffness is inversely related to stretch amplitude and is considerably lower than the ►dynamic stiffness during stretch. The switch from spring-like to damper-like mechanics appears to be less prominent in muscles of

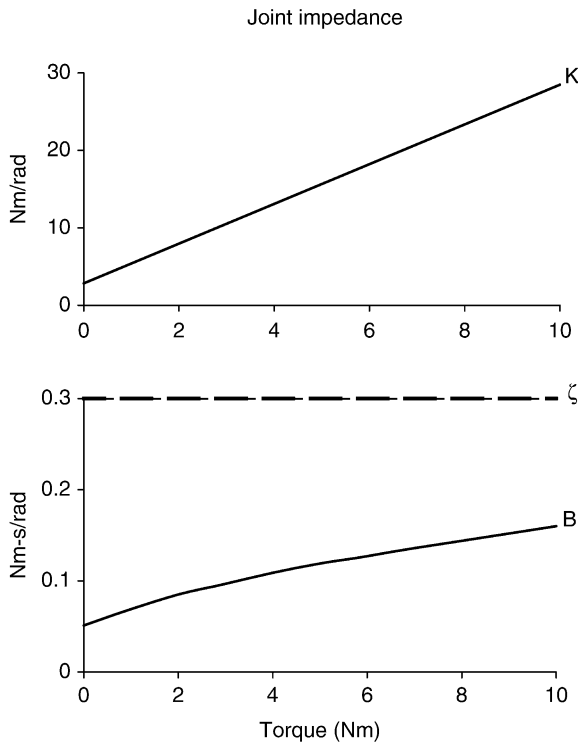
mixed fiber type than pure slow twitch muscles, which may be related to faster crossbridge dynamics.

## Joint Impedance

The mechanical impedance of joints tends to depend less on the characteristics of imposed displacements than does muscle impedance. In particular, there is no switching from spring-like to damper-like mechanics during rapid step displacements, nor is there a marked difference between the dynamic stiffness and ►steady-state stiffness. This may be due in some measure to the contribution of ►feedback loops. Feedback loops originating from ►muscle spindles and ►Golgi tendon organs provide a mechanism for a delayed change in muscle activation, which can modulate muscle force in relation to changes in length or velocity. These changes in activation have been shown to create a more linear response to displacement, by replacing crossbridges that undergo forcible detachment when displacements exceed short-range stiffness [3]. Most estimates of joint impedance cannot distinguish between the contributions of intrinsic muscle properties and feedback loops.

Responses to both continuous, small amplitude stochastic displacements and rapid step displacements suggest that joint stiffness increases in a linear fashion with ►muscle torque [4], although ceiling effects may occur since ►feedback gains decline at high torques. However, joint stiffness is not an invariant function of displacement amplitude. It decreases in a linear fashion with joint displacement. This suggests that feedback loops do not completely compensate for forcible crossbridge detachment on short time scales. However, when the imposed movement is relatively large, e.g., 30°, and the duration is in the order of seconds rather than tenths of seconds, the impedance can be adequately represented by a single stiffness value. If the joint has been stationary prior to the imposed displacement, there is an initial high stiffness region of about 1°, beyond which it drops to a lower value that is effectively constant even when the imposed movement is sinusoidal. Damping is also evident when the imposed movement is large, and although there is some evidence that it decreases as velocity increases, this has not been conclusively established. Like stiffness, damping varies with muscle torque [4], although it is proportional to the square root of torque such that the ►damping ratio, ζ, remains constant (Fig. 1).

Whereas muscle torque is proportional to the ►muscle moment arm, joint stiffness and damping are proportional to the square of the ►moment arm. Consequently, a change in muscle force has a greater effect on joint stiffness and damping than on muscle torque. At the level of a single joint, it becomes possible to exert independent voluntary control over the impedance and net torque because of the ability to independently control ►antagonist muscles. A single pair of antagonist



**Impedance Control. Figure 1** Typical relations between stiffness (K), damping (B) and torque. Stiffness increases linearly with torque, whereas ►damping increases as the square root of torque to keep the damping ratio (ζ) constant.

muscles can achieve a selected net torque by means of a range of activations. Consequently, for a selected net torque there is a range of possible impedances. The minimum impedance corresponds to exclusive activation of the muscle that produces the selected torque. However, the same net torque can be achieved by increasing its activation and coactivating its antagonist muscle. This will result in greater joint impedance since the impedances of the two muscles sum. Such coactivation is used to counteract destabilizing effects of environmental forces [5].

Co-contraction of a pair of antagonist muscles is the most primitive control of mechanical impedance. In general, more than two muscles act at a joint. This allows for more sophisticated control of impedance. Each activated muscle will contribute to the joint impedance as a function of its activation and the square of its moment arm. Since the impedances of all muscles acting at a joint sum, a desired combination of net torque and joint impedance can be achieved in a variety of ways. For example, if two ►synergist muscles have moment arms of different lengths, the same muscle torque can be achieved by activating either one muscle or the other or by activating both muscles. The highest impedance will be realized if only the muscle with the

longer moment arm is activated, whereas the lowest impedance will be realized if only the muscle with the shorter moment arm is activated. Any impedance between these two values can be realized with some combination of activation levels of both muscles. This allows independent control of muscle torque and impedance without the need to coactivate antagonist muscles. Coactivation of antagonist muscles allows impedance to be controlled over a larger range with an even greater selection of activation levels. Since a joint may have multiple degrees of freedom, a single muscle frequently produces torque about more than one axis of rotation. This presents even more versatility in the independent control of net torque and impedance.

## Feedback Modification of Impedance

The ability to control the feedback gain independently of muscle activation presents an additional means of controlling impedance independently of muscle torque. It appears that the gain of the fastest spinal feedback loop (monosynaptic stretch reflex) co-varies with the level of muscle activation, a property known as automatic gain compensation, which would act to reinforce changes in impedance achieved through voluntary control of muscle activation. There are situations, however, where the feedback response can be qualitatively transformed. An example of this is ball catching. There is a reversal of the feedback response in elbow muscles that shorten during impact of the ball. Rather than exhibiting an unloading response, which normally silences the shortening muscle, the feedback activity increases such that there is phasic coactivation of both the stretching and shortening muscles [6].

Longer latency feedback loops, which may involve supraspinal, as well as, spinal pathways appear to have a greater degree of independent gain control. In particular, the intention to resist a disturbance can lead to profoundly greater resistance than when the intention is to yield to the disturbance. Similarly, the gain of these feedback loops is greater when the objective is to control position as opposed to force.

It must be stressed that an increase in the feedback gain does not inevitably result in higher joint impedance. Due to sensory receptor dynamics, loop delays, low-pass filtering characteristics and various nonlinear properties of muscle, the contribution of feedback loops to joint impedance is highly dependent on the frequency content of the imposed motion. Since impedance due to feedback assists movement at certain frequencies it can reduce damping and stiffness, which has the potential to reduce dynamic stability if the feedback gain is sufficiently high [7].

## Impedance of Multi-Articulated Body Structures

In the case of multi-articulated limbs, impedance can be represented in terms of the resultant properties at the end of the limb. Endpoint or ►driving point impedance is a function of the impedance of each joint, the joint angles and the limb segment lengths. The dependence of endpoint impedance on limb geometry provides another mechanism for control. It is possible to change the inertia, as well as the viscoelastic components of the impedance by simply changing the kinematic configuration of the limb without requiring any change in muscle activation [1]. This is a particularly effective way to change the endpoint impedance in postural tasks. In particular, redundant degrees of freedom may be exploited to vary the impedance at a particular endpoint location.

Endpoint and joint impedances are linked by the following transformations.

$$K_j = J^T K_e J + \frac{dJ^T}{d\theta} F$$

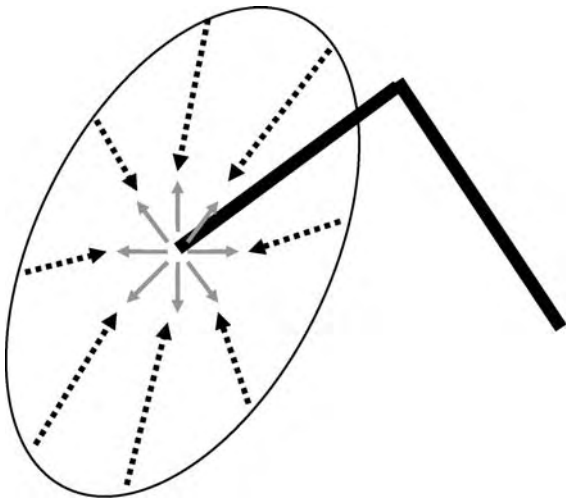
$$B_j = J^T B_e J$$

$$I_j = J^T I_e J$$

where $\boldsymbol{J}$ is the ►Jacobian matrix. Endpoint impedance is multi-dimensional; $\boldsymbol{K}_e$, $\boldsymbol{B}_e$ and $\boldsymbol{I}_e$ are the endpoint stiffness, damping and inertia matrices, respectively. The number of dimensions depends on the number of degrees of freedom of motion at the limb endpoint. In general, there would be six degrees of freedom—three translational and three rotational. However, constraints on how a limb can move may effectively reduce this number. The impedance of the three translational degrees of freedom is conveniently portrayed as an ellipsoid, where the orientation and shape are determined by the eigenvectors and eigenvalues of the impedance matrices (Fig. 2).

The distance from the center of the ellipsoid to any point on its surface represents the magnitude of the impedance along that translational direction. An important point is that the direction of the force response is generally not aligned with the direction of the perturbation, due to the way in which the ►kinematics of the limb transform torque into endpoint force. The two are aligned only along the principal axes of the ellipsoid. Due to this misalignment, the impedance will tend to change the direction of an imposed motion.

As implied by the equations above, endpoint stiffness and damping are linked kinematically to joint stiffness and damping, as well as through their mutual dependence on muscle activation. Endpoint stiffness and damping increase as a function of torques in such a way that the damping ratio remains relatively constant across muscle activation levels [8]. Significant differences in the shape and orientation of endpoint stiffness and damping ellipses do appear with increasing endpoint force in certain force directions (Fig. 3).



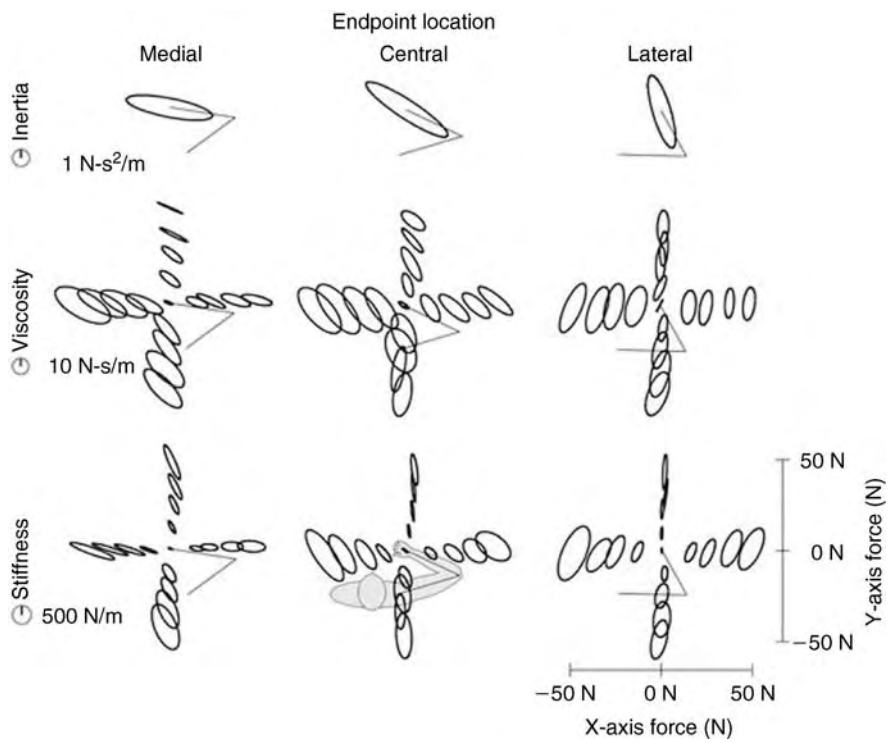
**Impedance Control. Figure 2** The endpoint impedance of a limb is usually depicted as an ellipsoid, shown here in a planar view. The forces (*dashed arrows*) are generally not aligned with the changes in acceleration, velocity or displacement (*solid arrows*) that they resist. The major and minor axes of the ellipse represent the directions of the eigenvectors corresponding to the maximum and minimum eigenvalues of the impedance matrix, respectively.

However, this can be attributed to the force dependent term in the transformation linking endpoint stiffness and joint stiffness, which is absent in the transformation linking endpoint damping and joint damping in the equations above.

### Locomotion

The impedance of the leg is likely controlled in activities such as walking, running, hopping and jumping to regulate energy transfer, mechanical efficiency or dynamic stability. Muscle activity and leg kinematics are modified in a way that suggests that the leg impedance is adapted to the impedance of the support surface [9]. For example, there is greater coactivation of ankle flexor and extensor muscles prior to landing on a rigid surface than a compliant surface, as well as greater knee flexion. Progressively greater coactivation of ankle muscles is also observed when landing from increasing heights.

H-reflex studies of ankle muscles suggest that the feedback gain is modulated to reinforce intrinsic muscle impedance. In walking, running and hopping the gain is low during the time that the foot is in the air, but increases in parallel with muscle activation during the support phase. In landing from a jump and in walking

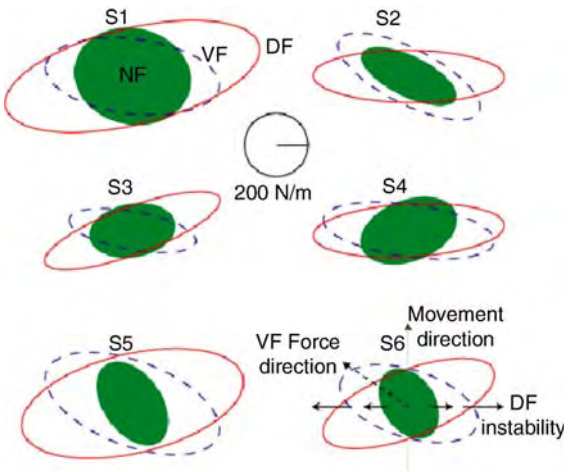


**Impedance Control. Figure 3** Inertial, viscosity (►damping) and stiffness ellipses for the arm for different hand force magnitudes and directions. The location of the center of each ellipse corresponds to the hand force being exerted during the impedance measurement.

on balance beam, ankle flexor and extensor muscles are coactivated during the support phase. Feedback gain is attenuated relative to activities where coactivation is not observed, viz. hopping and walking on a wide support surface, respectively. This suggests that feedback gain may be reduced when postural stability is critical and feedforward mechanisms, such as voluntary coactivation of antagonist muscles are used instead to increase joint impedance.

### Manipulation

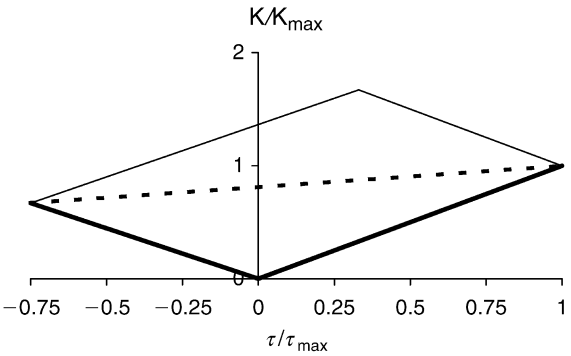
The endpoint stiffness after adaptation to novel mechanical environments that engender a stable interaction with the hand during manipulation appears to vary directly with torque. However, when the interaction is unstable or unpredictable, or when surprised by an unfamiliar mechanical environment, subjects begin to coactivate ►antagonistic muscles. A uniform increase in the coactivation of all antagonistic muscles would result in an increase in the viscoelastic components of the endpoint impedance without altering the shape or orientation. This may be how the central nervous system deals with uncharacterized disturbances, although when subjects repeatedly experience the same disturbance and can adapt to it selective changes in shape and orientation may occur. When adapting to a lateral instability, subjects increased the stiffness in the direction of the instability without any significant change in stiffness along the movement direction [10] (Fig. 4).



**Impedance Control. Figure 4** Endpoint stiffness ellipses of hand before (NF, filled green) and after adaptation to a velocity-dependent force field (VF, dashed blue), which produces a stable perturbation and a divergent force field (DF, solid red), which produces an unpredictable (unstable) perturbation. Movement direction and force field directions are indicated by arrows.

### Constraints on Impedance Control

The impedance range corresponds to the difference between the minimum impedance, which occurs when only the agonist is used to produce the desired net torque and the maximum impedance, which occurs when the agonist is activated maximally and the antagonist produces whatever torque is needed to reduce the net torque to the desired value. In principle, when the desired net torque is small, the maximum impedance should be considerably greater than when either muscle is maximally activated on its own. However, the maximum impedance appears to be limited to what an individual muscle can produce (Fig. 5).



**Impedance Control. Figure 5** Theoretical region of joint stiffness that can be achieved by coactivation of antagonist muscles is bounded by solid lines. Values are expressed relative to the maximum stiffness ($K_{max}$) and maximum torque ($\tau_{max}$) that can be generated by the stronger muscle (positive torque). Practically, only values below the dashed line are possible.

When antagonist muscles are coactivated, the maximum activation of each muscle is reduced, likely due to reciprocal inhibition. Since antagonists mutually inhibit each other, the effective torque that each can produce is reduced in proportion to its counterpart's activation.

Although the kinematics of multi-articulated body segments provide a means of varying impedance independently of muscle activation when changes in posture are possible, they can impose constraints when posture is fixed. In particular, as joints are extended towards the extremes of their range of motion, the ellipsoids representing the viscoelastic components of impedance tend to become elongated and aligned with the extended body segments. No matter how selectively particular muscles can be activated, the ability to change the orientation of the ellipsoids or to increase impedance along the minor axes declines. Similarly, with large endpoint forces the kinematics also impose constraints

I

on impedance geometry due to the force-dependent term in the equation linking endpoint stiffness to joint stiffness.

## Impedance (Z) (Acoustic)

### Definition

Acoustic impedance of a medium is the mathematically complex ratio of the sound pressure on the surface of the medium to the flux (particle velocity multiplied by area) through the surface. It can be expressed in mechanical terms as the square root of the sum of the square of resistance (R) and reactance (X). Resistance is not dependent on sound frequency while reactance is. In terms of the complex ratio that defines impedance, resistance is the real component of impedance and reactance is the imaginary component.

## Implicit Brain Functions

### Definition

Cognitive or perceptual processes not directly accessible to conscious awareness.

►Latent Learning

## Implicit Learning

### Definition

A type of learning resulting in enhanced performance through an unconscious learning process, such as learning a physical or sport skill. Conversely, explicit learning involves intentional remembrance of information at a certain conscious level, such as learning of historical events, phone numbers, etc.

►Latent Learning

## Implicit Memory

### Definition

Implicit memory refers to an unconscious form of memory that does not require any explicit recollection for specific episodes. Non-declarative memory corresponds to implicit memory. Semantic knowledge retrieved by indirect memory test as word completion or lexical decision is also included.

►Long-Term Memory

## Importin

### Definition

Importin is a molecule that transports molecules into the nucleus by binding to a nuclear localization signal within the molecule.

# Imprinting

Hideto Kaba
Department of Physiology, Kochi Medical School, Nankoku, Kochi, Japan

## Definition

The young of many precocial birds, such as ducks and chickens will follow and become socially bonded to the first moving object they encounter. Konrad Lorenz employed the term "imprinting" to describe the process by which the social bond was formed. He also postulated that imprinting had a constellation of features which distinguished it fundamentally from conventional forms of learning: (i) it takes place only during a brief critical period, (ii) it is irreversible, and (iii) it influences patterns of behavior that have not yet developed. The many years of research since Lorenz made these claims have demonstrated that the traditional view of imprinting is incorrect. Imprinting is neither limited to a brief critical period nor irreversible. Instead the recent findings lead to the conclusion that imprinting occurs in many species, including man, and that it can be redefined as the biologically relevant learning that occurs during a "►sensitive period" coinciding with a particular developmental stage or physiological state [1].

The salient phenomena of the development of social preferences in birds have given rise to extrapolations to mammals and humans. The best characterized forms of imprinting in mammals, and those for which most is known at the synaptic and cellular levels, are the learning of male pheromonal signals by female mice during mating [2–4], the learning of newborn lamb odors after parturition in sheep [5,6], and the olfactory conditioning in neonatal animals such as rats and rabbits [1,7]. During a sensitive period of a few hours after mating, female mice form a memory to the urinary ►pheromones of the male partner. This olfactory memory is vital for preventing pregnancy block that might otherwise be induced by the male's pheromones. Pheromones from an unfamiliar male, for which no memory has been formed, activate a neuroendocrine reflex that results in pregnancy failure. Rats are altricial, and pups are confined to the nest environment with the main sensory input mediated by the olfactory and somatosensory modalities. Pups, however, must learn the odor of the mother to ensure nipple attachment and orientation to the mother. In fact, there is a developmentally determined sensitive period, during which olfactory learning is enhanced. Sheep are gregarious animals, and because they are seasonal breeders, hundreds of young may be born within a very short period. To restrict maternal investment to only her to own offspring, the mother rapidly forms the ability to recognize her lamb immediately after parturition, and will show severe aggressive responses to strange young that attempt to suckle her.

## Characteristics

### Higher Level Structures

Most mammalian species, with the exception of man and other higher primates, possess two major olfactory systems: the olfactory and vomeronasal systems (Fig. 1).

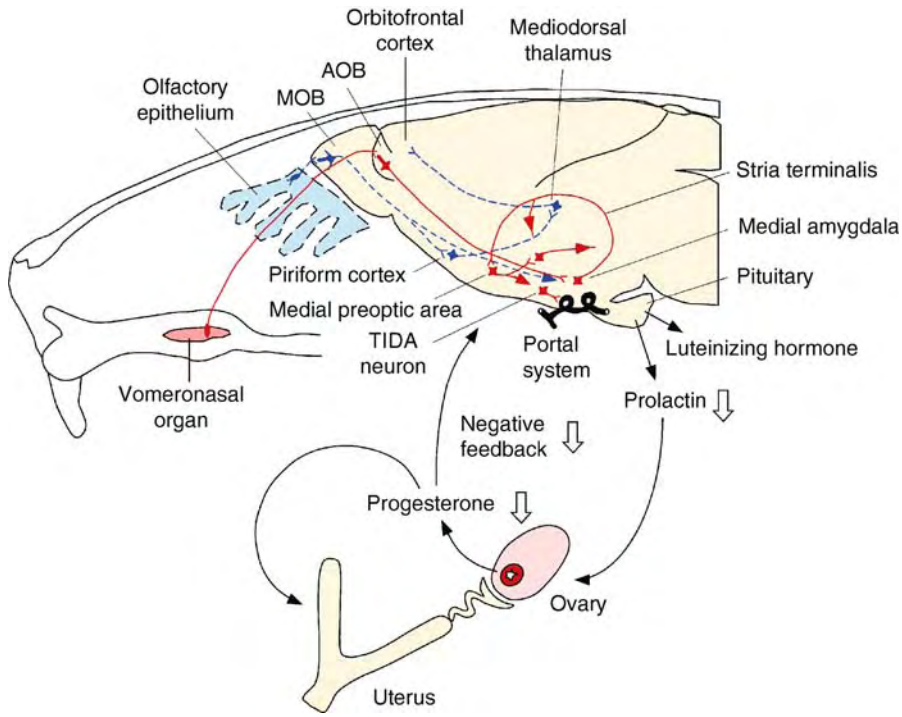
The sensory neurons for the olfactory system are located on the olfactory turbinates and septal wall of the nasal cavity; those for the vomeronasal system we located within the vomeronasal organ, which is a bilaterally-paired tubular structure lying on either side of the nasal septum. Whereas the olfactory sensory neurons send their axons, which are bundled to form the olfactory nerve, to the main olfactory bulb (MOB), the vomeronasal sensory neurons send axons, which together make up the vomeronasal nerve, to the accessory olfactory bulb (AOB), a structure that is spatially and histologically distinct from the MOB and is located at the caudal-dorsal end of the main bulbs. The MOB projects to the anterior cortical nucleus and posterolateral cortical amygdaloid nucleus, anterior olfactory nucleus, the olfactory tubercle, the tenia tecta, the piriform cortex, and the entorhinal cortex. In contrast to the diverse projections of the MOB, the projections of the AOB are much more limited. The principal neurons of the AOB send their axons primarily to the medial and posteromedial cortical nuclei of the ►amygdala and send lesser projections to the nucleus of the accessory olfactory tract and the bed nucleus of the stria terminalis.

### Lower Level Components

The main functions of the olfactory bulb, which has a relatively simple architecture, can be separated into two distinct levels: the level of input processing within the glomeruli and the level of output control in the external plexiform layer (Fig. 2).

Within the glomeruli, the olfactory and the vomeronasal nerve terminals form axodendritic synapses onto the dendritic tufts of both the mitral cells and the intrinsic periglomerular cells. Glutamate is a transmitter at the olfactory and vomeronasal nerve synapses on the mitral and periglomerular cell dendrites in the glomerulus. After the initial input to the mitral and periglomerular cells, further processing may take place within the glomerulus through the dendrodendritic microcircuits. The periglomerular cells are dopaminergic or GABAergic in both the MOB and AOB, but very few of the periglomerular cells in the AOB contain dopamine. At the second level of organization, the main type of microcircuit is the dendrodendritic reciprocal synapses between mitral cells and granule cell interneurons. The mitral cells, when activated by olfactory or

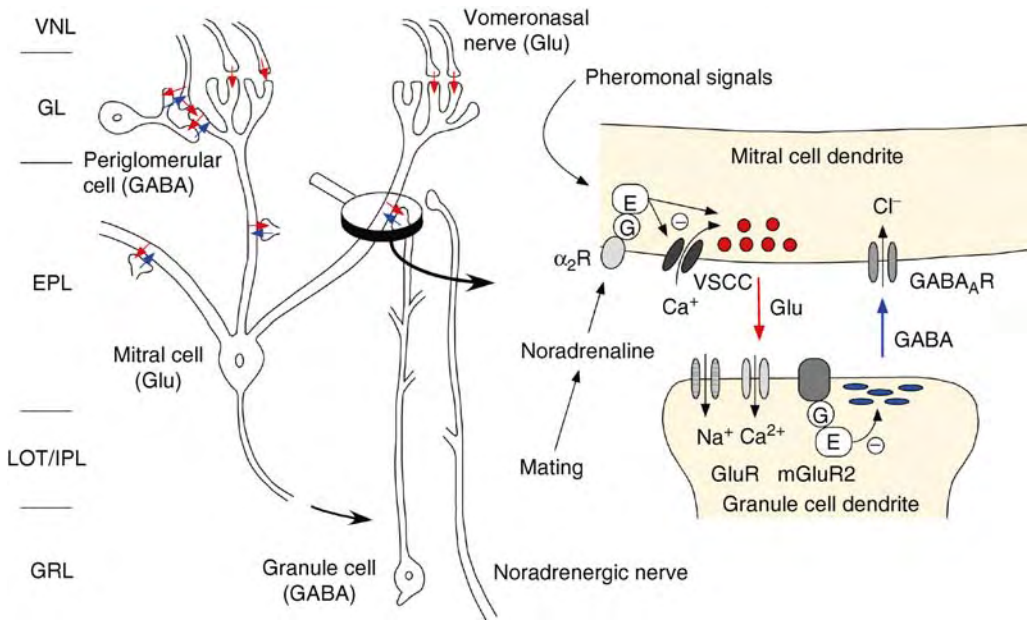
I



**Imprinting. Figure 1** The neural circuitry of olfactory and vomeronasal systems in mammals. Male chemosignals activate an excitatory pathway, via the AOB, medial amygdala and medial preoptic area, to tuberoinfundibular dopaminergic (TIDA) arcuate neurons. The excited TIDA neurons release dopamine into the hypophyseal portal circulation, which in turn inhibits prolactin secretion from the anterior pituitary. Without this luteotrophic support, progesterone secretion from the corpus luteum decreases. This causes implantation failure and releases the hypothalamo-pituitary axis from the negative feedback action of progesterone, resulting in a return to estrus. The medial amygdala receives input from both the vomeronasal and olfactory structures, and is a major site for the integration of chemosensory signals with other sensory cues and hormonal states. Part of the projections of the olfactory system are shown.

vomeronasal nerve inputs, depolarize the granule cells by means of glutamate released at the ►dendrodendritic synapses (Fig. 2). This depolarization in turn releases γ-aminobutyric acid (GABA) from the granule cells and hyperpolarizes the mitral cells.

The synaptic circuitry of the olfactory bulb has much in common with that of the retina. There are, however, significant differences between them. One of the striking differences is that the olfactory bulb, unlike the retina, receives the wealth of centrifugal projections from specific brain areas, including ascending cholinergic, noradrenergic and serotonergic systems. From this point of view, the olfactory bulb is more similar to higher cortical structures, which receive extensive "association" projections from other cortical areas. Hence, it is not surprising to learn that the olfactory bulb not only functions as a relay conveying information to its projection sites, but also serves as a structure which has the capacity for neural plasticity involved in learning and memory. This is true for all three specialized forms of olfactory imprinting. Although they involve very different behavioral contexts, they share several common features, including a dependence on the association of the olfactory (conditioned) and somatosensory (unconditioned) signals in the olfactory bulb. In both pheromonal learning in mice and maternal recognition in sheep, vaginocervical stimulation arising from either mating or parturition triggers olfactory imprinting. Neonatal rabbits and rats can be classically conditioned to odors using tactile stimulation of the peri-oral region during suckling and one of a myriad of potential unconditioned stimuli such as milk, stroking and electric-shock, respectively. The somatosensory signals are conveyed by noradrenergic projections from the pontine nucleus ►locus coeruleus to the olfactory bulb. In each case, olfactory imprinting is prevented by noradrenergic lesions or the infusion of adrenergic receptor antagonists directly into the olfactory bulb. The neural changes underlying the pheromonal learning in mice occur in the AOB. Although the neural mechanisms of the maternal recognition in sheep and the neonatal olfactory learning in rats and rabbits are more distributed, they also involve changes occurring in the MOB.



**Imprinting. Figure 2** Cellular hypothesis for olfactory imprinting in mice. Mating-induced releases of noradrenaline in the AOB facilitate the induction of *N*-methyl-D-aspartate (NMDA) receptor-dependent long-term potentiation (LTP) at the mitral to granule synapses by enforcing high-fidelity synaptic transmission. This ability of noradrenaline stems from a decrease in glutamate (Glu) release via the activation of presynaptic $\alpha_2$-adrenoceptors ($\alpha_2$R). The activation of mGluR2, a metabotropic glutamate receptor, also leads to LTP, independently of NMDA receptors. Consequently, LTP results in a sequence of changes in the morphology of the reciprocal synapses and an increased release of GABA. Red and blue arrows show direction of glutamatergic and GABAergic transmission, respectively. The signaling pathways that inhibit transmitter release are marked by minus signs. E, intracellular effector; EPL, external plexiform layer; G, G protein; $GABA_AR$, $GABA_A$ receptor; GL, glomerular layer; GluR, ionotropic glutamate receptor; GRL, granule cell layer; LOT/IPL, lateral olfactory tract/internal plexiform layer; VNL, vomeronasal nerve layer; VSCC, voltage-sensitive calcium channel.

## Structural Regulation

A notable feature of the olfactory and vomeronasal sensory neurons is that they are continuously replaced from ►stem cells in the epithelium throughout adult life. A second source of neural plasticity during adulthood occurs at the level of the olfactory bulb [8]. Adult-born cells arising from the ►subventricular zone of the telencephalon are incorporated as granule cells and periglomerular cells of the MOB and AOB. How is olfactory imprinting so far discussed related to ongoing neurogenesis in the mature system? The pheromonal memory in mice lasts for at least 30 days but fades by 50 days when recently mated females are exposed to an unfamiliar male to block their pregnancy. Accordingly, the memory could outlast the gestation period of 20 days and prevent the mate's pheromones from inducing oestrus, making a second pregnant less likely to occur. The likelihood of this sequence of events occurring in the wild is presumably rare; most females remain pregnanct after mating. Notably, the endocrine environment during pregnancy curtails the duration of the memory, which may be related to an increased rate of turnover of vomeronasal sensory neurons. In a different learning paradigm, the ability of a mother rodent to recognize and nurture her young is associated with an increase in newborn neurons that are integrated into olfactory bulb circuitry. Neurogenesis might therefore favor flexibility, stability, or both, in the adult brain.

When at 12 days of age rat pups are trained in a ►classical conditioning paradigm in which odor is paired with shock or stroking, they develop a conditioned aversion or preference for that odor, respectively, depending on the context. Paradoxically, however, at 9 days of age pups trained in the same paradigm demonstrate a subsequent odor preference regardless of whether the unconditioned stimulus is appetitive or aversive [9]. Thus, neonates have a sensitive period for rapid, robust odor learning characterized by increased ability to learn odor preferences and decreased ability to learn odor aversions. This sensitive period is supported by the hyper-functioning neonatal locus coeruleus and the hypofunctional amygdala. Pups' endogenous ►corticosterone, which is modulated by maternal stimulation, is important in sensitive-period termination and developmental emergence of olfactory fear conditioning that acts via the amygdala as a switch between fear and attraction.

I

In the mother's absence, odor-shock conditioning produces amygdala activation and learned odor aversions in preweanling (12–15 days old) rats. With maternal presence, this same conditioning yields an odor preference without amygdala activation [10]. These studies suggest that the neonatal brain is not an immature version of the adult brain but is uniquely designed to optimize attachment of the mother.

## High Level Processes

The neuroendocrine pathway by which male pheromones in mice exert their pregnancy block effect (►Bruce effect) has been characterized extensively and is shown in Fig 1.

## Lower Level Processes

There are several important anatomical differences between the AOB and the MOB that may reflect differences in the processing of chemosignals. The glomerular layer is less distinct in the AOB than in the MOB. In addition, periglomerular cells in the AOB are far fewer than in the MOB, implying that the glomeruli in the AOB are less involved in the input processing of chemosignals than those in the MOB. The most significant differences between the AOB and MOB are those of mitral cell morphology, which influence the sampling of glomerular signals and the function of inhibitory mechanisms [4]. A single mitral cell in the AOB projects several primary dendrites to several different glomeruli, whereas a single mitral cell in the MOB projects a primary dendrite to a single glomerulus. Mitral cells of the MOB have an extensive network of secondary dendrites that project radially, in the external plexiform layer, in a plane tangential to the mitral cell layer. In contrast, mitral cells of the AOB have poorly developed secondary dendrites; the dendrodendritic reciprocal synapses in the AOB are formed mainly on the primary dendrites rather than on the secondary dendrites. Although dendrodendritic reciprocal synapses in the AOB are capable of mediating both ►self-inhibition and ►lateral inhibition, the balance may be shifted toward self-inhibition. Thus, the inhibition mediated by the reciprocal synapses may be placed to disrupt the transmission of the pheromonal signal to the mitral cell soma.

## Process Regulation

A further feature common to all three forms of olfactory imprinting, in the mouse, sheep and neonatal rat and rabbit is their dependence on noradrenergic transmission that induces structural and functional changes at mitral/granule cell reciprocal synapses in the olfactory bulb. In the context of pheromonal learning in mice, the association of the mating male's chemosignals with increased levels of noradrenaline in the AOB results in potentiation of the mitral to granule cell synapses that receive input from the mating male's chemosignals (Fig 2). During subsequent exposure to the mating male's chemosignals, the mitral cells with the potentiated synapses would be subject to enhanced feedback inhibition from the granule cells, which could selectively disrupt or modulate the transmission of the mating male's pregnancy-blocking signal at the level of the AOB. Urinary chemosignals from an unfamiliar male would activate a different subpopulation of mital cells without potentiated synapses that would transmit the male chemosignals finally to the hypothalamus, resulting in pregnancy block. Indeed, *c-fos* expression, a marker of neuronal activity, is attenuated in the medial amygdala of mated females in response to the mating male's chemosignals.

Maternal recognition in sheep is associated with neural changes at mitral/granule cell reciprocal synapses in the MOB [5,6]. These changes involve both β-adrenergic receptors and a ►retrograde messenger action of nitric oxide that promote glutamate release from the mitral cells and a resultant upgrading of the mitral to granule cell synapses, with more GABA being released in response to the learned odors of the ewe's own lamb. Oxytocin release within the olfactory bulb during parturition may act to modulate noradrenaline release, facilitating maternal recognition. The increases in GABAergic transmission would represent a sharpening of the odor-induced pattern of activity, due to increases in lateral inhibition. In fact, a small proportion of the mitral cells respond preferentially to the learned odors of the ewe's own lamb, although mitral cells display almost no response to lamb odors before parturition.

In the context of neonatal learning in rats, the association of olfactory signals and somatosensory stimulation-induced releases of noradrenaline and serotonin in the MOB reduces habituation of mitral-cell odor responses during training, and elevates cAMP levels in mitral cells [7]. The elevated cAMP levels increase ►cAMP response element binding protein (CREB) phosphorylation and subsequent protein synthesis changes that lead to an odor-specific, long-term change in spatio-temporal output patterns of mitral cells, primarily expressed as an enhanced probability of inhibitory responses to the learned odor.

## Function

Humans, as Spinoza famously noted, are "a social animal," and hence, it is our social attachments that we live for. Contrary to the desirability of family ties, domestic violence often occurs. There has an alarming increase in child abuse and neglect throughout the world. Therefore, the establishment of an appropriate approach to child abuse and neglect should be a requirement in all nations. To understand social attachments in humans, we have found it valuable to learn from the detailed and precise observations of a wide range of animal species, since the requirements of

preserving the species may have led to the evolution of similar behavioral patterns in humans and other animals. This essay has focused on the neural basis of olfactory imprinting in three specialized contexts that occur during sensitive periods of enhanced neural plasticity and emphasized some of their common features. All three specialized forms of olfactory imprinting are associated with neural changes in the olfactory bulb at the first stage of sensory processing. These changes require the association of the olfactory and somatosensory signals in the olfactory bulb. They all depend on somatosensory stimulation-induced releases of noradrenaline that induce structural and functional changes at mitral/granule cell reciprocal synapses in the olfactory bulb, resulting in increases in inhibitory transmission. In the AOB, this would reflect the enhanced self-inhibition of mitral cells, which could selectively disrupt the transmission of the mating male's pregnancy-blocking signal at this level. In contrast, an extensive network of secondary dendrites of mitral cells in the MOB would result in a sharpening of the odor-induced pattern of activity, due to increases in lateral inhibition, leading to maternal recognition in sheep and neonatal learning in rats. Clearly, the studies described here show that inhibitory interneurons play a critical role in olfactory imprinting. Further work on how these neurons shape olfactory circuit function could be an excellent way to understand memory functions of interneurons in other systems.

# Impulse

►Action Potential

# Impulse Propagation

## Definition

►Action Potential Propagation

# Impulse Response

## Definition

The output of a system when a delta function is input into it. The impulse response is frequently used in order to classify a system, e.g. finite or infinite impulse response.

►Delta Function
►Signals and Systems

# In cis

## Definition

A factor is said to act in cis if it interacts with other proteins within the plasma membrane, cytoplasm or nucleus of the same cell.

## In trans

### Definition
A factor is said to act in trans if it interacts with proteins expressed on the plasma membrane of other cells, or if it binds to the regulatory sequence of a gene loci.

## In silico Biological Analysis

►Bioinformatics

## In situ Microscopy

►Neuron-Glia-Imaging

## In Vitro

### Definition
Refers to situations where experiments are performed on cells or tissue that is removed from a living organism. The principal advantage of using in vitro techniques is that the external medium can be tightly controlled. Another notable advantage is that more techniques can often be used since the tissue is more accessible. The main disadvantage is that some behaviors observed in vivo cannot be mimicked using in vitro preparations.

## In vitro Brain Preparations

►Brain Slices

## In Vivo

### Definition
Refers to situations where experiments are performed using living organisms. The principal advantage of using in vivo techniques is that that the connectivity between cells within their normal extracellular environment is preserved. Indeed some experiments, especially those that measure behavior, can only be completed using in vivo approaches. The main disadvantage is that the external environment is more difficult to control compared to in vitro approaches.

## Inactivation

►Ion Channels from Development to Disease

## Inactivation Gate

### Definition
Inactivation of voltage-gated $Na^+$ or $K^+$ channels is thought to result from specific gates closing upon depolarization, one possible mechanism being a conformational change of the channel or a subunit different from the activation-related part, and another possible mechanism being plugging of an open channel from the inside by a tethered molecule.

►Action Potential

## Inactivation Gating

### Definition
Specialized molecular regions of the channel protein, which undergo conformational changes leading to inactivation (open-non conductive configuration). The inactivation gate can be controlled either by voltage or

$Ca^{2+}$ ions and leads the channel to an open-non conductive configuration which differs from the closed-non conductive configuration that the channel assumes at rest. A typical example of inactivation gating is the "ball-and-chain" model of voltage-gated $Na^{+}$ channels.

## Inattentional Blindness

### Definition

Is the inability of humans to recover any information from unattended sensory stimuli and is thought to be part of an important cognitive mechanism, namely that of focusing or "concentrating" on a task to be performed.

►Attention

## Incentive Motivation

### Definition

Motivation is a theoretical construct used to describe processes within the brain and mind that govern the selection and vigor of specific patterns of behavior required to achieve specific goals and objectives.

Incentive motivation emphasizes the capacity of environmental stimuli to attract and guide approach behavior toward events that have biological significance for the organism. Incentive stimuli such as odors or visual properties may have innate significance whereas other visual or auditory stimuli acquire their incentive properties through association with primary reward stimuli. A critical principle of incentive motivation implies that information external to the organism attracts it toward specific stimuli. This concept is in distinction to the 'push' attributed to internal drive states arising from physiological deprivation.

►Learning and Motivation

## Incentive Value

### Definition

The incentive value of an outcome controls goal-directed action selection for that outcome, such that the greater the incentive value, the more the animal will perform responses in order to obtain that outcome. The incentive value of an outcome can be modulated by extrinsic properties of the reward, such as the magnitude or quantity of reward delivered, as well as by intrinsic properties of the animal such as motivational state i.e. the degree of hunger or satiation, as well as through associative mechanisms by for example pairing that outcome with stimuli that elicit an aversive affective state such as illness.

## Incisional/Postoperative Pain

Timothy J. Brennan
Departments of Anesthesia and Pharmacology, University of Iowa Carver College of Medicine, Iowa City, IA, USA

### Synonyms

Acute pain; Posttraumatic pain; Postsurgical pain

### Definition

Postoperative pain is pain occurring after a surgical procedure. In fact, nearly all surgeries cause some degree of discomfort, making incisional pain quite common. Yet, postoperative incisional pain remains a costly, poorly understood problem for patients. In the past, it was suggested that postoperative pain could be sufficiently treated by administration of adequate doses of parenteral opioids. We now know that this is not the case [1]. Thus, it is important to examine how incisions cause pain so that we can better appreciate the etiology

of postoperative pain and develop a mechanistic-based approach to its treatment.

In order to understand mechanisms of pain after surgery and investigate potential new therapies to alleviate postoperative pain in humans, models for human post-operative pain have been developed using incisions in experimental rodents (Table 1). Behaviors indicative of pain are present, yet these models have several unique properties compared to other animal models of persistent pain. Importantly, the pharmacology of the models is unique and the time course of pain behaviors has similar characteristics to pain assessments in postoperative patients [2].

## Characteristics

### Human Postoperative Pain Measurements

In clinical postoperative pain, a variety of measures are used for pain caused by surgery. For example, in patients undergoing thoracic and abdominal surgery, we typically obtain ►pain scores at rest, with ambulation and during cough. It is optimal if the measurement for pain is related to outcome for the surgical procedure (e.g. pain with coughing after thoracic surgery). After total knee replacement, pain measurements at rest and during flexion are typical, and range of motion can be used as a functional measure of improvement. Different measurements may be relevant to each type of surgery; for example, adequately controlled pain with ambulation after spine surgery may be a milestone for discharge from the hospital. A problem with some evoked pain measurements like pain during cough is difficulty in standardizing and measuring effort.

Other quantitative tests have been utilized to measure postoperative pain in patients. One of these tests is punctate mechanical ►hyperalgesia, usually mapped or quantified using a small punctate mechanical stimulus applied adjacent to the area of an incision. In many examples, a touch stimulus from a weak punctate stimulus elicits pain in the area near an incision. This hypersensitivity is termed ►primary hyperalgesia, and hyperalgesia outside the injured area, remote to the incision, is termed ►secondary hyperalgesia. Central nervous system sensitization causes pain in the secondary (remote) zone because the primary afferent sensory fibers function normally outside the area of injury; therefore the central nervous system must contribute. ►Nociceptor sensitization at the incision causes primary hyperalgesia, although amplification in the central nervous system may contribute. Using a pressure algometer, a blunt mechanical device, evoked pain adjacent or distant to an incision can also be used to quantify postoperative pain [3].

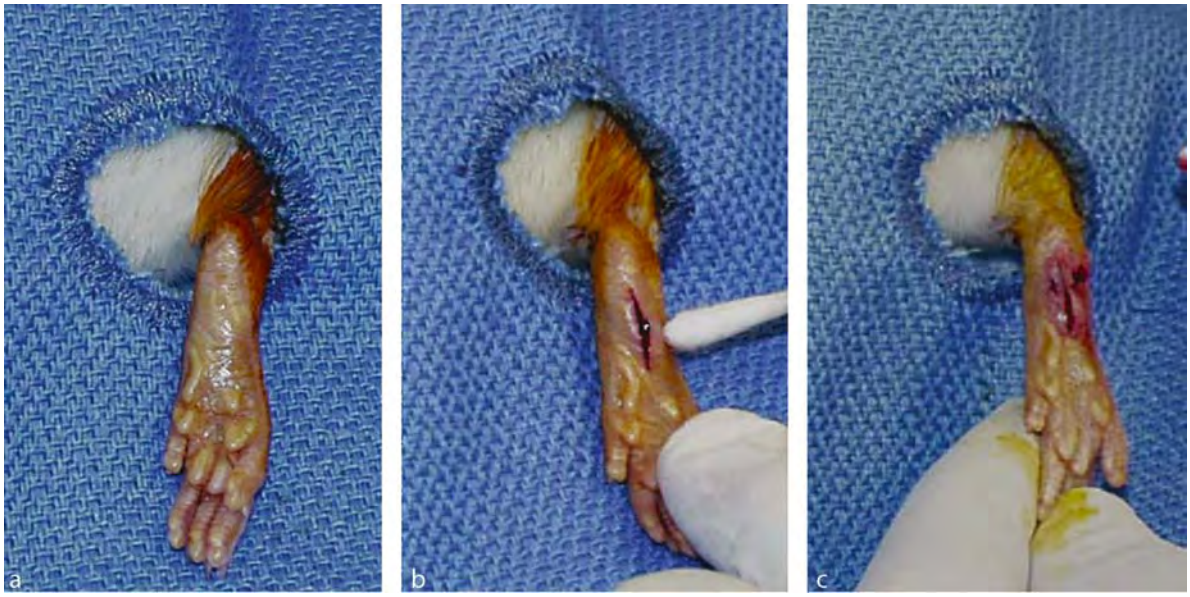
### Description of Incisional Pain Models

A distinguishing feature of postoperative pain models is the performance of surgery using a sterile technique to reduce the incidence of confounding infection-driven inflammation. Many persistent pain models rely on inflammation to produce robust, reliable pain responses; importantly, inflammatory processes in postoperative/incisional pain are not fully understood.

Most experiments have been performed on adult rats [2]. General anesthesia is always utilized, usually induced with a volatile anesthetic like isoflurane mixed with air or oxygen in a sealed box. After induction, anesthesia is delivered via a nose cone. The area of the incision is prepared in a sterile manner with a sterile solution like 10% povidone-iodine solution or an acceptable alternative. A sterile drape surrounds the sterile area separating the sterilized and non-sterile regions. For example, in the plantar incision model, the hindpaw is placed through a hole in a sterile dressing (Fig. 1). A 1 cm longitudinal incision is made with a number 11 blade, through skin and fascia of the plantar aspect of the hindpaw, starting 0.5 cm from the proximal edge of the heel and extending toward the digits. After hemostasis with gentle pressure, the skin is apposed with two sterile sutures, which are removed under general anesthesia at a later time. Typically the wounds are well healed within 5–6 days. Infection and hematoma must be avoided as they will likely exacerbate any pain caused by the incision. In surgical models, there appears to be little evidence for severe discomfort because spontaneous pain behaviors like vocalization or persistent flinching have not been observed postoperatively.

### Pain-Related Behaviors in Incisional Models

Because pain is a subjective experience typically associated with tissue damage or threatened tissue damage, behaviors in animal models are carefully evaluated as a surrogate to pain reports generated in human studies. Therefore, these behaviors in animals are pain-related. For animal models of incisional pain or any pain model, noise or other disturbances will likely affect the responses in an unpredictable manner. Thus a quiet, enclosed area for testing pain-related behaviors is a necessity.



**Incisional/Postoperative Pain. Figure 1** Photographs of the different stages of the rat plantar incision. (a) A one cm longitudinal incision is made through the skin and fascia starting 0.5 cm from the proximal hindpaw and extending toward the distal paw. (b) The underlying flexor muscle is elevated and also incised longitudinally. (c) After hemostasis, the wound is opposed with the first of two nylon mattress sutures.

### *A Plantar Incision Model for Postoperative Pain*

Many laboratories have studied the plantar incision model and the behavioral responses have been widely used in many studies. Several pain related behaviors in rats have been measured after plantar incision (Table 2).

As rats are placed undisturbed in the testing environment, we noted that they did not bear weight on the incised hindpaw for several days after plantar incision. A cumulative guarding score quantified this pain-related behavior based on hindpaw position and compared the score to the contralateral, unincised hindpaw. In general, after plantar incision, the pain score was increased through two days, gradually decreasing to where no guarding was appreciated at later times after the incision. This pain score is a result of the position chosen by the rat after the incision rather than a provoked response to a stimulus [2]. The cumulative pain score is relatively short-lived compared to other measurements and differences between these tests should be expected.

**Incisional/Postoperative Pain. Table 2** Methods to measure pain-like responses in incisional pain modes. Modified from Ref. 5 with permission

| Incisional Pain Models |
|---|
| Heat withdrawal latency |

| Secondary mechanical withdrawal threshold |
| Guarding |
| Weight bearing |
| General Activity |
| Conditioned responses |
| Primary mechanical allodynia |
| Secondary mechanical allodynia |
| Graded hyperalgesia |
| Graded allodynia |

Pain in response to mechanical stimulation at the incision represents primary mechanical hyperalgesia, an exaggerated response caused by activation of sensitized primary afferent fibers. Withdrawal responses to mechanical stimulation are measured using calibrated, punctate monofilaments applied from underneath the cage through openings in the mesh floor to an area adjacent to the incision. Each filament is applied once starting with small force usually in the range of 10–15 milliNewtons (mN) and continued until a withdrawal response occurs or a strong force (500 mN, the cutoff value) is applied. The median withdrawal threshold in the incised hindpaw decreases from strong forces (approximately 500 mN) before incision to weak forces 10–60 mN through 3 days after incision. Withdrawal responses usually remain exaggerated for up to 5 or 6 days. Importantly, the reduced withdrawal threshold is sustained for a greater duration than the non-evoked guarding behavior.

A third stimulus used in the plantar incision model is hindpaw withdrawal to radiant head applied directly to the incision [4]. Rats are placed individually on a glass floor covered with clear plastic cage and allowed to acclimate. Withdrawal latencies are assessed by applying a focused radiant heat source underneath the glass floor on the middle of the incision. The latency to evoke withdrawal is determined with a cut-off value for example, 20 s. Before plantar incision, the withdrawal latency to radiant heat is typically 10–12 s. The withdrawal latency to heat applied directly on the wound is usually decreased for 5–7 days after plantar incision. Other studies using the plantar incision pain model have also used a distant secondary mechanical withdrawal threshold, weight bearing and pressure pain threshold (Table 2) [5].

Mouse models of postoperative pain using plantar incision have also been described. The behaviors caused by plantar incision in the mouse roughly parallel those in the rat. However, guarding pain behaviors are not as evident in the mouse [6,7].

### *Hairy Skin Incisions*

Most surgery is performed in hairy skin in humans. The innervations of hairy skin and glabrous skin are different. In the first hairy skin incision model, a 1-cm-long incision was made in the skin of the hindquarter. The withdrawal threshold to mechanical stimulation produced by calibrated monofilaments was measured. Withdrawal responses to punctate stimulation by von Frey hairs adjacent and distant to the incision were maximally decreased 30 min after the incision was performed. These exaggerated responses were sustained for at least 4 days [8].

A recent study by Duarte et al. examined several new tests for pain following a hairy skin incision on the paraspinal region of the rat (Table 2) [9]. First, the intensity of the response was measured, rather than an “all on none” response. Second, the responses were separated into allodynic-like and hyperalgesic-like responses based upon careful characterization of the stimuli. Finally, in this model, the regions of primary and secondary hypersensitivity are easily distinguished and these had distinctive time courses and unique responses to treatments. The model allows comparisons to a variety of tests; primary (the incised region) and secondary (remote to the incision) responses and the intensity of the responses can also be measured.

### *Laparotomy Models for Postoperative Pain*

The initial postoperative models developed for incisional pain were laparotomy models like ovariohysterectomy. Mechanical nociceptive thresholds distant to the incision were measured using a paw pressure test and a reduced threshold was observed after laparotomy (Table 2). In a new rat model, a subcostal incision that penetrated into the peritoneal cavity was performed. Exploratory locomotor activity, ambulation and rearing were decreased by laparotomy. Laparotomy also decreased conditioned operant responses and food-maintained behavior after surgery [5,10].

## Sensitization of Pain Pathways by Incisions

The basis for pain-related behaviors is activation and sensitization of nociceptive pathways. Primary afferent nociceptors are an ideal target to better understand acute pain mechanisms and hyperalgesia The characteristic features of experimentally-induced peripheral sensitization of primary afferent fibers are a lowering of response threshold, an increase in response magnitude to suprathreshold stimuli, enlarged receptive fields, or an increase in spontaneous activity. Evidence for these types of changes occurs after incisions; thus, the mechanisms that subserve incisional pain at the level of the primary afferent fiber are beginning to be understood.

Central nervous system dorsal horn neurons are also activated and sensitized by incisions. Results from recordings of dorsal horn neurons demonstrate that an incision causes activation of dorsal horn neurons. Dorsal horn neurons have increased background activity that is driven by activated primary afferent fiber and likely transmits evidence for non-evoked ongoing pain (e.g., guarding behaviors). Because the threshold of all dorsal neurons does not decrease to the range of the withdrawal responses in behavioral experiments, only certain dorsal horn neurons likely contribute to the reduced mechanical withdrawal threshold observed in behavioral experiments.

## Conclusion

There are advantages of incision models of postoperative pain compared to clinical studies. First, some mechanistic studies that can not be performed in humans can be undertaken in experimental models. Second, clinical studies utilize a particular intervention to modify two variables: pain score(s) and opioid utilization. Studies examining novel pain treatments can result in a mixed effect: a reduction in opioid utilization with the same pain score(s), or a reduced pain score and the same opioid requirement. In models of incsional pain, a behavioral assessment of pain-related behavior usually can be made independent from rescue analgesic treatments. Of course, in animal models, in the event behaviors suggesting uncontrolled pain occur, analgesic treatments are always available.

## Indoleamine 2,3-dioxygenase or Indoleamine-pyrrole 2,3-dioxygenase (IDO or INDO EC 1.13.11.42)

### Definition

Indoleamine 2,3-dioxygenase or Indoleamine-pyrrole 2,3-dioxygenase (IDO or INDO EC 1.13.11.42) is an immuno-modulatory enzyme secreted by some alternatively activated macrophages and other immuno-regulatory cells (also used as an immune subversion strategy by many tumors or viruses). This enzyme catalyzes the degradation of the essential amino acid L-tryptophan to N-formylkynurenine. IDO is the first and rate-limiting enzyme of tryptophan catabolism through the kynurenine pathway, thus causing depletion of tryptophan, which can cause halted growth of microbes as well as T cells.

►Neurodegenerative Diseases: Tryptophan Metabolism

## Induced Activity (Novel Wheel)

### Definition

Induced activity, either by confining an animal to a running wheel or by presentation of a novel running wheel, is a non-photic stimulus that can have substantial effects on the circadian clock. Induced activity can produce phase shifts as large as those produced by light, depending on the time of day of confinement to the novel wheel and the rodent species. The phase-response curve of novelty-induced wheel running is different from that of light, with exposure during the day resulting in phase advance, while exposure during the subjective night produces phase delays. It is not known what aspect of induced activity cause phase shift. The amount of activity induced is a good predictor of the magnitude of the phase shift with greater activity tending to produce greater phase shifts. Photic and non-photic responses can interact to alter the magnitude of a phase shift.

►Clock
►Masking (Positive/Negative)

## Inducible Nitric-Oxide Synthase (iNOS)

### Definition

The inducible isoform of nitric-oxide synthase (NOS) is also known as NOS2. The iNOS enzyme catalyzes the NADPH-dependent oxidation of L-arginine to nitric oxide and citrulline. In most cell types iNOS levels are either very low or undetectable. However, stimulation of these cells with cytokines, growth factors or traumatic insult leads to increased transcription of the iNOS gene with subsequent production of high concentrations of NO.

## Inertia

### Definition

The proportionality constant for a linear dynamical system that relates the force (or torque) produced in response to an imposed acceleration.

►Impedance Control

## Infant-directed Speech

### Definition

Speech directed to infants and young children ("motherese," "baby talk") differs from speech directed to adults in speed (slow pacing), in phonology (exaggerated intonation and stress), as well as in syntax and semantics (short, simplified sentences). Not only parents, but all adults simplify their speech when talking to infants, and young children do, too.

Motherese is helpful in enhancing infants' interest in speech, in helping infants make phonological distinctions, and in helping them segment utterances at the boundaries between clauses.

►Cognitive Development

## Infant Psychology

### Definition

The scientific study of cognitive, emotional, and motor development in human infants (i.e. in the first two years

of life). It addresses the infants' psychological functioning at birth, the development of these functions, the role of the environment in development, as well as the infants' developing ability to engage in social interaction with caretakers.

►Cognitive Development

## Inferior Cerebellar Peduncle

### Synonyms
Pedunculus cerebellaris inf.; Inferior cerebellar

### Definition
peduncle Afferents: olivocerebellar tract (from olive), posterior spinocerebellar tract (from spinal cord, trunk) vestibulocochlear tract (directly and via vestibular nuclei), cuneocerebellar tract (from cuneate nucleus, neck), trigemino-cerebellar tract (face). Efferents to vestibular nuclei: cerebellovestibular tract (directly from cerebral cortex), uncinate fasciculus (from fastigial nucleus).

►Cerebellum

## Inferior Colliculus

Douglas L. Oliver
University of Connecticut Health Center, Department of Neuroscience, Farmington, CT, USA

### Synonyms
Posterior colliculus; Corpora quadrigemina

### Definition
The ►inferior colliculus (IC) is the main component of the ►central auditory system located in the ►midbrain (►mesencephalon). The dorsal portion of the midbrain, the ►tectum, contains four protrusions, the ►corpora quadrigemina. The two caudal protuberances are the IC, while the anterior protuberances are the ►superior colliculi. In the human, the IC is often called the ►posterior colliculus. The IC receives inputs from virtually all parts of the central auditory system. The main output is to the ►medial geniculate body in the thalamus, but other smaller outputs to the superior olive and cochlear nucleus are found.

### Characteristics
#### Higher Level Components
The IC is subdivided into a ►central nucleus and a cortex that covers the dorsal, caudal, and lateral surfaces [1]. The IC is dorsal to the midbrain ►tegmentum, medial to the ►central gray, and caudal to the ►intercollicular tegmentum (►intercollicular area) that separates the IC and the superior colliculus. The ►brachium of the IC and its nucleus contain the main output fibers of the IC that ascend to the thalamus.

The central nucleus, the main part of the IC, is defined by the presence of ►fibro-dendritic laminae. These are narrow layers (<200 μm thick) formed by the principal neuron type and the axons of the major inputs from the lower brainstem auditory system. The

principal neurons are flat, ►disc-shaped cells with dendritic fields only 50–70 μm thick, while the other dimensions of the dendritic field range from 300–1,000 μm [2]. To form the laminae, the flat surfaces of the dendritic fields parallel each other. About 80% of the neurons in central nucleus are disc-shaped. Depending on the species, the non-disc-shaped neurons have dendrites that are unoriented or perpendicular to the laminae (►stellate neurons), or 'less-flat' neurons with dendrites oriented parallel to the laminae. Axons of central nucleus cells often have local collaterals that terminate within central nucleus, but a specific cell type has not been identified as an interneuron. Local axons of disc-shaped neurons are confined to the neuron's own lamina. The axons in the fibro-dendritic laminae form layers approximately 200 μm thick in parallel to the dendritic fields of the disc-shaped cells. Laminar axons in the central nucleus originate from the ►dorsal and ►ventral cochlear nucleus, ►medial and ►lateral superior olivary nuclei, the ►dorsal and ►ventral nuclei of the lateral lemniscus, and the contralateral IC. The fibro-dendritic laminae create the anatomical substrate for ►tonotopic organization in the central nucleus.

The ►dorsal cortex is usually regarded as a separate anatomical and functional area in the IC and is similar to the thin, less well-studied, caudal cortex. Dorsal cortex is dorsomedial to the central nucleus in most species, usually thicker in the rostral part of the IC. Unlike the central nucleus, the dorsal cortex has poorly defined layers parallel to the surface of the IC, and is composed of stellate and oriented neurons. A comparison of the superficial dorsal cortex (also called pericentral in the older literature) and deeper dorsal cortex (previously called dorsomedial nucleus of central nucleus) shows that the neurons in the deeper portions tend to be larger, although the size changes are gradual. The deepest parts of dorsal cortex receive inputs from the primary auditory neocortex (A1), cochlear nucleus, and contralateral IC. This is the main region in IC where both ascending and descending inputs may interact. More superficial layers of dorsal cortex receive inputs exclusively from the non-primary, belt regions of auditory neocortex, and they lack the inputs from the lower brainstem.

The ►lateral cortex, identified by many different names, may integrate auditory activity with that in other sensory systems. Lateral cortex is part of a larger, heterogeneous region called the external nucleus in the older literature, which included all of the areas rostral and lateral to central nucleus (see intercollicular tegmentum). The deep part of the lateral cortex receives inputs from the lower brainstem auditory structure and from the somatosensory system (spinal cord, dorsal column nuclei, and trigeminal system), and is part of an extralemniscal auditory pathway that may modulate auditory processing in the context of somatosensory activity. The superficial lateral cortex and the nucleus of brachium of the IC are regions that receive their main inputs from the central nucleus of IC. In the barn owl, this region of lateral cortex contains a map of space [3]. This information is transmitted to the superior colliculus that controls ►gaze, i.e. the movement of the head and eyes towards a visual target.

## Lower Level Components

*Neurons in the IC* are defined by morphology, neurotransmitter synthesis, axonal target, and responses to sound. The disc-shaped cell in central nucleus of IC does not represent a single cell type, but should be viewed as the common structural mode in the IC required for laminar organization. Both disc-shaped and stellate neurons project to the medial geniculate body, the main target of the IC. Specific cell types involved in projections to the superior olive, cochlear nucleus, and contralateral IC have not been identified.

The IC has both excitatory and inhibitory output neurons. Most IC neurons are likely to use glutamate as a neurotransmitter, since only 20% of the IC neurons synthesize GABA and none synthesizes glycine. There is no evidence of cholinergic or monoaminergic neurons in IC. However, 20–40% (depending on species) of the IC neurons that project to the medial geniculate body are GABAergic [4]. Parallel excitation and inhibition of the thalamus by the IC may be an important mode of action by the auditory system not evident in other sensory systems.

The *intrinsic membrane properties* can define IC neurons [5]. Firing patterns of IC neurons differ due to the presence of specific potassium currents in different cell types. About half the IC neurons respond to hyperpolarization with a $Ca^{++}$-sensitive rebound depolarization; and they respond to depolarization with regular firing, transient responses (rapid adaptation) or slow adaptation. Different $Ca^{++}$-activated potassium conductances cause the adaptation. Non-rebound neurons in IC include regular firing, pause-build, and onset firing patterns. Pause-build cells have an A-type potassium conductance, and onset cells have a high-threshold delayed rectifier conductance. The use of a GAD67-GFP knock-in mouse has allowed the initial investigation of the intrinsic properties in GABAergic IC neurons, and suggests that the non-rebound regular firing and pause-build cells are GABAergic [6]. Further work is required to clarify the neurotransmitters, morphology, and axonal targets of IC neurons with different membrane properties.

*Organization of inputs to the IC into synaptic domains*. The fibrodendritic laminae of the central nucleus appear to be further divided into two or more functional zones called synaptic domains [1]. While one frequency-band laminae contains axons with a similar range of best frequencies, the function in each zone may depend on the source of the axons from the auditory

brainstem. This creates synaptic domains that partition a lamina into dorsal-ventral parts or rostral-caudal parts. Some inputs, such as those from the dorsal cochlear nucleus, terminate over an entire lamina. Others from the lateral superior olive terminate ventrally in the high-frequency IC, and inputs from the medial superior olive terminate only in the low-frequency IC in the caudal half of the lamina. Since the olivary inputs are binaural, it suggests that there is a segregation of different types of monaural and binaural processing.

*The IC has both excitatory and inhibitory inputs* that ascend from the lower auditory brainstem. Major excitatory, likely glutamatergic, inputs for monaural processing come from the cochlear nucleus; and the main excitatory input for binaural processing comes from medial superior olive. On the other hand, binaural inputs to the IC from the lateral superior olive contain at least three populations of neurons: glycinergic neurons that make inhibitory synapses in the ipsilateral IC and two sets of glutamatergic neurons that synapse in either the contralateral or ipsilateral IC. Thus, the action of this nucleus on the IC depends on which input from the lateral superior olive is in the domain. Another mixed excitatory-inhibitory input is that of the commissure from the opposite IC. About 25% of the commissural neurons that project to the opposite IC are GABAergic. Some IC inputs are exclusively inhibitory. The dorsal nucleus of the lateral lemniscus is a binaural nucleus, whose GABA-containing neurons project to the IC, and the inputs from the ventral nucleus of the lateral lemniscus (ventral complex of nuclei) come from neurons that co-localize both glycine and GABA.

## Structural Regulation

Most of the molecular mechanisms that control the development of the IC remain to be determined. Since the final structure of the fibro-dendritic lamina is not complete until after the onset of hearing, activity-dependent processes may play an important role in regulation of the structure of the IC.

## Higher Level Processes

The fibro-dendritic laminae provide a structural basis for ►tonotopic organization in IC. In the IC of the cat, each layer is a ►frequency-band lamina that represents a step of roughly one-quarter of an octave in the ►best frequency of the neurons, the frequency where the response of the neuron is maximal in amplitude and minimal in threshold [7]. This range could differ in other species.

Neurons in the IC respond to the frequency and intensity of sound and exhibit ►tuning curves of different shape. "V-type" tuning curves are similar to those seen in the auditory nerve, where the neurons respond to a broader frequency range as sound intensity increases from the minimum intensity required to define the best frequency. Other IC neurons have inhibitory areas in their tuning curves that modify the shape. "I-type" tuning curves have inhibitory side bands that prevent the spread of responses over a larger range as the sound intensity increases. Neurons with "O-type" tuning curves respond only to low intensity stimuli and are inhibited as the sound intensity increases.

Many neurons in the IC are part of the binaural system, due to inputs from the superior olivary complex, and they respond to ►interaural time differences (ITD) and ►interaural level differences (ILD). IC neurons have ITD curves that are narrower than those found in the superior olivary complex, and, thus, may respond to smaller locations in space along the azimuth.

IC neurons also respond to amplitude modulation, frequency modulation, the duration of the stimulus, and to novel stimuli [8]. Many of these responses to complex stimuli are monaural.

The IC is also involved in the control of the cochlea. Neurons in the central nucleus project to the periolivary regions of the superior olivary complex and control the responses of the medial ►olivocochlear system. The ventrolateral region of lateral cortex is implicated in the control of the lateral ►olivocochlear system [9].

## Lower Level Processes

Excitatory ►synaptic transmission in the IC most commonly uses glutamate as the neurotransmitter. All IC neurons appear to have receptors for AMPA and NMDA. Inhibitory synapses are found on all IC neurons and employ GABA-A or glycine receptors. Some IC neurons may also have receptors for nicotine (acetylcholine), serotonin, noradrenaline, or enkephalin.

## Process Regulation

Responses in the IC may be modified by pathology in the lower parts of the auditory system, especially in young animals. Some inputs from the cochlear nucleus on the side opposite an ablated cochlea in a young animal may expand their projection to the ipsilateral IC. Changes in the responses of the IC neurons in an adult animal may be influenced and controlled by inputs from the neocortex. Electrical stimulation of the cortex can modify the tuning of IC neurons [10].

## Function

The IC, as a part of the auditory pathway, is involved in hearing, auditory processing, and the efferent control of the cochlea.

## Pathology

Lesions of the IC may impair hearing and sound localization. In some species, loud sound will evoke ►audiogenic seizures that begin in the IC.

# Inferior Frontal Gyrus

## Synonyms

Gyrus front. inf.

## Definition

The inferior frontal gyrus comprises the following:

– Inferior frontal gyrus, orbital part
– Inferior frontal gyrus, triangular part
– Inferior frontal gyrus, opercular part

In the areas of the frontal gyrus close to the precentral gyrus is situated the premotor cortex, which plays an important role in planning effector voluntary movements and has close interaction with the cerebellum, thalamic nuclei and basal ganglia.

In the inferior frontal gyrus, opercular part, lies the motor speech center (Broca). Here speech is planned but not executed. Damage to the inferior frontal gyrus causes motor aphasia. Comprehension of spoken and written language is preserved, with mistakes occurring only on generating one's own language, whose severity correlates with the extent of damage and can range from impaired word-finding ability through agrammatism to complete loss of language.

►Telencephalon

# Inferior Oblique Muscle

## Definition

Inferior oblique is one of the six eye muscles.

►Eye Orbital Mechanics

# Inferior Olivary Nucleus

## Definition

A neuronal group in the medulla that is associated with the cerebellum. It is present in all vertebrates and is well developed in species with a large cerebellum. It is the source of the climbing fiber input to the cerebellar cortex. It receives input from many regions of the brain including the spinal cord, various cranial nerve nuclei, the motor system, and the cerebral cortex.

►Cerebellar Functions
►Evolution of the Cerebellum

# Inferior Olive

## Synonyms

Oliva inf

## Definition

A large nucleus directly beside the pyramid, on the lower margin of the pons. Part of the motor system. Afferents come from the red nucleus and, as collaterals, from the pyramidal tract, from the precentral gyrus (motor cortex). Efferents course as the olivocerebellar

tract to the contralateral cerebellum, thus participating in the feedback loops between cerebellum and cortex regulating movement coordination.

►Myelencephalon

## Inferior Parietal Lobule

### Synonyms
Lobulus parietalis inf.

### Definition
In the direction of the occipital pole, the inferior and superior lobules unite at the postcentral gyrus. Analogous to the secondary motor cortex there is also a secondary sensory cortex for the somatosensory control; this is believed to stretch across both lobules and to be responsible for analysis, recognition and assessment of tactile information.

While dysfunctions of this area do not undermine tactile perception, they do subvert the accompanying recognition, judgmental and associative processes. The ensuing condition is called tactile agnosia.

►Telencephalon

## Inferior Rectus

### Definition
Inferior rectus is one of the six eye muscles.

►Eye Orbital Mechanics

## Inferior Temporal Cortex

### Definition
This area is the underside of the temporal lobe comprised mainly of portions of the inferior temporal, fusiform (occipitotemporal) and parahippocampal gyri. This area contains many visual neurons thought to be involved in identifying specific objects.

## Inferior Temporal Gyrus

### Synonyms
Gyrus temporalis inf

### Definition
The inferior temporal gyrus lies on the lower edge of the parietal lobe, passing on the basal side to the occipitotemporal sulcus.

►Telencephalon

## Inflammation

### Definition
Inflammation is the first response of the immune system to infection or irritation and may be referred to as the innate cascade. Inflammation is characterized by the following quintet: redness (rubor), heat (calor), swelling (tumor), pain (dolor) and dysfunction of the organs involved (functio laesa).

►Neuronal Cell Death and Inflammation

# Inflammatory Cascade

## Definition

A sequence of cellular events following injury to the central nervous system. The sequence of events leads to cells being killed or damaged.

# Inflammatory Pain

Michael R. Vasko
Department of Pharmacology and Toxicology, Indiana University School of Medicine, Indianapolis, IN, USA

## Definition

Inflammatory pain is the perception of and affective response to noxious stimuli that occur during an inflammatory or immune response.

## Characteristics

The inflammatory response represents a series of well orchestrated physiological processes that occur after injury or infection in an attempt to combat and resolve the pathology. It is characterized by five classic symptoms: redness (*rubor*), heat (*calor*), swelling (*tumor*), pain or hypersensitivity (*dolor*), and loss of function (*functio lasea*). Under normal conditions, ►inflammation is an important protective mechanism essential for wound healing. Despite this, acute inflammation produces overt pain through the direct activation of sensory neurons that conduct the pain signal (Fig. 1).

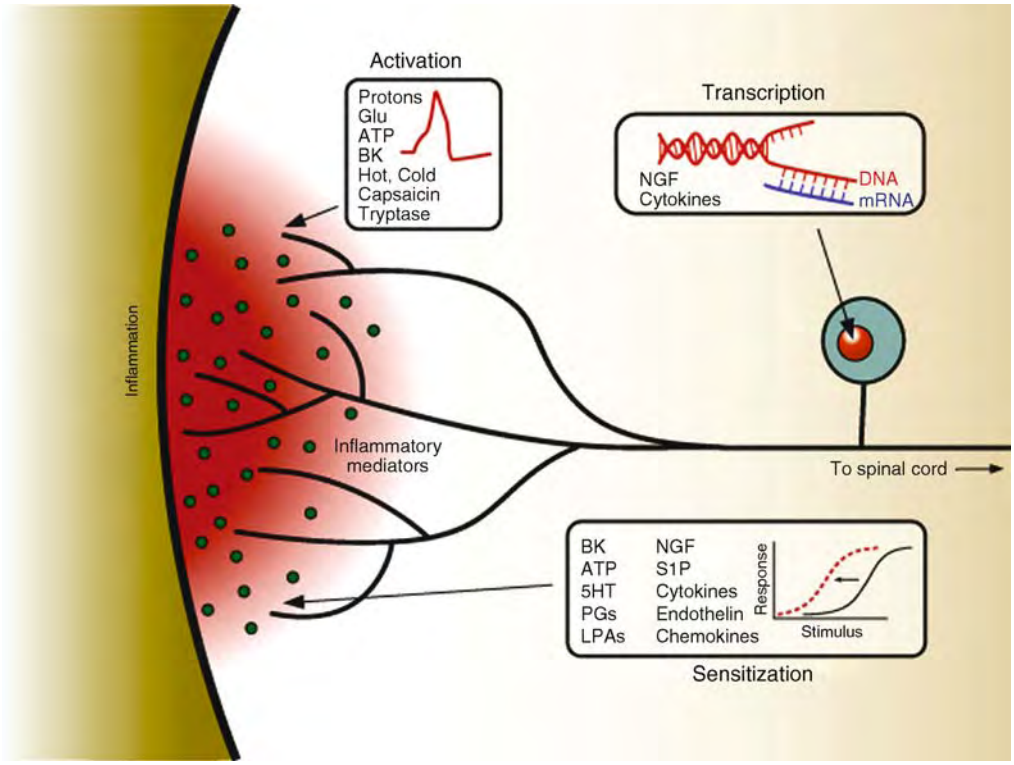
More frequently, inflammation results in a reduced threshold for activation of sensory neurons (principally nociceptors) and/or an increase in the firing of these neurons in response to a given stimulus (Fig. 1). This phenomenon is termed peripheral sensitization and causes an increase in sensitivity to noxious stimuli (hyperalgesia) or the perception of non-noxious stimuli as painful (allodynia) [see ►Hyperalgesia and Allodynia].

Of greater clinical concern, however, is chronic inflammatory pain which occurs in diseases like rheumatoid arthritis (an autoimmune disorder; see ►Immune System and Pain) and osteoarthritis. Chronic inflammatory pain can result from a sustained inflammatory or immune response and from changes in the expression of proteins that contribute to altered excitability of sensory neurons (Fig. 1). It is important to note that inflammation-induced increases in the firing of sensory neurons also may result in an augmentation of the synaptic response that occurs in the dorsal horn of the spinal cord over time. This increase in synaptic activity is termed central sensitization and results in an increased responsiveness of dorsal horn nociceptive neurons to peripheral stimuli. Central sensitization is considered a major component of non-inflammatory chronic pain syndromes known as neuropathic pain syndromes ([1]; see also ►Neuropathic Pain). Although inflammatory and neuropathic pain may share some common mechanisms, they are generally thought of as separate entities both in terms of etiology and treatment.

Although a number of different cell types release inflammatory mediators that contribute to the inflammatory response, it is the activation of a subset of the small diameter sensory neurons (i.e., those associated with thinly myelinated A-δ fibers or unmyelinated C-fibers) that conduct noxious information from the periphery to the dorsal horn of the spinal cord. These specialized sensory neurons (nociceptors) have slow conduction velocities and are usually activated by high threshold thermal and/or mechanical stimuli or by chemical stimuli. Subsets of small diameter sensory neurons also conduct non-noxious thermal sensation or itch from the periphery to the dorsal horn of the spinal cord [see ►Nociceptors and Characteristics]. Although sensory neurons innervate cutaneous, muscle, joint and visceral tissues throughout the body, the cell bodies of these neurons are localized in the dorsal root ganglia (from the neck down), in the trigeminal ganglia for sensory neurons innervating the head and neck, and in the nodose ganglion for sensory neurons innervating much of the viscera. Sensory neurons innervating tissues have a single axon traversing from peripheral tissues to the dorsal horn of the spinal cord [see ►Visceral Pain re. Visceral Innervation]. These neurons also are called primary afferent neurons because their major function is to convey sensory information from the periphery directly to the spinal cord. However, these small diameter sensory neurons also release transmitters from their nerve endings in the periphery and thus subserve an efferent function (see below). Nociceptive sensory neurons form synaptic connections on nociceptive specific or wide dynamic range dorsal horn neurons in laminae I, II, and V of the spinal cord, which then conduct the nociceptive signal to supraspinal sites including brain stem nuclei, thalamus, hypothalamus, etc. [see ►Ascending Nociceptive Pathways].

### Activation of Nociceptive Sensory Neurons

Direct activation of sensory neurons occurs when thermal, mechanical, or chemical stimulation causes sufficient depolarization to result in the firing of an action potential (see Fig. 1). Stimuli that directly activate nociceptors include temperatures in excess of 42°C or below 17°C [2], high pressure mechanical stimuli,



**Inflammatory Pain. Figure 1** Mechanisms for the initiation and maintenance of ►inflammatory pain. Inflammatory pain is initiated by activation of nociceptive sensory neurons by hot or cold thermal stimulation, by mechanical stimulation, or by inflammatory mediators as indicated. Depolarization of sensory nerve endings in the periphery generate action potentials that travel to the spinal cord, thus conveying the noxious information. Inflammatory mediators can also reduce the threshold of activation of nociceptive sensory neurons, thereby producing ►peripheral sensitization (see text). Maintaining sensitization occurs with a sustained inflammatory response and with an increase in transcription, resulting in enhanced expression of proteins that regulate the excitability of sensory neurons. (Abbreviations: *Glu*, glutamate; *ATP*, adenosine triphosphate; *Bk*, bradykinin; *5Ht*, 5-hydroxytryptamine; *PGs*, prostaglandins; *LPAs*, lysophosphatidic acids; *NGF*, nerve growth factor; *S1P*, sphingosine 1-phosphate).

and an increase in the concentration of protons. In addition, a number of putative inflammatory mediators including (but not limited to) ATP, bradykinin, proteinases, and endovanilloids are released during inflammation and directly activate sensory neurons. The depolarizing effects of heat, protons and endovanilloids on a subset of nociceptive sensory neurons are mimicked by exogenous administration of capsaicin, the active ingredient in hot peppers. Depolarization of sensory nerve endings by inflammatory mediators results from activation of distinct receptors which increase their permeability to cations and thus generate inward currents. Prominent receptors include transient receptor potential (TRP) channels such as TRPV1 (activated by capsaicin, heat, protons) and TRPA1 (activated by cold). Additional receptors include acid sensing ion channels activated by protons, P2X channel receptors activated by ATP, proteinase-activated receptors activated by trypsin or tryptase, nicotinic acetylcholine receptors, glutamate receptors, and bradykinin receptors. Once nociceptors are depolarized, action potentials travel from the periphery to the dorsal spinal cord. In sensory nerve terminals in the spinal cord, the incoming action potentials depolarize their central nerve terminals, causing release of neurotransmitters such as glutamate, ►substance P (SP) and ►calcitonin gene-related peptide (CGRP). Once released, these transmitters activate receptors on dorsal horn neurons which depolarize these cells. Thus, in the conduction of pain information from the site of injury or inflammation, sensory neurons transduce mechanical, thermal, or chemical energies into electrical signals which are then converted, by release of transmitters, to a chemical signaling process in the spinal cord.

Small diameter sensory neurons also release neurotransmitters from their peripheral endings and this release contributes to the inflammatory response. For example, the release of SP from peripheral sensory endings contributes to plasma extravasation in part by degranulating mast cells, whereas CGRP release results in a direct action on the vasculature and local vasodilation [3]. This neural component of the

inflammatory response is termed neurogenic inflammation. The release can be the result of local depolarization of nerve endings accompanied by an influx of extracellular calcium. It has long been proposed that depolarization of one branch of a sensory neuron not only results in conduction of action potentials toward the spinal cord, but also action potential invasion of nerve terminal branches that travel antidromically (i.e., from a more proximal to distal site) and thus depolarize and release transmitter(s) from other peripheral branches of the same sensory neuron [4]. This "►axonal reflex" is postulated to account for the classic flare that is observed in cutaneous regions near the site of local injection of histamine or other inflammatory mediators ([5]; see also ►Nociceptors and Characteristics).

Another proposed mechanism for producing neurogenic inflammation is through ►dorsal root reflexes, which are action potentials that travel from the spinal cord to the periphery after depolarization of central endings of ►sensory neurons [6]. Indeed, it has long been appreciated that high threshold stimulation of dorsal roots of sensory neurons results in peripheral vasodilation [7]. Furthermore, electrophysiological evidence shows that sensory nerve endings in the spinal cord and dorsal roots can be depolarized by gamma aminobutyric acid; a phenomenon known as primary afferent depolarization. Although dorsal root reflexes are observed under experimental conditions, their relative importance in generating neurogenic inflammation *in situ* remains a point of debate.

## Peripheral Sensitization

Although injury results in direct firing of small diameter sensory neurons, it is peripheral sensitization that appears the most important mechanism for generating and maintaining ►hypersensitivity during inflammation. The increased sensitivity of small diameter sensory neurons reduces their threshold of firing and augments transmitter release from both their peripheral and central terminals. The clinical consequences of peripheral sensitization are neurogenic inflammation, hyperalgesia and/or allodynia. For example, under normal conditions, a temperature below 40°C is perceived as warm (non-noxious) rather than hot (noxious). However, if an individual has a cut or burn that causes an inflammatory response, the 40°C stimulus is perceived as hot and painful. In a similar manner, non-noxious or mildly noxious mechanical stimuli also may be perceived as noxious.

A number of inflammatory mediators do not produce overt pain, but rather cause peripheral sensitization (see Fig. 1). These agents act by binding to receptors on sensory neurons which in turn activate signal transduction cascades that cause posttranslational modifications of ion channels and/or other proteins that increase excitability of sensory neurons [8]. The classic inflammatory mediators that produce peripheral sensitization are the prostaglandins, $PGE_2$ and $PGI_2$. These compounds are synthesized and released in response to acute injury and/or after chronic inflammation by the actions of cyclooxygenases on arachidonic acid. Indeed, the major mechanism to explain the analgesic actions of aspirin and other nonsteroidal anti-inflammatory drugs is inhibition of cyclooxygenases, which prevents prostaglandin synthesis [9]. There are a number of additional compounds synthesized and released during inflammation that contribute to peripheral sensitization. These include cytokines and chemokines, nerve growth factor and other trophic factors, lysophosphatidic acids, sphingosine 1-phosphate, 5-hydroxytryptamine, and endothelin-1 (see Fig. 1). Furthermore, agents that directly depolarize sensory neurons such as ATP and bradykinin also alter the sensitivity of these neurons to other stimuli. Their direct versus sensitizing actions depend on their concentration and on the relative expression of different receptors on sensory neurons. For example, ATP induces inward currents in sensory neurons by binding to P2X receptors (ligand-gated ion channels), but this nucleotide also binds to P2Y receptors (G-protein coupled receptors; GPRCs) and alters the sensitivity of nociceptive sensory neurons.

Based on the accumulated evidence, peripheral sensitization is mediated largely by posttranslational modifications of surface receptors and ion channels which alter the excitability of sensory neurons. Inflammatory mediators drive these alterations by activation of various signal transduction cascades. For example, pro-inflammatory prostaglandins bind to specific GPRCs that are linked to an increase in cAMP production with activation of protein kinase A and exchange factors activated by cAMP (Epacs). Bradykinin and ATP binding to their GPRCs increase the activity of phospholipase Cβ, which liberates insoitol trisphosphate (IP3) that releases calcium from intracellular stores and diacylglycerols (DAGs) that activate protein kinase C (PKC). Protein kinase A and PKCs, in turn, phosphorylate voltage-gated and ligand-gated ions channels that enhance excitability of sensory neurons [10]. Chemokines, lysophosphatidic acids and sphingosine 1-phosphate also bind to GPRCs expressed on sensory neurons, although the signaling pathways and effects for these inflammatory mediators are yet to be determined. Other inflammatory mediators, such as nerve growth factor (NGF) and cytokines, cause peripheral sensitization by binding to tyrosine kinase receptors or TNF-like receptors, thereby activating a number of downstream signaling pathways involved with posttranslational modification of proteins in sensory neurons. Effectors activated by NGF and cytokine receptors include phospholipase Cγ, PI3 kinases, and small G-proteins such as ras. The activation of PLCγ liberates IP3 and DAGs, while PI3 kinases activate

another protein kinase, AKT, and small G-proteins activate MAP kinases (p38, ERKs, JNKs).

Peripheral sensitization is maintained during chronic inflammation by two major factors: a maintenance of inflammatory and/or immune response over time, and the ability of inflammatory mediators to increase gene expression of neurotransmitters, receptors, or channel proteins that increase the excitability of nociceptive sensory neurons (Fig. 1). Both cytokines and NGF bind to their respective receptors and activate various transcription factors. In addition, inflammatory mediators that increase cAMP levels in sensory neurons also may increase gene expression by activation of the transcription factor CREB (cAMP response element binding protein). Cytokines contribute to maintaining hypersensitivity by increasing the expression of an inducible from of cyclooxygenase (COX2) in various tissues with a concomitant increase in prostaglandin production. Both inflammation and exogenous administration of NGF increase the expression of SP and CGRP in sensory neurons, and this increase can augment release of these peptides in the periphery and the spinal cord. Recent evidence also suggests that inflammation increases expression of ligand-gated and voltage-gated ion channels in sensory neurons. Whether these alterations in gene expression only affect the sensitivity of small diameter nociceptive sensory neurons or recruit large diameter touch and proprioceptive sensory fibers to conduct noxious information is yet to be determined.

# Influence of $Ca^{2+}$ Homeostasis on Neurosecretion

Amy Tse, Andy K. Lee, Valerie Yeung-Yam-Wah, Frederick W. Tse
Department of Pharmacology, Centre for Neuroscience, University of Alberta, Edmonton, AB, Canada

I

## Synonyms

$Ca^{2+}$ clearance; Exocytosis

## Definition

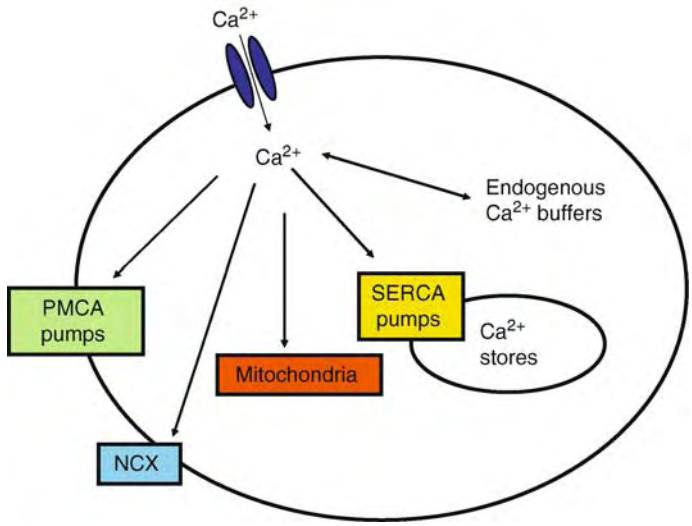
$Ca^{2+}$ homeostasis refers to the ability of cells to regulate the cytosolic concentration of $Ca^{2+}$; neurosecretion refers to the secretion of hormone and neurotransmitters from neurons and neuroendocrine cells.

## Characteristics

### Multiple Mechanisms Determine the Time Course of the Cytosolic $Ca^{2+}$ Clearance

In most neurons and neuroendocrine cells, agonist stimulation frequently elicits a rise in cytosolic $Ca^{2+}$ concentration ($[Ca^{2+}]_i$). The amplitude and duration of the agonist-induced $Ca^{2+}$ signals in turn regulate exocytosis of hormone or neurotransmitter containing granules. The shape of the $Ca^{2+}$ signal is regulated by multiple mechanisms. The rising phase of the agonist-induced $Ca^{2+}$ signal is mainly determined by the amount of $Ca^{2+}$ entry via voltage-gated $Ca^{2+}$ channels (VGCCs) or $Ca^{2+}$ release from endoplasmic reticulum (ER) stores (e.g. the inositol trisphosphate ($IP_3$–) stores and the ryanodine-sensitive $Ca^{2+}$ stores). Following $Ca^{2+}$ release from ER stores, the activation of capacitative or non-capacitative entry of extracellular $Ca^{2+}$ is important for the refilling of the ER stores. The decay phase of the $Ca^{2+}$ signal is regulated by endogenous $Ca^{2+}$ buffers and four $Ca^{2+}$ clearance mechanisms: mitochondria, plasma membrane ►$Na^+$-$Ca^{2+}$ exchanger (NCX), plasma membrane $Ca^{2+}$-ATPase (PMCA) and ►sarco-endoplasmic reticulum $Ca^{2+}$-ATPase (SERCA) pumps (Fig. 1).

The influence of VGCCs and intracellular $Ca^{2+}$ release in shaping the $Ca^{2+}$ signal and triggering of exocytosis has been well documented in many cell types. Recently, there is increasing evidence that endogenous $Ca^{2+}$ buffers and $Ca^{2+}$ clearance mechanisms



**Influence of $Ca^{2+}$ Homeostasis on Neurosecretion. Figure 1** Multiple $Ca^{2+}$ clearance mechanisms. When extracellular $Ca^{2+}$ enters the cell (e.g. via VGCCs), some $Ca^{2+}$ are rapidly bound by endogenous $Ca^{2+}$ buffers and some are taken up by mitochondria or pumped into the intracellular $Ca^{2+}$ stores via SERCA pumps. The removal of $Ca^{2+}$ from the cytosol to the extracellular space by PMCA pumps and NCX on the plasma membrane further lowers the cytosolic $Ca^{2+}$ concentration.

can influence the shape of the $Ca^{2+}$ signal and thus affect exocytosis. Different cell types appear to utilize various combinations of $Ca^{2+}$ buffers and $Ca^{2+}$ clearance mechanisms to regulate their $Ca^{2+}$ signals. In this chapter, we shall discuss the relative contribution of these mechanisms to the $Ca^{2+}$ dynamics and secretion in neurons, neuroendocrine and endocrine cells.

## Endogenous $Ca^{2+}$ Buffers

When extracellular $Ca^{2+}$ enters the cell (e.g. via VGCCs), only a very small fraction (~1–5%) ends up as free $Ca^{2+}$. A large fraction of the $Ca^{2+}$ is rapidly and reversibly bound to endogenous $Ca^{2+}$ buffers. Multiple types of $Ca^{2+}$ buffers are present in neurons and neuroendocrine cells. In general, they can be classified as mobile or immobile $Ca^{2+}$ buffers. Immobile endogenous $Ca^{2+}$ buffers refer to buffers which do not wash out of the cytoplasm during whole-cell patch clamp recording (via diffusion into the recording electrode). The very slow mobility of these $Ca^{2+}$ buffers suggests that they either have a large molecular mass or that they are anchored to some proteins (thus preventing diffusion). The immobile $Ca^{2+}$ buffers have low $Ca^{2+}$ binding affinities (several μM) and their molecular identity remains unclear. Because of their overall properties, the immobile $Ca^{2+}$ buffers are postulated to be important in maintaining the $Ca^{2+}$ microdomains near the VGCCs. In contrast, the mobile $Ca^{2+}$ buffers are diffusible and they may contribute to the acceleration in the collapse of the $Ca^{2+}$ microdomains following the closure of VGCCs. Examples of mobile endogenous $Ca^{2+}$ buffers include the cytosolic proteins calbindin D-28k and parvalbumin. The $Ca^{2+}$ affinity of these mobile buffers is in the nM to μM range, similar to the well known exogenous $Ca^{2+}$ buffers, EGTA and BAPTA. Calbindin D-28k has fast $Ca^{2+}$ binding kinetics and it reduces the amplitude of the depolarization-triggered $Ca^{2+}$ signal as well as slows the decay of the $Ca^{2+}$ transient. In contrast, the slower $Ca^{2+}$ binding buffer, parvalbumin does not affect the amplitude of the $Ca^{2+}$ signal but accelerates the decay of the $Ca^{2+}$ transient.

The literature shows that the mobile $Ca^{2+}$ buffers play important roles in the modulation of short-term facilitation of transmitter release in synapses. Short-term synaptic plasticity is typically estimated by paired-pulse facilitation. This procedure involves the delivery of a pair of presynaptic action potentials within a short time (<1 s) interval. An increase in the amplitude of the second postsynaptic potential when compared with the first postsynaptic potential reflects facilitation. As the time interval between the two presynaptic action potential increases, there is a gradual reduction in facilitation (referred as the decay in facilitation). Multiple mechanisms have been proposed to underlie paired-pulse facilitation, including the "residual $Ca^{2+}$ accumulation" model and the "partial $Ca^{2+}$ buffer saturation" model [1]. According to the "residual $Ca^{2+}$ accumulation" model, the decaying $Ca^{2+}$ signal (residual $Ca^{2+}$) from the first presynaptic action potential adds to the amplitude of the $Ca^{2+}$ signal triggered during the second one, thus increasing transmitter release and results in a larger amplitude in the second postsynaptic potential. The "residual $Ca^{2+}$ accumulation" model also

suggests that a slow $Ca^{2+}$ buffer such as EGTA can reduce residual $Ca^{2+}$and blocks paired-pulse facilitation. In contrast, the "partial $Ca^{2+}$ buffer saturation" model proposes that $Ca^{2+}$ entry after the first presynaptic action potential causes a progressive and local saturation of the fast endogenous $Ca^{2+}$ buffers at the release site, resulting in a larger local $[Ca^{2+}]$ rise during the second presynaptic action potential and thus more transmitter release. According to the "partial $Ca^{2+}$ buffer saturation" model, the fast $Ca^{2+}$ buffers can effectively compete with the $Ca^{2+}$ sensor (e.g. synaptotagmin) for binding to $Ca^{2+}$. The fast $Ca^{2+}$ binding kinetics of calbindin D-28k makes it a suitable candidate for this model. Consistent with this notion, paired-pulse facilitation in some synapses, including the hippocampal and cortical synapses have been shown to be dependent on calbindin D-28k [2]. Although the slow $Ca^{2+}$-binding kinetics of parvalbumin does not fit the profile of the fast $Ca^{2+}$ buffer in the "partial $Ca^{2+}$ buffer saturation" model, a recent study in the Calyx of Held synapse [3] has shown that parvalbumin which accelerates the decay of the $Ca^{2+}$ transient, does not affect the amplitude of the paired-pulse facilitation but accelerates the decay of the facilitation (see above). This finding suggests that parvalbumin may be important in limiting residual $Ca^{2+}$ accumulation between a pair of presynaptic action potentials. Thus, both fast and slow mobile $Ca^{2+}$ buffers may modulate short-term facilitation in synapses. Since the expression of the various $Ca^{2+}$ buffers in synapses changes with development and the dominant $Ca^{2+}$ buffer is different among the various types of synapses, an important challenge in future research is to understand how the various immobile and mobile endogenous $Ca^{2+}$ buffers interplay to shape the $Ca^{2+}$ signal and influence synaptic transmission in different synapses.

## Mitochondria

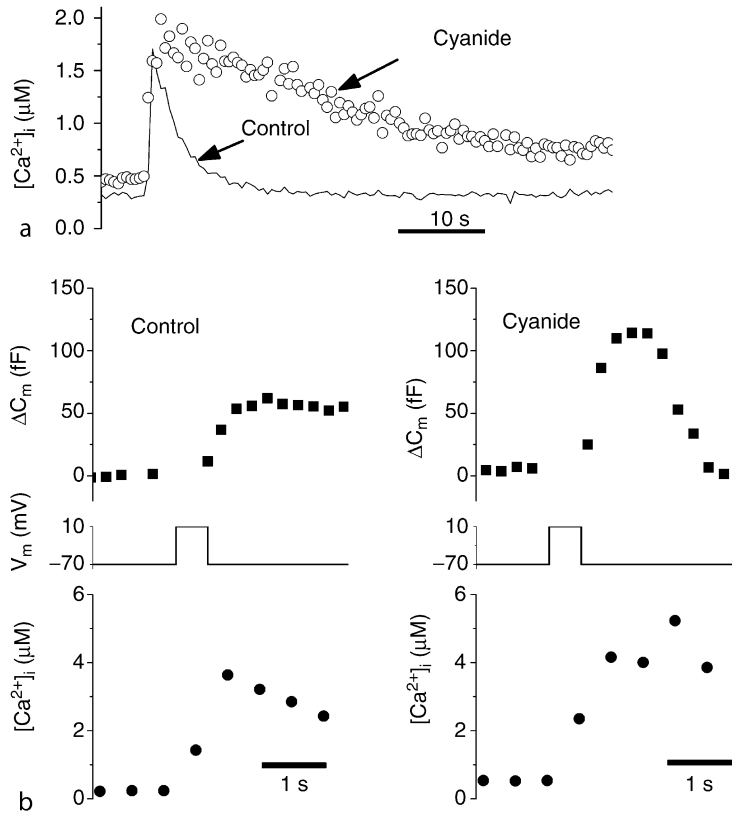
Mitochondria are the major supplier of cellular ATP. It is well known that ATP is essential for the increased metabolic demand during the different processes of secretion including exocytosis, endocytosis and granule mobilization. The metabolic role of mitochondria in neurotransmitter release will not be addressed here. Instead, this section will discuss the influence of mitochondria in the shaping of the $Ca^{2+}$ signals which in turn regulates secretion. $Ca^{2+}$ uptake into the mitochondria is regulated by the ►mitochondrial uniporter and is driven by the large (150–200 mV) inside-negative mitochondrial membrane potential. Because of the low $Ca^{2+}$-affinity of the uniporter ($K_d > 10$ μM at physiological $Mg^{2+}$ concentration), it has been long believed that mitochondrial $Ca^{2+}$ uptake occurs only in conditions of cellular $Ca^{2+}$ overload. However, it is now clear that in many cell types, mitochondria are in close apposition to VGCCs and/or ER stores such that the generation of $Ca^{2+}$ microdomains during the opening of VGCCs or $Ca^{2+}$ release from ER stores triggers mitochondrial $Ca^{2+}$ uptake. When $[Ca^{2+}]_i$ decays, $Ca^{2+}$ in the mitochondria is extruded into the cytoplasm via the actions of the mitochondrial $Na^+$ $Ca^{2+}$ exchanger and possibly via the opening of the mitochondrial permeability transition pore. Inhibition of mitochondrial $Ca^{2+}$ uptake causes an increase in the amplitude of the $Ca^{2+}$ signal and/or a slowing in the decay of the $Ca^{2+}$ transient in some neurons and neuroendocrine cells. In some neuroendocrine cells, such as ►chromaffin cells and pituitary cells, mitochondrial inhibition results in enhancement of secretion. For example, the dominant mechanism for cytosolic $Ca^{2+}$ clearance in pituitary ►corticotropes is the mitochondrial $Ca^{2+}$ uptake [4]. As shown in Fig. 2a, application of cyanide (a mitochondrial inhibitor) dramatically slowed the decay of depolarization-triggered $Ca^{2+}$ transient in corticotropes.

Figure 2b shows that in corticotropes, the increase in the duration of $Ca^{2+}$ transient during mitochondrial inhibition in turn caused an increase in the amount of exocytosis (measured with ►capacitance measurement). While these findings suggest that mitochondria may play a role in limiting excessive secretion in neuroendocrine cells, the influence of mitochondria in transmitter release from nerve terminals is more complex. For example, in motor nerve terminals, inhibition of mitochondrial $Ca^{2+}$ uptake causes a reduction in phasic release (i.e. release triggered by a train of action potentials in high frequency) [5]. Thus, in nerve terminals, mitochondrial $Ca^{2+}$ uptake may be important for maintaining neurotransmission during high frequency stimulation.

## Plasma Membrane $Na^+$-$Ca^{2+}$ Exchanger

Two families of $Na^+$-$Ca^{2+}$ exchanger (NCX) proteins have been described in mammalian tissues: the cardiac type NCX and the $K^+$-dependent NCX (NCKX). Both NCX families are expressed in the brain. In the forward mode (i.e. extrusion of $Ca^{2+}$ from the cell), NCX exchanges one $Ca^{2+}$ for three $Na^+$. In contrast, the stoichiometry of NCKX is one $Ca^{2+}$ and one $K^+$ to four $Na^+$. Thus, $Ca^{2+}$ clearance by NCX depends on the $Na^+$ gradient (low intracellular $[Na^+]$) but NCKX depends on both the $Na^+$ and $K^+$ gradients (high intracellular $[K^+]$). Small axon terminals have high surface-to-volume ratio. This property may render the axon terminals more vulnerable to accumulation of $Na^+$ (thus high intracellular $[Na^+]$) during bursts of action potentials. Under this condition, the reduction in $Na^+$ gradient may be less favorable for the forward mode of NCX. However, because of its dependence on $K^+$ gradient, NCKX can still extrude $Ca^{2+}$ efficiently even when intracellular $[Na^+]$ is high. NCKX is a major $Ca^{2+}$ clearance mechanism in the axon terminals of rat neurohypophysis but has little contribution to $Ca^{2+}$ clearance in the somata of the supraoptic magnocellular

I



**Influence of $Ca^{2+}$ Homeostasis on Neurosecretion. Figure 2** Mitochondrial inhibition slows the decay of the $Ca^{2+}$ signal and enhances exocytosis in rat pituitary corticotropes. (a) Superimposed depolarization-triggered $Ca^{2+}$ signal before and after mitochondrial inhibition by cyanide (5 mM). The cell was whole-cell voltage clamped at −70 mV. The pipette solution contained 5 mM ATP. $[Ca^{2+}]_i$ was monitored with indo-1 fluorometry. Note that the decay of the $Ca^{2+}$ signal slowed dramatically in the presence of cyanide. (b) Simultaneous measurement of exocytosis (reflected as increase in membrane capacitance; $\Delta C_m$) and $[Ca^{2+}]_i$ from a corticotropes before and in the presence of cyanide. Following mitochondrial inhibition, the same voltage step triggered a more sustained $[Ca^{2+}]_i$ elevation and the amount of exocytosis was increased by ~2-fold.

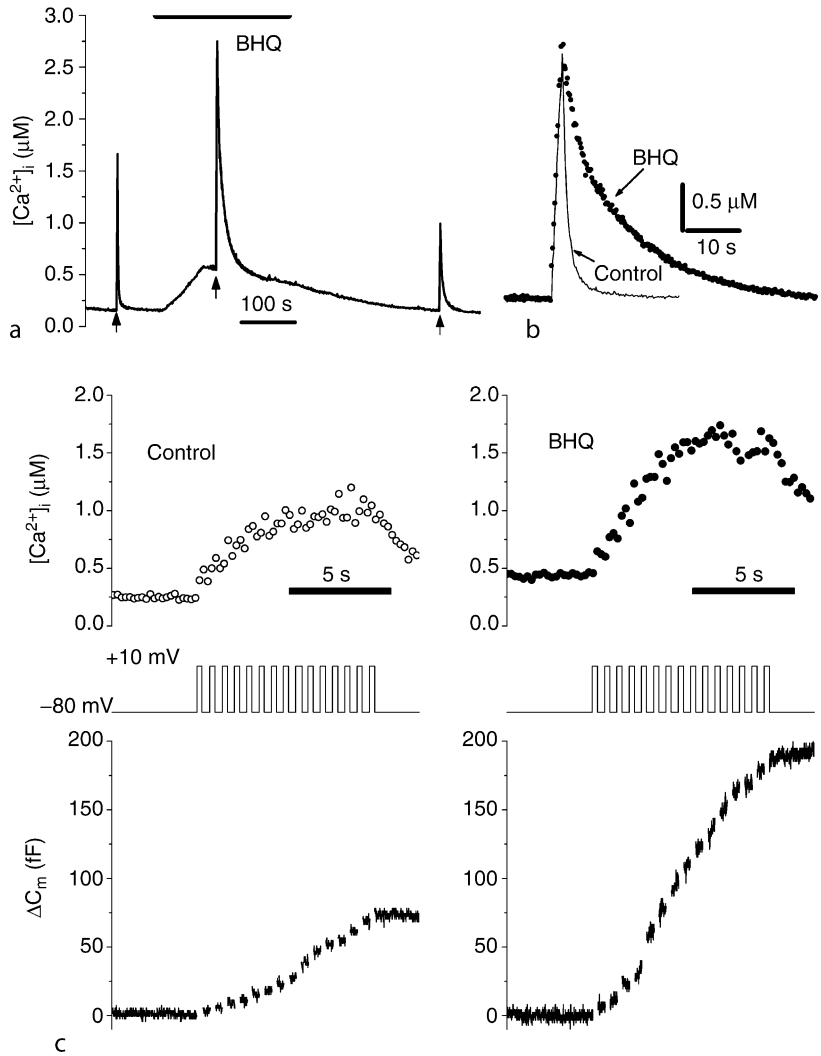
neurons which project their axons to the neurohypophysis [6]. While inhibition of NCX and/or NCKX have been shown to slow the decay of the $Ca^{2+}$ signal in some nerve terminals, their influence on neurotransmitter release from nerve terminals is not clear. However, NCX as well as NCKX knock-out mice exhibit changes in synaptic plasticity in the hippocampus (for example, see [7]). Thus, the neurotransmission in some synapses may be strongly dependent on the $Ca^{2+}$ clearance mechanism of NCKX and/or NCX.

## Plasma Membrane $Ca^{2+}$-ATPase

The plasma membrane $Ca^{2+}$-ATPase (PMCA) removes cytosolic $Ca^{2+}$. This process is dependent on ATP hydrolysis and in exchange extracellular protons are transported into the cell. PMCA binds $Ca^{2+}$ with a high affinity (0.2–0.6 μM) and thus have an important role in the regulation of the resting $[Ca^{2+}]_i$ in many cells. However, the capacity of PMCA to extrude $Ca^{2+}$ from the cell may be limited by its slow turnover rate (i.e. the amount of $Ca^{2+}$ transported per carrier per unit time). Thus, NCX which has a lower $Ca^{2+}$ affinity but higher turnover rate than PMCA is suggested to be more important in cytosolic $Ca^{2+}$clearance during a substantial $[Ca^{2+}]_i$ rise. Nevertheless, because of the proximity of PMCA to VGCCs as well as the high surface-to-volume ratio in small nerve terminals, PMCA may be an effective $Ca^{2+}$ extrusion mechanism in some nerve terminals. Consistent with this, inhibition of PMCA in the peripheral sensory nerve terminals slows the decay of the $Ca^{2+}$ transient by approximately twofold but inhibition of NCX in the same preparation has little influence on $Ca^{2+}$ homeostasis [8]. A direct demonstration of the effect of inhibition of PMCA on transmitter release is lacking. However, mice with targeted or spontaneous mutation in certain PMCA isoforms have balance and hearing defects that may involve changes in neurotransmission [9].

### Sarco-Endoplasmic Reticulum $Ca^{2+}$-ATPase

The uptake of cytosolic $Ca^{2+}$ into the ER stores by sarco-endoplasmic reticulum $Ca^{2+}$-ATPase (SERCA) pump is important for the replenishment of $Ca^{2+}$ in the ER stores. Inhibition of SERCA pumps leads to depletion of ER stores and is associated with ER stress and apoptosis. In many neurons, SERCA pump is also an important $Ca^{2+}$ clearance mechanism. For example, in the somata of supraoptic magnocellular neurons, inhibition of SERCA pumps slows the decay of the depolarization-triggered $Ca^{2+}$ transient by ~50% [6]. A major function of supraoptic magnocellular neurons is the secretion of vasopressin and oxytocin in their terminals (neurohypophyses). However, the dominant $Ca^{2+}$ clearance mechanism in the neurohypophyses is NCKX [6]. Thus, it is unclear whether the activities of SERCA pump have any influence on hormone secretion from the supraoptic magnocellular neurons. Nevertheless, in endocrine cells such as pancreatic β cells, where SERCA pump is the dominant $Ca^{2+}$ clearance mechanism, inhibition of SERCA pump can dramatically affect exocytosis [10]. Figure 3a shows



**Influence of $Ca^{2+}$ Homeostasis on Neurosecretion. Figure 3** Inhibition of SERCA pumps increases the amplitude of the depolarization-triggered $Ca^{2+}$ signal and enhances exocytosis in rat pancreatic β cells. (a) Inhibition of SERCA pump by BHQ elevated the basal $[Ca^{2+}]_i$ and increased the amplitude of the depolarization-triggered $Ca^{2+}$ signal. The cell was whole-cell voltage clamped at −80 mV. The *arrows* indicated the delivery of a train of depolarizing voltage steps. (b) Dramatic slowing of the decay of the $Ca^{2+}$ transient in the presence of BHQ. Superimposed $Ca^{2+}$ signals before and after SERCA pump inhibition. The amplitude of the $Ca^{2+}$ signals in control was scaled to match that in BHQ. Same cell as in (a). (c) Simultaneous measurement of exocytosis ($\Delta C_m$) and $[Ca^{2+}]_i$ from a β cell before and during BHQ. Following SERCA pump inhibition, the same train of depolarizing voltage steps triggered a larger $[Ca^{2+}]_i$ elevation and this was accompanied by ~3-fold increase in the amount of exocytosis.

that inhibition of the SERCA pump by 2,5-di-(t-butyl)-1,4-hydroquinone (BHQ) caused an increase in the amplitude of the depolarization-triggered $Ca^{2+}$ signal as well as a dramatic slowing in the decay of the $Ca^{2+}$ transient (Fig. 3b). Simultaneous measurement of $[Ca^{2+}]_i$ and exocytosis shows that the increase in the amplitude of depolarization-triggered $Ca^{2+}$ transient during SERCA pump inhibition was accompanied by an increase in the amount of exocytosis (Fig. 3c).

## Conclusion

Following the opening of VGCCs, the $Ca^{2+}$ entering the cytosol can be rapidly taken up by the fast endogenous $Ca^{2+}$ buffers, the mitochondria, as well as the SERCA pumps. Thus, these three mechanisms are important in limiting the amplitude of the $Ca^{2+}$ signal. On the other hand, the slow endogenous $Ca^{2+}$ buffers, the mitochondria, the SERCA pump, the plasma membrane NCX, as well as PMCA pump, contribute to the acceleration in the decay of $Ca^{2+}$ signal, thus limiting the duration of the $Ca^{2+}$ signal. The relative contribution of individual $Ca^{2+}$ clearance mechanism varies not only with different cell types but also with different cellular compartments (e.g. soma versus axon terminals). These complexities may reflect the adaptations of individual cell types or cellular compartments to meet their specific demands. For example, because of the high-surface-to-volume ratio in the small axon terminals, NCX and PMCA which are on the plasma membrane can extrude $Ca^{2+}$ efficiently. On the other hand, for neuronal somata and neuroendocrine cells with a low surface-to-volume ratio, the large $Ca^{2+}$-handling capacity of the mitochondria and SERCA pumps may be more efficient in lowering cytosolic $[Ca^{2+}]$.

Since the $Ca^{2+}$ sensor in the triggering of exocytosis may operate in a co-operative fashion, a small increase in the amplitude of the $Ca^{2+}$ signal can dramatically enhance secretion. On the other hand, a slowing in the decay of the $Ca^{2+}$ signal can also influence secretion. In many neuroendocrine and endocrine cells, the secretory granules are not in close proximity to the VGCCs and exocytosis can continue to occur briefly after the closure of the VGCCs (see for example, in Fig. 2b, exocytosis in corticotropes continued to occur for ~500 ms after the termination of the voltage step). Therefore, a slowing in the decay of the $Ca^{2+}$ signal can dramatically increase exocytosis in these cells. On the other hand, in synapses, synaptic vesicles are tightly coupled to VGCCs and exocytosis terminates with the closure of VGCCs (collapse of $Ca^{2+}$ microdomains). Therefore, in synapses, a slowing in the decay of the $Ca^{2+}$ transient may have little immediate effect on exocytosis. However, a slowing in the decay of $Ca^{2+}$ transient may enhance short-term facilitation in synapses (for example as described in the "residual $Ca^{2+}$ accumulation" model) and a modest elevation of $[Ca^{2+}]_i$ is known to increase the rate of mobilization of granules to the readily releasable pool. Thus, changes in the duration of the $Ca^{2+}$ transient can affect synaptic plasticity. Since the activities of many of the $Ca^{2+}$ clearance mechanisms can be regulated by kinases and intracellular messengers (e.g. modulation of SERCA pump by protein kinase C), such modulations may allow individual cell type to fine tune its $Ca^{2+}$ signals to meet its specific secretory demand.

## Synonyms

True proposition; Information content

## Definition

In everyday life "information" means either the act of giving someone some knowledge that he or she did not have yet or the content of this knowledge. Information in the latter sense can be produced, lost, destroyed, concealed, changed, distorted, picked up, sold, exploited etc. During the time of scholastic philosophy "informatio" meant the formation of matter such that, after this process, it had a certain form [1,2]. In this sense, a wooden block is informed when a statue is made out of it. The notion of giving form to something can also be applied to the mind, and informing the mind can be understood as impregnating it with various forms [3].

The relationship between information as a form-giving act or process.[1] and information as an act that conveys *knowledge* of something is such that the latter is a subset of the former. Every act of a person that conveys knowledge of something to another person is at the same time an act that forms the mind of the second person in a certain way. But not every such formation does also convey knowledge.

For the concept of information considered so far the notion of content is absolutely central. Information is either the content of some knowledge or the act of conveying this knowledge (which implies conveying the content). In the case of verbal information (i.e. verbal transmission of knowledge) this content is mostly propositional since propositions are the contents of sentences and sentences make up the bulk of vehicles or transmission items in verbal communication.

## Description of the Theory

### Information and Information Theory

There is a theory about the transmission of signals that deals with questions concerning the efficiency of signal transmission from a source to a destination. This theory is known as "information theory [4]." Information theory is not directly concerned with information as true propositions. It is not interested in the question what and how many true propositions are conveyed by a signal. Nevertheless it does ask how much information is conveyed by a signal. But it doesn't count information in terms of the number of propositions. Rather it measures the amount of information transmitted from a source to a destination in terms of the number of different types of messages at the source and the probability of their occurrence at the source. The leading idea is that information is something that reduces uncertainty and that the amount of information should be greater the greater the initial uncertainty. Suppose that two children of two different classes get a prize for the best essay in English. One class has fifteen students, the other twenty five. The event that Nancy of the class with fifteen students gets a prize produces less information than the event that John of the class with twenty five students gets a prize because in the latter case more possibilities (viz. 24) are excluded (more uncertainty is reduced) than in the former case (14). On the one hand we have the production of information and a measure of this information that takes into account the respective space of possibilities and the various probabilities of these, on the other hand we have the transmission of information through a channel (air, cable, etc.) and a measure of the information that arrives at the destination point. The amount of information that is produced at a source can decrease during the transmission process because of various adverse conditions which are called "noise."

In the diagram the "message" can be any event that reduces a space of possibilities to one. The transmitter is a device for coding the event into a signal. This signal is propagated through a channel where it may be affected by "noise." The received signal is the one that arrives at the receiver *after* having been exposed to noise. The receiver decodes the signal into a comprehensible message (although not necessarily into the same kind of event that produced the information at the source). The amount of information that is generated at a source depends on the size of the space of possibilities. Without such a space the amount of information associated with an event cannot be determined.

In principle there are various ways to express the amount of information numerically, but Shannon and Weaver, the originators of information theory, adopted the convention to express it as the logarithm to the base 2. So if the space of possibilities is 64 (e. g. the position of the king on a chessboard) the information associated with the event (e.g. king on c3) is 6, $2^6$ being 64.

However, Shannon and Weaver were not interested in the amount of information associated with particular events, but rather in the average amount of information of events occurring at a certain source. If the probabilities of various types of events are not equal, the information associated with an event of a certain type is given by $\log 1/p(s_i)$ where $p(s_i)$ is the probability of events of type i. The average amount of information of events occurring at a certain source is then a weighted sum of the amount of information associated with the various types of events: $\sum p(s_i) \log 1/p(s_i)$. This is the average amount of information generated at the source (the classroom, the chessboard, etc.). In order to calculate the amount of information that arrives at the receiver the impact of the noise has to be subtracted. From the point of view of information theory it doesn't matter whether the events at the source are linguistic or non-linguistic events nor does it matter whether these events are representations of something like pictures and sentences or not. What matters for the application of

[1] "Process" is here understood as referring to series of events that are not initiated by agents, i.e. entities with a self.

information theory is what the various probabilities of the event types are and what size the space of possibilities is.

According to Fred Dretske there is, however, a certain connection between information theory and information in the sense of "true proposition [5]." A plausible principle concerning information in the latter sense is that if an event *A* carries the information that *B* (that an individual *s* has the property *F*), and *B* carries the information that *C* (that an individual *t* has the property *G*), then *A* carries the information that *C*. For example, if a doorbell rings only if its button is depressed and if the button is depressed only if some person depresses it then the ringing of the doorbell will not only carry the information that the button of the doorbell (*s*) is depressed (*F*), but also the information that someone (*t*) depressed it (*G*).

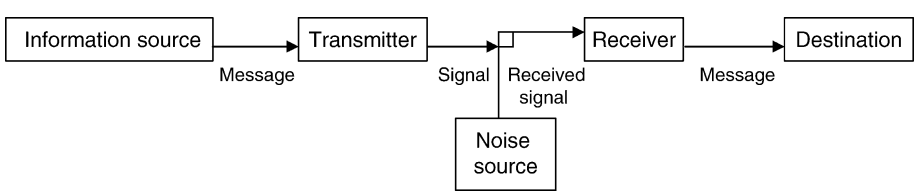
This principle, which Dretske called the Xerox principle, places a certain constraint on the transmission of information if what is being transmitted is information in the sense of true propositions: The *amount* of information carried by a signal (i.e. information in the information theoretic sense) must be the same as the amount of information generated at the source. A communication chain (Fig. 1) in which a signal *A* carries the information that *B* and *B* carries the information that *C* can be such that in the transmission process from *C* to *B* a little amount of information is lost and also in the transmission from *B* to *A*. By adding more links to this chain the more distant links may carry amounts of information that are close to zero. In this case these links would carry no information about *C*, contrary to the Xerox principle. If information in the sense of true propositions is to be transmitted and if the Xerox principle is to be satisfied then the amount of information in the information theoretic sense generated at the source has to be the same as the amount of information carried by the signal. Thus, for the transmission of information in the sense of true propositions the *whole* amount of information in the information theoretic sense is necessary.

## Information and Semantics

One can exploit the notion of information content of a signal for a theory of the *semantic* content of mental representations. The first step of this enterprise is to define the notion of informational content. According to Dretske's definition, a signal *r* carries the information that *s* is *F* if and only if the conditional probability of *s*'s being *F*, given r, is 1, i.e. p(F(s)/r) = 1. This definition captures the sense of information as being a true proposition since a signal cannot carry the information that *s* is *F* without it being the case that *s is F*. Only such information are carried by a signal for which there is a *lawful connection* between properties. This connection may be nomological as in the case of heat and expansion or it may be logical as in the case of being a square and being a rectangle. A signal that carries the information that *s* is *F* carries every other information that is logically or nomologically connected with *s*'s being *F*.

The fact that something, a signal, a physical occurrence of some sort, carries as information all the propositions that are nomologically and logically connected to a certain proposition *p* distinguishes informational content from semantic content. When we consider thoughts as signals and look at their contents then they have single propositions as contents (they may be complex but they can still be counted as *one* complex proposition) and not many. The thought that a certain liquid is water does not also contain the proposition that this liquid is $H_2O$. A theory of semantic content that wants to have informational content as an essential ingredient must therefore embody a further element that selects one out of the many propositions which constitute the informational content.

Dretske himself opted for a teleological element [6]. What selects a certain proposition as the semantic content of a signal is the function of the signal. Hearts, for example, have various properties. Among them are the following three: They pump blood, they make a thumping noise and they exert a gravitational force on other bodies. The function of hearts, however, is only to pump blood. In this way informational semantics accounts for the fact that meanings of representations can be specific, that not every proposition being part of the informational content of a signal belongs to the meaning of that signal. A problem for informational semantics arises out of the fact that representations have their meanings, e.g. <a horse far away>, even if the corresponding proposition isn't true. In short, there are misrepresentations, representations of states



**Information. Figure 1** General structure of a communication system.

of affairs that do not obtain. The animal seen from afar that looks like a horse may in fact be a cow. Since informational semantics requires that the conditional probability of *s*'s being *F*, given the occurrence of the signal *r*, is 1, *s must* be *F* if *r* occurs, i.e. the proposition that *s* is *F* must be true and misrepresentation seems therefore to be impossible.

Dretske tries to solve this problem in the following way. The basic idea is that once a state of an organism has adopted *the function* (e.g. during the evolution) to carry information about certain states of the world, it can keep this function even if this state has stopped to carry information about the world. According to this account, misrepresentation occurs only in cases where once there was an informational relation between a state of an organism and a state of the world, where the state of the organism has adopted the function to carry information about certain states of the world and where, for one reason or other, the informational relation has been broken.

This explanation of misrepresentation makes it clear that the conditional probability of *s*'s being *F* given that the signal *r* occurred has to be relativized to a certain habitat, to the absence of genetic or developmental accidents and to an orderly state of the representing mechanism in question. Otherwise this conditional probability will just never equal 1 and nothing would stand in an informational relationship to anything else.

However, there seem to be cases of misrepresentation that occur when the relevant organs are in good shape, when there is no genetic accident and when the organism is in its natural habitat. A case in point is misperception of something under less than optimal conditions (of sight, hearing, etc.). Although one might deal with such cases along the lines already presented, a deeper problem reveals itself if one asks whether it was ever the case for any kind of organism and any kind of detection mechanism that the conditional probability of some *s*'s being *F*, given the occurrence of signal *r* was 1. If this seems questionable, the informational ingredient in a semantic theory that combines informational and teleological aspects turns out to be questionable as well.

### Information and the Empirical Content of Scientific Theories

The idea of information in the context of probability theory has been used by Karl Popper in order to distinguish scientific theories according to their epistemic value, i.e. according to how much they tell us about reality [7]. Popper's basic idea was that a theory is the better the more it forbids and the easier it can be refuted by empirical evidence. A theory that forbids nothing, i.e. that is compatible with *every* possible evidence does tell us nothing about reality and is cognitively useless. Popper thought that Marxism and psychoanalysis were such theories or theoretical programs. The empirical content of a theory $T_1$ is higher than the empirical content of a theory $T_2$ if $T_1$ excludes more observation sentences than $T_2$. For example, the sentence that all trajectories of heavenly bodies are circles excludes more possibilities than the sentence that all trajectories of planets are ellipses because the latter sentence is compatible with the state of affairs that heavenly bodies move in squares or straight lines or that planets move in ellipses that are not circles (a circle being a limiting case of an ellipse, viz. an ellipse where the two foci collapse into one). Since the sentence that all heavenly bodies move in a circular fashion excludes more possibilities than the sentence that all planets move in an elliptical way it is said to have greater empirical content. The greater the empirical content of a theory the more it tells us about reality where this "more" is not to be understood as "more propositions" but as "more information," information in exactly the sense of information theory. According to information theory more information is generated at a source by an event if the space of possibilities that is reduced by the event is greater. A theory contains zero information if it doesn't rule out anything, if it is compatible with every way the world may turn out to be. It may seem that a theory which can explain everything in its domain and which is refuted by nothing is intellectually superior to a theory which is unable to explain everything in its domain and which would be refuted by many possible observations. But in fact, the price that has to be paid for the irrefutability of a theory is its empirical emptiness, its missing contact with reality.

## Synonyms

A mathematical theory of communication; Shannon theory

## Definition

Information theory is above all a branch of communication theory. According to Claude Shannon [1]: "The fundamental problem of communication is that of reproducing at one point either exactly or approximately a message selected at another point." These two points may be separated in time and/or in space. Information theory addresses this problem and tells us what the ultimate rate of communication is over a noisy channel. Information theory also tells us what the ultimate data compression rate is. In general, information theory is concerned with stating what can and cannot be done in various communication settings. The theory also suggests schemes to achieve those limits and analyses the performance of those schemes. The insight and principles embodied in the theory form the foundation for virtually all modern communication systems.

The enormous influence of information theory on manmade communication systems has inspired many neuroscientists to try to harness the theory to the investigation of neural communication processes (possibly the first such attempt, [2], came only four years after Shannon's publication). In this context, sensory neural systems are probably the most popular subject of information theoretic analysis (see the comprehensive study of [3]), along with synaptic transmission (e.g. [4]) and intracellular communication (e.g. [5]).

However, the meaning of the Shannon information rate in the context of sensory systems research (and neuroscience in general) is sometimes misinterpreted. This is in sharp contrast to the situation in information theory, where the information rate has a very accurate operational meaning. We therefore pay special attention in this essay to the clarification of this issue. The two most important results of information theory, the ►source coding theorem and the ►channel coding theorem, will be presented. (Both are due to the pioneering work of Shannon, [1].) We formulate an operational interpretation for the information rate measured in a sensory system, an interpretation that places the information rate in the context of stimulus discrimination experiments. In addition, other information theoretic viewpoints are presented and briefly discussed.

## Characteristics

### Introduction

Most information theoretic studies of sensory systems concentrate on estimation of the ►mutual information rate between the input and output of a sensory system. (See, for example, several different estimation methods: [3,5–8].) What does the mutual information rate actually mean? One type of interpretation is the following.

Consider two random variables, $X$ and $Y$, which are the input and output of a system, respectively. The ►entropy rate, $H_x$, is interpreted as the uncertainty with respect to $X$. The ►conditional entropy rate, $H_{x|y}$, is interpreted as the uncertainty that remains about $X$, after having observed $Y$. Thus, the mutual information rate, $H_x - H_{x|y}$, is interpreted as the reduction of uncertainty about the input $X$, after having observed the output ($Y$). This "subjective" interpretation does not really tell us what can, or cannot be done with the signals (or channels) at hand.

In contrast, information theory goes beyond the subjective interpretations and offers operative interpretations. ►Entropy and mutual information are related to well defined communication problems, and are used to place limits on what can or cannot be done with them.

When the logarithm in the definition of mutual information is in base 2, the units of mutual information are bits. Suppose that in an experiment, a neurophysiologist estimates the mutual information rate between two signals, and arrives at an estimate $R$. What is the meaning of $R$ bits per second measured between the input and output of a neural sensory system? Surely, we can use the subjective interpretation. However, we would like to associate an operational meaning to the results of such an experiment. For that purpose, let us briefly review the definition of mutual information and it's relation to channel capacity. We will describe some of the classical information theoretic interpretations and then describe the operational meaning we associate with such an experiment.

### Source Coding and Compression

Let us consider the two random variables $X$, $Y$ with joint probability distribution

$$p(x,y) = \Pr\{X = x, Y = y\}, x \in \mathbf{X}, y \in \mathbf{Y} \qquad (1)$$

where $\mathbf{X}$ and $\mathbf{Y}$ are finite sets, called the alphabets of the random variables $X$ and $Y$. Let the marginal probability distributions be $p(x)$ and $p(y)$, respectively. The "randomness" or "uncertainty" in a single random

variable (say $X$) is usually taken as the entropy of $X$, denoted $H(X)$, and defined by

$$H(X) = -\sum_{x\in\mathbf{X}} p(x)\log p(x). \tag{2}$$

(All logarithms are to base 2.) Let $X^n = (X_1, X_2, \cdots, X_n)$ be a random vector, the components of which are generated by $n$ independent drawings of the random variable $X$. The entropy, $H(X)$, is related to compression via the following well-known result [1,9].

### Theorem 1 (The source coding theorem, direct part)

For any $R > H(X)$, any $\delta > 0$, and $n \geq n(\mathrm{R}, \delta)$ sufficiently large, there exists a pair of mappings,

$$f_E : \mathbf{X}^n \to \{0,1\}^N \text{ and}$$

$$f_D : \{0,1\}^N \to \mathbf{X}^n$$

where $N = \lceil nR \rceil$, such that

$$\Pr\{f_D \circ f_E(X^n) \neq X^n\} < \delta.$$

The mappings $f_E$ and $f_D$ are called encoder and decoder, respectively. The essence of Theorem 1 is that it is possible to encode (compress) the random sequence $X_1, X_2, \cdots$ into a binary sequence with $H(X)$ bits per symbol. This is the operative interpretation of the entropy of a random variable. We illustrate that with an example.

### Example 1

Nine cars participate in a car race. Suppose the odds of winning the race for each of the cars are $\left(\frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \frac{1}{16}, \frac{1}{32}, \frac{1}{128}, \frac{1}{128}, \frac{1}{128}, \frac{1}{128}\right)$. The entropy of the car race can be calculated:

$$H(X) = -\tfrac{1}{2}\log\tfrac{1}{2} - \tfrac{1}{4}\log\tfrac{1}{4} - \tfrac{1}{8}\log\tfrac{1}{8} - \tfrac{1}{16}\log\tfrac{1}{16} - \tfrac{1}{32}\log\tfrac{1}{32} - \tfrac{4}{128}\log\tfrac{1}{128} = 2\text{bit}$$

Assume we would like to communicate the result of the race to a distant location. One option would be to send the index number of each car. That description would use 4 bits for any of the cars ($0_D = 0000_B$, while $8_D = 1000_B$; $D$ for decimal, $B$ for binary). However, a better alternative would be to assign shorter descriptions for more probable cars, and longer descriptions for less probable cars. For example, let us use the following bit strings to represent each of the nine cars: (0,10,110,1110,11110,1111100,1111101,1111110,1111111). The average description length in this case is 2 bits, as opposed to 4 bits in the previous case. According to the theorem, it is impossible to find an encoding scheme with a better average description length. The reason this scheme achieves the limit is that the win probabilities are negative powers of 2, i.e. $2^{-K}$. In other cases, a more elaborate scheme would have to be used in order to achieve the limit. In particular, one would have to communicate results of many independent car races (many independent drawings of the random variable X), in order to approach an average description length of 2 bits per result of one car race.

The mutual information between variables $X$ and $Y$ is defined as:

$$\begin{aligned} I(X;Y) &= I(Y;X) \\ &= \sum_{x\in\mathbf{X}, y\in\mathbf{Y}} p(x,y)\log\frac{p(x,y)}{p(x)p(y)} \\ &= H(X) - H(X|Y) \end{aligned} \tag{3}$$

where

$$H(X|Y) = -\sum_{x\in\mathbf{X}, y\in\mathbf{Y}} p(x,y)\log p(x|y). \tag{4}$$

is the conditional entropy of $X$ given $Y$. Thus, following (**3**), the subjective interpretation of mutual information is "the reduction of uncertainty of $X$ due to the knowledge of $Y$" [1].

The mutual information between two random variables also has a compression-related operational interpretation. Suppose, for example, it is required to compress the random sequence $X_n$. Theorem 1 tells us that we can do this with $H(X)$ bits per symbol. However, if the communicating parties both know the sequence $Y_n$, we can use it to enhance the compression of $X_n$. In fact, a simple extension to Theorem 1 tells us that we can do this with $H(X|Y)$ bits per symbol. Thus, following (3), mutual information can be interpreted as the reduction in the encoding length of $X_n$, when we can also use $Y_n$.

Although the subjective interpretation of mutual information (reduction of uncertainty) sounds promising at first, it is clear that the operational interpretations presented so far (compression) do not agree with the problem of sensory information transmission. First, the sensory system is not about compression of sequences. It certainly does not use the input sequence in order to facilitate the compression of the output sequence, or vise versa. Second, note that these operational interpretations require the knowledge of both $X$ and $Y$. In contrast, the central nervous system (CNS) receives only spike trains, coming from the output of a sensory system. With knowledge of the output of the sensory system alone, the CNS must extract information on, or make decisions with respect to, the unknown state of the world outside the sensory system.

## Channel Coding and Channel Capacity

Transmission of information, rather than compression, seems more related to sensory information transmission. Therefore, we show here the essentials of the channel coding theorem.

A discrete memoryless channel is characterized by the channel transition probability matrix

$$p(y|x) = \Pr\{Y = y|X = x\}. \tag{5}$$

The channel is memoryless if

$$p\left(y_1^n|x_1^n\right) = \prod_{i=1}^{n} p(y_i|x_i) \tag{6}$$

The probability distribution of the input, $p(x)$, induces a certain mutual information, $I(X;Y)$, across the channel. The channel "information" capacity is the maximal mutual information, maximized over all admissible input distributions.

### Definition 1: Channel information capacity

$$C_{\text{inf}} = \max_{p(x)\in\mathbf{P}} I(X;Y) \tag{7}$$

where **P** is the set of admissible input distributions.

The input distribution that achieves the maximum in (**7**), denoted $p^*(x)$, is called the capacity achieving distribution. Note that the definition of channel information capacity, in itself, is just a maximization problem over the set of "single letter" input distributions – it does not refer to the communication problem over the actual channel. In contrast, the operational definition of capacity, cited below, is given in terms of an actual communication problem [1,10].

### Definition 2: A code

An $(M, n)$ code for the channel $(\mathbf{X}, p(y|x), \mathbf{Y})$ consists of the following:

- An index set $I_M = \{1,2,\cdots,M\}$.
- An encoding function $f:\{1,2,\cdots,M\}\rightarrow X^n$ yielding codewords $X^n(1)$, $X^n(2)$, $\cdots$, $X^n(M)$. The set of codewords is called the codebook.
- A deterministic decoding function $g:Y^n\rightarrow I_M$ that assigns a guess to every received vector.

### Definition 3: Probability of error

The maximal probability of error for an $(M,n)$ code is defined as:

$$\lambda^{(n)} = \max_{i\in I_M} \Pr\{g(Y^n) \neq i|X^n = f(i)\}.$$

### Definition 4: The rate

The rate $R$ of an $(M,n)$ code is $R = \frac{\log_2 M}{n}$ bits per transmission.

### Definition 5: Achievable rate

A rate $R$ is said to be achievable if there exists a sequence of $(\lceil 2^{nR}\rceil, n)$ codes for which $\lambda^{(n)}\rightarrow 0$ as $n\rightarrow\infty$.

### Definition 6: Channel "operational" capacity

Operational channel capacity $C_{\text{op}}$ is the supremum of all achievable rates.

It is important to understand that the message that goes across the channel is the index $i$, chosen out of the index set $I_M$ (see Fig. 1a). Each index is associated with a codeword $X^n(i)$. If the codewords are chosen appropriately, the received output block $Y^n$ can be used to find the message index $i$ with arbitrarily low probability of error. A good choice of codewords means that they are "widely spaced" (see Fig. 1b). The wide (or "appropriate") spacing of codewords means that the noise in the channel rarely throws the transmitted codeword too far off, in a manner that would result in a decoding error. On the other hand, a bad codebook may result from an inappropriate selection of codewords, or the selection of too many codewords (see Fig. 1c).

The two definitions – operational-capacity ($C_{\text{op}}$) and information-capacity ($C_{\text{inf}}$), are distinct. From the definitions alone, it is not at all clear that they are related. It is Shannon's channel coding theorem that unites them and gives an operational interpretation to the channel information capacity. Basically, it tells us that channel information capacity is the maximum rate, in bits per channel use, in which information can be sent with an arbitrarily small probability of error. In other words

$$C_{\text{op}} = C_{\text{inf}}. \tag{8}$$

The formal statement follows [10].

### Theorem 2: (The channel coding theorem)

For any discrete memoryless channels, the following hold:

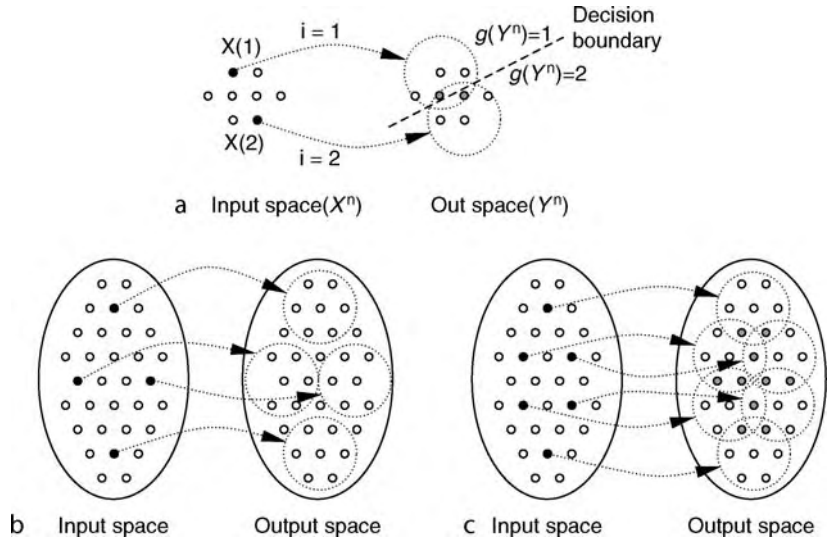
(I) All rates below the "information" capacity $C_{\text{inf}}$ are achievable. Specifically, for every $\varepsilon > 0$, rate $R < C_{\text{inf}}$, and sufficiently large $n$, there exists a $([2^{nR},n])$ code with maximum probability of error $\lambda^{(n)}<\varepsilon$.

(II) Conversely, any sequence of $([2^{nR},n])$ codes with $\lambda^{(n)}\rightarrow 0$ must have $R\leq C_{\text{inf}}$.

The appropriate spacing of codewords incurs a limit on the number of codewords $M$, that is, the rate of the code. The theorem tells us that if we increase the dimensionality of the input space (i.e. increase $n$, the block length) the rate $R$ can approach $C$ with an arbitrarily small probability of error. Since for the current channel model, the operational and informational capacity are the same, it has become customary to use one term, Capacity($C$), to denote both.

### Example 2

Suppose we have an alphabet of 16 symbols (say 0123456789ABCDEF). We assign each symbol a binary number, from $0000_B = 0_D$ up to $1111_B = 15_D$ (see Fig. 2a). We attempt to use those 16 binary codewords to communicate with a distant site over a noisy binary channel. Alas, the channel flips a bit every once in a (rare) while (Fig. 2b). The (4,7) Hamming code shown in Fig. 2a can help us. Every 4-bit source word is assigned a



**Information Theory. Figure 1** Example of codeword selection and expurgation. (a) An ($M$ = 2, $n$ = 3) code. Two codewords (black filled circles) are selected from the eight possible words in the input space (thus $n = \log_2 8 = 3$). Due to channel noise, after a codeword is sent over the channel, any one of the output words that are within the dotted circle can be received. Decoding is based on the decision boundary. If the received word is above (below) the boundary, $i = 1'$ ($i = 2'$) is detected. Reception of the gray filled output words may cause decoding errors. The rate of this code is $R = \log_2 2/3 = 1/3$. The maximal probability of error is $\lambda^{(3)}$, which can be calculated if the noise characteristics are known. (b) An ($M$ = 4, $n$ = 5) code. A good spacing between the codewords results in a low probability of error. (c) An ($M$ = 6, $n$ = 5) code. A bad spacing between the codewords, or the selection of too many codewords, may result in a relatively high probability of error.

**Information Theory. Figure 2** The (4,7) Hamming code, and example of a simple error correction code. (a) Every 4-bit source word is assigned a 7-bit codeword. (b) Without coding errors are received. (c) The (4,7) Hamming code can recover from, at most, a single bit flip in every 7 bit codeword.

7-bit codeword. Since the channel flips the occasional bit, the output of the channel might be any of the 128 7-bit strings. Every 7-bit output string is decoded to be the codeword closest to it in Hamming distance, which is just the number of different bits between binary words. Note that every pair of the 7 bit codewords is different in at least 3 bits. Thus, this code can recover from a single bit flip in every codeword, as shown in Fig. 2c.

It is important to realize that since most physical system satisfy $I(X;Y) < H(X)$, the number of blocks (words) that are allowed into the channel in order to accomplish reliable communication is only a small subset of the space of input blocks (this process is sometimes called "expurgation," and is reflected in the number of black circles versus the total number of circles in Fig. 1).

$$M = \lceil 2^{nR} \rceil \leq 2^{nC} < 2^{nH^*(X)} \leq |X|^n \qquad (9)$$

where $H^*(X)$ is the entropy of the capacity achieving input distribution $p^*(x)$, and $X \in \{0, 1\}$. Here $|X|$ denotes the size of $\mathbf{X}$, the alphabet at the channel input. The relation $[2^{nR}]<2^{nH^*(X)}$ is of particular interest, because it implies that the number of codewords must be exponentially smaller than the number of typical sequences according to $p^*(x)$ in the input space [1] (note that $R$ and $H^*(X)$ are fixed as $n$ grows).

Although $p^*(x)$ achieves the maximum in (7), using $n$-blocks that originate from the distribution

$$p^*(X^n) = \prod_{i=1}^{n} p^*(x_i) \qquad (10)$$

as the input to the channel will not allow us to decode messages with an arbitrarily low probability of error, unless they are expurgated appropriately, resulting in a codebook exponentially smaller than the typical set of $X^n$.

It is important to emphasize that, as easily seen from Theorem 2, the role of $p^*(x)$ is only in determining the number $C_{\text{op}}$, the operational capacity. A common misinterpretation of the terms "information" and "mutual information" is the following: if an information source $p(x)$ is presented at the channel input, inducing the mutual information $I(X;Y)$ between the channel input and output, then, by observing the channel output $Y$ one can "extract" $I(X;Y)$ information bits on $X$ from $Y$. Note, however, that such a claim is not well defined, since it is not clear what the term "extract" in this context means. If it is meant that portions of the input vectors $X^n$ can be fully decoded from the output $Y^n$, then such an interpretation is not true, and does not follow at all from any of the results in information theory. In fact, if we just imply a distribution $p(x)$ at the input, without any expurgation or operation on it, we will not be able to extract information on $X$ from $Y$ with a small probability of error. This can be clarified by the following example.

### *Example 3*

Consider the binary symmetric channel (see Fig. 3)

$$p(y|x) = \begin{cases} p & x \neq y \\ 1-p & x = y \end{cases} x, y \in \{0, 1\} \qquad (11)$$

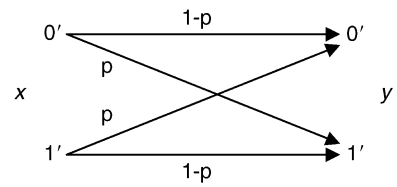
Assume that $0 < p < \frac{1}{2}$. The capacity of this channel is

$$C = 1 - h(p)$$

where

$$h(p) = -p \log p - (1-p) \log(1-p)$$

is the binary entropy. The input distribution that achieves capacity is uniform $p^*(x) = \left[\frac{1}{2}, \frac{1}{2}\right]$. Thus, if $p^*$ is the input distribution to the channel, the mutual information between the input and the output would be $I(X;Y) = C = 1-h(p^*)$. (Note that for $0 < p < \frac{1}{2}$, $0 < h(p) < 1$). According to the channel coding theorem, in order to convey information with rate $R < C$, one must use no more than $2^{nR}$ blocks of size $n$. However, with $p^*(\mathrm{X}^n)$ as input distribution, for each $n$, there exist $2^n$ possible input blocks $\mathrm{X}^n$, all equally probable, and typical according to $p^*(\mathrm{X}^n)$. It is as if the codebook has included all the $(2^n)$ probable sequences emitted from the source $p^*(\mathrm{X}^n)$ (i.e. no expurgation), with rate $R' = 1 > C$. As evident from the converse to the channel coding theorem, this means that the average probability of error is bounded away from zero. In fact, it can be shown that as $n \to \infty$, the average probability of error converges to one.



**Information Theory. Figure 3** The binary symmetric channel. The transmitted bit is $x$, the received bit is $y$. The probability of bit error is $p$.

The channel coding theorem implies that control over the input distribution of the channel is essential in order to establish reliable coded communication. Control over the input distribution manifests itself as the codebook, a collection of carefully chosen blocks, which are the only blocks allowed into the channel.

### Interpretation to the Neural Channel

Let us now consider a sensory neural channel. In a typical experiment (see for example [3]), the sensory system is stimulated, and the information rate between the input and the output of the system is estimated. The input stimulus is a waveform $s(t)$ that is generated according to some predefined probability distribution $P\{s(t)\}$. The estimated information rate between the input and output of the sensory system is denoted $\hat{R}$. Let us ignore, for the sake of argument, the properties of the estimator and assume that the estimator is perfect. The first conclusion we can draw from Theorem 2 (channel coding) is the following[1].

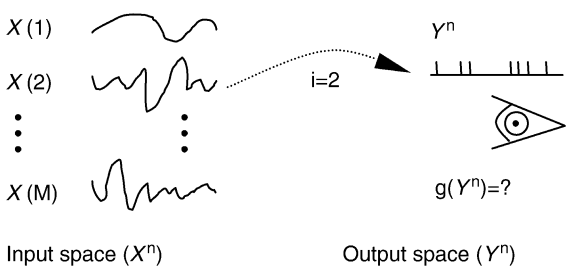
[1] Theorem 2 dealt with discrete channels, whereas now we deal with waveform channels. An extension to waveform channels exists, although the expressions are more complicated [3]. Nevertheless, the implications and interpretations with respect to waveform channels are essentially the same. Note that the duration of the waveform, T replaces the block length, n. Thus, the codebook consists of $M = [2^{\mathrm{TR}}]$ waveforms, instead of $M = [2^{\mathrm{nR}}]$. The rate is given in bits per second instead of bits per transmission.

The fact that the estimated information rate across the channel is $\hat{R}$ bits per second, does not mean that the same amount of "information" can actually be extracted from the output. This can only be done with proper expurgation of the input, or, in other words, proper design of the "encoding function" $f$ of the system input.

The situation in the experiment (and in the behaving animal) is very similar to the situation described in Example 3 above. In both cases, the entire input space is allowed into the channel. This does not allow reliable communication. Although the mutual information rate is $\hat{R}$, actual reliable communication does not necessarily take place.

A possible interpretation, which does follow from Shannon's results, and is consistent with the classical meaning of the mutual information function, is the following (see Fig. 4). One can choose a set of $M = [2^{RT}]$ waveforms, each waveform with duration $T$. Every $T$ seconds one out of $M$ waveforms is presented as input to the channel. Every $T$ seconds the observer of the neural channel output must decide which of the $M$ waveforms was presented. Theorem 2 (channel coding) tells us that if the waveforms are chosen wisely, and for $T$ long enough, an arbitrarily small decoding error can be achieved. Note that the theorem does not tell us explicitly how to choose the waveforms (how to encode).

This interpretation allows us to put the information rate estimation experiment in the context of stimulus discrimination experiments. Those are experiments in which a discrete set of stimuli is presented to a sensory system. The researcher tries to discriminate between the different stimuli based on observation of the neural output alone. The information rate estimation experiment basically tells us what would be the ultimate result of such an experiment. The advantage is that we are free from the need to design the codebook (i.e. choose the waveform set) and the decoder (i.e. find the decision rules). This is a big advantage, because the design of the optimal encoder and decoder can be very complicated. Moreover, a sub-optimal choice can have a huge impact on the results.



**Information Theory. Figure 4** A neural waveform channel. Every $T$ seconds the observer of the output spike train(s) tries to determine which one of the $M$ input waveforms was presented at the input.

### *Remark 1*

Note that we did not address the problem of finding the capacity achieving input distribution. In some information rate estimation experiments, the input distributions were chosen using heuristic arguments based on the physiology of the system [3]. It is important to emphasize that for a given input distribution, the induced mutual information rate over the channel is an achievable (operative) information rate.

### *Remark 2*

In the terms of information theory, the estimated mutual information rate $\hat{R}$ places a lower bound to channel capacity. It is a lower bound because the input distribution used in the estimation procedure, $P\{s(t)\}$, is not necessarily the capacity achieving distribution.

## Conclusions

We presented the two fundamental results of information theory: the source coding theorem (compression) and the channel coding theorem (error-free communication over a noisy channel). We related those theoretic results to neuroscientific concepts and provided an interpretation to the mutual information rate in the context of the neural channel.

The subjective interpretation portrays the mutual information rate between the input and the output of a system as "reduction in uncertainty of the input, after having observed the output." We claimed that this interpretation does not give us an operational meaning. We presented the operational meaning of the mutual information rate, as it emerges from the channel coding theorem. Let us recapitulate.

Assume that a mutual information rate $\hat{R}$ is measured between the input and output of a sensory system. Then, one can choose a set of $M = [2^{RT}]$ waveforms, each with duration $T$. Every $T$ seconds one of these waveforms is presented as input to the channel. The channel coding theorem tells us that if the waveforms are chosen wisely, and for $T$ long enough, the observer of the output can decide which of the $M$ waveforms was presented with an arbitrarily small decoding error. Thus, measuring the mutual information rate $\hat{R}$ gives us the ultimate result of a stimuli discrimination experiment, yet without the need to actually build the codebook (choose the waveforms) or find the decoding function (decide which waveform was transmitted).

## Information Processing

### Definition

In nervous systems the translation of information received by a cell into information transmitted to another cell, usually measured as yes-no electrical events (e.g. action potentials) recorded from cells.

►Evolution and Brain-Body Allometry

## Infradian Rhythms

### Definition

Rhythms with a period longer than 24 h. Formally, this category comprises circannual rhythms (period length about 1 year), circalunar rhythms (period length about 29 days) and some of the circatidal rhythms (e.g., those with a period length of 24.8 h). Usually, the term infradian is reserved for those endogenous biological rhythms which have no counterpart in the natural environment and are characterized by allometric relationships. Examples are estrus cycles and population cycles.

►Circannual Rhythms

## Infundibular Nucleus

### Synonyms

Nucl. arcuatus; Arcuate nucleus

### Definition

This nucleus, also called arcuate nucleus, lies in the intermediate group of the medial zone of the hypothalamus in the tuber cinerum, directly at the attachment of the infundibulum. It contains neurons producing release and release-inhibiting factors, which regulate hormone secretion in the anterior lobe of the hypophysis. The axons of these neurons course in the tubero-infundibular tract to the median eminence, where they anchor at blood vessels.

►Diencephalon

## Infundibulum

### Definition

The infundibulum is the neurohypophyseal part of the hypophyseal stalk. It emerges from the tuber cinerum and, in its upper segment, it surrounds an evagination of the third ventricle, the infundibular recess. In the infundibulum run primarily the axons of the supraoptic nucleus and paraventricular nucleus, which release their hormones ADH and oxytocin into the blood.

►Diencephalon

## Inherited Retinal Conditions or Inherited Retinal Diseases

### Definition

Describes a family of retinal diseases that are associated with genetic mutations. They typically affect individuals at different ages, although most affect vision at an early age. These conditions may be predominantly affecting central vision, eg., juvenile macular degeneration, or the family of conditions described as “Retinitis Pigmentosa” that originally impair peripheral vision.

►Inherited Retinal Degenerations

## Definition

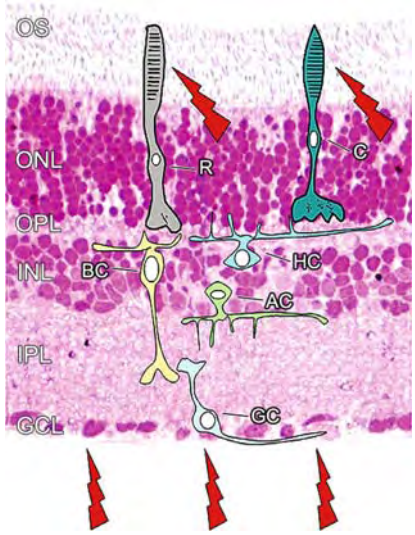
The ►vertebrate retina is susceptible to a number of inherited retinal conditions (►Inherited retinal conditions or inherited retinal diseases) that lead to vision loss. Although relatively few people inherit these devastating diseases (1:4000), they have been the target of considerable research effort. This is largely because many of the events that occur in retinal degeneration are also features of more common retinal conditions such as ►Age-related macular degeneration (AMD); treatments developed that prevent or slow retinal degeneration are likely to have broad application in the management of retinal disease. In addition, the mechanisms that lead to photoreceptor (►Photoreceptors) death are common to neuronal death in other regions of the Central Nervous System (CNS). The retina is an easily accessible part of the CNS and therefore much can be gained about the function of neurons in general by examining specific aspects of retinal function. The purpose of this chapter is to provide an overview of the research that has lead to our understanding of retinal degeneration and outline key research results that have provided useful insights to develop treatment options for this family of ocular conditions.

## Characteristics

### Structure of the Normal Retina

The mammalian retina is a complex array of neurons and glia that converts light energy into electrical impulses to begin the visual process (►Phototransduction). The light-sensitive cells of the retina are the photoreceptors, which subsequently interact with postreceptoral cells leading to the encoding of the spatiotemporal-colour information of our visual space. The two types of photoreceptors operate over different light levels: rod photoreceptors at low or ►scotopic light levels whereas the cone photoreceptors operate over a large ►photopic range extending from twilight to very high light levels. There are two major pathways in the retina: the through-pathway involves *photoreceptors→bipolar cells→ganglion cells* (►Retinal bipolar cells, ►Retinal ganglion cells), although the rod pathway in the mammalian retina incorporates a unique amacrine cell (AII), as part of the through-circuit [1]. Ganglion cells are the output cells of the retina sending their axons to the central visual pathway. The lateral elements of the retina (►retinal horizontal cells and ►amacrine cells) play critical roles in the encoding of visual information through lateral interactions (►Lateral interactions in the retina; ►Retinal direction selectivity: role of starburst amacrine cells) with the elements of the through pathway (Fig. 1).

The retina is a laminated structure of alternating synaptic and neuronal layers (Figs. 1 and 2). The most distal layer, comprising the outer segments of photoreceptors, sits amongst the microvilli of the ►Retinal pigment epithelium (RPE). Rhodopsin is the visual pigment located in rod photoreceptor outer segments, while the cone photoreceptors have different cone photopigments (►Photopigments). Both rod and cone photopigments are composed of a protein (►opsin) and a ►chromophore (a vitamin-A derivative called 11-cis retinal). The different spectral sensitivity of mammalian photoreceptors is derived from different opsins with all photoreceptors sharing the same chromophore. There is an intricate relationship between photoreceptors and the underlying RPE. Vitamin A and other retinoids are transported from the blood stream across the RPE cells to the photoreceptor outer segment. In addition, the RPE cells actively phagocytose the end tips of the photoreceptor outer segment as part of the outer segment



**Inherited Retinal Degenerations. Figure 1** Basic fuchsin stained cross section of the rat retina with schematics of the different cell types. Light (red "lightning rods") must traverse the whole retina before reaching the photoreceptor outer segment. Abbreviations: *R*, rod photoreceptor; *C,* cone photoreceptor; *BC,* bipolar cell; *HC*, horizontal cell; *AC*, amacrine cell; *GC,* ganglion cell; *OS*, outer segments of photoreceptors; *ONL*, outer nuclear layer; *OPL*, outer plexiform layer; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *GCL*, ganglion cell layer.

renewal process. These important photoreceptor-RPE functions are crucial for maintaining vision, and defects in these interactions result in many forms of retinal degeneration.

The more proximal layers of the retina, the inner nuclear layer and ganglion cell layer, contain the somata of the second and third order neurons, bipolar, horizontal, amacrine and ganglion cells. The photopigment captures light leading to a cascade of events where the electrical potential is altered, causing changes in ►neurotransmitter release at the photoreceptor terminal. Horizontal cells are the first to provide lateral interaction modifying the signal that is transmitted by bipolar cells. Bipolar cells transmit the signal from photoreceptors to the inner retina where further interactions occurs with amacrine cells. Complex interactions at the two synaptic layers, outer plexiform and ►inner plexiform layers, are crucial to transmit and shape the signal originally encoded by photoreceptors. The ►outer plexiform layer contains the synapses between photoreceptors and bipolar and horizontal cells. The inner plexiform layer contains synapses between bipolar and ganglion and amacrine cells (Fig. 1).

## The Retina and Inherited Diseases: General Principles

The retina is susceptible to a wide range of ocular diseases that may be inherited, acquired or associated with external insult such as excessive light levels. Retinal cell death can involve all retinal layers with some diseases affecting specific cell classes. Figure 2 outlines the different anomalies causing inherited forms of retinal degeneration. Inherited retinal diseases and the dry form of AMD are characterized primarily by photoreceptor loss, whereas ►glaucoma preferentially affects retinal ganglion cells. In addition, the retina has a very high metabolic demand receiving blood supply from both an inner and outer retinal source. Consequently, any systemic condition affecting circulation impacts on retinal function. Acute disruption of

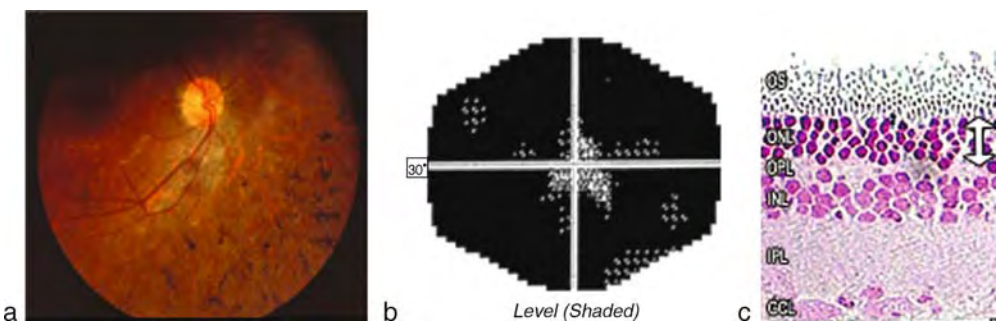
the blood supply leads to major retinal anomalies and includes cell death secondary to ischemia (lack of both oxygen and metabolites), hypoxia (low oxygen availability) or hypoglycemia (low glucose availability).

A prevailing concept is that diseases targeting a specific cell class leave the remaining neurons structurally intact and retinal circuitry unaltered. This view has been challenged recently with results showing ►anatomical remodeling of the whole retina secondary to photoreceptor loss [2], and more importantly, remodeling involving retinal circuitry (►neurochemical remodeling), reflected by changes in neurotransmitter receptor expression or receptor function likely affecting the retina secondary to any "insult" (for examples see [3–5]). Remodeling is of major clinical and scientific significance, especially for developing strategies that restore rudimentary vision to those with permanent vision loss. For example, the use of stem cells to replace damaged cells or electronic implants designed to provide rudimentary vision, have not met *clinical expectations* [6]. These approaches have not met clinical expectations because not only do anatomical changes in the damaged retina impair the accessibility to the remaining neurons of implanted cells or devices, but even if access to remaining neurons is gained, altered retinal circuitry means that the signal will be modified. This altered circuitry may render the signal "jumbled" and the transmitted signal will not be able to be decoded, or worse, the neurons may not be able to send a signal: the collision circuit theory of Marc and co-workers [3]. Although relatively new in the retina, the concept of neuronal remodeling (circuitry alterations) is a large active area of research in the ►somatosensory domain: i.e., the ►phantom limb syndrome. Patients who have had limbs amputated experience sensations, including pain, which has now been found to be due to alterations in cortical circuitry. The *basic science* questions relate to understanding how retinal neurotransmitter modification leads to altered receptor expression and functionality. The retina provides a perfect model to study, firstly, the basic mechanisms of both normal receptor expression and function and, secondly, the molecules that determine the alterations that cause major circuit alterations. Clearly, a better understanding of basic science questions will provide appropriate strategies to be employed to significantly improve the clinical outcome of patients with degenerative diseases.

## Retinitis Pigmentosa

►Retinitis pigmentosa (RP) refers to a family of hereditary diseases, affecting around 1:4000 people worldwide, that causes gradual photoreceptor loss and eventually blindness [7]. RP can be inherited with virtually any inheritances pattern including autosomal dominant, autosomal recessive, or X-linked mutations extending from the delivery/recycling of the chromophore to photoreceptor proteins, ►synaptic transmission and are the secondary to neoplastic syndromes (Fig. 2). Although most of the inheritance patterns follow Mendelian genetics, many RP sufferers have no family history of the disease.

The ocular fundus appearance in more advanced cases displays the typical bone spicule appearance (Fig. 3), which was originally mistaken to reflect an inflammatory response of the retina-hence the name "retinitis". We now know that cell death is through the process of ►apoptosis or programmed cell death and the condition is not due to an inflammation of the retina. Typically, patients with RP experience difficulties with ►night blindness during their teenage years, with



**Inherited Retinal Degenerations. Figure 3** Ocular fundus photograph from a patient with RP showing the characteristic "bone spicule" pigment on the retina (panel a). The patient has extremely restricted visual fields with only some functional vision available in the central ~5°. Most of the central visual field is dysfunctional (denoted by the black encoding from the visual field plot: panel b). Basic fuchsin stained retinal section from a mature rat model of RP (the P23H transgenic rat (►P23H rat) that has a human rhodopsin mutation: panel c). Note the markedly reduced number of photoreceptor layers in the outer nuclear layer: compare with Fig. 1. Abbreviations as in Fig. 1. We are grateful to Associate Professor Ian Gutteridge for providing to us the ocular fundus photograph and visual field of the patient with RP.

gradual loss of the peripheral visual field (Fig. 3), so that by the age of 40 many patients are legally blind, because of severely constricted visual fields. Considerable variation exists in the age at which symptoms are first recognized. Despite this variation in disease presentation, it is well recognized that the disease is caused by gradual death of rod photoreceptors. Later in the course of the disease, cone photoreceptors also die (Fig. 3).

Retinitis pigmentosa can also be associated with other sensory loss with approximately 20–30% of patients also having non-ocular changes leading to the identification of at least 30 syndromes [7]. ►Usher's syndrome is the largest, with patients experience both vision and hearing loss. Retinitis pigmentosa is caused by genetic mutations in proteins important for rod function such as rhodopsin, phosphodiesterase, photoreceptor structural proteins, or RPE proteins. Indeed, mutations in more than 150 different genes have been causally linked with RP. The majority of genetic mutations are in the rod photopigment, rhodopsin (see *http://www.sph.uth.tmc.edu/Retnet/disease.htm*, for continued updates on mutations leading to inherited retinal degenerations).

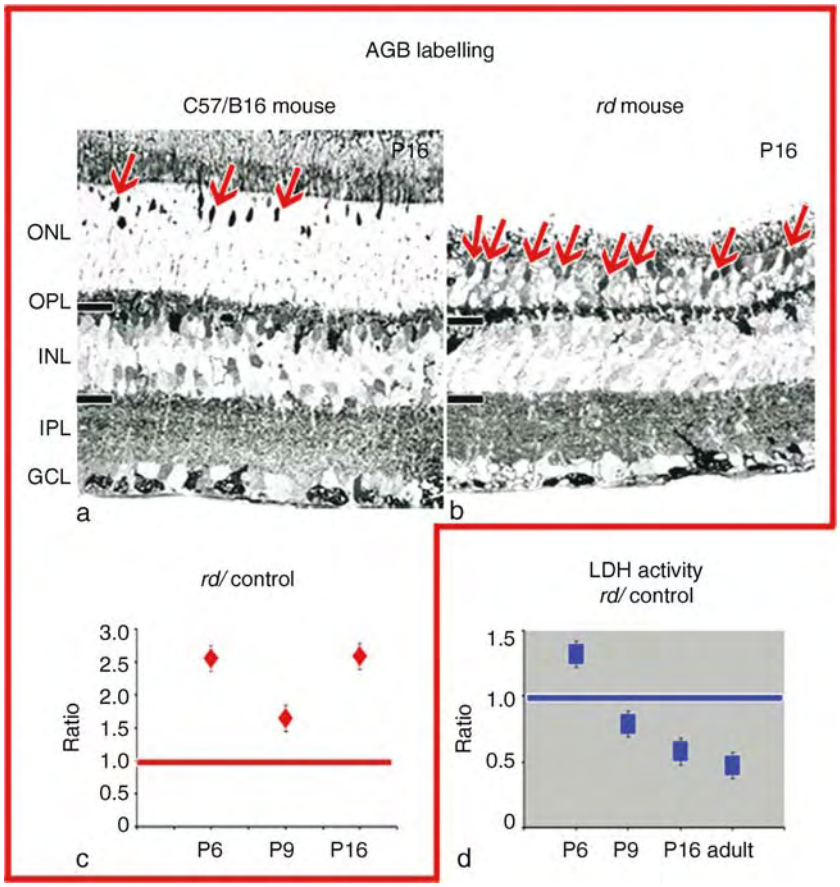
## Death of Photoreceptors is not Entirely Explained by Genetic Mutations

Although retinal degenerations are caused by genetic mutations, it is now recognized that other events take place that exacerbate photoreceptor loss. For example, in animals that have been created by combining the genetic encoding of a normal with an abnormal animal, regions of retina will express normal photoreceptors, whilst other regions will express photoreceptors that carry a mutation. When photoreceptor death was examined it was noted that it was not restricted to regions that contained only mutant photoreceptors. Rather, photoreceptors died in regions that had "normal" photoreceptors indicating that the mutation alone was not the only trigger for photoreceptor death. Also, a perplexing observation is the death of cone photoreceptors during retinal degeneration where the primary mutation is in rod photoreceptors. This highlights again that the mutation alone is not the only cause of photoreceptor death and other "intrinsic" factors cause cell death. External factors such as light exposure are known to accelerate photoreceptor death in both normal and animal models of RP. The light exposure does not necessarily imply extreme light levels but may involve routine clinical procedures such as clinical photography [8]. The relationship between light exposure and photoreceptor viability is complex. We know from our own work that neurochemical and metabolic changes occur within two hours of light exposure, and molecular biology studies have shown patterns of DNA-fragmentation peaks at different times post-light exposure, consistent with likely attempts of the retina trying to repair itself.

## Aetiology of Photoreceptor Death

Despite the large number of mutations and variety of proteins that these mutations affect, it is well known that photoreceptor death occurs via common pathways involving programmed cell death or apoptosis [9]. What is not clear is the factors that lead to the activation of these common apoptotic pathways. Considerable work has been undertaken with animal models of RP. The rd/rd mouse (rd/rd or rd1 mouse) carries a natural mutation in the beta subunit of phosphodiesterase, a rod-specific enzyme important in the phototransduction cascade (Phototransduction). These animals experience rod photoreceptor death from postnatal day 12, and are blind by 3–4 weeks of age. As a consequence of the mutation, the levels of ►cGMP rise within rod photoreceptors with anatomical changes present in photoreceptors of rd/rd mice well before they undergo apoptosis. Using a cation probe, ►agmatine (►AGB), photoreceptors destined to degenerate display higher labeling density compared to control tissue in two different models of RP: the rd/rd mouse and the Royal College of Surgeons rat (►RCS rat). The elevated agmatine labeling may reflect early photoreceptor dysfunction (Fig. 4). *What would be the consequences of early and sustained dysfunction in rd/rd photoreceptors?* One possible answer to this question is the increased energy requirements of abnormal photoreceptors. The energy requirements of photoreceptors are the highest of any cell within the body, because of energy-dependent ion pumps (►Ion transport) present in the inner segment of photoreceptors. Moreover, the light level imposes different energy requirements on photoreceptors; in the light, photoreceptors are hyperpolarized and have lower energy demands, whilst in the dark, photoreceptors are depolarized and have greater energy demands. We have shown that the level of the key metabolic enzyme, ►lactate dehydrogenase, was elevated prior and during the degenerative phase in rd/rd mice, suggesting that metabolic activity is higher in rd/rd mouse retinae prior to their degeneration (Fig. 4). These findings are in agreement with other studies that show that genes important for regulating metabolism are upregulated in several animal models of retinal degeneration prior to degeneration [9]. It is possible that the elevated energy demand of mutant photoreceptors cannot be sustained, leading to their demise.

There are other important changes that have been observed in degenerating photoreceptors that may also contribute to their death. It is well recognized that elevated intracellular $Ca^{2+}$ plays a key role in the early stages of photoreceptor death, perhaps stimulating the intracellular signaling pathways that lead to apoptosis. In rd/rd mice, the level of intracellular $Ca^{2+}$ within



**Inherited Retinal Degenerations. Figure 4** Agmatine (AGB) photoreceptor labeling in control (a) and rd/rd mice with the phosphodiesterase mutation (panel b). The number of agmatine labeled photoreceptors (red arrows) per unit area is significantly increased in the rd/rd retina compared to the control (panel c depicts the ratio). The lactate dehydrogenase activity is significantly elevated before photoreceptor degeneration at post-natal day (P6) in the rd/rd mouse retina (panel d depicts the rd/control lactate dehydrogenase activity). The marked reduction after photoreceptor degeneration (P9 and older) is likely an epiphenomenon due to decreased metabolic demand due to the loss of photoreceptors. Data modified after Acosta and co-workers: Molecular Vision 11: 717–728.

photoreceptors increases approximately 190% compared to control photoreceptors, and genes that are known to be important in regulating intracellular $Ca^{2+}$ (e.g., ►calbindin, ►vinsin-like 1 and ►sparc) are elevated during the early phase of retinal degeneration [9]. One possible reason for the increase in intracellular $Ca^{2+}$ is influx of $Ca^{2+}$ through voltage dependent $Ca^{2+}$ channels (►Calcium channels – an overview). Sustained increases in intracellular $Ca^{2+}$ could be induced by activation of neurotransmitter receptors present on photoreceptor terminals. Receptors to the neurotransmitters ►glutamate and ►ATP have been described on photoreceptors; however, their detailed role in causing elevated $Ca^{2+}$ within photoreceptors is not well understood. Glutamate levels and expression of glutamate transporters are elevated within the retina at a stage during the rod degeneration phase. However, further work is necessary to define the role of abnormal neurotransmission in photoreceptor death.

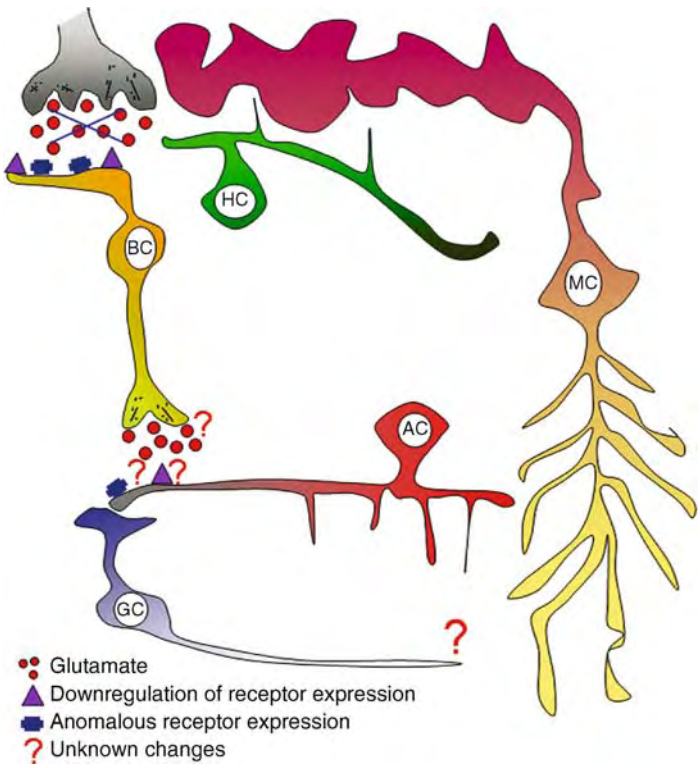
The mechanism of cone death is not well understood. Cone photoreceptor death follows that of rod photoreceptors suggesting that cones depend in some way on the presence of rods for their survival. One possible explanation is cone death via ►oxidative stress. The vasculature of the choroid does not autoregulate, meaning that blood flow in this vascular bed is not tightly tuned to the energy needs of the overlying retina. As the rods die, the oxygen level within the photoreceptor layer increases, possibly causing oxidative stress [10]. Other studies have shown altered byproducts of lipid peroxidation and the beneficial effects of antioxidants. Several reports indicate that cone survival may depend on the release of a cone-survival factor from rods. A third possible explanation of cone death is that rods or

perhaps microglial cells release a toxic substance that is detrimental to cone photoreceptors. Further work is needed, however, to fully define this possibility.

## Neuronal Remodeling During Retinal Degeneration

A central tenet in neuroscience is the plasticity of the brain, especially in infants and following loss of input. Similarly, de-afferentation of photoreceptors during retinal degeneration is associated with wide-spread remodeling of second- and third-order retinal neurons. Gaining a better understanding of the processes that occur during remodeling is significant for at least two reasons. First, for treatments, which involve implantation of stem cells, photoreceptors, or retinal prostheses to be successful, adequate control of the remodeling needs to be taken into consideration. Secondly, although the examples provided imply that remodeling is a negative outcome, this may be far from the truth. Indeed, if the cellular processes that lead to remodeling could be controlled in some way, this may be beneficial for long-term treatment.

Four stages of retinal remodeling have been described in a vast number of animal models of retinal remodeling [2]. During the phase of rod loss, there is active loss of bipolar cell dendrites, and reshaping of second-order bipolar cells. In addition, in transgenic animals that either lack rods or cones, rod bipolar cell dendrites reconnect with cones, and the dendrites of cone bipolar cells reconnect with rods. These results suggest that remodeling is an active process; de-afferented second-order neurons attempt to maintain functional contacts where possible. Following the loss of both rods and cones, a larger scale remodeling takes place. In particular, glial cells form a scar in the outer nuclear layer. In addition, there is widespread migration of neurons into "►neuromas" and the establishment of aberrant synapses throughout the inner plexiform layer [2] (Fig. 5). In animal models of RP, there appears to be a down-regulation and aberrant expression of glutamate receptors with the continual preservation of receptors on OFF cone bipolar cells [3]. In end-stage of the disease ON and OFF cone bipolar cells lose glutamate receptor expression [3,4]. The characteristics of such neurochemical changes need to be fully understood before external intervention strategies can yield fruitful outcomes.



**Inherited Retinal Degenerations. Figure 5** Schematic of anatomical and neurochemical remodeling in the degenerating retina. Müller cells (MC) proliferate and enclose the whole retina. Abnormal glutamate release, down-regulation of glutamate receptors and anomalous glutamate receptors are shown in the outer plexiform layer (photoreceptor-bipolar cell interactions). Within the inner retina, unknown changes are present in neurotransmitter release, and yet unknown receptor properties likely leading to neurochemical remodeling within the inner plexiform layer. Other abbreviations as in Figs. 1 and 2.

### Possible Treatment Strategies

Currently there are no standard treatments that are effective in preventing or slowing photoreceptor death. Large multi-centre clinical trials have evaluated the potentials for high dose vitamin A, combined vitamin A and E as well as anti-oxidants to slow photoreceptor loss in patients. Most studies demonstrate small if any improvements in slowing the rate of progression [6,7]. Over the last few years, several animal studies have shown promising results. Gene therapy and stem cell therapy have all been shown to be beneficial in the treatment of retinal degeneration in animal models. A remarkable improvement in vision was obtained in dogs that carry a gene that causes ►Leber's congenital amaraurosis, a rare bilateral retinal degeneration affecting infants. This is one example where clinical expectations have been met. Stem cells have received interest as possible treatments of a wide number of CNS diseases. Injection of haemopoietic stem cells or neural precursor cells, rather than stem cells lead to visual improvement in rodent models of retinal degeneration.

### Conclusions

Inherited retinal degenerations represent a devastating family of diseases that are characterized by gradual photoreceptor death and blindness. Although they are caused by genetic mutations in proteins important for rod function, many other factors contribute to the death of rods as well as cones. A great deal is known now about how photoreceptors die in these conditions, setting the stage for the development of treatment strategies. However, a greater understanding of how photoreceptor function normally, factors important in their death, and when and how the retina undergoes retinal neurochemical remodeling, has broad applicability to other retinal diseases and neurodegenerative disorders of the CNS.

## Inhibitory Burst Neurons (IBNs)

### Definition

In the horizontal system for controlling rapid eye movements, IBNs are medium-lead burst neurons that make monosynaptic inhibitory connections with contralateral abducens motoneurons and interneurons, with contralateral prepositus nucleus neurons, and with contralateral excitatory burst neurons. Their somata are located in the medial portion of the medullary reticular formation just below and behind the abducens nucleus.

IBNs with vertical preferred direction are in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) in the midbrain reticular formation near the oculomotor nucleus.

# Inhibitory Mechanisms in Developing Nociceptive System

## Definition

A broad description for the peripheral and central processing that leads to inhibition of nociceptive responses or pain perception. Although the growth of descending inhibitory projections to the dorsal horn is well-advanced comparatively early in development, physiological maturity occurs some time later, possibly due to insufficient levels of serotonin or other neurochemicals or delayed maturation of dorsal horn interneurons. This functional immaturity appears to be one of the reasons for much lower reflex thresholds in the infant as compared to the older child and adult.

## Definition

Damaged nerve fibers (axons) in the brain and spinal cord that comprise the central nervous system (CNS) fail to regrow. This lack of axonal regeneration in the CNS results in permanent paralysis, sensory loss, and loss of bowel and bladder function that is seen after spinal cord injury. Seminal work published in 1981 by David and Aguayo [1] showed that neurons in the adult mammalian CNS have the ability to regenerate their axons for long distances if they are provided with an appropriate glial (non-neuronal) environment. Many factors in the non-neuronal environment can influence the regeneration of damaged axons. These include the absence of sufficient amounts of positive factors such as growth factors or neurotrophins (link to *neurotrophins and regeneration* – Matt Ramer), and the presence of negative factors such as axon growth inhibitory molecules. In this essay we present the structural and functional characteristics of a number of axon growth inhibitory molecules, which are currently thought to play a crucial role in the failure of axon regeneration in the CNS.

## Characteristics

Several inhibitors of axon growth have been identified, which are associated with either ►myelin or the glial scar [2]. Myelin, the insulating membranes that wrap around axons is produced by ►oligodendrocytes a type of glial cell, while the glial scar is produced mainly by another glial cell type, the ►astrocyte. Myelin contains three well-characterized inhibitors – Nogo-A (MW = 250 kDa), myelin-associated glycoprotein (MAG; MW = 100 kDa), and oligodendrocyte-myelin glycoprotein (OMgp; MW = 110 kDa). Recent studies also suggest that two other molecules in myelin produced by oligodendrocytes, Sema4D and ephrin-B3, also have axon growth inhibitory activity. The inhibitors in the glial scar are ►chondroitin sulfate proteoglycans (CSPGs) (MWs = ranging from 145 to 500 kDa for different CSPGs). Nogo-A and OMgp are minor components of myelin, while MAG comprises about 1% of all myelin proteins. In this review, we will focus on four well-characterized inhibitors.

### Description of Structure

*Nogo-A.* This is a glycoprotein that belongs to the reticulon family of proteins, which in general are associated with the endoplasmic reticulum. However, there is evidence that a proportion of Nogo-A produced by oligodendrocytes is localized to the cell surface and in myelin membranes where it can contact damaged axons and prevent their growth. Nogo-A has two transmembrane domains that result in the formation of a 66-amino acid extracellular loop. Two inhibitory domains have been identified in Nogo-A: the 66-amino acid loop (Nogo-66) and a domain near the N-terminal region (amino-Nogo). Nogo-A may have different topologies within the membrane in terms of the orientation of the N-terminal region, with evidence for both the Nogo-66 and the N-terminal regions being located extracellularly.

*MAG.* This is a glycoprotein that belongs to the immunoglobulin (Ig)-superfamily of proteins. It has five Ig-like domains that are located extracellularly, one transmembrane domain and a short cytoplasmic tail. The extracellular portion of the molecule containing the five Ig-domains is thought to form a hairpin-shaped

bend. MAG has an abundance of sugar residues making it a highly glycosylated protein. It also binds sialic acid and its Ig-like domains have homologies to members of the SIGLEC family (sialic acid binding Ig-like lectins). The axon growth inhibitory domain(s) in MAG have not been fully identified.

*OMgp.* This is also a glycoprotein that is attached to the cell or myelin membrane via a lipid anchor (glycosylphosphatidylinositol [GPI]). It therefore has no intracellular domain. It is largely localized to the paranodal loops of myelin. A major inhibitory domain of OMgp is a region that contains leucine-rich repeats.

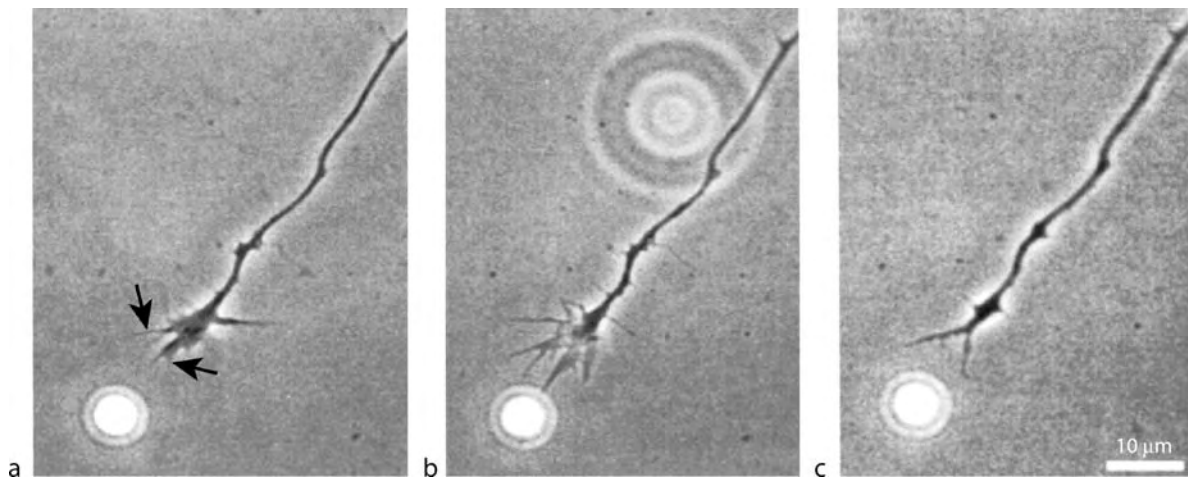
*CSPGs.* Unlike the three inhibitors associated with myelin described above, which are membrane-bound proteins, CSPGs belong to a large, diverse class of extracellular matrix (ECM) molecules. ECM molecules are secreted by cells and deposited in a matrix around cells. There are many families of ECM molecules. CSPGs belong to the proteoglycan family, which are molecules that have a protein core to which is attached long sulfated sugar (glycosaminoglycan; GAG) chains. A number of CSPGs are expressed in the CNS that include brevican, aggrecan, NG2, phosphacan and neurocan [3]. Their inhibitory activities largely reside in their GAG chains.

### Higher Level Structures

These axon growth inhibitors exert their effects at the ►growth cone, a specialized structure at the growing tip of axons. Growth cones are highly motile and possess finger-like extensions called filopodia that constantly move and sense the chemical environment. When they encounter attractive chemical cues such as growth factors or adhesion molecules they respond by forward growth. On the other hand when they encounter repulsive cues such as axon growth inhibitory molecules, the filopodia retract and the entire growth cone, which has an expanded structure (lamellipodia), collapses, thereby arresting its forward growth [4]. For example, this effect of MAG was demonstrated *in vitro* by confronting growth cones of hippocampal neurons with polystyrene beads coated with MAG [5]. Within a few minutes after the growth cones contact the MAG coated beads, the filopodia retract and the growth cones collapse (Fig. 1).

Similar effects have been observed with the other inhibitors using different *in vitro* assays. Filopodial retraction and growth cone collapse is mediated via receptors on the surface of growth cones that bind the axon growth inhibitors. Interestingly, the receptor that was first identified as a receptor for Nogo-66 (NgR; MW = 85 kDa) was subsequently found to also serve as a receptor for MAG and OMgp. NgR is a GPI-anchored protein that partners with the transmembrane proteins $p75^{NTR}$ or TROY and the Nogo-binding protein LINGO-1 to form a receptor complex. When NgR binds to one of its ligands in myelin the receptor complex triggers the activation of an intracellular signaling molecule RhoA, which causes changes in the cytoskeletal components of the growth cone that results in collapse [4] (Fig. 2).

Although CSPGs do not bind to NgR, their effects are also mediated via the activation of RhoA, a member of the Rho GTPase family. Activation of other members



**Inhibitory Molecules in Regeneration. Figure 1** Time-lapse video microscope images showing a hippocampal axonal growth cone growing toward a polystyrene bead coated with MAG. (a) Shows the growth cone prior to contacting the MAG-coated bead. Note the numerous finger-like extensions called filopodia (*arrows*). (b) Shows the growth cone contacting the bead with a few filopodia. (c) Shows that approximately 17 min after first contacting the MAG-coated bead most of the filopodia have retracted, the body of the growth cone called the lamellipodia has collapsed, and the entire growth cone has retracted from the bead. **Inhibitory Molecules in Regeneration.**
**Figure 2** Schematic diagram showing the three inhibitory molecules in myelin, Nogo-A, MAG and OMgp. The diagram illustrates that these inhibitory molecules bind to NgR, which partners with either $p75^{NTR}$ or TROY and LINGO-1. This receptor complex activates RhoA, which triggers changes in the growth cone cytoskeleton leading to growth cone collapse and repulsion.

of this family, namely Rac or Cdc42 leads to forward motility of the growth cone and axonal growth. Therefore extracellular cues can signal axon growth or inhibition by signaling these intracellular pathways. If such repulsive mechanisms are activated selectively on one side of the growth cone, it can cause the growth cone to turn, and thus serve as a mechanism to steer axons to their appropriate targets.

### *Regulation of the Structure*

During development, myelin appears after axons have grown to their targets. Therefore, Nogo-A, MAG and OMgp are not present when the nervous system is getting wired-up to appropriate targets. However, some axon fiber tracts in the CNS grow and become myelinated earlier than other fiber pathways. It has been suggested that inhibitory molecules in pathways that become myelinated earlier, play a role in corralling the later growing axons and thus help in the development of anatomically distinct pathways [6]. The inhibitors associated with myelin are present in the adult CNS and are thought to play a role in preventing unwanted sprouting in the uninjured nervous system. After CNS injury, damaged axons are likely to first encounter the inhibitors in myelin at the site of injury where myelin is damaged. Even if some of the axons are able to navigate past the site of the lesion, they are then likely to encounter inhibitors on the surface of oligodendrocytes and the outer wraps of the undamaged myelin sheaths. There are some reports that dorsal root ganglion neurons, which are part of the peripheral nervous system, are able to grow axons for long distances when transplanted into the adult CNS. It is not clear at present whether this is due to the unique properties of these neurons. In general, however, embryonic CNS neurons are unable to growth axons for long distances when transplanted into the adult CNS. CSPGs on the other hand are not expressed at substantial levels in the normal white matter fiber pathways. Their expression is markedly increased at the site of CNS injury. Since myelin is already present at the time of injury, whereas CSPGs are induced only after injury, it seems reasonable to assume that the inhibitors in myelin are the ones that are first encountered by damaged axons. Nevertheless, there is clear evidence that CSPGs contribute importantly to the failure of axon growth after CNS injuries [3].

## Function

The *in vivo* role of the axon growth inhibitors in myelin was first demonstrated in experiments in which the IN-1 antibody that neutralizes Nogo-A was infused into the injured (dorsal hemisection lesion) adult rat spinal cord [7]. Although only a small number of damaged axons regenerated, this work provided the first clear evidence that blocking such molecules can promote long distance axon regeneration. Subsequently, the IN-1 antibody was tested extensively to assess regeneration in various parts of the injured CNS. Our group immunized adult mice with recombinant Nogo-66 and MAG, and showed that this type of vaccine approach generated antibodies in these animals that neutralized these inhibitors and promoted axon regeneration after dorsal hemisection lesion in adult mice [8]. A peptide that blocks the interaction of Nogo-66 with its receptor was also shown to promote axon regeneration after spinal injury. Work from our laboratory indicates that myelin contains other inhibitory activities in addition to the three already identified, namely Nogo-A, MAG and OMgp [5]. In other work, we immunized mice with myelin using an immunization procedure that prevents autoimmune myelin disease but at the same time generates antibodies against myelin proteins [9]. We showed that the anti-myelin antibodies were able to neutralize the inhibitory activity of myelin, enter the spinal cord, and stimulate extensive growth of injured axons *in vivo*. Although this treatment approach cannot

be directly translated to use in humans because of the potential danger of producing autoimmune disease, it nevertheless provided a valuable proof-of-principle evidence of the importance of the inhibitors in myelin for the failure of axon regeneration after spinal cord injury. Vaccine strategies that are directed at the three inhibitors or their active domains, or the use of small blocking peptides are being developed for therapeutic use. Since Nogo-66, MAG and OMgp bind to the same receptor, NgR, treatments directed at blocking this receptor is another valuable therapeutic goal. Despite these exciting possibilities, recent work from several laboratories on mice which lack either Nogo-A or NgR have provided conflicting results. Whether the differences in the results obtained by the different laboratories are due to technical differences associated with the lesioning and neuronal labeling techniques, or to compensatory changes in the expression of genes sub-serving similar functions or other reasons is not yet resolved.

Interestingly, treatment with the IN-1 antibody that blocks Nogo-A also stimulates sprouting of uninjured fiber tracts, which then reinnervate denervated targets [2]. This sprouting of uninjured fiber tracts may contribute to the functional recovery detected in these experiments. Although the sprouting of uninjured axons may be an effective way to recover lost function, there is also the danger that inappropriate sprouting may cause abnormal motor or functional consequences. It is possible that appropriate rehabilitation techniques may help to refine and strengthen correct neural connections and eliminate incorrect ones.

Several studies have shown that CSPGs inhibit neurite or nerve fiber growth *in vitro*. CSPGs are thought to serve as barriers to axon growth in different parts of the developing CNS [10]. In addition, *in vivo* lesioning and transplantation studies in the adult CNS have shown that damaged or growing axons appear to stop at the boundary of CSPG rich areas adjacent to the lesion [3,10]. Degradation of the GAG chains of CSPGs with the enzyme chondroitinase ABC neutralizes its inhibitory activity. A number of recent studies using spinal cord lesioning models, including some that were combined with cell transplantation have shown that treatment of the injured spinal cord in rodents with chondroitinase ABC promotes axon regeneration and functional recovery [3]. CSPGs expressed in the normal gray matter are organized into perineuronal nets that may inhibit plasticity. Treatment of injured spinal cord with chondroitinase ABC may therefore affect not only the growth of injured fibers but may also promote plasticity of uninjured fibers which may contribute to the recovery of function. Various modes of delivery of this enzyme to sites of CNS injury are currently being tested to assess their therapeutic usefulness.

The neutralization of the myelin associated axon growth inhibitors with antibodies or peptides; and neutralization of CSPGs in the glial scar with enzyme treatments; or the blocking of their intracellular signaling molecules, namely RhoA or its downstream targets such as Rho-associated kinase, have exciting therapeutic potential for the treatment of spinal cord injuries, as well as other CNS disorders such as stroke and multiple sclerosis in which axon damage occurs.

# Inhibitory Postsynaptic Potential (IPSP)

## Definition

An inhibitory postsynaptic potential (IPSP) usually results from presynaptic activation and hyperpolarizes the membrane potential due to a temporal increase in postsynaptic membrane permeability for $K^+$ ions and/or $Cl^-$ ions, thereby bringing the membrane potential closer to the equilibrium potential of these ions.

►Membrane Potential: Basics
►Synaptic Transmission: Model Systems

## Inhibitory Synapse

### Definition

The synapse exhibits the feature that presynaptic stimulation decreases the excitability of a postsynaptic cell. At inhibitory synapses, transmitter binds to the postsynaptic receptors, allows anions to enter the cell, and drives the membrane potential away from threshold, maintaining a membrane potential that is negative relative to the threshold value.

►Synaptic Transmission: Model Systems

## Initial Segment

### Definition

Slim initial region of an axon where it originates from the cell body or a proximal dendrite; often site of action potential initiation.

►Action Potential

## Injury

►Transplantation of Olfactory Ensheathing Cells

## Innate

### Definition

Developing through a process of biological maturation, rather than by learning.

►Theory Theory (Simulation Theory, Theory of Mind)

## Innate Immune Responses

### Definition

Innate immune responses are non-specific host defense responses to tissue damage, infection and cancer. Innate immune responses are mediated through (i) anatomic barriers, such as skin and mucous membranes, providing physical barriers to most micro-organisms; (ii) physiologic barriers, such as high body temperature and acidic environment in the stomach; (iii) endocytic and phagocytic barriers which involve ingesting extracellular macromolecules and particulate materials; and (iv) inflammatory responses featuring increases in capillary permeability, influx of leukocytes and locally released cytokines, chemokines and other mediators.

The major leukocyte types involved in innate immunity are monocytes/macrophages, neutrophils, mast cells and natural killer cells.

►Chemokines
►Cellular and Humoral Immunity
►Cytokines

## Innate Immunity

### Definition

First line of defense against infection, in which phagocytic cells use primitive non-specific recognition systems to kill pathogens. Innate immune molecules can also recognize toxic cell debris such as apoptotic cells and mis-folded proteins and this function may represent the most ancestral role of the innate immune system.

►Innate Immune Responses

## Innate Knowledge

### Definition

Innate knowledge is knowledge that is not acquired by sense experience but is possessed (at least in a dispositional sense) from birth. Some think that the basic principles of language (natural logic) are known in this way.

►Knowledge

## Inner Ear

### Definition
Sensory organ containing multiple receptors subserving vestibular and acoustic sensitivity. Innervated by the octaval or eighth cranial nerve.

►Evolution of Mechanosensory and Electrosensory Lateral Line Systems

## Inner Ear Disorder

►Disorders of the Vestibular Periphery

## Inner Hair Cells

### Definition
The hair cells of the mammalian cochlea which stimulate most of the auditory-nerve afferent neurons.

►Cochlea

## Inner Nuclear Layer (INL)

### Definition
Layer in the retina, containing the somata of horizontal, bipolar, Müller and amacrine cells.

►Horizontal Cells
►Inherited Retinal Degenerations
►Retinal Bipolar Cells
►Retinal Direction Selectivity and Starburst Amacrine Cells

## Inner Plexiform Layer (IPL)

### Definition
Synaptic layer in the inner (proximal) retina where ganglion cell dendrites receive synaptic input from bipolar cells and amacrine cells. Dendrites of different ganglion cell types stratify at different levels of the IPL and contact different types of presynaptic neurons.

►Inherited Retinal Degenerations
►Retinal Bipolar Cells
►Retinal Direction Selectivity and Starburst Amacrine Cells
►Retinal Ganglion Cells

## Innervation

### Definition
The distribution of nerve fibers to a body region or organ.

## Innervation Ratio

### Definition
The number of individual muscle fibers in a given motor unit.

►Motor Units

## Inotropic

### Definition
Inotropic refers to that which influences the contractility of muscular tissue, and is defined as a positive or negative inotropic effect if the force increases or decreases, respectively.

## Input Unit

### Definition
A model network neuron that receives external signals such as sensory signals, signals from other networks,

etc. The stimulation of input units may change activities of hidden units to which they are connected.

►Neural Networks

## Insomnia

**Definition**

The complaint of repeated difficulty falling asleep, staying asleep or obtaining sufficient sleep despite adequate sleep opportunity. The sleep complaints are accompanied by a complaint about associated daytime dysfunction.

►Sleep-Wake Cycle

## Inspiration

►Nasal Passageways

## Inspiratory Drive Latency

**Definition**

The interval of time during which summating excitatory synaptic inputs depolarize respiratory neurons prior to the onset of the inspiratory motor discharge in cranial (e.g., XII) or spinal (e.g., phrenic) nerve motor output.

►PreBötzinger Complex Inspiratory Neurons and Rhythm Generation

## Inspiratory Inhibitory Reflex

►Hering–Breuer Reflex

## Inspiratory Off-switching (IOS)

**Definition**

The inspiratory off-switching (IOS) is the transition process of respiratory cycle from inspiration to expiration.

## Instinct

**Definition**

An innately determined behavior that is specific to a certain species, and appears in the same form in all members of the species.

►Neural Correlates of Imprinting

## Instinctive (Innate) Behavior

**Definition**

Behavior driven by inheritance.

## Instrumental Conditioning

**Definition**

►Operant Conditioning (Instrumental Learning)
►Operant Conditioning

## Instrumental (Operant) Conditioning

►Learning and Motivation

## Insula

### Definition
The insula (Latin for island) is region of cerebral cortex made up of several short and long gyri that are covered over by opercular parts of the frontal and temporal lobes, deep in the floor of the lateral fissure. The insula receives pain as well as other somatosensory input from viscera.

## Insular Cortex

### Definition
The insular cortex is an area of the cerebral cortex located within the lateral (Sylvian) sulcus. The insula is the site of cortical representation of taste, visceral, pain, and temperature sensations. It receives inputs from the ventromedial portion of the thalamus and is connected with the orbitofrontal cortex, amygdala, hypothalamus, and brainstem autonomic nuclei.

## Insulin

### Definition
Insulin is a hormone produced by beta cells in the islets of Langerhans of the pancreas. It is secreted into the blood in response to an increase in blood glucose and amino acid levels. The hormone promotes glucose utilization and storage, uptake of amino acid, and lipid synthesis, and it inhibits lipolysis and gluconeogenesis, thus decreasing blood glucose level.

## Integral Proteins

### Definition
Protein molecules that completely traverse the cell membrane, such as ion channels and ion pumps.

►Membrane Components

## Integrate-and-Fire Neuron

### Definition
A simple single-neuron model that captures the phenomenon of generation of action potentials observed in real neurons.

►Neural Networks

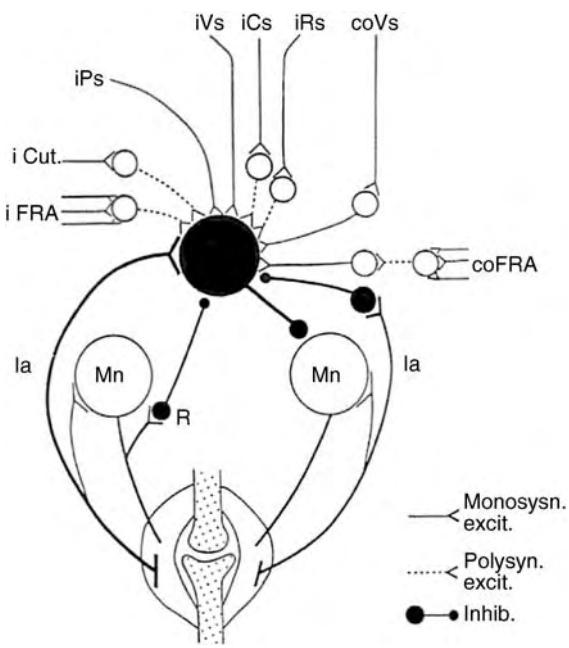
## Integration of Spinal Reflexes

Michael J. Grey, Jens Bo Nielsen
Department of Exercise and Sport Science &
Department of Neuroscience and Pharmacology,
The Panum Institute, Copenhagen, Denmark

### Definition
In general, the neural control of complex bodily functions involves the coordination of numerous responses to sensory input, ranging from the simplest automatic responses called reflexes, to the most complex responses involving the higher centers of the nervous system. This coordination or melding of sensorimotor mechanisms was originally described in the mid-nineteenth century by Ivan Sechenov as a sequential process whereby voluntary activity comprised chains of simple reflexes. Since then, many other neurophysiologists, most notably Charles Sherrington, John Eccles and Anders Lundberg, have used the word "Integration" to describe the central nervous process of modulating and combining sensorimotor mechanisms of varying complexity according to internal and external circumstances.

### Characteristics
#### Introduction
A century ago Charles Sherrington suggested that complex movements could be performed by the integration of a chain of "simple reflexes". Through a series of careful experiments in the early 1900s, Sherrington and his co-workers combined anatomical, physiological, and behavioral evidence to develop a comprehensive theory of reflex action that forms the basis for our current understanding of reflex physiology. This work was continued by John Eccles and his co-workers who, following the introduction of intracellular recording from single neurones in the spinal cord, successfully disclosed the underlying pathways for a number of reflex mechanisms during the 1950s and early 1960s (see [1] for a recent review). Subsequent work by Anders Lundberg

and his co-workers focused on the convergence of interneurones in identified reflex pathways from many different sources, including different classes of sensory afferents and descending fibers from various supraspinal centers [1]. The concept of integration of spinal reflexes in the execution of voluntary movement emerged from this work (Fig. 1). This concept has now been amply documented in human and animal experiments conducted within the last 20 years (see [2] for a recent review). To mention just one example, the Ia reciprocal inhibitory interneurones are facilitated by descending motor tracts (probably most importantly by the corticospinal tract) as much as 50 ms before the onset of the contraction in the target muscle (e.g., [3]; Fig. 2). In this way, the excitability of the motoneurones of antagonistic muscles is reduced even before the contraction has started. This mechanism helps to focus the descending excitatory command to the agonists and to reduce the risk of eliciting the stretch reflex activity that would otherwise be produced when the antagonistic muscles are stretched at the onset of movement. The facilitation of the Ia inhibitory interneurones is tightly linked to the activation of the agonist motoneurones and is in all likelihood conveyed by collaterals from the descending motor tracts that are responsible for activation of the agonist motoneurones (e.g., [4]). However, Ia inhibition may also be reduced in situations where co-activation of the agonist-antagonist muscles is advantageous. For example, this is the case during balancing tasks where co-activation of antagonistic ankle muscles ensures high stiffness of the ankle joint [4]. Co-activation requires that Ia inhibition is reduced, and this is effected by descending commands. The descending tracts probably do not exert direct inhibition on the interneurones themselves; it is more likely that they facilitate the activity of other interneurones, which in turn inhibit the Ia inhibitory interneurones. It is most likely that this occurs through Renshaw cells which mediate the recurrent inhibition from spinal motor collaterals. The main basic understanding that emerges from findings such as these is that reflex mechanisms are not fixed; instead, they are substantially modulated in order to help the brain to achieve optimal muscle activation in any given motor task.

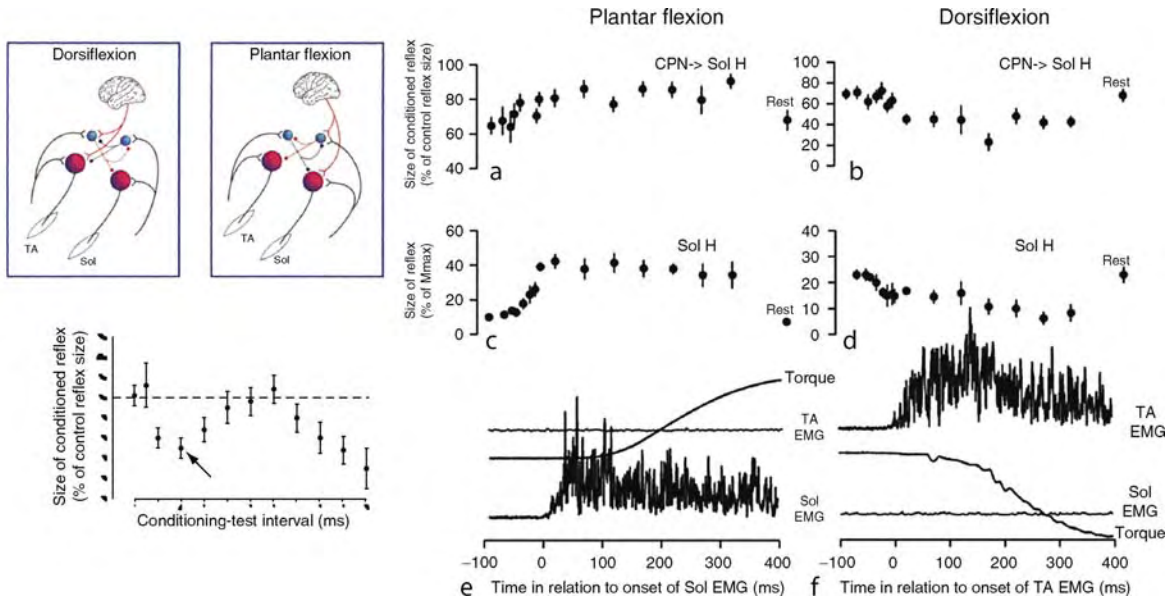


**Integration of Spinal Reflexes. Figure 1** Integration of descending motor tracts and sensory afferent fibers on common Ia inhibitory interneurones in the spinal cord. *Ia* Ia afferents, *Mn* motorneurones, *FRA* flexor reflex afferents, *Cut* cutaneous afferents, *Ps* propriospinal, *Vs* vestibulospinal, *Cs* corticospinal, *Rs* rubrospinal. The prefixes *i-* and *co-* designate that the input originates from the *ipsi-* or *contra*-lateral limb in the case of sensory inputs and the ipsi- or contra-lateral side of the brain in the case of descending motor tracts. This figure is adapted from Hultborn (1972) Acta Physiol Scand Suppl 375:1–42 with permission.

## Voluntary Movement Versus Spinal Reflex

Further support for the concept that integration of sensory feedback with descending motor commands is a fundamental principle in motor control may be found from investigations of the organization of the corticospinal tract. The corticospinal tract is the primary conveyor of descending commands for voluntary movement in humans. It projects directly onto all spinal motoneurones in most primates, and this is especially true in humans (e.g., [5]). However, as in the cat, the majority of the tract projects onto spinal *interneurones* in primates, and this is very likely also the case in humans (e.g., [2,5]). Therefore, to a large extent, the corticospinal tract exerts its effect on muscle activity by modulating the flow of information through spinal neural circuitries. The integration of sensory feedback with descending motor commands in spinal circuitries should therefore be considered as part and parcel of voluntary movements. We contend that it does not make sense to regard spinal reflexes and voluntary movements as two separate entities, as is done, in many contemporary textbooks. The prevailing evidence strongly suggests that the emphasis should instead be on how spinal neuronal circuitries are used by the descending motor commands to facilitate optimal activation of the muscles.

There are still many unresolved issues in this regard. For example, there is evidence to suggest that the direct corticomotoneuronal pathway may, to some extent, have replaced spinal control mechanisms through evolution, especially in the control of hand and finger muscles [6]. In both primates and humans, hand and finger motoneurones receive a greater number of direct projections from the corticomotoneuronal tract than do motoneurones of other muscles [5]. Does this mean



**Integration of Spinal Reflexes. Figure 2** Regulation of reciprocal inhibition in human subjects. Reciprocal inhibition between antagonistic ankle muscles may be investigated in human subjects by measuring the inhibition of the soleus H-reflex evoked that follows a conditioning stimulation of the common peroneal nerve. The time course of this inhibition is shown in the lower left corner of the figure. The horizontal dashed line in the figure designates the size of the control H-reflex without a conditioning stimulation, and the arrow indicates the conditioning-test interval at which a depression of the H-reflex is evoked. This depression is evoked by the activation of Ia inhibitory interneurones from the afferents in the common peroneal nerve. Prior to the onset of a plantar flexion the inhibition is reduced (a), whereas the inhibition is increased prior to the onset of a dorsiflexion (b). These changes in inhibition reflect the descending control of transmission in the reciprocal inhibitory pathway (diagram in upper left corner of figure). The changes in the unconditioned (control) H-reflex (c and d) reflect changes in motoneuronal excitability, and this is partly explained by this central modulation of reciprocal inhibition. This figure is adapted from Nielsen (1998) Dan Med Bull 45:423–435 with permission.

there are fewer corticospinal connections to the interneurones involved in the control of these muscles? Could it be that spinal reflex pathways play little or no role in the control of hand and finger muscles as the available data suggest [5]? Which control mechanisms would have changed through this evolutionary process from the spinal to the cortical level? Is activity in the "evolutionarily new" direct corticomotoneuronal system coordinated with activity in the "evolutionarily old" indirect corticospinal system via spinal interneurones, or has it replaced the older system so that the control of spinal interneurones in humans is primarily conveyed by collaterals from the corticomotoneuronal system? We do not have firm answers to these and many other similar questions; yet they are fundamental to our understanding of human motor control, and they are within reach of experimental inquiry.

## Reflex Versus Sensory Feedback

The manner by which reflex circuitries contribute to movements depends not only on how the supraspinal structures modulate transmission in the sensory pathways, but also on whether or not the sensory activity is within the range of the normal sensory feedback that is expected when a motor program is executed. By normal sensory feedback, we mean the normal *expected* changes in the afferent feedback signal that are generated by changes in muscle length, tendon tension, joint movement, skin stretching, etc. This feedback is different from that which is evoked by a sudden *unexpected* external perturbation that is imposed either at rest or during the execution of the movement. The feedback produced in response to such a perturbation might be considered an *error signal* that requires a change in the central motor command. The stretch reflex is an afferent burst that is elicited by a rapidly imposed joint perturbation, and it may represent an error signal that is interpreted by the nervous system differently than the afferent feedback that is associated with an unperturbed self-generated movement. Based on this reasoning, a stretch reflex response may be used experimentally to investigate corrective responses, but it may not be used to derive information about the typical afferent feedback that contributes to normal motor control. The temporal nature of the apperent burst likely helps the central nervous system to differentiate between normal afferent

feedback and a stretch reflex response that elicits a corrective action (e.g., [7]).

A better way to investigate the role of afferent feedback during motor control tasks may be to remove the feedback by rapidly unloading the muscle-tendon unit. Rather than imposing a perturbation that stretches the muscle-tendon unit and enhances the feedback, a rapid unloading reduces the afferent feedback from proprioceptors and results in a transient reduction of electromyographic activity. This technique has been used during walking in the leg [8,9]. We refer to this as the "unload response" in order to avoid confusion between the corrective reflex response that is evoked by a stretch of the muscle-tendon unit and the reduction of afferent feedback that contributes to a normal movement. It might be argued that the unload response simply reflects a reciprocal inhibition of the unloaded muscle due to the stretch of the antagonist. However, the unload response is not affected by an anesthetic block of antagonist muscle, thus demonstrating that it does indeed result from the removal of afferent feedback [9]. These results we extended by demonstrating that the unload response is not affected by the anesthetic block of cutaneous nerves that supply the foot and ankle [8]. The unload response, therefore, represents the removal of proprioceptive feedback to the spinal cord.

The importance of making the distinction between the stretch reflex response and the unload response may be illustrated with the example of walking. It is well known that the major contributor to the stretch reflex response is the muscle spindle receptor via the group Ia pathway. Dorsiflexion perturbations applied to the ankle produce a stretch reflex response in the soleus muscle (e.g., [10)], and this response has been used to conclude that spindle afferents contribute to the background locomotor activity. More recently, however, we have demonstrated that the plantar flexi on evoked unload response in the soleus muscle is delayed with respect to the stretch reflex response [8], and it appears that it is the feedback from Golgi tendon organ receptors via the group Ib pathway that makes the more important contribution to the locomotor activity, at least during the late stance phase of the step cycle.

## Concluding Remarks

Despite a rich tradition of more than 100 years of research, the integration of spinal reflex circuitries and descending motor commands still has many challenging puzzles to solve. As we have pointed out, there is still no consensus about the mechanism by which the most well-studied and meticulously characterized pathway, the monosynaptic stretch reflex, contributes to the activation of muscles during a fundamental motor behavior such as walking, if it makes a meaningful contribution at all. Solving this and a plethora of similar questions related to more complex spinal neuronal networks will keep researchers active for many years to come and hopefully continue to attract young research talents. This is a requirement for our future ambition of translating the basic understanding of the integrative properties of movement control into useful therapeutic strategies in the rehabilitation of neurological disorders such as stroke, spinal cord injury, and cerebral palsy.

# Integrin-dependent Adhesion Contacts

Stephanie Woo[1], Timothy Gomez[2]
[1]Department of Biochemistry, Biopyhsics, University of California-San Francisco, San Francisco, CA, USA
[2]Department of Anatomy, University of Wisconsin School of Public Health, Madison, WI, USA

## Synonyms

Focal adhesions; Focal contacts; Focal complexes; Point contacts

## Definition

Integrin-dependent adhesion contacts are macromolecular structures that mediate cell adhesion to the ►extracellular matrix (ECM). Cell adhesion sites consist of clustered integrin receptors bound to a plaque of adhesion proteins that ultimately link to the ►actin cytoskeleton. Over 50 unique proteins have been identified within cellular adhesions, making adhesion sites incredibly complex structures. Adding to this complexity is the dynamic assembly, growth, stabilization and disassembly of adhesions that occurs during cell migration and cellular morphogenesis. This process involves continuous modulation of inter-molecular interactions among adhesion proteins (e.g., by ►phosphorylation/►dephosphorylation), which alters cell-substratum binding. Importantly, adhesion-associated proteins often participate in multiple cellular functions. Thus, integrin-dependent adhesion contacts function to both physically link the extracellular matrix to the internal cytoskeleton of the cell, as well as act as sites of localized cell signaling.

## Characteristics

Integrins are ►integral membrane receptors that function as α/β heterodimers to bind ECM ligands such as laminin, fibronectin, vitronectin, and collagen. In humans, there are 18 alpha and 8 beta integrins that combine to form at least 24 distinct receptors [1]. Because the cytoplasmic tails of integrin receptors are relatively short, they rely on interaction with a large number of adhesion-associated adaptor proteins to link to the actin cytoskeleton. An expanding number of proteins have been identified that localize to adhesion contacts. Although it is impractical to list all integrin-associated proteins here, some of more common adhesion related proteins are identified in Table 1, and detailed discussions can be found elsewhere [2].

An important area of current study is focused on how adhesion contacts are formed and regulated during cell migration. Adhesion to the ECM is especially important for this process as it provides traction for motile cells. Cell migration begins with the extension of ►membrane protrusions driven by actin polymerization at the leading edge. These nascent protrusions are stabilized by the formation of small, punctate adhesion sites known as focal complexes. Most focal complexes are relatively labile, but some can stabilize and mature into focal adhesions (also termed focal contacts), larger structures that are elongated in appearance. Focal adhesions are coupled to contractile ►actin stress fibers, which provide the traction forces that can pull the cell forward. Finally, focal adhesions must be disassembled in the cell rear to allow the cell to continue moving forward.

►Neuronal growth cones at the tips of elongating axons, as well as many rapidly migrating cells, generally do not contain large focal adhesions, but instead form smaller and more transient structures known as point contacts ([3,4], Fig. 1).

Similar to the adhesion dynamics of non-neuronal cells, point contacts also initially form as small puncta that mature into elongated structures associated with actin bundles. However, even mature point contacts are on average five times smaller than non-neuronal cell focal adhesions and exhibit much shorter lifetimes. The dynamic assembly/disassembly of adhesion sites is thought to facilitate rapid cell migration.

### Regulation by Rho GTPases

Members of the ►Rho family of small GTPases regulate the assembly and organization of the actin cytoskeleton in many ways. In addition, recent evidence suggests that RhoA and Rac1 regulate the formation and stabilization of adhesion sites [5,6]. Rac1 activity is required to initiate focal complex and point contact formation, but the exact mechanism remains unknown. Integrin engagement increases the interaction between Rac1 and its effector, p21-activated kinase (►PAK). As PAK is known to activate several actin regulatory molecules, actin reorganization downstream of PAK at adhesion sites may be a necessary step in adhesion site formation.

While Rac1 is required for focal complex formation, RhoA activity promotes the maturation of focal complexes into focal adhesions and is similarly required for the maturation and elongation of neuronal point contacts. RhoA-induced adhesion maturation primarily involves activation of ►myosin contraction by the RhoA effector, Rho Kinase (►ROCK). Interestingly, studies in which external force was applied to cells with a glass micropipette showed that mechanical tension alone is sufficient to induce growth of focal adhesions. Although it is unclear how tension or contraction can induce adhesion maturation, one possibility is that

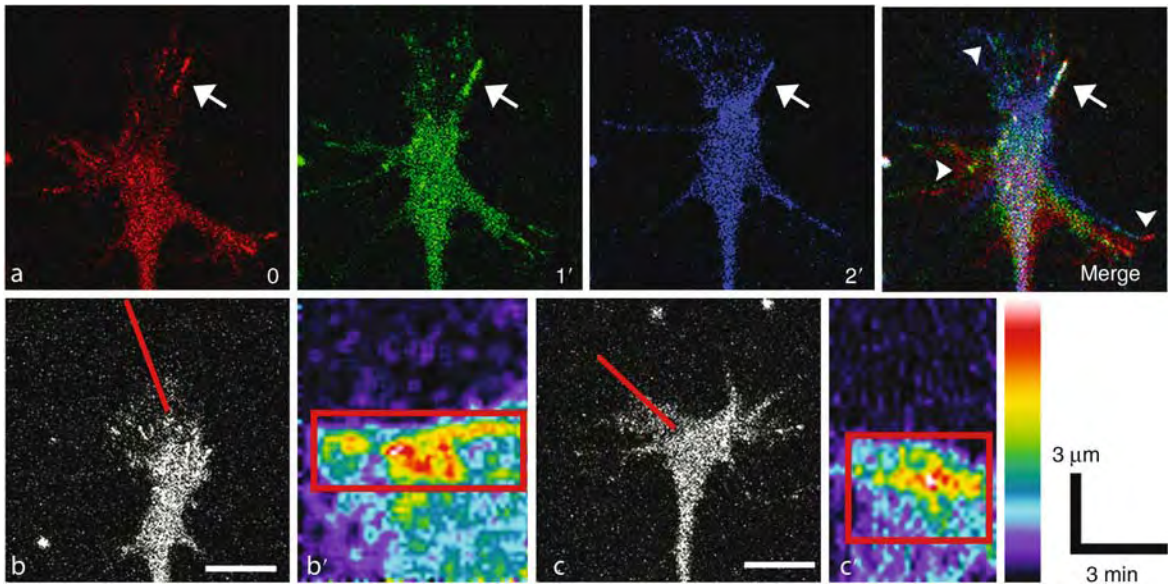
I



**Integrin-dependent Adhesion Contacts. Figure 1** Live point contact dynamics in neuronal growth cones. Green fluorescent protein (GFP) fused to the adhesion protein paxillin (paxillin-GFP) was expressed in *Xenopus* spinal neuron growth cones as a live marker for neuronal point contacts. Paxillin-GFP is organized into discrete puncta and "streak-like" structures that dynamically assemble, grow, and disassemble during growth cone advance on laminin. (a) Pseudocoloring three time points separated by one min red, green and blue help identify stable regions that display as white in the merged image. Large, stable point contacts appear white in the merge (*arrow*) while more transient contacts appear as separate colors (*arrowheads*). (b–c) Kymographs (►Kymography) through individual point contacts (b' and c') assembled from the lines indicated in the frames to the left show the dynamic assembly of individual point contacts. Pseudocolor scale indicates bright fluorescence as hot colors. Point contacts tend to elongate proximally, as and fluorescence intensity increases rearward during elongation (*red boxes*). In contrast, point contact disassembly occurs rapidly and with no directional bias. White scale bars, 5 µm. Black scale bars refer to the kymographs.

mechanical deformation of adhesion proteins may reveal new binding sites for additional proteins, leading to growth and/or maintenance of an adhesion site.

Interestingly, Rac1 and RhoA appear to have antagonistic roles during adhesion site dynamics. For example, expression of activated Rac1 in cultured fibroblasts results in an overabundance of focal complexes at the leading edge coupled with a loss of focal adhesions, whereas expression of activated RhoA had the opposite effect, since existing focal adhesions grow in size and focal complexes fail to form. These observations led to a model in which dynamic assembly and maturation of adhesions sites during cell migration is regulated by spatially and temporally restricted domains of active Rac1 and RhoA. Adhesion contacts initially form at the leading edge where active Rac1 is concentrated. As the cell continues migrating, these contacts transition into an area of elevated RhoA activity, which promotes their maturation. These domains of Rac1 and RhoA activity likely remain distinct through mutual antagonism.

However, this model may not hold true for all cell types. For example, in leukocytes, activation of RhoA is associated with a decrease in cell adhesion, whereas Rac1 is activated during adhesion and cell spreading. Moreover, using a ►fluorescent biosensor for RhoA, active RhoA appears concentrated at the leading edge of new protrusions. This suggests that mechanisms regulating cell adhesion, including the role of Rho GTPases, may vary according to cell type.

## Regulation by Tyrosine Kinase Signaling

Integrin-mediated adhesion sites are highly enriched in tyrosine-phosphorylated proteins [2]. In addition, many adhesion proteins contain ►Src-homology 2 (SH2) domains, which facilitate binding to phosphorylated tyrosine residues. Induction of cell adhesion is associated with an increase in tyrosine phosphorylation, suggesting that adhesion site assembly may be triggered by a cascade of phosphorylation events, followed by recruitment of SH2 domain-containing proteins. Two of the best-characterized adhesion-associated tyrosine kinases are focal adhesion kinase (►FAK) and Src.

Focal adhesion formation is associated with an increase in phosphorylated FAK [2,6]. Furthermore, studies in neuronal growth cones have shown that loss

of FAK results in loss of adhesive point contacts [4]. These studies suggest that FAK promotes adhesion assembly, perhaps by initiating a phosphorylation cascade that signals for additional protein recruitment. However, the role of FAK in regulating adhesion dynamics may be more complex. Rather than inhibiting focal adhesion formation, cells deficient in FAK and Src exhibit enlarged focal adhesions that are slow to disassemble [6]. Thus, although the presence of FAK/Src within nascent adhesion sites suggest they may be involved in assembly, the activity of these proteins also appears to be required for focal adhesion turnover.

How do Src and FAK promote adhesion turnover? Live imaging of ►fluorescent protein components of adhesion sites suggest that adhesions elongate by sequentially incorporating new proteins rearward (opposite to the direction of forward translocation), whereas turnover occurs by rapid dissolution with no apparent directional bias (Fig. 1). This suggests that structural linkages either among adhesion proteins or between adhesion components and the actin cytoskeleton can be rapidly broken down. Breaking those links may be promoted by FAK/Src activity. For example, FAK has been shown to phosphorylate the actin cross-linking protein α-actinin, which reduces its ability to bind to and crosslink actin into bundles. This may lead to weakened connections between actin stress fibers and focal adhesion components. Another possibility involves the protease ►calpain, which is indirectly regulated by FAK/Src activity. Many adhesion proteins are targets of calpain-mediated proteolysis, and cleavage of focal adhesion components contributes to adhesion site disassembly. FAK/Src signaling may also promote focal adhesion turnover through inactivation of RhoA, which as discussed earlier promotes adhesion stabilization. Src has been shown to phosphorylate and activate p190RhoGAP, a negative regulator of RhoA. *fak* −/− cells have elevated RhoA activity in addition to over-stabilized focal adhesions, suggesting that FAK normally acts to inhibit RhoA. However, this is complicated by the ability of FAK to bind the RhoA exchange factor p190RhoGEF, and in some studies, FAK has been linked to increased rather than decreased RhoA signaling. In fact, both Src and FAK contain multiple protein-protein interaction domains that allow them to participate in a variety of signaling pathways. Therefore, the role of FAK/Src signaling in adhesion site dynamics is complex and likely to vary under different conditions and among different cell types.

## Integrin-dependent Adhesion During Nervous System Development

Integrin receptors and associated adhesion proteins are important for several aspects of nervous system development. Given the importance of adhesion to cell migration, it is not surprising that integrin-dependent signaling is implicated in neuronal migration and axon extension. However, integrins have also been demonstrated to play roles in other processes including neuronal differentiation and synaptogenesis.

*Neuronal differentiation.* Integrin receptors activate signaling pathways common to growth factor receptors, and have been shown to regulate neuronal proliferation, survival, and cell fate determination [7]. During development of the mammalian cortex and chick neural tube, neural progenitors express high levels of β1-integrin, which decreases with the onset of differentiation. Concurrently, expression of laminin-1, a β1-integrin ligand, also decreases within the surrounding ECM. These findings suggest that changes in ECM composition and integrin subunit expression may function as a developmental switch during neuronal differentiation. This switch may be regulated by ►microRNAs (miRNAs) – short, single-stranded RNAs that negatively regulate gene expression by blocking translation of target messenger RNAs. The most abundant miRNA in developing neural tissue, mir-124, is upregulated during neuronal differentiation and targets both β1-integrin and the laminin γ1 chain. Also, introduction of mir-124 into nonneuronal cells alters gene expression to a more neuronal-like profile. Integrin-ECM interactions have also been implicated in the maintenance of ►neural stem cells [7]. Reducing levels of β1 integrin resulted in the loss of stem cell markers and ultimately led to altered differentiation or cell death. Therefore, integrins and the ECM may play a role in defining stem cell niches. FAK activity has also been linked to the regulation of gene expression and protein translation, suggesting that these processes may be initiated at sites of adhesion [6].

*Axon guidance*. ECM proteins such as laminin and fibronectin promote axon outgrowth and can guide developing axons if proteins are presented discontinuously. Studies performed both *in vitro* and *in vivo* demonstrate that growth cones often alter their direction of outgrowth at sites where ECM composition changes [3]. In addition, soluble ►axon guidance cues can modulate growth cone adhesion and thereby influence growth cone migration. Soluble guidance cues modulate adhesion by influencing the activation state of integrin receptors or by altering the activity of adhesion-associated signaling proteins [8]. For example, the repulsive guidance cue Semaphorin 3A has been shown to activate Rac1 and protein kinase C, leading to inhibition of point contact formation and stabilization, which reduces adhesion. In *Drosophila*, genetic studies have shown that the repulsive cue Slit interacts with talin, integrin-linked kinase, and integrins themselves. Also, several guidance cues have been shown to signal through the kinases Src and FAK, including Netrin-1 and both A- and B-type Ephrins. FAK has also

been demonstrated to be required for axon guidance decisions in vivo [3].

*Neuronal migration*. Integrin receptors are required for migration of cortical neurons into appropriate layers of the cerebral cortex [9]. For example, disruption of β1-integrin reduces overall cortical migration whereas mutations in α6-integrin result in neurons "overmigrating" and invading superficial layers. In addition, the α3β1 integrin has been shown to be a receptor for Reelin, an ECM protein that is critical for cortical development. However, α3β1 does not seem to directly regulate neuronal migration, but rather is required for the formation of the marginal zone basement membrane. This in turn regulates Reelin distribution as well as organization of the radial glia upon which cortical neurons migrate.

*Synaptogenesis*. Integrin-mediated adhesion also plays an important role in synapse formation and plasticity [9,10]. Conditional ablation of FAK in mouse Purkinje neurons resulted in increased axon branching and an increase in the number of axon terminals and synapses. This suggests that FAK is a negative regulator of branching and synaptogenesis. Interestingly, as FAK is known to promote adhesion contact disassembly, this further suggests that loss of adhesion may be a necessary step in pruning excess synapses. Integrin-dependent signaling may also be important for synaptic plasticity. In hippocampal slice studies, application of peptide inhibitors against integrin receptors blocked maintenance of ►long-term potentiation (LTP), and integrin mutations have been identified in a *Drosophila* mutagenesis screen for defects in learning and memory.

# Intention

## Definition

The specific purpose or the aimed goal of an agent in performing an action.

►Imitation Learning

## Intention Tremor

### Definition

A type of action tremor, usually seen in essential tremor. Intention (or trajectory) tremor is best brought out by finger-nose-finger test.

►Essential Tremor

## Intentional Attunement

### Definition

Mental attunement based on the understanding of intention of others.

►Imitation Learning

## Intentional Explanation

### Definition

An explanation is intentional if it refers to an intentional state (e.g., a belief or desire). Typically we use intentional explanations in order to explain someone's actions. For example, we explain Mary's entering the supermarket by mentioning her desire to buy some milk.

►Representation (Mental)

## Intentional Realism

### Definition

The view that intentional mental states are real in that they (i) are governed by folk psychological laws, (ii) have semantic contents, and (iii) are causally efficacious.

►Representation (Mental)

## Intentionality

### Definition

Intentional states are characterized as being about things; examples are beliefs and desires, plans and wishes. Different orders of intentionality are distinguished (zero-order, first-order, etc.).

### Definition

Some mental states are about things. For instance, the belief that the cat is white is about the cat. States that are about things are *intentional*, that is, they have *content*. The precise nature of intentional states is a matter of dispute. What makes some states, but not others, intentional? Of those states that are intentional, what makes them about what they are about as opposed to something else, i.e. what gives them their *specific* content?

### Description of the Theory

To naturalize intentionality is to give these questions scientifically legitimate answers. Philosophers consider this project important because they want to know where intentional states fit within our rich scientific picture of the world, which is rooted in other areas of scientific enquiry such as biology and physics. Many think that, if intentional states do not fit in this picture, then in some sense they do not really exist.

To understand the debates about intentionality, three distinctions are important. The first is between *narrow* and *wide* theories of content. Narrow theories explain the content of intentional states via conditions that are internal to the mind; wide theories do not. For example, some theories say that part of what makes the belief that the cat is white about *the cat* is the fact that it is caused

by the cat. Since the causal relation between the cat and the belief extends beyond the boundaries of the mind, these theories are wide. Narrow theories deny the relevance of any such mind-external conditions.

Our second distinction is between two persistent problems. Attempts to naturalize intentionality are often unable to account for mismatches between the way the world is and the way intentional states represent it to be. This is the *problem of error*. They are also often unable to capture the fine differences between related but distinct contents. This is the *problem of fine-grainedness*.

Our third distinction is between mental states and sentences of natural language. Both of these can be intentional, or about things. We are concerned mainly with the former, but it is worth noting that the project of naturalizing intentionality can cover both mental states and natural language. Terminologically, the issues are usually described in terms of *meaning* and *semantics* in discussions about language, *content* and *representation* in discussions about mental states.

One earlier project which overlapped with the naturalization of intentionality was the *causal theory of reference*. After Russell and Frege, the dominant theory of names in the early twentieth century was that they were abbreviations of much longer descriptions, e.g. "Napoleon" meant "the French emperor who did such-and-such…". Against this, Kripke and Putnam [1,2] claimed that the meaning of proper names and category names is set by causal and historical connections between the names ("Napoleon," "water") and what they refer to (Napoleon, water). This emphasis on causal relations gave encouragement to other philosophers that a general causal/scientific account could be given for language, mental states and any other intentional states. More fully developed and explicitly naturalistic theories of intentionality followed; they can be split into three major types.

The causal theory of reference had the most direct influence on *informational/causal* theories of intentionality, which elaborate the causal relations necessary for content in general. Informational theories, closely associated with Dretske [3], analyze the content of a state in terms of the information it carries: a particular mental state is about hammers, for instance, because it carries information about hammers. *Information* is then defined non-intentionally, the basic idea being that $x$ carries information about $y$ just in case there is some reliable generalization that, whenever $x$ obtains, so does $y$ (other things being equal). Smoke carries information about fire; tree-rings carry information about the tree's age; hammer-thoughts carry information about hammers.

This theory has trouble with the problem of error. Suppose that most people reliably thought "there's a frog" whenever they saw a toad, as well as a frog. The thought would carry the information that a frog or toad is present, but that would not be its content; thinking frog thoughts when only toads were about would be a mistake.

Fodor's [4] causal theory aims to solve the problem of error by restricting the causal relations that are relevant to content. Even if in general people have frog-thoughts in the presence of toads, that is irrelevant to the content of the thoughts, because this generalization *asymmetrically depends* on the generalization that people have frog-thoughts when they see frogs. It is not clear, however, whether the notion of asymmetric dependence can itself be specified naturalistically.

Teleosemantic theories like Millikan's [5] place informational accounts in an evolutionary context. According to such theories, the content of a state is given by its *biological function*: frog-thoughts have their content because their biological function is to carry information about frogs. Biological function is then defined in terms of natural selection: just as the heart was selected to pump blood, frog-thoughts were selected to carry information about frogs.

Teleosemantic theories readily handle the problem of error. Even if everyone now made mistakes with their frog-thoughts, and even if our ancestors did too, the thoughts would still be about frogs and not toads provided they were selected to carry information about frogs specifically. Where such theories might have trouble is in individuating finely-grained contents. For instance, suppose that in our evolutionary history we only came into contact with one species of frog. Then what makes our frog-thoughts about frogs in general, rather than about that particular species? It is not clear that teleosemantic theories can answer such concerns.

Another family of attempts to naturalize intentionality falls under the heading of *conceptual role semantics* (CRS). According to this sort of theory, advanced by e.g. Field [6], the content of a given mental state is determined by that state's conceptual role. Both wide and narrow versions of CRS have been advocated. Narrow versions take the conceptual role of a given mental state to be determined by its patterns of interaction with other mental states. Wide versions take the conceptual role of a mental state to be determined by its patterns of interaction with other mental states *as well as* features of the external world. For instance, part of the conceptual role of the belief that the cat is white, and thus part of what makes that belief about the cat, may be the fact that that belief tends to come to mind when one is looking at the cat. Since the cat is part of the external world, versions of CRS that subscribe to such views are wide rather than narrow.

There are many problems with CRS. The most important of these is that no one has yet been able to adequately explain how to pick out a specific pattern of interaction that is the conceptual role for the belief that the cat is white, as opposed to a similar but distinct

pattern of interaction that is the conceptual role for the belief that the cat is hungry, etc. Without such an explanation CRS has almost no resources for specifying content, and thus faces a particularly acute form of the problem of fine-grainedness.

In addition to the objections raised to each of these particular approaches to the naturalization problem, some philosophers have viewed the entire project as problematic. Such philosophers have been influenced by Quine's sophisticated arguments concerned with language [7], which supported two related doctrines: the *indeterminacy of translation* and the *inscrutability of reference*. Each of these questioned whether there is any fact of the matter about certain facts about meaning, such as what the correct translation of an utterance is, or what a particular term refers to. The totality of physical facts fail to fix the relevant semantic facts, Quine argued, and concluded from this that meaning facts have no place in a naturalistic worldview, and so semantic and intentional terms deserve no role in a serious science.

When behaviorism, which self-consciously refused to deal in intentional and other mentalistic terminology, was replaced by cognitivism as the dominant paradigm in psychology, the shift raised problems for Quine's conclusions. Psychology began producing robust theories that were couched in intentional terms, and which were therefore committed, at least on the face of it, to the existence of intentional states. For many philosophers, this only made the need to naturalize intentionality more urgent, and their subsequent efforts to produce an adequate account have led to the various theories described above.

Still, the project itself has continued to have its discontents, who take the proliferation of approaches, together with the outstanding lack of success (or even consensus), as indirect evidence for their own skeptical position. More specifically, Stich and Laurence [8] suggest that a fundamental confusion is generated by ambiguity in the notion of naturalization itself. They claim that although fear of *intentional irrealism* – the doctrine that no intentional properties exist whatsoever – has motivated the project of naturalization, the connection between irrealism and naturalization is much less clear than most naturalizers tacitly assume. Once they have surveyed all of the currently available accounts of "naturalization," Stich and Laurence argue that, however it is construed, failure of the naturalization project does not lead to such an unacceptable irrealism.

This issue of what naturalization amounts to emerges less explicitly in many other discussions as well, where "naturalize" is used to mean something like "legitimize." For some, the pressing question is whether a science *should* be committed to contentful states and intentional properties, as contemporary cognitive science is widely held to be. The answer lies in whether or not those intentional properties can be naturalized, and thus legitimized, according to some further, more stringent criterion. Others hold that if a successful natural science is committed to the existence of intentional properties, then this fact *suffices* to naturalize those properties. The search for some further method of legitimization is thus taken to be misconceived.

Other concerns about the viability of naturalizing intentional properties stem from an alleged relation between intentional and normative properties. Most notably, Kripke [9], under the influence of Wittgenstein, starts by considering the activity of rule following, and generates arguments that intentional properties are *essentially* normative. He suggests that since normative properties cannot be naturalized, neither can the intentional properties that essentially contain them.

In sum, the only thing beyond controversy is that, despite much work and debate, none of these issues have been definitely settled yet. Loewer [10] sees a pattern in the failures of the particular approaches, however. He notes that the accounts that successfully deal with the problems of error and fine-grainedness smuggle in and rely, tacitly or otherwise, on non-natural notions, while the accounts that employ only natural notions are unable to give satisfactory answers to the problems of error and fine-grainedness. It is possible that giving a fully adequate account that both solves the problems of error and fine-grainedness *and* uses only naturalistic notions is too complicated, given our formidable but limited cognitive resources. Perhaps, that is, we are *cognitively closed* with respect to the issue. Though some have endorsed this position in other areas of philosophy as well, urging that time and resources would be better spent addressing more tractable problems, it strikes others as defeatist, and methodologically unhelpful. For them, the project of naturalizing intentionality continues.

## Interaction Torques

### Definition

According to Newton's law, velocity of an object does not change in an inertial frame of reference if there is no force acting on the object. However, objects experience a force in an accelerating frame of reference, even when there is no physical force acting on the object. This is what happens in the forearm, when the upper arm rotates at the shoulder. The rotation of the elbow on a sphere implies a centripetal acceleration, which is experienced as a force acting on the forearm. The force on a one limb due to linear or centripetal accelerations of another (usually more proximal) limb is called interaction force. The corresponding joint torque is called interaction torque.

## Intergeniculate Leaflet

Lawrence P. Morin
Department of Psychiatry, Stony Brook University Medical Center, Stony Brook, NY, USA

### Synonyms

Pregeniculate nucleus (primates); magnocellular division of the ventral lateral geniculate nucleus (cat)

### Definition

The intergeniculate leaflet is a nucleus in the lateral thalamic complex bordered dorsally along most of its length by the dorsal lateral geniculate nucleus and ventrally by the ventral lateral geniculate nucleus. The lateral border is the optic tract and medial border, the super thalamic radiation. Toward the caudal end, the intergeniculate leaflet is bordered medially by the medial geniculate nucleus and lateral part of the zona incerta and ventrally it is bordered by the lateral terminal and subgeniculate nuclei.

### Characteristics

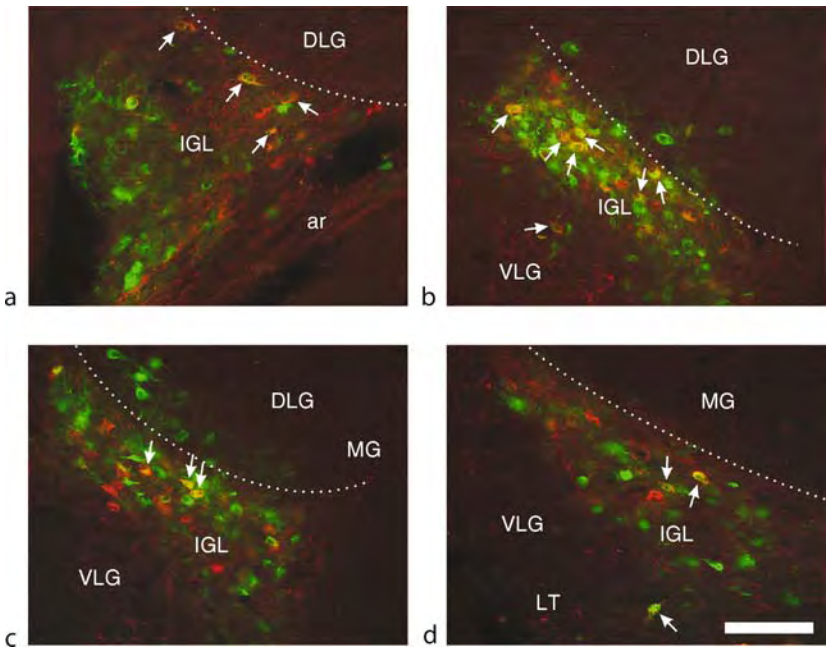
#### Development

The intergeniculate leaflet (IGL) is part of the thalamic lateral geniculate complex. It is homologous with the pregeniculate nucleus of primates and the ventrolateral geniculate nucleus, magnocellular division, of the cat. Developmentally, the IGL arises from the reticular neuroepithelial lobule in which are situated radial glial cells with their endfeet located in the lateral thalamic, primordial IGL [1]. ►Neuropeptide Y (NPY) cells differentiate medially and migrate to the IGL along the path of radial glial processes. As this is completed, the radial glial cells facilitating IGL development detach their cell bodies from the germinal zone of the reticular thalamic neuroepithelium and they are translocated to the IGL, there transforming into reactive astrocytes (found throughout the IGL). This process begins about embryonic day 15 in the hamster. At this time, the NPY cells in the IGL re-orient and send axons ventrally, with the NPY terminal plexus in the ►suprachiasmatic nucleus (►SCN) developing from postnatal day 3–10. In the adult, the IGL is situated ventral to the dorsal lateral geniculate nucleus, and dorsal and generally medial to the ventral lateral geniculate nucleus. For most of its length, it is a fairly thin lamination (Fig. 1b, c), but has an unexpectedly large volume because of its length (approximately 2 mm in the hamster).

#### Retinal Input

The IGL is densely retinorecipient with retinal axons penetrating and arborizing by embryonic day 15.5. The large majority of retinal innervation arrives from the contralateral eye. Both ipsi- and contralateral ►retinas innervate the IGL with substantially overlapping terminal distributions and no evidence of terminal density variation that is relative to the eye of origin [2]. The IGL receives much of its retinal input from ►intrinsically photoreceptive retinal ganglion cells (►ipRGCs), although a significant portion arises from one or more additional classes of ganglion cells. Some of the ipRGCs bifurcate and project to both the SCN and IGL [3].

I



**Intergeniculate Leaflet. Figure 1** (a–d) Coronal sections through four rostral to caudal levels of the hamster IGL showing cells projecting directly or indirectly to the SCN (green), cells projecting from the contralateral IGL to the ipsilateral IGL and direclty or indirectly to the SCN (yellow; arrows). The dotted line indicates the border with the DLG. Cells identified as green or yellow contain retrogradely transported transneuronal virus tracer injected into the SCN; those labeled with red or yellow contain retrogradely transported cholera toxin β-subunit injected into the IGL conralateral to the images shown. Such SCN injections of virus label very few cells in the pretectum despite te fact that many cells in this region project robustly to the IGL.

## Function as part of the Circadian Rhythm System

The only known function of the IGL is its involvement in circadian rhythm regulation. It was the first brain location distal to the circadian clock in the SCN that was identified as being part of the circadian rhythm system [4]. The anatomical connections of the IGL are widespread and complex, offering evidence that the IGL contributes to the regulation of non-rhythm-related activities (see below).

The IGL makes distinct contributions to both photic and ►non-photic control of circadian ►rhythmicity [5]. ►Photic – Animals with IGL lesions fail to show the expected lengthening of the circadian ►period that normally occurs in constant light and have slower re-►entrainment to a shifted light/dark ►photoperiod. Lesions of the IGL also disrupt the ability of animals to show normal photon integration. Although light information is received by IGL neurons and passed on to the SCN via the ►geniculohypothalamic tract (GHT), there does not appear to be a direct connection between retinal terminals in the IGL and cells projecting to the SCN [6,7]. Therefore, because of the many IGL-afferent connections with other retinorecipient nuclei, it is not possible to exclude the possibility that the important photic information arrives via one of the other nuclei. ►Non-photic – The IGL mediates the actions of several *non-photic* stimuli that modify circadian rhythm phase. For example, the benzodiazepine drug, triazolam, or locomotor activity in a novel wheel can elicit shifts in circadian rhythm phase the temporal and magnitude properties of which are described by an NPY-type ►phase response curve [5]. The target in the brain, at which triazolam acts to initiate the sequence of events that elicits a phase shift, is not known. With respect to activity in a novel wheel, it is not known what aspect of this behavior constitutes the actual stimulus that elicits non-photic ►phase shifts. Because the most robust such shifts occur following activity in a novel wheel during the rest portion of the animal's day, it has been thought that sleep deprivation might cause the phase shifts. However, it is now clear that sleep deprivation can occur without associated shifts in circadian rhythm phase.

The IGL is easily identified as the only place in the lateral geniculate region containing NPY cells. Many, but not all, of these cells project to the SCN and provide a dense terminal plexus throughout nearly the entire nucleus (it is less dense dorsomedially and dorsally).

In addition, hamster IGL neurons contain neurotensin co-localized in a subset of the NPY cells. Other IGL neurons also contain enkephalin or GABA which co-localize with each other and with NPY to varying degrees. All cell types project to the SCN via the GHT with similar terminal distributions [5].

NPY release from the GHT appears to be critical for the regulation of certain non-photically-induced phase shifts (e.g. by triazolam or activity in a novel wheel). IGL lesions destroy the GHT, eliminating the NPY terminals in the SCN. Stimulation (electrical or chemoexcitatory) of the IGL elicits phase shifts of the NPY-type. Elimination of endogenous NPY from the SCN also eliminates the ability of animals to show non-photic phase shifts [5,8].

The enkephalinergic component of the GHT may also contribute to circadian rhythm regulation. Opioid receptors are present in the SCN and activation of delta opioid receptors with an enkephalin agonist can induce NPY-type phase shifts. In addition, enkephalinergic delta opioid agonists attenuate magnitude of light-induced phase shifts [5].

The route by which non-photic stimulus information arrives at the IGL and is transmitted to the SCN is uncertain. Activity in a novel wheel induces FOS protein in IGL neurons containing NPY. However, these particular cells apparently are not among those contributing to the GHT. Similar results are found when light is the stimulus. Despite the fact that light-induced FOS seldom occurs in neurons giving rise to the GHT, those IGL neurons that do express FOS protein appear to be more sensitive than SCN neurons with respect to the FOS-inducing effects of light [6,7].

The neural substrates mediating phase shifts induced by triazolam treatment or activity in a novel wheel are different. Lesions of the deep ►superior colliculus/olivary pretectal nucleus eliminate the triazolam-induced PRC, but have no effect on shifts in response to novel wheel activity. The same is true for lesions that specifically destroy serotonergic neurons in the median (but not the dorsal) ►raphe nucleus. Thus, although several non-photic stimuli exert their ultimate effects upon the SCN through the "final common path" of the IGL and GHT, they appear to have different anatomical substrates afferent to the IGL [9].

## Extensive Connectivity with Sleep, Visuomotor and Vestibular Systems

One of the many regions afferent to the IGL is the dorsal raphe nucleus which provides both serotonergic and non-serotonergic input. The median raphe does not project to this region. Hence, it has been thought that the midbrain serotonergic system may exert both direct and indirect effects on the circadian clock. The former can occur via the median raphe projection to the SCN and the latter via the dorsal raphe projection to the IGL with final input to the SCN through the GHT. The dorsal raphe and its projection to the IGL may mediate novel-wheel activity-induced phase shifts, although the data are not entirely clear on this issue [5].

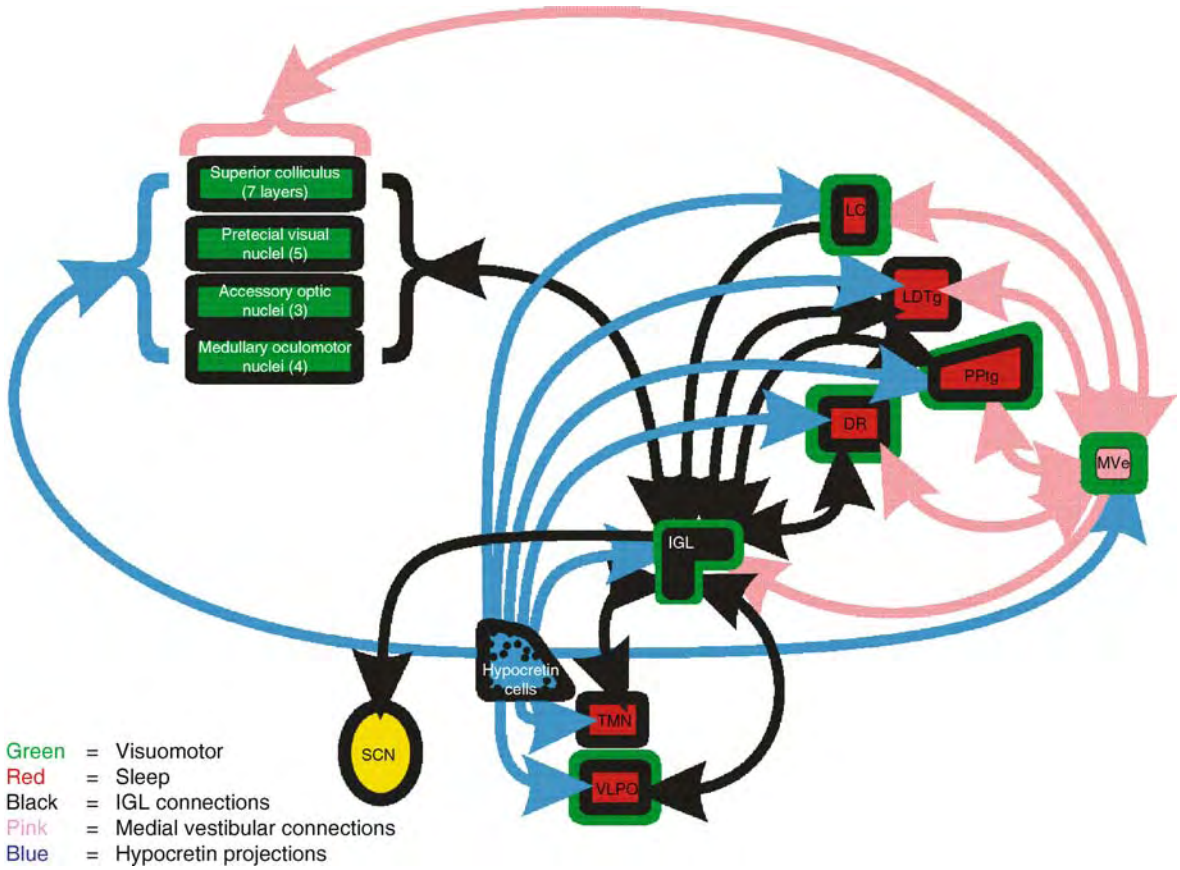
In the context of the role of the deep superior colliculus and ►pretectum with respect to circadian rhythm regulation, it is important to note that lesions of this general area can also prevent ►dark-induced REM sleep that occurs in certain rat strains.

The anatomical connectivity of the IGL is extraordinarily extensive and, as a consequence, complicated [10]. In addition to the multiple cell types contributing to SCN innervation via the GHT, some of the cell types (but not the same cells) project to midbrain ►pretectal nuclei and to the contralateral IGL. All pretectal nuclei plus the adjacent superior colliculus are also retinorecipient and form part of the ►subcortical visual shell consisting of 12 contiguous retinorecipient nuclei extending from the ventral lateral geniculate nucleus, ventrally, to the medial pretectal nucleus and superior colliculus dorsally and medially. Of the 12 nuclei, only those that are involved in classical vision processes (dorsal lateral geniculate and lateral posterior thalamic nucleus) do no receive IGL input.

The IGL connects with more than 100 brain regions with a pattern based on three general principles of organization: (i) extensiveness; (ii) bilaterality; and (iii) reciprocity of innervation between the IGL and its targets [10]. These characteristics, in conjunction with the known functions of specific targets, imply other functions of the IGL. For example, the IGL receives input from hypocretin/orexin neurons, as well as projecting to nearly all the targets of such neurons. Thus, the IGL projects to nearly all brain regions known to contribute to sleep regulation (e.g., dorsal raphe, ventrolateral preoptic area, lateral dorsal tegmentum, ►locus coeruleus) and most of these regions reciprocally innervate the IGL. The same is true for the regions involved in ►visuomotor function, including the medial vestibular nucleus (Fig. 2). The pattern of IGL anatomical connectivity strongly suggests that the IGL is involved in the regulation of rapid eye movements during sleep. This is further supported by the presence of two distinct classes of IGL cell, as defined by their connectivity. One set projects, directly or indirectly, to the SCN, while the other does not. Instead, the latter project to midbrain nuclei and more caudal structures.

## Non-Circadian Rhythm Studies

The available electrophysiological data support the idea that one IGL activity concerns visuomotor function in the monkey. Other studies in the rat have described a slow oscillation (about 20 Hz in a burst over 70 s) with a period of about 106 s. Lesions of the dorsal raphe



**Intergeniculate Leaflet. Figure 2** Connectivity (black) relationship between the IGL and a variety of brain regions involved in the regulation of visuomotor (green), sleep (red) and equilibrium (pink) functions, will emphasis on the relationship to projections of the hypocretin system (blue).

nucleus increase IGL cell discharge frequency by about 100%. The rhythmicity either originates outside the IGL or is dependent upon afferent activity for its expression. Whether the slow oscillatory bursting activity is related to circadian rhythm regulation, visuomotor activity or something else remains to be established [5].

## Interictal Phenomena

### Definition

Personality and emotional changes becoming apparent during periods between seizures (inter icti) in ►chronic temporal epilepsy and consisting of a decline in sexual interest often paralleled by increasing social aggressiveness, the patients often being extermely emotional, religious, moralistic and devoid of humor.

## Inter-Labyrinthine Line

### Definition

A line drawn through the right and left vestibular labyrinths.

►Galvanic Vestibulospinal Responses (Theory)

## Interleukin-2 (IL-2)

### Definition

Interleukin 2 (IL-2) was initially identified as a T cell growth factor and is produced by many cell types. It has widespread effects on the cells of the immune system, on microglia/macrophages, on oligodendrocytes and on astrocytes.

## Interleukin-6 (IL-6)

### Definition

IL-6 is a pleiotropic cytokine that is involved in the regulation of numerous physiological cellular processes (e.g., proliferation, differentiation and apoptosis) and in immune responses. The IL-6 receptor consists of two distinct subunits (IL-6Ra) and two signaling subunits (gp130). The gp130 subunit is also required for the signaling of other members of the IL-6 family such as IL-11, LIF, OsM, CNTF. IL-6 signaling is associated with JAK1, JAK2 and TYK2 that phosphorylate upon activation STAT3, STAT1 and the protein phosphatase SHP-2. The JAK/STAT pathway and the SHP-2 pathway have counter regulatory functions.

►Central Nervous System Inflammation: Cytokines and JAK/STAT/SOCS Signal Transduction
►Cytokines

## Interleukin-12 (IL-12)

### Definition

Interleukin 12 (IL-12) is a key pro-inflammatory cytokine in the regulation of immune responses. It is secreted mainly by macrophages, dendritic cells, and granulocytes after stimulation and exerts its effects mainly on T and B lymphocytes and natural killer (NK) cells predominantly through the activation of STAT4.

IL-12 induces the differentiation of CD4-positive Th cells from a Th0 (naïve) to a Th1 (activated) phenotype that is characterized by up-regulation of numerous pro-inflammatory cytokines, including several chemokines and interferon (IFN)-γ.

►Chemokines
►Cytokines
►Central Nervous System Inflammation: Cytokines and JAK/STAT/SOCS Signal Transduction

## Interleukin-6 Receptor (IL-6R)

### Definition

Following IL-6 binding the IL-6 receptor forms a complex with gp130, a highly promiscuous cytokine signaling co-receptor essential for various mammalian cell growth and homeostasis pathways. Ligand binding results in signaling through the JAK/STAT and MAPK pathways.

## Intermediate Layer of the Superior Colliculus

### Definition

The superior colliculus is a region in the dorsal part of the midbrain that controls saccadic eye movement and

other orienting movements. Its intermediate layer contains neurons that project to the brainstem and the spinal cord and that exhibit a burst of spikes before saccade.

►Saccade, Saccadic Eye Movement
►SC – Saccade Related Burst Neurons

## Intermediate Substance

### Synonyms
Subst. intermedia

### Definition
The gray matter of the spinal cord between posterior horn and anterior horn. Here the afferents of the touch receptors synapse, as do the viscero-afferents.

Afferents from the joints terminate here in rather ventromedial sections.

►Medulla Spinalis

## Intermediolateral Nucleus

### Synonyms
Nucl. intermediolat

### Definition
Also called intermediolateral substance. Part of the lateral horn in the thoracic cord with sympathetic neurons for vasomotor activities.

►Medulla Spinalis

## Intermittent Hypoxia

### Definition
Exposure to repeated brief periods of lower than normal oxygen levels. These exposures are normally seconds to minutes in duration, separated by similar periods of normal oxygen levels. The most common clinical manifestation of intermittent hypoxia is sleep apnea, a condition in which patients intermittently stop breathing during sleep due to instability in respiratory control, or collapse/obstruction of the upper airways.

# Internal Capsule

## Synonyms
Capsula interna

## Definition
Virtually all ascending and descending cortical pathways pass through the internal capsule. The capsule is v-shaped in horizontal sections and is composed of three regions:

- Anterior limb of internal capsule
- Genu of internal capsule
- Posterior limb of internal capsule. Depending on the position vis-a-vis the lentiform nucleus, two other portions can also be distinguished in the posterior limb:
- Retrolenticular part of internal capsule
- Sublenticular part of internal capsule

►Telencephalon

# Internal Desynchronization

## Definition
One of the definitions of a circadian rhythm is that the rhythm persists under conditions devoid of external time cues, although the rhythms period can slightly deviate from 24 h. Under these conditions, regular rhythms of body temperature and sleep-wake alternations are observed and in most cases, the rhythms of the various variables are phase locked. In some cases, the period of the sleep-wake cycle can spontaneously lengthen and therefore dissociate or desynchronize from the rhythms of other physiological variables such as body temperature that maintain their original period length. This phenomenon is referred to as internal desynchronization and does not occur in real life, except in certain blind individuals.

►Circadian Rhythm
►Internal Desynchrony

►Sleep-wake Autonomic Regulation
►Sleep-wake Cycle

# Internal Desynchrony

Ralph Mistlberger
Department of Psychology, Simon Fraser University, Burnaby, BC, Canada

## Synonyms
Spontaneous internal desynchrony; Transient internal desynchrony

## Definition
Loss of synchrony between two or more circadian rhythms within an organism.

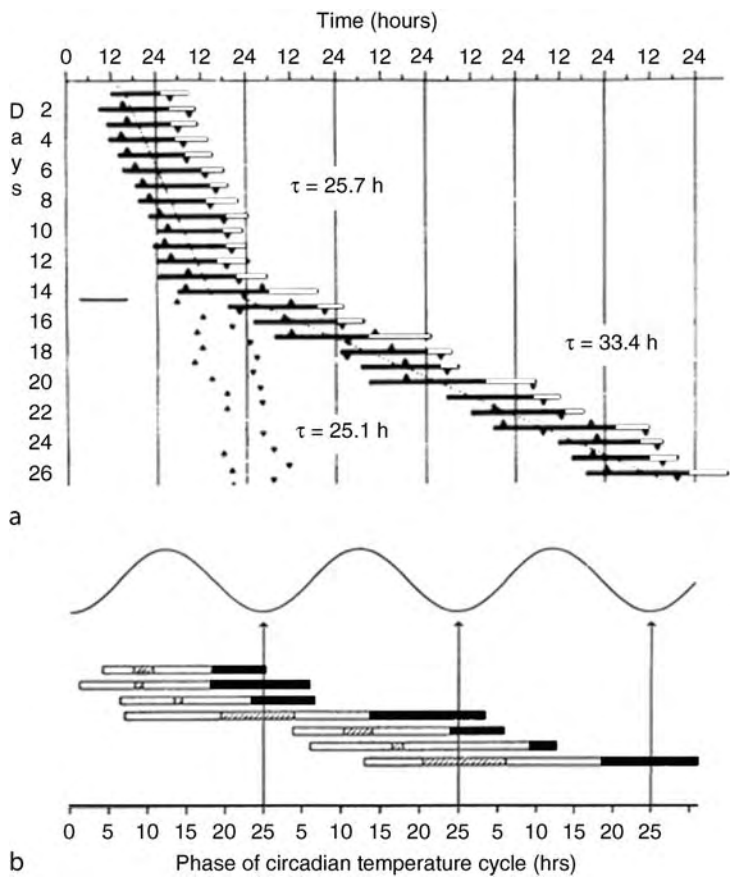
## Characteristics
### Overview of Circadian Systems
Circadian (~24 h) rhythms of biochemistry, physiology, and behavior are ubiquitous in living organisms. In the presence of an appropriate environmental stimulus (e.g., a 24 h light-dark or feeding cycle), these rhythms exhibit stable ►phase relations relative to local time and to each other. In the absence of such "entraining" stimuli ("zeitgebers", G. time giver), circadian rhythms ►free-run (persist) with a species-typic circadian ►period (denoted by the Greek letter "τ"), indicating control by one or more endogenous, self-sustaining circadian ►oscillators. Under steady-state conditions, phase relations among circadian rhythms are typically stable, suggesting that all circadian rhythms may be controlled by a single master oscillator (pacemaker) with multiple "hands." However, experiments employing ►zeitgeber shifts, multiple conflicting zeitgebers, or prolonged exposure to environments without zeitgebers (►constant conditions), and more recent experiments mapping circadian ►clock gene expression in multiple tissues, have revealed a more complex underlying circadian structure, with one or more ►circadian pacemakers specialized for entrainment to photic or nonphotic zeitgebers, and for coordinating "secondary" ►oscillator or ►slave oscillators that drive rhythms in local tissue functions. Components of this multioscillator system may exhibit stable coupling at one or more phase relations, and can become uncoupled, creating internal desynchrony. This essay will illustrate principles of internal desynchrony by reference to the mammalian circadian system. The order of subtopics reflects an approximate historical chronology of research.

### Spontaneous Internal Desynchronization: Humans
Like other species, humans maintained in constant conditions, or with self-control of environmental light but no knowledge of clock time, exhibit ►free-running

circadian rhythms with τ in the 24–25 h range. Under these conditions, the sleep-wake cycle initially assumes a delayed phase relative to the body temperature cycle, such that sleep-onset falls closer to the circadian body temperature minimum (which normally occurs near the end of the sleep period, in people entrained to a ►light: dark (LD) cycle). In the early foundational studies conducted in Andechs, Germany [1], most subjects exhibited an average τ of ~25 h, but this is now known to be an artifact of increased light exposure late in the ►subjective day, due to the delayed bedtime relative to the body temperature cycle (light late in the subjective day slows the circadian pacemaker; see ►phase-response curve to light) [2]. When light-exposure is controlled using special procedures (see ►forced desynchrony, below), τ is closer to 24.2 h. If temporal isolation is maintained for a month or more, most individuals exhibit an apparent spontaneous uncoupling of the sleep-wake and body temperature cycles, with other rhythms remaining synchronized to one or the other of these cycles (Fig. 1a; [1]).

During this so-called ►spontaneous internal desynchronization, the body temperature cycle may shorten slightly (e.g. from 25 h to 24.5 h in the original studies) while the ►sleep-wake cycle dramatically lengthens, with some cycles in the 30–50 h range (e.g. 30 h of wake alternating with 10 h or more of sleep). These long sleep-wake cycles occur sporadically among cycles closer to normal length, resulting in an average periodicity of 30 h or more.

Remarkably, during spontaneous internal desynchrony, subjects do not recognize lengthening of the sleep-wake cycle, and appear to experience an elapsed time of only ~24 h over the course of a 30–50 h day as



**Internal Desynchrony. Figure 1** (a) Circadian rhythm of sleep-wake and body temperature in a human subject in temporal isolation for a month. Each bar represents one sleep-wake cycle, with wake time opaque. The daily peaks and troughs of body temperature are marked by triangles and arrowheads, respectively. During the first 2 weeks of this record, the subject exhibits internal synchrony of sleep-wake and temperature, both expressing a circadian period of 25.7 h. During the second two weeks, the sleep wake cycle lengthened to an average of 33.4 h, while the temperature cycle shortened slightly (modified from 1). (b) Replotting of a similar record, with naps (striped sections) included. This reanalysis revealed that subjects usually were asleep during the trough of the body temperature cycle, although they sometimes identified this a nap, despite the length of some of these episodes (up to 8-h). Internal desynchrony disappears when the nap sleep is included (modified from [3]).

defined by the sleep-wake cycle. Estimates of short temporal intervals in the seconds to minutes range are normal, but estimates in the hourly range are proportional to the duration of the sleep-wake cycle. The passage of time is therefore underestimated. This may contribute to preservation of the normal internal structure of daily activities, such that individuals continue to eat only three meals per "day", despite unusually long inter-meal intervals [1].

The observation that different sets of rhythms can become uncoupled and free-run with different "circadian" periods suggests that there may be two circadian pacemakers, a so-called "strong" oscillator reflected in core body temperature, with a stable endogenous periodicity typically just below 25 h, and a "weak" oscillator reflected in the sleep-wake cycle, with a labile periodicity in the 25 to 50 h range. When internally coupled, the two pacemakers assume a compromise periodicity of ~25 h, thereby defining their relative coupling strengths.

This two-pacemaker model has been challenged by several observations. In the Andech studies, subjects were often instructed to refrain from napping, but to identify sleep episodes as naps or primary sleep episodes as they occurred. Naps that did occur were subsequently omitted from analyses. When naps were reincorporated, sleep episodes were found to occur at most or all body temperature minimums, thereby eliminating apparent desynchrony between sleep-wake and temperature rhythms (Fig. 1b; [3]). While not all of the data sets could be clearly explained in this way, the instructions not to nap, combined with altered perception of time and volitional control of bedtime, may have caused some subjects to delay sleep onset excessively, creating occasional long sleep-wake cycles. A critical role for instructions, time perception and volition can also explain the lack of evidence for apparent spontaneous internal desynchronization in truly blind humans that free run despite exposure to daily social cues.

## Spontaneous and Forced Desynchrony, Animal Models

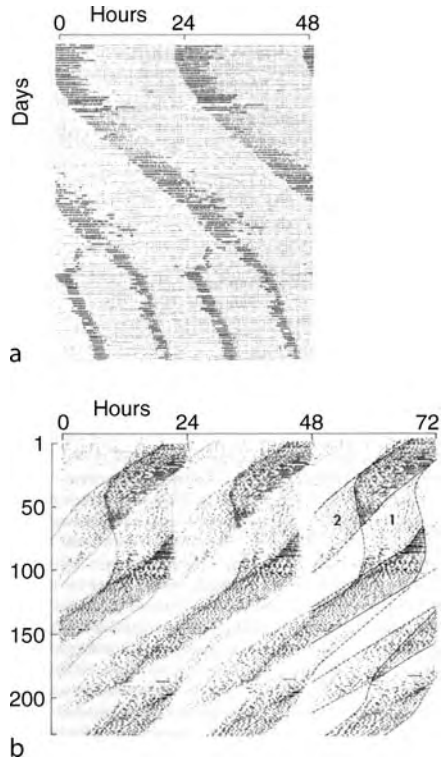
If there are two pacemakers driving different sets of circadian rhythms, it should be possible to identify similar phenomenology and neural correlates in animal models. Long-term continuous recordings of sleep-wake and brain temperature in rats free-running in constant dim light have yielded no evidence for spontaneous desynchrony in that species [4]. Similar results have been obtained in other species. Complete ablation of the ►suprachiasmatic nucleus (►SCN), now established as the master circadian pacemaker critical for the generation light-entrainable circadian rhythms, eliminates free-running rhythms of both sleep-wake and temperature in rodents and squirrel monkeys. Reports of persisting temperature rhythms following SCN-ablation are now believed to reflect masking (direct) effects of LD cycles or incomplete SCN lesions [5].

In human research, ►forced desynchrony is an experimental protocol used to dissociate circadian and homeostatic (time awake) contributions to sleep propensity and waking functions [2]. The protocol involves measuring these variables in subjects forced to maintain sleep-wake and light exposure schedules that are either too long (e.g. 28 h) or too short (e.g. 22 h) to entrain circadian rhythms, which consequently free-run. The effects of circadian phase and time awake can then be isolated by averaging the data, over at least one full beat cycle, at the period of the circadian temperature rhythm and at the period of the sleep-wake, respectively. In this protocol, the 22 h or 28 h sleep-wake rhythm is forced, and not the expression of a true rhythm, thus forced desynchrony and spontaneous internal desynchrony are conceptually distinct. A forced desynchrony protocol, employing a 22 h LD cycle, has been reported to induce desynchrony of slow wave sleep and core body temperature in the rat. Under this schedule, rats exhibit locomotor activity rhythms of both 22 h and > 24 h (free-running). Slow wave sleep also exhibits both components, while body temperature is reported to exhibit primarily a >24 h free-running component. It remains possible that, as in the human forced desynchrony model, the 22-h rhythm is imposed by the environmental condition, and is not a true endogenous rhythm; this will need to be considered in evaluating neural and molecular correlates.

## Splitting, Damping and Threading

Although free-running circadian rhythms can persist almost indefinitely in the absence of environmental zeitgebers, constant bright light or dark can induce rhythm damping and dissociations that reveal structural features of the circadian system [6]. In nocturnal rodents, constant bright light can induce splitting (►split rhythms), whereby the circadian rest-activity (►rest-activity cycle) rhythm divides into two components, one of which transiently slows while the other accelerates, until stable coupling is achieved in antiphase, creating the appearance of a 12 h free-running rhythm (Fig. 2a).

This new temporal organization is rapidly reversed in constant dark or LD. During splitting, circadian rhythms of activity, core temperature, and endocrine rhythms remain internally synchronized, i.e. all rhythms appear to split in unison. Splitting has been formally modeled as the output of separate circadian oscillators with two stable coupling modes 180° apart [7]. When entrained to normal LD cycles, the two oscillators are coupled within a range of phases determined by the length of the day, with one oscillator driving evening activity (and possibly light sensitivity), and the other driving morning activity (and light sensitivity). The phase relation between these



**Internal Desynchrony. Figure 2** Wheel running rhythms of a Syrian hamster in constant light (a) and a tree shrew in constant dark (b). In panel A, each line represents 48 consecutive hours, and consecutive days are also aligned vertically, creating a double-plot. Heavy lines indicate wheel running activity. The activity rhythm free-runs in the absence of a light-dark cycle. The period of the rhythm lengthens from near 24-h to over 25 h, until the daily active period (alpha) "splits" into two components, one with a shorter period, and one with a longer period. The two components recouple in antiphase. In panel B, the data are triple plotted, to illustrate the presence of two circadian activity components free-running with different periodicities. The two components appear to interact, as indicated by regular modulations of periodicity depending on the mutual phase relation. This type of interaction is known as relative coordination. Modified from [7] and Meijer JH, Daan S, Overkamp GJ, Hermann PM (1990) The two-oscillator circadian system of tree shrews (*Tupaia belangeri*) and its response to light and dark pulses. J Biol Rhythms 5:1–16.

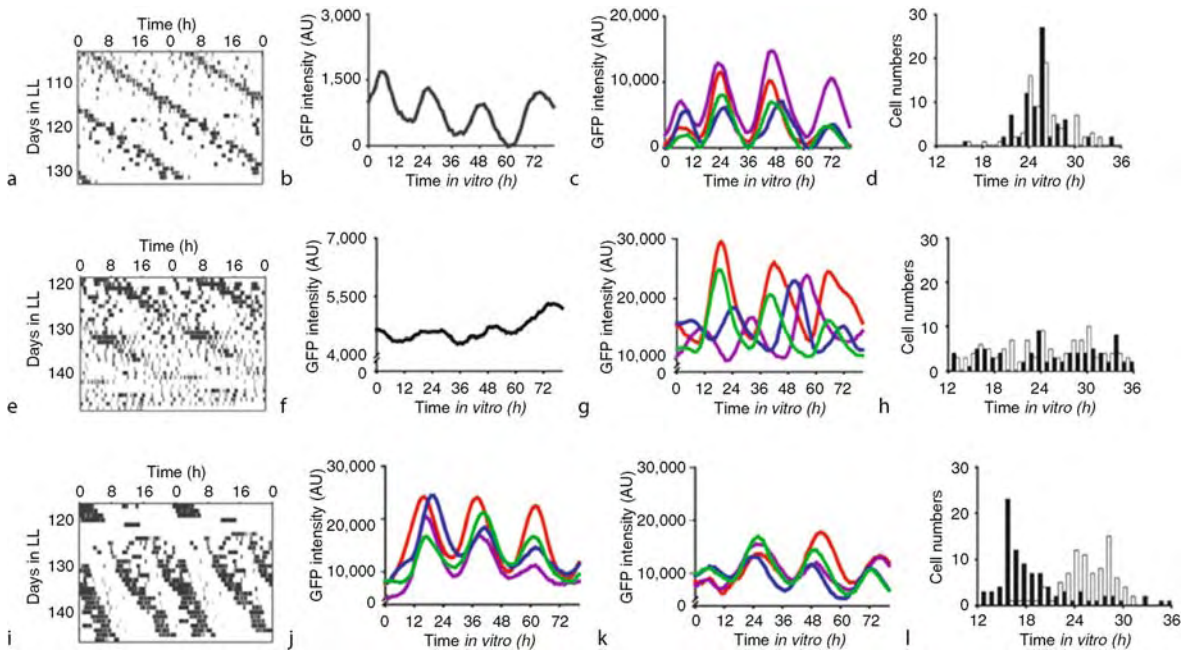
so-called Evening and Morning oscillators can thereby code for daylength, and serve as a calendar for annual rhythmicity. Exposure to constant light is thought to alter the circadian period of Evening and Morning oscillators differentially, driving them out of synchrony.

Splitting is readily induced in the Syrian hamster, a photoperiodic species. In this species, split components usually recouple in antiphase. Splitting can also be readily induced in the prosimian tree shrew, but in this ►diurnal (day active) species, continuous dark is the necessary condition, and the split components tend not to resynchronize, but instead may exhibit distinct but clearly interacting free-running circadian components indefinitely (Fig. 2b). In non-photoperiodic species of mice and rats, splitting is less common (but see Fig. 3i). Instead, constant bright light is associated with gradual damping and loss of rhythmicity (Fig. 3e). In rats, the process of rhythm damping has been described as "threading," suggestive of a population of circadian oscillators gradually uncoupling [4].

Synchrony of behavioral and physiological rhythms during splitting suggests that structural correlates of this state are to be found in the master pacemaker common to these rhythms, the SCN. The SCN is a bilateral structure comprised of ~16,000 neurons. A large percentage of these neurons are circadian oscillators ("clock cells"; Fig. 3a–d). Splitting may represent loss of coupling between left and right SCN, with sustained coupling among clock cells on each side. During splitting, the left and right SCN do oscillate in antiphase (Fig. 3i–l). Unilateral lesions of the SCN have been reported to eliminate one activity component in split animals, although splitting may also be lost by control lesions in other brain structures. Within each SCN, core-shell, ventrolateral-dorsomedial and other anatomical subregions have been defined based on neuronal phenotypes, responses to zeitgebers and patterns of afferent input. These subregions may also uncouple in split hamsters [8], which may account for cases of splitting observed in hamsters with unilateral SCN ablations. *In vitro*, SCN slices cut on the horizontal plane can also exhibit splitting of ipsilateral subregions. Although SCN subregions are evident in rats and mice, splitting may be less common in those species because of stronger intra- or inter-SCN coupling. Alternatively, the mechanism for synchrony among clock cells in each SCN may be weaker, and the population may thus be more likely to lose synchrony altogether (e.g. Fig. 3e–h) rather than to split into independently oscillating subunits.

## Desynchrony Induced by Conflicting Zeitgebers

Circadian oscillations are a property of individual cells, and are believed to emerge from daily cycles of expression of so-called clock genes and/or posttranslational modification of their protein products. Circadian rhythms of clock gene expression are characteristic of neurons in the SCN circadian pacemaker, and these cycles can be reset and entrained by light. Clock genes also exhibit circadian expression in many brain regions outside of the SCN, and in most if not all peripheral organs and tissues. For these extra-SCN and peripheral clock cells, food availability appears to be the primary zeitgeber, and entrainment to LD cycles may be secondary to the daily rhythm of food intake [9]. In



**Internal Desynchrony. Figure 3** Circadian rhythms of wheel running (a, e, i) and of green-fluorescent protein bioluminence reporting *per1* clock gene expression in SCN explants (b, f) from *per1:GFP* transgenic mice maintained in constant light for over 140 days. Behavioral rhythms and neuronal bioluminence rhythms are highly correlated. Mice that expressed normal free-running activity rhythms exhibited robust circadian oscillations of per1 expression at both the whole explant (b) and single neuron (c, each waveform represents a single neuron) levels. The time of peak expression in single neurons is tightly clustered in the population (d), indicating a high degree of synchrony among these oscillating cells. Mice in which the circadian behavioral rhythm damped out exhibited little circadian oscillation of per 1 at the whole explant level (f), but sustained oscillations at the single neuron (g) level that lack population synchrony (h). Mice with split behavioral rhythms exhibited robust oscillations at the single neuron level that were in synchronous within the left (j) and right (k) SCN, but in antiphase between SCN (l). Ohta J, Yamazaki S, McMahon DG (2005) Constant light desynchronizes mammalian clock neurons. Nat Neurosci 8:267–269.

nocturnal rodents, if food is restricted to the middle of the day, circadian oscillations in peripheral organs shift to remain aligned with mealtime. A ►food-anticipatory activity rhythm also emerges, resulting in both daytime and nighttime bouts of activity [6]. By contrast, rhythms of clock gene expression and neuronal activity in the SCN, and of pineal melatonin secretion (critical for measuring daylength in seasonal breeders), remain synchronized to the LD cycle. Thus, although the SCN normally has a dominant role in maintaining internal synchrony, the mammalian circadian system appears designed to support entrainment to conflicting zeitgebers, due in part to indirect (behaviorally mediated) coupling between the SCN pacemaker and peripheral oscillators. For these peripheral oscillators, coordination of tissue functions and metabolism with mealtime is presumably of primary importance. Conflicting zeitgebers can induce internal desynchrony, but the outcome can be construed as adaptive. Both photoperiodic time measurement, mediated by the SCN and the pineal gland, and synchrony of metabolic rhythms with daily cycles of food intake, are preserved.

## Desynchrony Induced by Shifts of Zeitgebers

While animals in natural environments may experience shifts in the best time of day to forage (e.g. due to seasonal variations in food sources), they do not normally experience abrupt, large temporal shifts of sunrise and sunset. Humans, by virtue of jet travel, do experience such events. To reestablish synchrony with local time, phase advance shifts are required for easterly flights less than 12 h, and phase delay shifts for westerly flights. The empirically-based rule of thumb is that it takes about 1 day per time zone to accomplish such shifts, although delays for westerly travel are achieved more quickly in most people. During the process of re-entrainment, humans may exhibit ►transient internal desynchrony, characterized by abnormal phase relations among different circadian rhythms. Some rhythms appear to shift more rapidly than others, although whether this is due to differential rates of resetting of different circadian oscillators, or to ►masking (direct) effects of altered light exposure, mealtimes and other factors, is unclear. At the level of the SCN pacemaker, different subregions of the SCN appear to shift at

different rates, and to the extent that outputs from these subregions to SCN targets are not fully redundant, this can be expected to contribute to differential resetting rates of other brain regions and organs [10]. Unlike entrainment to food, there is nothing adaptive about desynchrony induced by shifts of the solar day, a decidedly unnatural phenomenon. Transient desynchrony is likely the primary cause of ►jet-lag, and associated symptoms of fatigue, insomnia and gastrointestinal malaise. Similar disruptions of circadian timing are implicated in ►shiftwork malaise, and may underlie some of the adverse health consequences of working rotating shifts (e.g. increased risk of cardiovascular and gastrointestinal disease, and some types of cancer). These considerations underscore the importance of internal synchrony within the circadian system for optimal functioning of physiological processes.

# Internal Energy

## Definition

A quantity postulated by the first law of thermodynamics (namely the law of balance of energy). For a continuous body, it is given by the integral over the body of the internal energy density, assumed to be a function of state of the system (that is a quantity specified via a constitutive law).

►Mechanics

# Internal Forces

## Definition

Internal forces in a mechanical system are forces that occur within the system; that means they always have an equal but opposite equivalent internally, and so, do not contribute to the system's movement. For the distribution problem in biomechanics defined for a joint, the internal forces are typically considered the muscle, ligament and bony contact forces.

►Distribution Problem in Biomechanics

# Internal Forward Model

## Definition

A neuronal predictive mechanism that estimates a current state of body or external environments by integrating current sensory signals reporting past body states and efference copies of motor signals. This computation is called forward because a current state is calculated in a causal manner, essentially by solving body equations of motion. Forward models have several computational advantages: estimation of a current state, prediction of movement outcomes, and computation of a movement error needed for motor learning.

►Efference Copy
►Motor Learning
►Theories on Motor Learning

## Internal Interval Timer

### Definition

A biological time-keeping mechanism that operates by effectively counting time elapsed from a given event, such as a change in lighting conditions.

►Seasonality

## Internal Inverse Model

### Definition

A neuronal control mechanism that maps a desired effector (i.e., limb or eye) state to motor control signals that are needed to realize that desired state. This computation is called inverse because inverse models compute necessary control signals by substituting a desired effector state into equations of motion, in a way opposite to that of internal forward models. Motor commands produced by inverse models are referred to as feedforward control signals, in contrast to feedback control. Inverse models have a theoretical advantage such that fast and smooth feedforward control becomes possible without using sluggish and awkward feedback control.

►Theories on Motor Learning

## Internal Medullary Lamina of the Thalamus

### Synonyms

Lamina medullaris med

### Definition

This internal medullary layer subdivides the thalamus into three large thalamic nuclear groups:

- Medial thalamic nucleus
- Ventral thalamic nucleus and
- Lateral thalamic nucleus

►Diencephalon

## Internal Models

Paul Cisek
Groupe de recherche Sur le système nerveux central, Department of Physiology, University of Montreal, Montreal, QC, Canada

### Definition

The term ►internal model refers to the general notion that the central nervous system contains knowledge about properties of the body and of the external world. For example, when you get ready to pick up a box that you believe to be heavy, you prepare your posture for generating a large lift force long before you begin lifting. If the box turns out to be empty, it will move unexpectedly fast. One can say that your internal estimate of the ►dynamics of the object was inaccurate, or that you had the wrong internal model of its properties. As you used an incorrect internal model of the box to guide your actions, you generated unnecessarily large forces in trying to pick it up.

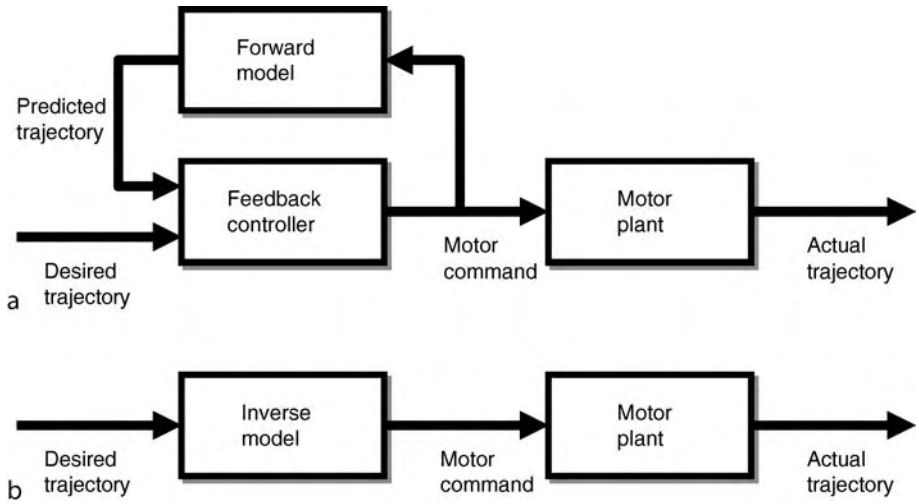
### Description of the Theory

Within the context of computational motor control, several specific kinds of internal models have been proposed and have found use both in theoretical discussions and interpretations of experimental results. These fall into two general categories: ►forward models and ►inverse models. Forward models are used to predict the consequences of a given action, such as predicting the motion of a ball after you strike it with a tennis racquet. They are called "forward" models because they capture the causal properties of the world in the forward direction, from causes to effects. Given some specific motor command (swing the racquet), you get a specific consequence (the ball travels in a new direction). With practice, you become better and better at predicting the consequences of your actions and this is one aspect of learning a skill.

Inverse models capture information in the opposite direction, by inferring causes given specific desired effects. For example, if you know which way you want the tennis ball to travel, what is the right way to hit it? An inverse model is thought to aid in this process. Given a particular desired outcome, an inverse model computes the required motor commands that can produce it.

Both forward and inverse models can be used to solve a variety of problems, and their roles are largely determined by their placement within a control system. Two examples are shown in Fig. 1.

In Fig. 1a, a forward model is used to predict the trajectory which results from a given motor command, and to thus provide the information that a feedback controller needs to generate a desired trajectory. This



**Internal Models. Figure 1** Examples of the two most basic types of internal models and their placement within a control system. (a) A forward model can be used within a feedback control system to provide a prediction of the trajectory that results from a particular motor command being sent to a particular motor plant. This can be used to compensate for plant properties without waiting for actual feedback about the resulting movement to return from the periphery. Thus, a forward model can be used to implement zero-lag feedback control. (b) If an inverse model of the plant has been learned, then it can be used to generate the required motor command to produce a given desired trajectory. Thus, an inverse model can be used to implement accurate feed-forward control.

is extremely useful because sensory feedback about movement is always significantly delayed, and these delays can cause a feedback circuit to fall into large oscillations. A prediction of feedback by a forward model essentially provides the circuit with zero-lag feedback, avoiding oscillations due to delays. In Fig. 1b, an inverse model is used to compute the command in a feed-forward manner. (Note that there is a potential confusion that can be caused by this terminology, since a "forward model" is often used within a "feedback" control scheme, while an "inverse model" is used for "feed-forward" control.) The concepts of forward and inverse models are similar to classic ideas on cybernetic control systems and theories of cerebellar deficits [2,8], which have been formalized into more recent theories of neural circuits underlying motor control [3]. These concepts are described briefly below (for an authoritative review, see Kawato [4]).

A forward model can predict the consequences of a particular motor command at various levels of detail, including (i) the sensory feedback that will result from the command (proprioceptive signals from stretch receptors, visual motion on the retina, etc.); (ii) the particular joint rotations that will be produced, or the ►intrinsic kinematics; (iii) the movement of the end effector through external space, or the ►extrinsic kinematics (e.g., the motion of the head of a tennis racquet); (iv) the effect of the action on task-relevant variables (e.g., the trajectory of the ball after it is hit); (v) and even higher-order knowledge about goals and task outcomes (e.g., winning the point). When the forward model is used to predict external events, it is sometimes referred to as an "output predictor," and when it predicts internal variables such as future joint configurations, it is referred to as a "state estimator." Again, the role that a forward model plays is determined by its placement in the control system. One particularly interesting role proposed for a forward model is to act as a "distal teacher" that trains the inverse model [3]. This is valuable because in general, learning an inverse model is harder than learning a forward model, but it can be made simpler and done off-line if a forward model is already present.

Inverse models also come in a variety of forms. One example of an inverse model is the sensorimotor transformation that converts a desired movement vector defined in extrinsic space into a vector of desired joint rotations. This can be called an ►inverse kinematic transformation from an ►extrinsic kinematic coordinate system to an ►intrinsic kinematic one. A second sensorimotor transformation may then convert that vector of desired joint rotations into a pattern of desired muscle torques. This would be called an ►inverse dynamics transformation from ►intrinsic kinematics to ►intrinsic dynamics. Any time that a representation of a desired outcome is used to compute the required control signals to accomplish that outcome, we can say that an internal inverse model is being used.

By these broad definitions, forward and inverse models are almost certainly used by the nervous system to control movement. The ability to move one's hand to a target defined by visual information requires that the visual information is used to compute control signals,

and ultimately, those control signals have to respect the features of the skeletomuscular system that produces the movement. Thus, an inverse model has to exist, at least implicitly (see below). There is some debate on whether control signals have to take into account the dynamics of the act (see ►equilibrium point hypothesis) [7], but they certainly have to be tailored to the geometry of the arm and the placement of individual muscles.

One must be careful when using these concepts for interpreting data to be clear about whether an internal model is *explicit* or *implicit*. Any control system whose input–output properties mimic attributes of the kinematics or dynamics of the body or the external world, and which can adapt to changes in those attributes, can be said to contain an internal model that is implicit within the parameters of the control system. However, while the concept of internal models captures the computational aspects of what the nervous system is doing, it does not necessarily have to correspond to a specific neural structure that *explicitly* performs that given operation. In other words, even if there is no specialized module within the brain to perform an input–output mapping that corresponds to inverse kinematics, the system as a whole may still implicitly solve the inverse kinematic problem. For example, it is possible that the computation of a required intrinsic dynamics command from a desired extrinsic kinematics command is done in a single step, which encompasses both the inverse extrinsic-to-intrinsic kinematics transformation and the inverse intrinsic dynamics transformation. This distinction between a computational description of what a neural system does implicitly and a putative physical neural module that explicitly performs that computation is important, because a great deal of evidence exists for the former but does not necessarily imply the existence of the latter.

Nevertheless, many studies aimed at elucidating the use of internal models in motor control have shown the value of these concepts. First, there have been numerous psychophysical experiments lending support to the use of internal models in motor control, and some of these will be briefly reviewed here. One influential study examined how human subjects adapt to changes in the force environment while performing simple point-to-point reaching movements with a planar manipulandum [9]. Shadmehr and Mussa-Ivaldi [6] showed that if the manipulandum was programmed to exert perturbing forces on the arm, each subject first exhibited curved trajectories and endpoint errors. With practice in the force-field, the trajectories straightened and accuracy was restored. However, when the forces were removed and the subject was once again moving in normal unperturbed conditions, trajectories were curved once again, in a direction opposite to the original effect of the perturbation. These "aftereffects" can be taken as evidence that the nervous system learned something specific about the force environment with which it was faced, and did not simply increase stiffness to become more resistant to perturbations in general. It is not known whether this specific adaptation occurs through changes in an inverse model that converts desired hand movement to required joint torques, or through changes in a forward model that predicts the imposed perturbation so that the controller can preemptively correct it. However, Shadmehr and Mussa-Ivaldi showed that the pattern of transfer of this kind of learning implies that it occurs in ►intrinsic and not ►extrinsic coordinates.

Psychophysical studies have also provided strong evidence for the use of forward models in motor control. For example, Flanagan and Wing [1] showed that when human subjects hold an object in their hand while they move their arm around in various ways, their grip force is scaled perfectly to compensate for any slippage which might occur. Importantly, this compensation occurs with *zero lag*, that is, it does not rely on sensory feedback from the fingers reporting actual slip. Instead, it must make use of a prediction of what slippage would occur given the current arm movement that is being performed. In other words, these results provide evidence for a forward model that functions as an "output predictor," which predicts how a given movement of the arm will produce slippage in the hand, allowing anticipatory grip compensation.

Internal models may capture many different aspects of motor control, and a question of recent interest concerns how the nervous system decomposes the problem of learning internal models. There are several possibilities. For instance, it is possible that learning of internal models that deal with kinematics is separate from learning of internal models that deal with dynamics. Evidence in support of this kind of separation has been provided by studies showing interference (i.e., a reduction in the speed of learning) when subjects try to learn two different kinematic transformations at the same time, or when they try to adapt to two different changes in dynamics at the same time [5]. However, there was no interference when subjects were adapting to a kinematic transformation at the same time as a change in dynamics. This suggests that the learning of kinematics is separate from learning of dynamics. However, another possibility is that learning of internal models is separated on the basis of the dependent variables involved. That is, learning the relationship between the required motor command and a variable such as position may be separate from learning the relationship between the command and a variable such as velocity. Tong et al. [10] provide evidence that this may be the case, showing that a position-dependent force field can be learned alongside a velocity-dependent force field.

In addition to psychophysical studies of internal models, efforts have been aimed at finding the neural structures that implement these putative computational

operations. One classic and prominent theory suggests that the cerebellum's role in motor control is equivalent to a forward model [2]. This proposal is supported by the kinds of deficits that accompany cerebellar damage and by the results of temporary cerebellar inactivation on the control signals sent from primary motor cortex to the spinal cord. More recent studies have examined how neural activity in primary motor cortex changes during adaptation to the kinds of force-fields that have been used in psychophysical studies of internal models [6]. While a straightforward mapping of neural structures to modules such as those sketched in Fig. 1 has not been established (nor indeed should one necessarily be expected), these studies do confirm that motor commands are indeed tailored to the specifics of particular kinematic and dynamic environments in a manner that is well captured by the concepts of internal models.

## Internal Representation

### Definition

The central representation of information critical for the performance of motor and non-motor tasks. Information related to the performance of movements may include properties and location of the target, extrapersonal space, features of the musculoskeletal system and/or body image (body schema), and elements of the motor sequence.

►Cerebellar Functions

## Internalist/Externalist Theories of Knowledge

### Definition

The distinction is drawn in a number of different ways. According to one common usage, internalist theories of knowledge claim, while externalist theories of knowledge deny, that some cognitively accessible form of justification is an essential condition for knowledge.

►Knowledge

## Internal model Hypothesis

### Definition

A hypothesis that the brain has neural mechanisms (internal models) that mimic input–output relationship of body or external objects such as hand-held tools or visual targets. Internal models are usually classified into two categories of prediction and control; an internal forward model that computes a current body state from delayed sensory signals and efference motor copies, and an internal inverse model that maps a desired body state onto needed motor control signals. This hypothesis has been tested and then supported successfully by various electrophysiological, psychophysical, and human imaging studies.

## Interneuron

### Definition

The interneuron is a neuron situated between two other neurons. A good example is the interneurons in the

intermediate part of the spinal cord gray matter. These neurons are involved in spinal reflexes and are located between a sensory neuron in the dorsal horn and a motoneuron in the ventral horn. In general sense interneurons are considered to be any neuron whose axons and dendrites are confined within an area near the cell body, such as the Golgi Type II neuron mentioned above.

## Internode

### Definition

Internode denotes the myelinated region of an axon between two nodes of Ranvier.

►Node of Ranvier

## Internuclear Neurons in Extraocular Motor Nuclei

### Definition

Groups of cells resident largely within or near an extraocular motor nucleus, and projecting to extraocular motoneurons innervating a synergist of the muscle controlled by that motor nucleus. The best studied are the abducens internuclear neurons.

►Extraocular Motor Neurons

## Internuclear Ophthalmoplegia

### Definition

Patients affected by this syndrome have disconjugate eye movements upon lateral gaze. Namely, with a left-sided syndrome the left eye does not cross the midline when attempting to look to the right.

►Extraocular Motor Neurons

# Intersegmental Coordination

Ronald L. Calabrese
Department of Biology, Emory University, Atlanta, GA, USA

## Definition

Wave-like behaviors such as undulatory swimming and ventilatory and locomotory movements of multiple appendages that depend on accurate progressive timing of muscular contractions in neighboring ►segments and appendages are said to show intersegmental coordination [1,2]. Even terrestrial locomotion of limbed animals such as vertebrates and insects can be thought to show intersegmental coordination, or interlimb coordination as the case may be. However, as there is often considerable flexibility in the coordination in such limbed terrestrial locomotion – expressed as changes of gait – the complexity is greater, and the focus here will be on wave-like movements where the coordination is more rigidly fixed [1]. Numerous studies have shown that the isolated nervous system is capable of producing rhythmic motor output in the absence of sensory feedback, which is similar to that required for specific behaviors in the intact animal [3]. The neuronal networks that produce this activity are called ►Central Pattern Generators (CPGs) and for wavelike behaviors, this output shows proper intersegmental coordination. For example, in the lamprey forward swimming is accomplished by means of side-to-side undulations that travel from anterior to posterior along the length of the body [4]. The isolated spinal cord will produce a ►motor pattern with the correct side to side alternation and intersegmental coordination of motor neuron bursts in response to stimulation with ►NMDA receptor agonists [4]. In the lamprey, as in other animals, the CPG that produces such wave-like motor patterns is distributed longitudinally along the neural axis [3]. This type of neural network consists of a chain of coupled segmental oscillators, local neural networks that are capable of independently generating rhythmic output [2]. The appropriate coordination between these segmental oscillators arises as an emergent property of the segmental oscillators and the coupling between them. Although this distributed organization is found in many different animals, there are large differences in terms of the properties of the segmental oscillators, the strength and symmetry of coupling, and the importance of sensory feedback. Here we focus on some of the similarities and differences in mechanisms that underlie intersegmental coordination in the swimming CPGs of two animals – one vertebrate and one invertebrate: the lamprey and the leech [5].

## Characteristics

### Quantitative Description

The parameters most commonly used to describe the intersegmental coordination for wave-like behaviors are period and phase [2]. The period is the time for one complete cycle of the behavior. Phase is the percent of the period that describes the delay between activity (e.g., motor neuron activity) in one segment and activity in the next caudal segment. In some cases, this percent is multiplied by 360° and expressed as degrees. Phase can be measured with respect to a designated reference segment (absolute phase or phase) or it can be expressed as a difference between adjacent segments (phase difference). Phase differences (and indeed absolute phase) thus vary between −50 (−180°) and 50% (180°). When the phase difference is 0% (0°), it means that activity in adjacent segments is simultaneous, whereas if the phase is 50% (180°) then activity in the next caudal segments is delayed by half the period; the activity is said to be antiphasic. Negative phase differences correspond to activity in the next caudal segment leading rather than lagging temporally. For many wave-like behaviors – but not for all – stability and efficiency of motion demand that there is a constant phase difference between segments, regardless of the period of the motion [2]. The delay in activity between segments must scale exactly with changes in period for such phase constancy to be maintained. The neuronal mechanisms that thus control intersegmental coordination must be able to produce intersegmental delays that scale with period.

Our understanding of the mechanisms, at the cellular, network, and abstract levels, for intersegmental coordination of wave-like behaviors has been greatly aided by quantitative modeling work, because the dynamic nature of the underlying oscillatory networks makes comprehension based on static circuit diagrams impossible. The use of models with different levels of detail has proven to be a particularly successful approach. Abstract models provide a general indication of the important features of a system [6], while models that are more detailed allow for a direct comparison with the biological system [1,7–10].

### Higher Level Structures

While there is a rich literature that suggests that higher level input can influence CPGs for wave-like behaviors, the mechanisms of intersegmental coordination appear to be local to the spinal cord in the case of vertebrates, or to the ventral nerve cord in the case of invertebrates. In addition, the brain may be removed without causing disruption of normal coordination in both isolated nervous system preparations and in more intact preparations [2,4].

## Lower Level Components

Motor neurons – segmentally arranged – represent the final output of CPGs and as such, they are the focus of attention in assessing intersegmental coordination. In most cases, the neuronal networks comprising CPGs are presynaptic to these motor neurons. Progress in studying the cellular mechanisms of intersegmental coordination are most advanced in invertebrates, simply because the relatively small number of neurons composing the ventral nerve cord compared to a vertebrate spinal cord has made cellular definition of the segmental oscillators and the coordinating interneurons that link them, i.e., the CPGs, more tractable. While these networks are beginning to be worked out in several vertebrates, only in lampreys [4,9] and Xenopus frog tadpoles [8] has this analysis progressed sufficiently to begin defining the mechanisms of intersegmental coordination. While it is clear that CPGs posses the necessary neuronal circuitry to generate the general dimensions of intersegmental phase differences for wave-like behaviors, there is mounting evidence that feedback from peripheral sensory neurons – particularly stretch receptors – play a crucial role in sharpening intersegmental phase differences, adjusting them to environmental realities [2,4,5].

## Higher Level Processes

The leech and the lamprey both swim in an undulatory fashion, with the body forming approximately one full wave at any given time during swimming. To maintain this mode of swimming as an animal changes its swim cycle period, the phase between the muscle contractions in different segments must remain constant [2,4,5].

### *Lamprey Swimming*

In the lamprey, which swim by side-to-side undulation, forward swimming results from a traveling wave of one body length that begins at the anterior end of the animal. The lamprey has about 100 body segments; therefore, the phase difference between body segments is about 1% in the intact animal. An identical phase difference occurs in the isolated spinal cord when rhythmic activity is induced with the NMDA receptor agonists [4]. Although it is not possible to identify individual interneurons as in the leech swim network, two classes of interneurons, excitatory (E) and inhibitory (C), appear to be essential for burst generation [4]. The E interneurons synapse ipsilaterally with other E interneurons and with C interneurons. The mutual excitation between E interneurons appears to support the generation of bursts in hemisegments. The C interneurons project contralaterally and inhibit other C interneurons as well as E interneurons. These interneurons are responsible for producing alternating activity between the right and left sides of the spinal cord, which is necessary for side-to-side undulatory swimming. Reciprocal inhibition is not, however, the primary factor that terminates bursts, but rather the activation of two types of ►$Ca^{2\pm}$-dependent $K^{\pm}$ channels (KCa) i.e., on the intrinsic membrane properties of the neurons.

Important early theoretical work [6] indicated that appropriate phase lags for lamprey swimming might be generated by two mechanisms: asymmetries in the coupling between segmental oscillators and differences in inherent segmental periods. Evidence for coupling asymmetries comes from a variety of experiments. Movements imposed on the isolated spinal cord can entrain the activity of the entire swim network by activating intra-spinal stretch receptors, which provide sensory feedback to the interneurons [4]. Movement applied to the caudal end of the spinal cord can entrain the system to a greater range of frequencies than movements applied to the rostral end. Additionally, split-bath experiments, in which the rostral and caudal halves of the spinal cord were bathed in pools with different concentrations of NMDA receptor agonist, demonstrated that the rostral spinal cord dominates the frequency of the coupled network. Physiological and computer modeling results suggest that longitudinal coupling is due primarily to ipsilateral excitatory coupling that is stronger in the descending direction than in the ascending direction [4,10].

There is also evidence of anatomical coupling asymmetries. For example, whereas the E interneurons project symmetrically over a few segments both rostrally and caudally, the C interneurons project 14–20 segments caudally but have only short rostral projections [4]. Evidence for, or against, the existence of a gradient of segmental oscillator frequency is more limited than for asymmetric coupling. Pharmacologically induced frequency gradients can alter and even reverse the normal rostrocaudal phase lags in the isolated spinal cord [4]. Although such experiments cannot demonstrate that such a gradient exists naturally, they show that, at least in principle, a gradient could produce the appropriate phase lags. Presumably, in the intact system a gradient of oscillator frequencies could be produced by a corresponding gradient of descending synaptic drive, as has been found in the swim network of *Xenopus* embryos [8]. In contrast to these results, surgically isolated sections of the spinal cord do not vary in frequency in a systematic way [4]. One problem with such studies, however, is that the rhythm is induced pharmacologically rather than by normal descending spinal pathways. To address this problem, a study was conducted in which fictive swimming was induced by pharmacological microstimulation of the brain. By blocking local rhythmic activity in either the rostral or the caudal half of the spinal cord with a low $Ca^{2+}$ saline, it was possible to measure the activity of independent sections of the spinal cord [2,4]. This study revealed faster

oscillations in the rostral spinal cord than in the caudal spinal cord. The extent of longitudinal coupling between segmental oscillators in the lamprey is doubtless another important factor for determining phase lags. Functional coupling that determines phase appears to extend over a much more limited range than the full projection range of 30–50 segmental reported for some interneurons. In one study, the lamprey spinal cord was placed in a chamber with partitions allowing the rostral, middle, and caudal sections to be bathed in different solutions [2,4]. Local synaptic activity was blocked in the middle section with a solution containing low-$Ca^{2+}$ and high-$Mg^{2+}$ without affecting spike conduction in axons spanning the middle compartment. The results indicated that although the maximal functional length of propriospinal coupling is 16–20 segments, phase was controlled by short-range coupling that spans only 4–6 segments.

It has been proposed that the interneurons that comprise a segmental oscillator act not only to generate the local rhythm but also project to, and influence, rhythm generation in other segments. The feasibility of this idea, which has been termed "synaptic spread," has been demonstrated in modeling studies in which the synaptic contacts made locally by an interneuron are also made with similar targets in neighboring segments but with lower synaptic strengths [4,10]. Models incorporating cellular and synaptic properties of the swim network can replicate many of the observed properties of the swimming animal such as a reversal of phase lag necessary for backward swimming.

### *Leech Swimming*

In the leech, which swims by dorsoventral undulations, forward swimming results from a traveling wave of one body length that begins at the anterior end of the animal. There are 18 body segments that are actively used for swimming. Thus, the phase lag between consecutive body segments is about 20° in the swimming animal [5]. Intersegmental phase lags that are nearly independent of cycle period are also observed in isolated chains of the leech nerve cord consisting of as few as two ganglia. However, in contrast to the intact animal, the phase lag per segment within a long chain of ganglia in vitro is only about 8°. A segmental oscillator of the leech swim CPG consists of a bilaterally symmetric network of oscillator interneurons within a single ganglion that drive segmental motor neurons. Oscillations originate within a single ganglion from the local circuit formed by these oscillator interneurons, which are connected almost exclusively by inhibitory synapses. Strong electrical and chemical coupling across the midline within the segmental oscillator ensures side to side synchrony in the activity. This activity pattern is appropriate since the leech swims by dorsoventral undulations, which require synchronous activation of muscles on the left and right sides of the body.

The segmental oscillators are coupled by ascending and descending projections of the oscillator interneurons, which synapse directly with oscillator interneurons in other ganglia. In principle, the generation of phase lags appropriate for swimming can be explained by a system consisting of a chain of coupled oscillators in which the anterior oscillators have shorter inherent periods than the posterior oscillators. When a system such as this is coupled, all segmental oscillators of the network share the same period, but the faster oscillators will lead in phase. In the case of the leech swimming, this explanation is not sufficient to explain swimming because experiments show that the segmental oscillators with the shortest cycle period lie at the midpoint of the ventral nerve cord. Experimental and modeling work has provided evidence that forward swimming most likely arises from asymmetries in the coupling between the segmental oscillators [7].

Intersegmental coupling, which is approximately equal in functional strength, spans six segments in both directions [5]. At the level of specific interconnections, however, there are many asymmetries. The oscillator interneurons are active at three different phases of a swim cycle separated by 120°. The interneurons in the 0° phase group all project their axons in the descending direction, whereas the interneurons of the 120° and 240° groups only project in the ascending direction [5]. In addition, the sole excitatory interneuron projects in the descending direction, whereas inhibitory interneurons project in both directions. Finally, the synaptic targets are asymmetric; ascending and descending projection neurons project to targets with different activity phases. A computer model that incorporates these asymmetries but not any inherent period differences produced a 8–10° phase lag, similar to that seen in long chains of isolated nerve cords as well as phase constancy with changing cycle period [7]. Although the model replicated activity in the isolated nerve cord, the 8° phase lag between segments is too small to produce a traveling wave of one wavelength along the body.

## Lower Level Processes

Sensory feedback is known to affect both the strength and timing of output from CPGs. To test the idea that sensory feedback from ▶stretch receptors embedded in the body wall and mechanical coupling between muscles in neighboring segments may contribute to the phase lag observed in the intact animal, and thus account for the discrepancy between the isolated nerve cord and intact leech, these mechanisms were added to the computer model [5]. The resulting computer model produced a phase lag of 17° per segment, which is similar to the value in the intact leech (20°), suggesting that sensory feedback and mechanical coupling are indeed important for appropriate coordination.

At first glance, sensory feedback appears to be less important for swimming in the lamprey than in the leech, since the motor output of the isolated spinal cord closely resembles the pattern of the intact animal in lamprey [4]. Indeed, experiments in which the nervous system was transected have shown that mechanical coupling and sensory feedback are more important for intersegmental coordination in the leech than in the lamprey. To assess the contribution of sensory feedback in the lamprey, a model was created that included the swim network, muscle activation, body mechanics, counteracting water forces, and sensory feedback [4,9]. In this model, stretch receptors had very little effect on swimming movements in still water. However, when the virtual lamprey swam in a cross current, a model incorporating stretch receptors performed much better than a model lacking them. In the latter, transversely flowing water forced the head to one side, eventually resulting in a complete change of direction. In the model with stretch receptors, the sensory feedback counteracted the perturbing effects of the current and allowed the simulated lamprey to swim straight. Therefore, although sensory feedback does not contribute strongly to phase lag as in the leech, in the lamprey it is necessary to counteract environmental perturbations.

### Function

This entry has focused on intersegmental coordination in two well-studied preparations. Discovering how motor patterns are coordinated in these model systems may help us to understand how coordination is accomplished in more complicated networks such as those responsible for terrestrial limbed locomotion [1]. At the most fundamental level of rhythm generation there are clear similarities between the systems we have discussed. For example, in the lamprey and leech swim CPGs, reciprocal inhibition and intrinsic membrane properties of the neurons both contribute to rhythm generation. However, at the greater network level, the differences are perhaps more striking than the similarities. For example, although the swimming behaviors of leech and lamprey are very similar, the two underlying neural circuits are very different in terms of their architecture and the role of sensory feedback. Perhaps a high degree of peripheral feedback is necessary in an animal such as the leech, which has a hydrostatic skeleton. In the future, researchers will need to do a better job identifying network mechanisms that transcend structural differences in circuit architecture but lead to similar function. To do so will necessitate more modeling work.

### Therapy

The loss of intersegmental or interlimb coordination resulting from spinal cord injury is severely debilitating. Thus, understanding the detailed cellular-level mechanisms for intersegmental coordination will be pivotal to understanding how to circumvent or replace their loss after injury or disease.

## Intestinofugal Neurons

### Definition

Intestinofugal neurons are neurons with cell bodies in the gut wall and axons that project to and make connections with neurons in prevertebral ganglia. These are afferent neurons serving reflexes between gut regions.

►Enteric Nervous System

## Intorsion

### Definition

One of the principal directions of an eye movement. The term designates the direction of a torsional eye movement, i.e., a rotation of the eye ball about the optic axis. During intorsion the upper limit of the eye ball rotates towards the nose, i.e., nasal-ward (a movement in the opposite direction is called "extorsion," i.e., rotation away from the nose: temporal-ward).

►Vestibulo-Oculomotor Connections

## Intorsion in Eye Movement

### Definition

One of the principal directions of an eye movement.

The term designates the direction of a torsional eye movement, i.e., a rotation of the eye ball about the optic axis. During intorsion the upper limit of the eye ball rotates towards the nose, i.e., nasal-ward (a movement in the opposite direction is called "extorsion", i.e., rotation away from the nose: temporal-ward). in the opposite direction is called "extorsion", i.e., rotation away from the nose: temporal-ward).

## Intracellular

### Definition

Literally means inside the cell. In all cells, a cell membrane exists which separates the intracellular and extracellular compartments. Partly due to the presence of transporters and ion channels within the cell membrane, the intracellular concentrations of many ions is different compared to the extracellular environment.

►Membrane Potential: Basics

## Intracellular Labeling

### Definition

When applied in non-anesthetized animals, this is the only presently available method to study morphology of single neurons together with their activity patterns, in the search for correlations between structure and function. The best results have been obtained with the use of horseradish peroxidase (HRP) as the labeling substance. In brief, micropipettes containing HRP are inserted in the cell body or in the axon.

Electrophysiological parameters, such as resting membrane potential and spike amplitude, are used to ascertain the intracellular position of the pipette. Cell activity during behavioral tests is then recorded, HRP is injected by iontophoresis and neurons are visualized thereafter in tissue sections undergoing a specific histochemical treatment. Three-dimensional images of the dendritic trees, axon trajectories, collaterals and terminals of the neuron are obtained by matching labeled segments of the neuron in series of a large number of consecutive histological sections.

►Horseradish Peroxidase (HRP)

## Intracellular Recording

Peter M. Lalley
Department of Physiology, The University of Wisconsin School of Medicine and Public Health, Madison, WI, USA

### Synonyms

Transmembrane recording

### Definition

The recording of a potential difference (voltage) or current generated by movement of ions across a cell membrane with a glass capillary electrode containing an electrolyte solution.

### Purpose

Current flow across a cell membrane and the resulting development of a transmembrane potential difference determine whether the cell is active, resting or in a suppressed or inhibited state. Intracellular recording provides information about the direction, magnitude and duration of membrane current flow and voltage changes. It can also be used to estimate a cell's size, its functional architecture and how the cell communicates with other cells.

### Principles

Intracellular recording of membrane current and voltage is based on the principle that when aqueous channels

that permeate a cell's enclosing membrane are open, they allow the passage of ions across the membrane under the influence of ion concentration and voltage differences between the inside and outside of the cell. The flow of ionic current across the cell membrane and the resultant development of transmembrane potential are picked up by electrodes positioned inside and outside the cell and passed to amplifiers and recorders.

## Advantages and Disadvantages

Intracellular recording allows measurement of neural events with a high degree of temporal and spatial precision. In many cases, sampling of many ►neurons in a single experiment is possible with minimal damage to nervous tissue. Events that go undetected by extracellular recording can be measured, such as resting membrane potential, postsynaptic potentials and postsynaptic currents, neuron ►input resistance, whole call capacitance and other passive membrane properties. Ions that move across the cell membrane to initiate postsynaptic potentials can be identified from their ►reversal potentials and from the effect of altering their transmembrane concentration gradients. Single channel currents and conductances are measurable with ►patch clamp techniques. The influence of intracellular signaling pathways on membrane potentials and currents can be assessed by intracellular injections of protein kinase activators and inhibitors. Neurons can be labeled intracellularly for subsequent localization, analysis of their morphological properties and synaptic connections with other neurons, or for the presence of releasable neurotransmitters or neuromodulators.

A disadvantage of intracellular recording, relative to other electrophysiological methods, is the need for extraordinary stability in order to obtain high quality recording.

## Membrane Resting Potential and Synaptic Potentials

Measurements of membrane potential were first made by inserting a glass capillary tube filled with electrolyte solution longitudinally into a squid giant axon (0.1–1.0 mm diameter). The potential difference at rest and during the active state evoked by an electric shock was picked up between the internal capillary electrode and a wire in the external electrolyte bath solution, amplified by vacuum tube amplifiers and displayed on a cathode ray ►oscilloscope (Cathode ray oscilloscope). The experiments elucidated the ionic mechanisms responsible for the resting membrane potential and the generation of the nerve ►action potential [1,2].

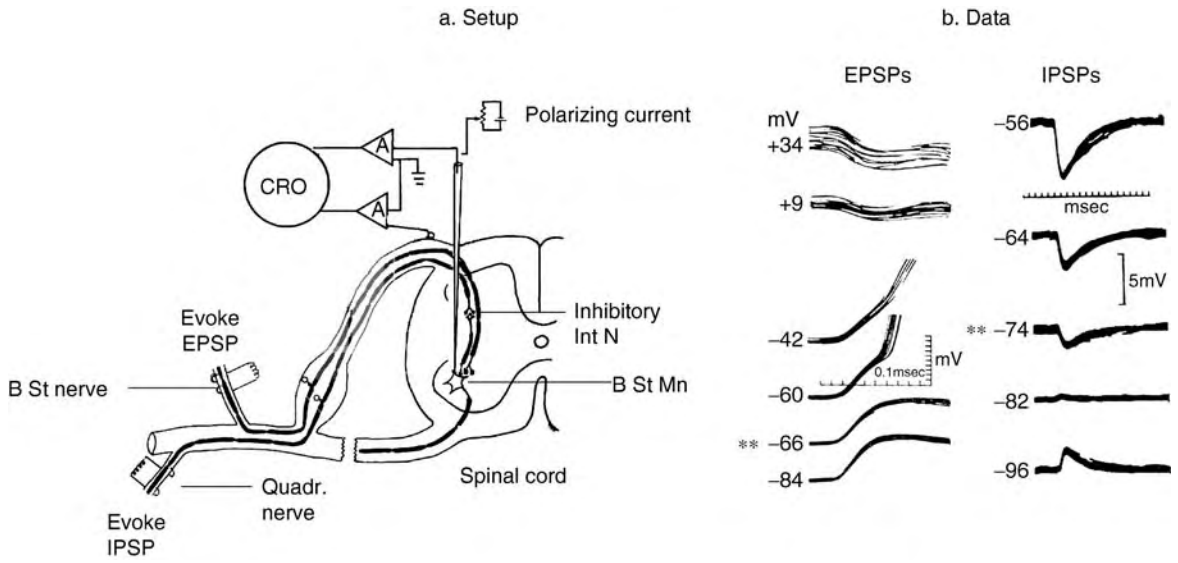
Recording membrane potential intracellularly from intact cells with ultra-microelectrodes was introduced by Ling and Gerard [3] and first used to measure the resting membrane potential of frog skeletal muscle fibers. Glass capillary tubing was flame heated and pulled to yield a needle-like profile with a fine tip, and then filled with KCl solution. A chlorided silver wire inserted into the pipette solution and connected to the grid of an electron tube amplifier made it possible to record a resting membrane potential of −90 mV when the microelectrode was inserted into a muscle fiber.

Modern microelectrode and computer technologies permit precise measurement of a variety of bioelectrical signals, such as ►postsynaptic potentials (PSPs) that determine the neuron's ►excitability state. ►PSPs are often evoked *in vivo* or *in situ* by stimulating afferent nerve fibers with electric shocks. When sharp micropipettes are used for recording membrane potential, they are filled with an aqueous potassium salt solution such as 3 M KCl, 2 M K-citrate or 2 M K-methylsulfate.

Eccles and colleagues provided a detailed description of stimulus-evoked PSPs in spinal cord experiments [4]. They demonstrated that electric shocks applied to hind limb afferent nerves evoke either ►inhibitory postsynaptic potentials (IPSPs) that transiently hyperpolarize motoneuron membrane potential and reduce the probability of action potentials, or ►excitatory postsynaptic potentials (EPSPs) that briefly depolarize and increase the likelihood of action potentials (Fig. 1). The magnitude of the PSP is proportional to the number of hind limb afferent nerve fibers that are depolarized to threshold by the electric shock, which is reflected in the size of the ►afferent volley recorded from a dorsal root. Simultaneous application of constant negative (hyperpolarizing) or positive (depolarizing) current through the microelectrode and across the cell membrane produces a steady shift of membrane potential that allows the PSP reversal potential, the value of the membrane potential at which the waveform of the PSP reverses direction, to be measured. IPSPs of spinal motoneurons in the adult cat reverse at about −80 mV (Fig. 1b, right column), indicating that the IPSP is caused by membrane diffusion of ions with a negative ►equilibrium potential, such as chloride or a combination of chloride and potassium ions. ►EPSPs reverse at about +5 mV, indicating that the depolarizing current is carried by combination of ions with positive ($Na^+$, $Ca^{2+}$) and negative ($K^+$) equilibrium potentials.

## Input Resistance

The degree to which membrane ion channels open and close during synaptic perturbations can be determined by measuring neuron input resistance. Current pulses of constant intensity and negative polarity are applied through the recording microelectrode. By knowing the current intensity and measuring the peak of the evoked ►electrotonic potential, one obtains the membrane resistance change from Ohm's law. A limitation of the method is that it may not detect membrane permeability changes that occur in remote regions of the dendrites.



**Intracellular Recording. Figure 1** Recording electric shock-evoked postsynaptic potentials (PSPs) from spinal cord motoneurons in vivo. (a) Setup for sharp capillary microelectrode recording of PSPs from a spinal cord motoneuron innervating the hind limb biceps semitendinosis (B St) muscle. Single electrical shocks delivered to nerve trunks innervating hind limb muscles evoke different types of synaptic potentials. Monosynaptic excitatory postsynaptic potentials (EPSPs) and action potentials are evoked when biceps semitendinosis (B St) afferent nerve fibers are stimulated. Disynaptic inhibitory postsynaptic potentials (IPSPs) are evoked by stimulating Quadriceps (Quadr.) afferent nerve fibers at sufficient intensities to activate inhibitory interneurons (Int). An extracellular amplifier (A) records the afferent action potential volley picked up from the dorsal roots with a monopolar electrode referenced to earth. Intracellular activity of the B ST motoneuron is recorded with an intracellular preamplifier (see Fig. 2) and registered on an oscilloscope (CRO) as superimposed traces (this figure, (b)). A dc current source is connected through the preamplifier to bring membrane potential to different steady levels. (b) Data from an in vivo intracellular recording experiment in the pentobarbital anesthetized cat. Records in the left column are EPSPs obtained from a B St motoneuron with a resting potential of −66 mV and brought to different levels of MP by dc polarizing currents. Subthreshold EPSPs marked by ** were recorded without current application. Records in the right column are IPSPs from another B St motoneuron, resting potential −74 mV. The IPSPs recorded without polarizing current are identified by **. The level of membrane potential where the stimulus-evoked PSP deflections were turned over (reversed) by polarizing currents reveals the approximate equilibrium potential: EPSPs, −3 mV; IPSPs, −82 mV. (a) was modified with permission from the original in Willis WD, Grossman RG (1973) Medical neurobiology. CV Mosby, St. Louis, p 97, Figs. 4–17. (b) was obtained with permission from Eccles JC (1964) The physiology of synapses. Springer-Verlag, NY, p 49, Fig. 17B and p 156, Fig. 60A.

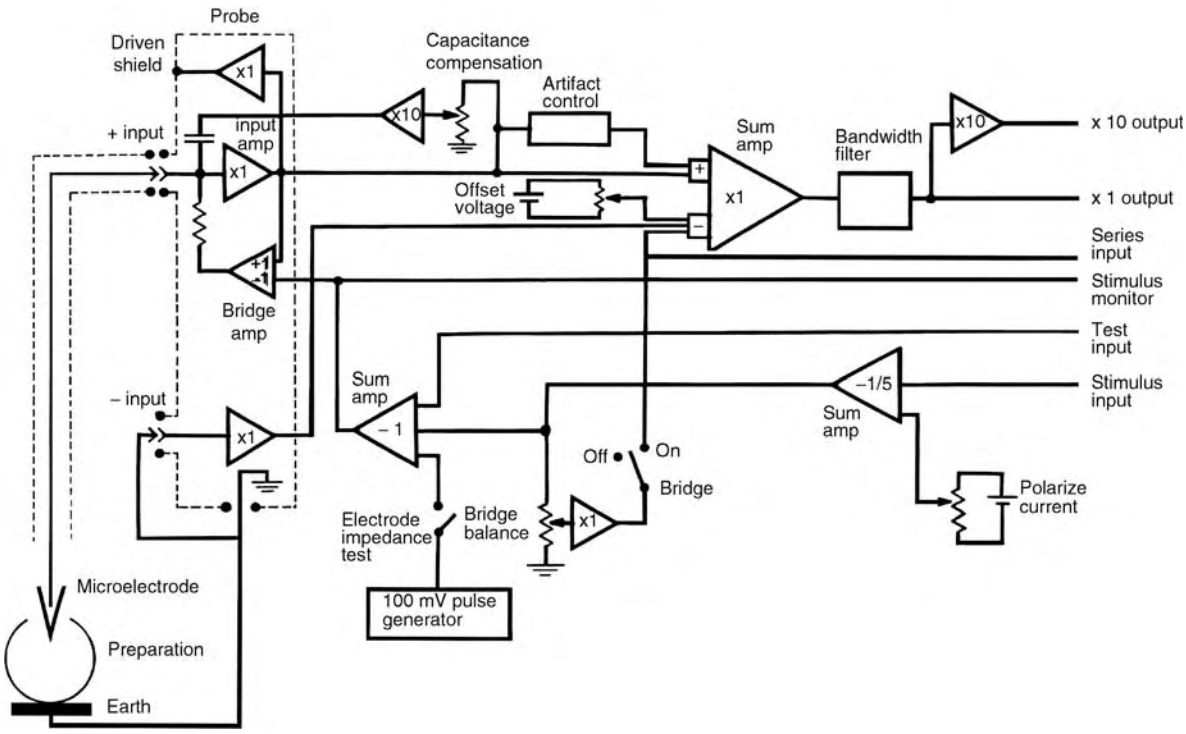
## Passive Membrane Properties

Membrane potential measurements are also used to derive passive electrophysiological properties that reflect their functional architecture of neurons, such as ►electrotonic length and total ►cell capacitance [5]. Electrotonic length (L) determines how ►synaptic potentials distribute between the soma and dendrites as a function of dendritic length and degree of branching. It is a useful measurement to analyze, for example, the effectiveness of a synaptic connection as a function of its distance from the action potential-generating regions of the input neuron. Total cell capacitance (C) is determined by the cell surface charging area, and in combination with membrane resistance (R) determines the temporal relationship between current flow and the resulting potential change. The product of R × C determines the time course of the synaptic potential. Larger values of RC cause synaptic potentials to build up and decay to baseline more slowly, and to temporally summate consecutive potentials more effectively toward or away from action potential threshold.

## Amplifiers and Recording Techniques

### *Recording in Balanced Bridge Mode*

Intracellular recording at present makes use of (i) solid state, fast responding amplifiers capable of picking up membrane potential and passing current through the same micropipette, (ii) an electrical stimulus source and (iii) recording devices with wide ►frequency bandwidths. Increasingly, all three components are computer-controlled. Figure 2 is a circuit diagram of a ►preamplifier designed for ►balanced bridge mode recording.



**Intracellular Recording. Figure 2** Block Diagram of a preamplifier for intracellular recording of membrane potential in balanced bridge mode. Circuit diagram illustrates components of a contemporary intracellular preamplifier. See text for a description of circuit components and why they are used (diagram adapted and used with permission from the Model 8500 Intracellular Preamp-Clamp Operating Manual, Preamplifier Block Diagram. Dagan Corporation, Minneapolis, MN, USA, p 8).

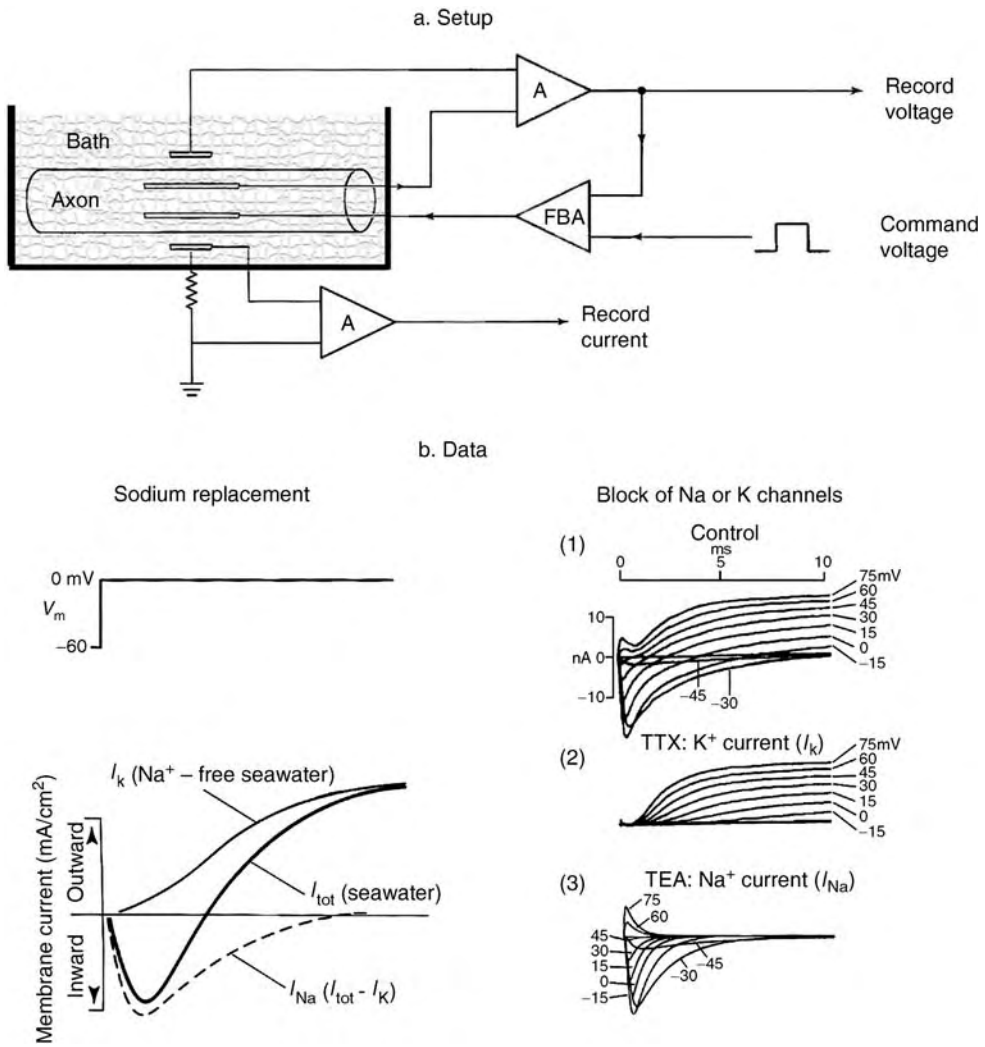
The preamplifier is equipped with the basic components needed to record membrane potential properties. An offset control cancels potentials due to series resistances that develop between the reference (earth) silver/silver chloride electrode and the input stage of the amplifier. The ►bridge circuit eliminates potentials developed across the microelectrode resistance, enabling accurate recording of membrane potential. An artifact control reduces fast transients at the beginning and end of intracellular current pulses. Capacitance neutralization minimizes stray capacitance sources at the input so that high frequency components of membrane potential signals are recorded faithfully. A high frequency cutoff control allows recording of membrane potential between DC and 10–300 kHz, although the high frequency cutoff is normally set at 10 kHz. An internal source provides steady positive or negative polarizing current to shift membrane potential. An impedance test circuit is used to measure microelectrode resistance in the tissue outside the cell or in the bathing medium. Amplifier outputs with gains of 1× and 10× are used to lead off signals to computers, oscilloscopes, strip chart and tape recorders.

### *Discontinuous Current Clamp Mode*

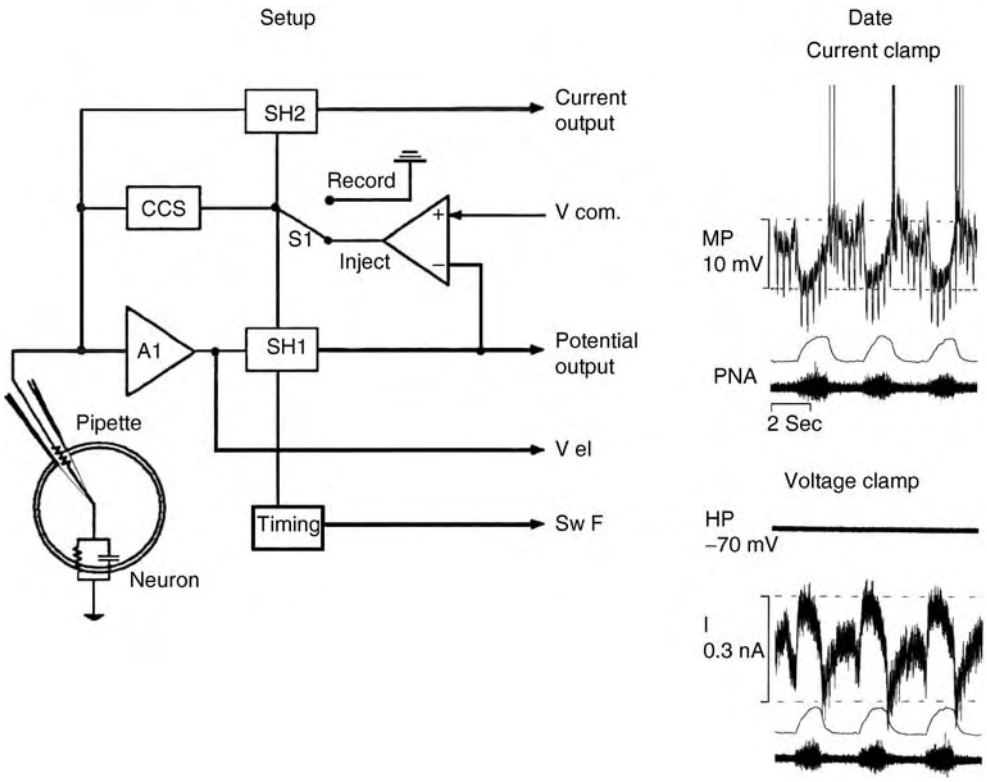
Another approach to recording membrane bioelectrical behavior is the discontinuous single electrode current clamp (dSECC) method. A preamplifier with sample-and-hold and switching circuits enables the microelectrode function to cycle at high frequency, typically in the range of 10–40 Hz, between passing current and picking up membrane potential (see Fig. 4, Setup). The arrangement allows the recording of membrane potential independently of the voltage change across the microelectrode resistance. Membrane input resistance during passage of current pulses can also be selectively measured (Fig. 4, right upper panel). A potential shortcoming of dSECC recording is that the signal-to-noise ratio may be reduced somewhat in smaller neurons with high input resistance due to electrical interference produced by switching between current application and recording.

### *Voltage Clamp Mode*

Measurements of the direction, magnitude and time course of ionic current flow across the nerve cell membrane provide information that can be used to identify ions, conductance mechanisms and temporal changes in cell excitability. ►Voltage clamp amplifiers with



**Intracellular Recording. Figure 3** Voltage and space clamp recording from an isolated squid giant axon. (a) Experimental setup. A large diameter axon (0.1–1 mm) is bathed in conducting seawater. Two wire electrodes have been inserted into the axon, one to record membrane potential and the other to pass current across the membrane. The amplifiers (A) record membrane potential (voltage) and current. The output of the voltage amplifier is also passed to the feedback amplifier (FBA) that, in addition, receives a ►command voltage to change membrane potential. Differences between the membrane potential and the command voltage are amplified by the FBA and passed to the current electrode, which generates a current that crosses the membrane to the pickup electrode in the bath solution. The amplifier records the transmembrane current when the membrane potential is brought to and held at a selected level by the command voltage. (b) Left. Effects of replacing sodium on depolarization-evoked currents. In normal seawater a voltage step from resting membrane potential (−60 mV) to 0 mV that would trigger an action potential under unclamped conditions evokes an initial inward current (shown as a downward deflection through the baseline on the oscilloscope trace $I_{tot}$ in the lower panel), followed by an outward current (upward deflection). Replacement of sodium with an equi-osmolar concentration of membrane-impermeable choline eliminates the inward current and reveals the time course and magnitude of the outward current, which turns out to be a potassium ion current ($I_K$, $Na^+$ – free seawater). Subtraction of this trace from the $I_{tot}$ trace reveals the magnitude and time course of the potassium current. (b) right. Isolation of the sodium and potassium currents responsible for the action potential with selective ion channel blockers. Panel (1) illustrates a family of superimposed current traces produced by stepping membrane potential to different levels from −60 mV in normal seawater. Panel (2) shows outward potassium current traces that remain after sodium channels have been selectively blocked by adding tetrodotoxin (TTX) to the bath. Panel (3) shows sodium currents after blockade of potassium channels with tetraethylammonium. (a) is modified with permission from Aidley DJ (1998) The physiology of excitable cells, 4th edn. Cambridge University Press, p 11, Fig. 2.3. Panels in (b) are modified and reproduced with permission from Kandel ER (ed) Handbook of physiology, Sect. 1, vol 1. American Physiological Society, Bethesda MD, pp 99–136.



**Intracellular Recording. Figure 4** Discontinuous single microelectrode current and voltage clamping. Left (Setup), circuit block diagram of the 05LX Single electrode current and voltage clamp system, version 1.2, npi Instruments for the Life Science, Tamm, Germany, copied with permission from the npi Operating Instructions and System Description, Fig. 2a. Right (Data), in vivo intracellular current clamp (upper) and voltage clamp (lower) records obtained from a postinspiratory neuron in the ventral medullary respiratory group of a pentobarbital anesthetized cat. Tracings recorded in current clamp mode are, from top to bottom, membrane potential (MP), integrated spike frequency (middle trace) and electroneurogram (bottom) of phrenic nerve action potential (PNA) discharges. In voltage clamp mode, traces are membrane voltage held steady at −70 mV, membrane current (I), integrated PNA frequency and PNA electroneurogram. Neuron membrane potential and membrane current oscillate with a respiratory rhythm along with PNA. In current clamp mode, neuron action potentials discharge with the cessation of PNA during the postinspiratory phase. Brief, regularly occurring downward deflections are constant current pulses used to follow changes of input resistance as MP oscillates. In voltage clamp mode, periodic bursts of inward current occur during the activated (postinspiratory) phase, and outward waves occur during the inhibitory (inspiratory) phase of the respiratory cycle (Lalley PM, unpublished data).

fast-responding ►feedback circuits permit membrane potential to be "clamped" at various selected levels while current is measured. The first voltage clamp recording was accomplished by threading two chlorided silver wire electrodes longitudinally within a giant axon of the squid and connecting them to feed-forward and ►feedback amplifiers (Fig. 3a). Measurements by Cole and associates (see [1]) and by Hodgkin et al. [6], linked sodium and potassium currents to the generation of the nerve action potential (Fig. 3b).

Two-microelectrode ►voltage clamping was later developed for recording membrane currents from nerve cell bodies, followed by voltage-clamp technology for recording with a single microelectrode. The single pipette technique, referred to as discontinuous single electrode voltage clamping (dSEVC), enables measurement of membrane currents with high temporal resolution in small as well as large neurons, and minimizes damage to nerve cells [7,8].

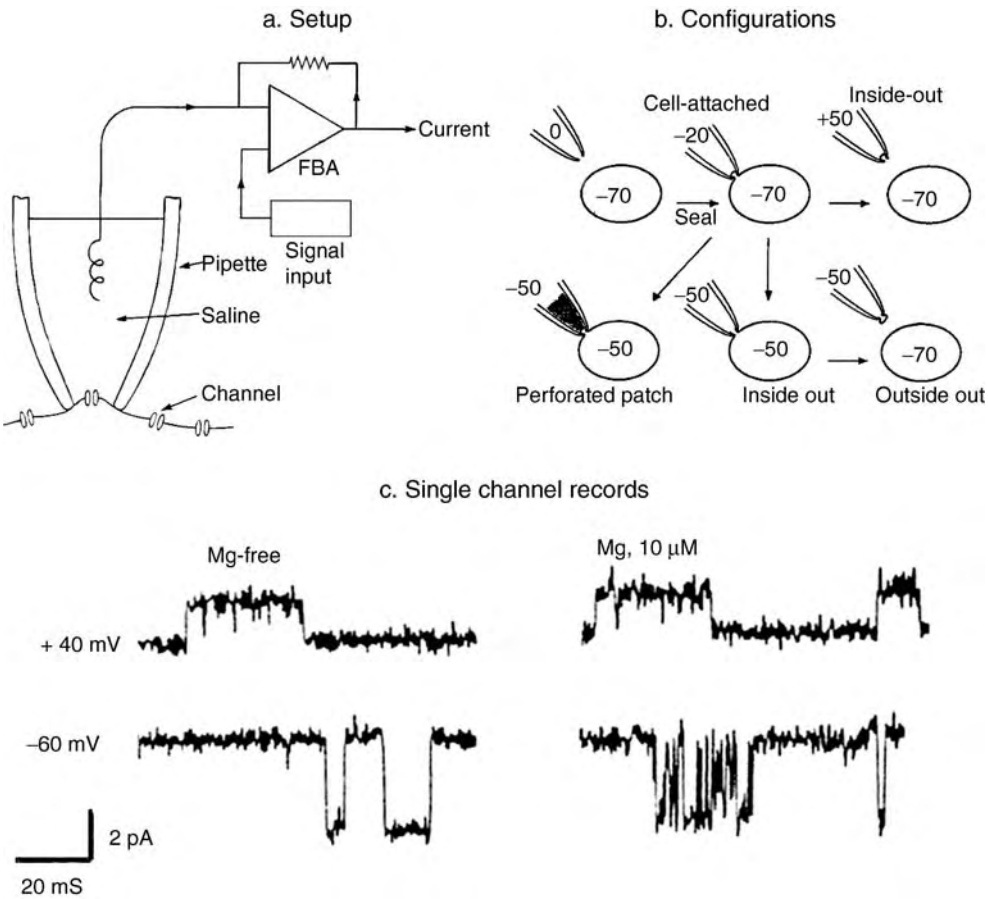
The dSEVC operating system (Fig. 4, setup) includes a command voltage source (►Command voltage (potential) source), buffer (►Buffer amplifier) and feedback amplifiers, ►sample-and-hold circuits and a switching circuit that alternates at high frequency between current-injecting and voltage-recording modes. A feedback circuit compares the cell membrane potential ($E_M$), sampled at a time when the voltage change across the microelectrode resistance has decayed to zero, with the ►command potential ($E_C$), and injects current to compensate for the difference ($|E_M–E_C|$). The injected

current is equivalent to the spontaneous or evoked intrinsic membrane current.

Potential limitations of dSEVC include (i) the limitation imposed on the method by cell size and geometry. In large cells with extensive dendritic arborizations, it is sometimes difficult to adequately voltage clamp regions of the cell where the clamping voltage doesn't reach unless large currents than can damage the cell membrane are applied. (ii) The high resistance and capacitance of fine-tipped micropipettes may result in incomplete decay of the electrode potential between switching from current injection to recording in some amplifiers, resulting in incorrect values of holding potential and current. (iii) The relative complexity of dSEVC recording and procedures increases the possibility of errors resulting from improper circuit adjustments. The last two factors depend on circuit design, and have been largely eliminated in the circuit illustrated in Fig. 4 and in some other recent dSEVC circuits [9].

### *Voltage Clamp-Controlled Current Clamp Recording*

A very recent and useful supplement to single microelectrode voltage clamping, called voltage clamp-controlled current clamp recording, involves the addition of ▶low-pass filters with selectable time constants to control the response time of the voltage clamp amplifier's



**Intracellular Recording. Figure 5** Patch Clamp recording and results. (a) Recording setup. A patch clamp filled with a recording solution that mimics the internal ionic environment of the cell (see text) is attached to the cell membrane by application of slight suction. The feedback amplifier holds the membrane potential steady while the current is measured. (b) Different patch clamp recording configurations. Mild suction allows recording of single channels in the cell-attached configuration. Breaking the patch with a pulse of suction or voltage, or adding nystatin or amphotericin to the pipette solution obtains whole cell recording. Withdrawal of the cell in the cell-attached configuration produces an inside-out patch, whereas withdrawal in the whole cell configuration produces an outside-out patch. Isolated inside out or outside out patch of membrane can then be submerged in bathing media containing drugs that alter ion channel activity. (c) Single channel currents evoked by the excitatory neurotransmitter glutamate in embryonic mouse brain cells. The experiment tests the effect of magnesium ions. Single channel currents are inward at −60 mV and outward at +40 mV (figure adapted with permission from Aidley DJ (1998) The physiology of excitable cells, 4th edn, Cambridge University Press, p 12. Figs. 2.4 and 2.5 and p 151, Fig. 8.24).

feedback circuit [9,10]. This modification allows slow oscillations of membrane potential to be selectively suppressed without influence on faster responses. In neurons that oscillate due to network interactions or ►pacemaker properties, for example brainstem respiratory neurons, it may be desirable to suppress such slow waves and hold membrane potential at different steady levels while recording and measuring PSPs or input resistance.

### *Patch Clamp Recording of Single or Small Aggregates of Channel Currents*

A major leap forward in intracellular recording technology came with the development of the patch-clamp method by Neher and Sakmann [10], which allows recordings to be obtained from single or small numbers of membrane channels from whole cells or from excised membrane patches *in vitro*. A heat-polished glass pipette containing an electrolyte solution and other chemicals to maintain cell integrity is brought into contact with the cell membrane and secured to it by suction, forming a seal with a high electrical resistance. Currents in the patch of membrane under the pipette orifice are detected with a minimum of background noise. Alternatively, the membrane can be ruptured by further controlled suction, sealing the membrane against the pipette's polished opening, so that whole cell currents are recorded. Either way, a patch clamp circuit is utilized that further reduces extraneous noise and improves frequency response (Fig. 5). Recording is quite stable because of suction-mediated attachment.

A disadvantage of conventional whole cell-attached ►patch clamp recording is that the cell is dialyzed with the solution inside the recording electrode, diluting nutrients and other components of the intracellular fluid that may cause rundown of responsiveness.

A variant of this technique, the "perforated patch" technique (Fig. 5b), uses chemicals such as nystatin or amphoteracin to permeabalize the membrane, i.e. produce small membrane openings for current flow without suction and avoids dialyzing the cytoplasm.

A third approach is to withdraw the electrode from the cell during applied suction, removing the patch from the rest of the cell. Membrane properties can be investigated pharmacologically by measuring currents in the excised patch during immersion in bathing solutions containing neurochemicals.

# Intracellular Staining

## Definition

This is a set of techniques in which a solution containing a marker molecule is driven into a single neuron via a pipette whose tip passes through the cells membrane and is in the cytoplasm. If the marker molecule is charged it can be driven into the interior of the cell by iontophoresis, i.e., applying current to the solution in the pipette. The marker solution can also be driven into the cell by applying air pressure to the back of the pipette.

# Intra cortical Facilitation (ICF)

## Definition

Phenomenon of increased cortical excitability evoked by conditioning stimuli and assessed by test stimuli in a conditioning-test paradigm.

►Transcranial Magnetic Stimulation

## Intra cortical Inhibition (ICI)

### Definition
Phenomenon of increased cortical inhibition evoked by conditioning stimuli and assessed by test stimuli in a conditioning-test paradigm.

►Transcranial Magnetic Stimulation

## Intracortical Microstimulation (ICMS)

### Definition
ICMS consists of repetitively applied electrical pulses delivered by a microelectrode. Currents are usually very low (6–12 μA) and very short (200 μs) but applied at high frequencies (about 300 Hz). The resulting temporally synchronized neuronal discharges are highly effective for the induction of re-organizational processes. ICMS has been successfully used to study rapid, i.e. plastic changes inducible within a few hours, in adult motor, somatosensory and auditory cortex and thalamus, which were fully reversible. The region of tissue that is stimulated by direct activation during ICMS is very small (50 to 100 μm).

►Somatosensory Reorganization

## Intrafusal Muscle Fibers

### Definition
►Muscle Spindle

## Intralaminar Nuclei

### Definition
A set of dorsal thalamic nuclei in mammals that lie between fiber laminae formed by the axons of other dorsal thalamic nuclear groups. They have diverse inputs and projections.

►Evolution, of the Dorsal Thalamus

## Intralaminar Thalamic Nuclei

### Synonyms
Nuclei intralaminares thalami; Intralaminar nuclei of thalamus

### Definition
The Intralaminar nuclei lie in the internal medullary lamina of the thalamus and are characterized by their double projections, with one going to the cerebral cortex and one to the corpus striatum. A distinction is made between

- Rostral group: lateral central nucleus, paracentral nucleus, medial central nucleus
- Caudal group: centromedian nucleus, parafascicular nucleus

Afferents from the globus pallidus, cerebellum, spino/trigeminothalamic tract.

►Diencephalon

## Intramural Ganglia

### Definition
Intramural ganglia are autonomic ganglia that lie within the walls of organs, such as the lungs, bladder, pancreas and intestine.

## Intramuscular Myofascial Force Transmission

Peter A. Huijing
Research Instituut
Faculteit Bewegingswetenschappen, Vrije Universiteit, Amsterdam, The Netherlands

### Synonyms
Lateral force transmission [1]; Myofascial force transmission [2,3]

### Definition
#### Myofascial Force Transmission and the Endomysial Stroma
Force transmission from or onto a muscle fiber as force is transmitted between a passive or active muscle fiber and

the collagen fibers embedded within its extracellular matrix. Exclusively, if those target collagen fibers are not a part of the aligned collagen fibers of the micro-tendon of the muscle fiber, we call such transfer of force ►myofascial force transmission. The fibrous connective tissue structure context within which each muscle fiber operates that fits this limitation is the ►endomysium. Myofascial force transmission may occur along the perimeter of the muscle fiber along its whole length.

As force transmission has to take place on a path that is almost perpendicular to the line of pull of sarcomere forces it cannot be tensile in nature. Instead, force transmission is mediated by ►shearing of the sarcolemma – ►basal lamina – endomysium complex (Fig. 1).

The shearing ►stiffness of this complex is dependent on the relative position of the sarcolemma and nearby endomysium.

Note that this endomysial ►stroma also constitutes the surroundings for capillaries and nerve branches to reach the muscle fiber. In fact, capillaries and nerve branches are embedded within the endomysial stroma and protected by its collagen fibers that bear most of the force.

## Characteristics

### Quantitative Description

The endomysial walls form "tunnels" for each muscle fiber to operate within. They create a 60–100 μ diameter honeycomb-like structure (Fig. 2).

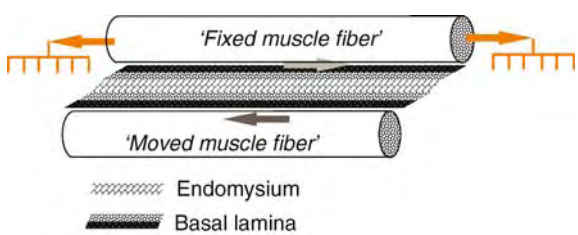
### Higher Level Structures

#### *Relevant Connective Tissue Structures*

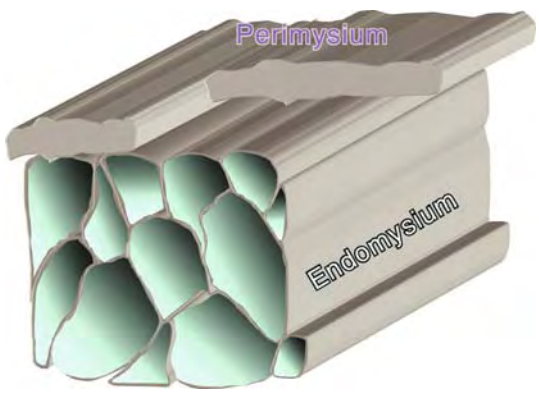
The type of honeycomb-like structure repeats itself at higher levels of organization and size:

1. ►Perimysium or fascicle ►fascia (also called perimysium internum).

Each muscular fascicle (i.e. bundle of muscle fibers) also operates within a connective tissue tunnel: the wall of this tunnel is formed by the perimysium. Its wall consists of a crossed-ply arrangement of collagen fibers that reorient on changing muscle sarcomere length [4]. The mean collagen fiber direction, relative to the longitudinal direction of the muscle fibers, ranged from ~80° at sarcomere length = 1.1 μ to ~20° at 3.9 μ. The perimysium is composed of several layers of 100–200 μ-thick sheets surrounding and attaching to the honeycomb structure of the fascicular endomysial stroma. The perimysial tunnels of neighboring fascicles are interconnected and form a network that can be sheared as the relative position of fascicles is changed. Note that the major intramuscular blood vessels and nerves are embedded and attached by collagen fibers to this structure [5] and are protected by the collagen fibers reinforcements of the perimysium that bear most of the local force. Note that muscular receptors (e.g. muscle spindles and the pressure sensitive Pacianian receptors) also operate within this mechanical context.



**Intramuscular Myofascial Force Transmission.**
**Figure 1** Schematic representation of two muscle fibers and their sheared extracellular matrix. If one muscle fiber is fixed and a neighboring muscle fiber is moved, the interface between the muscle fibers consisting of the basal lamina (*shown as two layers*) and the endomysium is sheared. As a consequence of the shearing deformation, elastic structures within the interface are lengthened and a shear force is exerted (*light grey arrow*). If the size of this shear matches the force that causes the movement or shortening of the other muscle fiber, the movement will stop due to myofascial force transmission.



**Intramuscular Myofascial Force Transmission.**
**Figure 2** Schematic representation of a small section of the endomysial stroma of a muscle fascicle. This image represents a part of a muscle with the muscle fibers removed. A set of "tunnels" remain, each of which was the domain of a muscle fiber. At the periphery of a fascicle, the endomysial stroma is continuous, with the epimysial fascia investing the whole fascicle. At higher levels of organization (not shown), this type of structure repeats itself until the collection of all fascicles form the muscle stroma, which is invested by the epimysial fascia. The walls of this structure are predominantly made up of type I collagen fibers running in many directions. The directions of collagen fibers within the endomysium are muscle fiber length dependent.

2. The ►epimysium or muscle fascia (also called perimysium externum).

   This structure is composed of two distinct layers of connective tissue sheets.

   1. The inner layer consists of collagen fibers lying in a regular wavy pattern parallel to the axis of the muscle fiber.
   2. The outer layer of epimysium is composed of several sheets of wavy collagen fibers that run transversely to the longitudinal axis of the muscle fiber. In a region of the epimysium, there is a thick wall of about 1 mm thickness, where collagen fiber bundles of 200–300 μ in diameter run longitudinally parallel to the axis of muscle fiber.

## Lower Level Components

Force is generated within the sarcomeres of the muscle fiber by its contractile proteins. Serial arrangements of sarcomeres are called myofibrils; the area attached at the myotendinous junction, but are also embedded within the intracellular non-contractile proteins of the cytoskeleton, which forms the connections between parallel myofibrils and a layer of molecules just below the sarcolemma (muscle fiber cell membrane).

The most peripheral layer of the cytoskeleton is connected by molecules that cross the sarcolemma and are attached to the molecules of basal lamina, which constitutes the part of the extracellular matrix that separates muscular and connective tissues. Non-fibril forming collagen type IV is a major constituent of the basal lamina. The network formed by these basal lamina collagen molecules is on its periphery, connected to the wall of the endomysial tunnel. Such connections are most likely made via proteoglycans [6].

## Higher Level Processes

As some force is transmitted between a muscle fiber and its endomysium, there are a number of paths potentially available for further transmission

1. Intramuscular paths [2,7]
   a. Along the endomysium to the tendon [1] (i.e. ►intramuscular myofascial force transmission). The endomysium is continuous with a similar structure (endotenon) that surrounds the longitudinal collagen fibers of the muscle fiber's micro-tendon. A collection of such micro-tendons forms the tendon or aponeurosis (tendon plate) of the muscle.
   b. Onto the cytoskeleton within a neighboring muscle fiber. This process of inter-fiber force transmission has been argued to be active [8] for so called ►non-spanning muscle fibers [9] i.e. muscle fibers that do not extend from proximal to distal tendon plate of muscle, but end with tapered ends within the belly of the muscle.
   c. As the endomysial tunnels of neighboring muscle fibers are connected, force can be transmitted, again by shearing along the connective tissue network that is a part of a fascicle (bundle of muscle fibers), across fascicles until the limits of the muscle are reached.
2. Epimuscular paths [10] (see accompanying essay of this encyclopedia):
   a. Extramuscular path [7,3]
   b. Intermuscular path [7,3]

A major difference between these two types of paths is that intramuscular effects will yield equal forces exerted origin and insertion of a muscle, whereas for epimuscular force transmission these forces should be different.

## Process Regulation

Within the muscle, a number of serial paths for myofascial and ►myotendinous force transmission are available. Most force will be borne by the stiffest connections.

## Function

In a classical view, active or passive force generated with sarcomeres is transmitted exclusively from sarcomere to sarcomere in arranged series until the end of the muscle fiber is reached, where the interface between a muscle fiber (muscle fiber) and its tendon is located (myotendinous junction). At this junction, force will be transmitted onto the tendon collagen fibers running almost exclusively in longitudinal direction, and from there to the bones.

Myofascial force transmission constitutes an additional mechanism of force transmission from the muscle: Force is transmitted from or onto the endomysial-perimysial-epimysial stroma, which acts as an integrator for forces exerted within the muscle. Furthermore, the intramuscular stroma, as an integrator of force as well as the location of neural receptors (muscle spindles, tendon organs, Pacianian corpuscles), provides global information to the central nervous system of the muscle's condition rather than information about very localized processes within the muscle.

In this essay, we have so far described force transmission more or less as a transmission of force out of muscle fibers onto the extracellular context. It should be realized that this is actually a bi-directional process: If the sarcomere can exert a force via the cytoskeleton onto the extracellular stroma, in principle, it should also be possible for the extracellular stroma to exert forces on the cytoskeleton (transduction). Such processes may play an important role in the adaptation of muscle fibers (regulation of hypertrophy or atrophy, or changes in number of serial sarcomeres). This would mean that mechanical stimuli on the cytoskeleton could play an important role in processes of muscular adaptation.

### Pathology

If one of the series molecules connecting the muscle fiber cytoskeleton to the endomysium is deficient, and myofascial force transmission may be absent or very limited, the sometimes very serious pathology of muscular dystrophy is present. The way this pathology and its effects are related exactly to myofascial force transmission is presently not fully understood.

## Intravenous Self-administration

### Definition

Knowledge about the neurobiological processes related to drug-addiction is essential for the control and treatment of this disorder and this in turn requires valid animal models of addictive behavior. Humans who use drugs to excess often use needles to self-administer these compounds intravenously. Animals, including rats and primates, prepared with indwelling intravenous catheters which can in turn be connected to a remotely operated syringe attached to an infusion pumps, readily acquire a response such a lever-press to self-administer the same range of drugs used by humans to induce euphoria and subsequently maintain a habit of drug abuse. Animals eventually extinguish voluntary responding for intravenous self-administration when saline is substituted for an active drug. Importantly, drug-seeking behavior is reinstated after a period of abstinence following presentation of a single "priming" dose of the drug, a cue or environment associated with drug-reward, and also exposure to an acute stressor, thus proving a model of relapse. Availability of drugreward during long-duration test sessions (>6 h) leads to increased consumption of the drug and the development of habitual patterns of behavior.

## Intrinsic Bursting

### Definition

Bursts of action potentials caused by intrinsic conductances.

## Intrinsic Excitability

### Definition

Intrinsic excitability refers to the canonical patterns of action potentials that can be produced in a neuron by

injection of a current pulse, independent of the activation of synaptic inputs. Intrinsic excitability depends on the genetic expression of specific types of ion channels in the neuron, as well as their placement in the cell membrane.

►Action Potential

## Intrinsic Primary Afferent Neurons

### Definition

## Intrinsic Properties of Auditory Neurons

Paul B. Manis
Otolaryngology/Head and Neck Surgery and Cell and Molecular Physiology, University of North Carolina at Chapel Hill, NC, USA

### Synonyms

Electrical Excitability; Membrane Properties; Channel Expression

### Definition

The ►intrinsic properties of neurons refer to the electrical excitability of the cell independent of ►synaptic inputs. All neurons use electrical signals and changes in their electrical properties in order to receive, process, and pass on information. The processing of electrical information is conducted by specialized proteins in the cell membrane called ►ion channels. Ion channels control how specific ions, such as sodium, potassium, calcium or chloride, pass into and out of the cell. Different classes of neurons express selected sets of ion channels. The particular pattern of channel expression gives each cell type a unique electrical signature that can be described as the ►intrinsic electrical response [1]. Ion channels shape the responses of the cells to synaptic inputs, by determining the patterns of ►action potential firing, and help provide important feedback to synapses about when cells are excited (or not). Ion channels are often subject to modulation by a variety of mechanisms that make the ►intrinsic excitability adjustable over a limited range. In any given cell, the role of intrinsic conductances in tuning neuronal firing patterns to natural stimuli or internal neural events depends on several factors: the relative strengths of synaptic and ion channel conductances, the shape of the dendritic tree, as well as the temporal patterns of synaptic excitation and inhibition that a cell receives.

### Characteristics

Auditory stimuli, particularly those with minute time differences, present a challenge to neuronal processing in the brain. Consider that the detection of the location of a sound source can require timing sensitivity in the order of tens of microseconds (μs, one one-millionth of a second), whereas the action potentials that signal information from one neuron to the next have widths of about 1 millisecond (ms, one one-thousandth of a second). Sounds used in communication, such as vowel sounds of speech, are also encoded in part by the timing of action potentials, with variability in the order of 100 μs. Timing information in the auditory system is conveyed by a phenomenon called ►phase locking, meaning that action potentials occur during a particular part of the stimulus waveform. Neurons in the auditory nerve and in the nuclei of the auditory brainstem transmit and process information within these time scales. Many auditory neurons are thus specialized to operate on time scales that are much shorter than those encountered in most other areas of the brain, and this ability depends in part in the ►intrinsic electrical properties of the neurons.

In the brainstem auditory system, neurons exhibit four fundamental intrinsic electrical signatures, suggesting that specific patterns of ion channel expression are needed for computation in this system. Each intrinsic electrical signature is characterized by the action potential is discharge patterns that are produced when a cell is depolarized by a current pulse from an intracellular electrode. Two of these patterns were first recognized by Oertel [2] in her groundbreaking studies of ►cochlear nucleus (CN) neurons in the brain slice, and a third pattern was identified by Manis [3] in another set of CN neurons in the brain slice. A fourth pattern appears in only a few types of CN neurons, and was identified by Zhang and Oertel [4] and Manis et al. [5]. Additional variations on the first three electrical signatures are seen

in neurons in other parts of the brainstem auditory system, including the superior olivary complex and inferior colliculus. Furthermore, each firing pattern has been seen in cells from homologous cell groups in a variety of mammalian species, as well as in cells with homologous connections and function in birds, attesting to an evolutionarily conserved role for specific combinations of ion channels in auditory information processing.

The first electrical signature is defined by the production of an evenly spaced train of action potentials. The spacing of action potentials in time becomes shorter as the cell is more strongly stimulated by current or synaptic input; therefore the firing rate reports the average strength of the synaptic inputs. The firing rate does not change during sustained constant stimulation, and is not sensitive to the membrane voltage of the cell before stimulation. Cells with this firing pattern are thought to convey information about sound intensity by their average firing rate. These neurons often have narrow action potentials, and can fire quite rapidly at frequencies up to 400 Hz. The cells with this signature often receive convergent input from many weak synapses. *In vivo*, these cells also fire very evenly spaced trains of action potentials to natural acoustic stimuli. Neurons of this type have membrane time constants of 7–10 ms, which is short by the standards of most neurons. Voltage-clamp studies have been used to characterize the ion channels found in these cells. Aside from the sodium channels whose activation creates the action potentials, these cells express a high-threshold delayed rectifier (very likely the Kv3.1 potassium channel), a hyperpolarization activated cation (Na and K permeable) conductance, and possibly a persistent sodium current. In computational models, the combination of the Na, K, and Ih currents is sufficient to recapitulate most of the responses of these cells found *in vitro* and to simulate natural patterns of synaptic activity recorded *in vivo*. Cells with this firing pattern and channel complement are found in the cochlear nuclei, as well as in other brainstem and midbrain auditory nuclei. The properties of these neurons are similar to those of fast-spiking cortical inhibitory interneurons, although most of these auditory cells are excitatory.

The second electrical signature is characterized by the ability to elicit only one or two action potentials at the onset of a current pulse. The action potentials can be very precisely timed to the onset of the pulse and are followed by a brief hyperpolarization, after which the membrane potential stays close to the resting potential. This pattern was first described by Oertel [2], and is found in specific subsets of cochlear nucleus neurons called bushy cells and octopus cells, as well as in other brainstem and midbrain auditory neurons. In many of these neurons, the action potentials at the cell body are quite small. In response to acoustic stimuli, neurons showing this intrinsic firing pattern either respond only at the onset of tones, or may respond with action potentials that occur at times similar to their inputs. Some of these neurons with these intrinsic properties can improve (sharpen) the temporal precision of firing of their inputs. Voltage clamp studies have shown that this firing pattern is founded on a very strong potassium conductance that is active at the resting potential, and which is activated by depolarization [6]. This conductance shows variation in strength and speed among different cell populations, but is most likely composed of membrane proteins containing both Kv1.1 and Kv1.2 potassium channels. These cells also express other potassium and mixed ion conductances, similar to the cells described above. The important role of this conductance in auditory processing will be discussed below.

The third intrinsic pattern is similar to the first one described above, in that the cells can fire regular trains of action potentials. However, the latency of the first action potential, or the duration of the interval between the first and second spike, is uniquely sensitive to the membrane potential prior to an excitation. These cells can show three different intrinsic firing signatures that are sensitive to the history of their synaptic inputs. In one, the first spike latency can be very long (from tens of milliseconds to about 300 ms). In the other pattern, first spike latency is short, but the time between the next two spikes is longer. After the first or second action potential, the firing pattern is regular. These patterns occur when the membrane potential is below the cell's resting potential for at least 10 ms before a strong depolarization. When the neuron is depolarized without prior hyperpolarization, a third pattern of regular discharge with short first spike latency, similar to the first (regular) pattern described above, can be elicited. Whether the cell fires with a long latency spike or a long first interspike interval is a function of both the strength of the depolarization and the prior membrane potential. When studied *in vivo*, cells with these intrinsic properties often show similar firing patterns, and some cells can show all three patterns depending on the auditory stimulus. Voltage clamp analysis of the membrane conductances in these cells has revealed a strong transient (inactivating) potassium conductance that is not present or is much weaker in other cell types. The transient conductance is both necessary and sufficient for the long first spike latency or first interspike interval, and imparts a sensitivity of the neurons' activity pattern to prior inhibition. This pattern, which was first seen in neurons of the dorsal cochlear nucleus, has also been reported in other neurons of the cochlear nucleus, as well as other midbrain and brainstem auditory nuclei. This pattern is thought to convey information about the history of activity using spike timing across a population of cells [7].

The fourth electrical signature is found in cells that can fire brief bursts of action potentials at high frequencies. Such bursting cells are found in the dorsal cochlear nucleus, where they have been identified as cartwheel cells, as well as in a few other midbrain auditory nuclei. The bursting pattern is supported by a combination of calcium and sodium conductances in the dendrites of the cells. There are no published voltage clamp studies on these cells. Cells with bursting properties also respond to sound with bursting patterns *in vivo*. Bursts are likely to have multiple functions. First, because they are associated with the opening of calcium channels, cells often have high intracellular calcium levels during the bursts. Such increased calcium can initiate changes in the strength of synapses onto the cells, and can also activate or modulate other ion channels. As such, the bursts may play a role in initiating synaptic plasticity. In addition, when action potential bursts reach the synaptic terminals of these cells, they cause increased transmitter release through repetitive activation of the synapses. In some systems, the bursts are thought to signal events of special significance to the cells.

Thus, neurons in the brainstem auditory system can be classified according to their intrinsic excitability. There are four main patterns of excitability, and each pattern appears to be present in specific types of cells that play different roles in auditory information processing. Cells with onset responses to current pulses are often involved in pathways that analyze timing information. Those with regular firing patterns are often involved in pathways that report intensity or slowly varying timing information. Neurons with variable first spike latencies are found in pathways that process complex patterns of synaptic input, and may signal temporal aspects of their synaptic input through spike times. Cells with complex spiking patterns may be involved in plastic circuits where activity-driven calcium entry is important. In addition, since each morphological class of neurons is associated with a particular intrinsic behavior, the developmental events that specify cell morphology and connections may also help specify the expression and localization of ion channels in the cell.

### The Functional Contribution of Intrinsic Patterns to Information Processing

The functional specialization of auditory neurons for rapid temporal processing is largely expressed by neurons that show the second intrinsic motif: single action potentials elicited by excitation, and the presence of low-voltage activating potassium conductances. These two features allow the cells to fire precisely timed action potentials. This has been demonstrated through modeling studies, and is supported by experimental analyses in brain slices and with knockout mice. The low-voltage activated potassium channels are active at the resting membrane potential, and consequently provide the main control of the cell input resistance and time constant at rest. These channels can be rapidly activated by depolarization, hence shape the voltage trajectory of synaptic potentials, and even provide intrinsic feed-forward inhibition. These channels are useful in neurons that need to detect the temporal coincidence of afferent inputs on a short time scale, since the voltage effects of synaptic conductance changes last less than a millisecond when these channels are present. This specialization is found in few other types of neurons in the brain.

## Intrinsic Properties of Neurons

### Definition

These are voltage dependent properties intrinsic to a neuron which modify the response properties of a cell.

In other words, a similar level of synaptic transmission can produce differing effects in two different cells depending on the individual conductances expressed in the target cell. These intrinsic properties are not fixed and can usually be altered by neuromodulators.

Changes in response properties of groups of cells can have a profound effect on network dynamics.

### Synonyms

Acoustic Sensillum; Auditory Sensillum

### Definition

A cuticular sense organ (sensillum) containing a specialized ►mechanoreceptor for transducing the particle velocity or pressure component of sound energy into electrochemical nerve impulses that are transmitted to the central nervous system (CNS) and which are used to mediate acoustically evoked behavior (e.g., detection and localization of mates, predators, prey or hosts).

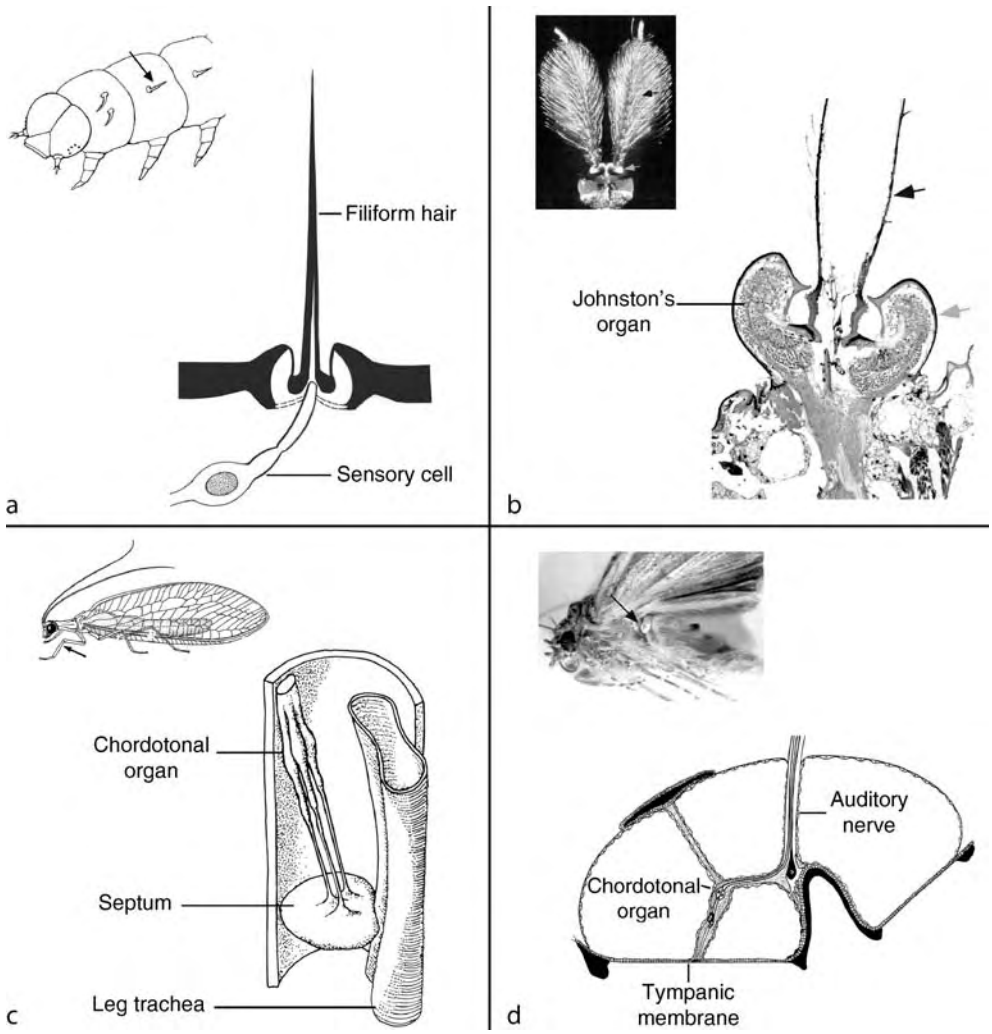
### Characteristics

Among invertebrates, a sense of hearing has been described only in arthropods. Except for a few species of Crustacea, members of the Insecta are the only invertebrates known to both produce and receive airborne sounds, and to use airborne acoustic signaling to mediate behavior. Some insect auditory organs, such as Trichoid Sensilla (Fig. 1a) or Johnston's Organs (Fig. 1b) are sensitive to the particle velocity component of sound, sometimes called near-field sounds. Particle displacement receivers are inherently directional because particle displacement occurs parallel to the direction of sound propagation and therefore the magnitude of the sensory response varies with the orientation of the receiver in the sound field. ►Tympanal Organs (Fig. 1d) detect sound pressure via the movement of a tympanal membrane (eardrum) that becomes deformed by fluctuations in the far-field pressure component of sound. Pressure detector receivers are used to obtain directional information by comparing responses from receptors that are separated in space and time. Sound localization is thus achieved using ►interaural level difference (ILD) and ►interaural time difference (ITD) cues. The detection of substrate-borne vibrations is widespread in invertebrates, has many parallels with airborne sound reception, and has been widely studied in insects, spiders and other arthropods. Little is known of insect vibration receptor organs, but the best known is the Subgenual Organ (Fig. 1c).

This essay will first discuss the ►chordotonal organ – the main type of acoustic sensillum innervating insect ears. We will then review the different types of acoustic receptors, with a concentration on tympanal organs but also including particle displacement and substrate vibration receptors.

### Chordotonal Organs

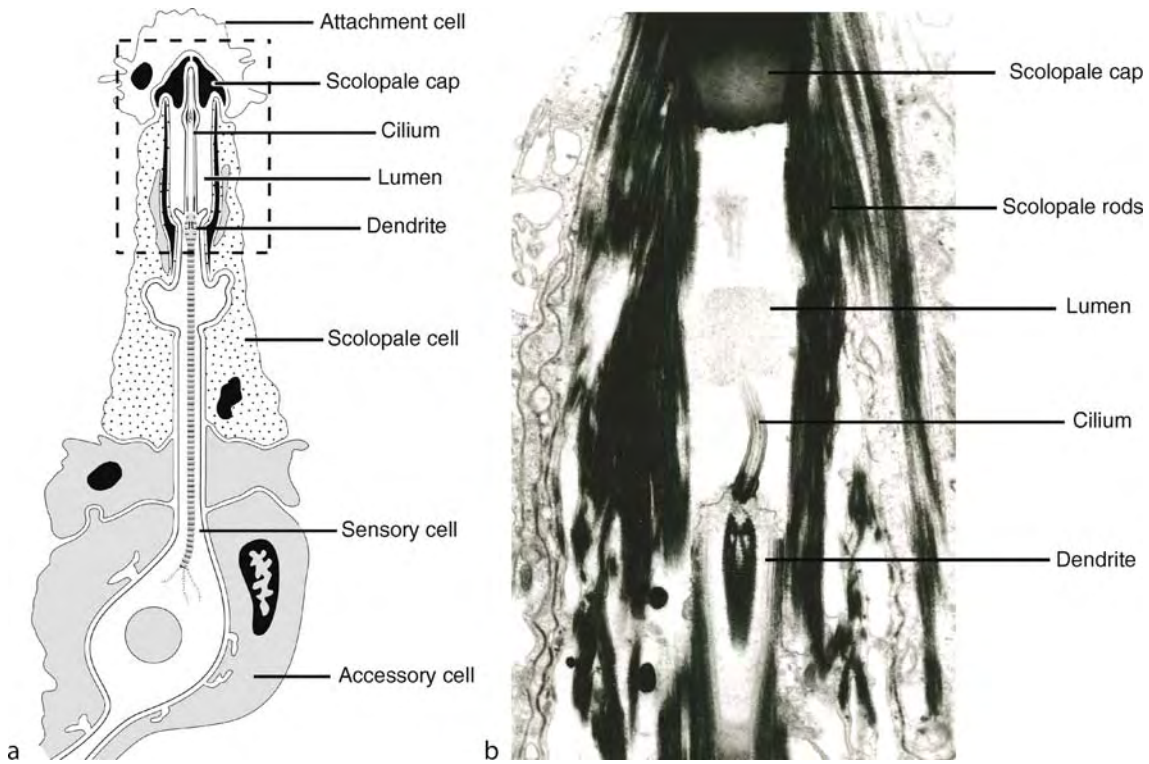
Insect auditory sensilla are derived from more generalized mechanosensory structures consisting of sensory cells, accessory cells, and cuticular structures [4]. The sensory cell is usually a ►bipolar neuron with a dendrite that becomes modified in its outer (distal) segment to contain a cilium constructed of microtubules – the ciliary dendrite that connects to the external cuticle. Accessory cells envelop and provide mechanical and nutritive support to the sensory neuron. Cuticular structures couple the point of mechanical stimulation, either directly or indirectly, to the sensory ciliary dendrite and aid in mechanoelectrical transduction.



**Invertebrate Ears and Hearing. Figure 1** Insects possess a diverse array of acoustic sensilla that detect a broad range of sounds and vibrations. (a) Trichoid Sensilla. Some caterpillars use long hairs (*arrow*) to detect near-field acoustic signals produced by flying parasitoid wasps. A bipolar sensory cell responds to deflections of the hair shaft. (Lepidoptera, Noctuidae) to particle movement in a sound field. *J Comp Physiol* 99:79–87, and [4], respectively.] (b). Johnston's Organ. Other insects, including many flies, detect near-field sounds of conspecifics with their antennae. Flight sounds cause the antennal flagellum (*black arrow*) to vibrate, stimulating chordotonal organs in the Johnston's organ located at the base of the antenna (*gray arrow*). A cross section of the antennal base shows that the Johnston's organ is comprised of thousands of scolopidia. [Photograph courtesy of D. Huber. Micrograph adapted from Göpfert MC, Robert D (2001) Active auditory mechanics in mosquitoes. *Proc R Soc Lond B* 268:333–339.] (c). Subgenual Organ. Many insects communicate using solid borne vibrations. The best-studied receptor of seismic signals in insects is the subgenual organ, illustrated here from the leg of a green lacewing (*arrow*). The chordotonal organ connects via attachment cells to a septum, and vibrations of the leg hemolymph result in stretching and stimulation of the constituent scolopidia. [Lacewing drawing courtesy C. Henry. Subgenual organ schematic redrawn with permission from Devetak D, Pabst MA (1994) Structure of the subgenual organ in the green lacewing, *Chrysoperla carnea*. *Tiss Cell* 26:249–257.] (d). Tympanal Organ. In noctuid moths, the ears are located on the posterior metathorax (*arrow*). Schematic drawing of the moth ear illustrates how the simple chordotonal organ, with only two sensory neurons, attaches to the tympanal membrane. [Redrawn with permission from Treat AE, Roeder KD (1959) A nervous element of unknown function in the tympanal organs of moths. *J Insect Physiol* 3:262–270.]

The most common auditory sensillum is the chordotonal organ (Fig. 2). Chordotonal organs are proprioceptive stretch receptors in crustaceans and insects [1,3]. Individual mechanosensory units within chordotonal organs are called scolopidia. Scolopidia consist of a linear chain of four cell types. (i) One or more bipolar neurons, each with a dendrite containing a modified $9 \times 2 + 0$ cilium. At present, the function of the cilium is unknown; however, it may act to mechanically support the dendrite and/or it may aid in the transfer of vibrational energy to the stimulus transduction region of the sensory neuron. (ii) A scolopale cell that forms a lumen around the dendritic cilium, and inserts distally into the extracellular scolopale cap (Fig. 2).

Within the cytoplasm of the scolopale cell, adjacent to the lumen, are the scolopale rods, which are bands of electron dense material composed of longitudinally oriented microtubules surrounded by actin filaments. The scolopale rods likely support and limit lateral movements of the dendritic cilium, thus providing a mechanism for restricting sensillum responses to specific locations or axes of mechanical stimulation. Scolopale cells are also thought to selectively transport ions into the space surrounding the dendrite, thus establishing an electrical potential difference between the lumen and the dendritic cytoplasm, which serves as the ionic basis for action potential generation during stimulus transduction. (iii) Attachment cells connect the scolopale cell to the external cuticle (or provide an internal anchor point for inverted scolopidia). In addition to providing mechanical support, they are likely important for transferring mechanical energy to the spike generation region of the neuron. (iv) Glial (accessory) cells envelop and provide nutritive and mechanical support to the sensory soma. Despite tremendous diversity in their form and function, all insect ears that respond to the pressure component of sound are innervated with chordotonal organs that have Type 1, monodynal, mononematic scolopidia (for definitions, see [1,9].



**Invertebrate Ears and Hearing. Figure 2** Chordotonal Organ ultrastructure. Chordotonal organs are comprised of individual sensory units called scolopidia. (a). ## Acoustic Receptive Organs

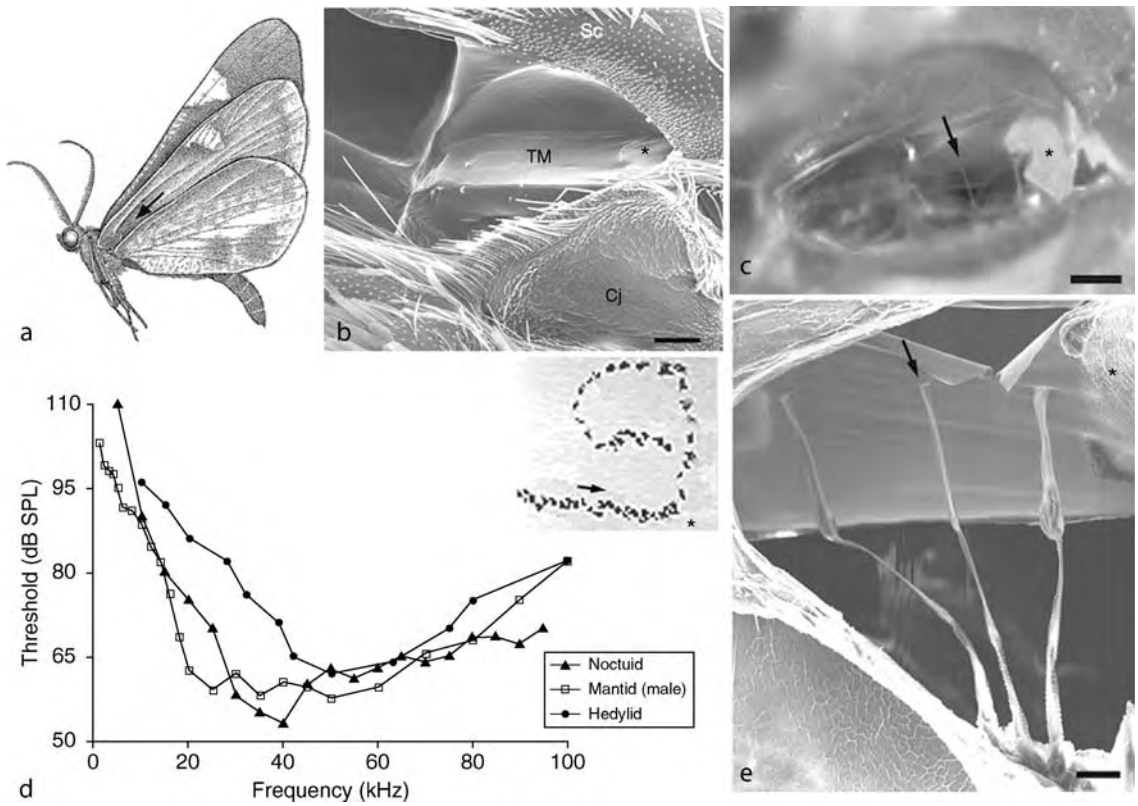
Four main types of acoustic receptive organs have been described for insects: Trichoid Sensilla, Johnston's Organ, Subgenual Organs, and Tympanal Organs [8,9].

1. *Trichoid (filiform) sensilla* (Fig. 1a) are hair-like cuticular projections specialized for the detection of near-field, low frequency sounds at close distances. The hair rests loosely in an epithelial socket and is innervated at its base by one or more sensory afferents that are bathed in a receptor lymph of special ionic composition. The neurons become depolarized in response to lever-like deflections of the hair shaft. Some caterpillars use trichoid sensilla to detect faint air currents caused by the wing beats of hymenopteran predators and parasitoids. Filiform hairs on the cerci of many insects, such as crickets and cockroaches, are used to detect air particle oscillations that are generated by predatory strikes and/or the wing movements of singing conspecifics.
2. *Johnston's organs* (Fig. 1b) are chordotonal sensory organs associated with the second antennal segment of insects. In some groups, including Diptera and Hymenoptera, the Johnston's organ is known to function in the detection of airborne sound [3]. The flagellar portion of the antenna oscillates in response to low frequency (near-field) sounds. The vibrations are then transmitted to mechanosensory scolopidia located at the base (pediculus) of the antenna. Many species of Diptera (e.g., mosquito) and Hymenoptera (e.g., honeybee) use the Johnston's organ to detect air currents produced by the wing beats of flying conspecifics, usually members of the opposite sex. The Johnston's organ is thought to be a diagnostic character for insects.
3. *Subgenual organs* (Fig. 1c) are chordotonal sensory organs located on the legs (proximal tibia) of most insects [1]. Substrate vibrations are thought to provide an adequate stimulus by setting into motion the fluid (hemolymph) within the leg, which in turn vibrates a septum to which the scolopidia are attached. Because subgenual organs are exquisitely sensitive to small-amplitude vibrations, they can effectively operate over long distances. Many terrestrial insects communicate with substrate vibrations, and the subgenual organ is thought to be the main vibrational receptor in adult insects. At present, little is known about how larval insects detect vibrations despite the widespread use of this modality by juvenile insects in a variety of taxa.
4. *Tympanal organs* (Figs. 1d, 3 and 4) are specialized for detecting the pressure (far-field) component of sound at relatively long distances and over a broad range of frequencies and amplitudes. Although anatomically and functionally diverse across taxa, insect tympanal organs are composed of three units: a tympanal membrane, a tracheal air space, and a chordotonal sensory organ. The tympanal membrane is a thinned region of cuticle that vibrates in response to changes in pressure between the external and internal sides of the membrane; the membrane vibrates most efficiently when the acoustic impedance of the sound medium is similar (matched) on the front and back sides. Insects obtain this impedance matching by modifying their internal, tubular tracheal (breathing) system to create an air space directly behind the membrane. The chordotonal organ is attached, either directly or indirectly, to the internal surface of the tympanal membrane. Oscillations of the membrane stretch the scolopidia. Longitudinal deformations of the sensory dendrite are thought to open membrane channels, resulting in a change of ion conductance, current flow, a change in receptor potential and the consequent generation of an action potential. The threshold of displacement for receptor activation can be as small as 1–10 nm [2]. Exact details of the spike generation mechanism are still unclear.

Most insects that detect acoustic far-field sounds have a pair of tympanal membranes, and a few species have multiple paired membranes. Across taxa, the most common placement for the pair is on either side of the thorax or abdomen. This is typically the widest body region and is best suited for generating maximal interaural level difference (ILD) and interaural time difference (ITD) cues for sound localization [6,10]. ILD cues are generated by sound diffraction, which varies as a function of frequency (wavelength) relative to the size of the diffracting body. ITD cues vary with distance (arrival time or phase) between the two ears. Many insects show excellent directional hearing while flying or walking. Peripheral (tympanal organ) mechanisms of signal reception can be highly selective for sound direction.

Insect auditory afferents share many physiological characteristics with vertebrate receptors. For example, variation in the number, rate and timing of action potentials is the basis of information coding by the CNS [5]. Most auditory afferents fire tonically or phasitonically with an intensity-dependent change in spike rate and latency, and show spike adaptation to prolonged or repeated stimulus presentations. Receptor populations also vary in their absolute sensitivity to sound amplitude (range fractionation). In most cases where receptors are tuned to different frequencies, there is clear anatomical variation in scolopidia size and/or the mechanics of attachment to the point of stimulation, although the possibility that receptors with variable tuning also differ in their intrinsic cellular properties has not been eliminated. While both receptors and interneurons show a high degree of temporal pattern copying to the amplitude envelope of the stimulus, owing to the



**Invertebrate Ears and Hearing. Figure 3** Tympanal ears used to detect the ultrasonic echolocation calls of predatory bats have evolved independently in several insect orders. (a). This nocturnal butterfly, belonging to the superfamily Hedyloidea, possesses a tympanal ear at the base of its forewing (*arrow*). (b). Scanning electron micrograph of the tympanal cavity, where the tympanal membrane (TM) resides. Modifications of the subcostal wing vein form a protective covering for the delicate tympanum and a canal that directs sound toward the ear. relatively high frequencies at which many species hear, insect auditory neurons typically do not phase lock to the fine waveform structure of the stimulus.

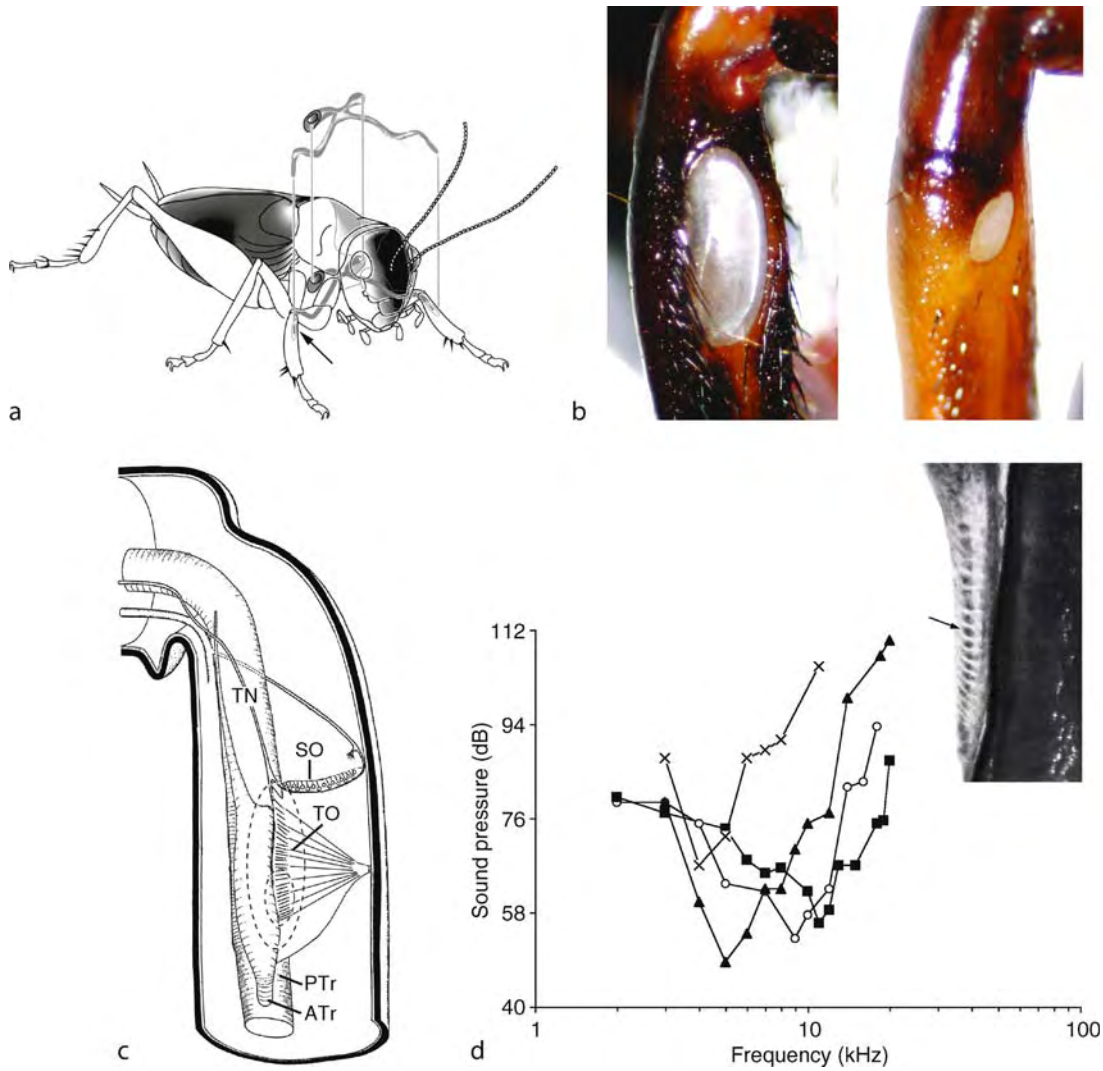
As in vertebrates, auditory behavior arises from serial and parallel central processing mechanisms [5]. Auditory afferents project to the ipsilateral auditory ►neuropile in the CNS where they synapse with interneurons (both intra- and interganglionic) that integrate with motoneurons. Central auditory neurons receive both excitatory (EPSP) and inhibitory post-synaptic potentials (IPSP) that vary in their strength, duration and latency. In some species a corollary discharge (efference copy) is used for processing self-generated sounds [7]. Central auditory neurons have responses that are tuned to stimulus frequency, amplitude, direction, or timing. Spectral tuning curves of interneurons are sharpened by frequency-dependent lateral inhibition. Extraction of directional information is achieved by integrating receptor spikes



**Invertebrate Ears and Hearing. Figure 4** Many insects use tympanal hearing organs for localizing and communicating with conspecifics. (a). Crickets use a pressure-difference receiver mechanism to localize sounds with wavelengths larger than the spatial separation of their ears, which are located on the proximal tibia of the forelegs (*arrow*). An H-shaped tracheal system (illustrated as floating above the cricket's body) internally connects sound inputs from both tympanal ears and from the acoustic spiracles located on opposite sides of the thorax. binaurally and is enhanced by reciprocal contralateral inhibition. A similar mechanism of mutual inhibition for contrast enhancement can also be used to extract stimulus amplitude or temporal pattern information.

## Diversity of Insect Ears

Tympanal hearing organs have arisen repeatedly in insects. To date, the count stands at 20 independent evolutions. Depending on the taxa, insect ears can be

found all over the external body surface, including the thorax, abdomen, wings, legs, and mouthparts. The organs may be highly visible or cryptically located, and in some cases have become internalized. It is now commonly believed that the present diversity of insect auditory organs is a result of their evolving from pre-existing chordotonal sensilla that primarily served a proprioceptive or low-frequency vibratory detection function at that body location. The evolution of tympanal membranes, through a progressive thinning of appropriate regions of the exoskeleton, increased the organ's sensitivity to stimulus amplitude and frequency. The ubiquity of such mechanosensors near the exoskeleton surface provides many potential locations for the evolution of ears.

The number of scolopidia, and thus sensory neurons per hearing organ, varies widely across taxa, ranging from 1–4 in moths, 2 in water boatman, 3–8 in beetles, 5–20 in lacewings, 20–75 in crickets and katydids, 60–100 in locusts, 100+ in flies, 600–2,000 in cicadas, and 2,000+ in some primitive grasshoppers. No clear relationship exists between the number of sensory afferents and the sensitivity of the tympanal organ to stimulus amplitude, frequency or phase (timing). Ears tend to be simplest in those groups that use hearing primarily for predator detection, and more complex in those groups that use sound for intraspecific communication.

Many of the simplest tympanal organs are the broadband pressure detecting ears found in moths and butterflies (Lepidoptera), lacewings (Neuroptera), beetles (Coleoptera) and mantids (Dictyoptera). Hearing in these groups has evolved primarily in the context of predator detection. More specifically, their ears function mainly to detect the ultrasonic echolocation signals of aerial insectivorous bats, and hearing in many species has been shown to mediate evasive flight maneuvers (Fig. 3).

Lepidopteran ears are often found on the thorax or abdomen, although a few species have evolved ears on their wings and mouthparts. The ears of lacewings are located in the radial vein at the base of each forewing. In beetles, ears have recently been described on both the abdomen and on the prothorax just behind the neck region. The ears of mantids are hidden within a groove along the ventral midline between the metathoracic legs. In many mantids, hearing is sexually dimorphic because the females are flightless and therefore are not subject to predation by aerial insectivorous bats; male mantids fly and thus their ears are better developed anatomically and have a higher sensitivity. A minority of lepidopterans use sound production and hearing for intraspecific communication. There is no behavioral or physiological evidence for frequency discrimination or well-developed directional hearing in these insect groups.

In two groups of Hemiptera the sense of hearing primarily serves intraspecific communication. In both groups the ears are normally sharply tuned to the sounds of calling conspecifics. With only two sensory cells, the mesothoracic ears of water boatman (Heteroptera) may appear to be simple, but are functionally complex. Each tympanal membrane connects to a clubbed cuticular process that alters the membrane resonance frequency and imposes a left–right hearing asymmetry. The membrane can vibrate effectively underwater because it contacts an air bubble that becomes trapped by the waxy integument when the bug submerges; the bubble oscillates in response to the stridulatory calls of conspecifics. During a dive, the volume of air depletes due to respiration, and this increases its resonance frequency. The ears of terrestrial cicadas (Homoptera) are also structurally complex. The tympanal membranes are located ventrally in a recess on the second abdominal segment; the chordotonal organ is contained in a rigid capsule connected to the membrane. Depending on the species, the organs may have thousands of scolopidia. The sense of hearing is often sexually dimorphic (commonly more sensitive in males). Male cicadas emit very loud songs to attract females from far distances. To avoid self-deafening while singing, the males fold (relax) their tympanal membranes and this dampens the dynamic range of their auditory sensitivity by >20 dB.

Invertebrate hearing is probably best understood in the Orthoptera, where hearing serves the functions of mate attraction, courtship display, territorial spacing, aggression, prey detection, and defense from predators and parasitoids. Within this group there is ample behavioral and physiological evidence for frequency discrimination and directional hearing [6]. Locusts (Caelifera) possess a tympanal ear on either side of the first abdominal segment, and the modes of vibration of the tympanum systematically vary with sound frequency. Frequency discrimination is achieved by having four groups of scolopidia attached to the membrane at different positions that correspond to locations of vibrational maxima at different frequencies. Crickets and katydids (Ensifera) have a pair of tympanal membranes (anterior and posterior) on the proximal tibia of each foreleg (Fig. 4a, b), although the anterior membrane is not sensitive in crickets. A tracheal chamber apposed to the interior tympanal surface forms an air space behind each membrane, thus providing impedance matching (Fig. 4c). The tracheal chamber is continuous with a complex system of acoustic tracheae that influence hearing sensitivity, frequency tuning and directionality (Fig. 4a). As in vertebrates, frequency discrimination is achieved by having receptors that are tuned to different frequencies (tonotopy). The chordotonal organ consists of a linear array of scolopidia that attach indirectly to the tympanal membrane. Although the mechanism of receptor tuning is unresolved, a mechanical basis is likely because scolopidia gradually taper in size within the organ; proximal cells are tuned to lower frequencies whereas distal cells are tuned

to higher frequencies (Fig. 4c, d). In katydids, the peripheral tonotopy is maintained with the CNS by the differential projection of receptors to interneurons within the auditory neuropile.

Some parasitoid flies (Diptera) have evolved tympanal hearing organs on the thorax just behind the head. Hearing is also sexually dimorphic in this group – poorly developed in males, whereas females use their ears to localize the songs of acoustic Orthoptera or Homoptera, and then deposit larvae on the host. Directional hearing in some female Diptera is among the most accurate in the animal kingdom. Although each ear has a single chordotonal organ connected to the inner surface of the tympanal membrane via an apodeme, the two membranes share a common tracheal air space and are also mechanically coupled. This has resulted in a completely novel and remarkably accurate sense of directional hearing [5].

# Invertebrates

►Evolution of the Vestibular System

# Inverted Pendulum

## Definition

A biomechanical model of the body, where the center of mass of the body is situated at the upper end of a rigid link that pivots about a joint at the base (i.e. the ankle).

In a multi-link inverted pendulum, the different segments of the body (e.g. foot, shank, thigh, trunk, etc.) are represented by separate links (each with its own mass and rotational inertia) that are interconnected at the joints (ankle, knee, hip, etc.).

►Center of Mass (CoM)
►Postural Strategies

# Involuntary Memory

Unconscious spontaneous memory.

►The Proust Effect

# Inwardly Rectifying $K^+$ Channel Family

## Definition

There are seven subfamilies of the inwardly rectifying potassium (Kir) channel family (Kir1.0, Kir2.0, Kir3.0, Kir4.0, Kir5.0, Kir6.0, Kir7.0) with two transmembrane domains, M1 and M2, linked by a pore loop (the H5 region) which is critical for K+ ion selectivity. The asparagine residue in M2 is critical for the rectification property.

►Neuronal Potassium Channels

# Ion Channel

## Definition

Ion channels are transmembrane proteins that have gated pores for the selective passage of ions across cell

membranes. Ion channels can be classified into those with and without a re-entrant pore-loop. Voltage-gated channels ($K^+$, $Ca^{2+}$, $Na^+$) and glutamate metabotropic receptors all bear an extracellular, re-entrant loop, that provides a highly selective aqueous pore for particular ions. All pore-loop channels are structural derivatives of inward rectifying potassium ($K^+$) channels. Other ion channels outside this class do not have an obvious evolutionary relationship. These include the Cys-loop receptor channels (AchR, GABA, GlyR, 5HT), connexins, M2, chloride channels, intracellular calcium release channels (IP3, RYR) and CFTR. Ion channels can also be classified as voltage-gating or ligand-gating.

Ion channel pore opening are usually controlled by gating mechanisms responding to voltage-changes, allosteric coupling of ligands to binding domains, as well as pH, stretch and temperature. Functional ion channels often require accessory subunits.

## Ion Channel Conductance

### Definition

Ion channel conductance is a measure of the ion flux through an ion channel at a particular voltage. Conductances are measured in the units of Siemens (S) and the scale of individual channel conductances are in the pico-Siemens range. Ion channel conductance is a dependent on the ion channel permeability and the concentration of permeant ion.

## Ion Channel Development

Martha M. Bosma
Department of Biology, University of Washington, Seattle, WA, USA

### Definition

Ion channel development encompasses the expression of ion channels, including transcriptional regulation, processing, localization and modulation, and the incorporation of those ion channels into the membrane excitability parameters regulating neuronal circuits and networks.

This entry will concentrate on membrane properties due to the expression of ion channels in immature excitable cells, how those properties can modify the expression of both the immature and mature ion channels in an activity-dependent manner, and the changes that are effected in ion channel expression as consequences of maturation and ion channel development.

### Characteristics

During the development of circuits in the nervous system, patterns of immature physiological properties are often created which are distinct from those in the mature animal. The function of immature behavior is crucial for the formation of the nervous system, while mature expression of ion channels is required to function within a developed nervous system. In many cases, however, it has been shown that the unique immature pattern is required for the appropriate mature circuit formation. A prototypical example of this interaction between immature and mature systems is found in the ►retina, in which waves of spontaneous activity (SA; not initiated by sensory input) that propagate across retinal domains are required to direct synaptic formation at the synapses of the ►retinal ganglion cells in the ►lateral geniculate nucleus (LGN) or ►tectum. Disruption of these waves, or manipulation of the extent or frequency of the waves, alters the mapping of the retina in ►retinotopic positions within the more central structures. This spontaneous activity is expressed for a limited time period, which differs between species, but in almost every case spontaneous activity ceases at the time of eye opening. In the mature retina, spontaneous activity is not present, and the output of retinal ganglion cells is determined by visual input. SA has been shown to occur in many brain regions, and can regulate diverse developmental events, including neurogenesis, migration, pathfinding and synaptic connectivity [1].

We will consider the modulation and development of three very general categories of ion channels, which determine spontaneous activity using one or two examples within each category: ►voltage-gated ion channels, ligand-(transmitter-) gated ion channels, and ►resting channels. In addition, discrete neuronal populations within brain regions, pacemaker or driver regions that initiate SA, will also be explored. It must be emphasized that although the topics are being addressed in a reductionist fashion, it is more than likely that a combination of several events from each ion channel category will actually create SA in any one neuronal population. References to examples from the older literature can be found in [1,2].

### Voltage-gated Ion Channels

#### *Inner Hair Cells*

►Inner hair cells (IHC) of the ►cochlea are non-neuronal sensory cells whose SA and synaptic output onto postsynaptic brainstem targets is required for the

I

survival of those targets. SA in IHC is recorded between approximately embryonic (E)18 (almost birth) to postnatal (P)12 (close to onset of hearing) in mouse, generated by the increased expression of $Ca^{2+}$ and $Na^{+}$ channels (►Calcium channels – an overiew; Sodium channels), which are down-regulated at the onset of hearing, terminating SA ($Na^{+}$ channels are down-regulated completely). The SA is also terminated by the appearance of a $Ca^{2+}$-stimulated $K^{+}$ current (►Neuronal potassium channels). The expression of this latter current is itself regulated by the SA, which precedes its appearance. Thus, SA, presumably functioning to drive specific genetic programs and to ensure survival of downstream brainstem nuclei, is self-terminating. This cessation of SA occurs at the same point in time when conventional sensory-driven use of the IHC cells begins. Thus, the immature state is quite different (spontaneous ►action potential generation) than the mature, non-action potential-driven transduction of sensory input, and this difference is caused by coordinated developmental up- and down-regulation of voltage-gated channels.

### *Ascidian Muscle*

In developing ascidian muscle, SA occurs during a 6-h window of time just after exit from the cell cycle. This activity is triggered by the temporary disappearance of an ►inwardly rectifying $K^{+}$ current ($I_{IR}$), which represents the resting conductance of these cells (see III, Resting Conductances, below). Activity is terminated by the reappearance of this resting current and by the appearance of an outward ►delayed rectifier $K^{+}$ current that activates much faster than the one present earlier in development. This latter event shortens the duration of the action potential, which would be expected to reduce $Ca^{2+}$ entry. This would be problematic for muscle cells that depend on $Ca^{2+}$ entry for contraction. To solve this problem, a large increase in $Ca^{2+}$ current density occurs at the same time as the rapidly activating delayed $K^{+}$ current appears. As in other cells, some of the developmental changes in ion channels in ascidian muscle – in this case the appearance of a rapidly activating outward $K^{+}$ current – depend on the SA that they help to terminate.

### *Xenopus Neurons*

In *Xenopus* spinal neurons, the action potential shortens by 2–10 folds over a time period of 1–2 days, due primarily to an increase in current density and activation kinetics of a delayed rectifier $K^{+}$ current. The long-duration immature action potential, which admits more $Ca^{2+}$ than the mature event, is required for the increase in $K^{+}$ current, as artificially shortening it by mis-expressing a related $K^{+}$ current during the immature time period alters the normal developmental changes.

## Ligand-gated Channels

In the examples given above, isolated cells, or cells in relatively small populations, are examined for individual SA events. In the present examples, large populations of developing neurons are undergoing SA, and often synchronized with other neurons around them. Thus, an additional component of SA is synchronization within a large population of developing networks.

### *Hippocampus*

SA in the ►hippocampus is recorded around birth and into the first postnatal week. Waves of spontaneous activity, known as ►Giant Depolarizing Potentials (GDP), occur within the entire neuronal population. Each GDP consists of bursts of action potentials associated with large synaptic depolarizations, and is based upon both GABAergic and glutamatergic components. Ligand binding to ►$GABA_A$ receptors at this developmental stage activates a conductance that is excitatory, as the reversal potential for $Cl^{-}$ ($E_{Cl}$) is positive to threshold in many developing neurons. This paradoxical response is caused by the slow developmental appearance of $Cl^{-}$ pumps (e.g. KCC2) that are not yet expressed; thus intracellar $Cl^{-}$ is high, and $E_{Cl}$ is set at a relatively depolarized potential (►Chloride channels and transporters; ►Ion transport). With the expression of KCC2 over developmental time, $E_{Cl}$ gradually shifts more negative, and the depolarizing "drive" that allows other inputs to bring cells to threshold is absent. Thus, SA termination is caused by decreased reversal potential for $Cl^{-}$. GDP activation in the hippocampus also includes a component of ►glutamate receptor activation, including ►NMDA receptors and ►AMPA receptors.

### *Cortex*

In the cerebral cortex, widespread spontaneous activity occurs during the 3–4 days around birth. Although this activity, unlike that in hippocampus, does not require $GABA_A$ excitation, it does require that $GABA_A$ action not be inhibitory, and thus that $E_{Cl}$ be above threshold. Two events terminate cortical spontaneous activity: the emergence of strong $GABA_A$ inhibition (as $E_{Cl}$ shifts to more negative potentials), and a decline in the participation of NMDA receptors in spontaneous bursts. Both of these events occur in the first postnatal week, and both are triggered by the spontaneous activity itself. Thus, as in other preparations, spontaneous activity is at least in part self-terminating [3,4].

## Resting Conductances

Developmentally regulated conductances that open at or near rest, or that provide a tonic inward current, would be crucial in the ability to both support SA, and to be modulated by developmental events that might then alter SA in that cell. Among others, classes of ion

channels that are known to regulate resting conductance developmentally are the $K^+$ inward rectifier ($I_{IR}$), an inwardly rectifying ►non-specific cation channel ($I_H$), and ►gap junction channels. $I_{IR}$ and $I_H$ are particularly appropriate to be involved in changes in excitability, as they are both activated near the ►resting membrane potential (►Membrane potential – basics), and set the resting conductance of the membrane [5]. With excitation, both channels close, increasing the resistance of the neuron and allowing depolarizing inputs to be amplified. In addition, $I_H$ is excitatory when the cell is hyperpolarized, as it allows $Na^+$ entry.

In mammalian muscle cells, which express $I_{IR}$ in the adult, innervation upregulates expression of $I_{IR}$ due to stabilization of the mRNA caused by increases in $[Ca^{2+}]_i$ generated by the activity of innervation, while denervation downregulates its expression. In ascidian muscle, $I_{IR}$ disappearance allows a window of SA that then triggers the re-appearance of both $I_{IR}$ and a voltage-gated IK to terminate the SA (also see section I above, Voltage-gated ion channels). In the hippocampus, the ability of hilar neurons to generate spontaneous activity (see also section IV below, Pacemakers) is dependent on the presence of $I_H$ in specific populations of neurons.

In gap junctional communication, ion channels called ►connexins pass both electrical signals and small molecules between cells in contact with each other, and are present in many developing neurons. In many cases, gap junctions disappear upon maturity. The role of gap junctions in development of SA is observed in the neocortex and hippocampus. In the cortex [6], discrete compartments of developing cells are coupled, and only some of those become uncoupled over postnatal time. In the hippocampus, the ►hilus acts as a pacemaker (see also section IV below, Pacemakers) and the neuronal elements within that pacemaker are electrically coupled. Gap junctions can act as a resting conductance that can be modulated with developmental events, changing the resistance of the cells and the effectiveness of inputs. In mammalian ►motor neurons, reduced gap junctional coupling by use of specific connexin knock-out transgenic animals [7] leads to a reduction in correlation of firing, and to premature synapse elimination. This suggests both an electrical and developmental role for gap junction communication during development.

## Pacemakers

In examples where large groups of neurons are able to participate in SA that is synchronized, the mechanism(s) initiating the SA have not been clear. In some cases, such as the spinal cord, network properties in which each neuron is an independent excitatory unit, able to modify neighbors which then in turn feed back onto itself, direct the rate and interval of SA events. This model requires mutual excitation between neurons, as well as post-activity depression, which is involved in directing the interval between events. However, in several systems, a discrete region of the tissue acts as a driver or pacemaker, and leads the tissue in SA participation.

### Hindbrain

An example of discrete pacemaker-driven SA is found in the hindbrain during early embryonic development in both mouse and chick. The hindbrain becomes the ►pons, ►medulla, and ►cerebellum, and is initially divided into distinct regions called rhombomeres, a fate-patterning system unique to the hindbrain. Each rhombomere encloses a group of progenitor cells and their resultant neurons that have a particular fate because of their initial position; at about E11.5 in the mouse embryo the rhombomere boundaries disappear. SA in individual labeled motor neurons derived from different rhombomeres, as measured by $[Ca^{2+}]_i$ recording, develops from very long (duration of minutes) events to shorter more frequent events between days E9.5–E11.0. Abruptly at E11.5, SA events between motor neurons, indeed between neurons encompassing the entire hindbrain, become highly synchronized, and remain synchronized until E13.5. Examination of the anatomical arrangement of SA revealed that midline neurons of the developing ►serotonergic raphe nuclei, found in former rhombomere 2, initiate all of the activity of the hindbrain, and propagate events in the rostral-caudal dimension along the midline, and to the lateral regions away from the midline. Separation of the raphe from lateral tissue obliterates SA in the lateral tissue, while maintaining it in the pacemaker raphe [8,9]. Thus, a small group of neurons within the tissue of the hindbrain are acting as a pacemaker. Although a distinct pacemaker region is now identified, it is clear that this only pushes the question of initiation of SA back one step: what causes the neurons within the pacemaker region to initiate activity?

Recent experiments using ►patch-clamp techniques have shown that serotonergic neurons in the initiation region are more highly coupled to one another than neurons in other regions. Neurobiotin (a marker that crosses through gap junction channels) in the pipette shows that anatomical coupling occurs within the initiation region at higher ratios than in other areas. In addition, application of low concentrations of $Ba^{2+}$, which blocks resting $K^+$ channels (most likely $I_{IR}$), has a larger effect on lateral neurons than on midline neurons, suggesting that midline (driver) neurons do not express a resting $K^+$ conductance that would tend to suppress their excitability.

### Hippocampus

In the hippocampus, evidence of an initiation region in the hilus is supported by separation experiments where

the hilus maintains activity, timing experiments showing that hilar events precede ►CA3 events, evidence for gap junctional coupling between hilar neurons, and possible pacemaker current expression in hilar neurons. However, there is other evidence, obtained in tissue slices with different orientations, that the ►septum may initiate activity within the hippocampus. Other experiments point to the ability of any isolated hippocampal region to initiate activity as evidence of network properties driving SA in the hippocampus.

### Conclusions

The expression of patterns of ion channels in immature excitable cells can determine whether they undergo SA. That SA can alter the developmental expression of both the original and the newly transcribed or synthesized channels that terminate SA, and pattern excitability as a mature cell. The ability to undergo SA may be present in individual cells, entire neuronal networks, or discrete pacemaker regions, but in each case may be part of a program to modify ion channel expression, and transform immature to mature physiological behavior.

## Ion Channel Modulation

### Definition

The process by which intracellular signaling cascades dynamically change the function of ion channels. For example, the phosphorylation of amino acid residues (e.g. tyrosine, serine) by protein kinases (e.g. PKA, PKC) has been shown to change the voltage gating behavior of certain ion channels. Modulation is thought to be an important part of the molecular basis for learning and memory in the nervous system.

►Sodium Channels

## Ion Channels from Development to Disease

Phuc H. Pham, Adriano Senatore, J. David Spafford

### Synonyms

Voltage-gated ion channels; Ligand-gated receptors; Pore-loop; Multimerization; Gating; Activation; Inactivation; Deactivation; Depolarization; Hyperpolarization; Selectivity

### Definition

►Ion channels serve as gate keepers to ion movement across cell membranes and mediate functions such as the excitation of nerve and muscle, control of hormone secretion, establishment and maintenance of ionic balance, sensory responses, cell proliferation and programmed cell death, and the capacity to learn and lay down memories [1]. Some 340 human genes encode ion channels and at least sixty ion channels have been linked to disease states [2]. Ion channelopathies, as they are termed, generally fall into either gain or loss of function phenotypes. The former is like a dam where control of the flood gates has been lost, as is the case with ion flow through voltage-gated sodium (Na) channels without inactivation gates to curb excitatory activity [3]. This clinically manifests as a hyper-active or seizure phenotype. In the opposite case, the flood gates never open, resulting in hypo-active or paralysis phenotypes caused by a decrease or loss of $Na^+$ flux [3]. The loss of function can be caused by impaired

membrane trafficking and expression of channels or weakened responsiveness of channels to voltage-changes [3]. The following text will provides a cursory review of the diverse subunit features of ion channel types and describe the typical ways that mutations can lead to altered channel activity.

## Characteristics

### Subunit Assembly and Selectivity

All ion channel genes encode pore-forming subunits that integrate into the lipid bilayer and contribute to aqueous-lined membrane pores. ►Pore-loop channels are modular derivatives of a minimal $K_{IR}$ structure composed of a re-entrant loop separating two single transmembrane segments (see Fig. 1); this design likely originated from a primordial ancestor structurally similar to the bacterial K (potassium) channel KcsA [4]. Crystallographic studies suggest that KcsA bears wide vestibules surrounding either side of a short and narrow selectivity filter [4]. The KcsA selectivity filter serves as more than a size delimiting barrier such as the sieve of an hourglass since $K^+$ ions but not smaller monovalent cations such as $Na^+$ ions permeate (by a 100–1,000-fold difference in permeability). As hydrated K ions pass through the channel, they must shed their water molecules to pass single file, in a rapid and intimate process along carbonyl oxygens of an invariant "GYG" backbone sequence lining the channel pore [4]. Other ions such as $Na^+$ do not possess a keylock fit, and thus are left stranded outside the gate with their hydration shells intact [4]. Voltage-gated calcium (Ca) channels exhibit similar selectivity against $Na^+$ ions (>1,000:1), but their strategy does not appear to involve backbone residues. Rather, an inner ring of four glutamate side chains face the pore to form a $Ca^{2+}$ attracting, chelator-like filter [5]. Na channels possess one positive and one neutral side chain replacing two of the four glutamate residues of Ca channels resulting in an asymmetrical pore filter that is less discriminatory against rival cations (permeability of one $Ca^{2+}$ for every ten $Na^+$ ions) [1].

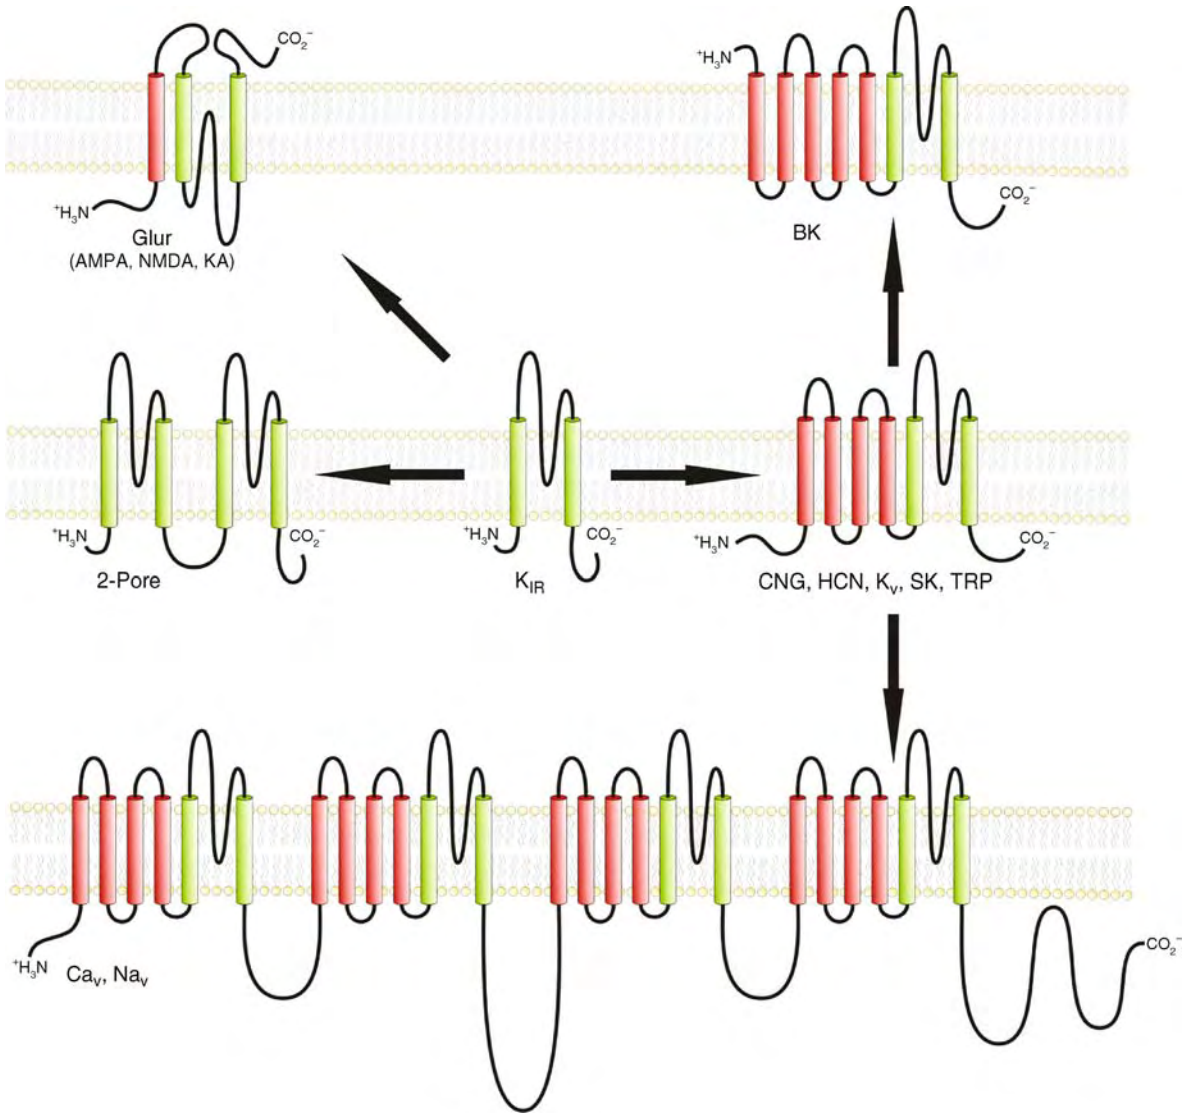
Ion channels outside of the pore-loop class do not possess the highly discriminatory re-entrant pore loop and are more diverse in structure. The ►chloride (ClC) channels, for example, lack the hydration vestibules of the pore loop K, Ca and Na channels, and instead possess long and narrow pores which serve as molecular sieves to discriminate anions of different sizes [6]. ClC channels will equally pass many monovalent anions of similar size (e.g. Br-, I-, $NO_3^-$), but the only relevant anions the ClC channel will encounter in biological terms, will be larger in size such as $PO_4^{2-}$ and $SO_4^{2-}$ [6]. ClC channels, like the chloride-selective receptor channels of the Cys-loop family (GABA and GlyR) (see ►Cys-loop receptors) attract anions and repulse cations by strategic positioning of rings of positively-charged residues within the pore [7]. In opposite fashion, the non-pore-loop cation selective channels such as the acetylcholine (AchR) or 5-HT receptors of the Cys-loop family, have electro-attracting negative charges which prevent anion permeation [7].

### Subunit Assembly and Selectivity in Disease

Subunit assembly is a significant factor which may attenuate or enhance the effectiveness of ion channel mutations. While Na and Ca channel genes form monomers, K channels form homo-tetramers (all four subunits are created from the same gene) [2]. Additional functional diversity is created upon heterotetramerization (multiple gene isoforms or different alleles of the same gene contribute subunits to form one channel). For example, individuals harboring one wild type and one mutated allele for a K channel gene may produce functionally compromised homo-tetramers comprised entirely of the mutated subunits, or phenotypic effects may be masked by hetero-tetramers or homo-tetramers of the wild type subunits [2]. It is also possible for mutant subunits within a hetero-tetrameric channel to have dominant-negative effects (mutation in one of four subunits prevents channel function completely), to have no effect (only one working wild type subunit is required for function), or to bear a dosage-dependent effect (mutation in one of four subunits alters channel function up to 25% of maximum).

Neonatal diabetes is a disease where the severity of the phenotype is related to the relative influence of the mutation on $K_{ATP}$ channel function [8]. Normally, ATP is bound to $K_{ATP}$ channels preventing their ion conductances which serves to repolarize the membrane potential and inhibit insulin secretion in pancreatic beta cells [8]. Therefore, mutations that reduce or eliminate ATP sensitivity of the $K_{ATP}$ channel cause neonatal diabetes [8]. Each channel subunit bears an ATP binding site, and the activity of only one subunit is enough to close the $K_{ATP}$ channel [8]. It would be rare for all $K_{ATP}$ channel subunits in a heteromultimer to bear a mutant and thus the disease phenotype affecting ATP binding is less severe. The more severe neonatal diabetes with extra-pancreatic effects is in those mutants that affect the opening of $K_{ATP}$ channel gates directly downstream of ATP binding [8]. These dominant-negative mutations bear consequences to channel gating even if only one of four subunits bears the mutation.

Similar to the K channels, multimerization of (Multimerization (of Ion Channels)) receptor-operated channel subunits creates diversity and determines the severity of subunit mutation. Such channels include the heteropentameric ligand-gated Cys-loop channel family (Ach, GABA, Glycine), the hetero-tetrameric



**Ion Channels from Development to Disease. Figure 1** Pore-loop channels are modular derivatives of the minimal $K_{IR}$ structure composed of a re-entrant loop separating two single transmembrane segments. Addition of three transmembrane segments and a fourth harboring positively-charged, voltage-sensing residues to the N-terminus of $K_{IR}$ converts it into a voltage-gated K channel. One round of duplication of $K_{IR}$ produces a tandem pore K channel. Two rounds of duplication of a voltage-gated K channel results in an overall structure that resembles voltage-gated Ca and Na channels. Other add-ons provide binding capacity such as ATP (KATP channels), calmodulin (Ca channels), $Ca^{2+}$ (BK channels) or cyclic nucleotides (cyclic nucleotide-gated (CNG) channels). Ligand-gated receptor channels such as glutamate receptors (GluR) are similarly composed of modular units. GluR subunits appear to be derived from an inverted $K_{IR}$ channel to which sequential bacterial gene modules have been appended to the amino terminus including a modulatory, periplasmic binding protein domain and a ligand-binding domain from G protein coupled metabotropic receptors.

GluR receptors, and the cyclic nucleotide-gated and $K_{ATP}$ channels [2]. AchR are comprised of distinct subunits resulting in several configurations: homopentameric $\alpha_7$ or heteropentameric $\alpha_2$ and $\beta_4$ channel complexes in neurons, and α, α, β, ε/γ and δ channel complexes at the neuromuscular junction [7]. AchR subunit mutations are the most common cause of congenital myasthenic syndrome (CMS). In this severe motor endplate disease, the deficit is in expression of the ε-subunit, which is compensated by the up-regulation of a fetal γ isoform [7]. Likely, the absence of a replacement isoform for the β and δ subunits proves lethal in individuals with loss of function mutations in either gene [7].

Another source of mutational phenotype in ►ligand-gated channels is in the high affinity ligand binding sites. Opening of a receptor-operated channel gate requires large conformational changes, since the gate can be considerably distant from the ligand-binding site [7]. Most often ligand-binding sites span the interface between adjacent subunits, facilitating large-scale structural movements [7]. For most ligand-gated channels, the switch for channel gating is ligand dependent, and requires the cooperativity of multiple ligands bound at once to induce channel opening (e.g. 2 for AchR) [7]. There is also rapid channel closure if multiple occupancy is lost. Ligand-gated channels are thus highly susceptible to mutations that alter ligand affinity and function. Mutations in different participating subunits of the AchR hetero-pentamer (either α, δ or ε) can lead to CMS, either from a gain of function phenotype (increasing AchR binding and occupancy time) or loss of function phenotype (reduced AchR binding and occupancy time) [7]. Interestingly, glutamate is the ubiquitous excitatory transmitter in the central nervous system and yet there are no human diseases associated with GluR subunits [9].

## Channel Gating

Besides ligand occupancy, ion channels gate in response to changes in voltage, pH, stretch and temperature [1]. The classical mechanism is the voltage-gate of K, Ca, Na channels requires dipole-conferring, charged residues within the fourth segment of each domain which rotate outwards in response to membrane ►depolarization [1]. S4 movements are modeled to spread open the pore at the C-terminal end of the S6 segments [1]. After a few ms of opening, most of these channels stop conducting current even in the presence of stimulus and enter an inactivated state, where channels are refractory to opening until the membrane potential has reset to a negative or hyperpolarizing potential [1]. Rapid forms of inactivation involve a tethered N-terminal plug which occludes the pore of *Shaker*-type K channels, or a hinged lid bridging the III-IV linker of Na channels [1]. A slower form of inactivation involves noose-tightening of residues surrounding the outer mouth of voltage-gated channel pores [1]. After opening, ►voltage-gated channels (►Excitable cells) can bypass the inactivation state altogether and rapidly transition from an open to a closed state (known as ►deactivation) [1].

Gating of ClC channels is different and illustrates that movement of as few as one amino acid (instead of the more dramatic structural changes in voltage-gated channels) is all that can be required for some forms of gating [6]. Other channels lack voltage-gating completely, such as the inward-rectifying and two-pore K channels, which are constitutively open at negative voltages, and likely contribute to the resting potential [2].

## Channel Gating in Disease

Opening of K, Ca and Na channels is dependent on voltage changes, with opening probability increasing 10-fold for ~10 mV of depolarization [1]. Disease states can result from slight changes in the kinetics or voltage-dependence of gating. Slowing or inhibiting inactivation of Na channels causes persistence of the Na current; a similar phenotype is observed if channel activation is shifted to more hyperpolarizing potentials causing channels to open more readily [3]. Since Na channels are responsible for the upstroke of the ►action potential, the net result of such mutations is hyperexcitability and enhanced firing, which manifests as epilepsy (►Generalized epilepsy with febrile seizures plus (GEFS+)) in the brain or persistent contraction and stiffness in skeletal muscle (myotonia), or a pathological broadened ventricular action potential of the heart (LQT syndrome) [3]. Furthermore, patients with hyperkalemic periodic paralysis bear a persistent Na current (1–2% of total current) as a result of a $Na^+$ channel mutation which sustains skeletal muscle fiber depolarization [3]. Patients suffer from intermittent bouts of muscle paralysis from Na channels undergoing inactivation from prolonged openings. K channels repolarize the membrane, functioning counter to Na channel activity and extinguish membrane excitability. As expected, loss of function mutations of K channels result in a similar hyperexcitable phenotype as gain of function mutations in Na channel, such as epilepsy, muscle disorders or LQT syndrome [2].

## Roles of Supportive Proteins

Most ion channels have accessory subunits and are also components of larger supportive protein complexes which regulate the membrane localization, expression levels, and gating of channel subunits [2]. Mutations in these supportive proteins can be equivalent to loss of expression and sometimes altered gating of their associated ion channels. The following outlines some examples of this phenomenon: mutation of the protein rapsyn, which normally functions to cluster AchR subunits, can cause CMS; mutation of SUR1, a protein necessary for $K_{ATP}$ channel function, is associated with congenital hyperinsulinemia; mutation of the $\beta_1$ subunit of the SCN1A/SCN1B Na channels causes a similar form of epilepsy as mutation of the channels themselves (known as GEFS+); finally, the etiology of LQT syndrome in the heart can be caused by mutation of Na, Ca or K ion channels, but also can be caused by MiRP1 or MinK, which are accessory subunits for hERG and KCNQ1 channels, respectively or ankyrin-B, an ion channel anchoring protein [2,3,5,7–9].

I

## Role of Cell Background

Expected consequences of altered ion channel function can be anticipated readily from *in vitro* studies, but the expression patters of a mutated gene will influence how it manifests into a phenotype. For example, specific L-type Ca channel types are dedicated specialists of a particular tissue, such as $Ca_v1.1$ which is a key element in excitation-contraction coupling in skeletal muscle, and $Ca_v1.4$ which is essential for transducing visual stimuli in the retina [5]. Their loss of function causes predictable localized deficits, such as a muscle disorder (hypokalemic periodic paralysis) or retinal disease (incomplete X-linked congenital stationary night blindness, type 2), respectively [5]. In comparison, $Ca_v1.2$ has a widespread distribution, and accordingly the mutations of $Ca_v1.2$ channels in ►Timothy's syndrome cause a more complex, less predictable phenotype affecting the brain (autism spectrum disorder), heart (LQT syndrome and arrythmias) and metabolism (hypoglycemia) [5].

Mutation phenotypes can appear counter-intuitive without guidance from the cellular context. As discussed earlier, gain of function mutations in $Na_v1.1$ channels lead to hyper-excitability and inherited epilepsy (GEFS+) [3]. Interestingly, loss of function mutations of $Na_v1.1$ channels can also cause epilepsy (►Severe myoclonic epilepsy of infancy (SMEI)) [3]. In excitatory neurons, loss of function of $Na_v1.1$ channels leads to a compensatory upregulation of other Na channel isoforms which reduces the severity of the mutation in these neurons [3]. Inhibitory GABAergic neurons, which depend on $Na_v1.1$ for 75% of their action potential upstroke, do not undergo compensatory upregulation and shut down when the Na channel is lost leaving no restraint on excitation of their target neurons [3].

The neurological disorder erythromelagia illustrates how an observed phenotype for an ion channel mutation depends on cell background [10]. A leucine to histidine mutation at position 858 in the $Na_v1.7$ channel peptide leads to hyper-excitability in nociceptive sensory cells in the dorsal root ganglion (DRG) manifesting as a severe burning-type pain in response to mild stimuli such as heat [10]. Paradoxically, the same $Na_v1.7$ mutation causes hypo-excitability in sympathetic ganglion neurons, leading to a loss of sympathetic vasoconstriction of peripheral blood vessels and redness of the extremities [10]. The $Na_v1.7$ mutation shifts the channels' voltage-dependence of activation in a hyperpolarizing direction and also causes a slowing of inactivation (transition from open to a closed state), both of which result in an increased willingness of $Na_v1.7$ mutant channels to open and stay open longer at rest [10]. Consequentially, a rise in ►resting membrane potential of 5 mV leads to hypo-excitability due to inactivation of Na channels which could contribute to the action potential upstroke in sympathetic ganglion neurons [10]. Nav1.7 mutation causes a similar rise in resting membrane potential in nociceptive DRG neurons, yet (as mentioned above) the resulting phenotype is opposite as that of sympathetic ganglion neurons [10]. The difference is in the expression of another sodium channel ($Na_v1.8$) expressed in nociceptive DRG neurons, but not sympathetic ganglion neurons. $Na_v1.8$ decloak from the cell background in nociceptive DRG neurons as the membrane potential rises in response to the $Na_v1.7$ mutation [10]. $Na_v1.8$ has a higher threshold voltage-dependence of inactivation than other resident Na channels translating into an active $Na_v1.8$ that assumes command of action potential electrogenesis leading to the hyper-excitable pain circuits observed for this mutation [10].

## Summary

Ion channels are essential players in most of life's processes. Most are bacterial homologs or close derivatives of prokaryotic ancestors and have adapted to play specialized roles in different tissues including neurons, skeletal muscle and heart. High resolution structures and biophysical studies have given us insights into the inner workings of these sophisticated molecular machines, especially their highly selective pores which permit ion flow near the limits of diffusion and intricate gating systems. Ion channels are often one of many cogwheels in complex signaling networks. Because of their interdependence in cellular processes, often the manifestation of an ion channel related disease depends on the cellular context in which these mutations are found.

Institute of Biotechnology, University of Helsinki, Helsinki, Finland

## Synonyms

Ion current; Ion flux/flow

## Definition

The movement of ions across biological membranes. The transport of ion species can be passive (facilitated) or active. Facilitated transport is mainly mediated through ion channels whereas active transport can be either conveyed by primary active (ion pumps) transporters and secondary active (ion cotransporters and exchangers) transporters.

## Characteristics

Ion transport through cell membranes and organelles is fundamental for many of the basic neuronal functions (►Cell membrane – components and functions). Ion pumps build gradients across the membrane, which are then used as an energy source by ion channels and other transport proteins to pump nutrients into cells, generate ►action potentials, regulate ►synaptic transmission, regulate cell volume, and secrete electrolytes across epithelial layers into the ►cerebrospinal fluid.

### Passive Versus Active Transport

*Fick's first law* states that movement of molecules by diffusion is always spontaneous, down a gradient of free energy or chemical potential until equilibrium is reached. The spontaneous downhill movement of ion species is termed passive diffusion. At equilibrium, no further net movements of ions can occur without the application of a ►driving force.

The driving force for diffusion of ions can be calculated from the difference in ►electrochemical potential between inside and outside the cell.

As the electrochemical potential is defined:

$$\tilde{\mu}_j = \tilde{\mu}_j^* + RT\ln C_j + z_j FE \quad (1)$$

where $\tilde{\mu}_j$is the electrochemical potential of a given ion species j in joules per mole (J $mol^{-1}$). The first part of the equation is composed of $\tilde{\mu}_j^*$that is the electrochemical potential under standard conditions. The next part is the concentration component where R is the universal gas constant, T is the absolute temperature, and $C_j$ is the concentration (activity) of j. The last part of the equation is the electrical term where z is the electrostatic charge of the ion (+1 for monovalent cations, −1 for monovalent anions, +2 for divalent *et cetera*), F is Faraday's constant, and E is the overall electric potential of the solution (with respect to the ground).

The driving force is then:

$$\Delta\tilde{\mu}_j = \tilde{\mu}_j^i - \tilde{\mu}_j^o \quad (2)$$

Substituting the appropriate terms from (1) into (2) gives

$$\Delta\tilde{\mu}_j = \left(RT\ln[j]^i + z_j FE^i\right) - \left(RT\ln[j]^o + z_j FE^o\right) \quad (3)$$

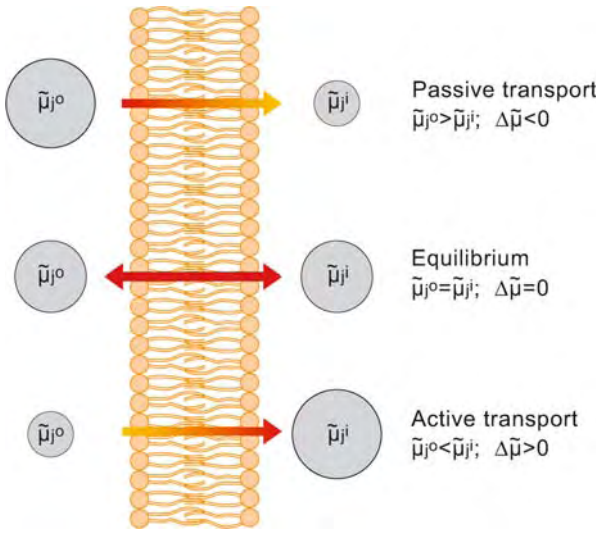
In general, during passive transport ions always move from the side of a permeable membrane with higher electrochemical potential downhill to the side with lower potential. Net Movement of ions against the

electrochemical potential is indicative of active transport (see Fig. 1).

## Ion Channels Dissipate Energy generated by Ion Pumps

Unlike small, neutral solutes (e.g., $O_2$, $CO_2$ or $N_2$) and uncharged polar molecules (e.g., urea, ethanol, and small organic acids), ions are practically impermeable for artificial lipid bilayers. The permeability coefficients of major monovalent ion species, $Na^+$, $K^+$ and $Cl^-$, are in the range of $10^{-15}$ and $10^{-10}$ cm $s^{-1}$, approximately 8–10 orders of magnitude smaller than the permeability coefficients of small non-polar solutes. The reason for this is that in the aqueous environment, ions strongly polarize the surrounding water so that dipoles of water molecules tend to align themselves with the electric field created by the ion. As the ion moves into the membrane, strong, favorable water-ion interactions are broken at a considerable free energy expense. The permeability of biological membranes for ions is significantly larger. This difference is made by the composition of specialized proteins in biological membranes that convey ion transport.

Ion channels are transmembrane proteins that function as selective pores, through which ions can diffuse across the membrane [1]. Thus, the major function of ion channels is to facilitate, usually for only very short durations, the movement of ions down the electrochemical gradients previously established across either the plasma membrane or the membranes of intracellular organelles. The size of the pore and the nature and density of fixed changes lining the walls of the pore determines the ion specificity. This is achieved without strong interaction with the ion allowing the characteristically very rapid diffusion through ion channels which is in the range of $10^8$ ions per second through each channel protein. On the contrary, the kinetics of transport proteins is much slower and typically requires several milliseconds per ion. This is because the significantly stronger ion-transporter interaction causes a conformational change that leads to the release of the ion on the opposite side of the membrane.



**Ion Transport. Figure 1** Relationship between the electrochemical potential $\tilde{\mu}_j$, and the transport of ions across the plasma membrane. The net flux of ion species j from outside to inside depends on the relative magnitude of the electrochemical potential on both sides of the plasma membrane (represented by the size of the circles around j). Movement down a gradient is spontaneous and is called passive transport. Movement against the gradient requires energy and is called active transport.

## Primary Active Transport Stores Energy in Ion Gradients

Active transport across biological membranes must couple the energetically uphill translocation of ion species with another energy releasing event so that the overall free-energy change is negative.

Active transport processes can be divided into primary active and secondary active or flux-coupled transport. Primary active transport is linked directly to a source of energy other than $\Delta\tilde{\mu}_j$, such as ATP hydrolysis.

The most important primary active transport systems are ion pumps (ion transporting ATPases or pump ATPases). The pump ATPases are classified into four groups.

Coupling factor ATPases (F-ATPases) are also called $H^+$-ATPases ($H^+$-transporting ATPases). In mitochondria, the "powerhouses" of the cell, the F-ATPase works in the backward direction, synthesizing ATP from ADP and phosphate as protons move down a concentration gradient. Cytoplasmic vesicles, such as lysosomes, endosomes and secretory granules, are acidified by the V-type (vacuolar) $H^+$-ATPase in their membranes [2]. Acidification by this V-ATPase is important for the activity of lysosomal enzymes that have acidic pH optima, and for the accumulation of drugs and ▶neurotransmitters in secretory granules.

P-ATPases form phosphorylated intermediates that drive ion translocation: the "P" refers to phosphorylation. These transporters have an active-site aspartate residue that is reversibly phosphorylated by ATP during the transport process. The P-type $Na^+/K^+$-ATPase in various tissues and the $Ca^{2+}$-ATPase in the ▶sarcoplasmic reticulum have important roles in maintaining cellular ion gradients. $Na^+/K^+$-ATPases [3] also create an electrochemical gradient of $Na^+$ and $K^+$ that produces the driving force for the function of many important secondary active transport systems (see below). The discharge of this electrochemical gradient is also fundamental to the process of action potential generation.

The ATP-binding cassette (ABC) transporters comprise the fourth active transporter family. "ABC" is the abbreviation for "ATP-binding cassette", referring to an ATP-binding region in the transporter. The members of this subfamily of transporters exert a variety of functions: P-glycoprotein (where ~"P" stands for permeability) and the MRP (multidrug resistance-associated protein) are thought to have a physiological role in excretion of toxic metabolites and xenobiotics; this is believed to contribute to resistance of cancer cells to chemotherapy. The TAP transporters, a class of ABC transporters associated with ►antigen presentation, are required for initiating the ►immune response against foreign proteins; they mediate antigen peptide transport from the cytosol into endoplasmic reticulum. CFTR (►cystic fibrosis transmembrane conductance regulator) is an ATP-gated chloride ($Cl^-$) channel (►Chloride channels and transporters). Mutations in the gene encoding this protein lead to cystic fibrosis.

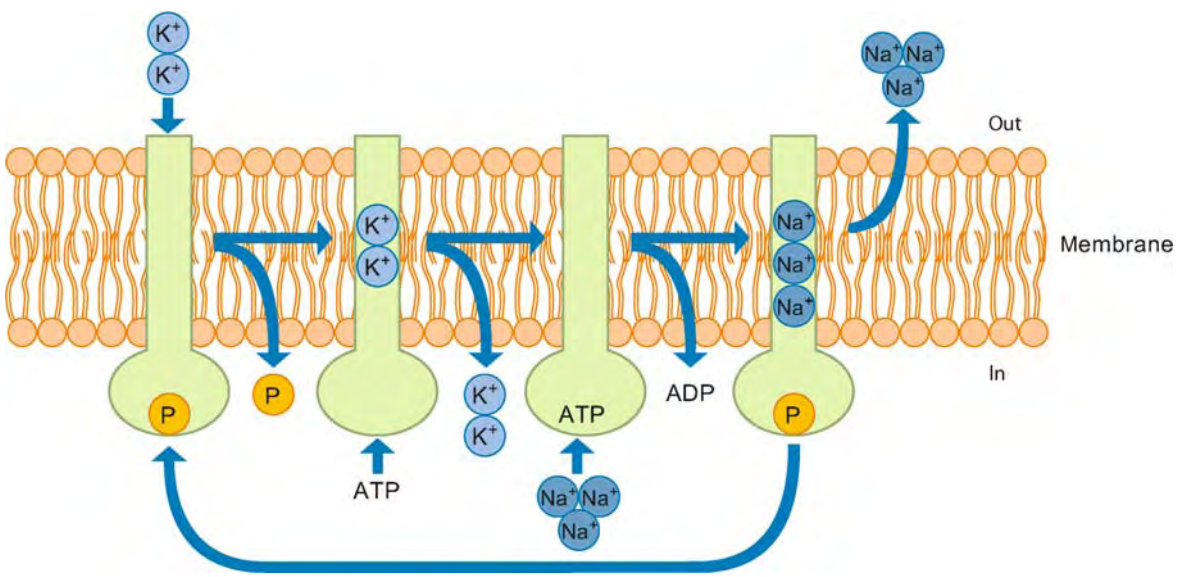
Ion pumps can be further divided into electrogenic and electroneutral depending on whether they produce a net movement of charges across the membrane. A prototypical example of an electrogenic transporter is the $Na^+/K^+$-ATPase. This ►ion pump moves three $Na^+$ ions out for every two $K^+$ ion in, resulting in a net outward movement of one positive charge (Fig. 2). In contrast, electroneutral transporters as the name implies do not move a net charge. In the case of the $H^+/K^+$-ATPase one $H^+$ is moved out of the cell for every $K^+$ in, yielding no net movement of charges across the membrane.

## Secondary Active Transporters

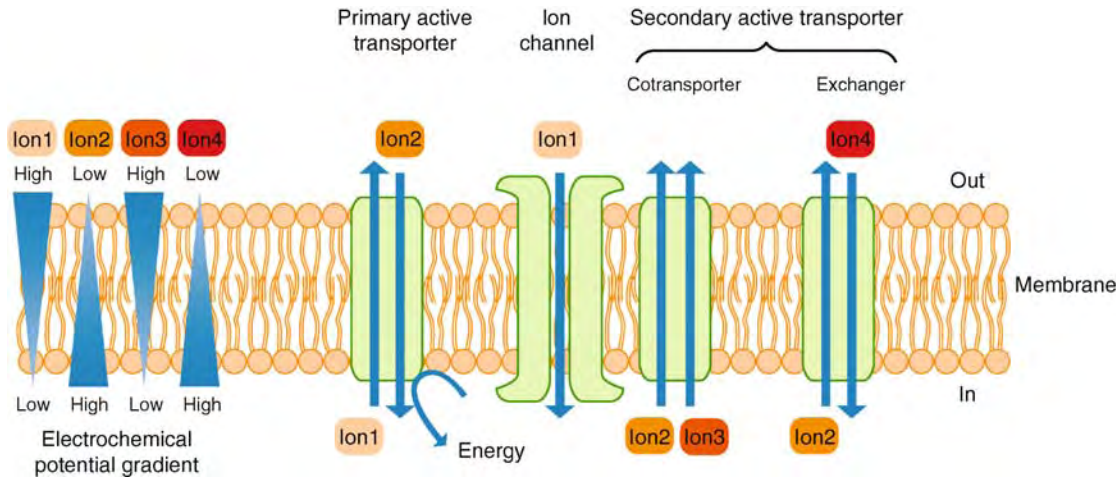
Secondary active transport systems use the energy stored in the electrochemical gradient of certain ions (such as $K^+$ and $Na^+$) accumulated by primary active transporters to drive the energetically unfavorable transport of other ion species. Secondary active ion transporters can be divided in ►cotransporters and exchangers (Fig. 3). Below are some examples of secondary transport systems important for normal brain function.

## Neuronal pH Homeostasis

There is a reciprocal relationship between electrical activity and pH. Increased electrical activity can produce rapid changes in pH, and vice versa fluctuations in pH affect neurotransmission and firing properties of neurons [4]. The regulation of intracellular pH in neurons and glia is in principle similar to that in other cells and is exerted mainly by $Na^+/H^+$ exchange, $Na^+$-driven $Cl^-/HCO_3^-$ exchange, $Na^+$–$HCO_3^-$ cotransport, and $Cl^-/HCO_3^-$ exchange. Molecular identification of isoforms of the transporters involved has revealed heterogeneity among brain regions and cell types. Whereas one of the isoforms of the $Cl^-/HCO_3^-$ ►exchanger AE3 and the $Na^+$-driven $Cl^-/HCO_3^-$ exchanger NDCBE1 are widely expressed in the brain, the five known isoforms of $Na^+/H^+$ exchanger (NHE1–5) show distinct preferences for diverse brain regions. Differences in the repertoire of transporter isoforms involved in pH regulation between various cell types and brain regions suggest that the exact mechanism for pH regulation may vary.



**Ion Transport. Figure 2** Model for electrogenic ATP-dependent $Na^+/K^+$ transport. $Na^+$ and $K^+$ are transported against their electrochemical gradients. The energy required for this process is provided by the hydrolysis of ATP which phosphorylates the pump. The flux of the ions is asymmetrical with two $K^+$ ions transported for every three $Na^+$ ions. This produces a net current across the membrane.



**Ion Transport. Figure 3** The interaction between primary, passive and secondary transport systems. Primary active transport drives the transport of ion species (ion 1 and 2) against their electrochemical gradient using another energy source than the electrochemical gradient, e.g., the energy released upon hydrolysis of ATP. Ion channels allow the passive transport of ion species (ion 1) downhill their electrochemical gradient. There are two major types of secondary transport systems: cotransporters drive the transport of different ion species in the same direction using the downhill transport of one ion (ion 2) to fuel the uphill transport of the other (ion 3). Exchangers promote the transport of ion species in opposite directions using the electrochemical gradient of one ion (ion 2) to drive the other (ion 4).

## Low $[Ca^{2+}]_i$ Is Maintained by $Ca^{2+}$-ATPase and $Na^+/Ca^{2+}$ Exchanger

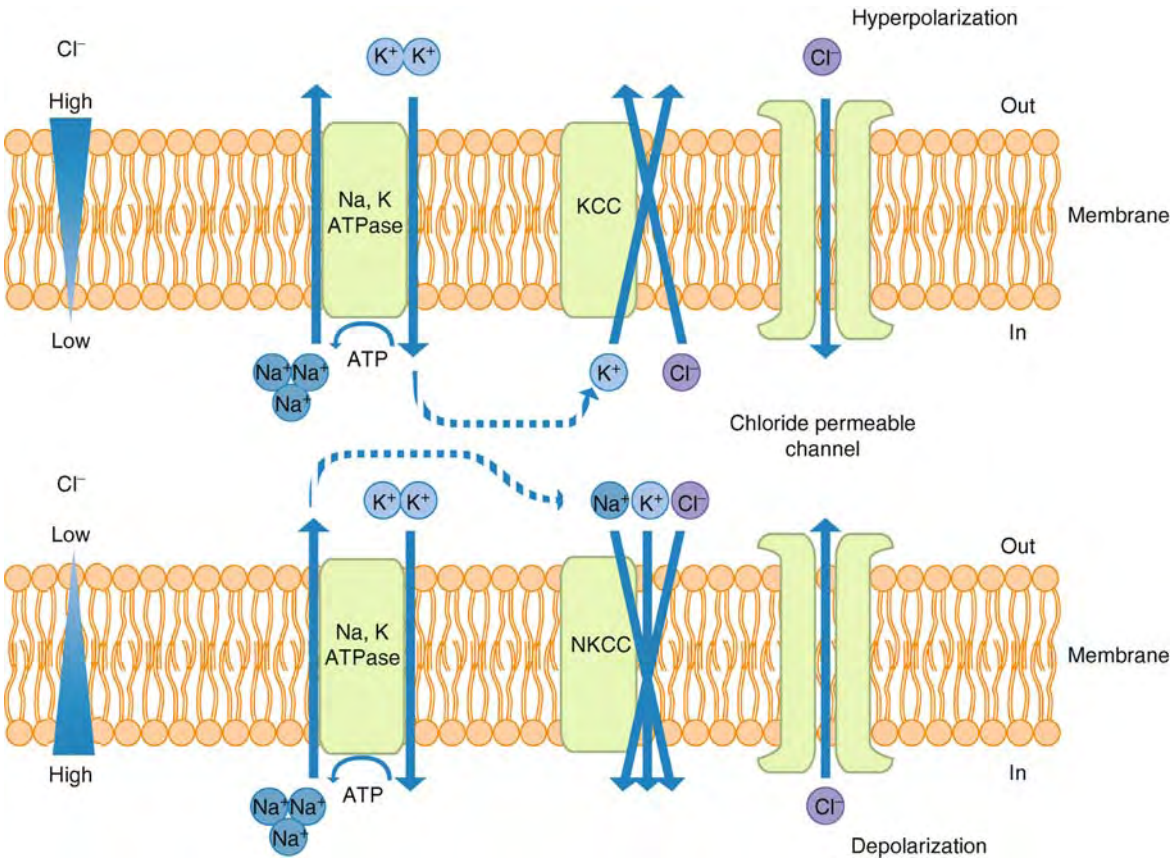
The maintenance of low $[Ca^{2+}]_i$ is crucial for $Ca^{2+}$ dependent intracellular signaling which relies on transient changes in cytosolic $Ca^{2+}$ [5]. Two systems are responsible for the export of $Ca^{2+}$ from cells [6]: a high-affinity, low-capacity $Ca^{2+}$-ATPase, and a lower-affinity, but much larger-capacity $Na^+/Ca^{2+}$-exchanger. The ATPase (commonly called the $Ca^{2+}$ pump) is the fine-tuner of $[Ca^{2+}]_i$, as it functions well even if the concentration of $[Ca^{2+}]_i$ drops below the μM level. It is a large enzyme, with ten transmembrane domains and a C-terminal cytosolic tail that contains regulatory sites, including a ►calmodulin-binding domain. The plasmalemmal $Ca^{2+}$-pump is different from the sarcoendoplasmic reticulum $Ca^{2+}$-ATPase (SERCA) pump whose main function is to accumulate $Ca^{2+}$ in the endoplasmic reticulum [7]. $Ca^{2+}$ calmodulin regulates the plasmalemmal pump but not the SERCA pump, allowing for rapid activation when cytoplasmic $Ca^{2+}$ rises.

Mammalian $Na^+/Ca^{2+}$ exchangers are members of three branches of a much larger family of transport proteins, the $Ca^{2+}$/cation antiporter (CaCA) superfamily which comprises the $Na^+/Ca^{2+}$ exchanger (NCX1–3), $Na^{2+}/Ca^{2+}$–$K^+$ exchanger (NCKX1–5) and the $Ca^{2+}$/cation exchanger (CCX). Although the main function of $Na^+/Ca^{2+}$ exchangers is to extrude $Ca^{2+}$ from the cytoplasm, they are reversible and may allow $Ca^{2+}$ entry under special conditions of subcellular localization and compartmentalized ion gradients. NCX3 and 5 are expressed mainly in the brain and skeletal muscle. NCKX1 is expressed in retinal rod ►photoreceptors, NCKX2 is expressed in cone photoreceptors and in neurons throughout the brain, NCKX3 and NCKX4 are abundant in the brain, but have a broader tissue distribution, and NCKX5 is expressed in skin, retinal epithelium and brain.

## Decrease in $[Cl^-]_i$ Sets the Hyperpolarization Shift in $GABA_A$-Mediated Responses During Development

During development the ►reversal potential for ►$GABA_A$-mediated responses ($E_{GABAA}$) experiences a shift to more hyperpolarized values. This change produces a qualitative change in $GABA_A$-mediated responses from depolarizing to ►hyperpolarizing in neurons where $E_{GABAA}$ becomes more negative than the resting membrane potential. $GABA_A$ receptors are $Cl^-$-permeable channels implying that the direction of the net ion flux through this channel is governed by the electrochemical gradient of $Cl^-$. Thus, during development there is a gradual decrease in $[Cl^-]_i$ that underlies the maturation of $GABA_A$-mediated responses [8].

The ►homeostasis of $[Cl^-]_i$ is mainly maintained by members of the cation-chloride cotransporter family. This family is comprised of nine gene products of which seven are know to function as transporters. These are: $Na^+$–$K^+$–$Cl^-$-cotansporters NKCC1 and 2, $Na^+$–$Cl^-$-cotransporter NCC and the $K^+$–$Cl^-$-cotransporters KCC1–4. Out of these only KCC2 is specifically expressed in neurons whereas NCC and NKCC2 are expressed predominantly in the kidneys. All other family members are expressed also in the brain as well as other tissues. The high $[Cl^-]_i$ in



**Ion Transport. Figure 4** Ionic mechanism for the developmental change in $GABA_A$-mediated responses. The transport of $Cl^-$ by secondary active transporters is driven by the concentration gradients of cations. In immature neurons the uptake of $Cl^-$ by NKCC1 (*bottom*) is driven mainly by the energy stored in the $Na^+$ gradient generated by the $Na^+/K^+$-ATPase. The resulting outward $Cl^-$ electrochemical gradient permits depolarizing $Cl^-$currents through the anion-permeable ►$GABA_A$ receptor. As neurons mature, $K^+$ $Cl^-$-cotransport becomes predominant due to the upregulation of KCC2. The $K^+$ gradient maintained by the $Na^+/K^+$-ATPase fuels the extrusion of $Cl^-$ by KCC2, which results in an inwardly directed electrochemical gradient for $Cl^-$ that generates hyperpolarizing currents across anion-permeable channels (*top*).

developing neurons is mainly maintained by NKCC1 that uses the electrochemical gradient of $Na^+$ (built up by the $Na^+/K^+$-ATPase) to drive $Cl^-$ uptake (Fig. 4).

Wile NKCC1 expression decreases during development, the expression of the $Cl^-$ extruder KCC2 increases. KCC2 employs the $K^+$ gradient that is also generated by the $Na^+/K^+$-ATPase to extrude $Cl^-$ from neurons rendering lower $[Cl^-]_i$ values that results in more hyperpolarized values of $E_{GABAA}$ [9].

## Ion Channels in Transporters

The traditional model of ion transport where large conformational changes in the protein accompany ion translocation (alternating access model) has been recently challenged [10]. Several results provide evidence for the existence of channels in transporters and vice versa ion channels that display transport activity. The marine toxin palytoxin presumably binds to the $Na^+/K^+$-ATPase forming an ion channel that is permeable for $Na^+$ and $K^+$. Several ion transporters show channel-akin properties, exhibiting brief electrical events that are comparable to discreet ion channel events. The glutamate transporters EAATs are confirmed to include an ion channel permeable for $Cl^-$, the DA transporter DAT-1 shows ►single-channel currents that are specific for $Cl^-$. Conversely, there are examples where proteins believed to be ion channels have turned out to be transporters, e.g., the CLC-ec1 that was predicted by homology to be a $Cl^-$ channel was shown to be a $Cl^-/H^+$ exchanger.

# Ionosphere

## Definition

The Ionized region of the upper atmosphere, starting at roughly 60 km in altitude. Ionization of gas particles is largely caused by the Sun's ultraviolet light, with wavelengths < 100 nm (EUV). In the lower layers of the ionosphere, the percentage of ionized gas particles is so minute that their motion is coupled to the neutral gas rather than being affected by the geomagnetic field. The electric conductivity of the ionized gas is due to free electrons, the motion of which is controlled by the magnetic field, giving rise to the observed dynamo effect. Animation: http://www.windows.ucar.edu/spaceweather/sun_earth9.html.

►Geomagnetic Field

# Ionotropic

## Definition

An influence on ion channel activity mediated directly by the binding of a neurotransmitter to a receptor channel complex. Transmitter binding to its receptor opens the associated channel by changing its conformation for the duration of binding. This is a relatively short-latency, short-duration event.

# Ionotropic Receptor

Kenji Sakimura
Department of Cellular Neurobiology, Brain Research Institute, Niigata University, Niigata, Japan

## Synonyms

Ligand-gated ion channel; Receptor channel

## Definition

Ionotropic receptors are membrane-spanning protein complexes that direct the coupling of the neurotransmitter receptor to the ion channel. They contain two functional domains: an extracellular site that binds neurotransmitters and a membrane-spanning domain that forms an ion channel. The neurotransmitter binding to the ionotropic receptor leads to a conformational change that is passed along to the closely associated ion channel, and as a result the channel properties are altered. This important feature of ionotropic receptors means that the modulation of ion channel properties varies with the length of time that the transmitter occupies the receptor. Therefore they mediate rapid-onset and rapidly reversible synaptic transmission, generally in millisecond orders. In contrast, the activation of metabotropic receptors produces much slower responses, ranging from hundreds of milliseconds to minutes or even longer. Ionotropic receptors that are cloned and characterized are shown in Table 1. The nicotinic acetylcholine receptor (nAChR), glutamate receptor channels, one of the serotonin receptors ($5\text{-}HT_3$) and certain purinergic receptors ($P2_x$) are permeable cations and contribute to postsynaptic excitation. The γ-aminobutyric acid A ($GABA_A$) receptors and the glycine receptors are permeable anions ($Cl^-$) and mediate inhibitory functions. Ionotropic glutamate receptors are divided into three classes and originally named after reasonably selective agonists; *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainate (KA).

In a broad sense of the definition, some kinds of channels which are activated by intracellular second messengers (such as $Ca^{2+}$ or the cyclic nucleotides, cAMP and cGMP) are also classified as ionotropic receptors (ligand gated-channels).

## Characteristics

### Structures

Ionotropic receptors are classified into three groups according to their structures. Comparison of the amino acid sequences of cloned ionotropic receptors shows that they are similar in their structure but different in their ancestral genes. One group comprises the nACh

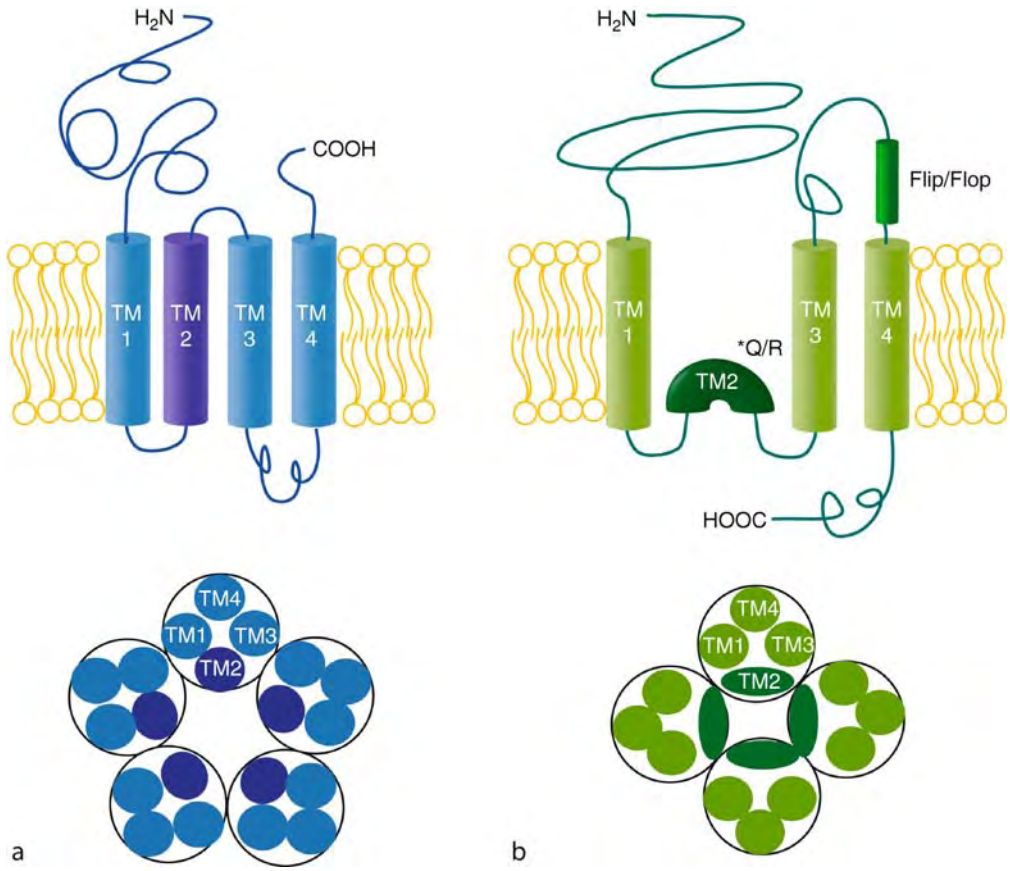
**Ionotropic Receptor. Table 1** Ionotropic receptor subtypes and functions

| Neurotransmitter | Receptor type | Permeable ion | Cloned subunit |
|---|---|---|---|
| Acetylcholin (Ach) | nACh | $Na^+$, $K^+$, $Ca^{2+}$ | α1-α10, β1-β4, γ, δ, ε |
| Glutamate (Glu) | AMPA Kinate NMDA | $Na^+$, $K^+$, ($Ca^{2+}$) $Na^+$, $K^+$ $Na^+$, $K^+$, $Ca^{2+}$ | GluR1-4 (α1-4, A-D) GluR5-7 (β1-3), KA1,2 (GluRγ1,2) NR1 (GluRζ1), NR2A-D (GluRε1-4), NR3A, B |
| GABA | $GABA_A$ $GABA_C$ | $Cl^-$ $Cl^-$ | α1-6, β1-4, γ1-4, δ, ε, π ρ1-3 |
| Glycine (Gly) | Gly | $Cl^-$ | α1-4, β |
| Serotonin | $5\text{-}HT_3$ | Non-selective cation | $5\text{-}HT_3$ |
| Purines (ATP) | $P2_x$ | Non-selective cation | $P2_{x1\text{-}7}$ ($P2_{x7}$/$P2_z$) |

receptors, the $GABA_A$ receptors, the glycine receptors, and the $5\text{-}HT_3$ receptor. The other group includes all types of glutamate receptor channels. Purinergic receptors ($P2_x$) belong to an independent group. The nACh receptor was the first to be characterized as a neurotransmitter receptor [1]. It was purified from the electric organ of a *torpedo*, accumulating huge amounts of nicotinic receptors (1000 fold higher than skeletal muscle). This receptor is composed of five subunits (Fig. 1) and has a native molecular mass of approximately 290 kDa. The subunits are named α, β, γ, δ, and each receptor complex contains two copies of the α subunit, each of which is bound to one molecule of ACh. Each subunit consists of four transmembrane-spanning domains referred to as TM1-TM4, with both the N- and C-termini being in the extracellular space. Five such subunits assemble to form a complex structure containing 20 transmembrane domains that surround a central pore. The membrane-spanning domains that line the pore are composed of the five TM2 regions. Transmitter binding induces rapid conformational changes that are translated into an increase in the diameter of the pore, permitting influx. The muscle nACh receptor is composed of five subunits: $\alpha_2\beta\gamma\delta$ (embryonic) or $\alpha_2\beta\varepsilon\delta$ (adult), and its molecular mass is approximately 280 kDa. Neuronal nACh receptors consist of only two types of subunits, α and β, that combine to produce the functional receptor. At least nine different αs have been identified as subtypes (α1 belongs to the muscle α subunit), and some are species specific (e.g. α9 is found only in rats). Four different β subtypes have been isolated (β1 belongs to the muscle β subunit), but neuronal β subunits are not closely related to the muscle β1 subunit and thus are sometimes referred to as non-α subunits.

The $GABA_A$ receptor is a heteropentameric glycoprotein of about 275 kDa composed of combinations of at least 19 different subunits. The subunits have 50–60 kDa molecular weight and have 20–30% sequence similarity between classes and about 70% similarity within a class (Table 1). In addition, splice variants exist in several subunits. The glycine receptor is a macromolecular complex of about 250 kDa composed of a combination of two homologous subunits, α and β. There is an approximately 50% amino acid sequence similarity between the α and β subunits, and they have a comparatively high homology to $GABA_A$ receptor subunits [2]. Usually a 93 kDa polypeptide named gephyrin is copurified with the glycine receptor.

Since the cloning of the first glutamate receptor GluR1 in 1989, 18 mammalian genes that encode structurally related proteins have been identified. They are currently classified into seven functional subfamilies according to their structural homologies [3]. Glutamate receptors are derived from a different ancestral gene and are structurally distinct from other ionotropic receptors. They adopt a different architecture from that previously described for the nAChR group. The TM2 domain of glutamate receptors constructs a pore forming loops instead of traversing the membrane. Furthermore, functional glutamate receptors are composed of four subunits. Thus, it appears that glutamate receptors are rather highly divergent from the nAChR group (Fig. 1). In fact, their structure conforms more closely to the family of K channels in that both appear tetrameric and both have a unique P segment (pore-forming domain that produces the selectivity filter). AMPA receptors are composed of four subunits that are termed GluR1–GluR4 (GluRα1–GluRα4, GluRA-GluRD) [3]. Each glutamate subunit consists of approximately 900 amino acids. The native form of AMPA receptor molecular mass is approximately 600 kDa. Thus, the size of the AMPA receptor is almost twice that of nACh receptor because of the large extracellular segment. Recently some members of voltage dependent calcium channel γ subunit family have been described as essential auxiliary subunits of native AMPA receptors [4]. They are γ2 (stargazin), γ3, γ4, γ7 and γ8 subunits and termed as TARPs (transmembrane AMPA receptor regulatory protein). KA receptors consist of two subunit subfamilies, GluR5–GluR7 (GluRβ1–GluRβ3) and KA1, KA2



**Ionotropic Receptor. Figure 1** Schematic structure of ionotropic receptors. (a) *Upper*, diagram highlighting the orientation of the membrane-spanning of one subunit of nACh receptor. The amino acid and carboxy termini extend in the extracellular space. Lower, top view of all five subunits highlighting the relative positions of their membrane-spanning segments, TM1–4, and the position of TM2 that lines the channel pore. (b) *Upper*, schematic structure of AMPA type glutamate receptor subunit GluR2 (GluRα2 or GluRB). Ionotropic glutamate receptors have four membrane-spanning segments. Unlike nACh receptor, however, only three of them traverse the lipid bilayer. TM2 forms a pore forming loops and re-exits into the cytoplasm. The large amino acid terminal region extends into the extracellular space, while the carboxy terminus extends into the cytoplasm. Two extracellular segments associate with each other to form the binding site for transmitter. There are two domains termed *flip* and *flop* between the TM3 and TM4, which are produced by alternative splicing. RNA editing of Q/R site that is critical for $Ca^{2+}$ permeability, is present in the TM2 segment. Lower, glutamate receptors are composed of four subunits and the loop forming TM2 lining channel pore.

(GluRγ1, GluRγ2). NMDA receptors consist of combination of the glutamate-binding NR2 (GluRε) subunit and glycine-binding NR1 (GluRζ) is essential NMDA receptor *in vivo* [5]. There are four NR2A-NRD (GluRε1–GluRε4) and one NR1 (GluRζ1) genes. Two NR3 subunits, which may carry the regulatory function are also reported. Two homologous subunits, GluRδ1 and δ2, remain unassigned to any particular receptor.

$P2_x$ receptors are membrane ion channels that open in response to the binding of extracellular ATP [6]. Seven $P2_x$ receptor subunits have been shown to share less than 50% identity and range in length from 379 to 595 amino acids. $P2_x$ receptor subunits share a similar structural topology consisting of two transmembrane domains connected by a large extracellular loop, containing the putative ATP binding site and intracellular N and C termini of various lengths.

## Function

The main function of ionotropic receptors is to convert extracellular chemical signals (neurotransmitters) into electrical information. These receptors are essential for synaptic transmission and other forms of cell-cell signalling phenomena. In the neuromuscular synapse, the binding of Ach to postsynaptic nACh receptors opens ion channels which are permeable to cations and generate excitatory postsynaptic responses. Functional characterizations of the neuronal nACh receptors

are carried out using exogenous expression systems. When certain pairs or triplets of cDNAs encoding neuronal α and β subunits are cotransfected into cells or their corresponding mRNAs are injected into oocytes, characteristic Ach-gated channel function can be achieved. The α4β2 subunit combination is major in the CNS, however its deficiency causes only limited changes. Four permutations of α4, α5, α6, β2 and β3 subunits are found in the striatum, and they mediate dopamine release. Several noticeable properties of the neuronal nACh receptors are their presynaptic localizations and regulation of several neurotransmitter releases. Continued exposure of nACh receptors to the agonist leads to desensitization of the receptors (►Receptor regulation, Desensitization). This diminution of the response is attributed to the presence of multiple conformational states of receptor-ligand complex.

Ionotropic glutamate receptors mediate major excitatory neurotransmission in the mammalian brain and spinal cord. They also play the leading role in brain functions such as development, learning and memory, and in brain disease. The KA and AMPA receptors are closely related, whereas the NMDA receptors are both functionally and structurally distinct from the KA and AMPA receptors. The KA and AMPA receptors activate cation channels that usually allow sodium and potassium ions to flow. Near a neuron's resting potential, the driving force for $K^+$ is low and that for $Na^+$ is high, so activation of the these channels leads to depolarization as a result of an inward sodium current. AMPA receptors are responsible for the majority of fast excitatory signals in the CNS (mediating, e.g., sensory information and motor commands). AMPA receptors that contain the GluR2 subunit are much less permeable to $Ca^{2+}$ than those assembled without GluR2. This important feature of AMPA receptors is determined by a single amino acid within the TM2 of the GluR2. A glutamine (Q) resides in this position in GluR1, GluR3 and GluR4, but an arginine (R) is present in GluR2; this site has thus been named the "Q/R" site. The genomic DNA sequence of GluR2 has a glutamine codon in the Q/R position, but its mature mRNA has an arginine codon in this site. A novel RNA editing (►Receptor Regulation, Editing) on the GluR2 mRNA is one cause of this phenomenon. In addition, the function of AMPA receptors is regulated by splicing (►Receptor regulation, Splicing). "Flip" and "flop" versions of the splice isoformes GluR1–GluR4 have been reported [7]. The flip and flop splice variants give rise to receptors that differ in desensitization rate and in their regional distribution in the brain. NMDA receptors have properties that distinguish them from other ionotropic receptors. One important feature of NMDA receptors is that they are more permeable to $Ca^{2+}$ than $Na^+$ (in contrast to AMPA receptors). This makes possible many postsynaptic effects of glutamate binding in addition to depolarization, because $Ca^{2+}$ can trigger a number of intracellular processes. Another feature of NMDA receptors is that they are blocked by extracellular $Mg^{2+}$ in a voltage-dependent manner. The binding of glutamate to the receptor opens it only if the membrane is already depolarized, for example, by the opening of AMPA receptors in the vicinity. Furthermore, NMDA receptors require two kinds of agonists to be activated: one is glutamate and the other is glycine. Thus regulation of their channels is more complex than that of other glutamate receptors. These properties are the basis for dynamic brain functions such as development, synaptic plasticity, learning, and memory, and are one of the causes of neuronal damage. NMDA receptors work only with the combination of NR1 and NR2 *in vivo*. Four NR2 subunits are major functional determinants of NMDA receptors [8]. Each of the four has a distinct expression profile during development and in areas of the mature brain.

Synaptic inhibitory transmission in the mammalian brain is mediated mainly by GABA receptors [9]. Among them, $GABA_A$ receptor is the most widespread ionotropic receptor. The subunits composing the $GABA_A$ receptor have sequence homology with the nACh receptor subunit family, and their general structures appear to be quite similar. Five different types of subunit subfamilies associated with $GABA_A$ receptors are named α, β, γ, δ, and ε. An additional subunit subfamily ρ is predominantly expressed in the retina, but the other subunits are widely distributed in the brain. Many subunits that belong to the subfamilies have been reported, for example, six α, four β, four γ, and two ρ. Like neuronal nACh receptors, these subunits mix in a heterogeneous fashion to produce complex $GABA_A$ receptors, which have been characterized by pharmacological and electrophysiological analyses. The expression of subunit mRNAs in oocytes indicated that the α subunit is essential for producing a functional receptor channel. The $GABA_A$ receptor's ion channel is selective for anion ($Cl^-$), and this important property is caused by positively charged amino acids that form a ring near the end of the ion channel. When GABA binds to the receptor, $Cl^-$ flows into the cell, producing hyperpolarization by causing the membrane potential to recede from the threshold for firing an action potential. Glycine receptors greatly resemble the $GABA_A$ receptors both structurally and functionally, and work as major inhibitory receptors in the spinal cord. They also work in the entire brain particularly in the brainstem. These receptors appear to be pentameric, and are most likely composed of three α and two β subunits. Three molecules of glycine must bind to the α subunits in order to open the anion channel.

The ionotropic serotonin receptor $5\text{-}HT_3$ is unique among serotonin receptors, and is a close relative of the

nACh receptor [10]. The 5-HT3 receptor is a homomeric complex composed of five copies of the same subunit, and has a structure most analogous to the α7 subunits of neuronal nACh receptors (which also form a homo-oligomeric complex). This receptor also resembles nACh receptors in that it is permeable to $Na^+$ and $K^+$ and is rapidly desensitized.

### Pathology

Some kinds of naturally occurring poisonous molecules and synthetic drugs can influence the nACh receptor functions and produce involuntary muscle contractions or muscle paralysis. Myasthenia gravis is an autoimmune disease that targets nACh receptors. Thus, normal nACh receptors are decreased at the neuromuscular junction and muscle weakness occurs. The symptoms improve following treatment with acetylcholinesterase inhibitors, which degrade acetylcholine at the neuromuscular junction.

Excitotoxicity refers to the ability of glutamate and related compounds to destroy neurons by prolonging their receptor activation. Ionotropic glutamate receptors are several candidates for mediating cell damage after abnormal excitatory activation. When nervous tissue receives insufficient oxygen (ischemia), as in severely reduced blood pressure, stroke, cerebral bleeding, etc., the extracellular glutamate concentration rises steeply and all kinds of glutamate receptors are presumably activated. Abnormal intense excitation may also occur during epileptic seizures. Of the glutamate receptors, NMDA receptors are especially important because they can produce a rapid increase of the intracellular $Ca^{2+}$ concentration that is crucial for cell death.

### Therapy

The $GABA_A$ receptor is the major molecular target for the action of many drugs used in brain treatment. Benzodiazepine is a well known drug and is used for the treatment of anxiety disorders such as panic disorder, agoraphobia, and other phobias. This drug binds to a site on the $GABA_A$ receptor and acts to make GABA much more effective in opening the chloride channel and producing inhibition. The site on the receptor that binds Benzodiazepine is thought to be used by a naturally-occurring brain chemical, and modulates channel functions, although the endogenous molecule has not yet been identified. The anxiolytic effects of alcohol are explained in that ethanol is also bound to another site on the $GABA_A$ receptor and stimulates GABA actions. Barbiturates are another type of drug commonly used therapeutically for anesthesia and control of epilepsy. They allosterically increase the binding of GABA to their binding sites at pharmacological concentrations, resulting in an increase of chloride flux. The 5-HT3 receptor is clinically significant because antagonists of 5-HT3 receptors have important applications as antiemetics, anxiolytics and antipsychotics.

## Ischemic Stroke

Claire Creutzfeldt, David Tirschwell
Harborview Neurology - Comprehensive Stroke Center University of Washington School of Medicine, Seattle, WA, USA

### Synonyms
Cerebrovascular disease; Cerebrovascular accident; CVA; Thrombotic stroke; Brain attack

### Definition
The sudden onset of focal neurological deficits due to a blockage of arterial blood flow and injury to a certain area of the brain, with symptoms lasting longer than 24 h.

### Characteristics
#### Epidemiology
Stroke is the second leading cause of lost disability-adjusted life years in high-income countries and of death worldwide, after ischemic heart disease; in 2001, an estimated 5.4 million people died from stroke worldwide [1]. In Western societies, approximately 80% of strokes are ischemic, and the remaining 20% are caused by hemorrhages. In the USA, there are approximately 500,000 ischemic strokes each year. One-month case fatality rate for ischemic stroke ranges from 8–20%, with the main predictors of early functional outcome being initial stroke severity, level of consciousness, size of infarct and type of neurologic deficit.

#### Etiology
Etiologic classification of ischemic stroke is based on clinical features and ancillary diagnostic test results. The TOAST classification differentiates between five subtypes: (i) large-artery atherosclerosis, (ii) ►cardioembolism, (iii) small-vessel occlusion, (iv) stroke of other known etiology, and (v) stroke of unknown etiology [2]. Anatomically, infarcts located in the ►cortex are

distinguished from ►subcortical infarcts. Age, gender and genetic predisposition are important non-modifiable risk factors. The main modifiable risk factors are arterial ►hypertension, ►atrial fibrillation, carotid artery stenosis, cigarette smoking, ►hyperlipidemia, ►diabetes mellitus, and a previous stroke or transient ischemic attack (►TIA). Less common causes for ischemic stroke are ►arterial dissection, inflammatory disorders of the arteries (vasculitis) and genetic disorders such as ►CADASIL. Knowledge of these risk factors is important for preventing a stroke in the first place and to avoid recurrence of one.

## Pathophysiology

Ischemic stroke is caused by an interruption in the blood supply, resulting in depletion of oxygen and glucose in the affected area. Brain tissue that no longer receives its blood supply can die within a few hours unless something is done to stop the damage. Three different mechanisms have been proposed that cause this interruption of blood supply: embolic infarcts, watershed infarcts and lacunar infarcts. Many times, however, we will find a mixed picture.

- *Embolic infarcts* are caused by dislodgement of an embolus (blood clot) from a proximal source, mostly the heart or a large to medium-sized artery, which then travels distally in the cerebral circulation, lodges at some point depending on size of thrombus vs. size of artery, thus impeding blood flow distal to this thrombus. ►Cardiac emboli can result from cardiac rhythm abnormalities (in particular atrial fibrillation), from changes in the wall of the heart in the setting of coronary artery disease or cardiomyopathy, or from diseased heart valves. ►Paradoxical emboli are clots that originate in the venous system (for example deep vein thrombosis) and reach the arterial system through a ►right (venous) to left (arterial) shunt. *Arterial emboli* originate from atherosclerotic plaques in any of the arteries from the aortic arch up to the brain (most commonly the internal carotid artery) Fig. 1. Embolic infarcts are also called territorial infarcts as they involve the area (territory) of the brain that is supplied by one artery and result in a typical combination of symptoms. For example, a middle cerebral artery (MCA) territory infarct in the dominant hemisphere commonly causes language impairment and contralateral hemiparesis (see below, vascular syndromes).
- *Watershed (Hypoperfusion)-infarcts* involve the distal fields of two non-anastomosing arterial territories where perfusion pressure is lowest. They occur in the setting of hemodynamic compromise, which can be either local (tight narrowing of an artery), systemic (low blood pressure) or a combination of the two. This phenomenon is often referred to as the "last meadow" comparing it to an irrigation system where the last meadow receives the least amount of water.
- *Lacunar infarcts* are small infarcts (2–20 mm in diameter) in the subcortical white matter, basal ganglia or pons, that are presumed to result from the occlusion of a single small penetrating branch of the large cerebral arteries [3]. Occlusion of a penetrating branch can be caused by microatheroma, microemboli or hypoperfusion. Even though the size of a lacunar infarct is small, the deficits can at times be severe (►lacunar syndrome).

## Signs and Symptoms

The symptoms of stroke depend on the type of stroke and the area of the brain affected. They are usually unilateral, occurring on the side of the body opposite to the affected side of the brain, i.e., "contralateral" ("ipsilateral" is when the same side of the body is affected). As is implied in the word *stroke*, symptoms typically develop suddenly and rapidly.

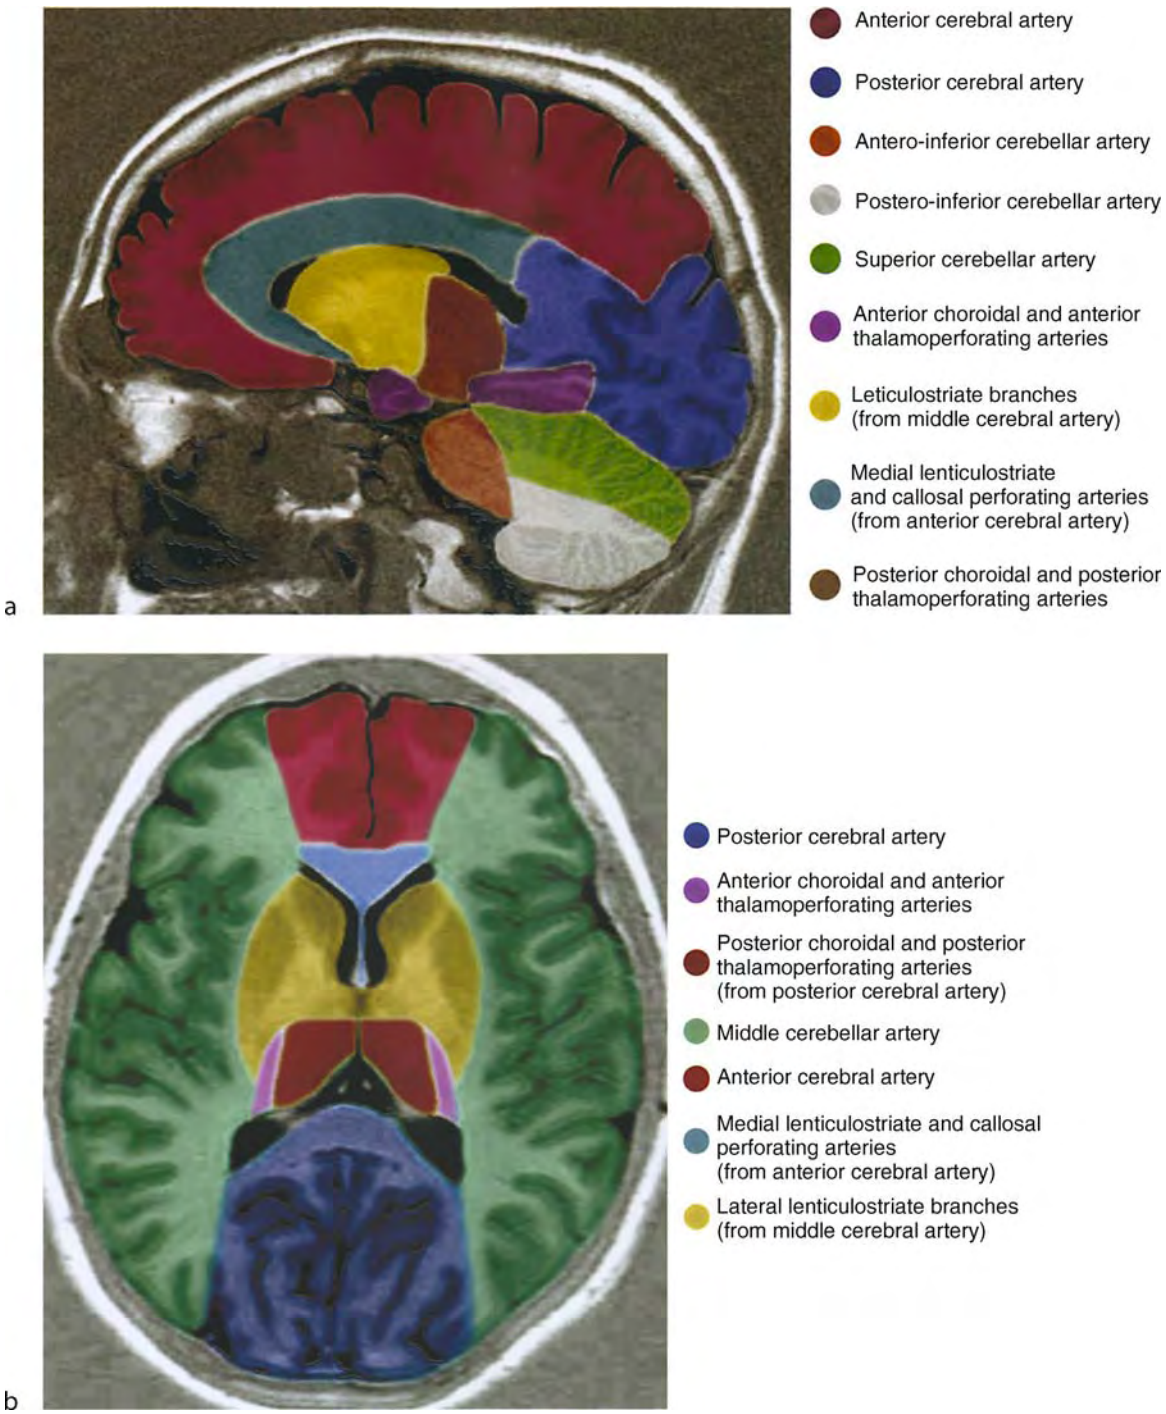
Common symptoms include weakness or numbness; confusion, trouble speaking or understanding; loss of vision in all or part of the visual field; loss of balance or coordination, trouble walking or dizziness. Less typical features are headache, impairment of consciousness, seizure at the onset or bilateral findings.

If symptoms are maximal at onset, the cause is more likely to be an embolic stroke. In watershed infarcts, symptoms tend to be more episodic, fluctuating or progressive [4]. Lacunar infarcts can be asymptomatic, their onset is often not as sudden as with embolic infarcts, and they may be identified by a typical combination of symptoms that constitute a "►lacunar syndrome." The term *vascular syndrome* refers to the association of certain neurological symptoms with impairment of one arterial territory. Even though the structures involved will differ from person to person, knowledge of the typical syndromes will help the clinician with localization and further management (see Table 1).

The *anterior circulation* includes the part of the brain that is supplied by the internal carotid arteries (ICAs), which give rise to anterior choroidal (AChA), anterior cerebral (ACAs), anterior communicating (AComm), middle cerebral (MCAs) and posterior communicating arteries (PComms).

The *posterior circulation* is made up of the vertebral arteries (VAs), which give off the posterior inferior cerebellar arteries (PICAs) before they join at the pontomedullary junction to form the basilar artery (BA), which gives rise to the anterior inferior cerebellar (AICAs), superior cerebellar (SCAs) and posterior cerebral arteries (PCA). In 20–25% of people, one of the PCAs is mainly supplied from the anterior circulation, and in 5–10% both PCAs are so supplied.

Occlusion of the basilar artery is particularly threatening because it supplies most of the brainstem, and it is



**Ischemic Stroke. Figure 1** Vascular supply Arterial Territories of the Brain. Gallucci M, Capoccia S, Catalucci A (eds) (2007) Radiographic atlas of skull and brain anatomy. Springer, New York, p 322, 334 (with permission).

unpaired. Symptoms can be bilateral, and often times, the patient is comatose because of involvement of the reticular activating system, the collection of neurons and fibers in the brainstem that are responsible for arousal.

The most important manifestation of all brainstem infarcts are "crossed" signs, with cranial nerve deficits seen on the side contralateral to sensory or motor deficits in the body.

## Differential Diagnosis

See Table 2.

**Ischemic Stroke. Table 1** Vascular Syndromes

| Deficits | | | | | |
|---|---|---|---|---|---|
| **Anterior circulation** | **Motor** | **Sensory** | **Visual** | **Speech & Language** | **Other** |
| ICA | Contralateral arm/leg weakness | Contralateral arm/leg numbness | Ipsi lateral eye (►amaurosis fugax) | See MCA | See MCA |
| AChA | Contralateral arm/leg weakness | Contralateral arm/leg numbness | Contralateral ►homonymous hemianopia | – | – |
| ACA | Contralateral arm <leg weakness | Contralateral arm <leg numbness | – | – | – |
| MCA | Contralateral arm/leg weakness | Contralateral arm/leg numbness | Contralateral ►homonymous hemianopia Eyes are often deviated to side of the infarct | ►Aphasia is typically caused by involvement of the ►cortex in the dominant (left in 95% of people) hemisphere: with the frontal branches affected, an expressive aphasia is seen; with temporal branches a receptive aphasia; parietal branches can cause a conduction aphasia and may cause ►Gerstmann's syndrome. | ►Hemispacial neglect and ►Anosognosia are seen with involvement of cortical branches in the non-dominant hemisphere. |
| Posterior circulation | Motor | Sensory | Visual | Speech & Language | Other |
| PICA (see also ►Wallenberg syndrome) | Ipsilateral ataxia | Contralateral arm/leg numbness | – | Slurred speech, hoarseness | ipsilateral facial numbness, and Horner's syndrome; contralateral arm/leg numbness, trouble swallowing |
| SCA | Ipsilateral ataxia | Contralateral loss of pain and temperature | – | Slurred speech | Nausea, vomiting, vertigo |
| AICA | Ipsilateral ataxia | – | ►Nystagmus | – | Horner's syndrome Nausea, vomiting, vertigo Ipsilateral deafness, tinnitus |
| PCA | – | – | Contralateral ►homonymous hemianopia | Involvement of the ►cortex in the dominant (left in 95% of people) hemisphere, can cause ►aphasia | Involvement of deeper branches can affect the ►thalamus and cause contralateral sensory changes. Imbalance, confusion, headache |

## Diagnosis

See Algorithm for Acute stroke evaluation (Fig. 2).

Deficits are identified by a careful ►neurological examination, and the severity assessed using one of the standardized stroke scales, i.e., the National Institute of Health Stroke Scale (http://www.ninds.nih.gov/doctors/NIH_Stroke_Scale_Booklet.pdf). A shortened version of the NIHSS, appropriate for

placement in the medical record, is seen in the NIH stroke scale which can be viewed from the link http://www.ninds.nih.gov/doctors/NIH_Stroke_Scale.pdf.

- ►Laboratory workup should include basic metabolic panel with glucose, complete blood count, markers of cardiac ►ischemia and coagulation parameters. In the appropriate setting, ►hypercoagulable workup and vasculitis testing may be indicated, as well as hepatic function tests, toxicology screen, blood alcohol level, pregnancy test and arterial blood gas.
- ►Imaging: Even though an ischemic stroke may not be visible on CT within the first 6–12h after onset of symptoms, non-contrast head CT remains the most commonly used initial imaging modality: it is more widely available, faster and less expensive than MRI and immediately rules out the presence of a hemorrhage which would preclude the administration of intravenous ►thrombolysis (the only approved treatment for acute ischemic stroke). MRI is more sensitive for detection of acute ischemic stroke and is better at identifying acute, small cortical, small deep, and posterior fossa infarcts, and at distinguishing acute from chronic stroke [5]. CT- or MR-Angiography are helpful noninvasive methods to identify any cervical or intracranial stenoses and can detect aneurysms in 95% of the cases [6]. Venous sinus thrombosis can usually be detected on MRI, but if there is clinical suspicion for it, CT- or MR-Venogram should be obtained.
- ►Ancillary tests:
- EKG followed by cardiac monitoring for at least 24 h after the event, to identify arrhythmias, acute or previous myocardial infarction.
- Echocardiogram is an ultrasound study of the heart that can look for any source of cardioembolism, for example wall motion or valvular abnormalities. "Bubble studies" can identify a right to left ►cardiac shunt as a cause of paradoxical embolism.
- Ultrasound of the arteries in the neck and brain (carotid ultrasound, transcranial ultrasound) evaluates the presence and degree of vessel narrowing and may identify emboli traveling through that vessel.
- Catheter based cerebral angiography most directly visualizes the arteries and veins in the cerebral circulation, and remains the gold standard for vascular imaging, but with the increasing quality of CT and MR angiography, this more invasive and risk laden technique is seldom necessary.

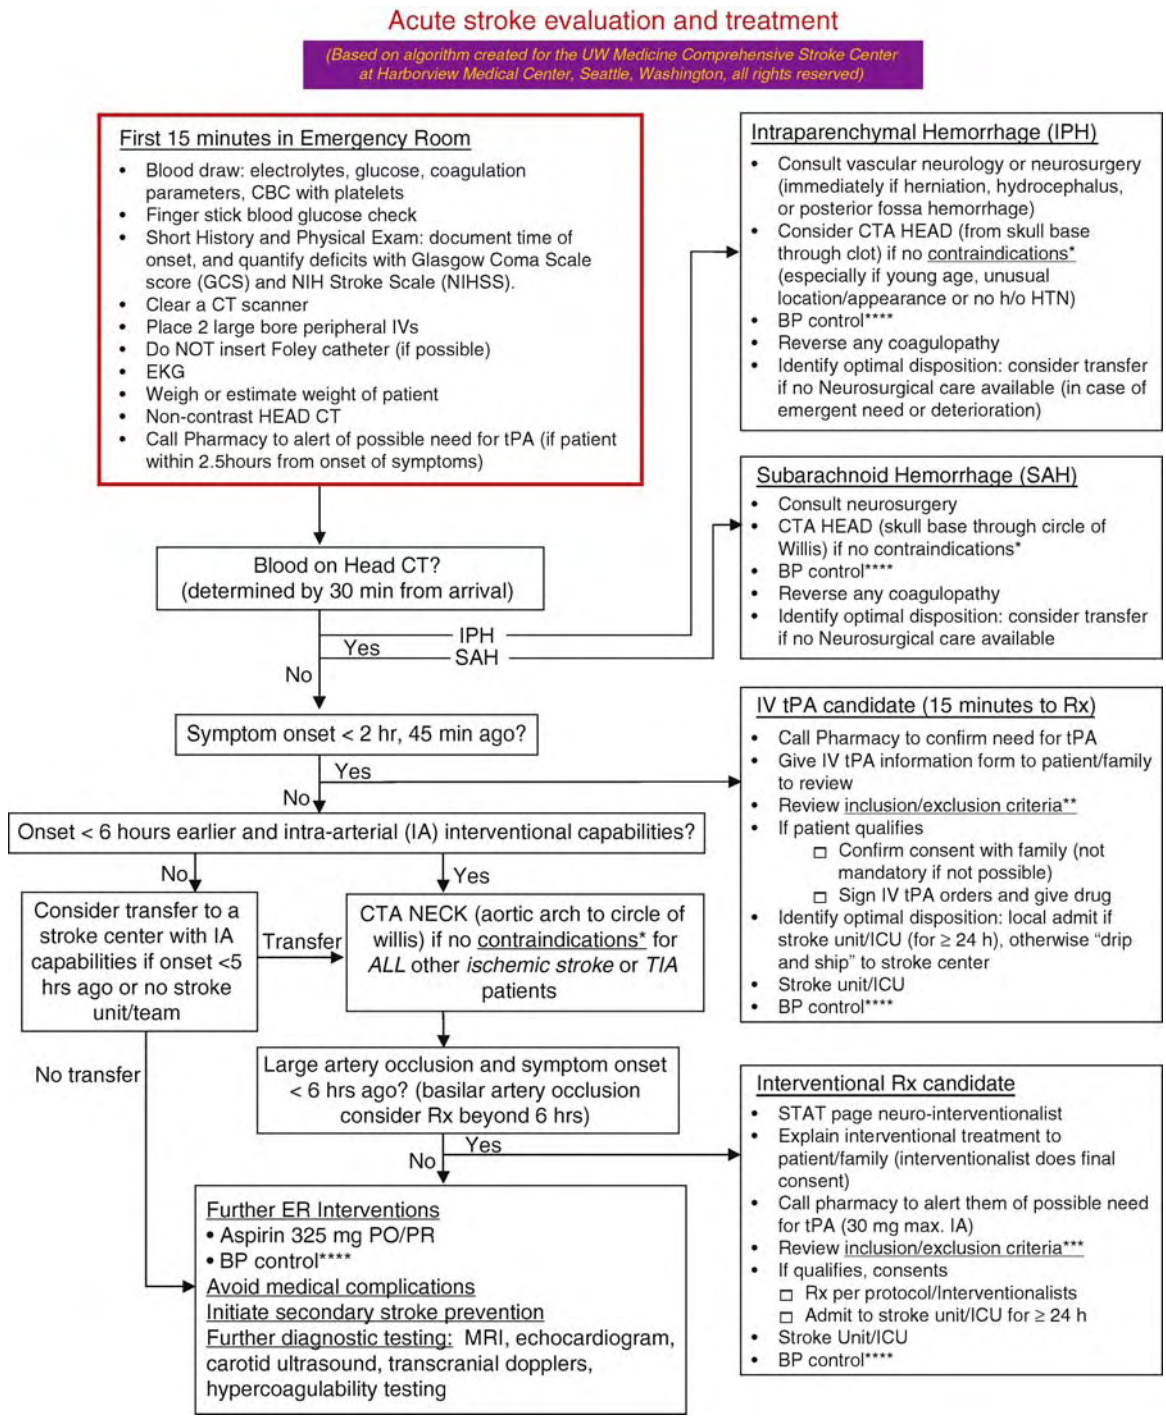
## Acute Management (See Algorithm, Fig. 2.)

An ischemic stroke is a medical emergency – "time is brain ". Patients treated in hospitals with a dedicated Stroke Team or Stroke Unit and a specialized care program for stroke patients are more likely to recover and less likely to die. Thus, if a stroke is suspected, emergency medical services should be activated immediately [5].

The goals of therapy are to restore blood flow to the ischemic area and to limit any further injury (neuroprotection). In an attempt to restore blood flow in the acute setting (less than three hours after onset of the event), ►intravenous thrombolysis is the standard of care if the patient meets the strict inclusion and exclusion criteria [5]. If the patient presents for medical care later than three hours, intraarterial thrombolysis or mechanical thrombectomy may be considered.

*Blood pressure* should be monitored carefully. If it is too high, brain edema, hemorrhagic transformation and damage of other organs may be exacerbated. If blood pressure is too low, perfusion to the rim of ischemic, but salvagable brain tissue surrounding the center of the stroke ►(the ischemic penumbra) is impaired and could enlarge the stroke. Unless the systolic pressure is >220 mmHg or the diastolic pressure is >120, blood pressure lowering medications should be withheld [5].

Other therapies are aimed at limiting further injury and salvaging brain tissue at risk (ischemic penumbra). Aspirin (ASA) should be started within 24–48 h after onset of stroke. The indications for the use of other antiplatelet agents (clopidogrel, dipyridamole) in the acute ischemic stroke setting are not clear. Anticoagulant therapy is not routinely recommended in



**Ischemic Stroke. Figure 2** Acute Stroke Algorithm.

the acute setting, but may still be considered in special circumstances (e.g., arterial dissection, thrombus seen on Echocardiogram). Neuroprotective agents such as glutamate antagonists or free radical scavengers have not been shown to be effective to date.

Finally, emphasis should be made on preventing further medical complications such as infection, hyperthermia, hyperglycemia, malnutrition, dehydration or thromboembolic events (deep vein thrombosis and pulmonary embolism).

### Secondary Stroke Prevention

Survivors of a TIA or stroke are at increased risk of another ischemic – cardiac or cerebral – event: almost a third of all strokes are recurrent attacks [7]. Thus, careful attention needs to be paid to all vascular risk factors [8]. The ways to reduce the risk of a recurrent stroke are very similar to those that can prevent a stroke in the first place. In addition to the prevention measures described in the general section on stroke, two additional procedures are sometimes important for the prevention of ischemic stroke.

- Carotid stenosis: If diagnostic workup reveals significant (>70%) carotid stenosis in a patient with a recent ischemic stroke or TIA in the vascular territory supplied by the stenosed carotid, surgical intervention (►carotid endarterectomy) is indicated. ►Carotid angioplasty and stenting can be considered in patients who are at high risk from a standard carotid endarterectomy procedure, or in the research setting. There is no role for anticoagulation in carotid stenosis.
- ►PFO: The optimal secondary prevention strategy (i.e., antiplatelet agents vs. anticoagulant therapy vs. PFO closure) is still uncertain, and current recommendations are based on insufficient evidence [9].

### Prognosis

Prognosis depends on the patient's age, type of stroke and how severe the symptoms are at the onset. Within one month of an ischemic stroke, approximately 20% of victims die, and many of survivors have some long-term disability.

### Stroke Rehabilitation

Early stroke rehabilitation services are very effective in reducing long-term disability and improving quality of life as well as reducing overall health care costs [10]. Rehabilitation doctors, Speech and Language therapists, Physical and Occupational therapists should be involved early on in the care of a stroke patient.

## Isochoric Motion

### Definition

A motion that preserves the volume of every part of a material body. Incompressible materials are characterized by the fact that the only possible motions are isochoric.

►Mechanics

## Isocortex

### Definition

Isocortex (also called neocortex) refers to the six-layered cerebral cortex, which in humans makes up the bulk of cortex. It is opposed to allocortex with different structure (the Greek "allos" means other).

►Neocortex

I

## Isodendritic Core

►Reticular Formation

## Isoforms

### Definition

Distinct types of proteins that result from alternative splicing of a pre-mRNA encoded by a single gene.

►Alternative Splicing and Glial Maturation

## Isofrequency Stripe in Auditory Cortex

### Definition

A band of neurons with very similar characteristic frequencies in the primary auditory cortex or any other auditory cortical field with a well defined tonotopy.

►Tonotopic Organization (Maps)

## Isografting

Synonym: isotransplantation

Transplantation of tissues and organ pieces between monozygotic twins, or from one animal to another of the same strain.

## Isolated Nervous Tissues

►Brain Slices

## Isometric

### Definition

The force response when a skeletal muscle or muscle fiber is stimulated to contract with muscle length held fixed. As a result, force is generated but the muscle does not undergo external shortening. Although the absence of shortening allows the muscle to generate maximal force, isometric activations produce neither work nor power.

►Force Depression/Enhancement in Skeletal Muscles
►Force Potentiation in Skeletal Muscle

## Isometric Contraction

### Definition

A period of muscle activity during which the length of the muscle fibers does not change.

►Energy/Energetics

## Isomorphism

### Definition

An *isomorphism*, defined relative to some specified structural relations, is a one-to-one correspondence between two sets of objects $A$ and $B$ that preserves those structural relations. Thus, whenever $a_1$ is related to $a_2$ in $A$, then the isomorphism corresponds these to $b_1$ and $b_2$, respectively, which are related in the same way in $B$.

The notion of isomorphism is thus dependent on the particular structural relations being considered, and a correspondence that is an isomorphism with respect to say, order, may not be an isomorphism with respect to, say, distance.

►Physicalism

## Isotherm

### Definition

A region of constant temperature within a thermal gradient.

## Isotonic

### Definition

The force response when a skeletal muscle or muscle fiber is stimulated to contract with unfixed muscle length. Muscle shortening occurs when generated force exceeds that needed to move the external load.

Although muscle shortening reduces force compared to the isometric condition, isotonic activations produce mechanical work and power. The ability of a muscle to shorten against a load is described by the force–velocity relation.

►Force Potentiation in Skeletal Muscle

## Isotropic Definition

Isotropic means having the same properties (e.g. elasticity or viscosity) in all directions.

## ITD

### Definition

►Interaural Time Difference (ITD)

## Jacksonian Motor Seizures

### Definition

►Partial seizures (or focal seizures) characterized by focal motor symptoms indicating the location of brain lesions. Focal (Jacksonian) motor seizures may result from localized lesions (injury or tumor) to the contralateral ►primary motor cortex (M1) and may start as local rapid (clonic) contractions, often at a finger, great toe or mouth corner, and then spreading over the body with loss of consciousness (Jacksonian march).

►Motor Cortex – Hand Movements and Plasticity
►Motor Cortex – Output Properties and Organization
►Primary Motor Cortex (M1)

## Jacksonian Sensory Seizures

### Definition

Epileptic attack with abnormal sensory experiences. Numbness and ►paresthesias may first be felt at a restricted spot of the body surface and thence spread over the ipsilateral body surface.

►Paresthesia

## Jacobian ($\partial x/\partial \Theta$)

### Definition

The mathematical relation that represents the amount of displacement of the endpoint position vector, $\boldsymbol{x}$, for a differential displacement of the joints, $d\boldsymbol{\Theta}$.

►Impedance Control

## JAK

### Definition

►Janus Kinases (JAKs)

## Jamming Avoidance Response (JAR)

### Definition

A behavior found in wave-type electric fish, in which two individuals with similar electric organ discharge (EOD) frequencies shift their frequencies away from each other, to reduce jamming of their active electrolocation systems and to improve discrimination of conspecific EOD waveforms.

►Conspecific
►Electric Communication and Electrolocation
►Electric Fish
►Electric Organ Discharge
►Electroreceptor Organs

## Janus Kinases (JAKs)

### Definition

Members of a family of intracellular tyrosine kinases that are involved in the JAK-STAT pathway. JAK participates in the signaling cascade of cytokines by associating with one of the intracellular domains of a cytokine receptors as a result of ligand binding. JAKs phosphorylate STATs, which then dissociate from the receptors and regulate gene expression.

►Cytokines

# Jerk

## Definition

Rate of change of acceleration (i.e. jerk is to acceleration what acceleration is to speed), or the third derivative of position with respect to time.

►Arm Trajectory Formation

# Jet Lag

## Definition

Jet lag occurs after traveling by plane across time zones. Sleep can be more or less forced into the appropriate time at destination, but it takes about a day for every time zone crossed for the other circadian rhythms to completely adjust. Rate of adjustment can be increased two- or threefold by scheduling low-dose melatonin before and after travel and by scheduling sunlight exposure after travel, depending on the phase response curves for light and melatonin. It is also important to avoid sunlight at certain times after travel across more than six time zones.

►Circadian Rhythm
►Circadian Sleep Phase Syndromes
►Melatonin

# Joint Equipollence Equations

## Definition

The joint equipollence equations relate the intersegmental forces and moments to the corresponding forces and moments produced by all internal forces about a joint. The equipollence equations state that the vector sum of all internal forces and moments about a joint is equal to the intersegmental forces and moments calculated using the inverse dynamics approach.

►Distribution Problem in Biomechanics
►Intersegmental Forces and Moments
►Inverse Dynamics Approach

# Joint Pain

Hans-Georg Schaible
Institute of Physiology, Friedrich-Schiller-University of Jena, Jena, Germany

## Synonyms

Articular pain

## Definition

Pain in a healthy joint is elicited by the impact of tissue-damaging stimuli on the joint such as hitting and twisting. These stimuli activate high-threshold nociceptors in the joint nerve and nociceptive neurons in the central nervous system that receive nociceptive joint input. Clinically relevant pain in the joint is evoked by injury, inflammatory and degenerative joint disease. Major neuronal mechanisms of clinically relevant pain include sensitization of nociceptive joint afferents and the development of central hyperexcitability.

## Characteristics

### Pain Sensation in the Joint

The major sensation from deep tissue such as joint and muscle is pain. Although sensory information from deep tissue continuously controls the activity of the motor system and supports the sense of movement and position, we are not aware of these processes. Pain influences the motor control system and usually forces the patient to restrict movements.

Joint pain is often dull and aching, and poorly localized, and is thus different from precisely localized cutaneous pain. In the normal joint, acute and short-lasting pain is elicited by hitting or twisting the joint. However, clinically relevant joint pain is different and usually appears as ►hyperalgesia or persistent pain at rest. In the hyperalgesic state, noxious stimuli cause more pain than normal, and pain is elicited by mechanical stimuli whose intensity does not normally elicit pain, such as movements in the working range and gentle pressure (palpation) [1,2].

In order to study conscious pain sensations arising from articular tissue, experimental invasive sensory testing has been carried out in humans. Pain in the normal joint can be elicited when noxious mechanical and chemical stimuli are directly applied to the fibrous structures such as ligaments and fibrous capsule. No pain is elicited by stimulation of cartilage, and stimulation of normal synovial tissue rarely evokes pain. Stimulation of fibrous structures with innocuous mechanical stimuli can evoke pressure sensations [3].

## Causes of Clinically Relevant Joint Pain

Joints are a major site of injury (e.g., sport injuries), acute and chronic inflammatory processes (e.g., gout and rheumatoid arthritis) and degenerative disease (e.g., osteoarthritis, OA, which is characterized by severe cartilage degradation and osteophyte formation). During chronic joint inflammation, such as in rheumatoid arthritis, the synovial tissue and the articular and periarticular soft tissues are initially the most important sites of inflammation, but with time the joint undergoes structural changes such as cartilage degradation, pannus formation and bone deformation. Presumably all of these changes contribute to pain, and mechanical as well as inflammatory factors may activate the nociceptive system.

OA pain shows similarities and differences to inflammatory pain. It is usually worsened by exercise and relieved at rest. Some patients suffer from night pain [4]. The site and nature of OA pain are discussed here because the cartilage is not innervated and the correlation between radiological signs (narrow joint space and osteophytes) and joint pain is poor [4,5]. MRI reveals more abnormalities, such as synovial hypertrophy, synovial effusions, and subchondral bone marrow edema lesions (which may increase intraosseal pressure), in painful OA joints than in non-painful OA joints [5]. Thus, inflammatory mechanisms may be predominant in early OA, but capsular fibrosis and muscle contracture around the joint may contribute to late OA pain. Obesity and psychological factors also may influence OA pain [4].

## Peripheral and Central Processing of Noxious Stimuli Applied to the Joint

*Joint innervation*. Joints are supplied by branches descending from main nerve trunks or their muscular, cutaneous and periosteal branches. Joint nerves contain thick myelinated Aβ (group II), thinly myelinated Aδ (group III) and a high proportion (~80%) of unmyelinated C (group IV) fibers. The latter are either sensory afferent or sympathetic efferent (each ~50%). Aβ fibers terminate as corpuscular endings of the Ruffini-, Golgi- and Pacini-type in fibrous capsule, articular ligaments, menisci and adjacent periosteum. Articular Aδ and C fibers terminate as free nerve endings in the fibrous capsule, adipose tissue, ligaments, menisci, the periosteum, and in the synovial layer. The cartilage is not innervated [1,2].

A large proportion of articular sensory neurons are peptidergic, containing substance P, CGRP, and somatostatin, but neurokinin A, galanin, enkephalins and neuropeptide Y have also been found. Neuropeptides influence the inflammatory process in the periphery and modify spinal processing of joint input. They may also affect joint afferents themselves [2].

*Response properties of joint afferents*. In single fiber recordings, joint afferents have been classified according to their mechanosensitivity. More than 50% of the Aδ fibers and most C fibers with a detectable receptive field are able to encode noxious mechanical stimuli applied to the joint. They are either weakly activated by innocuous stimuli (light to moderate pressure and movements within the joint's normal working range) and strongly activated by noxious stimuli (high intensity pressure that causes pain when applied to humans, and movements against the resistance of the tissue beyond the limit of the joint's normal working range), or they are exclusively activated by noxious stimuli. Fibers activated by noxious mechanical stimuli are thought to be the nociceptors that cause pain upon forceful twisting of the normal joint [1,2].

Some Aδ fibers and a significant proportion of C fibers do not respond to any mechanical stimulus applied to the normal joint. These "initially mechanoinsensitive" or "silent nociceptors" are only activated during inflammation [1,2]. In contrast, most Aβ fibers and about half of the Aδ fibers are low threshold units and are strongly activated by innocuous mechanical stimuli. Their message might be used to control movements and to prevent unphysiological movements. Although these units may maximally discharge during noxious stimuli, their overall discharge pattern does not discriminate between innocuous and noxious stimuli [1,2].

Most Aδ and C fibers are chemosensitive (e.g. respond to inflammatory mediators such as prostaglandins, bradykinin and others). Chemosensitivity plays a major role in the excitation and sensitization of neurons during inflammation (see below).

*Spinal cord neurons with joint input*. Neurons with joint input are located in the superficial and deep dorsal horn. Their distribution matches the spinal termination of joint afferents which project to the superficial and, in particularly Aβ and Aδ fibers, to the deep dorsal horn [1,2]. These neurons are either exclusively driven by input from deep tissue (typically from the joint and adjacent muscles), or they exhibit convergent inputs from skin, joint and adjacent muscles. Most neurons with deep input only are high-threshold and require noxious pressure onto joint and/or muscle and noxious movements to be activated, like articular nociceptors. Most neurons with convergent inputs from deep tissue and skin are wide dynamic range neurons which respond to innocuous and noxious pressure applied to deep tissue in a graded fashion. They may be activated by movements in the working range, but show much greater responses to painful movements. Often deep tissue receptive fields are located more rostral than cutaneous receptive fields [1,2].

Neurons with joint input project to different supraspinal sites (e.g. cerebellum, spinocervical nucleus,

thalamus, reticular formation) that subserve the generation of the conscious response and adaptations to pain, or they project to intraspinal (segmental) interneurons and motoneurons [1,2]. Noxious stimulation of joint afferents, acute chemical stimulation and inflammation of the knee can evoke nociceptive withdrawal reflexes and enhance spinal motor reflexes. However, during joint inflammation some γ-motoneurons develop progressive inhibition rather than facilitation, showing modification of the reflex pattern. Articular dysfunction and ligamentous strain can elicit muscle spasms [2].

Most spinal cord neurons with joint and muscle input are tonically inhibited by descending inhibitory systems that modulate spinal cord activity. These neurons are also inhibited by DNIC, diffuse noxious inhibitory control mechanisms [2].

*Supraspinal neurons with input from the joint*. The thalamus and cortex contain nociceptive neurons that are activated by nociceptive input from the joint. Most of these neurons have convergent inputs from skin and deep tissue. In the thalamus, such neurons are located in the ventrobasal complex, in the posterior complex and in the medial nucleus. Similarly, the somatosensory cortex contains a large proportion of neurons that respond to noxious stimulation, and a small proportion of these neurons is driven by deep input [2].

## Peripheral and Central Sensitization During Joint Inflammation

*Sensitization of joint afferents*. An important mechanism for the heightened pain sensitivity during inflammation is increased mechanosensitivity of joint afferent fibers. During development of inflammation in the joint, some low threshold Aβ fibers show transiently increased responses to joint movements. Importantly, the majority of Aδ and C fibers show persistent increased mechanosensitivity. Many low threshold Aδ and C fibers show increased responses to innocuous and noxious movements. Most strikingly, a large proportion of high threshold afferents is sensitized and begin to respond to innocuous movements; they may also develop ongoing discharges in the resting position. Mechanical sensitization is also an important neuronal basis for persistent hyperalgesia during chronic arthritis [1,2].

Furthermore, initially mechanoinsensitive (silent) nociceptors are sensitized. While these fibers are unresponsive to mechanical stimuli applied to the normal joint, they can develop mechanosensitivity within 1–4 h after onset of inflammation, after which they respond to movements of the joint and a receptive field upon mechanical stimulation of the inflamed tissue. Thus inflammation "recruits" further nociceptive sensory neurons for signaling of noxious events [1,2].

*Development of ►spinal hyperexcitability*. In the course of joint inflammation, spinal cord neurons with joint input develop a state of hyperexcitability. Spinal cord neurons with high threshold show a decrease of their excitation threshold such that they are activated by innocuous stimuli applied to the inflamed tissue. Both high threshold and wide dynamic range neurons show a marked increase in response to noxious stimulation of the inflamed tissue. These mechanisms contribute to ►primary hyperalgesia at the inflamed joint. With a similar time course, the neurons also give enhanced responses to mechanical stimuli applied to adjacent and even remote healthy tissue, and the total receptive field may expand. Thus the sensitivity of the spinal cord neuron is increased so that previous subthreshold inputs are now sufficient to excite the neuron. Central sensitization can persist during chronic unilateral arthritis and chronic polyarthritis [1,2].

The changes in the spinal cord are likely to account for deep referred pain and ►secondary hyperalgesia that are induced in humans by noxious stimulation of deep tissue. Numerous pathological conditions such as inflammation and OA seem to be associated with central sensitization. When a noxious stimulus (e.g., intramuscular injection of 6% NaCl), is applied to a muscle, the area in which pain is felt is larger during pathological conditions such as OA [6], suggesting a state of central sensitization.

Sensitized nociceptive afferents from inflamed tissue play a key role in initial sensitization. Obviously, these afferents not only evoke enhanced synaptic activation of spinal cord neurons to stimulation of inflamed tissue, but they also trigger the processes that increase sensitivity of spinal cord neurons. Interestingly, stimulation of primary afferents from deep tissue (muscle and joint) evokes more prolonged facilitation of nociceptive flexor reflexes than stimulation of cutaneous afferents, and capsaicin injection into deep tissue elicits more prolonged hyperalgesia than injection of capsaicin into the skin, suggesting that deep input is particularly able to induce long-term changes in the nociceptive system [2].

Tonic descending inhibition as well as DNIC are increased during acute inflammation, but may be normalized in the chronic stage of inflammation. Interestingly, inhibition is mainly observed on neurons with input from the inflamed region (thus attenuating primary hyperalgesia), but processing in neurons with input from neighboring tissues may instead be enhanced, thus facilitating secondary hyperalgesia [2].

*Enhanced activity at the thalamacortical level*. In polyarthritic rats, many neurons in the ventrobasal complex respond to movements and gentle pressure onto inflamed joints and often show long-lasting afterdischarges whereas only few neurons respond to these stimuli in normal rats. Furthermore, neurons in the nucleus centralis lateralis acquire input from the inflamed joint that is not apparent in normal animals. Similarly, neurons in superficial cortical layers that do

not respond to joint stimulation in normal rats start to respond to joint stimulation in polyarthritic rats [2]. These findings indicate substantial neural plasticity at the thalamocortical level that may contribute to inflammatory deep tissue pain. It is unknown whether these alterations mirror the altered spinal processing or whether additional elements of neural plasticity are generated in the thalamus and/or cortex.

## Molecular Mechanisms of Peripheral Sensitization

Sensitization (►Peripheral sensitization) results from the effect of inflammatory mediators that bind to receptors in the membrane of sensory nerve endings, and from changes in the intrinsic properties of the neurons. Dorsal root ganglion (DRG) or trigeminal neurons from inflamed tissue maintain enhanced excitability even when the neurons are removed from the ganglion and acutely dissociated several days after inflammation of the joint [7].

Effects of inflammatory mediators on joint afferents have been summarized in detail elsewhere [2]. These mediators affect Aδ and/or C fibers, not Aβ fibers, they have an effect only in subpopulations of the units, they may affect high as well as low threshold Aδ and C fibers, and they render some silent nociceptors mechanosensitive.

Injection of bradykinin into the joint artery causes an immediate short-lasting activation (<1 min) of joint afferents and a sensitization to subsequent mechanical stimuli that lasts minutes (even when bradykinin did not excite the neuron). Both $PGE_2$ and $PGI_2$ cause ongoing discharges and/or sensitization to mechanical stimulation of the joint and sensitize joint afferents to the effects of bradykinin. $PGE_2$ and bradykinin together can cause a greater mechanical sensitization than bradykinin or $PGE_2$ alone. Conversely, NSAIDs such as aspirin and indomethacin, which block prostaglandin synthesis, reduce spontaneous discharges from acutely and chronically inflamed joints and attenuate responses to mechanical stimulation. Serotonin also sensitizes joint afferents to mechanical stimuli [1,2]. Cytokines such as TNFα, interleukin1-β and interleukin-6 (IL-6) are of particular importance to the progression of arthritis. They play an important role in neuropathic pain, but IL-6 also induces a long-lasting sensitization of C fibers of the joint to mechanical stimulation [8].

ATP, adenosine, capsaicin and anandamide excite proportions of joint afferents (the latter suggesting the presence of the TRPV1 receptor). Substance P and VIP (vasoactive intestinal polypeptide) increases, whereas somatostatin and endomorphin reduces mechanosensitivity in numerous afferents; galanin, neuropeptide Y, and nociceptin sensitize some neurons and reduce responses of other neurons. Whether the different patterns of peptide effects (excitation or inhibition) are dependent on the functional state of the neuron is not known.

Receptor expression in DRG neurons can change in the course of arthritis (e.g. downregulation of mu-opioid receptors or biphasic regulation of somatostatin receptors [9]). Disease processes are dynamic and, therefore, it is likely that different cells and molecules are important at different times in chronic inflammatory or degenerative processes [4]. Hence the molecular mechanisms of nociception may change over time.

## Molecular Mechanisms of Spinal Sensitization

During development of inflammation in the joint, the intraspinal release of glutamate and neuropeptides is enhanced [2]. In the normal joint, only noxious compression of the joint enhances the intraspinal release of substance P, neurokinin A and CGRP above baseline. In the inflamed joint, these excitatory peptides are released intraspinally even by innocuous joint compression [2]. In addition, the intraspinal milieu is altered by (enhanced) release of other mediators (e.g. $PGE_2$) [2].

Both AMPA/kainate (non NMDA) and NMDA receptors are involved in the generation and maintenance of inflammation-induced spinal hyperexcitability. Antagonists at both receptor types can reduce responses of spinal neurons to mechanical stimulation even in a chronic model of inflammation [2]. The excitatory neuropeptides (see above) facilitate the responses of spinal neurons to mechanical stimulation of the joint and further the development of inflammation-evoked hyperexcitability [2]. Topical application of $PGE_2$ to the spinal cord surface facilitates the responses of spinal neurons to mechanical stimulation of the joint, as also produced by knee joint inflammation, and topical application of the COX inhibitor indomethacin to the spinal cord before inflammation attenuates the development of hyperexcitability, showing that spinal prostaglandins are involved in the generation of inflammation-evoked spinal hyperexcitability [10].

## Definition

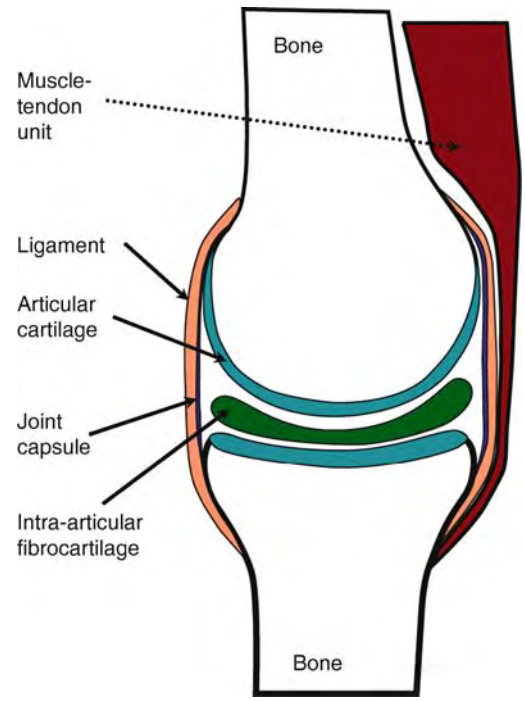
The union of two or more rigid elements of the skeleton. Commonly referring to an articulation of the skeleton where two or more adjacent bones meet and move relative to one another. Also refers to articulations of the exoskeletal elements of invertebrates – especially arthropods and bivalves. In vertebrates, each joint is an independent organ system that is variously composed of bones, ►cartilages, articular cartilages, intra-articular ►fibrocartilages (e.g. disc, meniscus, labrum), joint capsule, ligaments, tendons, retinaculae, fat pads, and ►synovium (Fig. 1).

## Characteristics

Joints can be classified into two types based on macroscopic inspection: diarthroses have a cleft that separates the skeletal elements; in synarthroses, solid tissue connects the skeletal elements. This macroscopic classification is extended by microscopic inspection. Diarthroses are all termed "synovial" joints, whereas synarthroses are subclassified based on histomorphology into "cartilaginous" and "fibrous" joints.

Synovial joints are characterized by hyaline articular cartilages, which form a thin veneer on the ends of the bones, and contain a small volume of synovial fluid in the so-called joint cavity. Synovial joints are enveloped by a joint capsule, which consists of a tough outer layer that helps stabilize the joint, and a delicate inner synovial layer, which produces synovial fluid. Synovial joints typically allow substantial movement (e.g. the knee and hip); a few synovial joints such as the sacroiliac joint have relatively little motion between



**Joints. Figure 1** Joints may be classified based on their histomorphology, shape, or the quantity and quality of joint movement.

the bony segments, as its joint capsule is highly reinforced with many stout ligaments. Embryonic movement caused by muscle contraction is necessary for the normal development of synovial joint tissues, as well as for the formation of the joint "cavity." Normally the joint cavity contains a small volume of synovial fluid, which is viscous and is enriched with special molecules (notably hyaluronan and the glycoprotein known variously as lubricin, superficial zone protein, and megakaryocyte stimulating factor [1]) that have very low coefficients of friction.

Cartilaginous joints lack joint cavities characteristic of synovial joints, and their apposing bone surfaces are joined by cartilaginous or fibrocartilaginous elements. Compared to most synovial joints, cartilaginous joints allow relatively little movement. The pubic symphysis and the ►intervertebral disc are typical examples of cartilaginous joints. During long bone growth, the growth plate cartilage separates two parts of the growing bone, and is said to form a cartilaginous joint known as a synchondrosis. Fibrous joints also lack joint cavities, and the apposing bone surfaces are joined by a fibrous rather than cartilaginous connective tissue. Compared to synovial and cartilaginous joints, fibrous joints typically allow even less motion among the skeletal elements. In humans, there are three types of fibrous joints: ►suture, syndesmosis and gomphosis. Suture is found between the flat bones of the skull, syndesmoses refer to the tibiofibular and radioulnar interosseous membranes, and gomphoses refers to the union of the teeth and the jaw bones, which are connected in the tooth socket by the specialized periodontal ligament.

Joints can also be classified based on shape (Table 1). As shape is a primary determinant of joint motion, it is possible to define the primary motions allowed by the number of rotational axes (uniaxial, biaxial, triaxial). Gliding joints may not have any rotational axes and their motion can be called multiaxial.

Joints serve two functions in opposition: motion and stability. The geometry of the bones and cartilages largely determines the mobility of a joint; the degree of internal and external support offered by the geometry of the ligaments and intra-articular cartilages largely determines joint stability. The bones, cartilages, capsule, and ligaments confer "static" stability to the joint; the tendons, by virtue of their attachment to skeletal muscle, confer "dynamic" support to the joint and can influence joint stability depending on the state of neuromuscular tone. The static constraints of joints define the normal range of joint motion; when this normal range is exceeded, one or more of the static constraints of the joint sustains a so-called hyperextension or hyperflexion injury. When the stabilizing structures fail to keep the bones in their normal position, the joint is said to be either fully or partially dislocated (subluxed). Dislocation or subluxation is a pathological state of the joint, typically associated with excessive laxity (e.g. Ehlers Danlos, a family of genetic diseases of collagen and other extracellular matrix proteins) or trauma.

Joints can also be classified functionally [2,3], based on the relative quantity of movement taking place at an articulation (Table 2). Similarly, the quality of movement between the opposing elements of a joint can be categorized (Table 3). Common movements of freely moving joints have special denominations (Table 4).

With the possible exceptions of synovium and bone, the physiology of the various connective tissue organs in joints is typically absent from textbooks. As the main function of the joint is to transmit loads from bone to bone, the functional anatomy of joints historically has been described in textbooks of biomechanics (the study of mechanical and material behavior of biological organs) and kinesiology (the study of bodily movement). Until recently, joint connective tissue organs have challenged physiologists, in part because many of the traditional physiological methods (e.g. measurements

**Joints. Table 1** Joints categorized by shape

| Shape category | Primary motion | Example |
|---|---|---|
| Ball-and-socket | Triaxial | Hip, shoulder |
| Hinge (ginglymus) | Uniaxial | Ankle, elbow |
| Saddle (sellar) | Biaxial | Thumb |
| Ellipsoid (condyloid) | Biaxial | Knee |
| Plane (gliding) | Multiaxial | Sternoclavicular joint |
| Pivot | Uniaxial | Atlantoaxial joint |

**Joints. Table 2** Joints categorized by amount of movement

| Relative movement | Functional category | Morphological classifications |
|---|---|---|
| Minimal movement | Synarthroses | Fibrous joints (sutures, gomphoses) |
| | | Cartilaginous joints (growth plates) |
| Modest movement | Amphiarthroses | Fibrous joint (interosseous ligaments) |
| | | Cartilaginous joint (symphysis, intervertebral disc) |
| Free movement | Diarthroses | Synovial joints |

**Joints. Table 3** Joints categorized by type of movement

| Joint movement | Description of movement |
|---|---|
| Gliding | Surfaces sliding against one another |
| Angulation | Movement of a bone at an angle relative to a point of contact (rolling/sliding) |
| Rotation | Rotation (spin) about an axis with respect to a point of contact |
| Circumduction | Complex circular motion of a bone with respect to its contact surface that may include gliding, angular movement, and rotation |

**Joints. Table 4** Joints movements action

| Movement | Definition | Example |
|---|---|---|
| Adduction, Abduction, | Toward, away from the midline | Arm, fingers |
| Flexion, Extension | Reduces, increases angle of joint | Elbow, knee |
| Plantarflexion, dorsiflexion | Foot aimed down, up | Ankle |
| Protraction, retraction | Outward, inward | Jaw |
| Elevation, depression | Up, down | Jaw, Shoulders |
| Inversion, eversion | Medial, Lateral rotation | Foot |
| Pronation, Supination | Medial, lateral rotation | Forearm, Foot |
| Circumduction | Complex movement arc | Shoulder, thumb |
| Opposition | Moving thumb to fingers | Thumb |
| Lateral flexion | Movement from the midline | Spine |

of blood flow, gas exchange, electrolyte flux, and electrophysiology) are relatively insensitive when applied to tissues that contain relatively few cells, vessels, and nerves. Nonetheless, joint physiology, particularly the physiology of joint pain, is a rapidly emerging and important area of study.

Unlike articular cartilage, which lacks both vessels and nerves, the synovium and the bones are rich in small diameter blood vessels as well as nerves, which make them common sites of joint inflammation that is known as ►arthritis, a disease that is often associated with joint pain known as ►arthralgia. The collection of antigen-antibody complexes in the small vessels of the synovium can induce the release of bioactive factors from reactive leukocytes and cause arthralgia, either acutely (e.g. the common cold) or chronically (e.g. systemic inflammatory diseases). Inflamed synovial joints typically contain large volumes of dilute synovial fluid and can contain numerous leukocytes. In certain autoimmune diseases characterized by chronic systemic inflammation (e.g. rheumatoid arthritis), the inflamed synovium forms a so-called "pannus," a membranous structure filled with inflammatory cells that can secrete various enzymes and factors that are locally destructive. Some metabolic diseases promote the formation of crystals (e.g. sodium urate, calcium pyrophosphate, calcium oxalate, homogentisic acid) in joint tissues, which typically induces a destructive inflammatory response. Synovial joints are normally sterile, but they can frequently be seeded with infectious organisms, a condition known as septic arthritis, which can cause considerable destruction of joint tissues. Possibly, due to their hypovascularity, neoplastic diseases of joints are exceedingly rare, though some bone tumors may cause joints to fail when the weakened bony support beneath the articular cartilages collapses.

The destruction of joint tissues, whether by injury or inflammation, leads to abnormal joint function, which is known as ►arthropathy. The progressive destruction of joint tissues ultimately leads to joint failure when the joint can no longer function properly. Joint failure can be initiated by insufficiencies in the cartilages, ligaments, bones, and intra-articular fibrocartilages. The loss of the articular cartilage is a hallmark pathological feature of osteoarthritis, a so-called degenerative joint disease. Osteoarthritis is the most prevalent joint disease; it most commonly involves the mobile weight-bearing joints (hip, knee, shoulder) as well as the fingers, but occurs only rarely in the ankle. The etiology of osteoarthritis is unknown and its course is both insidious and progressive. As the articular cartilage contains no nerves, the underlying disease process may precede significantly the onset of symptoms. Treatments and therapies for osteoarthritis

are directed at managing the symptoms of the disease, primarily to reduce pain and inflammation.

Depending on the size and location, failed joints may be replaced by artificial joints (endoprostheses), either totally or partially. Total joint replacement (total joint ►arthroplasty) involves the complete surgical replacement of the articulating surfaces of the joints and usually their bony support with artificial materials, typically with composites of metal and plastic. Partial joint replacements (hemiarthroplasties) are surgeries in which one side of a joint or one surface of a joint is replaced. Interpositional arthroplasty is reconstructive surgery that reshapes part of a joint and adds an artificial ►prosthesis (e.g. a plastic or metal disc) between the bones forming a joint. Regardless of material, artificial joints do not have the regenerative abilities of biological tissues and repeated loading of these inanimate materials eventually leads to material fatigue and failure. Hence, after receiving a joint replacement, younger active patients may be faced with a revision or replacement arthroplasty. There is currently considerable interest and research in bioprosthetics, which are biological replacement materials developed by ►tissue engineering, for use in arthroplasty.

## J1/Tenascin

### Definition

Also called tenascin-R and is one member of the tenascin family.

## Jun

### Definition

A family of proteins involved in the formation of trancriptionally active complexes. Members of the Jun family (c-Jun, JunB and JunD) can dimerize with each other as well as members of the Fos protein family to form these active complexes. In some neuronal populations axon injury increases the expression of c-Jun and the active transcription factor AP-1.

## Junctin

### Definition

A 20-kDa transmembrane protein located in the junctional sarcoplasmic reticulum (terminal cisternae) that forms a supramolecular complex with casequestrin, triadin and RyRI, the sarcoplasmic reticulum $Ca^{2+}$ release channel in skeletal muscle, which functions to anchor calsequestrin and thereby increase $Ca^{2+}$ buffering close to sites of SR $Ca^{2+}$ release.

## Kölliker-Fuse Nucleus

### Synonyms
Nucl Subparabrachialis (Kolliker-Fuse); Subparabrachial nucleus (Kolliker-Fuse)

### Definition
The nucleus belongs to the parabrachial area and partially corresponds to the functionally defined pneumotactic center. The nucleus receives afferents from the caudal part of the solitary nucleus and the ventrolateral superficial reticular area.

Efferents ascend to the preoptic area and to the central amygdaloid nucleus. The most important efferents go to the lower myelencephalon and the spinal cord.

## KCC2

### Definition

A neuron-specific K-Cl cotransporter that induces a developmental shift to render GABAergic transmission from depolarizing to hyperpolarizing.

►Development of the Respiratory Network

## K-complex

### Definition

A high amplitude (>100 μV), slow potential (~0.5 s) recorded on the electroencephalogram (EEG) from the cerebral cortex. It was originally observed following auditory stimulation (K for knock) in drowsy individuals. More recently, a similarly shaped wave was recognized in the slow EEG oscillations during sleep, particularly Stage 2 slow wave sleep in humans. In this case, the K-complex is often followed by a sleep spindle (spindle shaped bursts of waves at 12–14 Hz), recurring several times a minute and also evocable by sensory stimulation.

## Kernicterus

### Definition

Kernicterus is the pathological term to indicate the deposition of unconjugated bilirubin with a characteristic pattern in the brain causing degenerative lesions.

Brainstem regions typically affected in kernicterus include the basal ganglia, especially the globus pallidus and subthalamic nucleus, metabolic sector of the hippocampus, oculomotor nuclei and ventral cochlear nuclei. Other susceptible areas are the cerebellum, especially Purkinje cells. Abnormalities of the auditory brainstem nuclei are associated with deafness, hearing loss, and a new entity known as auditory neuropathy. The term bilirubin encephalopathy is used to denote the clinical condition associated with elevated bilirubin.

►Encephalopathy (or Acute Organic Brain Syndrome)
►Glial and Neuronal Reactivity to Unconjugated Bilirubin

## Key Stimulus

### Definition

Stimulus that elicits a certain behavior just as a key fits into a lock. The red belly of a stickleback male elicits fighting behavior in other males (see also Sign Stimulus).

## KH Domain

### Definition

An RNA binding motif identified first in the hnRNPK (heterogeneous nuclear ribonucleoprotein K).

►Alternative Splicing and Glial Maturation

## Kidney

►Visceral Afferents

## Kinase

### Definition

An enzyme that regulates a phosphorylation–dephosphorylation reaction.

## Kinds, Natural

### Definition

A natural kind is a class of (relevantly) similar things; membership in that class is determined by the presence of a presumed underlying common nature. Natural kind terms like "oak," "water" or "tiger" refer to classes of things with theoretically interesting essences which may be unknown to us or about which we may be mistaken. Scientific essentialism holds that the essences of kinds – what it is for something to be an oak, water or a tiger – are not stipulated by definition, but discovered by means of empirical investigation. That for something to be water is for it to be $H_2O$, for instance, was the empirical discovery of the essence of the thing people use to call "water" (but did not change the meaning of the term "water"). If this is correct, reality is populated by mind-independent natural kinds of things, which are characterized as such by the fundamental, intrinsic causal powers which they possess, although there are lively debates in biology and philosophy about precisely what factors determine a kind's essence.

►Epiphenomenalism

## Kinematics

### Definition

As regards biomechanics, kinematics refers to the description of the orientation and motion of objects (position, velocity, acceleration) using words, diagrams, numbers, graphs, and equations, without considering the forces that act on these objects.

## Kinematics of Deformation

Marcelo Epstein
Schulich School of Engineering
University of Calgary, Calgary, AB, Canada

### Definition

The part of ►mechanics that deals with the geometric description of motion and ►deformation.

### Description of the Theory

Leaving aside the rigorous definition of a ►material body and of classical space-time as ►differentiable manifolds, the notion of a ►*configuration*, that is a manifestation of the body in space, is accepted as a primitive concept. Two configurations are related by a *deformation*, namely a mapping between the positions of the material particles (making up the body) in the first (or *reference*) configuration and their counterparts in the second (or *spatial*) configuration. The reference configuration is assumed to be fixed, while the spatial configuration evolves in time. Adopting (for simplicity, Cartesian) coordinate systems $X^I$ and $x^i$, respectively in the reference and spatial configurations, a deformation is represented by three smooth invertible functions of the form $x^i = x^i(X^1, X^2, X^3)$, with $i = 1, 2, 3$. A *motion* is a one-parameter family of deformations $x^i = x^i(X^1, X^2, X^3; t)$, the parameter $t$ representing time. The ►*deformation gradient* at a point $\mathbf{X}$ and at time $t$ is the two-point tensor $\mathbf{F}$ whose matrix representation in the coordinate systems used is:

$$F^i_I = \frac{\partial x^i}{\partial X^I}, \tag{1}$$

where the partial derivatives are calculated at the point in question and at the given time.

To interpret its physical meaning, let $dx^i$ be the components of a small spatial segment made up of the material particles comprising the segment with components $dX^I$ in the reference configuration. By the chain rule of differentiation:

$$dx^i = F^i_I \, dX^I. \tag{2}$$

In this formula and henceforth, ►Einstein's summation convention for diagonally repeated indices is used. The matrix $\mathbf{F}$ contains thus all the information regarding the first-order approximation of the deformation in the neighborhood of the point. For obvious reasons, it is convenient to split this information into that part that corresponds to a mere rigid-body motion of the neighborhood and the part corresponding to an actual change of size and shape. According to the ►*polar decomposition theorem* of algebra, every non-singular

matrix **F** is uniquely decomposable into the product of an orthogonal matrix **R** and a symmetric positive-definite matrix **U**, as follows: **F** = **RU**. The orthogonal matrix **R** represents a rigid rotation (possibly followed by a reflection), while the matrix **U**, when expressed in an orthogonal eigenbasis, can be reduced to a diagonal form, clearly showing that it represents stretches in three mutually perpendicular (principal) directions. Each of the principal stretches is the ratio between the new and the original length of an infinitesimal length element along the corresponding principal direction. The tensor $\mathbf{C} = \mathbf{U}^2$ is called the *right Cauchy-Green tensor*. The tensor $\mathbf{E} = (\mathbf{C}\text{-}\mathbf{I})/2$ (**I** being the identity) is known as the *Lagrangian strain tensor*. It vanishes if, and only if, the deformation of the neighborhood is rigid. There exists an alternative (left) polar decomposition of the form **F** = **VR**, where $\mathbf{V} = \mathbf{R}\mathbf{U}\mathbf{R}^{\mathrm{T}}$ is symmetric and positive-definite. It differs form the previous one by the order in which the effects of stretching and rotation are applied. The square $\mathbf{B} = \mathbf{V}^2$ is called the *left Cauchy-Green tensor*. Let $J$ denote the determinant of **F**. Since the rotation tensor **R** has a unit determinant, it follows from the polar decomposition theorem that $J = det(\mathbf{U}) = det(\mathbf{V})$. But the determinant of **U** is the product of the three principal stretches and therefore represents the ratio between the spatial and the referential volume elements occupied by the same material particles. Denoting the referential and spatial volume elements respectively by $d\omega$ and $d\Omega$,

$$d\omega = J\, d\Omega. \tag{3}$$

A motion with a point-wise constant $J$ (as time goes on) is called ►*isochoric* or *volume preserving*. Let **N** and **n** denote the unit exterior normals to elements of area $dA$ and $da$ in the reference and spatial configurations, respectively, comprising the same material particles. It can be shown that they are related by:

$$da\ \mathbf{n} = J\, \mathbf{F}^{-T}\, dA\ \mathbf{N}. \tag{4}$$

Equations 2, 3 and 4 clearly display the geometrical significance of the deformation gradient in relating linear, area and volume dimensions of corresponding first-order material neighborhoods in the reference and spatial configurations.

The ►*velocity* **v** of a particle **X** at time $t$ is given in spatial components as:

$$v^i = \frac{\partial x^i}{\partial t}, \tag{5}$$

where the partial derivatives are calculated at **X** and $t$. Any field $\psi$ of interest (for example, temperature), can be given in its *spatial* (or ►*Eulerian*) or in its *referential* (or ►*Lagrangian*, or ►*material*) description. In the spatial description the field is specified as a function of the spatial coordinates $x^i$ and time, $\psi = \psi(x^i, t)$, while the referential description makes use of the referential coordinates $X^I$ and time, $\psi = \psi_o(X^I, t)$. The two descriptions are related by the motion, namely,

$$\psi = \psi(x^i, t) = \psi(x^i(X^I, t), t) = \psi_o(X^I, t). \tag{6}$$

The partial time-derivative of the function $\psi_o(X^I, t)$ represents the rate of change of $\psi$ at a specific particle, while the partial time-derivative of the spatial description $\psi(x^i, t)$ represents the rate of change of $\psi$ as seen by an observer fixed in space. Thus, for instance, in steady-state conditions of flow of a liquid through a tapered pipe, the spatial observer would report a zero rate of speed, while in fact the particles themselves are accelerating. To recover the particle-wise rate of change from the spatial description the chain rule of differentiation is applied to the previous equation to obtain:

$$\frac{D\psi}{Dt} = \dot{\psi} = \frac{\partial \psi_o}{\partial t} = \frac{\partial \psi}{\partial t} + \frac{\partial \psi}{\partial x^i} v^i, \tag{7}$$

where two alternative notations have been used to denote this ►*material time-derivative*. An interesting application is the calculation of the ►*acceleration* ***a*** when the velocity field is given in the Eulerian description, as is often the case in fluid mechanics:

$$a^i = \frac{Dv^i}{Dt} = \frac{\partial v^i}{\partial t} + \frac{\partial v^i}{\partial x^j} v^j. \tag{8}$$

It is important to note that in the Lagrangian description (namely, when the velocity field is given as $v^i = v^i(X^I, t)$), the acceleration is simply the partial time-derivative. The extra term needed in the Eulerian description is sometimes called the *convective term*. It consists of the contraction of the spatial gradient of the velocity with the velocity itself.

A hidden dependence on the choice of reference configuration affects the expression of physical quantities, particularly in the Lagrangian description. Let $\mathbf{F}_0$ and $\mathbf{F}_1$ represent the deformation gradients of the same spatial configuration with respect to two different reference configurations, with coordinates $X^I$ and $Y^I$ respectively and let **H** denote the deformation gradient of the second with respect to the first, namely:

$$H^I_J = \frac{\partial Y^I}{\partial X^J}. \tag{9}$$

Clearly, by the chain rule, $\mathbf{F}_0 = \mathbf{F}_1\ \mathbf{H}$. Taking the material time-derivative yields $\dot{\mathbf{F}}_0 = \dot{\mathbf{F}}_1\, \mathbf{H}$, since **H** is independent of time. The product $\mathbf{L} = \dot{\mathbf{F}}_0\, \mathbf{F}_0^{-1} = \dot{\mathbf{F}}_1\, \mathbf{F}_1^{-1}$ is, therefore, independent of reference configuration. To find its physical meaning, consider the material time-derivative of the polar decomposition, namely:

$$\dot{\mathbf{F}} = \dot{\mathbf{R}}\mathbf{U} + \mathbf{R}\dot{\mathbf{U}}, \tag{10}$$

whence:

$$\mathbf{L} = \dot{\mathbf{F}}\mathbf{F}^{-1} = \dot{\mathbf{R}}\mathbf{U}\mathbf{F}^{-1} + \mathbf{R}\dot{\mathbf{U}}\mathbf{F}^{-1}. \tag{11}$$

Since, as shown, this expression is independent of the reference configuration, the present configuration may be adopted as reference, whereby $\mathbf{F}_t = \mathbf{R}_t = \mathbf{U}_t = \mathbf{I}$, where the subscript $t$ is a reminder of the peculiar choice of reference configuration. It may be concluded that:

$$\mathbf{L} = \dot{\mathbf{F}}_t = \dot{\mathbf{R}}_t + \dot{\mathbf{U}}_t. \tag{12}$$

It follows from the first equality in (12), by the commutativity of mixed partial derivatives, that $\mathbf{L}$ is the *spatial* ►*velocity gradient*, so that Eq. 8 can be rewritten as:

$$a^i = \frac{\partial v^i}{\partial t} + L^i_j v^{j.} \tag{13}$$

Moreover, the tensors $\mathbf{D} = \dot{\mathbf{U}}_t$ and $\mathbf{W} = \dot{\mathbf{R}}_t$ are, respectively, the symmetric and skew-symmetric parts of $\mathbf{L}$ and, according with Eq.10, can be interpreted as the "infinitesimal" versions of $\mathbf{U}$ and $\mathbf{R}$ in the polar decomposition theorem. They are known, respectively as the ►*stretching* (or *rate of deformation*) and the ►*spin* (or *vorticity*) tensors. Their component versions are:

$$D_{ij} = \frac{(v_{i,j} + v_{j,i})}{2}\ ,\ W_{ij} = \frac{(v_{i,j} - v_{j,i})}{2}, \tag{14}$$

where commas denote partial derivatives.

The content of an extensive physical quantity within a spatial volume ω may be given in terms of the integral of a density ψ. As time goes on, this content will in general change. If the rate of change of this content is calculated following the material particles, the volume ω will itself be a function of time, so that this is another instance of a material time-derivative. According with *Reynolds' transport theorem*:

$$\frac{D}{Dt}\int_\omega \psi\, d\omega = \int_\omega \left(\frac{D\psi}{Dt} + \psi\, div(\mathbf{v})\right) d\omega, \tag{15}$$

where *div* stands for the spatial divergence. Note that *div*(**v**) = *trace*(**L**). Invoking the *divergence theorem* of vector calculus, this equation can also be written as:

$$\frac{D}{Dt}\int_\omega \psi\, d\omega = \int_\omega \frac{\partial \psi}{\partial t} d\omega + \int_{\partial\omega} \psi\, \mathbf{v}.\mathbf{n}\, da. \tag{16}$$

Just as in classical mechanics, the motion of a body presents itself differently to different observers. From the technical point of view, the physical space is a *Cartesian affine space*, which is roughly something that becomes a vector space once an origin is chosen. This vector space is endowed with a special inner ("dot") product (consistent with the theorem of Pythagoras), which is assumed to have an intrinsic physical meaning. A *frame* consists of the choice of an origin and of a right-handed orthonormal basis (three unit and mutually perpendicular vectors). The coordinates of one and the same point present themselves in two different frames, therefore, in ways that are not completely arbitrarily related, precisely because of this orthonormality. In other words, both frames must agree on the measurement of distances, and this is possible if, and only if, the coordinates $x^i$ and $x^{*i}$ in the two frames are related by the formula:

$$x^{*i} = c^i + Q^i_j x^j. \tag{17}$$

Here, $Q^i_j$ are the entries of an orthogonal matrix, thus guaranteeing the preservation of the dot product, while $c^i$ are the components (in the "starred" frame) of the vector that joins the two origins. Notice that a change of frame does not affect the reference configuration, only the spatial one. In fact, the reference configuration can be seen, in principle, as just a coordinate chart of the body manifold, without any connotation of "presence" in physical space.

As far as time is concerned, in the non-relativistic setting two observers may disagree only to the extent that their time measurements are related by $t^* = t + a$, $a$ being a real constant. Returning now to the complete space-time notion of observer, it is established that two physical observers can differ only by a time-dependent change of frame, so that the motions recorded by two observers must be related by:

$$x^{*i} = c^i(t) + Q^i_j(t)\, x^j. \tag{18}$$

Two observers are said to be *inertially related* if $\ddot{c}^i(t) = \dot{Q}^i_j(t) \equiv 0$, where a superimposed dot indicates differentiation with respect to time. These formulas correspond to the statement that the origins of the frames recede from each other at a constant velocity, while the relative orientation of the bases remains constant (no "relative angular velocity"). The equivalence relation of being inertially related splits all possible observers into equivalence classes, of which Isaac Newton affirms that one, and just one, is to be preferred to all others for the formulation of the laws of mechanics.

## Kinetic Energy

### Definition

In classical mechanics (of particles) the kinetic energy of a particle is given by one-half of the product of the mass of the particle times the square of its speed (the speed being the magnitude of the velocity vector). In continuum mechanics, the kinetic energy density is obtained in a similar manner using the mass density instead of the mass. The total kinetic energy is then obtained as the integral of the kinetic energy density over the body.

## Kirchhoff's Conservation Laws

### Definition

Kirchhoff's current law states that, at any instant of time, the sum of the instantaneous values of all the electrical currents flowing towards a point (node) is equal to the sum of the instantaneous values of all the electrical currents flowing away from the point.

Kirchhoff's voltage law states that, at any instant of time, the algebraic sum of the voltage rises is equal to the algebraic sum of the voltage drops, both being taken in the same direction around the closed loop.

## Klenow Fragment

### Definition

DNA polymerase I from E. coli is commonly used in many applications of molecular biology. This holoenzyme not only has DNA polymerase activity but it also has 5'-> 3′ and 3′-> 5′ exonuclease activity. However, 5′-> 3′ exonuclease activity is undesirable in some applications. When DNA polymerase I is exposed to the protease subtilism the molecule is cleaved into two fragments. The smaller fragment retains the 5′->3' exonuclease activity. The larger fragment, the Klenow fragment, retains the DNA polymerase and 3'->5' exonuclease activity.

## Klippel-Feil Syndrome

### Definition

Klippel-Feil syndrome results from an unusual connectivity of ►corticospinal neurons that bifurcate to make connections to ►motoneurons on both sides resulting in bilateral voluntary movements.

►Corticospinal Neurons

## Klüver-Bucy Syndrome

### Definition

A behavioral syndrome first produced in 1937 when Heinrich Klüver and Paul Bucy removed large portions of the temporal lobes in monkeys. Monkeys with these ablations exhibited a profound loss of fear, as well as hypersexuality, hyperactivity and inappropriate mouthing of inedible objects. In general, it appeared that these amygdalectomized monkeys were unable to recognize the emotional or behavioral significance of visual stimuli. Subsequent studies suggested that most of these behavioral abnormalities were due to the removal of the amygdala in the ablations.

►Amygdala

## Knockout

### Definition

A transgenic knockout is an animal that has been engineered so that the protein encoded for by a gene is eliminated. In this way the function of the gene can be studied by comparing a biological process in the knockout and wildtype organism.

## Knowledge

Gerhard Ernst
Seminar für Philosophie, Logik und Wissenschaftstheorie, Ludwig-Maximilians-Universität München, München, Germany

### Definitions

One of the main concerns of epistemology is to answer the question of what, by its very nature, knowledge is. In order to elucidate the nature of (personal propositional) knowledge an analysis of the sentence "(Subject) S knows (the proposition) that p" in terms of (individually) necessary and (jointly) sufficient conditions for this sentence to be true (►Conceptual analysis) has been sought.

### Description of the Theory

#### The Standard Analysis of Knowledge

A necessary condition hardly ever disputed for the sentence "S knows that p" to be true is that it is the case that p. A second necessary condition widely accepted is that S believes that p. Some philosophers, however, question this condition. They either claim that not

belief, but acceptance, conviction or psychological certainty is needed or they deny that any belief-like attitude is a necessary condition for knowledge (►Personal Knowledge). The following example – the "fortune-teller example" – shows that these two conditions, taken together, are not sufficient. A fortuneteller told Mary that she would win the lottery, she believed what he said and, as it turned out, she in fact won the lottery. Certainly it could not be said that she knew that she would win the lottery, although she had a true belief. So a third condition is needed in order to complete the analysis of knowledge. There is much disagreement about what this third condition should be. Given the fortuneteller example, a natural proposal is that S has to be justified in believing that p. Mary is not justified in believing that she will win the lottery because she acquired her true belief in an irresponsible manner. And this seems to be the reason why knowledge would not be ascribed to her. The tripartite definition of knowledge arrived at – knowledge as justified true belief (JTB analysis) – goes back at least to Plato. It is sometimes called the "standard analysis" of ►propositional knowledge.

## The Gettier Problem

There are, however, counterexamples. Here is Goldman's "barn example." Henry, on a drive out in the country, sees a barn. He thereby justifiably acquires the true belief that there is a barn. What he doesn't know though, is that (for whatever reasons) there are hundreds of barn facades (fake barns) placed in the vicinity in such a way that, had Henry seen them, he would have taken them to be real barns too. It was by mere luck that he encountered the only real barn within miles. Surely, we would not say that Henry's justified true belief is knowledge. So, the three conditions considered so far are not sufficient. The ►Gettier problem [1] is the problem of finding an analysis of knowledge that avoids such counterexamples.

Two main strategies should be distinguished. Many philosophers hold that the JTB analysis has to be supplemented by a fourth condition. Since they claim that a cognitively accessible form of justification, i.e. justification "internal" to the cognitive perspective of S, is an essential condition for knowledge, the resulting definitions are sometimes called ►internalist theories of knowledge. Other philosophers try to find an alternative to the JTB analysis. According to them it is mainly "external" factors that distinguish knowledge from true belief (►Externalist theories of knowledge). (Note that the internalist/externalist distinction is drawn in several different ways in the literature.)

## Internalist Accounts of Knowledge

Internalists disagree about how exactly to avoid Gettier style examples. The following fourth condition seems to do the trick: S's grounds establish the truth of S's belief that p. (Henry's ground – i.e. seeing something which looks like a barn – does not establish that there is a barn.) Avoiding redundancy the following analysis results:

S knows that p if and only if S justifiably came to believe that p on grounds that establish the truth of p [2].

Unfortunately the price that has to be paid for adequacy is indeterminateness. Because the crucial question is: when do S's grounds establish the truth of p?

►Indefeasibility theories (e.g. Lehrer, Pollock) try to answer this question along the following lines. Henry's justification would be adequate if it would not be "defeated" by the fact that there are fake barns in the vicinity. This point can be generalized. S's grounds establish the truth of what S believes just in case S's justification is indefeasible. But what has to be the case for the justification to be indefeasible? Obviously, it is not enough that it does not rest on any false lemma because Henry's justification does not rest on any such lemma. It has also been proposed that S's justification must not be undermined by further information. But this seems to be demanding too much as Keith Lehrer's "Grabit example" shows. John sees Tom Grabit taking a book, hiding it under his jacket and leaving the library. He justifiably arrives at the (true) belief that Grabit stole a book. It could be said that he knows that Grabit stole the book. But now let us assume that – unbeknown to John – Grabit's father, who has been driven mad by Grabit's thieving ways, tells everyone who cares to listen that his son has got a twin brother who really is the one to blame for all the thefts. Certainly, we still would say that John knows that Grabit stole the book. Nevertheless, if he were given the information that Grabit's father believes in a twin brother, but not the information that the father is demented, his justification would be defeated. Therefore it cannot be necessary for knowledge that S's justification is not undermined by *any* kind of further information – some defeaters are misleading and therefore irrelevant. The main problem for indefeasibility theories is how to distinguish relevant from irrelevant defeaters. There is no universally accepted answer to that question.

## Externalist Accounts of Knowledge

According to ►Externalist theories the reason why we do not ascribe knowledge to Mary in the fortuneteller example is not that she is not justified in her belief, but that this belief somehow came about in the wrong way from an external point of view. ►Causal theories of knowledge for example, claim that the reason why she did not know that she would win the lottery is simply that the fact that she wins the lottery was not the cause of her belief (and there was no common cause for that fact and her belief either). These theories get into trouble when confronted with the barn example because

Henry's belief that there is a barn seems to be caused by the fact that there is barn. Subjunctive (or counterfactual) accounts of knowledge try to deal with the example by pointing to the fact that Henry would have believed that there is a barn even if there had not been one (but a fake barn instead). The method he used to acquire his belief was not reliable (►Reliabilism) (e.g. Goldman). It has also been said that Henry does not have conclusive reasons (Dretske); his true belief does not track the truth (Nozick). It would not be true in a nearby possible world. Nevertheless, eventually externalists are confronted with a rather similar problem as internalists. Because in the Grabit example John does know that Grabit stole the book, even though he would have had the very same belief if Grabit's father had not been demented and a twin brother of Tom Grabit had really stolen the book. The possible world in which this alternative obtained seems to be too "remote." Therefore the alternative is irrelevant. But how can we distinguish between relevant and irrelevant alternatives? Again there is no universally accepted answer to this question.

Virtually the same problem occurs for all philosophers who claim that knowledge is true belief arrived at in a reliable manner. For, what is the relevant method by which a belief is acquired? How general must its description be (►Generality problem)? Does Henry (in the barn example) acquire his true belief by just looking or by looking where there is no fake barn? The latter, surely, is a reliable method for finding out where there are barns (even in an environment with many fake barns) while the former (in the example) is not. Why is it that we want to say that Henry used the more general method? Reliabilists are hard put to it to answer that question.

►Virtue epistemology (e.g. Plantinga, Sosa, Zagzebski) is another variety of reliabilism. The basic idea is that S's true belief has to be the result of S's intellectual virtue in order to count as knowledge. There are various attempts to elucidate what "being the result of an intellectual virtue" exactly amounts to.

According to some philosophers (e.g. Quine, Goldman, Kornblith) we have to look to the natural sciences in order to learn more about what knowledge is (►Naturalized epistemology). Others suggest that there is no general answer to the question which defeaters/alternatives/methods are relevant. What is relevant in one context might not be relevant in another. ►Contextualist theories of knowledge (e.g. Cohen, DeRose, Williams) (in the narrow sense of the term) claim that the context of the person ascribing knowledge has to be taken into account when the question whether or not S knows that p is evaluated. There is no ascriber independent "fact of the matter" about knowledge. Whether these theories are convincing is one of the focal issues in current epistemological research.

## Objects of Knowledge

Following Gilbert Ryle a distinction is often made between knowing that (propositional knowledge) and knowing how. But, as it stands, this distinction is unfortunate. Knowing how to start the record player for example, is nothing but knowing that this or that is the right button to press. Some cases of knowing how seem to be mere abilities. Knowing how to ride a bicycle seems to consist merely in being able to ride it. But one has to be careful here because you can be able to do something without knowing how to do it and vice versa. Chicken sexers are able to distinguish male from female chickens but they don't usually know how (i.e. by which method) they distinguish them. (Most of them think that they can see the difference while in fact they smell it.) A team coach on the other hand, may very well know how to play soccer without being able to do it. A worthwhile distinction can be drawn between cases in which what we know can be (easily) communicated and cases in which it cannot (at least not fully and satisfactorily). Knowing how high the Eiffel Tower is belongs to the first class of cases, whereas knowing how to play the piano belongs to the second; knowing what Peter said belongs to the first, knowing what pictures of Picasso look like belongs to the second and so on. The first class has been characterized as symbolic, conceptual or propositional knowledge (since what is known is captured in our concepts and can be expressed using symbols and propositions) while the latter is referred to as pictorial (in cases where what is known is what something looks like), ►non-conceptual knowledge or non-propositional knowledge (since concepts don't suffice to capture what is known in these cases and propositions are not apt to express the knowledge – it is implicit knowledge, shown rather than communicated).

It must be kept in mind that these distinctions concern the objects of knowledge. But a difference in what is known must not be confused with a difference in what it is to know something. Some philosophers claim that there is a contrast between knowing things (►Knowledge by acquaintance), for example knowing Peter, and knowing about things (►Knowledge by description). But whether these are really two fundamentally different ways of knowing is contentious.

# Knowledge Argument

Frank Hofmann
Philosophisches Seminar, Universität Tübingen, Tübingen, Germany

## Definition

The knowledge argument was originally presented and clarified by the Australian philosopher Frank Jackson in two papers [1,2]. It is, and was intended as, an argument against ►physicalism. In this connection, "physicalism" is the thesis that all knowledge is physical knowledge. The knowledge argument is concerned with features of experiences that are commonly called "phenomenal" or "experiential features," or simply " ►qualia." To explain these qualia has become one of the most central questions in contemporary philosophy of mind and the other sciences of the mind. So the knowledge argument belongs to the same family of anti-physicalist arguments as Saul Kripke's modal argument, Thomas Nagel's "what it is like to be" argument, Joseph Levine's explanatory gap argument, and David Chalmers's Zombie argument. It is fair to say that the knowledge argument presents some of the most challenging and instructive considerations to the physicalist. In the meantime, a "standard response" to the knowledge argument has evolved and become widely accepted, though by no means universally. It has been developed by Paul Churchland [3], Brian Loar [4], and others. The standard response tries to solve the problem by invoking a distinction between facts and ways of knowing facts (or "modes of presentation" of facts, as they are also called), and it attempts to rescue ►physicalism by insisting that all facts are physical facts, whereas there may very well be many different ways of knowing these facts; there is no gap between the physical world and some nonphysical world, there are only different ways of knowing one and the same physical world, by means of different ►concepts (different "modes of presentation").

## Description of the Theory

In the following, Jackson's argument will be stated first, and the relevant notions and background explained. Then, some misunderstandings will be cleared away. After that, two responses will be discussed, the ability hypothesis and the "standard response." Further, and open, questions will be mentioned at the end.

The argument consists of two premises and a thought experiment. The thought experiment is supposed to provide evidence for one of the premises; the other premise is simply a supposition of the thought experiment.

Here is the thought experiment. Imagine Mary, a brilliant scientist, who has acquired all physical knowledge, but has never had any experience of red herself. This is so because she has been living in a black and white room all her life, and had to investigate the world by means of a black and white television monitor. Nevertheless, Mary has managed to learn all the lessons of physics, chemistry, biology, and so on. Taking "physical" in a wide sense here, which includes chemistry, biology, and all other "physical sciences," and making the idealization that physics in this sense has been completed, we can say that Mary has complete physical knowledge of the world. Note that Mary's physical knowledge includes all physical knowledge about what goes on in human beings when they see ripe tomatoes and use terms like "red," "green," and so on. She knows what goes on in their nervous systems, and she knows all the intrinsic physical properties of the brain states and their functional roles and relations to their environment, including everything physical about their history. (It seems possible that Mary could, in principle, have arrived at such a complete physical knowledge, since all such knowledge can be taught by means of black and white television, at least in principle.) Thus, the first premise of the argument is the following supposition:

1. Before her release Mary has complete physical knowledge of the world (including, of course, complete physical knowledge of the workings of nervous systems).

   Now that Mary has been released from her black and white room and sees a ripe tomato for the first time. It seems quite plausible to say that she will learn something new about experiences on this occasion. She will come to know something about the visual experience that people undergo when they see things. She comes to know what it is like to see something red. Mary did not have this knowledge about experiences before her release. So her knowledge about experiences was not complete before her release.

2. Before her release Mary did not know everything about other people's experiences.
   Therefore,
3. Physicalism is false: There are truths which are not included in the complete physical story.

Sometimes, Jackson states the conclusion in terms of facts: There are facts which are not physical facts. Presumably, this amounts to the same defeat of physicalism.

Clearly, the argument could be run for various other mental states, such as hearing, tasting, bodily sensations and so on. Nothing hangs on the sense modality; all that matters is that we are dealing with states that have specific experiential features (qualia).

The argument can be described as an inference from (the incompleteness of) a certain kind of knowledge to (the incompleteness of) certain facts: because physical knowledge is incomplete there are nonphysical facts. Conceived of in this way, the argument may appear dubious, and Frank Jackson himself has become skeptical about the soundness of the argument in the meantime (cf. [5], p. 43f., fn. 21).

Three possible misunderstandings should be avoided. The first is to see the problem as a problem of mapping language onto experience. This is not the real problem, however, since it is irrelevant whether Mary knows which predicate applies to an experience. Even if Mary had been able to say truly before her release "The experiences of these people are red experiences," she would not have known what she now knows by uttering the same sentence. For, before her release she would not have known what she was talking about when speaking of "red experiences." At least, her knowledge about what she was talking about would not have been complete.

The second possible misunderstanding is to think that the problem is trivial since the answer simply is that for knowing all the experiential features of an experience it is necessary and sufficient to have the experience. It may be correct that one must have had an experience in order to know all the experiential features of it, and that everybody who has had the experience knows these features, but it would be highly problematic to claim that knowing an experiential feature simply consists in nothing else but having the experience. To know what it is like to have a headache is not simply to have one. For, first, one can know a quale even if one does not currently have it. Second, and more importantly, even if one has a headache, that in itself is not enough for knowing it's experiential features. Here, the gap may seem very small, indeed, vanishingly small. But still there is a gap, since having an experience is not in itself yet a piece of knowledge. Rather, having the experience is something like an enabling condition for knowing its experiential features. It provides one with the kind of "access" to the experience which enables one to know its experiential features. But it is not identical with having this knowledge.

A third possible misunderstanding is to think that what Mary learns on her release is simply the fact that she undergoes a visual experience of seeing something red. It is obvious that Mary learns something when she is let out, namely that she is now having a red experience, but that is not the objection against physicalism. The objection to physicalism is that Mary's conception of the phenomenal states of other people has been so impoverished before she was let out that she did not know everything about the experiences of others (even though she was supposed to have complete physical knowledge).

One ingenious response to the knowledge argument has been worked out, independently from one another, by Laurence Nemirov [6] and David Lewis [7]. They hypothesize that knowing the qualia of an experience is an ability rather than a piece of propositional knowledge-that. It is the ability to remember, recognize and imagine (states with) these qualia. A problem with this response, however, is that these abilities do not appear to be necessary for knowing the experiential features. For, on the occasion of her first encounter with a red experience, a person can plausibly be said to know what it is like to have the experience, even though she may forget all of this a moment later. Having the experience may not leave any of the traces that amount to the Lewis–Nemirov abilities. At least, it does not seem necessary for knowing qualia that the subject is in possession of these abilities, even though the two may frequently come together.

Another response to the argument has become popular in the meantime, the "standard response," as I would like to call it. Most prominently, it goes back to ideas of Paul Churchland [3] and Brian Loar [4]. According to this view, we have to distinguish between what there is – the facts, what belongs to our ontology – and our epistemic access to what there is. As physicalists we can hold that there are only physical facts; no fact escapes the physical sciences. At the same time, we may concede that there are nonphysical ways of knowing physical facts. Physical ways of knowing facts are the ways that one can learn from physics books and lessons. If one knows a (physical) fact in a physical way, one represents it by means of physical concepts. In the philosopher's jargon, one employs a physical "mode of presentation." If one knows that a certain brain state exhibits a 40 Hz oscillation of a certain kind, this fact is given to one in a physical mode. But there are other ways of knowing facts. Most importantly, introspection provides one with a different access to one's own mental life. In introspection, one comes to know that what one is currently undergoing is a red experience. This fact is not given to one in a physical mode of presentation, but rather in a more direct, introspective mode of presentation. One

employs a " ►phenomenal concept," as many say. The normal subject who has had red experiences is in possession of a special concept, the phenomenal concept ►red experience. Having a red experience, or red experiences, somehow "triggers" the acquisition of this concept. The special functional role that connects the concept to one's own experiences in a direct way is part of its mode of presentation. This is why one comes to know immediately (without having to make observations of one's behavior and to draw inferences) that one is having a red experience whenever one has it and asks oneself what experience one is currently undergoing. Having the phenomenal concept normally enables one to imagine and conceive of the experience, and to remember and recognize it. But it is a representation of its own, not just the sum of these abilities. As a conceptual representation, the concept red experience has its own characteristic mode of presentation.

The standard response prompts new questions. As much depends on the details of one's theory of concepts and modes or presentation, it is desirable to develop a full theory of ►phenomenal concepts and to integrate it into a theory of concepts in general. One question here is whether phenomenal concepts have certain "copies" or exemplars of experiential states associated with them (as, for example David Papineau [8] claims). Does imagining a pain involve having a pain-like mental "image"? Other questions concern the relation between phenomenal concepts and experiences. What exactly is the "direct" connection between phenomenal concepts and experiences? How do phenomenal concepts refer to experiences? Are they somehow indexical? These and other related questions are the topic of much contemporary debate. In the end, it depends on answers to questions like these whether the knowledge argument can be rejected on solid grounds.

## Labeled Lines in Olfaction

### Definition

In sensory physiology, refers to the dedication of a set of neurons to the detection, transmission and processing of a particular type of stimulus. This can include specialized receptors and specialized central brain structure. A typical example in the field of olfaction is the pheromone-detection system of moths. Female sexual pheromone is a blend of a few chemical components detected on the male moth antenna by olfactory sensory neurons, each dedicated to the detection of one of these components. Sensory information then projects to the brain via a specialized subsystem. Thus, in the antennal lobe, the primary olfactory center of moths, the processing of the female sexe pheromone components is carried out by a macroglomerular complex, made of a few specialized glomeruli. This term, referring to a neural sensory pathway that is necessary and sufficient for coding stimulus quality, is often presented in opposition to "across-fiber pattern," which refers to a system in which stimulus quality is coded by multiple neurons in a combinatorial way.

►Olfactory Plasticity

## Labeled-Line Code (also: Dedicated-Line Code)

### Definition

Hypothesis stating that neural information is essentially coded in the activities of specialized neurons with distinct sensitivities, such as modalities and submodalities, place etc.

►Sensory Systems

## Labyrinth

►Evolution of the Vestibular System

## Labyrinth (Vestibular Labyrinth)

### Definition

Vestibular labyrinth consists of two functional components: (i) the otolith organs (the utriculus and the saccule), which are sensitive to gravity and linear acceleration, and (ii) the three semicircular canals, which detect angular acceleration in the three perpendicular planes during rotating movement of the head.

►Peripheral Vestibular Apparatus
►Saccule
►Semicircular Canals
►Utriculus

## Labyrinthectomy

### Definition

Ablation of the membranous labyrinth of the inner ear. In the context of vestibular compensation, either the entire labyrinth may be destroyed or only the vestibular portion of the labyrinth may be removed, leaving the cochlea intact (though the extent to which cochlear function is retained, may vary). As an alternative to surgical labyrinthectomy, ototoxic drugs may be injected into the middle ear, to achieve a "chemical labyrinthectomy" where the labyrinth remains anatomically intact but the hair cell sensory receptors are destroyed.

►Vestibular Compensation and Plasticity

## Labyrinthine Receptors

### Definition

Ciliated cells located within a specific region of the membranous labyrinth, a closed structure consisting of ducts formed by an epithelium and containing a fluid (endolymph). The membranous labyrinth is contained within cavities of the mastoid bone filled by another fluid of different composition (perilymph). The cilia of the receptors protrude towards the endolymph and one of them (kinocilium) is longer than the remaining ones (stereocilia). The receptors are excited (depolarized) when the kinocilium is bent towards the stereocilia and inhibited (hyperpolarized) by displacements in the opposite direction. Ciliary movements are induced by linear or angular accelerations imposed on the head. According to their anatomical location, labyrinthine receptors can be distinguished as macular or ampullar receptors.

►Peripheral Vestibular Apparatus

## Lacertid (Type)

### Definition

Referring to the family Lacertidae, small lizards worldwide.

►Evolution of the Brain: At the Reptile-Bird Transition

## Lactate Dehydrogenase (LDH)

### Definition

A metabolic enzyme that interconverts lactate and pyruvate.

## Lacunar Syndrome

### Definition

Lacunar infarcts are small infarcts (2–20mm in diameter) in the subcortical white matter, basal ganglia or pons, that are presumed to result from the occlusion of a single small penetrating branch of the large cerebral arteries.

►Basal Ganglia
►Stroke

## Lagrangian Density

### Definition

The difference between the kinetic and the potential energy of a system. In analytical mechanics, it is postulated that the integral over time of this quantity attains a stationary value when the system follows its actual trajectory.

►Mechanics

## Lagrangian Description

### Definition

A formulation of the equations of continuum mechanics in terms of fields whose independent variables are the referential (or material) coordinates and time. Also called the referential (or material) description.

►Mechanics

# Lambert-Eaton Myasthenic Syndrome

Masaharu Takamori
Neurological Center, Kanazawa-Nishi Hospital and Kanazawa University, Kanazawa, Ishikawa, Japan

## Definition

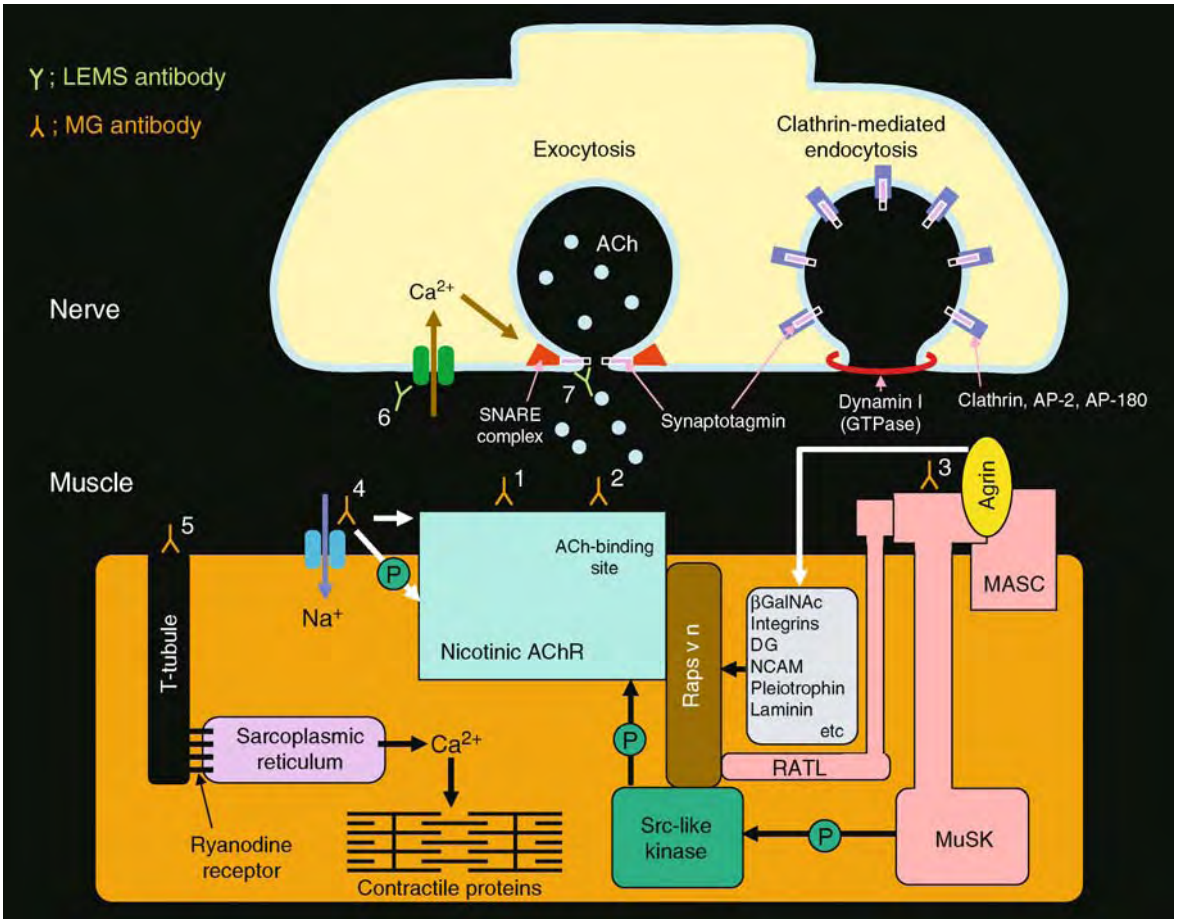
►Lambert-Eaton myasthenic syndrome (LEMS) is a disease of neuromuscular transmission, in which antibodies directed against the P/Q-type ►voltage-gated calcium channels (in most cases) and ►synaptotagmin (in some cases) present on the presynaptic nerve terminal play a crucial role in causing a deficient quantal release of acetylcholine, resulting in skeletal muscle weakness and autonomic dysfunction (Fig. 1).

This syndrome is often associated with cancers, particularly ►small-cell lung carcinoma (SCLC), and is thought to result from a disturbance remote from the site of the tumor (termed "paraneoplastic syndrome"). The motor nerve terminal and carcinoma cell may share a common antigen, suggesting an immunological cross-reactivity between the two, which provides a neurological disorder.

## Characteristics

### Remote Effect of Cancer

The voltage-gated calcium channel (VGCC) is expressed in SCLC, as demonstrated by the SCLC cells being capable of generating calcium spikes and LEMS IgG exerting an inhibitory action on the depolarization-induced calcium flux into SCLC cell line. Anti-VGCC antibodies that recognize the SCLC may react with a homologous target in the motor nerve terminal, resulting in a presynaptic defect of neuromuscular transmission [1]. The same is postulated for the presynaptic impairment caused by anti-synaptotagmin



**Lambert-Eaton Myasthenic Syndrome. Figure 1** Schematic representation of neuromuscular synapse. The Lambert-Eaton myasthenic syndrome (LEMS) is caused by antibodies to P/Q-type voltage-gated calcium channel (antibody-6), and, in a proportion of patients, to synaptotagmin (antibody-7). Antibodies numbered 1–5 are referred to the section of Myasthenia gravis (MG).

antibodies because synaptotagmin is also expressed in SCLC [2].

The etiology of LEMS developed in patients without SCLC (approximately 40%) is unclear, but they tend to be associated with immunological disorders. The high frequency of HLA-B8 in non-cancer LEMS suggests the distinct genetic predisposition and immunological routes to the similar clinical presentation of LEMS with or without SCLC [3].

## Type of Calcium Channels Involved in LEMS

Among various neuronal VGCCs, the P/Q-type VGCC, found predominantly at the neuromuscular junction and also in SCLC [2], is highly recognized by LEMS antibodies [1] (Fig. 1, antibody-6). LEMS IgGs bind to the surface of the P/Q-type VGCC cell line and cause a significant reduction in whole-cell calcium currents [4]. The LEMS antibodies, directed against not only P/Q-type but also other types, downregulate the P/Q-type VGCC function and upregulate the other types of VGCC functions [4]. This finding suggests a plasticity to compensate neurons for defective presynaptic function in LEMS.

In addition, the anti-P/Q-type VGCC antibodies are detected in some SCLC, with cerebellar ataxia in both the presence and absence of concomitant LEMS [5]. The postmortem cerebellar tissue from ataxic patients showed a reduction of P/Q-type VGCC [6]. The autonomic dysfunction that occurs in approximately 80% of LEMS patients is also caused by the anti-P/Q-type VGCC antibodies [7].

The search for epitopes in the molecular structure of P/Q-type VGCC, by use of synthetic peptides and recombinant protein, indicates the extracellular S5-S6 linker regions in 3 of 4 domains as immunodominant sites [1]. These regions can be immunogenic in the induction of the animal model of LEMS [1].

### *Synaptotagmin as Pathogenic Antigen in LEMS*

Synaptotagmin I functions in highly organized stimulation-secretion coupling at the synapse as one of calcium sensors [8]. It is enriched in synaptic vesicles and participates in calcium-dependent synchronous release of neurotransmitters, and also shares a key property with many ►clathrin accessory proteins in the clathrin-mediated endocytosis to recycle synaptic vesicles [8] (Fig. 1). In this functionally VGCC-associated presynaptic protein, the segment that exposes extracellularly during exocytosis can be antigenic in the detection of LEMS antibodies, and immunogenic in the induction of the LEMS animal model [1].

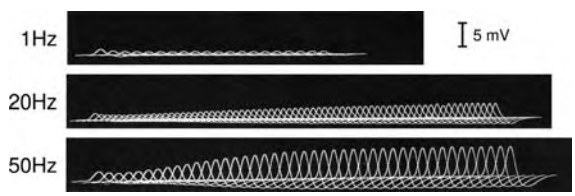
## Clinical Features, Diagnosis and Treatments

The disease begins in mid to late life, and presents with proximal skeletal muscle weakness and fatigue, a reduction or absence of tendon reflexes and autonomic dysfunctions (dry mouth, sexual impotence, constipation, postural hypotension, impaired sweating and dilated pupils responsive poorly to light). Weakened muscle strength and decreased tendon reflexes may improve by having the patient briefly contract the corresponding muscle. The oropharyngeal and extraocular muscles may be affected, but not so marked to the degree seen in myasthenia gravis. Some patients present with respiratory failure [9].

LEMS patients with underlying SCLC may have other ►paraneoplastic syndromes such as sensorimotor neuropathy, cerebellar ataxia and inappropriate secretion of antidiuretic hormone [9]. LEMS is a warning to latent cancer as reported by that in most patients, the cancer is discovered within the first 2 years after the onset of LEMS and virtually all patients within 4 years [9]. Reportedly, some LEMS patients have lymphoproliferative malignancies, or cancer of breast, stomach, colon, prostate, bladder, kidney or gallbladder [9].

Anti-cholinesterase drugs are not so effective (diagnostic) as in the case with myasthenia gravis. The diagnosis can be confirmed by characteristic findings on electromyographic studies: the muscle action potential amplitude is small with single nerve stimulation but markedly increased during 20–50 Hz repetitive nerve stimulation (Fig. 2).

The anti-P/Q-type VGCC antibodies are positive in 80–90% of LEMS patients by the immunoprecipitation assay using omega-conotoxin MVIIC-labeled VGCC (extract from cerebellar tissue) (Fig. 1, antibody-6). The anti-synaptotagmin I antibodies can be detected in some of LEMS patients by immunoblotting assay using a recombinant protein (Fig. 1, antibody-7). The anti-acetylcholine receptor antibodies, specific for diagnosis of myasthenia gravis, are found in some LEMS patients, but this may be considered as epiphenomenon.



**Lambert-Eaton Myasthenic Syndrome.**
**Figure 2** Muscle action potentials evoked by repetitive nerve stimulation at rates of 1, 20 and 50 Hz. The initial response is small in size. With rapid rates of stimulation (such as 20 and 50 Hz), the successive responses show a progressive increment in amplitude. These phenomena are provided by the increased membrane depolarization, which compensates the acetylcholine quantal release for the defect by impaired calcium entry into the nerve terminal due to the antibodies to P/Q-type voltage-gated calcium channel.

Prior to the internal treatment, the attention should first be focused on an extensive search for malignancies by including radiographs and computer tomography scans (CT) of the chest, and bronchoscopy. This search is indispensable to smokers and patients with less than 2 years' history of LEMS. Even if no tumor is detected, the search for occult malignancy should be repeated periodically. The treatment aimed at cancer therapy takes precedence over any immunosuppressive treatments.

As the symptomatic management, the drug to improve neuromuscular transmission by facilitating the release of acetylcholine (►3,4-diaminopyridine) is advocated rather than anti-cholinesterase drugs. When weakness is severe, plasmapheresis or high-dose intravenous immunoglobulin may be used. Immunosuppressants (corticosteroids, azathioprine and cyclosporine A) can be added in an attempt to produce more sustained improvement [9]. However, the attention should be focused on the fact that SCLC patients with LEMS have an increased survival rate, compared with those without LEMS, suggesting that the immunosuppression limits the immunological suppression of tumor growth and metastasis [10]. The immunotherapy is justified in the LEMS patients who do not have cancer, decided after careful and repeated search, and have evidence for a coexisting autoimmune disease.

# Lamellipodium

## Definition

Lamellipodium is a broad membrane expansion on the leading edge of migrating cells and neuronal growth cones. It is filled with a cross-linked actin filament meshwork that provides a two dimensional framework for focal contacts and can generate mechanical tension to direct the cellular movement. A lamellipodia that occurs in between two filopodia is known as a veil, and whether it expands or contracts depends on flanking filopodial stability. When lamellipodia lose their adhesion with the substratum they form ruffles that fold back away from the leading edge.

►Growth Cones

# Lamina Splendens

## Definition

The most superficial layer of articular cartilage with a thickness of about 2 μm and randomly aligned collagen fibers.

►Articular Cartilage

# Laminin

## Definition

A significant element of the basal laminae of epithelial cells where it serves to anchor these cells to the underlying basal laminae. It is able to interact with a range of molecules including type IV collagen, heparin

and integrins and is important for the migration of some cell types and promotes outgrowth from neurons in culture. Laminin is a molecule classically described as "cross-shaped," composed of three polypeptide chains: two α-chains and one β-chain. There are at least 15 variant forms of laminin known.

►Axonal Pathfinding and Network Assembly

## Laminin-Alpha2

### Definition

One type of laminin and is related to myelination.

►Myelin

## Lamor Frequency

### Definition

The Lamor frequency is the specific frequency at which specific atomic nucleus positioned in a magnetic field absorb energy from an electromagnetic pulse. The Lamor frequency is linearly proportional to the magnetic field strength. For example, the Lamor frequency for hydrogen in a magnetic field strength of 1.5 Tesla is approximately 63.87 MHz.

►Magnetic Resonance Imaging (MRI)

## Landmark

### Definition

A landmark is a stable environmental cue that guides navigation. Landmarks plays a role in either beacon or map-based navigation. Landmarks are inferential cues in that landmarks, while not the goal location themselves, have stable spatial relations to a goal location.

►Spatial Learning/Memory

## Language of Thought

Klaus Sachs-Hombach
Otto-von-Guericke University Magdeburg, Magdeburg, Germany

### Definition

The language of thought hypothesis – originally worked out by Jerry A. Fodor [1,2] and supported, e.g., by Zenon W. Pylyshyn [3] – is a highly influential approach in the philosophy of mind and particularly in cognitive science. It provides a basic framework for the computational model of the mind. According to this model, two levels of the ►cognitive architecture can be distinguished: the level of physical ►symbol processing and the level of ►mental representations. Theories referring to the former were developed in computer science, particularly in Artificial Intelligence, most famously by Herbert A. Simon and Alan Newell. They describe computational processes as formal operations on so called "physical symbols" [4]. Theories referring to the latter consider mental representations as intentional states that stand for something and have a representational, semantically interpreted content. Both kinds of theories are combined in the computational model of the mind as hierarchical levels of information processing. Since the basic level is the level of formal operations performed on syntactical properties only, semantic properties must, in order to be causally relevant, rely on corresponding syntactical properties. Thus, cognitive activities depend in general on syntactically individuated symbols that require an internal code, namely a language of thought. This language is conceived of as a propositionally structured medium. The language of thought is sometimes (e.g. by G. Harman or H. Field, cf. [5]) regarded as an internalized spoken language of a thinker. Normally however, it is taken to be more abstract than natural languages, only language-like and also called "Mentalese."

Fodor has combined the language of thought hypothesis with a number of controversial claims: (i) The language of thought is innate, (ii) it is fundamental, i.e. not derived from something else, and (iii) the assumed internal symbols are not just theoretical but real entities, physically implemented in the brain [2].

The language of thought hypothesis has been confronted with various critical replies both from the philosophy of mind and from cognitive science. Opposing views from philosophy question the existence or the explanatory value of a language of thought and of mental representations in general. Cognitive scientists normally accept the representational theory but postulate different representational formats, e.g., a propositional and a pictorial format (►pictorialism).

A different, also highly influential critique within cognitive science directed against both the representational theory and the physical ►symbol processing theory was launched by the connectionists who consider cognitive processes mainly as sub-symbolic processes that can be performed by ►neural networks without involving internal symbols or mental representations.

## Description of the Theory

The philosophical background of the language of thought hypothesis is ►functionalism that replaced behaviourism in the second half of the twentieth century as the predominant view in the philosophy of mind and in cognitive psychology. The main assumptions of functionalism are that mental states can be individuated by their functional or causal role within the cognitive system. The functional role, in turn, is defined as a relation between sensory inputs, behavioral outputs and other mental states. According to Ned Block, functionalism can thus be seen as a sophisticated theory of mind that is closely related to behaviourism [5]. Compared to behaviourism, functionalism proposes a stronger criterion for something to be a mental system, namely that it has beliefs and desires in addition to the relevant input-output relations. At the same time, however, functionalism weakens this criterion insofar as the characterization of functional states abstracts from the physical realization. This opens the possibility of ascribing mental states also to computers; likewise it justifies the functionalist claim according to which computing machines may serve as an empirical example of how mental states can be realized within a cognitive architecture.

Since the computational theory of mind is mainly interested in how mental states function within a network of formal rules, it is not intended to be a biological theory. Although the internal code – i.e. the language of thought – is usually assumed to be implemented in a neural network, functional analysis is not reducible to neurophysiology, but provides an independent level of description. To explain the behavior of cognitive systems therefore requires referring to semantically interpreted representations. Although being non-committal about different realizations of cognitive states, the computational model of the mind, particular in Fodor's version, nevertheless demands an answer to the question of how to relate the different levels of the cognitive architecture. Possible solutions can be distinguished depending on how the relation between (i) syntactically performed operations in different kinds of hardware and (ii) semantically interpreted representations is conceived of. According to Fodor's version of the language of thought hypothesis, the cognitive architecture is hierarchically organized so that complex cognitive abilities are split up into smaller, less complex abilities and less intelligent components and processes. Those components are then split up again into still smaller and less intelligent components until the level of ►primitive processors is reached at a purely mechanical level.

Having in mind the philosophical background described above, it becomes clear why Fodor postulates a language of thought as an internal propositional code. It permits him to account for the basic assumptions of folk psychology within the framework of the computational model of the mind. According to folk psychological explanations, our behaviour is determined by intentional states like beliefs and desires. We therefore normally account for performing a certain action by referring to ►propositional attitudes that include a semantically evaluable content and therefore presuppose also conditions of truth or satisfaction. In our ordinary understanding, propositional attitudes are the basic units of the mind. The language of thought hypothesis comes into play by assuming (i) that cognitive states are relations between an organism and its internal representations – between an attitude and a propositional content – and (ii) that representations are causally relevant due to their formal or syntactic features. This requires, of course, that the internal code must preserve various features of the propositional attitudes like the conditions of truth or satisfaction, systematicity, and productivity. Since thoughts and sentences are alike in many respects, the language of thought is described as a propositional, language-like medium.

The language of thought hypothesis emphasizes the functional role of propositional attitudes for adequately explaining behaviour. A functional analysis of mental states is therefore taken to be an irreducible task of cognitive science [1,3]. This has been criticized for different reasons. The language of thought hypothesis has sometimes been understood as purely syntactical. But if propositional attitudes are only causally relevant in virtue of their syntactical properties, semantic content of ►mental representation becomes superfluous. According to Stephen Stich, this would lead to an eliminativist position with respect to propositional attitudes in particular and folk psychology in general [6]. A more cautious conclusion has been drawn by Daniel Dennett. He states, contrary to Fodor, that mental representations cannot be regarded as real entities. He is therefore sceptical about the causal influence of the semantically interpreted content of propositional attitudes. According to his instrumentalist view however, the ascription of intentional states is a useful device for the explanation of the behaviour of humans and even of computing machines [7].

A quite different philosophical critique results from taking the semantic aspect of mental representations as fundamental. This is done, e.g., by John R. Searle who objects that the computational model of the mind is

not able to account for intentionality as the basic property of mental states [8]. He supports his claim by denying (i) that the brain is a syntactic engine and (ii) that a purely syntactic engine is able to produce semantic content. Searle's reason for the first claim is that brains, unlike computers, are biological systems with quite specific mechanisms for information processing. Although we might be able to describe a system computationally, it does not necessarily have to be a computational system. The second claim is illustrated by Searle's highly controversial Chinese Room argument. According to this argument, a purely syntactical machine may display exactly the verbal behaviour of a person who does understand a language, even if the machine evidently has no verbal understanding whatsoever.

An influential critique of the language of thought hypothesis within cognitive science comes from ►pictorialists [5]. Stephen M. Kosslyn, the most prominent proponent of the pictorialist view, concedes that there may be a propositionally structured medium for representing and processing information; still he claims that visual information has to be encoded in a picture-like format as well. Whereas propositionally organized representations describe relevant properties and relations explicitly in a language of thought, the pictorial encodings are thought of as a pixel matrix that preserves visual information particularly of spatial relations implicitly, not by explicit description. The encodings are said to be analogue, i.e., they represent information by isomorphism.

A more radical critique of the language of thought hypothesis stems from ►connectionism that is nowadays acknowledged as the most promising competitor to the computational model of the mind. An influential version of the connectionist view is the parallel distributed processing approach (PDP) that was developed by David Rumelhart, James McClelland and colleagues [9]. While the classical symbol processing account orientates itself towards Artificial Intelligence, the connectionist view draws on research in neurophysiology. The main assumption of connectionism is that information processing does not require symbol structures but can be carried out by neural networks. One of the main objections against the computer model of the mind (►computer theory of the mind) is that it does not account for the specific neural "implementation" of human cognition. Instead of describing cognitive processes as manipulating single representations, connectionists postulate patterns of activity that are distributed over groups of units and that process information by adjusting the connection strengths between neurons. Fodor and Pylyshyn have objected that this approach cannot account for the systematicity and productivity of natural languages. Those features require a compositional syntax and semantics. The connectionist view therefore does not provide an alternative to the computational model of the mind but only a different realization of it [10].

# Large Deformation, Large Strain

## Definition

Most soft tissues undergo deformations and strains that are well beyond the range where the relationships between strain and displacement gradients and between stress and strain are linear. This is certainly the case for arterial wall deformation and heart wall deformation. It means that the analysis of such materials needs to be based on "finite deformation elasticity" and not on the classical linear elasticity used in most engineering problems.

►Cardiovascular Mechanics

# Large-fiber Sensory Neuropathy

Jonathan Cole
University of Southampton Clinical Neurological Sciences, Poole Hospital, Dorset, UK

## Synonyms

Acute sensory neuronopathy; Acute and chronic ataxic neuropathy

## Definition

A condition giving rise to degeneration of large myelinated sensory (afferent) nerve cells. When the primary lesion involves peripheral axonal degeneration or loss, this may be called an axonopathy (or commonly a neuropathy), where the primary damage is to the cell body of the neuron in the dorsal root ganglia, then this may be called a neuronopathy.

## Characteristics

### Quantitative Description

Large myelinated sensory nerve fibers arise from receptors of cutaneous touch and movement and position sense in the skin and muscles and tendons, and travel to the central nervous system in nerve trunks. These have been divided between A alpha for afferents underpinning movement and position sense and A beta for cutaneous light touch. Their cell bodies are in the dorsal root ganglia. They synapse either in the ipsilateral dorsal horn before ascending in that dorsal column or pass through the spinal cord to synapse in the dorsal column nuclei and other rostral structures.

Their size is 7–15 μ, with conduction velocities in humans between 35 and 70 m/s and they comprise ~40% of the axons in a peripheral sensory nerve.

## Function

Cutaneous touch, muscle and position sensation or proprioception. However much of the afferent activity within this system is not presented to consciousness and enables motor control by providing the brain with continuous information about the position and state of the moving parts.

Though loss of touch sensation may be easy to imagine, the effects of loss of proprioception are quite difficult to understand and are best appreciated by analysis of those few people with large fiber neuropathy.

## Pathology

Pure large fiber neuropathy is rare, being predominant in less than 5% of large series of neuropathies. It is, however, seen selectively in very rare conditions in which large fibers or their cell bodies are specifically targeted by disease. These fall into two broad areas. A specific concentration of a toxic agent and/or selective vulnerability to that agent (or its lack) may be the cause of large fiber neuronopathy/neuropathy in cisplatin and vitamin B6 neuropathies, in Freidrich's ataxia and in vitamin E deficiency [1]. In other diseases of the large sensory nerve an immune reaction appears to target the large fiber cell bodies in the dorsal root ganglia. This appears to be the case in carcinomatous sensory neuropathy, IgM neuropathy, Sjogren's syndrome and acute sensory neuronopathy.

Onset can be insidious and progressive, as in some carcinomatous and Sjogren's syndrome related neuronopathy, or can be acute and severe, with all large sensory nerve cells being destroyed in days, as in some acute sensory neuronopathy syndromes. In most large fiber axonopathies, sensory loss predominates, but in some neuronopathy syndromes ataxia is the main and presenting symptom, suggesting a selective loss of proprioceptive afferents.

### Selective Toxicity of Large Sensory Nerve Fibers

Vitamin B6 in large doses is neurotoxic to large sensory fibers or their cell bodies. This is reversible if the doses are stopped in time. In these severe toxicities other symptoms of central and peripheral nervous system affects are also seen, with autonomic disturbances, lethargy and respiratory depression [2].

Neuropathy associated with cisplatin therapy, then mainly used in gynecological cancers, was reported soon after the drug was employed. Though some early patients presented with parasthesiae and sensory loss in a classical glove and sticking distribution later, as the syndrome became more recognized, it has been realized to be primarily a neuronopathy rather than a dying back axonopathy. Post-mortem studies have shown necrosis of the large fiber cell bodies in the dorsal root ganglia as well as loss of peripheral axons. In a sample of 21 patients post mortem, Gregg et al. [3] found that tissue platinum levels were highest in the dorsal root ganglia and lowest in tissue protected by the blood-brain barrier. They suggested a linear relationship between platinum levels and cumulative dose and that cisplatin was retained indefinitely in a neurotoxic form. If the development of neuronopathy with cisplatin therapy is dependent on dose and exposure duration, then this must limit its usefulness, at least in those for whom survival times are long. More recently though it has suggested that limited prolonged use may be possible.

In inherited spinocerebellar atrophies, of which Friedreich's ataxia (FA) is the most common, the ataxia is associated with peripheral loss of large sensory fibers over and above any cerebellar cause. It is an autosomal recessive disease, which, in addition to degeneration in the central and peripheral nervous system, is also associated with cardiomyopathy, skeletal abnormalities and increased risk of diabetes; it is progressive and remorseless. Friedreich's ataxia is caused by expansion of a GAA triplet located within the first intron of the frataxin gene on chromosome 9q13. Frataxin is a mitochondrial protein that plays a role in iron homeostasis, with deficiency resulting in

mitochondrial iron accumulation, defects in specific mitochondrial enzymes and free-radical mediated cell death [4]. Though the precise pathological mechanism is unknown its dependence on a defect in oxidation allows potential treatment with anti-oxidants.

### Immune Mediated Neuronopathy

Autoimmune neuropathies are a subset of the sensory/ataxic neuropathies. These often present with ataxia, rather than cutaneous sensory loss. Their causes include sensory variants of the Guillain-Barre syndrome, sensory neuronopathy syndromes, subsets of immunoglobulin M paraproteinaemic neuropathy, paraneoplastic neuropathy and the neuropathy associated with Sjogren's syndrome. The targets for autoantibodies are varied, but include gangliosides, myelin associated glycoprotein, Hu antigen and extractable nuclear antigens [5]. The major site of pathology in autoimmune ataxic neuropathies is the dorsal root ganglion, but dorsal roots and peripheral nerve myelin and axons may also be affected. The discovery of the autoimmune origin of some of these neuropathies has led to trials of immune suppressant therapy, though with mixed results as yet.

IgM associated sensory neuropathy is a predominantly axonopathy which presents with ataxia but also with distal large and small fiber symptoms. It is associated with serum IgM binding GalNAc-GD1a and GM2 gangliosides and causes, unusually for these diseases, a demyelinating neuropathy. It is slowly progressive over years and may be treated with IVIg [6].

Paraneoplastic sensory neuropathy occurs almost always in smokers with small cell carcinoma of the lung, though at time of presentation of the neuropathy, no tumor is evident in ~50%. The presentation can involve pain, suggesting small fiber involvement and includes motor nerve involvement too in up to 50% in some samples [7]. About 80% are positive for anti-Hu antibodies [8]. It can also be associated with other nervous system dysfunction including LEMS, cerebellar ataxia and autonomic problems. Tumor resection sometimes improves the neuropathy, though median survival is poor, with ~20% surviving 3 years.

Large fiber sensory neuropathy is a rare but well-known neurological problem seen with Sjogren's syndrome. The majority presented with numbness and parasthesia. Most follow a rather indolent but progressive course, despite treatment with steroids, cyclophosphamide or intravenous immunoglobulins [9].

The acute sensory neuronopathy syndrome was first described in 1980 in three adults who, after an infection, (and antibiotics), rapidly and irreversibly developed sensory loss and ataxia [10]. They were followed for 5 years without evidence of coexistent neoplasia or immunological disease. Subsequently more patients with this condition have been described in clinical series. In parallel, detailed neurophysiological and neurophenomenological work has been done on these subjects to elicit the role of proprioception in motor control [see Large-Fiber Sensory Neuropathy: Effect on Proprioception].

Large fiber sensory neuropathy is therefore a rare subset of peripheral neuropathy/neuronopathy, but important to diagnose since its causes are limited and depending on the cause its prognosis is broadly understood, with treatments possible. Where not treatable, it becomes even more important to explain the symptoms of loss of proprioception to the patient and their family and to ameliorate its effects as best one can.

# Large-fiber Sensory Neuropathy: Effect On Proprioception

Jonathan Cole
University of Southampton, Clinical Neurological Sciences, Poole Hospital, Dorset, UK

## Definition

A condition giving rise to degeneration of large myelinated sensory (afferent) nerve cells. When the primary lesion involves peripheral axonal degeneration or loss this may be called an axonopathy (or commonly a neuropathy), where the primary damage is to the cell body of the neuron in the dorsal root ganglia then this may be called a neuronopathy.

## Characteristics

### Function

Large fiber sensory neuropathy deprives the patient of both cutaneous touch sensation and sense of movement and position, i.e. proprioception, in the body and limbs.

Proprioception means, in its simplest definition, knowledge of self but is usually considered to be knowledge of the body's position and movement (see Proprioception, Kinesthesia). One can logically talk of peripherally originating proprioception, the senses of movement and position sense, but also of visual proprioception, knowledge of these from visual inspection. Much of the afferent information arising from muscle spindle and Golgi tendon organs and from low-threshold large cutaneous afferents, which signal movement and position in the face and to an extent in the hand, is not perceived and therefore seems to lie outside the sense of proprioception. This essay follows the convention of using proprioception to mean peripherally originating senses of movement and position sense. Then, since the large myelinated sensory nerve fibers convey all information concerning movement and position sense and cutaneous touch, the effect of a complete loss of these fibers is to abolish peripheral signals underlying proprioception.

Proprioception was first described by Bell in the 1830s though named later by Sherrington. Bell considered it the sixth sense, but it is so basic within us that it has not really been considered in these terms. Though Purdon Martin wrote in 1967 of a man who had had a penetrating knife wound in the neck, severing his dorsal columns, who was "de-afferented" for proprioception and touch and who was shown standing [1], it effct to make one longer sentence was not until the 1970s and beyond that the full effects of proprioceptive loss were understood.

One of the first detailed descriptions was of a man who had a loss of distal proprioception in the limbs, though clinically he had a large and small fiber pan-sensory axonal dying back neuropathy [2]. This man was able to do a range of pre-programmed finger movements and could produce three different levels of force at the thumb pad once learnt. But he could not maintain a constant motor output after a few seconds without vision. Despite success in many laboratory tests, he was practically useless in daily life, being unable to fasten shirt buttons or to hold a cup.

In 1980 [3] the acute sensory neuronopathy syndrome was defined as an acute and severe loss of large sensory fibers as a result of a cross-immune reaction to a foreign antigen (see section on large fiber sensory neuropathy). Subjects with similar conditions have also been studied in more detail physiologically and phenomenologically. Sacks (1985) [4] wrote of a subject, "Christina" who had lost predominantly proprioception as "The Disembodied Lady." She felt disembodied by her inability to control movement and still felt this after she had re-learnt some movements. Other studies, mainly of two important subjects GL and IW, have taken place over many years. The subjects' complete losses of proprioception and cutaneous low threshold touch allowed the role of these to be assessed. The responses of these two has also allowed an understanding of the extents and limits of motor learning without peripheral feedback.

The case of GL was elaborated by Forget and Lamarre [5] and subsequently in innumerable studies (see http://deafferented.apinc.org). It is now over 20 years since she lost all large afferent sensory nerve function from the lower face (the third division of the trigeminal cranial nerve) down, so she has no touch or movement/position sense in her lower mouth and face, neck and body. Small fiber function and motor nerve function are normal. A second subject extensively studied, IW, has a lower level (round C3), so he has cervical afferents but none below the collar line. This difference between the upper levels of sensory loss may well be crucial. GL has to chew her food very carefully, but more importantly for movement, she has no automatic control of head position, whereas IW has both of these intact.

Any consideration of the effect of proprioception based on the effects of its loss must also consider the time of study after the acute loss and the time of life at which it happened. GL and IW were in their late teens and early twenties when they suffered their neuronopathy. They had learnt most motor skills and their rehabilitation was helped by their youthful sense of purpose. In contrast, subject CF was 60 when it occurred and has found recovery of functional movement far more difficult.

Without proprioception all subjects find that controlled movement is impossible and require full nursing

care for several weeks after the loss. Initially the effects of the neuronopathy are devastating. But both GL and IW discovered that movement was possible, using visual feedback to replace peripheral originating proprioception and cognitive control of all movement. It was as if they had effectively been deprived of subconscious motor schema and were using their conscious body image in a novel way to control movement. Both learnt to dress and feed themselves over months [6]. GL, with her additional loss affecting neck proprioception decided to live in a wheelchair; IW younger and without family responsibilities, spent 17 months in rehabilitation re-learning movement. After 1 year, he managed to stand and a few months later could walk. He has lived independently for years and worked as a civil servant and more recently in disability access management. In addition to locomotion and instrumental movements, writing, dressing etc, both re-learnt to gesture consciously, so that they appear emotionally and linguistically embodied, like others.

Research on these subjects has encompassed a large number of areas. With eyes open the ability to distinguish the weight of an object was similar to controls, with the deafferented subjects making a certain movement force and seeing whether the lifted weight moved faster/further than the last. With eyes shut, the liminal difference for the percept was about 100%, though still present, This might reflect a peripheral originating percept (in remaining small afferents) or be read from, say, associated head movement using vestibular afferents. These subjects tend to use an amplitude model in moving single joints between two places, rather than a moving end point one [7].

In a reaching task, with vision of the target but with manipulation of the seen position of the moving hand, GL was able to move to a target accurately despite the reach direction being altered and despite her being unaware of the alteration [8]. This study offered evidence that motor efference processes, in themselves, are insufficient for conscious experience of our own actions. More recently Olausson et al. [9] were able to show the existence of a novel class of sensory afferents, called C-touch, which may underlie the affective aspect of light touch, in GL (and subsequently in IW). Functional imaging studies of a number of subjects with varying pan-sensory neuropathies and with clinical loss of peripheral proprioception have shown that in order to move, these subjects activate premotor and cerebellar areas more than controls without visual or proprioceptive input [10].

Subject IW appears to move using a complex combination of pre-visualization and forward planning, with visual supervision. By the latter it is suggested that he does not use vision for strict real time on-line feedback, but rather to correct errors in a higher order way. Some automaticity of movement may have also returned, since it is difficult to conceive that he could walk if concentrating on all aspects of that movement at all times. He himself agrees, saying that walking now takes round 50% of his attention at the least, whereas originally it was 100%. Similarly his gestures seem automatic and since they do not require accuracy in place, but in time and in shape, these may be the most automatic of movements in this group.

Though the subjects studied over many years have learnt to move with degrees of smoothness and control unexpected from the earlier studies, there are still movements that are beyond them. Their reaction times for simple movements are normal but coordinated sequential fast movements are impossible; IW can neither run nor walk fast. Fine dextrous finger movements are difficult and of course active touch without vision impossible – they cannot take keys or coins from their pockets. Simultaneous accurate movements are also difficult. Lastly, their movements remain under conscious attention and so are very vulnerable. This is not always apparent, such is the skill these subjects have developed. But IW, for instance, retires to bed if he has a head cold or flu and can never afford even gentle intoxication. He cannot cope with the attentional demands of movement if not clear in the head.

These subjects are very rare but have allowed a new understanding of the ability to coordinate movement without proprioception, substituting vision feedback and cognitive control for automatic motor programs. Thus far these subjects have been adults when deprived of movement and position feedback. One imagines that a young child, so deprived, before skilled motor programs had developed, would be more incapacitated.

Laryngeal apnea

## Definition

The laryngeal chemoreflex (LCR) is a complex behavioral response elicited following stimulation of laryngeal receptors by liquids and consists, to variable degrees, of apnea, respiratory inhibition, coughing, swallowing, arousal, bradycardia and redistribution of blood flow to vital organs. It is one of a family of airway protective reflexes such as the dive response and the cough reflex.

## Characteristics

### Stimulus

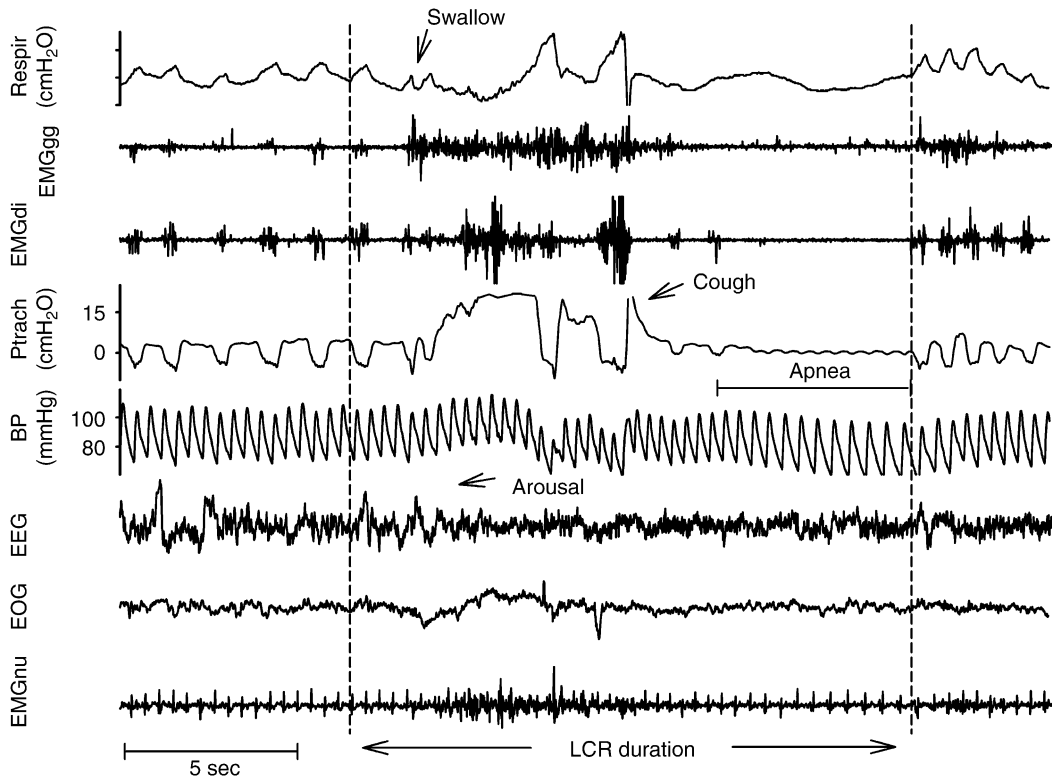
The laryngeal receptors mediating the LCR are stimulated by hypo-osmolar solutions with a low chloride concentration. The reflex response varies inversely with the chloride concentration in the solution; as the chloride concentration rises, the reflex response diminishes [1]. Water alone is, therefore, an effective stimulus, whereas saline is relatively ineffective. Solutions containing anions with larger hydrated volumes than chloride (e.g., $F^-$, acetate, $SO_4^-$, etc) also elicit the LCR, as do solutions with elevated potassium concentrations. Fluids with a low pH stimulate the LCR regardless of the chloride concentration in the fluid. Thus, gastric liquids with a low pH are potent stimuli of the LCR when gastroesophageal reflux occurs.

The afferent receptors for the LCR are located in and around the larynx. The receptors are particularly dense on the epiglottis, interarytenoid space and aryepiglotic folds, but extend into the body of the larynx below the glottis. The water receptors are slowly adapting, so receptor activity persists until the offending solution is removed. The afferent information from the receptors is conducted to the central nervous system in fibers in the superior laryngeal nerve (SLN), and for that reason, cutting the SLN completely abrogates the reflex response to laryngeal stimulation of water receptors. The nerves within the SLN terminate in interstitial and medial subnuclei of the nucleus of the solitary tract (NTS).

### Response

The LCR occurs often in neonates and infants and consists of apnea, laryngeal closure, coughing, swallowing and a period of variable respiratory inhibition (Fig. 1).

The reflex response may include cardiovascular responses such as bradycardia, mild hypertension and peripheral vasoconstriction and a redistribution of blood flow to sustain oxygen delivery to vital organs such as the brain and heart. The elements of the response fall into two categories: airway clearance and a set of defensive reflex responses that limit inspiration of the liquid stimulus into the lungs and preserve oxygen delivery to vital organs. Thus, coughing and swallowing remove the offending stimulus and clear the airway, but apnea, laryngeal closure and the cardiovascular elements of the reflex response seem designed to limit further damage and preserve vital functions. The cessation of breathing causes carbon dioxide levels to rise within the body and oxygen levels fall as the period of respiratory inhibition



**Laryngeal Chemoreflexes. Figure 1** An example of the LCR from a neonatal piglet at 9 days of age during NREM sleep after muscimol dialysis in the brainstem. Water (0.05 ml) was introduced into the larynx at the *left vertical dashed line*. Note the occurrence of swallowing, coughing after arousal, apnea and respiratory disruption, and note that when swallowing occurs, respiratory activity of the diaphragm ceases so that the multiple events of the LCR are well coordinated. Respir, respiratory trace from the plethysmograph; EMGgg, genioglossus (tongue) electromyogram; EMGdi, diaphragm electromyogram; Ptrach, tracheal airway pressure; BP, blood pressure; EEG, electroencephalogram; EOG, electro-oculogram; EMGnu, nuchal electromyogram. Figure adapted from [2], used with permission of the American Physiological Society.

persists. These stimuli, hypercapnia and hypoxia, may be important in terminating the respiratory inhibition elicited by laryngeal stimulation. When the LCR occurs during sleep, arousal, whether directly from the laryngeal stimulation or as a consequence of hypercapnia and hypoxia that develop during the period of apnea, is an important part of the process limiting the duration of the LCR and clearing the airway. Coughing does not seem to occur during sleep, and airway clearance is, therefore, deficient until arousal from sleep occurs.

The manifestations of the LCR vary depending on the intensity of the stimulus. When the volume of fluid is small and not acidic, the reflex response in newborn animals and humans may consist of brief apnea, swallowing and mild respiratory disruption. Coughing emerges as a more prominent part of the LCR, and apnea and bradycardia become less common as neonates mature. As the stimulus intensity increases, the duration of the apnea, coughing, swallowing and respiratory disruption increases and bradycardia, hypertension and redistribution of blood flow may develop. In anesthetized animals, it is possible with large volume stimuli to elicit a LCR with apnea of sufficient duration to lead to an asphyxial death in the animal unless resuscitation efforts are begun. The hierarchical pattern of responses, in which mild stimuli elicit swallowing and coughing, but apnea, bradycardia and redistribution of blood flow occur only as the stimulus intensity increases, suggests that the airway restorative aspects of the LCR are the first line of defense, but to the extent they are ineffective, those aspects of the reflex aimed at conserving vital organ function emerge.

## Central Integration

After the afferent impulses in the SLN terminate in the NTS, interneurons process and distribute sensory information from the larynx throughout the brainstem and activate the wide variety of behaviors that constitute

the LCR. Electrical stimulation of the SLN, which mimics many aspects of the LCR, or stimulation the laryngeal mucosa with water inhibits phrenic motor neuron activity and inhibits inspiratory and expiratory neurons in the ►ventral respiratory group and depolarizes post-inspiratory neurons. Stimulation of the SLN seems to prolong expiratory time by preventing inhibition of post-inspiratory neurons in the ventral respiratory group; the depolarized state of the post-inspiratory neurons has been labeled "post-inspiratory apneusis"; [3], and the transition between the depolarized "apneustic" state in post-inspiratory neurons early in expiration and their hyperpolarized state during late expiration seems to require the activity of chloride-dependent inhibitory post-synaptic potentials. Reflex prolongation of the post-inspiratory period after SLN stimulation is associated with the suppression or absence of inhibitory post-synaptic potentials that usually hyperpolarize post-inspiratory neurons in the ventral respiratory group, terminate the effect of SLN stimulation and thus prepare the way for the final phase of expiration and the next inspiration. The inspiratory and expiratory inhibition is mediated by GABAergic mechanisms, and bicuculline administration attenuates the duration of apnea and respiratory inhibition associated with SLN stimulation. Thus, ventral medullary sites seem to mediate the respiratory effects of SLN stimulation on the LCR.

Laryngeal motor neurons are excited during SLN stimulation, and this is consistent with the activation of laryngeal muscles that close the glottis during the LCR. Swallowing is generated by a central pattern generator in the NTS and distributed to the large variety of motor neurons involved in swallowing by another group of neurons within the ventral medulla in or near the nucleus ambiguus [4]. Similarly, a central pattern generator for coughing seems to be activated during laryngeal stimulation. Many of the individual activities use a common set of premotor neurons, and the activity of one behavior often precludes the others. Thus, swallowing inhibits coughing and respiratory activity (see Fig. 1). Although it is clear that one activity prevents the others, the neurophysiological mechanisms whereby this reciprocal inhibition among multiple behavioral central pattern generators is achieved have not been established.

## Interactions

The duration of the LCR is modified by a variety of factors, and in general, there is an inverse relationship between the duration of the LCR and respiratory drive in unanesthetized animals. Hypercapnia generally shortens the duration of the LCR [5]. On the other hand, focal dialysis of muscimol, a $GABA_A$ receptor agonist, in the rostroventral lateral medulla decreases the ventilatory response to $CO_2$ in piglets and also prolongs the LCR [6]. Moreover, stimulation of muscle afferents, which enhances ventilation, also shortens the LCR in lambs. Hyperoxia, on the other hand, prolongs the LCR in awake and sleeping piglets.

The effect of hypoxia on the LCR is less consistent. In different studies, hypoxia has been shown to prolong or shorten the LCR in anesthetized piglets and enhances apnea duration and bradycardia associated with the reflex, but hypoxia also shortened apnea duration in the same species in a related study. Hypoxia reduces the duration of apnea after stimulation of the SLN in decerebrate piglets. Often hypoxia prolongs the LCR in anesthetized animals, but shortens the LCR in studies of unanesthetized animals. However, hypoxia prolongs the apnea associated with laryngeal infusion of water in unanesthetized infants.

The duration of the LCR also increases during sleep. The LCR is generally longest during REM sleep, of intermediate duration during NREM sleep and shortest during wakefulness in neonatal piglets and lambs. Minute ventilation and the ventilatory response to $CO_2$ are also least in REM sleep, intermediate in NREM sleep and greatest during wakefulness, and, some of the prolongation of the LCR may be due to a state-dependent reduction in ventilatory drive. It is an attractively simple hypothesis to suggest that the duration of the LCR is inversely related to the level of respiratory drive (and some data support this concept), but the control of the LCR is more complicated than this simple hypothesis suggests, especially when one considerers the effects of hypoxia.

The body temperature also alters the duration of the LCR, and this is not associated with any clear change in respiratory drive. Haraguchi et al. [7] first noticed that elevating the body temperature of puppies approximately 2°C reduced the threshold of SLN stimulation necessary to activate the thyroarytenoid muscles, which contribute to the glottic closure typical of the LCR. The thermal reduction in threshold was most apparent in young animals and was absent in adult dogs. Elevating the body temperature of decerebrate neonatal piglets by 2°C also prolongs the LCR quite significantly. The activity of water receptors in the larynx is not altered in the temperature range of 38–42°C, and focal heating of the NTS, while body temperature remains constant, is sufficient to elicit the thermal prolongation of the LCR. Therefore, the thermal prolongation of the LCR is centrally mediated within or very near to the NTS. Moreover, the prolongation seems to depend on GABAergic processes since focal administration of gabazine, a $GABA_A$ antagonist, in or near the NTS completely reverses the thermal prolongation of the LCR without affecting other aspects of respiration in decerebrate piglets [8]. Similar prolongation of the LCR is apparent in newborn rats, although the thermal prolongation wanes by

postnatal day 21 even though the apnea associated with the LCR persists at that age.

Finally, upper respiratory tract infections, particularly respiratory syncytial virus, increase the sensitivity of the LCR so that respiratory inhibition is greater in the setting of upper airway infection for any level of stimulation of the LCR. The sensitization is centrally mediated by uptake of cytokines from sensory neurons in the laryngeal mucosa.

## Developmental Features

The manifestations of the LCR change as animals mature [2]. Swallowing, cough, apnea, bradycardia and redistribution of blood flow frequently occur in neonatal animals when the LCR is elicited, but cough and swallowing become the sole manifestations of the LCR in older animals and adults – respiratory inhibition and cardiovascular manifestations of the LCR, which tend to conserve the function of vital organs, are absent in adults. The rate at which apnea, respiratory inhibition and bradycardia cease to be part of the LCR varies among species. In premature lambs delivered two weeks early, apnea and bradycardia are present at postnatal day 7, but absent when the LCR is stimulated at postnatal day 14. Lambs, which are a precocial species, have little or no apnea and bradycardia at postnatal days 4–6 following a normal gestation period. Apnea is also absent at one month of age in neonatal piglets when the larynx is stimulated even though apnea is common in younger animals. In more altricial species such as cats, apnea is present at postnatal ages 5 and 14 days, and swallowing becomes a major manifestation of the LCR by one month of age, but the adult pattern of frequent swallowing does not emerge until two months of age. In puppies, apnea is prominent during the first 10 days of postnatal life, but is not an important component of the response after one month of age. In anesthetized rat pups, apnea remains a prominent part of the LCR at least through postnatal day 21. It is interesting to note that the thermal prolongation of the LCR described above disappears as animals mature before the apnea is lost as a manifestation of the LCR. This suggests that the neurophysiological processes controlling the thermal prolongation of the LCR and the respiratory inhibitory parts of the LCR are controlled by different mechanisms in the brainstem. This separation of processes is also supported by what limited neuroanatomical information exists: thermal prolongation of the LCR seems to be controlled in or near the NTS, whereas the apneic and bradycardic manifestations of the LCR seem to be controlled by structures in the ventral respiratory area and ventral medulla.

Many investigators feel that the LCR contributes to the ►Sudden Infant Death Syndrome (SIDS) [9]. SIDS may begin with apnea related to the LCR. Moreover, a variety of risk factors for SIDS are associated in experimental animals with prolongation of the LCR. Gastro-esophageal reflux and upper respiratory tract infections have been associated with some SIDS deaths: gastric fluid is a potent stimulus of the LCR, and some respiratory tract infections enhance the sensitive of the LCR. In addition, infants who died of SIDS are thought to lack a variety of neurotransmitter receptors in the brainstem, and when decreased neuronal activity within these brainstem areas is induced in neonatal piglets by dialyzing muscimol into the rostroventral lateral medulla, the LCR is prolonged. Moreover, SIDS usually occurs during sleep, and the LCR is longest in REM sleep and longer in NREM sleep than during wakefulness in neonatal piglets and lambs. Hyperthermia is a risk factor for SIDS in humans, and hyperthermia in neonatal piglets prolongs the LCR. Finally, apnea and bradycardia wane as manifestations of the LCR as animals mature, and the risk of SIDS also diminishes in human infants as they mature, although the actual relationship between the transformation of the LCR to an adult pattern in humans and the decline in the risk of SIDS has not been studied in detail.

## Summary

The LCR is a behavioral response to laryngeal stimulation that contains many elements, which both clear the airway and protect and preserve respiratory and cardiovascular function. The protective elements of the reflex are dominant in neonatal animals and may represent a holdover from fetal life, when the adaptive alternatives to hypoxic stress are limited. The airway clearance mechanisms tend to dominate the adult response. The persistence of respiratory inhibition and cardiovascular responses to laryngeal stimulation may contribute to the risk of SIDS [9], and interventions that shorten the LCR or reduce its apneic and respiratory inhibiting elements may, in the future, be shown to reduce the risk of SIDS.

# Laser Trap

## Definition

Laser traps or optical traps are instruments that use a focused laser beam to capture small (micron sized or smaller) particles. In biomechanics, laser traps are typically used to measure the mechanical properties of isolated molecules. Micron-sized beads that can be captured with the laser trap are attached to the ends of molecules. Each end of the molecule can be controlled, and so the molecule can be extended and the force associated with the extension can be calculated by the distance that the bead moves out of the centre of the laser trap and the specific stiffness of the trap.

►Molecular and Cellular Biomechanics

# Latch Neurons

Charles Scudder
Portland, OR, USA

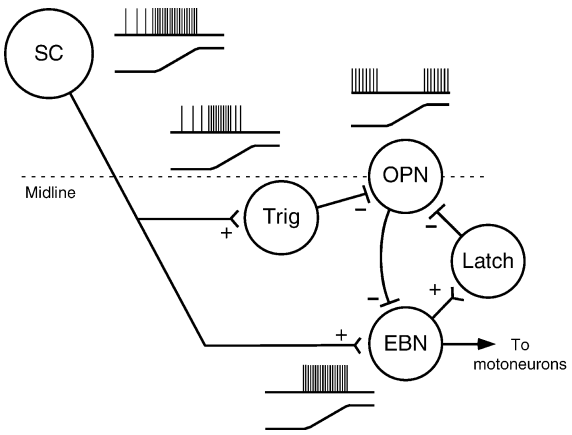
## Definition

Latch neurons are a component of the ►saccadic burst generator and are hypothesized to inhibit the ►omnipause neurons (OPNs) for the duration of the saccade. Inhibition of the OPNs is necessary to permit the high-frequency bursts of ►medium-lead burst neurons (►Burst cells – short lead) that provide the powerful excitation and inhibition of agonist and antagonist motoneurons, respectively. As originally formulated, they form interneurons in a loop of reciprocal inhibitory connections between OPNs and ►excitatory burst neurons (EBNs). This positive feedback loop "latches" the OPNs in an inhibited state and the EBNs in an excited state, until this state is reversed when the saccade reaches its target.

## Characteristics

### Description and Function

The partial diagram of the saccadic burst generator illustrated in Fig. 1 shows one idea of how latch neurons



**Latch Neurons. Figure 1** Schematic diagram of a portion of the brainstem saccadic burst generator showing the proposed function of the latch neurons. Schematized spike discharges are illustrated next to each neuron type. The latch neurons (Latch), the omnipause neurons (OPN), and the excitatory burst neurons (EBN) are connected in a positive feedback loop consisting of two inhibitory connections (−) and one excitatory connection (+). The positive feedback makes the circuit bistable such that the OPNs are "latched" off (no discharge) when the EBNs are discharging, or the EBNs are latched off when the OPNs are discharging. The OPNs are thought to have some excitatory input that causes them to tonically discharge when there is no inhibitory input. When the superior colliculus (SC) begins to discharge just before a saccade, the trigger neurons (Trig) are excited and the tonic discharge of the OPNs is inhibited. This allows the EBNs to respond to their input from the SC and to maintain inhibition of the OPNs via the latch neurons. The OPNs cannot resume firing until the excitatory input to the EBNs has been removed.

might operate. Central to the diagram are the OPNs, which are tonically active during fixations and must be inhibited before the medium-lead EBNs can discharge. This is brought about first by the ►trigger neurons, which receive early excitation from higher-level inputs such as the ►superior colliculus. Once the OPNs are inhibited, the EBNs can begin to fire. In the illustrated schema, the latch neurons receive all their excitation from EBNs, and therefore have discharges that are nearly identical to those of EBNs except for a slight delay. The firing of the latch neurons accelerates the inhibition of the OPNs, and the regenerative inhibitory loop produces a sudden onset of EBN firing and a sudden cessation of OPN firing. Towards the end of the saccade, the EBN firing rate declines as its excitatory input declines. When the firing rate of the latch neurons decline sufficiently, the OPNs begin to fire, the EBNs are inhibited, and the regenerative inhibitory loop produces a rapid onset of OPN firing and a rapid offset of EBN firing.

As originally formulated by Robinson [1], the trigger neurons discharged briefly, and the job of maintaining the inhibition of the OPNs fell to the latch neurons. Moreover, the tight coupling between EBNs and latch neurons insured that the OPNs would not begin firing again (to terminate the saccade) until EBN firing had dropped to a critical level. This allowed the "motor error" input that was hypothesized to comprise the functional input signal to the EBNs, to control the amplitude and durations of the saccade, so that the saccade landed on target (see ►Local feedback and ►brainstem burst generator).

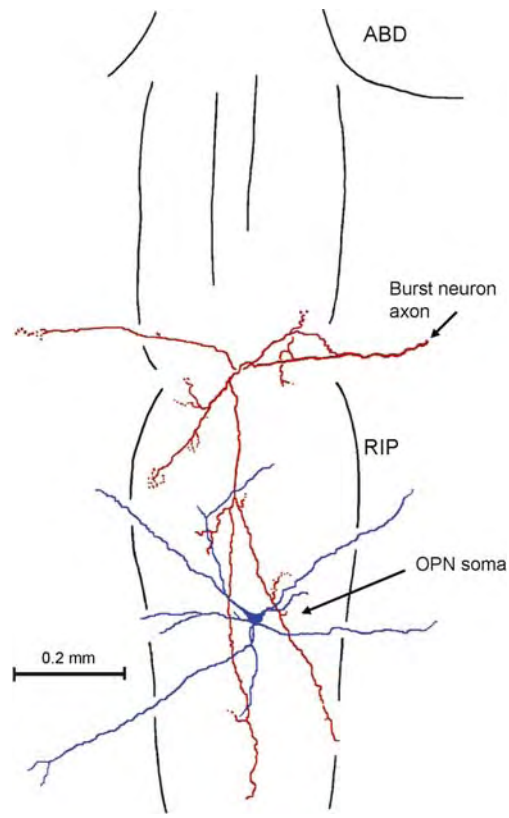
## Higher Level Structures

As a discrete population of neurons that perform the function of latch neurons has not been identified physiologically, the exact inputs to latch neurons are not known. Current proposals expand on Robinson's idea that the input comes from EBNs, while preserving the two functions of latch neurons that Robinson considered.

As outlined above, one function is to form part of a positive feedback loop that causes a rapid change in the firing rates of OPNs and EBNs. However, many ►long-lead burst neurons (LLBNs) (►Burst cells – long lead (LLBNs)) have an abrupt-onset high-frequency component to their burst in addition to their low-frequency early discharge [2,3]. Hence, inhibitory input to OPNs from these LLBNs might produce a rapid cessation of OPN firing, and it may not be necessary to have such a powerful positive feedback loop to produce the rapid cessation. The LLBNs, which could include the ►saccade-related burst neurons (SRBNs) in the superior colliculus and ►ponto-pontine LLBNs, might be expected to use the latch neurons as the inhibitory interneuron.

The second function is to maintain OPNs in a "latched" off state until the saccade reaches its target (amplitude control function). However, in many modern models of the saccadic burst generator, the control of saccade amplitude is accomplished by local feedback loops that do not exclusively pass through the EBNs [cf.4,5]. As these feedback loops have a need to control the duration of the pause in OPNs, the output of such feedback circuits might also impinge on the latch neurons. Input from the cerebellum is a likely possibility [6] (see also ►Cerebellum – role in eye movements).

In summary, the latch neurons could serve as less specialized interneurons that mediate the inhibition of



**Latch Neurons. Figure 2** Reconstruction of intra-axonally labeled neurons in the region of raphe interpositus (RIP), the locus of omnipause neurons (OPNs). The arborization and synaptic terminals of a physiologically identified saccadic burst neuron are illustrated in red. The soma and dendrites of physiologically identified OPN from a different experiment are illustrated in blue. The burst neuron is well positioned to synapse on the OPNs in the RIP and could possibly be a latch neuron. ABD = abducens nucleus. Data were obtained by R. McCrea, A. Strassman, and C. Evinger and were first illustrated in Moschovakis et al. [9].

OPNs. For instance, the functions of the trigger and Latch neurons could be somewhat merged.

### Evidence for Latch Neurons

There is both physiological and anatomical evidence for the existence of latch neurons. By recording intracellular potentials from OPNs in alert cats making saccades, Yoshida et al. [7] found that OPNs were subject to two phases of inhibition. An early phase which preceded EBN firing, and a later one in which the depth of inhibition mirrored saccadic eye velocity. As the EBN firing rate is correlated with eye velocity [8], EBNs are a likely source of input to the interneurons that inhibit OPNs. By definition, these neurons would be Latch neurons. The early phase of OPN inhibition is presumably provided by LLBNs.

Anatomical evidence consists of data from intra-axonal staining of physiologically identified saccade-related neurons in alert monkeys. Fig. 2 shows the soma and dendrites of an OPN and the axonal arborization in the ►raphe interpositus (RIP) of a burst neuron, whose soma was found ventral and medial to the abducens nucleus. The axonal arborization is clearly well situated to provide synaptic input to the OPNs in RIP.

## Late Selection

### Definition

A model, first proposed for attention, assuming that unattended signals are nevertheless processed on early cerebro-cortical levels and eliminated only on higher cortical levels of processing.

►Atention
►Sensory Plasticity and Perceptual Learning

## Latency of Response

### Definition

In event-related potentials, the timing of the response is referenced to the time of the stimulus-evoking event (light flash, noise burst, etc.). Latency is the elapsed time between stimulus and response.

►Event-Related Potentials

## Latent Inhibition

A CS which has been repeatedly presented in the absence of the US requires more pairings with the US to establish the conditioning. Such lowered conditioning performance, called latent inhibition, may be derived from the diminution of novelty and the development of safe learning to the CS or a failure of retrieval even if the association of the pre-exposed CS to the US proceeds normally.

►Conditioned Taste Aversion
►Learning and Extinction

## Latent Learning

Ryota Kanai, Daw-An Wu
Division of Biology, California Institute of Technology, Pasadera, CA, USA

### Synonyms

Incidental learning; Unreinforced learning; Implicit learning

## Definition

Latent learning is an acquisition of neutral information in the absence of external reinforcement or punishment. In latent learning, the acquisition of information does not lead to an immediate change in behavior until the subject is given an incentive to demonstrate the knowledge.

## Characteristics

### A Brief Introduction

Learning is typically defined operationally as a process whereby pre-existing behavioral patterns undergo long-term modification. However, there are many cases in which the impact of a learning process may not immediately express itself, instead remaining latent. For example, one may learn how to perform a task by observing someone else, but this acquired knowledge may not become behaviorally expressed until performance of that task becomes necessary some time in the future. The study of latent learning helps to bridge behaviorist, operational definitions of learning with the more traditional introspective definitions involving the internalization of concepts.

### The Classical Animal Study

In one of Tolman's most famous experiments [1], a number of rats were allowed to explore in a maze for several days. One group was rewarded with food at the goal box and another group did not receive any reinforcer. After the 11th day, both groups were given food in the goal box. As soon as the unrewarded rats were given food, they began to perform as well as the rats that had been trained with the reward, and much better than a third group of rats that had not been familiarized with the environment at all. This indicated that, although the rats performing unreinforced exploration did not exhibit alterations in their behavior, there were unseen internal changes that could become expressed as a behavioral alteration once incentive was provided. Because this form of learning is not externally observable until the reinforcer was introduced to the maze, it is termed latent learning.

Latent learning processes can be separated into three phases: pre-exposure, training and the test [2]. In the pre-exposure phase, rats are allowed to explore a maze, but no reinforcer (e.g., food) is available in the maze. In the training, the rats are trained to learn association between food and a location in the maze, but they are confined to one location. In the expression phase, the rats are again allowed to freely explore the maze without a reinforcer. Because this experimental design isolates the learning of spatial layout from the association of reward with a location, changes in the rats' way-finding performance during the test phase should reflect latent learning processes occurring during pre-exposure phase. If the rats spend more time at the location associated with the reinforcer in the test phase, it is inferred that they have learned about the spatial relationship between the locations during the pre-exposure phase.

Latent learning contrasts with conditioning (reinforcement) learning in which animals learn the association between a reinforcer and a location as they explore the environment. The presence of latent learning indicates that reinforcement is not a requirement for learning.

Furthermore, the existence of latent learning is often taken as evidence that animals acquire "cognitive map" of the environment, rather than simply associating a fixed series of behavioral steps with food reward. This internal perceptual representation of external environmental features and landmarks allows animals to generalize their behavioral strategies. They can more readily utilize short cuts to the food, and can compensate for changes in their initial placement in the maze. As such, latent learning paradigms are an extension of reinforcement learning paradigms, allowing animal investigators operating within the behaviorist framework to address issues such as internalized concepts.

### Latent Inhibition

Latent inhibition is an effect which runs in opposition to latent learning [3]. In latent inhibition, exposure to a stimulus without consequence disrupts subsequent associative learning regarding that stimulus and a reinforcer. However, latent inhibition is induced by a slightly different experimental conditions. One difference is attributed to the active involvement of the animals in the exploration. Latent inhibition occurs when animals are exposed to the environment in a passive fashion, whereas latent learning occurs as a consequence of active exploration. The amount of exposure is another factor which might determine whether pre-exposure leads to inhibition or facilitation of subsequent learning.

### Incidental Learning in Humans

While the term "latent learning" is commonly used in the context of animal behavior, the acquisition of information or skills in humans without intention to learn is more commonly referred to as *incidental learning* or *implicit learning*.

One popular method to study implicit learning in humans is *artificial grammar learning* [4]. Artificial grammar learning typically involves pre-exposure of subjects to letter strings generated from an artificial grammar structure. After the exposure phase, subjects are tested with a new set of letters strings and asked to judge whether the strings follow the same rules or not. Usually, subjects can discriminate grammatical from nongramatical strings above the chance level. However,

they usually do not have a conscious knowledge of the nature of the artificial grammar.

*Serial reaction time* experiment is another example of implicit learning [5]. In a serial reaction time experiment, subjects are asked to press a corresponding button to each location on a screen. The order of the stimulus sequence is structured. Subjects can perform the task without becoming aware of the sequence structure. However, subjects typically respond faster when the sequence structure is consistent over many trials than when it is switched to another. The fastening of the response speed indicates that people learn the task-irrelevant structure despite the fact that in many cases, they are not consciously aware of the presence of such a structure in the sequence.

*Contextual cueing* is yet another form of implicit learning [6]. In contextual cueing, subjects perform a visual search task for target objects among distractors (e.g. the letter "T" among "L"s) and report the orientation of the target letter. The target appears on every trial and surrounded by distractors that form a context for the target. The spatial arrangements of the target and distractors are fixed, and the target appears at a consistent location for each configuration. Thus, the global context of the overall arrangement of distractors predicts where the target should be. As subjects perform the task, they learn to direct their attention to the target location more quickly in the repeated patterns compared with trials with a new randomly generated configuration. As in other types of implicit learning, subjects usually do not have explicit memory about the repeated patterns.

Perceptual learning refers to improvements in sensory processing over training and occurs in the absence of apparent reinforcement [7,8]. Usually, the improvement in performance is highly specific to the stimulus and in the case of vision spatial location. These observations suggest that perceptual learning occurs at an early sensory processing stage. While perceptual learning occurs without conscious effort and even exposure to subthreshold stimuli is sufficient for learning [9], whether attention and internal reinforcement signals play a role in perceptual learning is a matter of debate [10].

## Lateral Hypothalamic Area

### Definition
The lateral hypothalamic area is the area coupled to the central regulation of hunger and thirst.

## Lateral Intraparietal Area

Carol L. Colby
Department of Neuroscience Center for Neutral Basis Cognition, University of Pittsburgh, Pittsburgh, PA, USA

### Synonyms
LIP

### Definition
The Lateral Intraparietal Area (area LIP) is a region of cortex in monkeys located in the lateral bank of the intraparietal sulcus. It was originally defined on the basis of its axonal projections to the frontal eye field. Physiologically, it is defined on the basis of its unique constellation of single neuron response properties.

### Characteristics
#### Higher Order Structure
Area LIP is part of the parietal association cortex. It is a subdivision of Brodmann's area 7.

## Parts of This Structure

Area LIP has been described as containing a dorsal (LIPd) and a ventral (LIPv) subdivision. These subdivisions differ in their myeloarchitecture and in their anatomical connections [1].

## Functions of This Structure

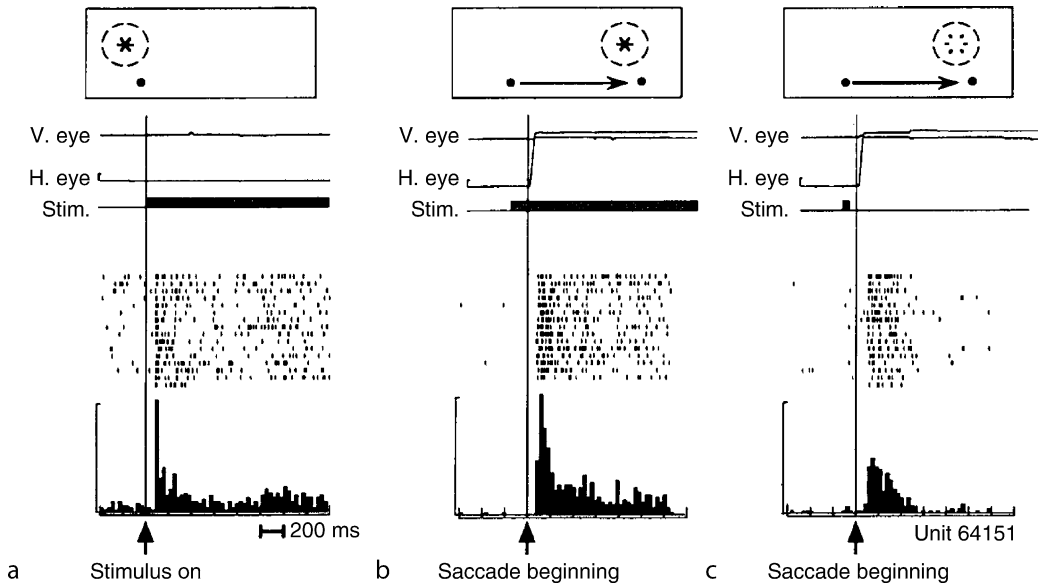
In awake, behaving monkeys, LIP neurons exhibit several different kinds of task-related activity [2]. First, LIP neurons, like neurons elsewhere in striate and extrastriate visual cortex, respond to the onset of a visual stimulus in the neuron's receptive field. Second, these visual responses are enhanced when the monkey attends to the stimulus: the amplitude of the visual response is increased when the stimulus or stimulus location becomes the focus of attention. This enhancement occurs no matter how the monkey will subsequently respond to the stimulus. Regardless of whether the task requires a hand movement, or an eye movement, or requires that the monkey refrain from moving toward the stimulus, the visual response of an LIP neuron becomes larger when the stimulus is made behaviorally relevant. This means that the same physical stimulus arriving at the retina can evoke very different responses in cortex as a result of spatial attention. Area LIP contributes critically to the guidance of spatial attention. When neurons in LIP are inactivated, monkeys are impaired at allocating their attention to objects in the contralateral visual field [3]. A third significant feature of LIP neuron activity is the sustained responses observed when the monkey must remember the location at which the stimulus appeared. In this task, a stimulus is flashed only briefly but the neuron continues to fire for several seconds after the stimulus is gone, as though it were holding a memory trace of the target location. A particularly intriguing question in understanding spatial representation concerns the fate of this memory-related activity in area LIP following an eye movement, as will be described below. A fourth kind of activation commonly observed in LIP neurons is specifically related to performance of a saccade – a rapid eye movement – toward the receptive field. LIP neurons fire just before the monkey initiates a saccade, which will move the fovea onto a target presented in the receptive field. This saccade-related activity reflects the fact that area LIP is closely interconnected with structures that contribute to the planning and execution of eye movements. Indeed, saccades can be evoked by injecting small amounts of current into area LIP [4,5]. These microstimulation effects are likely mediated by pathways linking area LIP to the frontal eye fields and superior colliculus [6].

LIP neurons have overlapping sensory and motor fields, just like neurons in the superior colliculus. In a task in which the animal has to make a perceptual decision, the activity of LIP neurons reflects both the impending eye movement and the sensory information that was used to choose that particular response [7]. Finally, LIP neuron activity can be modulated by the position of the eye in the orbit [8]. For instance, the visual response of a given cell may become larger when the monkey is looking toward the left part of the screen than when it is looking toward the right. This property is striking because it suggests that neurons in area LIP may contribute to spatial representations that go beyond a simple replication of the retinal map. These higher-order representations appear to be essential for guiding accurate spatial behavior. When neurons in area LIP are temporarily silenced, monkeys perform less accurately on an eye movement task that relies on non-retinotopic information. In sum, individual LIP neurons have retinal receptive fields and carry visual, memory, and saccade-related signals that can be modulated by attention and by eye position. Activity in area LIP cannot be characterized as a simple visual or motor signal. Rather, the level of activation in a given LIP neuron reflects the degree to which attention has been allocated to a location within the receptive field [9].

## Higher Order Function

Every time we move our eyes, each object in our surroundings activates a new set of retinal neurons. Despite this constantly changing input, we experience a stable visual world. How is this possible? More than a century ago, Helmholtz proposed that the reason the world appears to stay still when we move our eyes is that the "effort of will" involved in making a saccade simultaneously adjusts our perception to take that specific eye movement into account. He suggested that when a motor command to move the eyes is issued, a copy of that command, or corollary discharge, is sent to brain areas responsible for generating our internal image of the world. This image is then updated so as to be aligned with the new visual information that will arrive in cortex after the eye movement. A simple experiment demonstrates that Helmholtz's account must be essentially true. When the retina is displaced by pressing on the eye, the world does seem to move, presumably because there is no corollary discharge. Without that internal knowledge of the intended eye movement, there is no way to update the spatial representation of the world around us.

Single neuron recording experiments indicate that neurons in area LIP contribute to this updating of the internal image [10]. The experiment illustrated in Fig. 1 shows that the memory trace of a stimulus is updated when the eyes move. The activity of a single LIP neuron was recorded under three different conditions. In the first set of trials, the monkey looked at a fixed point on the screen while a stimulus was presented in the receptive field (panel A). The visual response shown in this left panel is typical of that observed in neurons



**Lateral Intraparietal Area. Figure 1** Responses of a single LIP neuron in three tasks. (a) Fixation task. In the cartoon at the top, the dot is the fixation point, the dashed circle shows the location of the receptive field, and the asterisk represents the visual stimulus. The time lines just below the cartoon show that the vertical and horizontal eye position remained steady throughout the trial, demonstrating that the monkey maintained fixation. The stimulus time line shows that the stimulus appeared 400 ms after the beginning of the trial and continued for the entire trial. The raster display shows the electrical activity of a single LIP neuron in 16 successive trials. In these rasters, each dot indicates the time at which an action potential occurred, and each horizontal line of dots represents activity in a single trial. The rasters show that in each trial there was a brief initial burst of action potentials shortly after the stimulus appeared, followed by continuing neural activity at a lower rate. The histogram at the bottom of the panel shows the average firing rate as a function of time. (b) Saccade task. At the beginning of the trial, the monkey looked at the fixation point on the left, and the rest of the screen was blank. Then, simultaneously, a new fixation point appeared on the right and a visual stimulus appeared above it. The monkey made a saccade from the old fixation point to the new one, indicated by the arrow. The eye movement was straight to the right, so only the horizontal eye position trace shows a change. At the end of this saccade, the receptive field had been moved to the screen location containing the visual stimulus. The rasters and histogram in this panel are aligned on the time that the saccade began. (c) Remapping task. While the monkey fixates, a stimulus flashes for 50 ms at a location outside the receptive field. The neuron is activated when an eye movement brings the receptive field onto the previously stimulated location.

in many visual areas: the neuron fired when a stimulus appeared in the neuron's receptive field. In the second set of trials (panel B), a visual response occurred when the monkey made an eye movement that brought a stimulus into the receptive field. In each trial, the neuron began to respond after the receptive field had landed on the stimulus. This result is just what would be expected for neurons in any visual area with retinotopic receptive fields.

The surprising finding is shown in panel C. In this third set of trials, the monkey made a saccade that would bring a stimulus into the receptive field, just as in the second set of trials. The only difference was the duration of the stimulus, which lasted for a mere 50 ms instead of staying on for the entire trial. As can be seen on the stimulus time line, the stimulus actually disappeared before the saccade began. This means that the stimulus was never physically present in the receptive field. Nevertheless, the neuron fired as though there were a stimulus in its receptive field. This result shows that LIP neurons respond to the memory trace of a previous stimulus. Moreover, the representation of the memory trace is updated at the time of a saccade. The general idea of how a memory trace can be updated is as follows. At the beginning of the trial, while the monkey is looking at the initial fixation point, the onset of the stimulus activates those neurons whose receptive fields encompass the stimulated location. Some of these neurons will continue to respond after stimulus offset, encoding a memory of the location at which the stimulus occurred. When the monkey moves its eyes toward the new fixation point, a copy of the eye movement command is sent to parietal cortex. This corollary discharge causes the active LIP neurons to transmit their activity to the new set of neurons whose receptive fields will encompass the stimulated screen location after the saccade. By this means, LIP neurons encode the spatially updated memory trace of a previous stimulus.

The significance of this discovery lies in what it demonstrates about spatial representation in area LIP. It indicates that the internal image is dynamic rather than static. Tonic, memory-related activity in area LIP not only allows neurons to encode a salient spatial location after the stimulus is gone, but also allows for dynamic remapping of visual information in conjunction with eye movements. This updating of the internal visual image has specific consequences for spatial representation in LIP. Instead of spatial information being encoded in purely retinotopic coordinates, tied to the specific neurons initially activated by the stimulus, the information is encoded in eye-centered coordinates. This is a subtle distinction, but a very important one in generating accurate spatial behavior. Maintaining visual information in eye-centered coordinates tells the monkey not just where the stimulus was on the retina when it first appeared, but where it will be on the retina following an intervening eye movement. As a consequence of this remapping, the monkey always has accurate information with which to program an eye movement toward a current or a remembered target. The creation of such a spatially accurate representation in LIP suggests that LIP contributes to solving the problem of spatial constancy, and allows us to construct and maintain a stable image of the world.

## Lateral Occipitotemporal Gyrus

### Synonyms

Gyrus occipitotemporalis lat

### Definition

On the underside of the hemisphere, two well-developed gyri spread across the occipital lobe and temporal lobe. They are called:

- Lateral occipitotemporal gyrus: runs parallel to the hippocampal gyrus, which lies on the other side of the collateral sulcus. This marks a transition zone between the allocortex and cerebral cortex.
- Medial occipitotemporal gyrus: area 17, the striate cortex, is situated in the occipital portion, directly on the calcarine sulcus.

►Telencephalon

## Lateral Preoptic Area

### Definition

The part of the subcortical basal forebrain located between the ventral pallidum and anterolateral hypo-thalamus, bounded medially by the medial preoptic area and laterally by the sublenticular region.

►Basal Forebrain
►Hypothalamus
►Ventral Striatopallidum

## Lateral Pyramidal Tract

### Definition

In the pyramidal decussation 70–90% of the fibers cross to the contralateral side forming the lateral pyramidal tract, descending in the lateral column of the spinal cord. The tract features a somatotopic arrangement (the lateralmost fibers pass to the lowest, the medialmost to the highest spinal segment). Its fibers terminate in the motoneurons (or interneurons of the motoneurons) of the distal extremity (forearm, hand) and play a major role in fine motor control.

## Lateral Rectus

### Definition

Extraocular muscle for abduction of the eye.

►Eye Orbital Mechanics

## Lateral Reticular Formation

### Definition

This small-celled region of the reticular formation is limited to the pons and medulla. It has six different sections:

- Ventrolateral superficial reticular area
- Parvocellular reticular area
- Lateral pontine area
- Noradrenergic cell groups A1–A7
- Adrenergic cell groups (C1, C2)
- Cholinergic cell group (Ch1–Ch6).

These areas are involved in brainstem reflexes, cardiovascular, respiratory and gastrointestinal regulation and pain suppression.

## Lateral Septum

### Definition
Lateral part of the septum, an area in the medial wall of the cerebral hemispheres, contains cholinergic cells in many species.

►Evolution of Subpallial Cholinergic Cell Groups

## Lateral Sulcus

### Synonyms
Sulcus lat.; Lateral sulcus = Sylvian fissure

### Definition
Large and deep lateral sulcus, caudally contiguous with the temporal lobes and supporting the insula at its deep level.

The lateral sulcus has two important lateral branches: the posterior branch around which the supramarginal gyrus lies, as well as the ascending branch and anterior branch, around which the inferior frontal gyrus is grouped. The primary and secondary auditory cortices are grouped at the lateral sulcus.

►Telencephalon

## Lateral Superior Olive

### Definition
One of the primary nuclei in the superior olivary nuclei located most laterally and important for encoding interaural level disparities.

►Superior Olivary Nuclei

## Lateral Vestibular Nucleus (Deiters)

### Synonyms
Nucl. vestibularis lat. (Deiters)

### Definition
Cluster of neurons located in the rostro-lateral portion of the complex of the vestibular nuclei. It contains giant cells of large diameter characterized by a high conduction speed. The lateral vestibular nucleus provides for close coupling of vestibular nuclei with the cerebellum and can be viewed as being an outpost cerebellar nucleus. The large cells have afferents from Purkinje cells of the vermis cerebelli, posterior spinocerebellar tract as well as the auditory tract. Efferents go to the motoneurons of the spinal cord, eye muscle nuclei, red nucleus and the sensory cells in the labyrinth.

►Pons
►Vestibular Nuclei
►Vestibulo-Spinal Reflexes

## Lateral Vestibulospinal Tract

### Synonyms
Tractus vestibulospinal lat

### Definition
Bundle of axons arising from the lateral vestibular nucleus (with a minor component from the descending vestibular nucleus) traveling trough the ipsilateral ventro-lateral funiculus of the spinal cord, up to its lumbosacral segments. At these levels, its position in the ventral funiculus is displaced medially.

►Lateral Vestibular Nucleus
►Vestibulo-Spinal Reflexes

## Lattice Spacing

### Definition
Lattice spacing is defined as the distance between myosin and actin filaments. According to isovolumetricity considerations, the lattice spacing decreases (increases) with increasing (decreasing) sarcomere lengths.

►Sliding Filament Theory

## Law, Lawfulness

### Definition

The terms law and lawfulness are used in various contexts: we find, for example, laws of thought, laws of nature, or laws in legal practice. They all have in common that something – an action, an event, a transition, etc. – is constrained by what the laws demand. For example, the logical law of excluded middle tells you that for any statement *S* you cannot truly assert "*S* and not *S*." A legal law threatens you with penalties in case your actions fail to comply with what it demands, and a law of nature governs the natural course of events.

►Meaning
►Necessity, Nomological

## Law, Natural

### Definition

Our universe is said to be governed by laws of nature, like Newton's law of gravitation. The empirical sciences seek to discover those laws. They figure in explanations and predictions and are often supposed to underpin causal relations: that the earth's gravitational field causes a stone to fall down is explained and can be predicted by reference to Newton's law. Mostly, law statements are general, exceptionless, and conditional sentences that do not contain reference to particular space-time regions or individuals: "whenand wherever C happens (or is the case) then E will also happen (or be the case) – or, for probabilistic laws, E has a certain objective chance to happen (or be the case)."

►Meaning
►Necessity, Nomological

## Leading Process

►Growth Cones

## Leak Conductance

### Definition

Ion permeability at resting membrane potential, allowing a constant flow of current through the cell membrane due to channels that remain open at resting membrane potential

►Membrane Components
►Membrane Potential - Basics

## Leakage Potassium Current ($I_{K\text{-}Leak}$)

### Definition

A catch-all classification for $K^+$ selective channels that influence input resistance and baseline membrane potential.

## Leaky Integrate-and-Fire Models

### Definition

Leaky integrate and fire models represent a specific type of connectionist networks (artificial neural networks) which incorporate real-time dynamics. Unit activation is computed according to a differential equation relating the change in activation level of a specific unit to its net incoming activation and any loss of signal that naturally occurs over time.

►Connectionism

## Leaky Integration in Oculomotor Control

### Definition

Several oculomotor functions require neural activity be integrated in the mathematical sense, an operation

which can be viewed as an accumulation, or counting, of incoming action potentials and which is thought to be achieved by positive feedback loops ("reverberating circuits"). For perfect integration feedback gain would have to be unity, but for reasons of stability it is generally less; as a result, the integrator gradually looses the accumulated activity much like leaky vessel looses the stored liquid.

- *Glissades*. These are slow onward or backward drifts occurring in the aftermath of saccades when the saccadic innervation pulse does not bring the eye exactly to where its integral, the saccadic innervation step, thereafter will hold the eye.
- *Donders' law*. The statement that the amount of eye torsion about its line of sight, measured relative to a space fixed reference, is uniquely specified by the eye's horizontal and vertical deviation from its primary position, regardless of which path led the eye to this position. Thus, to the extent that this law is valid, the eye's rotational degrees of freedom are effectively reduced from 3 to 2; without a mechanism implementing this law, a horizontal eye rotation followed by an elevation would lead to a different torsion relative to space as when the same position of the line of sight is reached by first elevating the eye and than rotating it about its vertical axis.

## Learned Helplessness

### Definition

Learned helplessness is a term applied to a task in which animals are initially trained to fear a neutral stimulus (CS) in a classical fear conditioning procedure, and are later tested for performance in a bidirectional shuttle box. The uncontrollable, inescapable shocks delivered in the classical fear conditioning training are said to impair learning of active avoidance, or escape responses. The functional explanation for learned helplessness is still of considerable debate. While initially classified as a model of depression, it is now regarded as a more accurate model of anxiety. Learned helplessness is sensitive to both anti-depressants and anxiolytics.

L

### Definition

The acquisition of new information or knowledge or the process to acquire knowledge or skill by systematic study or by trial and error.

### Characteristics

Learning can be defined as the process to acquire knowledge by systematic study or by trial and error. Two types of learning are known in psychological studies; ►*associative learning* and ►*non-associative learning*. The associative learning is the learning of associations between events. In associative learning, a subject learns the relationship between two different stimuli or between the stimulus and the subject's behavior. *Classical conditioning*, *operant* (or instrumental) *conditioning*, and *category learning* (►Category Learning/Memory) are typical examples of the associative learning. On the other hand, non-associative learning can be defined as a change in the behavioral response that occurs over time in response to a single type of stimulus. Non-associative learning would be the simplest form of learning. ►Habituation and ►sensitization are typical examples of non-associative learning.

### Classical Conditioning

One of the typical examples of associative learning is *classical conditioning*. In classical conditioning, a subject learns about the relationship between two stimuli. In a typical case of classical conditioning,

originally neutral stimulus (conditioned stimulus, CS) eventually produces a certain behavioral response (conditioned response, CR) by repetitive presentation of both the CS and a stimulus that produces the CR reflexively (unconditioned stimulus, US). For example, an application of rather strong stimulus (e.g. touch or electric shock) to any body part (e.g. siphon, tail, or mantle) elicits a quick withdrawal of the gill in *Aplysia* [1]. This phenomenon is known as the gill withdrawal reflex. When a mild touch to the siphon (CS), which is weak enough to produce the gill withdrawal reflex, is presented together with a stronger electric shock to the tail (US), the gill withdrawal reflex is elicited. If these two stimuli (CS-US pair) are presented repeatedly for several 10s trials, only a mild touch to the siphon (CS) eventually elicits the gill withdrawal reflex (CR). This is a typical example of classical conditioning. Once classical conditioning is established, it is maintained for several days. However, if these two stimuli (CS-US pair) are presented in an unpaired or random manner, a mild touch to the siphon could not elicit the gill withdrawal reflex. Based on these observations, two important rules have been known in classical conditioning; *temporal contiguity* and *contingency*. In order to establish classical conditioning, CS must precede US by some critical interval (usually several seconds). This rule is called *temporal contiguity*. In addition, to establish classical conditioning, CS must predict the occurrence of US. This rule is called *contingency*. Once classical conditioning is established, a mild touch to the siphon (CS) elicits the gill withdrawal reflex (CR). However, if only CS is applied repeatedly, the strength of CR gradually becomes weak and eventually the effect of classical conditioning is vanished. This phenomenon is called *extinction*. Thus, classical conditioning provides the simplest example of the rules for associating two events.

## Operant Conditioning

In *operant conditioning*, a subject learns about the relationship between a stimulus and the subject's behavior. An animal not only reacts to stimuli but also behaves in a way to produce changes in the environment. For example, when a dog is left alone in a room, it behaves in a variety of ways, such as walking around, jumping up on the sofa, sniffing, picking up a stick or a ball, playing a ball, and so on. When the dog plays a ball, whether or not the dog continues to play a ball depends on its outcomes. In this situation, a dog is not responding to a particular external stimulus. It is thought that a dog is operating on the environment.

In the typical case of operant conditioning, a subject is placed in an experimental box named the *operant box*, which usually has a small lever and a food well. When the subject is placed in the operant box at the first time, the subject knows nothing about the meaning of the lever. The subject spontaneously walks around inside the box and occasionally touches the lever. If a food pellet is delivered when the subject accidentally presses the lever, the probability to press the lever by the subject gradually increases. If the subject recognizes that the food pellet is delivered whenever the subject presses the lever, the probability to press the lever dramatically increases. Eventually, the subject repeatedly presses the lever to get the food. Since the food has the value as a reward and reinforces the lever press behavior, the probability of the lever press behavior dramatically increases. Thus, the subject learns the relationship between the lever press behavior and the food delivery as an outcome in the operant box. This is operant conditioning.

If a particular behavior is followed by a *reinforcer*, the probability of the occurrence of that behavior either increases or decreases. If the probability increases, the reiforcer is called a *positive reinforcer* or a reward. If the probability decreases, the reinforcer is called a *negative reinforcer* or punishment.

Operant conditioning is widely used in psychological studies as well as neurophysiological studies [1,2]. For example, a delayed matching-to-sample task and a delayed non-matching-to-sample task are used for studying functions of episodic memory [1]. A delayed-response task, a delayed alternation, a delayed object alternation, and a conditional task using position, color, or object are frequently used for studying functions of the prefrontal cortex in animals [2].

## Category Learning

*Category learning* (or *categorization*) refers to the process of assigning an object to a concept. A *concept* is the set of properties that we associate with a particular class. For example, the concept of "elephant" includes the properties of having a big body, a long nose, four legs, and so on. When we categorize an animal as an elephant, we consider this animal as if this animal has many of the properties associated with the concept of "elephant," including properties that we have not directly perceived. To categorize an object appropriately, we need to have the *prototype* of the concept, which is one set of properties that describe the best examples of the concept. The prototype of the concept can also be established by learning [3].

We categorize whenever we recognize an object, whenever we encounter a problem, and so on. We always use concepts to categorize something in our world. When we categorize something, we usually apply a rule. For example, if she is the female parent of his parent, she is his grandmother. There have been many studies of rule-based categorization with well-defined concepts. They show that the more properties are present in the rule, the

slower and more prone to error the categorization process becomes, since in the rule-based categorization, the properties may be processed one at a time. In other cases, we often rely on similarity between an object and the prototype to categorize, when we categorize an object using fuzzy concepts, in which we do not know enough properties.

## Non-Associative Learning

Another type of learning is *non-associative learning*. When a stimulus (e.g. a loud noise) is presented repeatedly over time, the magnitude of the behavioral response to that stimulus (e.g. an orienting response to the noise) progressively decreases and eventually the response no longer occurs even though the stimulus is still present. This phenomenon is called *habituation*. On the other hand, if a harmful stimulus, for example, is unexpectedly applied to an animal, sensitivity to a variety of stimuli increases and behavioral responses not only to this harmful stimulus but also to other stimuli increase. This phenomenon is called *sensitization*. In both cases, learned changes in behavior would persist for hours to days in some cases.

## Habituation

There are several types of non-associative learning. *Habituation* is one of non-associative learning leading to decreased behavioral responses to a certain stimulus when it appears repeatedly and is innocuous. Habituation can be observed in our daily life. For example, a loud screech sound would startle us when we hear it first time. However, if this screech sound occurs repeatedly during a short period of time, the magnitude of our startle response to each sound progressively decreases. This is a typical example of habituation.

Neural mechanisms of habituation have been examined using *Aplysia* by Kandel and his group [1]. When a mild touch is applied to the siphon of *Aplysia*, *Aplysia* produces a gill withdrawal reflex and immediately hides away the gill within the mantle shelf. However, if a mild touch is repeatedly applied to the siphon, the amount of the gill withdrawal reflex gradually decreases. Eventually, a mild touch to the siphon elicits no reflex at all. The process of the gradual decrease of the reflex by repeated application of a mechanical stimulus to the siphon can be called habituation. Kandel and his group [1] showed that habituation observed in the gill withdrawal reflex in *Aplysia* is caused by a decrement of the synaptic transmission between sensory neurons innervating in the siphon and motor neurons controlling muscle contraction of the gill. This can be seen as a progressive decrease of the magnitude of EPSP (excitatory post-synaptic potential) observed in motor neurons by repetitive stimulation of the siphon. Since a decrease in the number of synaptic vesicles at release sites within the active zones was observed in the terminal of sensory neurons, it is suggested that some factor affects $Ca^{2+}$ channels to decrease $Ca^{2+}$ influx to the pre-synaptic terminals, although what factor suppresses the opening of $Ca^{2+}$ channels is not yet known.

## Sensitization

*Sensitization* is another type of non-associative learning that results an increase in responses in general or responses once habituated (▶*dishabituation*). Sensitization typically occurs when noxious or fearful stimuli are presented to an animal. Animals usually learn about the properties of a harmful or threatening stimulus by sensitization. If the animal encounters a threatening or harmful stimulus, it quickly responds more vigorously to a variety of stimuli, even harmless neutral stimuli. Sensitization is somehow similar to the phenomenon of arousal, because both sensitization and arousal increase the sensitivity to stimuli.

As is seen in habituation, repeated touch to the siphon eventually elicits no gill withdrawal reflex in *Aplysia*. However, after the response is habituated, an electric shock applied once to the tail immediately restores the gill withdrawal reflex which is caused by a touch to the siphon [1,4]. Similarly, a mouse startles when it first exposes to a loud noise. When that noise is repeated, the mouse will habituate to the noise and no longer exhibit startle responses. However, by applying a single sensitizing shock to the leg, the startle response to the noise can be quickly restored [3]. The quick restoration of a habituated response by applying a sensitizing stimulus is called *dishabituation*.

Neural mechanisms related to sensitization have been examined extensively using *Aplysia* by Kandel and his group [1,4,5]. As is seen in habituation, repeated touch to the siphon eventually produces no gill withdrawal reflex in *Aplysia*. However, after the gill withdrawal reflex is habituated, if rather strong electric shock is applied once to the tail, this electric shock will not only restore the reflex itself but also increase responsiveness to a variety of stimuli. Kandel and his group [1] showed following mechanisms of sensitization in *Aplysia*. The electric shock to the tail produces strong excitatory response in sensory neurons innervating in the tail. This excitatory response of sensory neurons produces excitatory responses in modulatory interneurons, which make synapses on the pre-synaptic terminals of siphon's sensory neurons attaching on the gill's motor neurons. Therefore, modulatory interneurons modulate synaptic transmission from siphon's sensory neurons to gill's motor neurons. Modulatory interneurons use serotonin as a neurotransmitter. When modulatory interneurons are excited by applying an electric shock at the tail, these interneurons release

serotonin from their pre-synaptic terminals. Released serotonin interacts with the serotonin receptor in the pre-synaptic terminal of siphon's sensory neuron. As the serotonin receptor is classified as a metabotropic receptor, a molecule named cyclic-AMP (cAMP) is used as a second messenger to modulate ion channels. The binding serotonin to serotonin receptor activates an enzyme named adenylyl cyclase through the activation of G-protein and synthesizes cAMP from ATP. cAMP then activates cAMP-dependent protein kinase (PKA). PKA closes down $K^+$ channels by phospholylating these channels, causing a broadening of the action potentials. The broadening of the action potential increases the influx of $Ca^{2+}$ through $Ca^{2+}$ channels and consequently increases transmitter release from the pre-synaptic terminal of siphon's sensory neuron to gill's motor neuron. This increase of transmitter release restores the gill withdrawal reflex from habituation. Although this is a specific case observed in *Aplysia*, similar mechanisms would be observed in other animals in sensitization [1].

# Learning Algorithm

## Definition

A systematic procedure describing how to adjust synaptic connections between neurons so the underlying network performs a specific input-output transformation task.

►Neural Networks

# Learning and Extinction

Devin Mueller, Gregory J. Quirk
Department of Psychiatry, University of Puerto Rico School of Medicine, San Juan, Puerto Rico

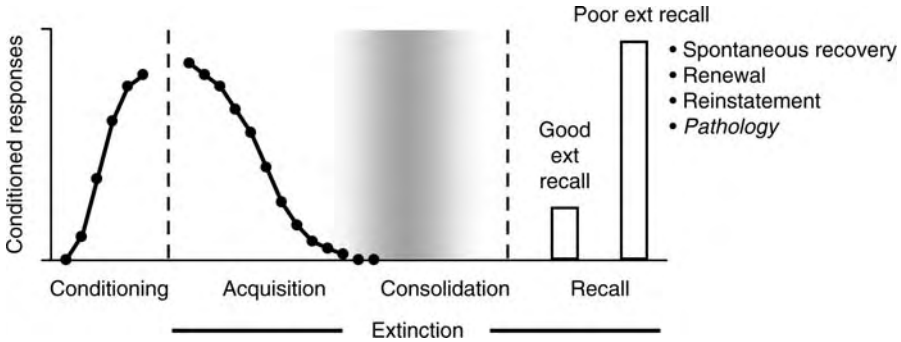
## Definition

Extinction is the decline in the frequency or intensity of a conditioned response following the withdrawal of reinforcement. In ►Pavlovian conditioning, the conditioned response declines when the conditioned stimulus (CS) is no longer followed by the unconditioned stimulus (US). The term extinction can be used to describe a procedure, a result, or a process. Extinction refers to (i) the procedure in which the CS is repeatedly presented in the absence of the US (►extinction training), (ii) the decrease in conditioned responding to the CS that is observed under these conditions (►response extinction), and (iii) the associative or cellular processes responsible for this decrease in responding (►extinction memory).

## Characteristics

From the behavioral point of view, extinction represents a reversal of the original conditioning phase of learning and, like conditioning, is characterized by an "S" shaped learning curve. There are two possible mechanisms by which extinction could occur: (i) elimination of the original conditioning memory, or: (ii) the acquisition of a new memory, but of an inhibitory nature. Predominant evidence from behavioral and neurobiological studies supports the second alternative. Following extinction training, the CS has two different associations with the US: the original excitatory association and the new inhibitory association. Which of these associations will be recalled depends on the situation in which the CS is encountered. Return of the conditioned response after extinction is observed under several conditions: (i) following the passage of time (►spontaneous recovery), (ii) following a change in context (►renewal) or (iii) following the presentation of the US or other stressor after extinction training (►reinstatement). The re-emergence of the conditioned response after extinction constitutes the *prima facie* evidence that extinction does not eliminate the original conditioned association but, as originally observed by the Russian physiologist Pavlov, is a form of ►inhibitory learning.

Like other types of learning, extinction occurs in three phases: acquisition, consolidation, and recall (Fig. 1). Acquisition of extinction is the initial learning that occurs as conditioned responses decline within the training session. This is followed by a consolidation



**Learning and Extinction. Figure 1** Schematic representation of the three phases of extinction. Acquisition is characterized by a decrease in conditioned responses to the presentation of a CS without the US. Consolidation is a time-dependent process during which a long-term extinction representation is formed. Recall of extinction is a test at a later time, in which the CS is presented alone. Good recall is characterized by low levels of conditioned responses, whereas poor recall is characterized by high levels of conditioned responses. Poor recall of extinction is observed during renewal, reinstatement, spontaneous recovery, or in pathological conditions in which extinction fails.

phase, lasting one to three hours, in which physiological and molecular processes strengthen ►extinction learning. Subsequent to this, presentation of the extinguished CS triggers recall of extinction, as evidenced by low levels of conditioned responding. Failure to recall extinction is characterized by high levels of conditioned responding to the CS, reflecting expression of the original conditioning memory.

Extinction learning is one of several closely related forms of interference paradigms. In conditioned inhibition, the US that normally follows a CS ("A") is omitted when the CS is presented in conjunction with a new stimulus "X." Thus, "A" is followed by the US, but the compound "AX" is not. Under these conditions, the "X" stimulus acquires an inhibitory association with the US and becomes a conditioned inhibitor. In ►latent inhibition, the CS is repeatedly presented without any consequences prior to pairing it with a US, resulting in slowed rates of conditioning.

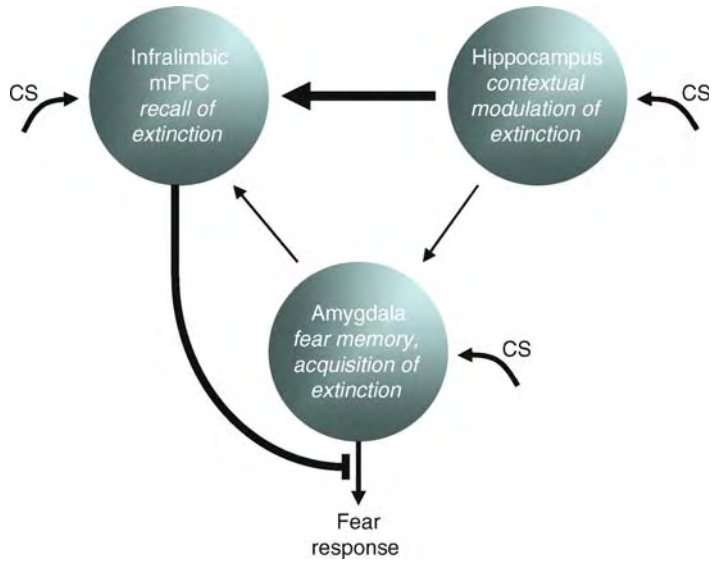
## Neurobiology

Much of what we know concerning the neural circuitry underlying extinction comes from studies of fear conditioning, in which animals or humans are exposed to a CS (e.g., a tone) that co-terminates with an aversive US (e.g., a shock). A quarter century of research on the neurobiology of fear conditioning has laid the groundwork for examining the neurobiology of extinction. ►Fear extinction is dependent upon a network of brain regions that includes the amygdala, the medial prefrontal cortex (mPFC), and the hippocampus (Fig. 2).

It is well established that fear conditioning is acquired, consolidated and expressed by the amygdala [1]. Tone-induced neural activity in the lateral amygdala is potentiated following the pairing of a tone CS with a shock US. During extinction, however, the responses of many of these cells return to pre-training levels. Because expression of fear is dependent on amygdala, expression of extinction is thought to be reflected in decreased amygdala output. Acquisition and expression of extinction requires *N*-methyl-D-aspartate (NMDA) receptor activity in the amygdala, activation of downstream signaling molecules such as mitogen-activated protein (MAP) kinase and phosphatidylinositol 3-kinase (PI-3 kinase), and the γ-aminobutyric acid (GABA) receptor clustering protein gephryin [2]. Extinction is associated with an increase in surface expression of GABA receptors in the amygdala, and expression of extinction is thought to involve GABAergic inhibitory interneurons within the amygdala, particularly the intercalated neurons which directly inhibit amygdala output neurons [3]. Thus, the amygdala is necessary for the acquisition and expression of extinction.

Despite the behavioral evidence that extinction is not erasure of fear memory, recent findings suggest that extinction may reverse conditioning-induced plasticity within the amygdala [2]. Extinction increases phosphatase activity in the amygdala, reversing conditioning-induced increases in phosphorylated Akt and CREB. This results in a depotentiation of synapses and weakening of the original conditioning memory. There is even evidence that extinction can erase conditioning entirely, if done within an hour of conditioning, at a time when fear memory has not been fully consolidated. Thus, extinction could weaken conditioning memory in the amygdala, even though this memory remains intact elsewhere.

In contrast to the amygdala, the mPFC is responsible for consolidating and recalling extinction learning. Inhibition of protein synthesis in the infralimbic (IL)



**Learning and Extinction. Figure 2** Neural circuitry of fear extinction. The amygdala stores both conditioning and extinction memories. CS information is processed by the amygdala, hippocampus, and mPFC. The mPFC integrates CS information with contextual information from the hippocampus in order to determine extinction recall. In the extinction context, mPFC inhibits amygdala output via projections from the infralimbic cortex (IL). Outside the extinction context, amygdala output is not inhibited.

mPFC leaves acquisition of extinction intact, but impairs recall of extinction the following day [4]. Post-training infusion of a MAP kinase inhibitor or an NMDA receptor antagonist into IL impairs consolidation of extinction, and blockade of NMDA receptors reduces extinction-induced bursting of IL neurons [4,5]. Finally, during recall of extinction, IL neurons exhibit potentiated responses to the CS [4], which activate inhibitory networks within the amygdala. In support of this, stimulation of IL decreases conditioned fear and inhibits amygdala output [4]. Thus, expression of amygdala-based fear memories is subject to cortical control following extinction.

The hippocampus provides for contextual modulation of the consolidation and expression of extinction to a CS. Temporary inactivation of the hippocampus prior to extinction does not prevent extinction learning, but results in impaired extinction recall [6]. In addition, inactivation prior to a retention test prevents renewal. Lesions of hippocampus also interfere with context-specific reinstatement effects [6]. For extinction of contextual fear conditioning and inhibitory avoidance, the hippocampus is itself a site of extinction plasticity. These forms of extinction require activation of NMDA receptors, MAP kinase, and protein synthesis in the hippocampus. The hippocampus and IL are interconnected and may work together to gate the expression of extinction under a variety of circumstances.

Relative to fear extinction, there are few studies on the neurobiology of appetitive extinction. The available evidence, however, suggests that the amygdala, mPFC, and hippocampus perform similar roles in appetitive extinction as in fear extinction [6,7]. Lesions of the amygdala attenuate acquisition of extinction of drug-seeking behavior, whereas inactivation of IL increases reinstatement of drug-seeking behavior, consistent with a failure to recall extinction. IL is thought to inhibit drug seeking through interactions with the nucleus accumbens, the site of expression of drug-seeking behaviors [7]. Inactivation of the hippocampus prevents context-dependent reinstatement of drug seeking, suggesting that the hippocampus may be important for contextual modulation of appetitive extinction. Thus, the amygdala, mPFC, and hippocampus may constitute a general extinction network.

Functional neuroimaging is revealing homology between rats and humans in the learning and expression of extinction. The amygdala, hippocampus, and the ventral mPFC are all activated at various stages of extinction learning and recall [8,9]. For hippocampus and ventral mPFC, the degree of activation is correlated with the degree of extinction recall. Thus, the neural mechanisms of extinction appear to be conserved across species.

## Clinical Relevance

Perhaps more than any other field in learning and memory, extinction is directly applicable to the treatment of various clinical disorders, which arise when conditioned responses are pathologically over-expressed. In the

appetitive domain, over-expression of conditioned responses can lead to addiction, whereas in the aversive domain, over-expression of conditioned fear responses can lead to ►anxiety disorders and phobias. Extinction-based exposure therapies are used to treat anxiety disorders, and are beginning to be used for addiction. Extinction deficits are observed in patients with ►post-traumatic stress disorder (PTSD) [9]. Thus pharmacological treatments that enhance extinction offer promise for PTSD and other anxiety disorders. Cognitive enhancers such as the NMDA partial agonist D-cycloserine (DCS), which facilitate fear extinction in rats, augment the therapeutic response to exposure therapy for phobias [10]. With respect to addiction, extinction of drug-seeking behavior in rats is also facilitated by DCS, suggesting that DCS may improve the therapeutic outcome of extinction-based treatments for addiction. Neuroimaging has revealed a general decrease in basal metabolic activity in mPFC in addicted individuals, suggesting a lack of cortical inhibition. Thus, pharmacologically enhancing metabolic activity in mPFC may improve extinction recall in addicts and reduce the probability of relapse.

Molecular and Integrative Emotional Neuroscience, Graduate School of Medicine, University of Toyama, Sugitani, Toyama, Japan

## Introduction

Learning refers to processes of acquiring or encoding information and developing the capability to carry out new behaviors. Learning continues throughout our lives, we learn to deal appropriately with other individuals, to adapt properly with complex systems in our societies, and learn to acquire experiences. Therefore, learning influences almost all aspects of our social behavior. Studies of learning have emphasized a relation between changes of behavior as a result of an individual's experiences.

Memory sometimes refers to an engram (i.e., memory trace) that is acquired by learning, and is formed and processed through encoding, storage, and retrieval of information. Encoding refers to the initial acquisition of information, storage is the retention of encoded information over time, and retrieval refers to the processes involved in using stored information. A breakdown in one of these stages can intervene in a successful recall of information.

The concepts of ►learning and ►memory are closely related, and the terms often describe roughly the same processes. In a thread of consequential relation, learning is the process of acquiring new information, while memory refers to the persistence of learning in a state that can be recalled at a later time, so memory is the usual consequence of learning. Nowadays, the term ►learning/memory process is used as a means of incorporating all aspects of acquisition, storage, and retrieval. Naturally, learning and memory are features seen in all creatures, and they are pivotal to the survival of humans and all living organisms. The psychology of learning and memory is broad, and though these two processes are intermingled, this synopsis will discuss them in parts.

## Learning

There are many types of learning including simple and complex ones. Simple forms of learning consist of habituation and sensitization [1]. Habituation refers to a process that an individual becomes accustomed with a stimulus after repeated presentation of it. An example of habituation is the orienting response, in which a new sight or a loud sound can firstly attract an individual's attention. If the stimulus is presented repeatedly but with no consequences, the orienting response will abate. Sensitization is another simple type of learning, and refers to the increase in response to stimuli of an

individual after an exposure to an intense stimulus. With habituation individuals learn about the properties of a benign stimulus, allowing individuals to ignore repetitive and insignificant stimuli. With sensitization an individual learns about the properties of harmful or threatening stimuli, which is helpful for survival, especially in the wild nature. Habituation and sensitization refer to learning of the stimulus itself.

There are complex forms of learning [1,2]. People or animals learn to associate two stimuli occurring in sequence in ►classical conditioning, or learn to form an association between a behavior and its reward or punishment consequences in ►operant conditioning (►instrumental conditioning), or learn by observation, etc. The following parts concern principles of these complex forms.

## Classical Conditioning

In classical conditioning, organisms learn to form an association between two stimuli occurring in sequence, and in which a natural response transfers from one stimulus to another. Classical conditioning was discovered serendipitously by Russian physiologist Ivan P. Pavlov in the early 1900s, when he was conducting experiments on digestion. He gave a dog food and monitored the amount of saliva secreted while the dog ate the meal. After the dog performed this procedure a few times, then Pavlov found that the dog would begin salivating before getting any food. This basic type of learning is now known as classical conditioning or ►Pavlovian conditioning. The conditioning process generally has the same general procedure and components including unconditioned and conditioned stimuli, conditioned and unconditioned responses. The relationship between conditioned and unconditioned stimuli occurs and their influence on the consequences of learning are concerned in the ►theory on classical conditioning. Pavlov and his colleagues determined the main processes in classical conditioning, which include acquisition, ►extinction, generalization, and ►discrimination.

The acquisition phase is the initial step for conditioning an animal, for instance, to train the dog to salivate at the sound of the bell. The sequential and temporal order of unconditioned and conditioned stimuli can affect the forming of conditioning. The conditioned stimulus should come prior to the unconditioned stimulus and can easily produce a conditioned response, and more difficultly in producing a response if this order is inversed.

Extinction is used to describe the decline in the conditioned response by repeatedly presenting the conditioned stimulus in the absence of the unconditioned stimulus (extinction training), which then consequently induces a response extinction and extinction memory. The conditioned salivation response will gradually abate if the experimenter rings the bell repeatedly giving no food.

Generalization refers to a process in which an animal has been conditioned to a particular stimulus, it may also respond to a similar stimulus without training of this new stimulus.

Discrimination refers to a process in which an individual learns to respond differently in the presence of distinct stimuli.

This classical conditioning is suggested to account for some changes in human social behaviors, such as phobia, a phenomenon of excessive fearing of specific objects or circumstances. Classical conditioning is also used to deal with certain behaviors.

## Operant Conditioning

Operant conditioning, is also called instrumental conditioning [1,2], and refers to a process involving changes of behaviors by reward or punishment. In operant conditioning the subjects must perform or operate certain behaviors in order to get a reward or punishment. Research in operant conditioning was pioneered by American psychologists Edward L. Thorndike and B.F. Skinner.

Edward L. Thorndike conducted research on operant conditioning at the end of nineteenth century using several species of animals such as chicken, dogs, and cats [1]. He placed an animal in a so-called puzzle box, and if the animal responded correctly, the door would open and the animal would get out and have some food placed outside the box. The first time the animal took a long time to make the correct response and making the door open to receive rewards. As he put the same animal in the box repeatedly, the animal would respond in a correct manner more quickly. Based on these experiments, Thorndike proposed a principle that was called the law of effect, which states that behaviors that are followed by pleasant or unpleasant consequences will be strengthened or weakened, and will be more or less likely to occur in the future, respectively. His law coincides with what is now called operant conditioning.

B.F. Skinner, a famous psychologist, from the beginning of 1930s discovered important principles of operant conditioning, a type of learning involving reward and punishment, using rats and pigeon [1]. He trained the animal in chambers, which are now known as Skinner boxes. In such a box, the animal could get food by making responses, such as pressing a lever or pecking at a hole. A device attached to the box recorded the animal's responses, and he could observe the influence of food delivery on an animal's behavior. From his discoveries, he argued that the rewards and punishments could also manipulate human behaviors. There are several principles of operant conditioning

including reinforcement, punishment, shaping, extinction, discrimination, and generalization.

In operant conditioning, positive reinforcement strengthens behaviors with a following pleasant stimulus, and negative reinforcement strengthens a behavior by removing a following unpleasant stimulus. Reinforcements can control the behavior of humans and other living organisms [1,2]. Appetitive reinforcers, such as food or water, typically increase the probability of responses on which they are contingent. Reinforcement schedules are rules that specify the timing and frequency of reinforcers. There are several types of reinforcement schedules, such as continuous reinforcement, fixed-ratio schedule, variable-ratio schedule, etc.

Punishment or ►aversive reinforcers weaken behavior, reducing the chances that the behavior will occur again, which is ►aversive learning. There are positive and negative punishments. Positive punishment refers to reducing a behavior by delivering an unpleasant stimulus if the behavior occurs, and negative punishment refers to reducing a behavior by removing a pleasant stimulus if the behavior occurs.

Shaping method refers to a process of training animals or people to learn behaviors that they have never performed before, by reinforcing the behavior the learner can perform from easy steps to more difficult ones. This method is often used to train animals to perform some specific behaviors.

Extinction in operant conditioning is the elimination of a trained behavior by extinguishing the reinforcer for that behavior. The lever pressing for food or drink in rats can be eliminated if such a reward is not delivered anymore.

In general, individuals perform a learned behavior in one circumstance and in other similar circumstances, for example we learn to apply the greeting "congratulations" to several happy circumstances of other people, such as when a person is promoted or when another one has good news on business.

Discrimination is learning when a behavior will be and will not be reinforced with reward in different circumstances, such as not to say "congratulations" to a person in an uncomfortable situation since it may not produce a good result at all.

## Observational Learning

Though classical and operant conditionings are important, living organisms can learn a great deal through observing others, which is observational learning/memory or ►imitation learning. Learning by observation refers to a process including observation of the behavior of others and imitating their behavior. People learn languages as a means of communication, and learn to develop social behaviors, skills, and personality by observing others and gaining experience. Many other species can also learn by observing other members of their societies.

Albert Bandura, a Canadian-American psychologist, in the early 1960s conducted experiments on how observational learning influences the behavior of children [1]. In one experiment, he showed preschool children a movie of an adult showing aggressive behavior to a doll, and then found that the children witnessed the movie mimicked that aggressive behavior. Bandura's theory, also called social learning theory, mentions that there are some components in observational learning, including attention, retention, reproduction and ►motivation. The learner at first needs to pay attention the behavior of others; secondly the learner must have retention of that observed information; thirdly the learner should mimic to reproduce the same behavior, and finally the learner should also have the desire or motivation to mimic the observed behaviors. Though neuronal substrates for imitation learning are still unspecified, the mirror neuron systems found in the monkey cortices are considered as a contribution to imitation. In human society, observational learning has a wide influence on people's social behaviors and interaction, especially through education and media.

## Other Forms of Learning

Learning and comprehending language are essentially important for people since they use language as a means to communicate with other people. It is one of the most complex types of learning, and all children learn this skill in the first few years of their lives. Since 1950s American linguist Noam Chomsky proposed that humans have an innate ability to deal with word meanings and other grammatical rules. Later on scientific evidence shows that there are regions in the human brain as domains for language. Since people communicate using their language, so they can learn tremendous information by listening and by reading also. For humans, language is a specific signaling system, yet it can play roles as rewards or punishments in specific circumstances. Using language, people can develop a concept of objects in their environment, and more extraordinarily, they can have the abstract concepts. Other species also have their specific vocalization as a means to interact with their society's members.

There are other forms of learning/memory such as ►perceptual learning, habit learning, and ►sensorimotor learning. ►Perceptual learning refers to sensitivity enhancements in perception such as auditory, visual sensation, as a result of training. Sensorimotor learning, a type of procedural learning, refers to a process of learning to do physical movements in a coordinated manner. Motor skills, once mastered, can be performed unconsciously, such as riding a bicycle or playing a musical instrument.

More specialized terms have been developed concerning particular aspects of learning, such as ►latent learning, ►metalearning/metacognition, ►value-based learning, and ►spatial learning, etc. In latent learning, learning would occur without reinforcement, which is contradicted with reinforcement learning. Metalearning refers to the self-regulatory process of cognitive processes while engaging in the task. Value-based learning refers to a process of learning to obtain rewards and avoid punishments available in the environment, which encompasses principal components of both classical and operant conditionings.

A ►learning curve [3] is applied as a tool to analyze learning processes, in which correct and error performance of tasks through a time course of training are measured.

Mathematical and computational sciences have used simulated ►neural networks to decipher more computational traits of learning and memory. Principles of learning applied to artificial neural networks as in ►competitive learning, ►associative learning/memory, and ►connectionism studies are helpful in elucidating learning functions, contributing to the development of intelligent machines and brain machine interface.

## Factors Affect Learning

Learning is complex, and learning ability is different among species. For example, a monkey may take several months to master a task that a child can learn simply within a few minutes. Within a species, some factors such as age, experience, and mental conditions can affect learning ability.

Learning in animals and people occurs at all ages, but it is not similar at all ages. For example, at infant age, children quickly learn a new language, but learning a new language to some extent is harder for aged people. Many residents in Quebec, a province of Canada, are bilingual native speakers as they speak fluently both English and French languages, since they are exposed to both languages naturally from their infant age. Prior exposed experience is helpful to learn new ones that have some similar aspects. Matured people master the logical and abstract thinking more easily, as they experienced many abstract ideas previously, as the adult more easily understands a concept of "passion" or "tolerance" than adolescence. Various developmental disorders can intervene in the learning ability and influence one's behaviors. Children with attention-deficit hyperactivity disorder (ADHD) or autism have difficulty in learning and developing their social behaviors. In adults, aged-related and degenerative diseases, such as Alzheimer's disease (AD), can severely impair the learning/memory ability. Consolidation of learning/memory is enhanced with ►sleep, and it has been shown beneficial for some types of learning.

Learning is also individually different and somewhat influenced by motivation and ►emotion. In one class pupils may have different achievements of study, though they share the same schooling conditions, since they are different in their level of intelligence. There are people who have specific ability and skills to learn some subjects, such as are talented at music or mathematics but may not be excellent at the others. Therefore, encouraging the specific learning ability of people, motivating and taking care of people having learning problems should be publicly considered.

## Memory

Memory, as mentioned, is formed and processed through initial acquisition, retention, and retrieval of information in the brain. Memory is essential for the existence of all animals, it allows people access to the past, to form experience, and therefore to learn many skills. Memory has been a fascinating issue to many physiologists, thinkers and philosophers. Consider a life as a thread of events and facts that are recorded by one's memory, we may then recall the proclamation of Rene Descartes "I think therefore I am". There are several types, processes, and interesting phenomena in memory.

### General Division of Memory

Memory generally is divided into three main categories: sensory memory, short-term or working memory, and ►long-term memory [4]. Each of these categories is further divided.

#### *Sensory Memory*

Sensory memory refers to the initial recording of information in sensory systems. The brief encoding of visual or acoustic information is called iconic memory or echoic memory, respectively. Analogously, sensory memory is encoded in other sensory modalities. Our sensory systems often receive a large amount of information; they work unconsciously and retain sensory memory for a brief period of seconds or less, and only a handful of information that captures attention can be registered into ►short-term memory.

#### *Short-Term Memory*

William James in 1890 used the term primary memory to refer to the process of the information that forms the focus of attention and occupies the stream of thought.

The term short-term memory refers to the ability to hold information in mind over a brief period of time. The term working memory was created by Baddely and Hitch, and since 1974 has provided a broader concept of short-term memory, referring to a workspace or memory buffer that stores and allows access to use the stored information. Repetition of information can help to hold information in memory, but if something

interferes with the information holding process then we can quickly lose or forget information from the working memory. Hermann Ebbinghaus, a German philosopher, developed a measure for forgetting, and found that forgetting is rapid immediately after a study period but the rate of forgetting slows over time. Working memory can hold a limited number of information at one time. As estimated by American psychologist George Miller, generally the limited number that can be stored in the working memory is seven items. The working memory is also thought as having correlation with intelligence.

### *Long-Term Memory*

The term long-term memory is used to refer to a brain system that can store a great deal of information on a long-lasting basis. This terminology may describe the storage of all traces from something learned just minutes before and memories of a long period ago. There seems to be infinite storage capacity of long-term memory. For example, people can recall events that occurred a few decades ago, and can also retain a vast amount of information of various types throughout their lives. There are some views on how information engages in long-term memory. The classical view supposes that firstly information enters the short-term memory, and then may be processed somehow and transferred to long-term memory. Another view supposes that information may be processed separately and entered simultaneously into short-term and long-term memories. Long-term memory is further divided into two categories as declarative and non-declarative memories with main domains: ►episodic memory, semantic memory, and procedural memory.

## Divisions of Long-Term Memory

Long-term memory is divided by some ways with specific terms serving as synonyms.

### *Declarative Memory and Non-Declarative Memory*

Declarative memory refers to memory that can be consciously recalled and described verbally, and non-declarative memory is memory that can be unconsciously recalled and only expressed through behaviors.

#### *Declarative Memory*

Episodic memory refers to memories of specific episodes in one's life. Episodic memories are linked with a specific time and place, it is a memory to answer "when" and "where" questions. Episodic memory stores the autobiographical details of our lives. We would rely on episodic memory to recall the events, such as memory of a nice trip to a beautiful resort (where) with friends last year (when). Since individuals can consciously recall events, facts and then can linguistically declare them, episodic memory is assigned as a type of declarative memory or explicit memory. In human society, declarative memory is largely associated with spoken information, which is referred to as ►verbal memory.

Semantic memory refers to general knowledge of the world and all of the facts we know. Knowing that Paris has the Eiffel tower or Japan has Mount Fuji is a kind of semantic memory. Whereas episodic memory is closely related to time and place, semantic memory is not related to the particular time and place of learning the fact. We do not need to remember when and where we learned that Mount Fuji is in Japan. Semantic memory is also assigned as a type of declarative memory, yet semantic and episodic memories may have a different neural basis for their capacities.

#### *Non-Declarative Memory*

Non-declarative memory refers to memory that does not require conscious effort to recall. Non-declarative memory includes procedural memory, priming, simple classical conditioning such as eye blink response, and others such as perceptual, ►emotional, and habit learning/memory. Mainly procedural memory is mentioned here.

Procedural memory refers to the procedures and skills that an individual possesses. Playing a musical instrument, riding a bicycle, writing skills are examples of procedural memory. In contrast to episodic and semantic memories, procedural memory is expressed through performance and typically does not recall consciously; therefore it is called non-declarative memory. Practice plays an important and direct role in procedural memory; for example, a pianist can still improve his skills and performance through repetitive rehearsals over time.

Long-term memory is divided into two categories, and there are activities that require a pure memory component. Yet human activities also require blended involvements of these components. For example, people learn to play sports firstly need to receive instructions given in words or witness images (declarative components), and once they master these skills perfectly (procedural component), they can describe more precisely the skills. Thus, declarative memory and procedural memory may have certain mutual effects on each other.

### *Explicit Memory and Implicit Memory*

In other words, memory is classified into implicit and explicit memories. The psychologist William McDougall distinguished these terms in 1924.

#### *Explicit Memory*

Explicit memory refers to the process of conscious retrieval of facts and past events. Explicit memory is consistent with declarative memory. Recall about a trip

to Mount Fuji last summer requires explicit memory. For testing explicit memory, there are tests for recall and ►recognition components. Showing a list of words, subjects would then be asked to write down as many words as they could, this is an example of a recall test. This type of test requires explicitly recalled information from memory. Showing a list of items and then asking subjects to classify which they have seen before and which are newly added items, this is an example of a ►recognition memory test.

### Implicit Memory

Implicit memory refers to using stored information without any effort to retrieve it. Implicit memory is consistent with non-declarative memory. In daily living, people capture and store experiences, and can then use them unconsciously. Very often we hear and see others, some time later we may say out the word we heard or imitate the other's behavior without realizing it. The automatic retrieval of information resulting from prior exposure is called priming effect. Subjects in experiments study a list of words (for example, friend, tower), they are then shown a list of fragmented words (fr_ _nd, t_ w_r) and are required to complete these fragmented words with the first word that come to their mind. Since previous exposure to the word "friend" and "tower," the subjects are primed to complete the fragmented words with what they have seen in the first list. Priming effect often occurs in daily life.

## Consequences of Memory

Encoding and storage are essential processes to attain and retain information. Encoding or perception refers to the process of perceiving information and conveying it into the memory system. Encoding is the first process, it convert information from one form to another. Proper analogue signals from the outside world enter sensory systems. The receiving parts of sensory modalities convert the received analogue signals to bioelectrical signals and then send them to the brain to be interpreted in forms that we can perceive. Individuals receive a vast amount of information, and much of it is encoded unconsciously. Prior experience is helpful for recording new information; repetitive rehearsal of information, changing information into images or a meaningful set can efficiently help the encoding ability and routine to store in memory.

Retrieval allows using stored information, and this process is crucial for accessing memories. There are several retrieval phenomena, which people may have experienced sometime [4,5].

Concerning consequences of memory, there are some interesting phenomena that one may have experienced at some moment, such as the following.

*Flashbulb memory.* Many American people remember well where and when they heard the exceptional news such as the event that occurred with the twin trade towers in New York in 2001, since it created a flashbulb memory for them. This specific type of memory is associated with important emotional events in one's life, such as our marriage, or the birthday of our own babies.

*Déjà Vu.* French originated word *déjà vu*, with its meaning as "seen before," is the hallucination of having been somewhere before, or experienced the current situation before, even though it has never experienced. Déjà vu is supposed that aspects of the current situation act as cues for retrieval that unconsciously evoke an earlier experience, resulting in a sense of familiarity.

*Jamais Vu.* Also a French originated word, *jamais vu*, with meaning as "never seen," is the feeling when people feel they are experiencing circumstances for the first time, even though they know they have experienced it before. Jamais vu is explained that even though the similarity of the current and past circumstances, the cues of the current situation do not match the encoded trace of the past circumstance.

*Tip-of-the-tongue state.* The *tip-of-the-tongue state* refers to the situation in which a person tries to retrieve a familiar name, word, or fact, but finds it impossible to do so. The correct retrieval may come after sometime of trying to recall some other relatively close items. This phenomenon is explained as memory of other items that may prevent the retrieval of the correct item, or another possible explanation is that only a part of the information is insufficient to the retrieval of the correct item.

Memory is sometimes recalled differently from what actually occurred, as memory may undergo typical transformation over time, including omissions, deletions, reconstruction, and distortions. ►Memory distortion can occur as information is transformed serially through a number of people (social factor), or can also occur by our own recollection of memory. In memory processing sleep plays a certain role, especially in the consolidation process of learning and memory across animal species.

## Forgetting

A reverse side of memory is forgetting, which is defined as the decay and loss of information as time passes. Hermann Ebbinghaus in his memory experiments had used lists of nonsense syllables consisting of three letters with a vowel in between two consonants such as QAP or PIH. He learned a list until he could recall the list without error, and knew how long and the number of trials he took to master the list, then he tested his memory of the list over intervals from 20 min to 31 days. He found that rapid forgetting occurs at first and then the rate of forgetting was consistent as more time passes. His forgetting curve demonstrated the decay of stored information in long-term memory. It is thought

that forgetting occurs because of interference from other information over time. Forgetting is troublesome in some aspects, but it is a natural process and useful to wash out outdated unnecessary information.

## Neural Substrates of Memory

### *The Search for the Engram*

The biological basis of learning and memory is one of the most intriguing topics in cognitive science, with exciting questions such as where is the storage of memory. Psychologists in the early and mid of 1900s engaged in the "search for the engram" [4]. The term engram (i.e., memory trace) is used to refer to the changes in the nervous system that have occurred as a result of experience, or in the other word, it refers to specific loci of memory. American psychologist Karl Lashley surgically removed various parts of the brains of rats after they were well trained to solve a maze. He found that the rats still retained the ability to solve the maze. Now a modern concept of distributed memory across the brain is widely accepted.

### *Brain Regions Involved in Memory*

Many brain regions are involved in encoding, storing, and retrieval of different information in different memory-related processes, and they seem partially to work in interaction. However, there are brain regions that are involved specifically in processing and storing of specific memory. The case of the patient H.M. demonstrates the significance of the hippocampal formation in episodic memory. In 1953, 27-year-old H.M. underwent brain surgery as a final solution to treat his intractable epileptic seizures. The surgeons removed bilaterally his medial temporal lobes including the hippocampus, amygdala, and surrounding cortices. The surgery successfully controlled his seizures, yet it unexpectedly led H.M. to cope with a new syndrome that he was unable to perform basic activities as a normal people. He could not remember anything that happened to him after the surgery; he had amnesia. His memory of events before the surgery was almost intact, but he could not remember new people or new events even only for few minutes. Brenda Milner and her associates investigated his case for nearly 40 years but she needed to introduce herself every time meeting him. Researchers concluded that the hippocampal formation plays a critical role in episodic memory, a memory type that links events with a specific place and time.

In 1937 Papez proposed a circuit called the emotional circuit, but that circuit was lately regarded as a memory circuit, and some components of his proposed circuit are now classified as parts of emotional circuits. In fact, memory and emotional circuits are interconnected and have mutual interaction [4–6], for example, in a flashbulb memory, the emotional factor strongly influences the memory. Other brain regions, such as the cerebellum, striatum, brainstem, amygdala, and other sensory and motor systems are importantly involved in non-declarative learning/memory [4–8]. Further evidence for the importance of these regions and other brain areas has been provided by advanced brain imaging techniques. Studying verbal memory suggests that the left hemisphere processes verbal information and the right hemisphere processes visuospatial information. Numerous studies also found that the left and right cerebral hemispheres do not contribute equally in some mental functions, suggesting a phenomenon of ▶hemispheric asymmetry of memory and the split brain.

### *Synaptic Mechanisms for Declarative Memory*

It is interesting to look at how neurons and their synapses contribute to learning/memory. Donald O. Hebb, a Canadian psychologist, in 1949 proposed a way that learning might take place at the level of synapses [9]. Suppose that there are two neurons A and B that are interconnected but have a weak synaptic relation. If on some occasions A neuron fires and the impulses from A reach B, then a functional link between the two cells is formed. Consequently, when A fires then the possibility for B also firing is increased. The strengthened connection between two cells in this way is now called Hebbian synapse. Hebb's hypothesis was interesting but was unproved about how learning might take place for many years [10]. In 1973, from a series of studies of hippocampal synaptic function carried out by Tim Bliss and Terje Lømo showed a phenomenon that the magnitude of the synaptic response could be increased by applying a brief period of electrical stimulation (tetanus) at a very high rate (100 Hz) [11], which is now so called long-term potentiation (LTP). Following researches on LTP has identified this is the mechanism making Hebbian plasticity possible. LTP has interesting properties. LTP can occur within each of three principal pathways through which information flows in the hippocampus: the perforant pathway, the mossy fiber pathway, and the Schaffer collateral pathway. It is rapidly induced, and once induced it is stable for hours or days or longer (if the tetanus is repeated). LTP has features of the memory process itself. It can be formed quickly at appropriate synapses and it lasts for a long time. In 1971 John O'Keefe and John Dostrovsky made the extraordinary discovery that the hippocampal pyramidal cells, the very cells that exhibit LTP, have a specific firing location in an environment [12]. These cells are called "place cells," and they are thought as an internal representation-a cognitive map-of its spatial environment. Place-related activity was also found by Ono et al. in the monkey's hippocampus [13]. Research showed that defects in LTP interfere with the stability of the

spatial map over time. This unstable map in turn reveals itself in behavior as an unstable ►spatial memory. Given together, the findings of place cells, grid cells, and head direction cells support ►neural bases of spatial learning and memory.

Another phenomenon of ►synaptic plasticity was found by Masao Ito in 1982 [7], which is called long-term depression (LTD), it was firstly found in the cerebellum, an important structure in ►theories on motor learning, but lately was also found in other neural pathways [14]. LTD would be induced by applying a low-frequency stimulation (1–4 Hz) to a certain neural pathway. LTP and LTD have been attractive candidates for mnemonic function.

Research on memory has also focused on biochemical and genetic aspects of learning and memory, as numerous studies investigated the role of neurotransmitter systems on learning and memory [4,6]. A number of proteins, substances, and receptors, such as a protein called N-methyl-D-aspartate (NMDA) and its receptors, and dopamine and it receptors have been determined as having an important role in learning and memory, and their molecular mechanisms.

## Impairment of Memory

### *Amnesia*

►Amnesia [5] refers to impairment or loss of memory. It is classified into functional amnesia, organic amnesia, and infantile amnesia. Amnesia caused by brain damage is called organic amnesia, whereas one caused by psychological trauma is called functional amnesia. The H.M. case described above is an example of organic amnesia. Inability to remember new information is referred to as anterograde amnesia, whereas unable to remember events of the past is referred to as retrograde amnesia.

Childhood or infantile amnesia refers to the phenomenon that people can recall only a little about the first few years of their lives.

### *Dementia*

►Dementia is a progressive neurodegenerative disease causing intellectual impairment observed in elderly people (senile dementia) [5]. There are many kinds of memory, and each kind has a different fate in patients with the most common form of dementia, Alzheimer's disease (AD). The distinct forms of memory are differently compromised dependent on the neuroanatomic distribution of disease in AD. This disease strikes younger people in a form known as presenile dementia.

## Methods for Improving Memory

►Memory improvement refers to the enhancement of cognitive functions such as attention, learning and memory in healthy subjects as well as subjects with cognitive deficits.

Some healthy individuals have a striking ability in their memories. D.C. Shereshevskii has been mentioned as a typical example of a man having a remarkable memory [5]. He could learn a blackboard full of materials and could recall them after years. Shereshevskii used a method called mental imagery by creating rich images to represent information.

There are some typical techniques for improving memory, which have been used for a long time. Techniques for memory involve encoding and storing information in a way that are easy to recall, and using hints or cues to recall information.

An old mnemonic method is the method of loci (loci means "locations"). According to this method, subjects generate vivid images between locations and items to be memorized, and then put each item into a location where it can be seen in the mind.

Pegword method refers to a way that people learn words to serve as cues, and those cues can trigger a memory when needed. Making the pegwords rhyme as in a poem to remember items more easily is an example of this method.

In cognitive deficit persons, there are substances which would help to enhance memory, such as NMDA receptor antagonists, radial scavengers [4,5]. Various agents are currently being investigated or used as cognitive enhancers or anti-dementia agents, including acetylcholine esterase inhibitors. Neuroprotective agents that can prevent neurons from neurotoxic substances may also help improve memory. Proper physical exercise and training in a rich environment could also help to enhance memory.

There are more methods for improving different kinds of memories and some of them maybe used automatically by us sometimes but we may not recognize them. For example, we may have tried to learn a book by skimming through it, address questions to self-test what we have read, and read carefully, etc. However, we do not recognize that this is also a mnemonic method. For enhancing procedural memory, practicing regularly is effective.

Learning and memory are interesting and important for living organisms. Continuously learning throughout life could help greatly in improving memory.

# Learning and Motivation

Anthony G. Phillips
Department of Psychiatry, University of British Columbia, Vancouver, BC, Canada

## Synonyms

Learning: Classical (Pavlovian) conditioning; Instrumental (Operant) conditioning; Response acquisition; Habit formation; Memory; Habituation; Sensitization; Imprinting; Play
Motivation: Drive reduction; Emotional arousal; Incentive motivation; Reward; Reinforcement; Outcome-expectancy

## Definition

Successful engagement with a specific ecological niche is essential for survival of all species on earth and for those with the capacity to move on land, within sea or air, the development of patterns of behavior which ensure the necessities for life is often based on trial and error, which constitute different forms of learning. Formal theories of learning recognize several distinct categories, including Non-associative (habituation, sensitization, imprinting. play) and Associative-learning which encompasses Operant and Classical conditioning. With respect to Associative learning, Classical conditioning refers to the capacity of stimuli with no intrinsic significance (a conditioned stimulus) to gain the ability to elicit an adaptive reflex when associate closely in time with a second class of stimuli (an unconditioned stimulus) that can trigger a more robust reflexive response in aid of survival or protection of the organism. Operant-conditioning underlies the capacity of an organism to "operate" on the environment in a manner whereby its actions can achieve a specific outcome or reward. The increased occurrence of motor responses which enable access to a reward constitutes reinforcement of those specific components of behavior. The capacity of the brain, and hence the mind, to store newly learned responses and associated information within its synaptic structure and chemistry, which in turn can be used to guide future thought and action is referred to as Memory.

A second psychological process underlies the biology of adaptation and survival and is referred to as ►motivation; a theoretical construct invoked by experimental psychologists as a motive force behind the selection, initiation, vigor and persistence of behavior in humans and in many other species. Behavioral neuroscientists have been guided in their search for neural substrates of motivation by two different theoretical perspectives namely Drive-reduction theory and ►Incentive motivation. The former idea postulates that homeostatic imbalance within specific regulatory systems such as those responsible for energy, fluid or thermoregulation, gave rise to specify 'drive' states. Reduction of a specific 'drive' state by consumption of food or water reduces motivation to seek these stimuli and also provides reinforcement which increases the probability that action patterns that brought the organism into contact with these natural reward stimuli will be repeated (Thorndike's Law of Effect).

In contrast to Drive-reduction theory as an internal motive force pushing the organism into action, Incentive motivation emphasizes the control over behavior exerted by stimuli external to the organism. The attractant properties of biologically- significant stimuli may be characterized as exerting a 'pull' on the organism that helps an organism to locate, move toward (or away) from the stimulus and in the case of positive incentive stimuli, eventually gain access to objects which are often essential for life. As reliable predictors of objects of desire, incentive stimuli become powerful attractors of orientation and approach behaviors which are the hallmarks of motivation. The subjective psychological state triggered by salient incentive stimuli is characterized as 'wanting' by Berridge and Robinson [1] in distinction to "liking" used to covey

an attraction to the hedonic properties of many reward stimuli.

The relationship between learning, memory and motivation is considered further under the heading Characteristics, with an emphasis on the role of the neurotransmitter ►dopamine in incentive motivation and its relation to memory. A brief discussion of aberrant behaviors that constitute ►addiction is provided in the context of the Incentive motivation theory of addiction.

## Characteristics

### An Ecological Perspective on Motivation

Ecological theories of animal behavior provide a functional behavioral perspective on motivation by emphasizing the distinction between preparatory and consummatory behaviors. Preparatory behaviors also referred to as appetitive or approach behaviors such as foraging and hoarding represent flexible patterns of activity designed to located and bring the organism into contact with goal objects such as food or water. As such, these aspects of motivated behavior can be sustained over extended periods a fact that must be considered when seeking a biological basis for incentive motivation. Following contact with a reward stimulus, this pattern of behavior is terminated and is usually replaced by a separate class of consummatory behaviors such as chewing, swallowing and licking in the case of feeding, which have precise response topographies that facilitate ingestion of food. It is noteworthy that different patterns of preparatory behavior may lead to identical consummatory responses. With respect to the concept of incentive motivation, preparatory behaviors can be readily triggered by presentation of a conditioned incentive stimulus paired with the delivery of food.

### Dopamine and Incentive Motivation

The modern era of research into the synaptic mechanisms of motivation can be traced to the classical studies of Ungerstedt from the early 1970's in which severe aphagia and adipsia were induced by stereotaxic injections of the neurotoxin 6-hydroxydopamine into afferent projections of the mesocorticolimbic dopamine system. These findings were amongst the first to link the neurotransmitter dopamine to motivation. Further evidence linking brain dopamine function to motivational processes came from studies on the neurochemical bases of ►brain-stimulation reward. Converging evidence from neurotoxic lesions, neuropharmacological studies with selective dopamine agonists and antagonists, and in vivo measurement of dopamine efflux, all confirmed that dopamine plays a critical role in brain-stimulation reward. Brain dialysis studies also confirmed significant increases in DA efflux during food or fluid consumption and sexual behavior. Collectively these data gave rise to the dopamine theory of reward and motivation.

Shultz and colleagues [2] postulate that dopamine activity serves as an error detection signal which facilitates temporal difference learning. Specifically, dopamine neurons in the ventral mesencephalon of the rhesus monkey show increased rates of firing when the value of a received reward stimulus exceeds the predicted value. Importantly, a significant decrease in the firing rate of these dopamine neurons also reflects situations in which the magnitude of reward is less than predicted, including those when reward is omitted all together. McClure and colleagues [3] in developing their computational model of incentive salience note that the functional correlate of increased dopaminergic activity is to predict the occurrence of future reward and to ensure that appropriate actions are selected and initiated to maximize the opportunity to obtain the reward.

### Motivation and Memory

Motivated behavior is rarely seen as a random search strategy for locating the essentials for life. Indeed, preparatory behaviors are optimized by prior experience which enables many organisms to associate specific features of the environment including spatial locations with the objects they are seeking. The neural substrates of efficient foraging behavior have been studied extensively using radial-arm maze procedures pioneered by Olton. The hippocampus, the medial prefrontal cortex and the nucleus accumbens form interconnected neural circuits responsible for spatial cognition and memory. Activation of dopamine $D_1$ receptors in the prefrontal cortex is required for accurate foraging behavior guided by memory about the probable location of food. Neurochemical experiments confirm that dopamine in the medial prefrontal cortex is released in a phasic manner during recall thus ensuring an appropriate level of dopamine $D_1$ receptor activation essential for the retrieval of trial-unique information by memory processes which, in turn, can guide response selection during delayed response tasks. Computational models based on the effect of dopamine on a variety of biophysical measurements from pyramidal neurons within the frontal cortex suggest that tonic $D_1$ activity contributes to stability of memory engrams in the medial prefrontal cortex, by increasing signal to noise ratios of background activity at the expense of evoked activity. Encoding and maintenance of salient new inputs is linked to phasic activity at D2 receptors. Accordingly, there appears to be an important relationship between dopamine as a neurochemical substrate of incentive motivation, and it ability to modulate memory function in corticolimbic regions of the brain [4].

### Incentive Motivation and Addiction

The uncontrollable urge to seek mind-altering substances and other forms of highly arousing activity such as gambling and risky sexual behavior can be

attributed to aberrant motivational states and together they constitute different aspects of ►Addiction. Addiction is also maintained by compelling memories of previous behavioral episodes in which specific sensory events and environmental contexts figure prominently and may trigger relapse to addictive behavior when encountered in the future. Accordingly, addiction has also been attributed to the modification of synaptic plasticity mechanisms in neural circuits responsible for reward and incentive motivation, of which the mesocorticolimbic dopamine pathways to the nucleus accumbens and prefrontal cortex play a prominent role [5].

Long-lasting changes in neural circuits connecting the prefrontal cortex to the nucleus accumbens can be induced by intermittent exposure to many drugs of abuse including psychostimulants (amphetamines and cocaine) and opiates. The consequence of this pattern of drug exposure is enhanced motor activity to subsequent administration of the same or other drugs and this defines the phenomenon of behavioral sensitization. Robinson and Berridge [6] first proposed that drug-induced sensitization of the mesocorticolimbic dopamine pathways, and the ensuing distortion of incentive motivation, could explain the powerful control over behavior and thought processes (extreme 'wanting') that is often exerted by addictive stimuli. Here it is important to note that the hedonic property of drugs ('liking') is not enhanced by repeated ►intravenous self-administration in humans or experimental animals.

An alternate hypothesis proposed by Kalivas and Volkow [7] acknowledges the primary role of the mesocorticolimbic pathways in initiation of drug-seeking behavior, but emphasizes the role of drug-induced pathophysiology of synaptic plasticity within glutamateric projections from the prefrontal cortex to nucleus accumbens. As a consequence, the capacity of the cortex to ascertain the consequences of specific actions (executive control) is diminished, along with decreased value of natural rewards and increased control over behavior by drug-associated stimuli; the net effect of which is compulsive behavior that typifies the thoughts and actions of addicts.

## Definition

Learning curve is a performance change as a function of a time course or a trial number of training.

## Characteristics

►Learning curves are shown in a wide rage of different research fields from education to robotics. The shape of a learning curve depends on both independent and dependent variables, subjects, and contexts.

Traditionally, encoding and retention in memory and learning have been thought to occur in clearly different stages of the time course. ►Supervised learning and

non-supervised learning (►unsupervised learning) algorithms that are described in the glossary have been developed mostly to describe the mechanisms of encoding of learning and memory [10]. However, recently a growing body of neurobiological evidence has shown that after encoding, rather than mere process of passively retaining learning and memory, progressive stabilization occurs. This process and the phase during which such stabilization occurs are called consolidation. In this section, we concentrate on learning curves in relation to consolidation. The time scale of learning depends on the consolidation process [1]. Beyond the consolidation period, resistance to external interfering noise becomes stronger. There are two types of learning consolidation: fast and slow.

The fast consolidation process is often called synaptic or molecular consolidation, which takes place within a time window of a few minutes to hours after encoding. The underlying mechanisms are studied at the molecular level including protein synthesis. By contrast, the long consolidation process is often called system consolidation, which appears to take place in much longer time scale, ranging from months to years. The time scale depends on the type of memory as described below.

Memory is often categorized into declarative and non-declarative memory. Declarative memory includes episodic memory and semantic memory. Non-declarative memory includes skill or habits. The dichotomy originally came from studies of patients with hippocampal damage or amnesia. While amnesic patients demonstrate the ability to carry out skill or procedural learning [2], they have difficulties in encoding new memories, suggesting that non-declarative memories and learning are independent of the hippocampal formation.

It is assumed that declarative memory is formed through the system consolidation via the hippocampal formation [3]. Interestingly, the time scale involved in the consolidation of skill learning seems closer to that of cellular consolidation. Several reports have shown that consolidation of visual or motor skill learning takes place within hours of the initial encoding. Non-declarative memory is thus presumed to form through the molecular consolidation in the relevant cortex, according to the time scale of the consolidation process.

The most dominant hypothesis in declarative memory formation postulates a two-stage model [4], in which memory initially depends on the hippocampus, and with the passage of time, depends on the neocortex. In procedure learning including perceptual learning, the time course of learning over days seems to take place further in two phases; a rapid learning phase and a slow learning phase. Right after the starting of practice, the degree of improvements seems larger. In contrast, after the few sessions of practice, the degree of improvements becomes smaller. This seemingly logistic learning curve in function of number of ►training session appears to take place in both vision and auditory [5]. However, interestingly, performance in visual learning has been shown to degenerate, not to improve, if repeated within a few hours in a day without intervening naps [6].

Moreover, recent evidence suggests that sleep is beneficial for both declarative and non-declarative memory including perceptual and skill learning [7–9]. Evidence suggests that the benefit of sleep on learning consolidation would originate in an internal biochemical process in the brain. However, a mechanism concerning how sleep improves system level consolidation is not yet fully understood.

### Definition
The coordinated activation of muscles on the left and right side of the body during rhythmic movements in vertebrates [1–10].

Locomotion in most animals is characterized by its rhythmic activity. Muscles involved in this activity need to contract and relax rhythmically, in a coordinated manner, to generate efficient movements. For example, in aquatic vertebrates such as fish or amphibian tadpoles, a wave of alternating contraction of the muscles in each body segment results in a sinusoidal movement during swimming. In limbed terrestrial animals, such as mammals living on land, corresponding muscles of the legs on the two sides contract, alternating while the animal walks. Various patterns of left–right coordination can be observed during different types of locomotion in these animals depending on their speed of movement. For example, during a high speed such as galloping, the activity in corresponding muscles on either side of the body becomes synchronous, i.e., simultaneous flexion and extension on the two sides.

### Characteristics
#### Quantitative Description
The basic patterns of such rhythmic movements are generated by a neuronal network called the central pattern generator (CPG) [2]. The CPG for locomotion is located in the spinal cord, since such coordinated rhythmic motor activity can still be evoked after the removal of higher brain structures. The CPG is capable of producing rhythmic activity in motor neurons that innervate the muscles, without rhythmic inputs from higher brain structures or sensory input. During the coordinated locomotor activity, the CPG activates motor neurons on the left and right side of the spinal cord in a sequential manner.

#### Higher Level Structure
The basic left–right coordinated rhythmic motor patterns for locomotion are generated by CPG located in the spinal cord. There are other examples of left–right coordinated rhythmic motor activities generated in other parts of the central nervous system, such as breathing that is produced by CPGs located in the brainstem [8].

#### Lower Level Components
Commissural interneurons (CINs) are essential for left–right coordination [1]. These CINs project their axons across the midline to convey information to the other side of the spinal cord. CINs are known to be active during locomotion [1], and the coordinated left–right pattern is disrupted if the axons of these neurons are severed at the midline of the ventral commissure of the cord [4]. Left–right coordination is regulated by CINs that function from the onset of the rhythmic activity in embryonic life (fish and tadpoles [9]), rodents [6]). In mammalian experimental models such as cat and rodent spinal cords, these CINs are located in the ventro-medial region of the spinal cord [1], where other CPG neurons are also localized [4]. These CINs exert either inhibitory or excitatory actions to their target CPG neurons on the other side of the cord, connecting the synergistic motor activity between the left and right side. Moreover, it has been shown

that some of the CINs can directly inhibit motor neurons on the contralateral side [1].

## Higher Level Processes

Local left–right coordinated activity in each part of the body is organized in a way so that patterned body movements are generated. For example, a local circuit coordinates alternating left–right rhythmic activity in each spinal segment in the lamprey. This circuit is connected to other circuits in neighboring segments during swimming to produce sinusoidal body movements along the body of the fish [2,3]. In quadrupeds, left–right coordination of forelimbs and hindlimbs are also coordinated during locomotion. CINs also receive direct inputs from the brainstem locomotor regions, presumably so that they can be activated directly when locomotion starts.

## Lower Level Processes

It has been shown in many experimental models of vertebrate locomotion, that one side of the spinal cord that is split in the midline contains a network capable of generating locomotor-like coordinated activity in the flexor and extensor muscles on the same side [3,4,7]. This has lead to the assumption that there are two independent rhythm and pattern generating networks on the left and right side of the spinal cord, which are connected by crossed excitatory and inhibitory pathways. Latter pathways are crucial for the left–right coordination in vertebrates. In particular, mutual inhibitory connections between the two sides of the spinal cord are thought to be responsible for generating alternating patterns between the two sides, since blocking the neurotransmission mediated by inhibitory amino acids, like glycine and GABA, disrupts the alternating pattern between the two sides. Reciprocal inhibitory coupling mediated by glycine has been shown to be crucial for producing alternating muscle activity patterns during swimming in lamprey [2] and amphibian tadpole [9]. Similar observations have been made in the spinal cord of rodents [7]. The synchronous left–right activity seen during hopping or galloping is mediated via crossing excitatory CINs. Mice with a targeted deletion of the axon guidance molecule EphA4 show a rabbit-like gait instead of an alternating gait seen in wild type mice [5]. In the spinal cord of these mice, the axon of some of the excitatory neurons that normally project only ipsilaterally crosses the midline. This characteristic synchronous left–right rhythm is generated by the spinal CPG in these animals, leading to the assumption that the imbalance between inhibition and excitation in the left–right coupling is causing this abnormal gait.

Interestingly, it has been shown that from the time of onset of the coordinated rhythmic motor activity in rodent embryos, left–right pattern of the rhythm is synchronous [6]. Unlike in mature animals, the synchronous pattern in embryos is likely to be due to excitatory effects of the inhibitory neurotransmitters GABA and glycine. Such excitatory effects of these inhibitory neurotransmitters during the early fetal period are likely to be caused by the high intracellular concentration of Cl ions in spinal neurons. Thus, generation of the reciprocal left–right pattern coincides with the emergence of inhibitory actions of the two amino acids in the spinal cord [7].

## Process Regulation

Left–right coordination during locomotion is modulated by descending inputs from higher brain structures. Inputs from diencephalic and mesencephalic locomotor centers in the brainstem can initiate locomotion and control its speed. For example, electrical stimulation of the mesencephalic region in cats can initiate locomotion, and its speed can be increased if the intensity of the stimulation is increased resulting in the change of gait i.e., walking (left–right alternating) to galloping (left–right synchronous) [10]. Neurons in the mesencephalic locomotor centers and resticulospinal neurons in these animals have direct inputs to CINs [1,3], indicating that these descending inputs have a strong influence on the left–right coordination during locomotion.

## Function

Left–right coordination is essential for the organism to move its body. Especially during patterned rhythmic body movements such as locomotion, a precise timing of contraction and relaxation in every muscle involved is crucial.

## Therapy

Left–right coordinated rhythmic motor activity is one of most common and essential behaviors in most vertebrates. Understanding their neuronal mechanisms can be utilized to develop ways of treatment and rehabilitation methods for patients suffering from spinal cord injury.

## Definition

The length-tension property of a whole muscle (or muscle fiber or sarcomere) is the relationship between muscle length and the force the muscle can produce at that length.

## Characteristics

### Quantitative description

#### *Introduction*

During a voluntary contraction a person has no sense that their muscles have an optimal length for producing force. The complexity of the muscle architecture, skeleton, and neural control masks this functional property. However, early experiments in excised frog muscle showed force was dependant on muscle length. Since these early observations, this important property has been extensively studied. The molecular basis is now quite well understood, but the functional implications during normal movement still remain in question.

#### Total, Active and Passive Components of the Length-Tension Curve

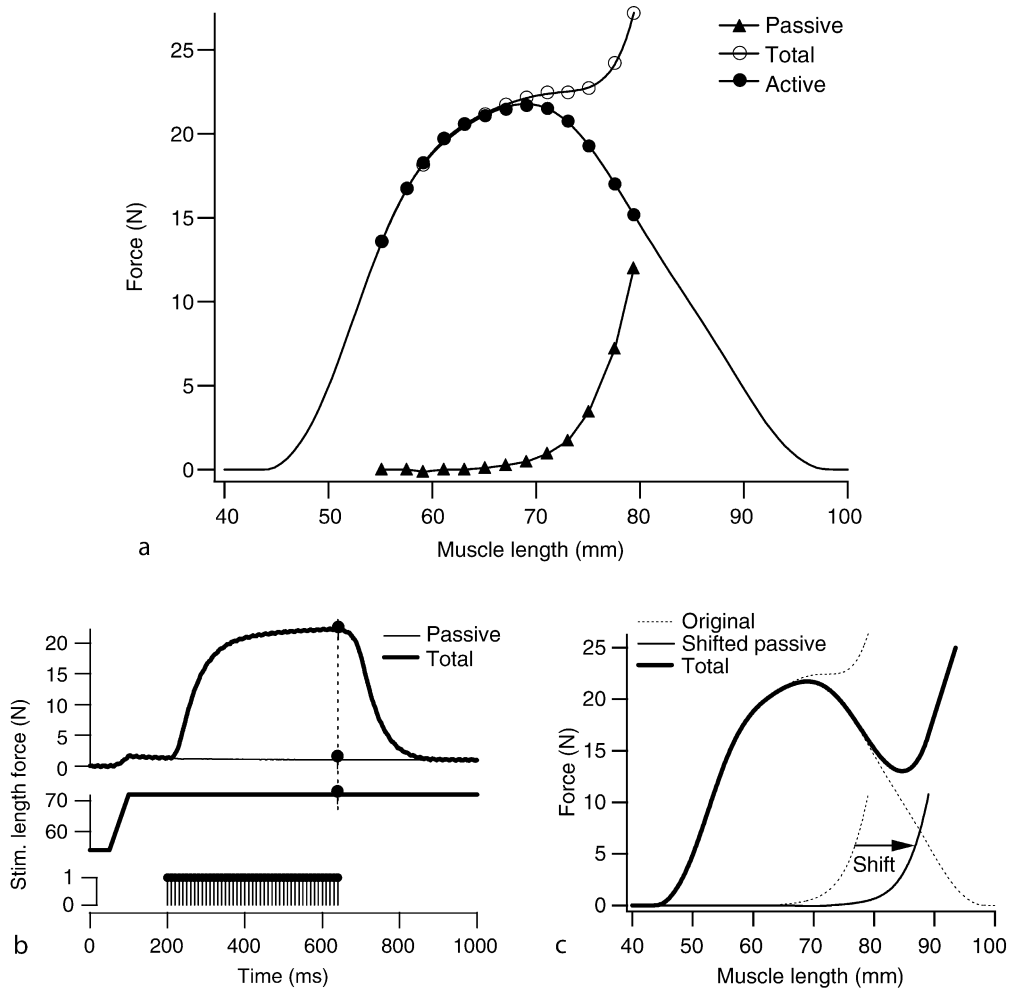
The length-tension curve has an active and passive component that results from different structures within the muscle. Fig. 1a shows a classic length-tension curve taken from cat soleus muscle.

The passive curve generally assumes an exponential shape. Force is zero at short lengths but increases rapidly when the muscle is stretched beyond resting length. The active portion has a hyperbolic shape. The length producing peak tetanic force is referred to as Lo. The rising portion of the curve (lengths less than Lo) is commonly referred to as the ascending limb, and the falling curve (length above Lo) the descending limb. Fig. 1b shows some of the raw data used to construct the length-tension curve. The data points are experimentally obtained by making static measurements at various lengths. This is important because different results are obtained depending on muscle length and activation history (see below). Different muscles show considerable variation in the passive length-tension properties. As a result, the total length-tension curve sometimes shows a dip at lengths longer than Lo, and sometimes monotonically increases with length (see Fig. 1c).

#### Active Component During Tetanic Stimulation

A seminal paper by Gordon et al. [1] showed the sliding filament theory can account for the active length tension curve in a frog sarcomere. Assuming each cross-bridge can produce the same force irrespective of its position, and the cross-bridges and their binding sites are spaced uniformly, then parts of the length tension curve are expected to exhibit a linear force-length relationship (Fig. 2).

At long lengths, the number of possible cross-bridge attachments follows this relationship. At the plateau



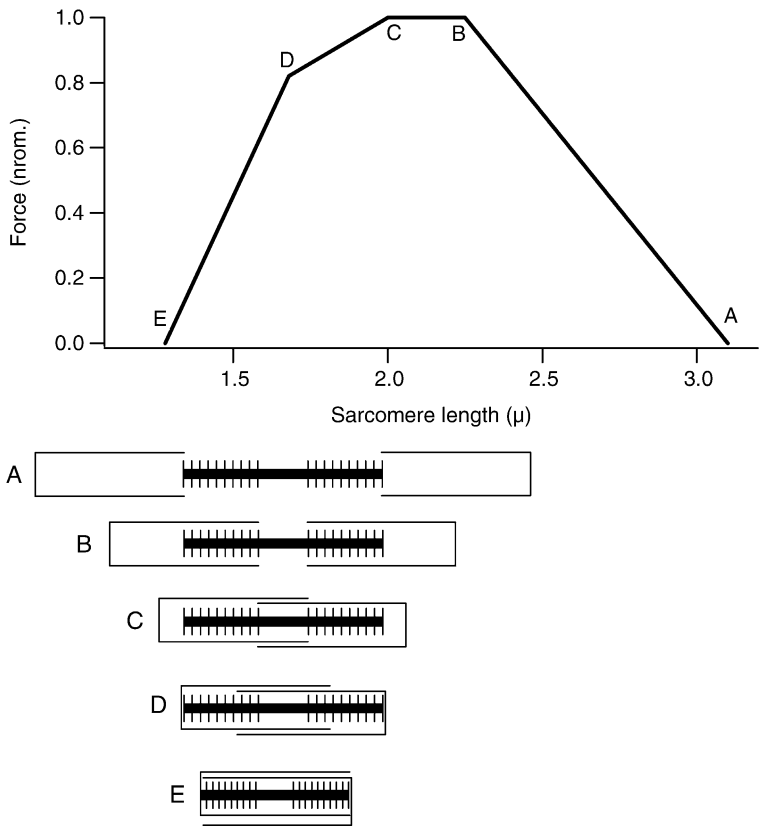
**Length-Tension. Figure 1** Length-tension curve measured from cat soleus. (a) Data points plotted and fit with curves. (b) Waveforms showing the procedures to measure the force at a single test length. The muscle is moved from slack length to the test length at time 50–100 ms. The muscle was stimulated at 100 Hz from 200 to 650 ms. The resulting total force is shown in the top trace. The identical movement is repeated without stimulating the muscle to measure passive tension. The difference between the two provides the measure of active tension. (c) Theoretical length-tension relationship obtained with a different passive length-tension relationship (unpublished data Sandercock and Heckman).

region, the number of attachments remains constant with length. The underlying mechanism is less clear at shorter sarcomere lengths. Region C-D may follow the same slope because the overlap of the thin filaments may block possible binding sites. At very short lengths, folding of the filaments may cause the steeper slope.

Actin filament lengths vary across species leading to different sarcomere length-tension relationships. Human muscle has a longer actin filament leading to a broader length-tension relationship.

## Normalized Whole Muscle Versus Sarcomere Length-Tension: Scaling Length-Tension

The active whole muscle length-tension curve can be related to that of a single sarcomere. Two sarcomeres in series should have a length-tension curve twice as wide (length axis) as compared to a single sarcomere. Two sarcomeres in parallel should produce twice as much force as a single sarcomere. Thus, assuming all sarcomeres are identical and lengthen synchronously, normalizing the whole muscle length axis by the number of sarcomeres in series, and the force axis by the number of sarcomeres in parallel (PSCA), should produce the sarcomere length-tension relationship. The series elasticity of the tendon and aponeurosis will broaden the whole muscle length-tension properties. The heterogeneity of individual sarcomere lengths will further broaden the length-tension curve for the whole muscle. Other factors altering the relationship include the angle of pennation, different fiber types, and



**Length-Tension. Figure 2** Theoretical determination of the active length-tension relationship. See text for details (modified from Gordon et al. [1]).

differences in fascicle length for different fiber types. In spite of these complications, the normalized length-tension curves from muscles in the cat hindlimb have approximately the same shape. The theoretical length-tension relationship of Fig. 2 fits whole cat soleus data if it is assumed there is a distribution of sarcomere lengths or fiber lengths (solid line Fig. 1a).

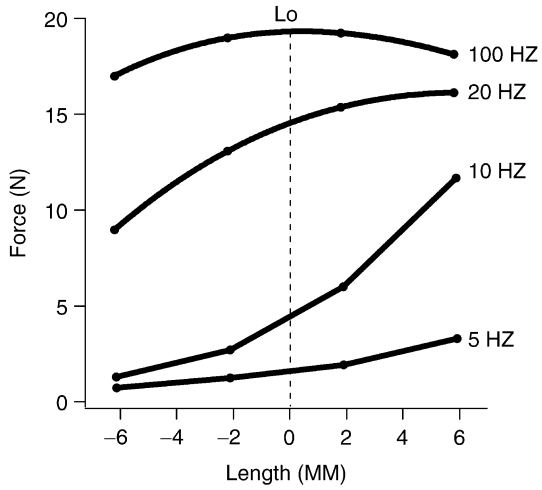
## Determinants of Passive Length-Tension Properties

When the muscle is inactive (no action potentials), the length-tension properties depend on the structural proteins within the muscle fibers as well the extracellular connective tissue structure linking the fibers. In individual fibers, the large protein titin plays a significant role in keeping the thick and thin filaments from pulling apart, particularly at longer lengths. Titin appears to have an ideal structure to act as a spring. Other proteins may also play a role. In whole muscle the properties depend on those of the constituent fibers, as well as connective tissue links between fibers. The aponeurosis and tendon also play a significant role since they are in series with the muscle fibers. The details of force transmission within a muscle have yet to be understood in detail, so the passive length-tension properties have not been linked to specific structures. The exponential shape shown in Fig. 1 is common to both individual fibers and whole muscles, but the zero point and the steepness of the rise vary considerably. For example, in the wallaby the gastrocnemius has few muscle fibers, and the passive tissue plays the major physiological role. In some disease states the passive properties of the muscle change such that passive force predominates and hinders movement.

## Active Component During Sub-Maximal Activation

During submaximal contractions, the length-tension curve is shifted to the right (see Fig. 3). The cause of this shift not fully understood. During tetanic contractions the length-tension curve depends primarily on filament overlap. Enough Ca2+ is released to fully activate the troponin binding site. However, during sub-maximal contractions Ca2+ dynamics play a significant role. Muscle length does not appear to effect Ca2+ release, but rather, the sensitivity to Ca2+ becomes length dependant [3].

As muscle is rarely fully activated during normal use, the shifted length tension curve is a more realistic measure of the contractile properties during voluntary contractions, and thus very important for motor control. The importance of this shift was demonstrated by Rack



**Length-Tension. Figure 3** Static length-tension properties measured during different stimulation frequencies in cat soleus (modified from Sandercock and Heckman [2]).

and Westbury [4] in cat soleus. They used a distributed low frequency stimulation to simulate natural activation and showed this produced a dramatically different length-tension curve. Sandercock and Heckman showed similar results during normal recruitment and rate coding in cat soleus [2].

## Changes in Length of an Active Muscle-Movement along the Length-Tension Curve

Length-tension properties depend strongly on the way they are measured. The classic curve shown in Fig. 1a is a static property. Passive muscle is moved to a test length and then activated. The muscle is allowed to relax and the next point is measured. Different results are obtained if an active muscle is moved through different lengths. Figure 4 shows results when active cat soleus muscle slowly moved and compared to the static length-tension curve. Force-velocity properties can't explain all the difference, since this cat soleus has a maximum velocity of shortening greater than 160 mm/s and the movement is very slow.

The underlying physiological reasons for the difference are not fully understood. Persistent tension excess or tension deficit are similar phenomena and it was initially believed that sarcomere inhomogeneities were responsible [5]. It was proposed that during a prolonged contraction, or with movement, the strong sarcomeres shortened at the expense of the weak ones, each sarcomere moving along its respective length tension curve until all produced the same force. Recent work in frog fibers, where every sarcomere length was measured, showed no substantial increase in the inhomogeneity with movement, suggesting inhomogeneities are not the cause.

## Use of the Length-Tension Curve in Mathematical Muscle Models

Simple muscle models, particularly those using some version of Hill's model, often incorporate a tetanic length tension curve in the model. For motor control studies this is probably worse than using no length tension curve at all. As muscles are rarely, if ever, activated at rates approaching tetanic stimulation frequencies, the length-tension curve will be right shifted. Furthermore, active stretch or shortening alters the relationship (see above).

## Operating Point on the Length-Tension Curve

Surprisingly, the length at which sarcomeres operate during normal movements is not well known. This is a result of the difficulty in measuring muscle force, tendon strain, and/or sarcomere length during voluntary movements. To make efficient use of a muscle, the operating point must be near Lo. Some have argued that the muscle will become unstable if operated at lengths beyond Lo because the strong sarcomeres will shorten at the expense of the weak ones [6]. This may be why runners, whose muscles tend to operate on a stretch-shortening cycle, may operate on the ascending limb of the length-tension curve, and bicyclists, whose muscles operate on a shortening-stretch cycle, may operate on the descending limb of the length-tension curve [7]. However, a detailed review of the available literature, examining vertebrate muscles in different animals, concluded the operating range of most muscles is quite narrow covering 94% ± 13% of Lo [8].

Muscle may be able to add or subtract sarcomeres to maintain the ideal operating range. Williams and Goldspink showed that muscles immobilized for several weeks, at a sarcomere length far from optimal, added or subtracted sarcomeres to restore the optimal sarcomere length for the new muscle position [9]. However, Friden et al. found the opposite – muscle immobilized at a long length had fewer sarcomeres [10]. The ability of muscles to regulate the number of sarcomeres may vary with the species, muscle, and exact conditions of use.

### *Higher Level Structures*

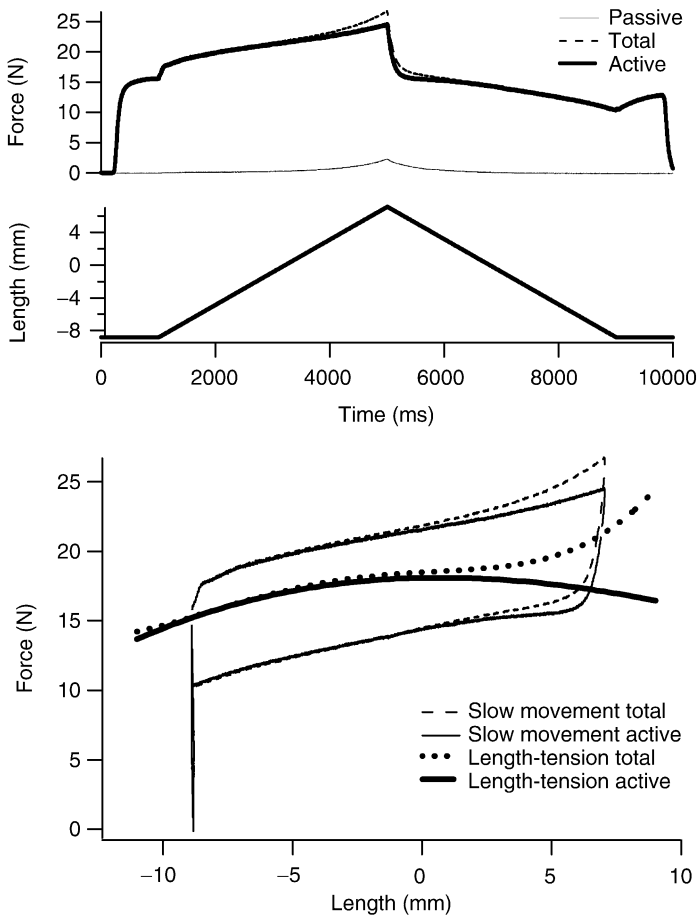
►See Muscle Modelling.

### *Lower Level Components*

Myofilament, myofibril, muscle fiber, sarcomere, cross-bridge.

### *Structural Regulation*

Sarcomeres may be added to or subtracted from a muscle to alter the length-tension characteristics. The extent to which this occurs in adult animals has not been determined [9].



**Length-Tension. Figure 4** Effects of movement on the relationship between force and length, measured in cat soleus. Plot A depicts muscle force during whole muscle stimulation at 100 Hz. The muscle was slowly stretched from 9 mm shorter than Lo to 7 mm longer than Lo. At t = 5s the direction was changed and the muscle shorted to the starting length (plot B). Plot C depicts the same data re-plotted as force versus length and plotted along with the standard length-tension properties. The length-tension curve was measured from the same muscle (*heavy lines*) using standard procedures (see Fig. 1). The stretch-shortening speed was only 4 mm/s (maximum velocity of shortening approximately 160mm/s) so the force velocity properties of the muscle can't account for most of the extra force. Note that on the descending portion of the length-tension curve force increases during stretch of the active muscle in spite of the decrease in the length-tension curve. Similar results are seen regardless of the starting point for activation and slow stretch (unpublished data Sandercock and Heckman).

### *Higher Level Processes*

The length-tension relationship is mapped to an angle-moment relationship via joint and skeletal anatomy.

### *Lower Level Processes*

Cross-bridge, excitation-contraction coupling.

### *Process Regulation*

Muscle activation must account for the change in force with length.

### *Function*

The length-tension property results from the structure of the muscle. The animal's skeletal anatomy and/or neural control must make use of, or correct for, this property.

### *Pathology*

Most muscle or connective tissue diseases will secondarily alter the length-tension relationship.

### *Therapy*

Tendon transfer and tenodesis are used to restore functionality and alleviate excess passive tension. The procedures are only partially successful. A better understanding of sarcomerogenesis may be helpful.

## Leptomeningeal Cell

### Definition
Also known as meningeal cells or meningeal fibroblasts these cells lie on the glia limitans (q.v.), forming the inner meningeal layer. The glia limitans results from an interaction with between leptomenginal cells and the underlying astrocytes. After CNS injury meningeal cells proliferate and invade the lesion. Together with endothelial cells and inflammatory cells they form most of the lesion core that is particularly prominent in spinal cord injuries, and which is a barrier to axon regeneration. The leptomeningeal cells express members of the semaphorin 3 family.

►Glial Scar

## Leukemia Inhibitory Factor (LIF)

### Definition
A cytokine involved in cell growth, cell differentiation, embryogenesis, inflammation and neuronal development. LIF was initially named because of its ability

to induce the terminal differentiation of leukaemic cells. LIF binds the LIF receptor (LIFR-α) and forms a heterodimer with the gp-130 signal transducing subunit leading to the activation of the JAK/STAT (Janus kinase/signal transducer and activator of transcription) and MAPK (mitogen activated protein kinase) pathways.

## Leukocytes

### Definition

Generally referred to as white blood cells, these cells develop from bone marrow stem cells, a process called hematopoiesis. Circulating leukocytes include lymphocytes (including T lymphocytes that can be further classified based on their functions into $CD4^+$ and $CD8^+$ T lymphocytes, B lymphocytes and natural killer cells); monocytes; and granulocytes (including neutrophils, eosinophils and basophils). Circulating leukocytes constantly circulate in the blood and lymphoid organs (where lymphocytes mature and adaptive immune responses are initiated). Under disease conditions, circulating leukocytes can cross blood vessels and enter into local injured tissue driven by local released factors (a process called extravasation). Tissue leukocytes include macrophages and mast cells. Additionally, resident tissue or circulating dendritic cells are specialized leukocytes that are the most effective professional antigen-presenting cells.

## Lexical-Gustatory Synesthesia

Julia Simner
School of Philosophy, Psychology and Language Sciences, University of Edinburgh, Edinburgh, UK

### Synonyms

Word-taste synesthesia

### Definition

Lexical-gustatory synesthesia is a sub-variant of the familial condition known as ►synesthesia, which is characterized by a merging of sensory and/or cognitive functions. In lexical-gustatory synesthesia, words trigger accompanying food sensations, and these are experienced as either veridical perceptions of flavor (e.g., the word *jail* tastes of bacon in the mouth) or as an overwhelming and automatic cognitive association between the inducing word and the food type (e.g., the word *jail* evokes the notion of bacon).

### Characteristics

#### Quantitative Description

Synesthesia is a multi-variant condition in which everyday activities (e.g., reading, listening to music) give rise to extraordinary experiences (e.g., colors, tastes). Each variant is characterized by the pairing of a particular type of synesthetic "inducer" (i.e., triggering stimulus) with a particular type of experience (or synesthetic "concurrent") and in the lexical-gustatory variant these are words and flavors respectively. Hence for lexical-gustatory ►synesthetes, hearing words, saying words, reading words, or even thinking about words, gives rise to associated food experiences [1–3]. For synesthete JIW, for example, the word *this* tastes of bread soaked in tomato soup, while the name *Philip* tastes of unripe oranges [1]. As in other variants of synesthesia, the condition is characterized by the consistency of inducer-concurrent pairings, which tend to remain constant across the synesthete's life-time. Hence, synesthetes typically score between 90% and 100% in retests of their word-food associations across many months or even years, and they significantly outperform controls subjects, even if these latter are tested over considerably

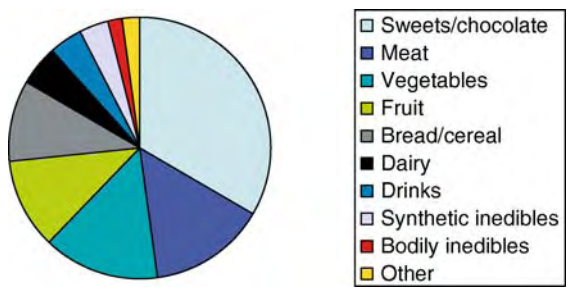
shorter intervals [1–3]. The condition is rare, even within the sphere of synesthesia, and although 11 cases have now been reported in the contemporary literature [1–4] along with four from historical sources (see [1,2]) no cases emerged in the population recruited for the most extensive prevalence study based on random sampling [5], and this suggests that the prevalence of lexical-gustatory synesthesia is less than 0.2% of the population (and may be considerably lower). As in other studies of synesthesia, the lexical-gustatory variant can be investigated by examining the nature of the concurrent experience, the nature of the inducing stimulus, and the processes by which these become associated, and we follow this structure in the essay below.

## Description of the Structure/Process/Conditions

Lexical-gustatory synesthetes can be divided into two groups according to the nature of their concurrent (flavor) experiences. For "projector synesthetes," these flavors are tasted as veridical perceptual experiences, with the same reported phenomenology as for flavors generated by food substances in the mouth (with the exception of having a substance to roll on the tongue). Synesthete MM [3], for example, reports that her mouth is flooded with the taste of baked cornbread when she encounters the name *John*. Some concurrent flavors are particularly strong and can persist for some time, often until the taste is overridden by another. For this reason, projector lexical-gustatory synesthetes can come to regard their synesthesia as a source of irritation, which makes it hard for them to read books, or concentrate in conversation. For "associator synesthetes," however, the food concurrent represents a cognitive association, which automatically enters into consciousness when the inducing word is encountered. Synesthete PS, for example, has the overwhelming notion of orange jelly when he hears the word *shoulder*. In all cases, food experiences are complex sensations (rather than generic tastes of bitter/sweet, etc.) and are highly specific and rich in detail, such that the synesthetes go to some trouble to describe them [1]. For synesthetes JG for example, the name *Adrian* tastes of lettuce coated with Caesar salad dressing, and for CS, *part* tastes of chicken noodle soup [2]. Associations can incorporate temperature and texture as well as flavor, so for synesthetes JIW for example, the word *jail* generates the experience of cold, hard bacon [1], while *tambourine* is very crumbly biscuit. For all reported projector synesthetes, concurrent tastes have a subjective location in the mouth and tongue area, while some synesthetes additionally report olfactory experiences. Researchers have been reticent to draw strong conclusions from this, however, (see [2]) given that taste and smell are difficult to separate subjectively, and there is a natural tendency to misattribute olfaction to taste sensations in the mouth (e.g., the rated intensity of taste sensations in the mouth is increased for all people in the presence of olfactory cues; [6]). In at least one case (an Italian speaker), however, the same word was reported to trigger different food experiences in the gustatory versus olfactory domains (e.g., *Alessandro* tasted of fried potatoes but gave the smell of burnt wool). Taken at face value, this historical report (for description, see [2]) would suggest that concurrents may indeed extend across both taste and smell.

Careful analyses of synesthetic concurrents reveal that certain flavors tend to dominate (e.g., sweets and chocolate) while others are often conspicuous in their absence (e.g., alcohol). The synesthetic flavor concurrents of synesthetes JIW are shown in Fig. 1 (data adapted from [1]), and this type of non-random response space can distinguish between synesthetes and controls.

The nature of the flavor concurrent in lexical-gustatory synesthesia is known to be shaped by dietary experience: the frequency of synesthetic flavors is related to the frequency with which the corresponding food is consumed in the synesthete's diet, such that commonly eaten foods are significantly more likely to occur as synesthetic concurrents [1]. Notably, however, synesthetic tastes are statistically more likely to reflect the diet eaten during childhood compared to adulthood. For instance, JIW is currently a heavy coffee drinker, but did not drink coffee as a child. Coffee rarely appears as a synesthetic concurrent, and when it does, it typically arises as coffee flavored chocolates [1]. Indeed, foods consumed during JIW's childhood are 10 times more likely to occur as synesthetic concurrents, compared to those consumed only in later life. This over-representation of childhood foods suggests that synesthetic associations are set during early development, and indeed, lexical-gustatory synesthetes report that their experiences date back for as long as they can remember (e.g., [2]). Figure 1 shows that a small number of synesthetic flavors represent non-food substances, and these include both bodily and



**Lexical-Gustatory Synesthesia. Figure 1** Summary of synesthetic flavor associations of synesthete JIW, elicited by 1,195 target words (data adapted from [2]).

non-bodily inedibles (e.g., earwax and plastics respectively). It is possible that such tastes may yet have been experienced during early exploratory eating behavior.

Descriptions of the inducers have remained remarkably similar across centuries and across continents (see [2]). Flavours are triggered by words, although there is a clear phonological component, in that similar sounding words tend to taste alike (e.g., for JIW, the words *message*, *college* and *village* all taste of sausage). Indeed, each synesthetic flavor can be traced to a particular ►phoneme (or phonemes), whose presence in a word endows a significant likelihood of generating that particular concurrent. For example, words containing /k/ (e.g., *York*) tend to taste of egg for JIW, and such relationships are largely independent of orthographic properties, since, for example, the egg concurrent arises whether the phoneme /k/ is spelt with a *c* (e.g., *accept*), *k* (e.g., *York*), *ck* (e.g., *chuck*) or *x* (e.g., *fax*) [1]. Some phoneme "triggers" have been shown to derive from food names (e.g., /l/, /n/ and /s/ trigger JIW's taste of mince) while others have less obvious roots (e.g., /f/ is associated with the flavor sherbet). Interesting, the synesthesia is sensitivity to fine-grained phonological constructs of which the synesthetes has no conscious awareness [1]. For example, different flavors can be associated to different ►allophones (i.e., acoustic/articulatory variants) of the same phoneme. Hence, JIW tastes both fingernails and potato from the phoneme /l/, although the former is associated, specifically, to the "dark" allophone (which has a secondary articulation in which the back of the tongue is raised towards the velum, as in *deal*) while the latter flavor is associated to the "clear" (unvelarized) allophone (as in *like*). JIW's synesthesia also responds to further distinctions within these allophones: the taste of Rice Krispies© is associated with a "syllabic" dark /l/ (i.e., one that fills the peak of an unstressed syllable, as in *bottle*) while the taste of fingernails is associated to the "non-syllabic" dark /l/ (as in *deal*) [1].

Although phonology may be important during development to determine the pairings of particular words with particular flavors, gustatory pathways may in fact target structures encoding word meanings ("lemmas"), at least in the adult brain [3]. There are several strands of evidence for this: first, associations between phonemes and flavors are not entirely productive, as might be expected if processing a phoneme were enough to trigger flavor (e.g., for JIW /g/ significantly associates with yogurt, but some /g/ words are tasteless). The presence of lexical gaps suggests that gustatory pathways target words, and can do so selectively. Other word-level influences, too, suggest that flavors are tied to lexical rather than phonological units (e.g., flavors are stronger from high- versus low-frequency words [2] and some associations are dictated by word-meaning; e.g., the word *blue* tastes inky) [1]. Third, synesthetic experiences are significantly weaker from non-words [2], which have no lemmas. Finally, synesthetic flavors can be triggered even when phonological information is temporarily inaccessible, as in "tip-of-tongue" states. Tip-of-tongue is the familiar experience in which a word is known but temporarily cannot be recalled from memory. This arises when the word's lemma, but not its phonemes, has been retrieved. When synesthetes are in tip-of-tongue states (which can be induced by showing pictures of uncommon objects such as gazebos, metronomes, platypuses, etc.) they begin to taste the word before they can say it [3]. One woman, for example, tasted Dutch chocolate while struggling to retrieve the word *phonograph*, and this is precisely her synesthetic flavor for that particular word. This phenomenon suggests that it is word meaning – not sound or spelling – that elicits the flavor sensation and this fact, together with the findings above, suggests that gustatory pathways may target lexical-semantic centers.

By examining the particular pairings of inducer and concurrent across different synesthetic variants, researchers have begun to understand the ways in which these might come to be associated in the synesthetic brain. The exact cause of synesthesia is unknown, although a genetic component is strongly implicated (e.g., [7]), and all contemporary theories emphasize changes in patterns of neural communication. Some accounts suggest that genetic inheritance may cause a greater retention of early anatomical connections (through a failure in ►apoptosis), while others propose a lack of inhibition in ►feedback pathways (see [8] for review). In both cases the outcome is assumed to be the same: an atypical, functional cross-talk between brain regions encoding the inducer and concurrent modalities. Hubbard and colleagues (e.g., [8]) have proposed a theory of short-range cortico-cortical connectivity, based on the observation that common pairings tend to arise from adjacent brain regions (e.g., ►grapheme-color synesthesia may reflect left fusiform adjacency between the visual word-form area, and the color-selective region hV4). Their adjacency account extends to lexical-gustatory synesthesia since they point out that regions implicated in language processing are local to cortical taste areas, distributed along ►insular cortex and opercular cortex. Their candidate regions include the frontal operculum extending into ►Broca's area, which may play a role in both speech perception and production, and the superior temporal gyrus and anterior ►temporal lobe, which have been implicated in lexical-semantic processing [9,10]. Indeed, ►fMRI data from a single projector synesthete demonstrates activation of Brodmann's area 43 when listening to words but not tones (while controls showed no such activity) and this is consistent with these proposals (Parslow et al., unpublished; see [1]). Such imaging data not only provides a clue to the neurological roots of the condition, but is strong evidence that the experiences of (projector)

lexical-gustatory synesthetes are, to some extent, perceptual in character.

In summary, lexical-gustatory synesthesia is a condition of unique interest to neuroscientists, psychologists, philosophers and linguistics alike. Its blending of linguistic constructs with perceptual flavor experiences has forced a redefinition of synesthesia beyond a purely perceptual viewpoint, as well as informing more general theories about the interplay between perceptual and non-perceptual systems. The gustatory and olfactory "reality" of the tastes, textures, temperatures and odors experienced by lexical-gustatory synesthetes allows us to see, in a very direct way, that perceptual sensations are the result of internal neurological processes, rather than external stimuli from the outside world, and shows that our perceptual inner worlds can be idiosyncratically constructed in the most surprising ways.

## Lhermitte's Symptom

### Definition

Lhermitte's symptom is an electrical sensation caused by neck flexion, which may radiate from the neck down the spine and/or into the arms and legs indicating a myelopathy. This may occur from an multiple sclerosis (MS) lesion in the cervical spine though is not specific to MS and can occur from spondylosis or other disorders of the cervical spine.

## Ligaments

Cy Frank
Department of Surgery, University of Calgary, Calgary, AB, Canada

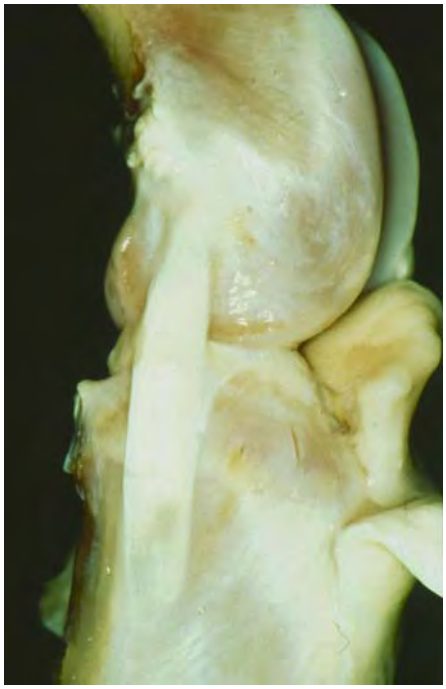
### Definition

As defined in several excellent reviews on this topic [1–3], ligaments are anatomically discrete bands of dense connective tissue that attach bones across joints (Fig. 1).

### Characteristics

#### Gross Anatomy

Each joint has several ligaments that connect to specific locations to serve their individual mechanical roles in resisting tensile forces while keeping the joint surfaces appropriately juxtaposed. The ligaments of each joint work together to guide its ►kinematic movements during normal joint motion, and they resist abnormal displacements of those bones when abnormal forces act on the joint. The ligaments are thus said to be the "passive stabilizers" of each joint. An additional function of ligaments is their ability to serve a sensory and ►proprioceptive/Proprioception role through the presence of ►mechanoreceptors. These sensory receptors respond to mechanical pressure or distortion, feeding back information to the central nervous system that



**Ligaments. Figure 1** Gross appearance of the New Zealand White rabbit medial collateral ligament.

relays information to the muscles, potentially affecting the resultant muscular function.

There is no standardized anatomic or biological nomenclature for ligaments. They are named according to a variety of descriptive characteristics: their relationships to a joint (e.g. collateral or "capsular") or to each other (e.g. cruciate), by the bones that they connect (e.g. acromioclavicular), or by their gross anatomic shape (e.g. deltoid). There are several hundred ligaments in the body thus having a variety of names.

## Histology and Biochemistry

Microscopically, it can be seen that ligaments contain both blood vessels and nerves. They are supplied superficially by small penetrating arterioles that are more abundant at their surfaces and near their insertions into bone, but which do not penetrate bone. Their ►innervation is a combination of ►nociceptive and proprioceptive nerve endings, again more abundant near their insertions into bone but not penetrating the bone.

Histologically and immunohistochemically, ligament substance is known to be made up of relatively densely packed parallel fibred material (collagen fibers) with a few interspersed cells. These ligament fibroblasts, although relatively few in number compared to other connective tissues, are nevertheless metabolically active and participate in the turnover of ligament ►matrix that occurs anywhere from months to years. For many years, it was assumed that ligament fibroblasts existed in isolation of one another, but we now know that their long cytoplasmic projections communicate via gap junctions, and this allows ligament fibroblasts to maintain continuous contact with relatively few cells spread throughout a large volume of tissue [4]. The collagen fibers of the matrix are made up of many so-called collagen fibrils. The fibrils are, in turn, made up of helically organized collagen microfibrils, and those, in turn, of helical collagen molecules. These molecules are cross-linked to each other at the molecular level, making this substance very stiff and strong (the strongest tensile resisting protein in the body). At higher levels of organization, the helix has an unusual "crimped" appearance when viewed with polarized light indicating some sort of multi-micron "kinking" of these fibrils along their long axes. As discussed below, this crimp is thought to be a key feature in facilitating low load tensile displacements along the long axis of ligament collagen fibers.

Although six genetically distinct types of collagen have been isolated from ligament, the major types of collagen present in ligament subunits are mainly collagen type I and quantitatively minor amounts of collagen types III and V. The spaces in between these fibrils contain tiny bead like filaments of type VI collagen, which serve as cross connections between the larger type I fibrils, binding to their surfaces at particular locations occupied by small ►proteoglycan molecules (e.g. decorin, lumican, fibromodulin and biglycan). A large proteoglycan, thought to be versican, is also present in normal ligaments. These proteoglycans contribute to water binding capability and likely help control water distribution within the matrix. Ligament matrix is about 65% water by weight, with the other 35% dry weight composed mainly of collagen (with small amounts of several subtypes of proteoglycans, elastin, fibronectin and several other glycoproteins).

Ligament substance is not homogeneous. The surface of ligaments is covered with a very thin epiligament layer that is more cellular, more metabolically active and more vascular than the underlying substance. Ligament insertions into bone are also heterogeneous and unique [5]. Direct ligament insertions consist of ligament substance transitioning into small zones of fibrocartilage and calcifying fibrocartilage leading into bone. Within the bone are so-called Sharpey's fibers that are, in fact, ligament collagen fibers that are encased in bone mineral.

## Structural Properties

Ligaments behave as non-linear ►viscoelastic materials that are ►anisotropic. When loaded in tension along their longitudinal axis (their normal functional axis in vivo), they exhibit increasing stiffness with increasing displacement up to displacements that cause damage to

their matrix. At that point, yield of some fibers occurs prior to progressive, sudden catastrophic failure. As compared with other tissues in the body, ligaments are considered relatively stiff and relatively non-compliant, but due to their unique fibrillar architecture and internal organization, they allow some modest (millimeter) amounts of displacement at very low loads prior to this increasing stiffness.

## Material and Viscoelastic Properties

Ligaments are viscoelastic. Under low loads and slowly applied tensile loads, ligaments are dominated by their viscous behaviors, which allows them to load-relax (decrease their tensile load when held at a fixed length) and to creep (increase their length when pulled in tension under a constant load) a few percent of their overall length [6]. This results in some subtle "adjustments" of length and loads within each structure as joints are cyclically loaded or elongated during function. Ligaments are also somewhat strain-rate sensitive (being a few percent stronger and stiffer at higher rates of loading). Their loading behaviors are thus said to be "load-history dependent."

At higher loads, ligaments become more elastically dominated, with higher stiffness and less viscous behavior. Their tensile strength is normally in the 80–100 MPa range. Under high load conditions, ligaments fail in tension either partially (a "sprain") or completely, with fibril disruption and subsequent joint laxity. Not every sprain results in symptoms, as ►neuromuscular control systems and/or conscious decisions to avoid the stresses that would render the damaged joint "unstable," may prevent it from being symptomatic [7].

### *Ligament Healing*

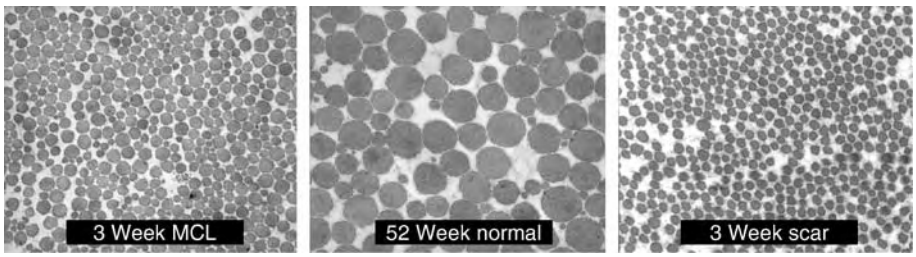
Ligaments heal with "scar tissue," which is a unique connective tissue that forms in adults. The scar, which is generally larger than the original injured structure, is produced by a combination of fibroblasts, recruited macrophages and other inflammatory cells that produce a scar matrix, which starts very disorganized but remodels and matures over months to years (Fig. 2).

The collagen fibrils in the scar are remodeled, and "aligned" fibrils (aligned with the load axis of the structure") make up the main replacement tissue over many years. This can make a ligament scar almost as strong structurally as a normal ligament, but its material strength remains quite a bit weaker than normal (only reaching 30–50% of normal ligament material strength and stiffness even after months to years of healing). Some ligaments have particularly poor healing potentials – e.g. the anterior cruciate ligament in the knee. There is somewhat variable scar production, remodeling and maturation under different loading and environmental conditions, making ligament healing variable between structures and between individuals.

**Ligaments. Figure 2** Gross appearance of the healing New Zealand White rabbit medial collateral ligament (6 weeks post injury). Note the central portion with scar tissue is more translucent than the uninjured ligament in Fig. 1.

Ligament scars are made up of many elements similar to normal ligaments but in different proportions. There is more Type III and V collagen and less Type I collagen in scars. There are also fewer collagen ►cross-links and abnormally large proteoglycans present in the scar. These alterations are implicated in the production of abnormally small collagen fibrils, which remain small for months to years during the healing and scar maturation process (Fig. 3).

Scars are generally more cellular than normal ligaments, and the elaborate cellular organization of normal ligaments with cell projections and ►gap junctions is altered. In some scars, it is replaced by areas devoid of cells and cytoplasmic projections, possibly leading to ineffective cellular communication. The small collagen fibrils, along with the abnormal collagen and proteoglycan types, abnormal collagen cross-linking, altered cellular communication and on-going presence of structural "flaws" in the scars (i.e. "holes" in the matrix: blood vessels, fat cells, inflammatory cells, loose or disorganized collagen) represent their "weak spots," and explain why ligament scars are permanently inferior to



**Ligaments. Figure 3** Typical transverse transmission electron micrographs of collagen fibrils in developing 3 week, 52 week skeletally mature and healing (3 weeks post injury) New Zealand White rabbit medial collateral ligaments. Note the bimodal distribution of large and small diameter fibrils in the mature ligament as opposed to the small unimodal distribution in developing and healing ligaments.

normal ligaments [8–10]. These processes and their potential enhancement are currently receiving considerable research attention.

# Ligand

## Definition

A molecule that binds specifically to a receptor site.

# Ligand-gated Channels

## Definition

Ligand-gated channels bear extracellular ligand binding sites which allosterically modulate the opening or closing of the channel in response to the binding of neurotransmitter. Binding of ligand often occurs at the interface between subunits composing the receptor channels. Most ligand-gated channels bear multiple ligand binding sites and there is positive cooperativity of ligand binding for channel opening. Ligand-gated channels include the Cys-loop receptor channels [acetylcholine receptor (AchR), γ-amino-butyric acid (GABA), glycine receptor (GlyR), serotonin (5HT)] and metabotropic glutamate receptors [glutamate (Glu), α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), kainate (KA)] as well as those that respond to ATP ($K_{ATP}$ channels), $Ca^{2+}$ (BK channels) or cyclic nucleotides (cyclic nucleotide-gated (CNG) channels).

►BK Channels

## Ligand-gated Ion Channel

### Definition

►Ligand-gated Channels
►Ionotropic Receptor

## Light-Dark Cycle

### Definition

Alternation of a light (or photo) phase, and a dark (or scoot) phase. Although denotations may differ, usually abbreviated as for instance LD 16:8, in case of a light phase of 16 h and a dark phase of 8 h.

►Circannual Rhythms

## Light Pulse

### Definition

Brief presentation of light used in circadian biology to test the effects of acute light exposure on the circadian clock, and on the rhythms it controls.

►Circadian Rhythm
►Clock

## Limb-girdle Muscular Dystrophy (LGMD)

### Definition

Group of muscular dystrophies characterized by different patterns of inheritance, age of disease onset and extent of limb weakness. While, as compared to ►Duchenne and Becker muscular dystrophies, muscular dystrophin is normal, the genes giving rise to sarcoglycans are abnormal due to mutations of the related gene. Since sarcoglycans appear to be necessary for normal functioning of dystrophin, the clinical LGMD syndromes may look similar to Duchenne and Becker dystrophies.

►Becker Muscular Dystrophy
►Duchenne Muscular Dystrophy

## Limb Kinetic Apraxia

### Definition

One of the types of apraxia designated by Liepmann (1910), caused by damage to the central region, namely the precentral motor cortices or the postcentral sensory cortex. It is characterized by the clumsiness of the hand without accompanied by paralysis nor sensory loss.

►Somatosensory Cortex I

## Limbic

### Definition

A descriptor, extracted from the term limbic system, used in reference to aspects of neural circuitry and function that are otherwise not regarded as subject to proper mechanistic consideration. Thus, reward, motivation and emotional expression and the neural circuits thought to subserve them are frequently referred to as limbic functions and limbic connections, respectively.

►Limbic Lobe
►Limbic System

## Limbic Lobe

### Definition

A term suggested by Pierre Paul Broca in 1878 (le grand lobe limbique) to describe a collection of cortical and subcortical structures forming a ring at the medial border of the cerebral hemispheres of all mammals. Broca's term included prepyriform cortex (primary olfactory cortex), diagonal band, medial prefrontal cortical areas, the cingulate gyrus, retrosplenial gyrus, the hippocampus, and parahippocampal gyrus (including the subiculum). Based on changes in emotional behavior correlated with brain pathology, Papez (1937) subsequently included the limbic lobe (particularly hippocampus and cingulate gyrus) in his cortical theory of emotions while adding anterior thalamic and hypothalamic nuclei as areas providing afferents directly or indirectly to the cingulate cortex. MacLean (1949) subsequently expanded on Papez's theory, including the amygdala within the system serving the sensory and expressive (motor) aspects of emotion.

MacLean later suggested the term "limbic system" as a term with neutral connotations for the structures within his expanded Papez's circuit. The limbic system and its core cortical structures have since remained a focus of research on the neural basis of emotional experience, and in pathology is thought to be etiological in the most severe mental illnesses which afflict mankind. Over the years since Broca's initial description, the Definition of the limbic lobe has been often modified.

Most recently, Heimer and van Hoesen (2006) have reviewed the history of the limbic lobe and suggested modifications limiting this designation to cortical structures and eliminating areas such as the diagonal band and olfactory tubercle. The latter arguably are better analyzed as part of largely parallel subcortical relays in the hippocampal-septal system, and ventral striatopallidal systems, respectively. In addition, Heimer and van Hoesen suggest that only the lateralbasolateral part of the amygdala be retained within the limbic lobe since this is cortical in nature and that the subcortical centromedial amygdala should not be included. They also urge the inclusion of bordering transitional areas such as the insular, temporal pole and perirhinal cortices. This modern view of the limbic lobe would thus not represent a closed circuit as has sometimes been envisioned for the interconnections characterizing the limbic lobe, but as interacting points of entry into cortical-subcortical circuits that both process extrinsic and intrinsic sensory information relevant to evoking emotions, and provide efferents modulating adaptive autonomic and somatic emotional expression via the emotional motor systems in the basal forebrain, hypothalamus and brainstem.

# Limbic System

Daniel S. Zahm[1], Lennart Heimer[2]
[1]Department of Pharmacological and Physiolgical Science, Saint Louis University School of Medicine, MO, USA
[2]Departments of Neurological Surgery and Neuroscience, University of Virginia School of Medicine, Charlottesville, VA, USA

The limbic system constitutes an indeterminate number of extensively interconnected brain structures located near the core of the brain and is said to be responsible for the genesis of ►emotions and emotional responses. The importance of emotional functions to the social fabric of animal societies and human cultures and to the mental health of individuals has fueled a near insatiable interest in the limbic system. Indeed, the limbic system is invoked at every educational level worldwide to explain the full spectrum of emotional behaviors, from the fearful to the affiliative, and the concept is securely embedded in the scientific and popular literature. However, what components comprise a limbic system and how they interact as a system to produce emotional functions have yet to be determined; i.e., a generally accepted theoretical framework addressing limbic system structure and function remains to be described. This lack of rigor in the conceptualization of the limbic system has caused opponents of the concept to advocate that it be abandoned [1,2]. In contrast, proponents argue that the limbic system, despite its limitations, has proven to be a durable and valuable conceptual framework that has survived over the course of many years and should be retained until suitably replaced [3]. Rudolf Nieuwenhuys, a prominent scholar of brain organization and proponent of the limbic system concept, has captured the gist of the discourse on the limbic system, commenting that "…the validity of the term and the concept behind it has been endlessly debated in the literature" [4].

Consistent with persistent conceptual snags that make it difficult to define the limbic system, the intellectual underpinnings of the concept have evolved in fits and starts over a period of nearly 130 years. The most frequently cited antecedent to the limbic system is "le grande lobe limbique," the great ►limbic lobe, which ►Paul Pierre Broca described on the basis of extensive comparative anatomical observations [5]. Broca, like ►Thomas Willis [6] and a few others (see [7,8], noticed that the callosal gyrus (►cingulate gyrus) and hippocampal gyrus (►parahippocampal gyrus) form a border (limbus) or circular cortical field around the corpus callosum and ►thalamus. Primary olfactory input appears to enter the parahippocampal gyrus and, to a lesser extent, the cingulate gyrus, begging the impression that olfaction must dominate the limbic lobe. Broca associated these olfactory influences with emotional coloration reflecting the "brute within" and thus thought his great lobe should be involved with the drives and emotions that underlie behavior.

In 1937, ►James Papez [9], although not directly referring to Broca, extended Broca's seminal conceptualization by drawing attention to a series of neural connections forming a circuit (the ►Papez circuit) in part involving Broca's great limbic lobe. Papez proposed that the cingulate gyrus projects via the cingulum to the parahippocampal gyrus, including the ►entorhinal area, which densely innervates the hippocampus (see ►hippocampal formation), which in turn projects massively via the ►fornix to the

►hypothalamus, including the ►mammillary body, associated with emotional expression. The mammillary body projects by way of the ►mammillothalamic tract to the anterior thalamic nucleus (see thalamus), which in turn innervates the cingulate gyrus, which would be important for emotional experience. Papez de-emphasized the olfactory influences on these structures and proposed that the relationships described above "constitute an harmonious mechanism which may elaborate the functions of central emotion as well as participate in emotional processes." Approximately coinciding with the emergence of Papez's functional-neuroanatomical construct, Klüver and Bucy [10,11] reported that bilateral lesions of the medial temporal lobe in monkeys, involving predominantly the ►amygdala, produce strikingly reduced fear and anger responses in combination with hyperorality and hypersexuality. These seminal findings were thought to confirm Papez's theory, at least in part, but also expanded appreciation of the role of the medial temporal lobe in emotional functions.

►Paul MacLean [12,13] expanded on the ideas of Broca and Papez. He argued, for example, that the hippocampus receives multisensory information via the ►association cortex and brainstem, noting that stimulation of the ►vagus nerve elicits robust hippocampal responses. Furthermore, the "►Klüver-Bucy syndrome" suggested that the amygdala is intimately associated with emotional behavior. MacLean went on to suggest that the amygdala, hippocampus and a number of other subcortical structures (e.g., the ►septal area, anterior thalamic nucleus and ►habenula) with relations to Broca's limbic lobe contribute to a system dedicated to emotional behavior. In attempting to provide a name for this system, MacLean first suggested "visceral brain" [12], using the term in the sense of strong, inward feeling, but he was soon confronted with complaints from physiologists, who define the term "visceral" more literally. MacLean subsequently reverted to Broca's original term, "limbic" [13], thinking that this term might be used in a more mechanistic and neutral, rather than connotative, sense. Ironically, this intent has been so perverted by subsequent developments that "limbic" currently seems to connote all things neural having anything to do with emotion.

With these modifications, the "limbic system" was soon subjected to additional liberal bouts of conceptual retooling. ►Walle Nauta conceived of a "limbic-midbrain axis" (see ►limbic midbrain area of Nauta) involving additional ►basal forebrain, mesencephalic (in the rostral brainstem) and rhombencephalic (in the caudal brainstem) "limbic" structures, such as the ►preoptic region, ►periaqueductal gray and dorsal raphe nucleus (see ►serotonergic system), which he showed to be intimately related by connections to each other and other "limbic" structures [14,15]. Also, with a view to its connections with the preoptic region, lateral hypothalamus and dopaminergic ►ventral tegmental area (see ►dopaminergic system), Nauta advocated for a "limbic" characterization of the ►nucleus accumbens, which Mogenson subsequently popularized as the "limbic-motor interface" [16]. Kelley et al. [17] noted that afferents from the amygdala, hippocampus, ►prefrontal cortex, ventral tegmental area and raphe nucleus converge not only in the accumbens, but also in medial and ventrolateral parts of the caudate-putamen (see ►basal ganglia; ►striatopallidum), giving rise to further extensions of the limbic system into a so-called "limbic" striatum and the (midline-intralaminar) thalamic (see thalamus) and (medial prefrontal and rhinal sulcal) cortical (see prefrontal ►cortex) areas that innervate it.

Nieuwenhuys's thorough review [4] of the limbic system concept culminated with a description of modern neuroanatomical, neurochemical and functional features, on the basis of which he defines the "limbic" system. Among these features, he included: (i) numerous discrete sites which, upon stimulation, elicit integrated behavioral and/or autonomic responses; (ii) many thin, varicose unmyelinated axons interconnecting with other limbic structures; (iii) presence of ►tanycyte-like neurons or ►circumventricular organ-like structures mediating analysis of cerebrospinal fluid and/or blood composition and conduction of the information into the local neuropil; (iv) presence of foci containing steroid-containing neurons; and (v) presence of an extraordinary diversity of classical and, particularly, neuropeptidergic neurotransmitter/modulators (see ►neuropeptide; ►synapse). As it turns out, these chemical-neuroanatomical features correspond precisely to those used earlier by Nieuwenhuys and colleagues in a description of the "core of the neuraxis," a construct aligned along or projecting into the main, predominantly unmyelinated, fiber tracts of the forebrain and brainstem, e.g., the periventricular, medial forebrain and dorsal longitudinal bundles [18]. Use of the same criteria to define the core of the neuraxis and the limbic system had the primary effect of expanding the limbic system further into the caudal brainstem, bringing into the "limbic" fold such structures as the pedunculopontine and laterodorsal tegmental nuclei (see ►mesopontine tegmentum), ►parabrachial nucleus, ►nucleus of the solitary tract and ►dorsal vagal complex. In contrast to the expansion of the limbic system advocated by Nauta and Mogenson, however, Nieuwenhuys excludes the limbic striatum and associated cortical and thalamic structures from his conceptualization of the limbic system, which he refers to as the "greater limbic system." It is interesting to note that nothing of Broca's limbic lobe is included in Nieuwenhuys's definition of the limbic system.

A strength of Nieuwenhuys's model of limbic system is that it defines "limbic" in terms of the general neurochemical-cytoarchitectural composition of the

included neural tissue, thus implying the kinds of neural mechanisms that might underlie "limbic" function. His limbic core is replete with diverse networks of largely unmyelinated neuropeptidergic and, to a lesser extent, neurosteroidergic fibers engaged in perhaps near equivalent amounts of synaptic, parasynaptic and paracrine neurotransmission and neuromodulation (see synapse). Neuropeptide transmitter/modulators bind largely to G protein-coupled receptors (see ►synapse) that give rise to synaptic potentials and intracellular signaling cascades of slow onset and long duration. Furthermore, numerous and diverse physiological stimuli are known to alter the genomic expression of forebrain and brainstem neuropeptides. Thus, the prominent neuronal response in Nieuwenhuys's multi-peptidergic corridor develops gradually, lasts relatively long and involves genomic regulation of neuromodulator levels, a combination of processes that fits with the gradual transitions that typically separate different emotional responses and states.

Despite its strengths, the "greater limbic system" of Nieuwenhuys is nonetheless subject to perhaps the most venerable criticism of limbic system hypotheses in that it lacks consideration as to how the cognate components of the system interact to carry out designated functions. This oft-mentioned deficiency of limbic system theories has led Joe LeDoux and like-minded neuroscientists, such as Thomas Insel and Antonio Damasio, into a more reductionistic approach aimed at identifying the neural circuitry and mechanisms committed to the execution of discrete emotions, such as fear [19], affiliative behaviors [20] or perceived emotional feelings [21]. The success of this approach is evident in the broad variety of published studies describing quite specific interventions involving, e.g., lesions, drug infusions, or gene deletions that target specific, typically "limbic," circuitry to modulate particular emotional behaviors. These kinds of experiments support a hypothesis that integrated emotional responses require the interactions of functionally specified subcircuits acting primarily, but not exclusively, within neural territories that are, or have been, regarded as part of the limbic system.

In order to facilitate the development of a more comprehensive mechanistic understanding of the genesis of emotions and their impact on behavior, neuroscientists were also concerned with the relationships of so-called "limbic" subcircuits with the rest of the brain. In this regard, and, from an unanticipated direction, a conceptual breakthrough occurred when it was shown in experimental neuroanatomical studies that the olfactory tubercle, despite its laminar morphology, is not a cortex [22,23], as previously portrayed in the neuroanatomical literature. The massive projection of the piriform (olfactory) cortex to the superficial layers of the tubercle is unaccompanied by a reciprocal projection from the tubercle back to the cortex (required if the tubercle is cortex). Rather, neurons in the superficial layer of the tubercle that receive robust cortical input project massively into the overlying subcommissural region where their axon terminations form a dense feltwork of inputs to aspiny neurons identical to those in the overlying globus pallidus (see basal ganglia; ►striatopllidum). This was the beginning of the idea of a ventral striatopallidal system (see ►striatopallidum; ►ventral). This connectivity and the medium sized, densely spiny morphology of superficial tubercle neurons argue that the tubercle is a striatal structure projecting to a pallidal target, which turns out to be a rostroventral extension of the globus pallidus and, accordingly, was called ventral pallidum (see ►striatopallidum; ►ventral). The nucleus accumbens, which Nauta and colleagues had designated as a limbic system structure due to massive input from the hippocampal ►subiculum and basolateral amygdala, was also shown to comprise largely medium spiny neurons and project to the ventral pallidum.

The upshot of these findings is that the entire cortical mantle is subserved by basal ganglia-like mechanisms, which now could be extended to involve so-called "limbic" structures. It is generally agreed that basal ganglia functions are critical to any kind of adaptive behavior, although precisely what a basal ganglia-like mechanism is remains elusive, even to this day. Nonetheless, these observations served notice that "limbic" mechanisms are unlikely to be fundamentally different from other neural mechanisms in the forebrain, and they dispelled the misconception of a limbic system-basal ganglia dichotomy, as reflected in expressions like "limbic versus basal ganglia" or "limbic versus extrapyramidal," which pervades twentieth century neuroscience literature. Subsequent tract-tracing studies showed that ventral pallidum projects to the mediodorsal thalamus rather than the ventral anterior/ventral lateral "motor" nuclei of the thalamus [24]. Since the mediodorsal thalamus is related to the prefrontal cortex rather than the motor and supplementary motor cortex, this discovery provided the first indication of segregated ►cortico-subcortical reentrant circuits through the basal ganglia to motor cortex and prefrontal cortex, respectively. The further elaboration of the notion of parallel cortico-subcortical reentrant circuits through the basal ganglia and thalamus [25] has been widely acclaimed, and the concept of parallel cortico-subcortical reentrant circuits through the ventral striatopallidal system has all but replaced the limbic system as a strategic approach to the study of neuropsychiatric disorders [26].

It was subsequently determined on the basis of strong evidence that will not be discussed in detail here (instead see [27,28], that the central nucleus of the amygdala (see amygdala; ►extended amygdala), bed nucleus of stria terminalis (see extended amygdala) and septum, all structures regarded as "limbic" by MacLean

and others that followed him, also exhibit neuroanatomical relationships consistent with designation as modified striatopallidum. Lateral septum (see septal area) gets cortical inputs predominantly from hippocampus supplemented by fewer from the prefrontal cortex and the cortical-like basolateral amygdala. The central amygdala-bed nucleus of stria terminalis complex, the so-called extended amygdala [29], receives its most prominent input from the basolateral amygdala and a lesser complement from the prefrontal cortex and hippocampus. In contrast, the nucleus accumbens receives more or less equivalently strong inputs from the prefrontal cortex, basolateral amygdala and hippocampus. Outputs from each of these structures descend in robust, fairly separate, albeit overlapping, trajectories through the forebrain and brainstem largely within the confines of Nieuwenhuys's greater limbic system, with some reaching all the way to its caudal pole. These pathways converge at various sites in the basal forebrain and brainstem, suggesting that outputs of the striatopallidal-like "►functional-anatomical systems" compete and cooperate [30] to influence motor function, via modulation of the activity of brainstem somatomotor (see ►motor system) and viscermotor (see ►autonomic nervous system) effectors and, via modulation of direct and trans-thalamic reentrant pathways, cognitive function in the frontal cortex [31]. The potential impact of these segregated, occasionally convergent descending systems on brainstem and spinal motor effectors and ascending cortical neuromodulatory projections (see ►ascending neuromodulatory projection systems) converges conceptually with functional implications proposed by Holstege [32,33] in his description of the "►emotional motor system."

Alheid and Heimer [27] and, more recently, Heimer and van Hoesen [34] have emphasized that the massive cortical inputs to the major forebrain striatopallidal-like functional-anatomical systems, including ventral striatopallidum, extended amygdala, and septal-preoptic system, originate largely in Broca's great limbic lobe, which, however, they define slightly differently than did Broca. First, their expanded conceptualization includes the hippocampus, a bona fide cortical structure, which, as discussed above, has been more or less uniformly included in the limbic system since the time of Papez and MacLean. Second, Heimer and van Hoesen include the cortical-like amygdaloid basolateral complex and cortical amygdaloid nucleus in the concept of the limbic lobe. This is based on connectivity and neurochemistry/cytoarchitecture, in accord with numerous earlier neuroanatomical analyses. Thus, the laterobasal-cortical amygdala receives and reciprocates cortical association connections and the neuronal morphology and transmitter/modulators of its principal and interneuronal cell types faithfully emulate those of cortex. From a conceptual point of view, Heimer and Van Hoesen's [34] modifications, formalized as the "greater limbic lobe," serve to reinvigorate Broca's original and functionally relevant anatomical concept of a ring-like, cortically based limbic lobe, which, over the course of many years, had been subjected to gradual, inexorable de-emphasis in favor of the limbic "system." In other words, with this expanded version of Broca's limbic lobe, the term "limbic" regains its literal meaning.

Outputs from the greater limbic lobe terminate profusely and almost entirely within structures that form the head ganglia of the "greater limbic system" of Nieuwenhuys [4] and outputs from those structures descend through the forebrain and brainstem to innervate structures almost entirely within that construct. In contrast to earlier iterations of the limbic system, however, considerable knowledge has been acquired regarding the specificity of these pathways with regard to their trajectories and many of the structures they innervate. This knowledge, however, is embryonic and much remains to be discovered. How are the descending pathways related anatomically and functionally to somatomotor and visceromotor centers and to direct and trans-thalamic reentrant pathways? How do the descending influences integrate with ascending sensory influences conveyed by the vagus nerve and collaterals of spinothalamic projections (see ►anterolateral sensory system)? How does interoceptive information arising in the circumventricular organs and preoptic nucleus and conveyed via the hypothalamus integrate within the system? How does Nieuwenhuys's greater limbic system inter-relate with other functional-anatomical constructs occupying the brainstem and forebrain, such as the ►reticular formation, its ►ascending reticular activating system and the HPA (hypothalamic-pituitary-adrenal), i.e., stress, axis (see ►stress response)? To summarize, current knowledge and discoveries anticipated to occur in the forseeable future seem consistent with the continuing development of more mechanistic, systems-oriented approaches to the problems of understanding the neural substrates of emotions. Indeed, the time may soon arrive when it will be generally agreed upon that reliance on a "limbic system" has outlived its usefulness. Until then, terms like "limbic system structures" and "limbic activation" will continue to inhabit the neurophysiological, behavioral and neuropsychiatric lexicons, as will the ambiguities and questions attached to them.

*In Memoriam* – Lennart Heimer passed away March 12, 2007.

## Limbic–Motor Interface

### Definition

A hypothetical construct, where limbic information was thought to be able to gain control of the mechanisms of motor control – an interface between "desire" and

action. The nucleus accumbens was once thought of as fulfilling this role, but it is more likely that this concept is better understood in a more distributed manner. For a brief discussion, see Winn P, Brown VJ, Inglis WL (1997) On the relationship between the striatum and the pedunculopontine nuclei. Crit Rev Neurobiol 11:241–261.

►Mesopontine Tegmentum

## Limits to Entrainment

### Definition

A range of periods (cycle duration) of a time cue (zeitgeber) that can entrain a self-sustaining oscillator.

►Zeitgeber

## Linear Damper

### Definition

A rheological element whereby the force is proportional to the speed. Also called a linear dashpot.

►Mechanics

## Linear Momentum

### Definition

In classical (particle) mechanics, the linear momentum is the vector obtained as the product of the mass of the particle times its velocity. In continuum mechanics, the linear momentum density at a point in space is obtained as the product of the mass density at that point multiplied by its velocity vector. The total linear momentum of the body is then obtained as the integral over the body of the linear momentum density.

►Mechanics

## Linear Spring

### Definition

A rheological element whereby the force is proportional to the elongation.

►Mechanics

## Linear Summation Hypothesis

### Definition

Shifting gaze toward a target involves the combined activation of both the saccadic system and the cephalic motor system. Thus, the eyes are potentially submitted to two simultaneous but opposite commands: a saccadic drive to shift gaze toward the target and a vestibulo-ocular reflex (VOR) slow phase drive elicited by the concurrent head rotation. The linear additivity hypothesis postulates that these two antagonistic ocular commands linearly add during the whole duration of gaze shift such that any physical contribution of the head to the gaze shift is in effect cancelled by the VOR. Thus, in this scheme, there is no need for the saccadic system to take the head movement into account to program and execute an accurate gaze shift. In contrast, the non additivity hypothesis, which is now largely accepted, states that the VOR is momentarily inhibited during the gaze shift, and therefore that a VOR-independent mechanism must take the head contribution into account to ensure gaze shift accuracy.

►Gaze Shift
►Saccade, Saccadic Eye Movement
►Vestibuloocular Reflexes (VOR)

## Linear System

### Definition

A system is linear if the output generated when a weighted sum of two input variables is equal to the weighted sum of the outputs generated when each variable is passed separately through the system.

►Signals and Systems

## Linearization

### Definition

The process of simplifying a non-linear system so that it can be described using linear equations. Linearization can be performed using several techniques, the most common of which is the Taylor series expansion.

►Signals and Systems

## LIP

►Lateral Intraparietal Area

## Lipid Raft

### Definition

A microdomain of the plasma membrane enriched in sphingolipids and cholesterol. Certain signaling proteins are enriched in these domains.

## Lipopolysaccharide (LPS)

### Definition

Lipopolysaccharide (LPS) is a component of the cell wall of gram-negative bacteria. It has been used experimentally to stimulate production of endogenous IL-1 and other cytokines, β-APP and complement proteins.

►Cytokines
►Neuroinflammation – LPS-Induced Acute Neuroinflammation

## Liprin-α

### Definition

An active zone-enriched scaffolding proteins that participates in functional multi-protein complexes, including direct or indirect interactions with CASK, ELKS, RIMs, and KIF1A (a motor protein), among others.

►Synaptic Proteins and Regulated Exocytosis

## Lissauer's Tract

### Definition

Fiber tract in the dorsolateral quadrant of the spinal cord that contains the central projecting axons of unmyelinated and thinly myelinated sensory fibers.

►Nociceptors: Adequate Stimulus

## Listing's Law

### Definition

Listing's law applies to voluntary, not reflex eye movements, and specifies that at each gaze direction, the eye is positioned as though that gaze direction had been reached from a specific primary gaze position by a single rotation around an axis in a head-fixed plane orthogonal to this primary position. This plane of axes is called Listing's plane. With Listing's law, primary gaze determines 3D eye position for all gaze directions.

►Oculomotor Control
►Vestibulo-Oculomotor Connections

## LLR

►Long Loop Reflexes

## Load Compensation

### Definition

Change in active force in response to a change in loading of a body segment or muscle.

►Feedback Control of Movement

## Loadstone, lodestone

►Magnetite

## Lobectomy

**Definition**

Removal of a particular lobe of the brain, i.e. frontal lobectomy, temporal lobectomy. This surgical procedure is done to remove the diseased part of the brain harboring a tumor or an epileptic focus. It can also be performed if a certain lobe was damaged by trauma or stroke.

## Lobster

**Definition**

Animal of the class Crustacea; a model system for studying small neural networks (see also gastric mill).

## Local Autonomic Ganglia

**Definition**

For many autonomically innervated organs, ganglia lie very close to the organs that they supply. These are local ganglia, and include ganglia close to the salivary glands, ganglia close to the airways, the cardiac ganglia, ganglia adjacent to the urinary bladder and uterus, and ganglia behind the globe of the eye (ciliary ganglia).

►Autonomic Ganglia

## Local Cues

**Definition**

The cues in the immediate vicinity of an animal, such as textures and odors on the floor or an object adjacent to the animal. Distinct from "distal cues", one typically moves amongst and around local cues.

►Spatial Learning/Memory

## Local Feedback

**Definition**

A proposed mechanism that monitors the output of the saccadic burst generator and shuts down the burst when an internally maintained estimate of the position of the eyes reaches an internally maintained estimate of the position of the intended saccade target.

►Brainstem Burst Generator
►Saccade, Saccadic Eye Movement

## Local Field Potential

**Definition**

The local field potential is an electrophysiological signal recorded with an extracellular microelectrode. The overall recorded potential is the summation of electrical changes produced by synaptic activity of all the neurons present around the tip of the electrode. It reflects the global activity of a large neuronal population.

►Extracellular Recording

## Local Global Interaction

►Contextual Influences in Visual Processing

## Local Image Motion

**Definition**

Motion of a visual object relative to the background.

## Local Immune Response

### Definition

Supportive reaction by the immune system, induced and expressed at the site of an acute or chronic lesion. Its components include microglia, blood-borne monocytes (innate immune cells), and T and B cells (adaptive immune cells).

►Autologous Macrophages for Central Nervous System Repair

## Local Navigation

### Definition

Map-based navigation. Typically contrasted with "taxon" or route-based navigation.

►Spatial Learning/Memory

## Local Protein Synthesis

►mRNA Targeting: Growth Cone Guidance

## Local Translation

►mRNA Targeting: Growth Cone Guidance

## Locked-in Syndrome

### Definition

Locked-in syndrome denotes a state, in which the patient is ►quadriplegic, incapable of facial movements and speech, but conscious and able to communicate by eye and eyelid movements. The syndrome results from bilateral lesions of the ventral ►pons, most often due to occlusion of the basilar artery, which leads to damage to the ►corticobulbar tracts and ►corticospinal tracts.

►Corticospinal Tract
►Quadriplegia

## Locomotion

### Definition

Motor behavior allowing an animal to move from one point to another. This motor behavior requires the activation of several hundreds of muscles in vertebrates.

## Locomotor Areas

►Locomotor Regions in the Midbrain (MLR) and Diencephalon (DLR)

## Locomotor Centers

►Locomotor Regions in the Midbrain (MLR) and Diencephalon (DLR)

## Locomotor Reflexes

Keir Pearson
Department of Physiology, University of Alberta, Edmonton, AB, Canada

### Synonyms

Afferent regulation of locomotion; Sensory control of locomotion

### Definition

Locomotor ►reflexes are involuntary modifications of locomotor movements produced by sensory signals from receptors in the limbs and body.

## Characteristics

Animals have the capacity to move with ease in a variable environment. This ability depends on using information from sensory receptors for three purposes: (i) to plan appropriate movements, (ii) to control ongoing ►motor commands according to the mechanical state of the body, and (iii) to respond quickly to unexpected changes in the environment. The rapid, automatic modifications of motor commands in response to changes in the state of the body and to features in the environment are known as *locomotor reflexes*. Over the past 20 years an enormous amount has been discovered about the organization and function of locomotor reflexes in a wide variety of animals, ranging from insects to humans. This has allowed the identification of some common features of locomotor reflexes [1].

## Locomotor Reflexes Originating from Muscle Proprioceptors

The muscles of the limbs and body of mammals are richly supplied with sensory receptors that detect mechanical events in the muscles, such as muscle length, the rate of lengthening and shortening of the muscle (velocity), and muscle force. Signals arising from these receptors, known as *muscle* ►*proprioceptors*, strongly influence the motor commands for walking. The two primary functions of muscle proprioceptors during walking are (i) to control the timing of the phase transitions from stance to swing and from swing to stance, and (ii) to regulate the ongoing activity in muscles during a single phase.

Two ►reflex pathways are known to have a role in controlling the stance-to-swing transition. The first is an inhibitory pathway from the force-sensitive afferents, ►*Golgi tendon organs*, in ankle extensor muscles onto the system generating bursts of activity in flexor ►motoneurons producing the swing phase, and the second is a pathway from length-sensitive afferents, ►*muscle spindles*, in flexor muscles acting at the hip onto the same flexor burst generating system [2]. These pathways are appropriate for controlling the stance-to-swing transition because the excitatory signal from the muscles spindles increases and the inhibitory signal from the Golgi tendon organs decreases during the latter half of stance, thus acting synergistically to promote the initiation of burst activity in flexor motoneurons, i.e. the initiation of the swing phase. Similar pathways are considered to play a role in controlling the stance-to-swing transition in walking humans, because leg unloading and hip extension have been shown to promote the stance-to-swing transition in walking human infants. The other major phase transition, the transition from swing to stance, may also be regulated by feedback from muscle proprioceptors. Imposed flexion of the hip in decerebrate walking cats initiates the swing-to-stance transition and the hip angle at which this transition occurs remains relatively constant when normal animals are walking in a variety of conditions.

The second major function of muscle proprioceptors during locomotion is to regulate the magnitude of motor commands to muscles. At all times during the locomotor cycle there is an enormous amount of sensory feedback from muscle proprioceptors, and some of this feedback is used to establish an appropriate level of activity in the motoneurons according the mechanical demands. The most detailed analysis of this phenomenon is positive force feedback (►Positive feedback) from the Golgi tendon organs in ankle extensor muscles onto the motoneurons innervating these muscles in walking cats and humans [3]. The positive force feedback increases the stiffness of the muscles and provides a mechanism for automatically increasing and decreasing the magnitude of muscle contractions when cat walk up and down slopes, for example, or in bouncing gaits such as galloping.

There are also indications that feedback from the length sensitive muscle proprioceptors, the muscle spindles, contributes to the regulation of ongoing activity in the soleus muscle of walking humans [4]. This contribution likely comes from the secondary endings of the muscle spindles. Surprisingly, there is very little direct evidence in either humans or cats that feedback from the primary endings of the muscle spindles has a significant role in controlling ongoing activity in leg extensor muscles during the stance phase. In fact, recordings from afferents from primary endings of extensor muscles in walking cats has revealed they have relatively modest activity during stance and that the temporal pattern is not strongly correlated with the pattern of muscle activation [3].

The extent to which feedback from muscle proprioceptors regulates activity in flexor muscles during the swing phase of locomotion in cats and humans is unknown. Nevertheless, there are powerful afferent pathways from flexor muscles onto flexor motoneurons that are enabled during the swing phase [5]. Thus it would be surprising if flexor activity in walking animals was not influenced to some extent by feedback from muscle proprioceptors.

## Locomotor Reflexes Originating from Cutaneous Receptors

Sensory receptors in the skin sensitive to touch and pressure are know to have two functions in walking mammals. The most obvious is to initiate reflexes to compensate for unexpected changes in the environment. The second is to regulate the magnitude of motor activity to control the ongoing biomechanical properties of the system, such as the location of the centre of pressure on the sole of the foot. The latter has been clearly demonstrated in the walking system of humans

in which reducing feedback from ►cutaneous receptors in the soles of the feet by cooling alters the pattern of pressure changes in the feet and the activity in variety of leg muscles. Reducing feedback from the paws of the hind legs in cats also produce changes in the mechanics and muscle activity, especially when animals are walking up and down slopes and over complex terrains that require visual signals to adjust stepping movements, such as walking across the rung of a ladder [6]. In the latter situation the animals fail to place their paws correctly on the rungs. Cutaneous sensory signals from the paws are also necessary for correct paw placement in cats with mid-thoracic spinal cord transactions (spinal cats) when they walk on a treadmill belt.

The fact that robust rhythmic stepping can occur in cats and humans in the absence of cutaneous signals from the paws and feet, respectively, indicates that cutaneous signals do not have a major role in the generation of the basic motor pattern for walking. Rather their influence is to regulate this basic pattern.

Currently very little is known about the neuronal pathways underlying the regulatory influence of cutaneous signals during walking. ►Spinal reflex pathways must be the main substrate for the regulating motor commands in spinal cats, and are likely important in controlling some aspects of motor activity in intact cats and humans when walking on flat surfaces. For more complex terrains, however, long-loop reflexes via supraspinal regions are almost certainly involved to allow the integration of perceptual information from cutaneous receptors into the forebrain systems involved in the planning and execution of leg movements.

The roles of cutaneous reflexes in compensating for unexpected events in the environment have been extensively investigated in the walking system of mammals [7]. Unexpected contact of an object with the dorsum of foot in humans or the paw in cats initiates a reflex response that first extends the leg to clear the object and then flexes the leg to rapidly lift it over the object. This is known as the ►*stumbling-corrective* reaction. The motor pattern underlying the stumbling-corrective reaction is complex, and in cats it involves the activation of some extensor muscles followed by activation of flexor muscles. The neuronal pathways underlying the stumbling corrective reaction have not been fully defined but the response appears to depend primarily on transmission of cutaneous signals via spinal reflex pathways. Cutaneous reflexes also play an important role in initiating compensatory movements in response to unexpected shifts in the terrain and thereby assist in the maintenance of balance.

## Locomotor Reflexes Originating from the Vestibular Apparatus

Surprisingly little is know about the functional characteristics of reflex pathways from the ►vestibular apparatus to the pattern generating networks for locomotion in the spinal cord of mammals. By contrast, considerable insight has been gained from studies of swimming in the lamprey [8]. Signals from the vestibular system of the lamprey form part of closed-loop negative feedback systems to assist in maintaining body orientation with respect to gravity during swimming. In mammalian walking systems vestibular signals may also have a similar function since damage to the vestibular system can cause marked ataxia and loss of balance.

Although the vestibular system is not necessary for the generation of the basis motor pattern for walking in mammals, phasic signals from the vestibular system can influence the pattern generating networks on a cycle-by-cycle basis. Furthermore, these reflex responses are highly phase- and task-dependent, being largest at the time of heel contact and absent during other rhythmic behaviors such as cycling. Thus reflexes from the vestibular system have the potential to immediately modify locomotor networks in response to movements of the head. Reflex responses in leg muscles evoked by galvanic vestibular stimulation are appropriate for stabilizing body movements around the roll axis [9].

Electrophysiological studies in walking cats have also provided some insight into the function of vestibular signals in regulating stepping. In intact animals, the activity of ►vestibulospinal neurons is rhythmically modulated in a manner that has suggested that they regulate the overall activity of extensor muscles in all four legs and thereby have a role in the control of balance. On the other hand, ►reticulospinal neurons receiving input from the vestibular system have rhythmic patterns of activity suggesting they have a more restricted role in regulating the activity in specific groups of flexor and extensor muscles [10].

## Summary

Locomotor reflexes play an essential role in the patterning of motor activity for walking. These reflexes have three major functions: (i) to regulate the timing of motor commands according to the mechanical state of the limbs and body, (ii) to control the magnitude of ongoing muscle activity, and (iii) to initiate corrective responses when the limbs or body are unexpectedly perturbed by events in the environment.

Locomotor centers; Locomotor areas

## Definition

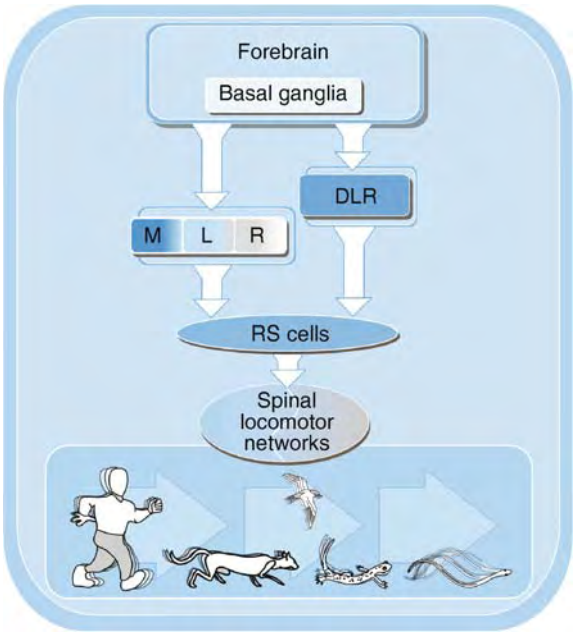
►Locomotion is a stereotyped rhythmical motor activity allowing an animal to move from one point to another. In vertebrates, locomotion is generated by specific networks of neurons in the spinal cord referred to as ►central pattern generators (CPGs). The initiation and control of locomotion both rely on supraspinal structures. A large number of studies carried out in different animal species have shown that stimulation of specific supraspinal regions elicits locomotor activity. However, not all these regions appear to be specifically devoted to the control of locomotion, nor does their stimulation elicit locomotion in a controllable fashion in all cases. Some of these areas relay sensory inputs known themselves to be capable of initiating locomotor activity. Therefore, a locomotor region should be defined as a neuronal area specifically devoted to the initiation of locomotion in a controllable fashion. One such center is a circumscribed region at the border between the midbrain and the hindbrain, first identified in cats by a group of neuroscientists in Moscow [1]. This area was named the *Mesencephalic Locomotor Region* (MLR). Interestingly, the MLR was identified in all vertebrate species examined. It elicits walking and running in quadrupeds, flying in birds, and swimming in fish. Because of its strategic location between higher brain structures and hindbrain neurons directly projecting to the spinal CPGs for locomotion, the MLR is believed to play a key role in goal-directed locomotion. Another locomotor region has been identified in the diencephalon. This diencephalic locomotor region (DLR) also projects to descending projection neurons of the hindbrain to activate locomotion. Both of these locomotor regions have been identified physiologically and their exact anatomical location is still the subject of debate.

## Characteristics

### Upstream Events

The MLR is controlled in large part by forebrain structures (Fig. 1).

The projections to the MLR were examined more extensively in mammals and it was proposed that the MLR is divided in three specific areas generating locomotion in different motivational contexts: exploration, defense, and food seeking (for review see [2]). The forebrain inputs to these three specific areas also differ as they originate from the basal ganglia, and two different parts of the hypothalamus: the lateral and medial hypothalamus. It was proposed that the part of the MLR involved in exploratory locomotion receives inputs from the basal ganglia. The activation of the nucleus accumbens, a part of the basal ganglia, elicits locomotion that is abolished by inactivation of the MLR. Projections from the nucleus accumbens to the ventral pallidum also in the basal ganglia, and then to the MLR are important components of this neural circuitry involved in controlling locomotion. It appears therefore that neurons located in the pallidum would be tonically active at rest, keeping the MLR under tonic inhibition using GABA as a neurotransmitter (for review see [3]). Activation of the MLR by the nucleus accumbens would thus result from disinhibition. Consistent with this view is the finding that injections of $GABA_A$ antagonists in the MLR induce locomotion. The hypothalamic projections to the MLR are involved in locomotion in two specific behavioral contexts. The medial hypothalamus projects to the MLR via the periaqueductal grey in the ►brainstem and this pathway is proposed to be involved in locomotion generated for



**Locomotor Regions in the Midbrain (MLR) and Diencephalon (DLR). Figure 1** Schematic representation of locomotor regions in the CNS. Two specific locomotor regions have been identified, one at the transition between the pons and mesencephalon (Mesencephalic Locomotor Region: MLR) and the other in the diencephalon (Diencephalic Locomotor Region: DLR). Both regions receive inputs from forebrain regions and, in turn, project directly to ►reticulospinal cells. Stimulation of these two locomotor regions elicits swimming in fish, flying in birds, as well as walking and running in tetrapods.

defensive purposes. In addition, the medial hypothalamus projects directly to the hindbrain reticular formation. The projection from the lateral hypothalamus was proposed to be involved in initiating locomotion for food seeking and there is also a direct lateral hypothalamic projection to the reticular formation [4] (for review see [2]). The inputs to the DLR have received less attention. Anatomical studies in fish revealed that several forebrain areas project to the DLR. These projections originate from the olfactory bulbs, different pallial regions thought to be the ancestral precursors of the cerebral cortex, the striatum, and the hypothalamus. Projections from the contralateral side were also seen originating from the ventral and dorsal thalami.

## Downstream Events

The MLR of mammals does not project directly to the spinal cord. The information is relayed by reticulospinal cells in the medial reticular formation of the hindbrain. Neural networks within the spinal cord collectively known as CPGs are responsible for generating the basic locomotor synergy in all vertebrate species and these spinal networks are turned on by reticulospinal cells in turn activated by the MLR. Therefore, reticulospinal cells play a role as command neurons for locomotion. They also receive peripheral inputs. Such a general organization has been demonstrated in all vertebrate species where the role of reticulospinal neurons has been examined. Numerous anatomical and physiological studies have confirmed this. The details of the connections between the MLR and the reticular formation (types of connections, neurotransmitters, and postsynaptic receptors) are still not established in higher vertebrates. However in lampreys where the general connectivity between the MLR and reticulospinal cells is remarkably similar, this has been recently detailed because of the greater accessibility of the *in vitro* preparation of the lamprey brainstem [5]. There are two neurotransmitter systems involved: cholinergic (nicotinic receptor subtypes) and glutamatergic excitatory projections from the MLR to reticulospinal cells [6]. One interesting feature of this connection between the MLR and reticulospinal cells is a regional variation in the strength of the connectivity. The MLR excitatory inputs are largest in reticulospinal cells located in the rostral half of the hindbrain. The strength of the inputs decreases as the reticulospinal cells are located further caudally in the hindbrain. The recruitment of reticulospinal cells with increasing strength of MLR stimulation also displays a specific pattern. The reticulospinal cells that are located in the rostral hindbrain are recruited at the lowest stimulation intensities, whereas those located more caudally require larger stimulation strengths [7]. Therefore, it is believed that rostrally located reticulospinal cells would be recruited to initiate slow locomotion and as more intense locomotion is required, caudal reticulospinal cells would then be recruited. The DLR also projects directly to reticulospinal cells in lampreys. The inputs are glutamatergic [8]. No other neurotransmitter systems have been identified in the connections between the DLR and reticulospinal cells. Interestingly, the excitatory synaptic responses can be potentiated with high-frequency stimulation of the pathway. Such potentiation will likely be important to produce sustained activation of reticulospinal cells to maintain locomotor activity.

## Involved Structures

Both the MLR and the DLR have been identified physiologically in different vertebrate species. However, the exact anatomical structures comprising these two locomotor regions have been subject of controversy and are still not firmly identified. The MLR was originally identified in cats in the early 1960s. It was then established that the cuneiform nucleus located at the mesopontine border was the main element forming the MLR. Another nucleus containing cholinergic neurons,

the pedunculopontine nucleus, was later proposed to also be part of MLR. In rats for instance, the group of Garcia-Rill showed a close relationship between the location of cholinergic neurons and specific sites from which controllable locomotion could be elicited in response to their stimulation [9]. The link between the MLR and cholinergic neurons is still a subject of debate in mammals. A group of cholinergic neurons more caudally located in the laterodorsal tegmental nucleus was also proposed as being part of the MLR. In lampreys there is a link between the location of cholinergic neurons and sites from which controllable swimming is elicited. Stimulation within the lamprey pedunculopontine area was initially shown to elicit locomotion. As additional experiments were carried out examining the MLR of lampreys, it became clear that locomotion could be elicited more readily by stimulating further caudally in the laterodorsal tegmental nucleus. Interestingly, the same area was also very efficient in eliciting stepping movements as well as swimming in salamanders [10]. Another common feature observed in all vertebrate species into which the MLR has been identified is the projection to the medial reticular formation in the hindbrain. At present, it is safe to assume that the MLR comprises more than one anatomical nucleus and that different parts of the MLR elicit locomotion in different behavioral contexts. The DLR has received less attention in different animal species. The first studies indicating that it was possible to initiate locomotion from the diencephalon suggested a subthalamic area. It was later shown that the zona incerta was the effective site for the initiation of locomotion in the subthalamic area. Therefore in addition to regulating several behavioral functions (arousal, attention and posture), the zona incerta plays an important rolein the initiation of locomotion. In mammals, neurons of the zona incerta project down to the caudal end of the hindbrain. In lampreys, the DLR is located in the ventral thalamus, a region that could be homologous to the zona incerta of mammals [8].

## Methods to Measure the Events

Locomotor regions have been identified physiologically. Locomotion was measured in behaving animals and it consisted of stepping movements in tetrapods, walking or flying in birds, and swimming in fish. The first demonstration of the presence of such a locomotor region in the CNS was made in cats in the early 1960s. The animals were decerebrated by removing most of the forebrain tissue above the mesencephalon. The animals were suspended over a treadmill belt and an electrode was inserted at the mesopontine border. Upon stimulation at low intensities, slow walking involving the four limbs was elicited. As the stimulation strength was increased, the animal exhibited faster walking movements until galloping was elicited. This stunning demonstration indicated that specific regions of the CNS are devoted to controlling stereotyped locomotor movements. Later on, it was shown that a similar rhythmical activity was elicited in response to stimulation of the same region in paralyzed animals. In this case, the recordings were made directly over the hindlimb peripheral motor nerves. Because neurotransmission was blocked between the nerve endings and the muscles and no actual movements were produced, the rhythmic activity recorded from the nerves was referred to as "fictive locomotion." In all animal species tested to date, it is also possible to record fictive locomotion in response to MLR stimulation. Interestingly, stimulation of the MLR in salamanders known to display two different modes of locomotion (walking or swimming), induces stepping movements of the limbs at low intensity of stimulation and swimming at higher stimulation strengths [10]. Again, the intensity of the locomotor output is proportional to the stimulation strength.

Chemical stimulation can also be used as a substitute for electrical stimulation to activate locomotor regions in the CNS. For instance, chemicals mimicking the action of some excitatory neurotransmitters are injected locally within specific regions of the CNS to selectively activate neurons in the vicinity. A micropipette is inserted into the locomotor region and small quantities of drugs are injected. Such experiments were originally done in cats and allowed the researchers to confirm that cell bodies of neurons located in the stimulated areas were the elements activated by the stimulation. Chemicals blocking inhibitory transmission have also been injected in the MLR and found to elicit locomotion indicating that neurons within the injected area are likely to be subjected to a tonic inhibitory control.

### Synonyms

Locomotor rehabilitation

### Definition

After a spinal cord injury in animals and humans, locomotion may be more or less impaired depending on the extent of the lesion (complete or partial). Intrinsic mechanisms of the nervous system leads to a certain degree of functional recovery below the lesion with re-expression of locomotion. However, systematic locomotor training supplemented by pharmacological stimulation can improve such functional recovery.

### Characteristics

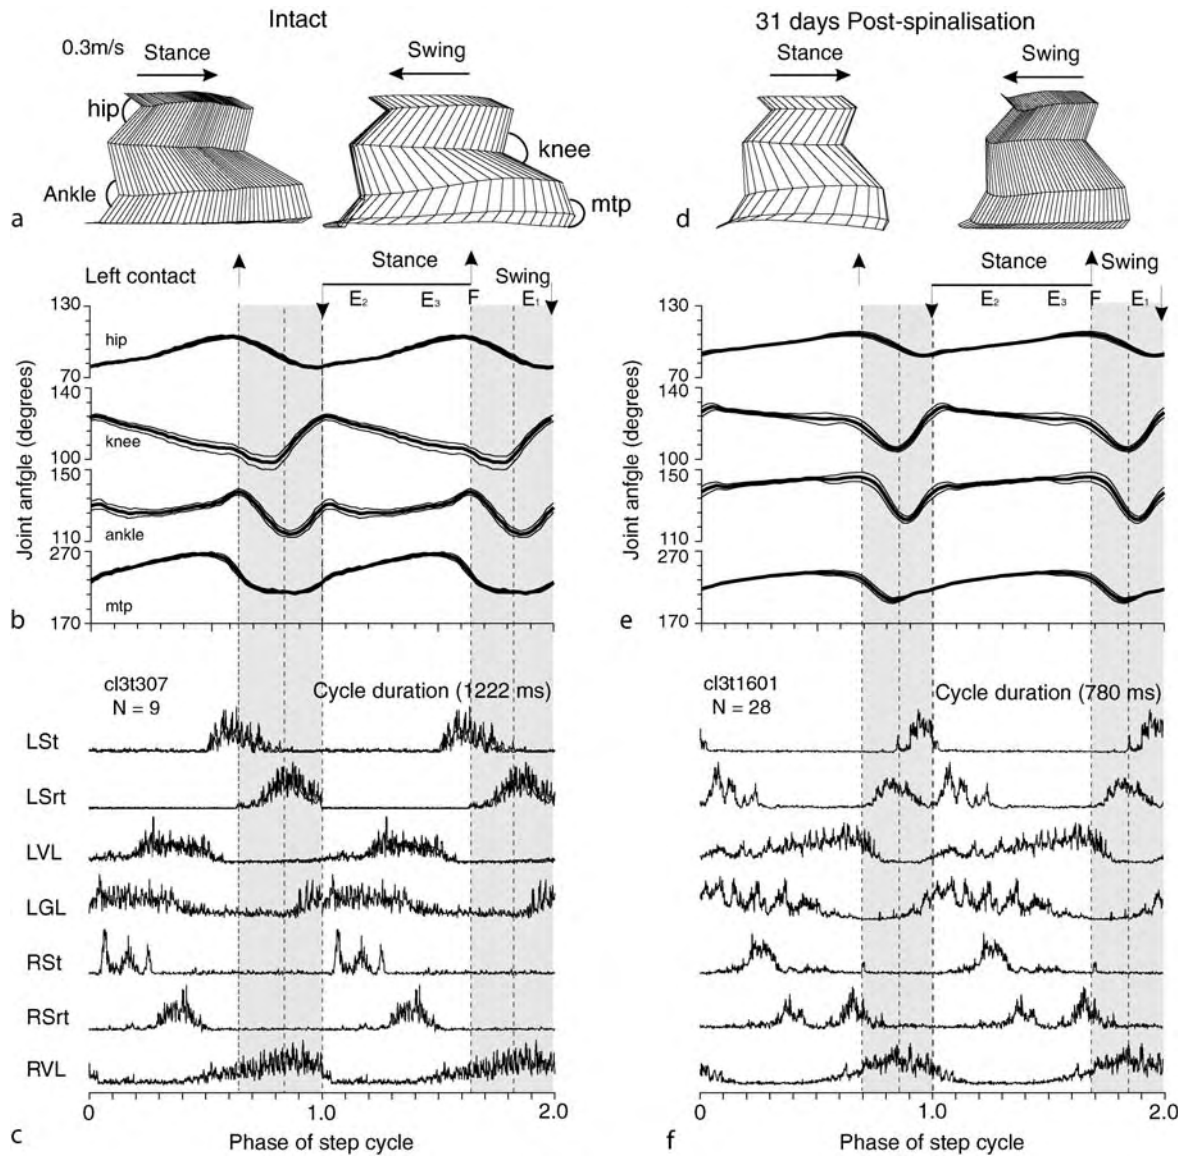
#### Quantitative Description

Most mammalian species can recover hindlimb locomotion on a treadmill after a complete section at the thoracic level [1]. For example, kittens spinalized early after birth can, after some days, express locomotor movements of the hindlimbs when the feet are placed in contact with a moving treadmill at increasing speeds. Since these animals have not learned to walk before spinalization, it can be concluded that the recovery of the locomotor pattern results from the expression of a genetically-determined sensory-motor circuit in the spinal cord called ►Central Pattern Generator, or CPG. Adult cats can also regain locomotion of the hindlimbs when trained with the feet positioned on the surface of a moving treadmill belt, while the forelimbs stand on a platform. With active daily training for 2–3 weeks on a treadmill, adult cats walk with their hindlimbs and make plantar foot contacts that allow them to support the weight of the hindquarters. Kinematic analyses and EMG recordings (Fig. 1) show that step cycles are generally shorter after spinalization (compare Fig. 1a and 1d). There is also quite often a foot drag at the onset of the swing phase (compare mtp joint in Fig. 1b and e).

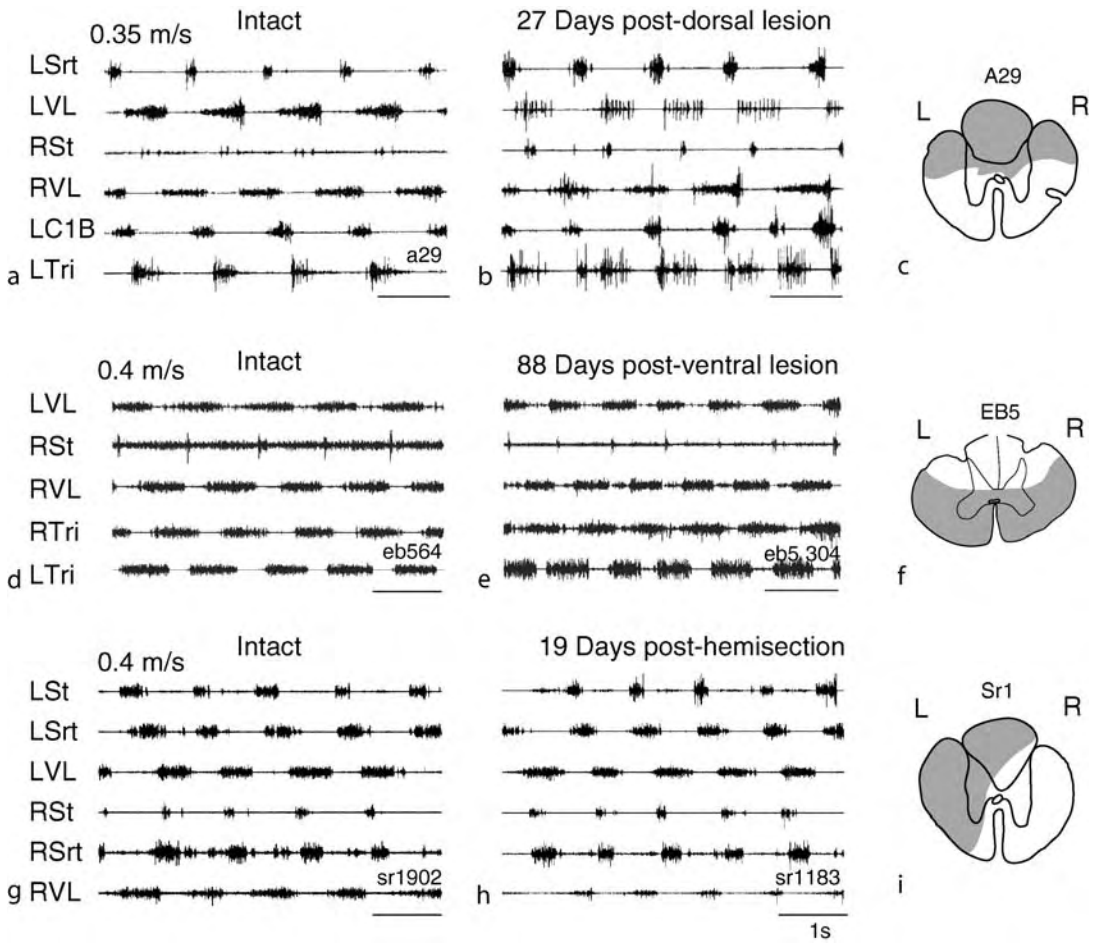
However, the time course of activation and coupling between muscles are largely preserved (compare Fig. 1c and f). For instance, the sharp increase in the burst of ankle extensors and the gradual onset of the knee extensors are preserved. The EMG pattern is often more "spiky" after spinalization, and the relative timing between flexor muscles of different joints may be perturbed (see differences in LSt-LSrt coupling and RSt-rSrt coupling). Rats spinalized as neonates or weanlings, recover the ability to walk spontaneously when becoming adult. However, adult rats spinalized as adults do not spontaneously recover any significant locomotion. This is in contrast to adult mice that recover hindlimb locomotion about two weeks after a complete spinal section at T8 [2]. Following a complete spinal lesion in humans, involuntary rhythmic activity of the lower limbs has been described in clinically complete spinal patients, suggesting that humans, like all other vertebrate, have a spinal CPG that participates in the control of locomotion.

Incomplete spinal cord lesions lead to less severe loss of locomotor function than complete spinalization. For example, voluntary quadrupedal locomotion can be regained after extensive lesions of the medial and medio-lateral (Fig. 2) pathways (see Fig. 2d–f and [3]).

The severity of the deficits varies with time after the lesion and on its size. With large lesions, sparing only part of the dorsal columns and part of one dorsolateral column, cats dragged their hindquarters over ground for 3–6 weeks as do complete spinal cats. However, all cats eventually regained quadrupedal locomotion. The forelimbs and hindlimbs could even walk at slightly different mean frequencies leading to occasional stumbling. Whereas normally cats use their hindlimbs to propulse the body, after such lesions the



**Locomotor Training. Figure 1** Comparison of hindlimb locomotion at 0.3 m/s in the same cat before and 31 days after spinalization at T13. (a) and (d). Stick figures reconstructed from video sequences of one-step cycle before and after spinalization. The swing and the stance phases, with arrows pointing in the direction of motion of the leg, are illustrated separately. The orientation of joint angle measurements is given. Note that to prevent overlap of the stick figures, each figure is displaced by an amount equal to the displacement of the foot on the horizontal axis and, therefore, the horizontal calibration seen in (d) is twice that of the vertical. (b) and (e). Angular excursion of the four joints averaged from nine steps in the intact state (c.d. = cycle duration with a mean of 1,222 ms) and from 28 steps in the spinal state 9 c.d. = 780 ms). Flexion always corresponds to a downward deflection of the angular traces. Mtp, metatarsophalangeal joint. The vertical dotted lines separate various epochs: F for flexion and E1 for first extension phase constitute the swing while E2 and E3, the second and third extension phases, constitute the stance phase of the step cycle according to Philippson, 1905. Note that the transition between E2 and E3 is not always obvious, and the two sub-phases have been merged together in these examples. (c) and (f). Average of rectified EMG traces of the corresponding cycles. *L* left hindlimb; *R* right hindlimb. Muscles are Semitendinosus *St* a knee flexor and hip extensor; Sartorius, anterior head *Srt* a hip flexor and knee extensor; Vastus Lateralis *VL*, a knee extensor; Gastrocnemius Lateralis *GL*, an ankle extensor. The step cycle is normalized to one and the display is repeated twice for clarity of illustration at turning points of the step cycle. The average is synchronized on foot contact, which starts at the onset of E2 on the left side.



**Locomotor Training. Figure 2** Recovery of locomotion after partial spinal lesions at T13. (a–c): Bilateral dorsal hemisection. (a) raw EMG records in the intact condition; (b) raw EMG records 27 days post-lesion; (c) outline of the spinal lesion from histological sections showing the area of greatest damage. Cleido-brachialis (ClB, a shoulder and elbow flexor) and Triceps brachialis (Tri, an elbow extensor). (d–e): Bilateral ventral and ventrolateral lesion. (d), (e) and (f) correspond to (a), (b) and (c). See [3]. (g–i): Over hemisection. The section includes most of the hemi-cord and impinges on the dorsal column on the other side. (g), (h) and (i) correspond to (a), (b) and (c).

forelimbs became propulsive. Cats with large lesions of the dorsolateral pathways can also walk over ground (Fig. 2a–c). Such lesions induce a short period of impaired voluntary quadrupedal locomotion lasting for 3–10 days, during which the animals adopted a crouched posture and the step cycle length that was prolonged at the end of stance. In contrast to cats with ventrolateral lesions, these cats could not correct properly for obstacles placed on the treadmill. Finally, after hemisection (see Fig. 2g–i), cats can also regain quadrupedal locomotion. Both after complete and incomplete spinal lesions, the functional locomotor rehabilitation can be improved dramatically by systematic treadmill training alone or in combination with appropriate pharmacological stimulation (see therapy below).

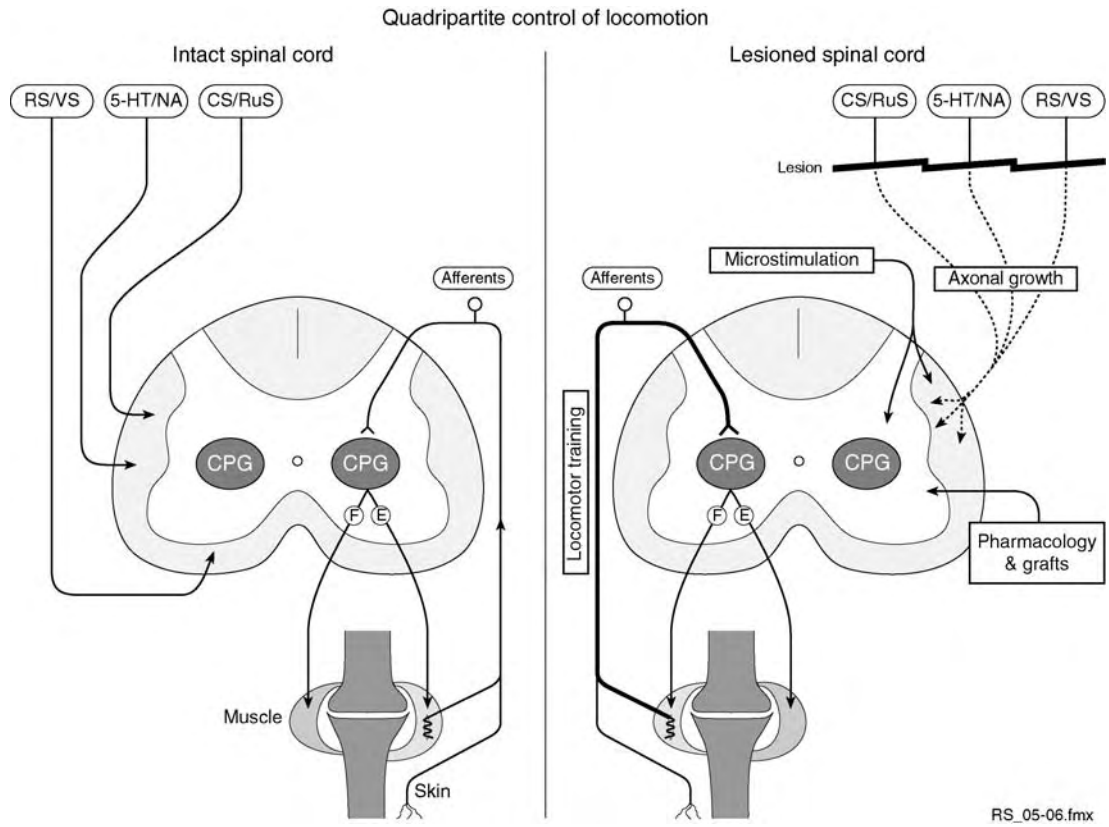
## Higher Level Structures

Four systems control normal (Fig. 3) locomotion (see Fig. 3, left).

These systems are: (i) the ▶CPG (Grillner, ERN), (ii) the afferent control of the CPG (Hultborn ERN), (iii) the descending controls of the CPG acting through fast pathways (Corticospinal *CS*; Rubrospinal *RuS*; Reticulospinal *RS*; Vestibulospinal *VS*) (Dubuc, ERN), and (iv) the neurochemically-defined pathways (NA, 5-HT). Plastic changes in one or several of these control structures are responsible for functional locomotor rehabilitation (see below).

## Lower Level Components

The locomotor recovery on a treadmill is largely dependent on afferent regulation of the spinal CPG



**Locomotor Training. Figure 3** The quadripartite locomotor control and rehabilitation after spinal cord injury.The left panel illustrates the spinal cord, including a CPG on which afferent inputs originating from muscles and skin as well as descending pathways eventually converge. These pathways include fast pathways of the lateral system (*CS* cortico spinal pathway; *RuS* Rubrospinal pathway) and the medial system (*RS* reticulospinal pathways; *VS* vestibulospinal pathways), as well as slow neurochemically-defined pathways such as noradrenergic pathway (originating from the locus coeruleus) and serotonergic pathway (originating from the raphe). The right panel shows how different locomotor therapies may be used to "replace" missing pathways or strengthen existing pathways. Thus, ►locomotor training can, by an enhanced activation of sensory afferents, improve the locomotor performance. Injections of drugs (NA, 5-HT systems) or neurotransmitters provided by intraspinal grafts may trigger or modulate the activity of the CPG. Electrical microstimulation of spinal structures (motoneuron pools or pathways) may also provide start-stop signals normally provided by descending pathways. These could eventually complement other approaches destined to promote axonal growth through the damaged cord.

(see Fig. 3, left) and by activity in descending fibers that have been spared in cases of partial spinal lesions.

Proprioceptive afferent inputs are implicated in modulating the frequency of stepping, the duration of EMG bursts as well as their duration so that locomotion can be achieved in various conditions. These fibers have access to the locomotor CPG. Cutaneous inputs, on the other hand, are responsible for the correct positioning of the foot [4] and for adequate phase-dependent responses to stimuli during walking. The effects are mediated through spinal neuronal circuits. Locomotor training will activate many types of sensory afferents that will influence the recovery of locomotion. Although it would be important to know which afferents play a critical role, our knowledge is still quite limited. However, experiments in cats with peripheral nerve lesions strongly suggest that both proprioceptive and cutaneous afferents are involved. It can thus be concluded that the role of sensory inputs is probably enhanced during locomotor rehabilitation, and that removing this sensory information prevents a proper rehabilitation. Studies in humans evaluating the importance of cutaneous inputs in the recovery of locomotion would be informative.

## Higher Level Processes

Much like most other neuronal circuits in the brain, there is increasing evidence that spinal circuitry

including the CPG can be subject to plastic changes. This suggests that locomotor recovery in spinalized animals is due to plastic changes in the spinal network and interactions with peripheral inputs. This further suggests that the spinal cord can be "changed" by the long-term sensory-motor experience so that that specific training will lead to the improvement of the specific task being trained (for example walking vs. standing [5]).

## Lower Level Processes

After spinalization, receptor density changes below the level of the lesion. For instance, fifteen and thirty days following spinalization, binding densities for $\alpha_1$-, $\alpha_2$-noradrenergic and serotonin$_{1A}$ (5-HT$_{1A}$) receptors significantly increased in lumbar segments. For longer survival times, binding densities returned to near control values. The pronounced up-regulation of various monoaminergic receptors, observed in the lumbar region in the first month after spinal transaction, represents a clear neurochemical plastic change and suggests that these receptors might be important during the period when cats normally recover locomotion of the hindlimbs [6]. There is no data on the effect of ►locomotor training on the regulation of these receptors. However, concentrations of glutamic acid decarboxylase 67 (GAD$_{67}$), the rate limiting enzyme in GABA synthesis, also increase after spinalization, suggesting an increase in GABA inhibition that could partly account for the reduced muscle activity. Locomotor training decreases the levels of GAD$_{67}$ and might constitute a biochemical marker for the beneficial effect of training [7]. Changes have also been observed in glycinergic pathways since strychnine can re-instate locomotion in poor walkers or cats trained only to stand.

Little actual electrophysiological work has been performed on the spinal circuitry to evaluate the effects of locomotor training. In spinalized cats trained to walk several changes in reflex responses have been observed [8]. All together, these changes will tend to decrease spasticity, which is pronounced after spinalization and prevents locomotion. Moreover, those changes tend to improve the potency of afferent related feedback to extensor muscles, which will improve weight-bearing capability.

Extensive work on the musculoskeletal changes after spinal transaction in cats have shown that the force generated by extensor muscles were smaller after spinalization even during treadmill walking. However, weight-bearing training markedly improved the EMG amplitude in these muscles that could even reach the level attained in normal cats. Intensive training also reduces the amount of muscle atrophy and conversion of slow fibers to fast fibers that are observed after spinalization. Of great interest is that locomotor training maintains the mechanical and metabolic properties of some extensor muscles much closer to normal than training to stand, probably because of the specific demand required during stepping.

## Process Regulation

The receding sections have established that a quadripartite system controls locomotion (CPG, afferent control and supraspinal controls), and therefore locomotion recovery after spinal section must depend on modifications of the interactions between the components of this quadripartite system. After complete spinal section, changes within the spinal cord (physiological and neurochemical) and sensory-motor interactions are changed. After partial lesions, compensatory mechanisms from intact systems can also compensate, to a certain extent, the deficits resulting from the lesion of specific pathways. These changes most probably involve molecular and biochemical changes, which eventually lead to the changes in synapses strength/formation. The exact nature of these processes is at the moment unknown.

## Function

The function of the recovery is to establish normal locomotion after complete or incomplete spinal lesions. The indication that the spinal cord can be modified by training suggests that locomotor training can induce long-lasting changes in the quadripartite locomotor control system, which may have an important functional outcome. For instance, humans trained to walk on a treadmill may, in some cases, become functional walkers i.e. perform safely some daily life locomotor tasks. Furthermore, locomotor training may have significant beneficial effects on cardiovascular functions as well as improve bone density.

## Pathology

The principles for locomotor recovery following spinal lesions outlined also apply to locomotor impairments following neurodegenerative diseases, like multiple sclerosis or stroke that may affect any part of the quadripartite control system of locomotion. Rehabilitative procedures should be evaluated within this framework.

## Therapy

Locomotor training procedures on a treadmill with partial body weight support has been initiated in humans [9]. Training can increase the weight bearing of the individuals, accompanied by an increase in activity of antigravity muscles and a reduction in unwarranted activity of flexor muscles. There is also an increase in endurance, speed and step length. These benefits are seen

not only after partial lesions but also after complete spinal sections, but whereas these benefits persist after training in partially lesioned patients, they disappear in completely spinal patients. As is the case for animals, it appears that sensory stimulation (i.e. loading of the ankle) is an important part of the training effect. Robots have been used to "teach" spinal rats to walk on a treadmill, but a similar approach has not yet been tested in humans.

Application of precursors or agonists of noradrenalin (cat) or serotonin (rodents) can initiate locomotion after an acute spinalization. There has therefore been a great interest in finding drugs that modulate the characteristics of the CPG also after chronic spinalization. There is intensive research in this area that might provide a potent adjuvant during locomotor training. Grafting of embryonic serotonergic raphe cells to a site below the spinal lesion in rats has also been used as a means to increase the excitability of the CPG [10] This treatment can induce a remarkable recovery of hindlimb locomotion. Further work has also suggested that chronic exposition of the spinal cord to serotonergic agonists significantly improved the spontaneous expression of locomotion, suggesting that the chronic activation of 5-HT receptors may preserve membrane characteristics of motoneurons or interneurons necessary for the operation of the spinal pattern generator.

Locomotion can also be evoked in spinal cats through electrical microstimulation of the spinal cord. Different approaches are being pursued i.e. combination of electrical stimuli of different motoneuronal pools or specific segmental activation to induce synergistically the locomotor pattern from restricted areas of the cord. Various attempts are being made to use epidural stimulation of the cord or intraspinal stimulation to improve the recovery of locomotor function. Instead of stimulating the cord directly, electrical stimulation of muscles or nerves has been used to improve the recovery of locomotion in humans. Such stimulation can increase the walking speed by 45%, even in patients who have had a spinal injury for many years.

# Locus Coeruleus

## Definition

A small nucleus in the rostral pons of animals and humans, in which it was first seen as a blue (coeruleus) site, due to its pigmentation in man. The pigment, melanin, develops from the catecholamine synthetic pathway, as the neurons of this nucleus synthesize noradrenaline (NA) in all mammals. The LC neurons project in a highly diffuse manner through the brain and spinal cord where they release NA in the vicinity of target neurons. Given their use of NA as a neurotransmitter and their diffuse projections, the LC neurons and nucleus resemble a peripheral sympathetic ganglion located within and providing innervation to the central nervous system. As in the periphery, NA is also released from terminals in a nonsynaptic manner in the brain and affects both neurons and glia in the vicinity to support activity. The LC neurons discharge during waking and arousal and cease firing during sleep. By the action of NA upon target cells, they stimulate both cortical activation and behavioral arousal with motor activity and muscle tone. They also by direct projections onto the sympathetic preganglionic neurons in the spinal cord excite the peripheral sympathetic system to support motor activity by appropriate physiological adjustments.

## Locust

### Definition

Insect of the order Orthoptera; has been a model system for studying flight and motor behavior.

## LOD (Logarithm of Odds) Score

### Definition

A statistical test often used in human and animal populations to determine if two markers or Mendelian traits are inherited in a linked fashion. Linkage is suggested by a LOD score greater than 3.0.

## Logic

Ralf Busse
Institut für Philosophie, Universität Regensburg, Regensburg, Germany

### Definition

►Logic is the systematic inquiry into the validity of inferences or arguments. However, the totality of logical relations between elements of a system of representation, in particular a language, is also called *the logic* of that system. The core of modern logic is elementary logic, the part of deductive logic which comprises ►propositional logic and (extensional) first-order predicate logic. The standard view of logic is called classical logic. Prominent non-classical alternatives are many-valued, intuitionistic, relevance, and ►non-monotonic logic. There is no consensus as to whether extensions of elementary logic such as second-order predicate logic, modal logic, so-called ►philosophical logics, or inductive logic fully deserve the name "logic".

### Characteristics

We shall focus on classical elementary logic in its usual ►model-theoretic treatment and shall be brief on alternatives and extensions. (See [1] for all topics mentioned.)

#### Deductive Inference: Propositional Logic as a Paradigm

The central topic of deductive logic is the (deductive) *logical validity of inferences*. While psychology can *describe* the actual way of human reasoning, the bearing of logic on inference is ►normative: it tells us what inference patterns we *ought* to follow. The usual view is that we ought to follow a certain pattern because the elements of an inference of that form stand in certain objective relations to each other which render the inference logically valid.

In modern logic inferences are identified with finite sequences of sentences $\varphi_1,\ldots, \varphi_n, \psi$ in an artificial language, where the $\varphi_i$ are the ►premises and $\psi$ is the ►conclusion. In a language **PL** for propositional logic sentence letters like $p$, $q$, $r\ldots$ roughly play the role of simple natural-language sentences like "Grass is green". The symbol $\rightarrow$ is read as "if – then", $\neg$ as "not" or "it is not the case that". Thus, the inference

$$\begin{array}{l} p \rightarrow q \\ \neg p \\ \therefore \neg q \end{array}$$

is read as "If $p$ then $q$, not $p$, therefore not $q$". (Quotation marks are dropped in ►references to expressions of artificial languages.) An inference is (deductively) *logically valid* if and only if (iff) it is excluded for logical reasons that all its premises are true but its conclusion is false. This is equivalent to saying that the conclusion $\varphi$ *follows logically from*, or is *logically implied* or *entailed* by, or is a *logical consequence* of the set of premises $\Gamma$. It is a topic of ►philosophy of logic what this exclusion for logical reasons consists in. The usual model-theoretic way of doing logic rests on three semantic principles (due to G. Frege and A. Tarski): (i) The central semantic properties are the truth and falsity of complete sentences. (ii) The semantic properties of any complex expression are determined by the semantic properties of its constituent expressions and their syntactic arrangement (principle of ►compositionality). (iii) A semantic theory (►Theory – Theoretical Expression) of a well-defined language takes the form of a recursive definition of truth conditions of its sentences (relative to an assignment of meanings to the ►descriptive vocabulary of the language).

The ►syntactical description of a language **PL** for propositional logic introduces the vocabulary and grammar of **PL**. The descriptive vocabulary consists of sentence letters $p$, $q$, $r$ etc. The ►logical vocabulary, i.e. the class of ►logical constants, consists of ►truth-functional sentential connectives, in particular of the negation sign $\neg$ and the conditional connective $\rightarrow$. The *grammar* is captured by a recursive definition of the notion of a sentence. An expression is a sentence of **PL** iff it can be obtained by possibly repeated application of the following rules: (i) every sentence letter $\sigma$ is a sentence. (ii) If $\varphi$ is a sentence, so is $\neg\varphi$ (the *negation* of $\varphi$). (iii) If $\varphi$ and $\psi$ are sentences, so is $(\varphi \rightarrow \psi)$ (the material *conditional* with the antecedent $\varphi$ and the consequent $\psi$).

The ►semantic description of **PL** starts with the notion of a possible assignment of meanings to the descriptive vocabulary of **PL**. A *valuation* **V**(σ) is a function that assigns to any sentence letter σ one of the two truth-values truth (T) and falsity (F). The second part of semantics is the recursive definition of *truth conditions* relative to valuations **V**: (i) A sentence letter σ is *true under a valuation* **V** iff the value of **V** for σ is T; otherwise it is false. (ii) A negation ¬φ is true (false) under a valuation **V** iff φ is false (true) under **V**. (iii) A conditional (φ → ψ) is true under a valuation **V** iff φ is false under **V** or ψ is true under **V** or both (i.e., iff it is not the case that φ is true and ψ is false under **V**), and false otherwise. Usually further connectives are added: ►Conjunctions (φ ∧ ψ), read as "φ and ψ", are true iff both conjuncts are true. ►Disjunctions (φ ∨ ψ), read as "φ or ψ", are true iff at least one of the disjuncts is true. ►Biconditionals (φ ↔ ψ), read as "φ if and only if ψ", are true iff either both φ and ψ are true or both are false. The connectives are truth-functional because the truth-value of compounds is determined by (is a function of) the truth-values of the constituents.

The meanings of the descriptive vocabulary vary with different valuations. By contrast, the meanings of logical constants such as ¬ and → are fixed once and for all by clauses like (ii) and (iii). ►Logical properties and relations are semantic features of sentences that are already determined by the meanings of the logical constants, independently of any particular valuation. A sentence φ is *logically true* (*false*) iff it is true (false) under any valuation **V**. φ and ψ are *logically equivalent* iff they have the same truth-value under any **V**. A set of sentences Γ is *consistent* iff there is a valuation **V** under which all sentences in Γ are true. Such a valuation is called a ►model of Γ; hence the name "model-theoretic approach". φ *follows logically from* Γ, in symbols Γ| = φ, iff there is no valuation **V** such that φ is false under **V** while all sentences in Γ are true under **V**, i.e. iff Γ ∪ {¬φ} has no model. An inference is *logically valid* iff its conclusion follows from the set of premises. The inference from $p \rightarrow q$ and $\neg p$ to $\neg q$ turns out invalid: any valuation **V** such that **V**($p$) = F and **V**($q$) = T is a counterexample to its supposed validity, for both premises are true under **V** while the conclusion is false under **V**. Contrariwise, validity of an inference can be proved by showing that the assumption that there is such a counterexample leads to contradiction.

In general, logical properties and relations are semantic properties and relations that can be defined by universal ("all") or existential ("there is") quantification over assignments of meanings to the descriptive vocabulary of a language without reference to particular assignments. An alternative to this model-theoretic approach is an ►inferentialistic understanding of logic which accepts the consequence relation (or specific cases of it) as primitive. This seems to have been Aristotle's idea of deductive logic in his ►Prior Analytics [2].

Typically the logic of a language is supplemented with a formal procedure, a ►calculus (or ►deductive system) **C,** within which sentences can be *derived* from given premises. A ►calculus of natural deduction for the logic of a language consists of a finite set of rules for moving from given sentences to further sentences according to purely syntactic criteria. (An ►axiomatic calculus specifies axioms and few rules.) E.g., ►modus ponens allows one to move from any two sentences φ and (φ → ψ) to ψ. A sequence of sentences is a ►derivation of φ in calculus **C** from a set of sentences Γ just in case it leads to φ from a finite number of elements of Γ by a finite number of applications of the rules of **C**. φ is *derivable* from Γ in **C** (Γ|—$_{\mathbf{C}}$φ) iff there is such a derivation. φ is a ►theorem of **C** (|—$_{\mathbf{C}}$φ) iff φ is derivable from the empty set. A calculus **C** is ►sound (or ►correct) iff for any Γ and φ, if Γ|—$_{\mathbf{C}}$φ then Γ| = φ. **C** is *complete* iff for any Γ and φ, if Γ| = φ then Γ|—$_{\mathbf{C}}$φ. There are calculi for propositional logic that are both sound and complete. Propositional logic is also *decidable*: there are ►decidability procedures, such as the truth-table technique, that for any Γ and φ determine in a finite number of steps whether Γ| = φ or not.

*Many-valued* alternatives to classical logic reject the classical semantic ►principle of bivalence, which states that all meaningful sentences are either true or false. According to three-valued logic, sentences may have a third value of indeterminateness (I) instead. ►Intuitionistic logic rests on an understanding of truth as provability or verifiability. Intuitionistic calculi are weaker than their classical pendants. Neither the principle ($\neg\neg p \rightarrow p$), which corresponds to the rule of ►Double Negation Elimination, nor the ►Law of Excluded Middle ($p \vee \neg p$) are intuitionistic theorems. ►Relevance logic seeks to exclude classically valid inferences that seem irrelevant, such as the inference from $\{p, \neg p\}$ to $q$. Non-monotonic logic deals with inferences that are valid by default but are defeasible, so that φ may be a consequence of Γ but not of all supersets of Γ [3].

## First-Order Predicate Logic

The sentences of **PL** are ultimately composed of unstructured sentence letters. A language **L1** for first-order predicate logic forms its simplest sentences from sub-sentential expressions. ►Individual constants like $a$, $b$, $c$ roughly play the role of ordinary proper names that designate particular ►things, persons, or (like "π") numbers. Monadic ►predicate letters like $F^1$ and $G^1$ can be compared to simple ordinary predicates such as "is red" or "is a dog". Dyadic (in general: $n$-place) predicate letters like $R^2$ (in general: $R^n$) are comparable to ordinary relational predicates such as "is larger than" or "is a child of". $F^1a$ and $R^2ab$ are ►atomic sentences

that, given an appropriate interpretation, can mean that Fido is a dog and that Ann is a child of Bob. Atomic sentences form truth-functional compounds such as $(F^1a \rightarrow G^1a)$. In addition, there are ►individual variables $x$, $y$, $z$… that can take the positions of individual constants. Variables do not stand for particular things, but "range over" a fixed ►domain of individuals. Hence expressions like $F^1x$, $R^2xy$ or $(F^1x \rightarrow G^1x)$ have no truth conditions and are not sentences, but mere *formulas*. Prefixed with ►universal quantifiers or ►existential quantifiers like $\forall x$ and $\exists x$ that bind the otherwise free variables in such formulas they yield quantified sentences. The ►universal quantification $\forall xF^1x$ can mean that everything we are talking about is a dog, the ►existential quantification $\exists xF^1x$ that at least one of the things we are talking about is a dog. "Every dog is brown" is construed as "For every $x$: if $x$ is a dog, $x$ is brown" and translated as $\forall x(F^1x \rightarrow G^1x)$. "Some dogs are brown" is translated as $\exists x(F^1x \wedge G^1x)$, "Everybody is a child of someone" as $\forall x\exists yR^2xy$.

Truth conditions are stated relative to ►interpretations. An interpretation **I** is a pair $\langle \mathbf{D}, \mathbf{I}\rangle$ of a non-empty set of individuals **D**, called the domain of **I**, and an ►interpretation function **I** (we use the same symbol for the interpretation and the interpretation function). **I** assigns to every individual constant an element of **D**, to every monadic predicate letter a subset of **D**, and to every dyadic (in general: $n$-place) predicate letter a dyadic relation, i.e. a set of ordered pairs $\langle$u, v$\rangle$ (in general: of $n$-tuples) of elements of **D**. A monadic atomic sentence such as $F^1a$ is *true under an interpretation* **I** iff $\mathbf{I}(a)$ is a member of $\mathbf{I}(F^1)$, e.g. iff Fido is a member of the set of dogs. The dyadic atomic sentence $R^2ab$ is true under an interpretation **I** iff the pair $\langle \mathbf{I}(a), \mathbf{I}(b)\rangle$ is a member of the relation $\mathbf{I}(R^2)$. Truth-functional compounds have truth conditions in accordance with propositional logic. E.g., $(F^1a \rightarrow G^1a)$ is true under **I** iff $F^1a$ is not true under **I** or $G^1a$ is true under **I**.

The truth conditions of quantifications like $\forall xF^1x$ or $\exists xF^1x$ cannot be reduced to those of a mere formula like $F^1x$, as it has no truth conditions. But replace in $F^1x$ the variable $x$ by an arbitrary individual constant that does not already occur in the quantification under consideration, e.g. by $a$. The truth conditions of $\forall xF^1x$ and $\exists xF^1x$ under an interpretation **I** can then be explained in terms of truth conditions of the sentence $F^1a$ under interpretations closely related to **I** [4]. An $a$-►variant of **I** is an interpretation that is exactly like **I** except for the fact that it may assign to the constant $a$ a different member of the domain **D** than **I** does. $\forall xF^1x$ is true under **I** iff $F^1a$ is true under every $a$-variant of **I**. $\exists xF^1x$ is true under **I** iff $F^1a$ is true under *at least one* $a$-variant of **I**. Modern logic systematically yields truth conditions for arbitrarily complex quantifications. E.g., $\forall x\exists yR^2xy$ is true under **I** iff $\exists yR^2ay$ is true under any $a$-variant **I**' of **I**; which is the case iff $R^2ab$ is true under at least one $b$-variant **I**" of any $a$-variant **I**' of **I**. If we read $R^2$ as "is a child of", $\forall x\exists yR^2xy$ is true iff, no matter which person is assigned to $a$, there will always be an assignment to $b$ such that the person assigned to $a$ is a child of the person assigned to $b$; in short, iff everybody is a child of someone.

A sentence of **L1** is *logically true* (false) just in case it is true (false) under every interpretation (rather than valuation). For example, $(\forall xF^1x \leftrightarrow \neg\exists x\neg F^1x)$ and $(\exists xF^1x \leftrightarrow \neg\forall x\neg F^1x)$ are logical truths. Similarly, logical equivalence, consistency, logical consequence, and logical validity are defined in analogy to the notions of propositional logic. A *model* of a set of sentences $\Gamma$ is an interpretation under which all sentences in $\Gamma$ are true.

A calculus for predicate logic is an extension of a calculus for propositional logic. Here are typical applications of the two natural deduction rules for universal quantifications: (i) From the premise $\forall x(F^1x \rightarrow G^1x)$ one may move by ►universal specialization to $(F^1a \rightarrow G^1a)$. Given $F^1a$ as a further premise, modus ponens yields $G^1a$. (ii) $(F^1a \vee \neg F^1a)$ is a theorem of propositional logic. Since its derivation does not draw on any premise that involves $a$, one may move by ►universal generalization to the theorem $\forall x(F^1x \vee \neg F^1x)$. There are complementary rules of existential specialization and generalization.

The standard calculi for first-order predicate logic are sound and complete: $\varphi$ can be derived from $\Gamma$ iff $\varphi$ is a logical consequence of $\Gamma$. But predicate logic is *undecidable*: there is no procedure that for any input $\varphi$ and $\Gamma$ stops after a finite number of steps to give output "YES" if and only if $\varphi$ is a consequence of $\Gamma$.

## Second-Order Predicate Logic

Elementary predicate logic is called ►first-order logic, because it only allows for variables in the places of *individual* constants. However, translating "Ann and Bob have something in common" as $\exists X^1(X^1a \wedge X^1b)$ requires quantification into predicate positions and hence a language **L2** for ►second-order logic. The price is *incompleteness*: there is no correct calculus **C** such that for any $\Gamma$ and $\varphi$ of **L2**, if $\Gamma| = \varphi$ then $\Gamma|\!\!-_{\mathbf{C}}\varphi$. Many philosophers think that predicate variables like $X^1$ would have to range over sets, that second-order logic is therefore ontologically committal and not part of logic proper. All results mentioned concerning completeness, undecidability and incompleteness go back to K. Gödel, A. Church and A. Turing.

## Modal Logic and Philosophical Logics

The semantics considered so far have been *extensional*. For example, sentence letters are assigned truth-values, but no intensional contents such as the proposition that grass is green. A model-theoretic approach to the logic of modal operators like "It is possible that…" ($\Diamond$) and

"It is necessary that…" (□) requires an *intensional* semantics. Sentences like $\Diamond p$, $\Diamond\Box\neg p$, $\Box(p \rightarrow q)$ or $(\Box p \rightarrow \Box q)$ for modal propositional logic are obtained by adding a clause to the syntax of **PL**: If φ is a sentence, so are ◇φ and □φ. The semantics rests on a structure $\mathbf{S} = \langle \mathbf{W}, \mathbf{R} \rangle$ that consists of a set **W** of entities w called ►possible worlds and an ►accessibility relation **R** between those worlds. A valuation **V**(σ, w) now assigns truth-values to sentence letters σ relative to worlds in **W**. **V** thereby determines for any letter σ a function from possible worlds in **W** to the truth values T and F. Intuitively, this intension of σ is the proposition expressed by σ because it tells us what a possible world scenario has to be like in order to render σ true.

As seen from our world, it is possible (necessary) that *p* just in case *p* is true at (or in) at least one (at every) possible world that is accessible from actuality. In general, ◇φ is true under **V** at world w iff there is a world w' that is accessible from w such that φ is true under **V** at w'. □φ is true under **V** at world w iff for every world w' that is accessible from w φ is true under **V** at w'. ◇φ is equivalent to ¬□¬φ, and □φ to ¬◇·¬φ. Logical truth of φ is its truth at any world w of any structure **S** under any valuation **V**. The other logical notions are defined accordingly. The sound and complete standard calculi K, T, B, S4 and S5 for modal propositional logic correspond to different formal restrictions on the accessibility relation **R** such as reflexivity, symmetry or transitivity.

Adding ◇ and □ to predicate logic yields ►quantified modal logic. Quantifiers and modal operators can interact in two different ways: $\Diamond\exists x(F^1x \wedge \neg F^1x)$ is a ►de dicto modal statement to the effect that it might have been the case that something is both F and non-F, which is logically false. $\exists x(F^1x \wedge \Diamond\neg F^1x)$ is a ►de re modal statement to the effect that there is something F that might have been non-F, which may well be true. The nature of possible worlds and de re modalities is a serious philosophical problem.

Philosophical logics such as ►tense logic, ►epistemic logic or ►deontic logic use the techniques of modal semantics to formulate theories for philosophically important concepts. E.g., "*s* believes/knows that *p*" is construed as meaning that *p* holds in all possible worlds that are compatible with what *s* believes/knows.

### Non-Deductive Reasoning and "Inductive Logic"

Not every intuitively "good" inference *guarantees* the truth of the conclusion given the truth of the premises. The fact that the polls are 58:42 in favor of the president 3 days before the election strongly *supports* the conclusion that the president will win, but cannot guarantee its truth. Theories of non-deductive rationality seek to specify this kind of support. Typically they apply the main theorem of classical probability theory: for a scientific hypothesis *h* and experimental evidence *e* Bayes' theorem $P(h|e) = P(h)\cdot P(e|h)/P(e)$ says that the probability of *h*'s being true given *e* equals the unconditional ►prior probability of *h* times the *likelihood* of *e* given *h* divided by the unconditional probability of *e*. Carnap's idea of inductive logic was that the prior probability of a hypothesis was determined by its logical structure, so that the degree of support of *h* by *e* was a completely objective affair. Today most philosophers believe that we must accept a subjective input (►Subjectivity). A family of theories of non-deductive rationality has emerged, some members of which are probability logic, confirmation theory, decision theory, and the theory of ►belief revision.

# Long Latency Reflex

►Long Loop Reflexes

# Long Loop Reflexes

Vaughan G. Macefield
School of Medicine, University of Western Sydney, Sydney, NSW, Australia; Prince of Wales Medical Research Institute, Sydney, NSW, Australia

## Synonyms

Transcortical reflex; Long latency reflex; LLR; M2; E2

## Definition

Long loop reflexes are automatic motor responses to somatosensory stimuli that are believed to operate via the cerebral cortex, hence the term ►transcortical reflexes. By definition, long loop reflexes occur at latencies too long to be mediated by segmental circuits

within the spinal cord yet too short to be mediated volitionally. For muscles in the hand, the fastest (spinal) reflexes (►Segmental reflexes) to muscle stretch occur at latencies ~35 ms; long loop reflexes occur at latencies ~60 ms, whereas volitional responses occur at ~140 ms. However, automatic motor responses of comparable latencies can also be generated by tactile (cutaneous) stimuli that do not involve muscle stretch, so the term "long loop reflex" should not be restricted to those generated by muscle stretch. The term "►functional stretch reflex" was introduced to describe the long-latency responses recorded in calf muscles following a sudden disturbance of the ankle joint, but given that these occur at volitional latencies this term should not be used synonymously with the long-latency response.

## Characteristics

### Muscle Reflexes

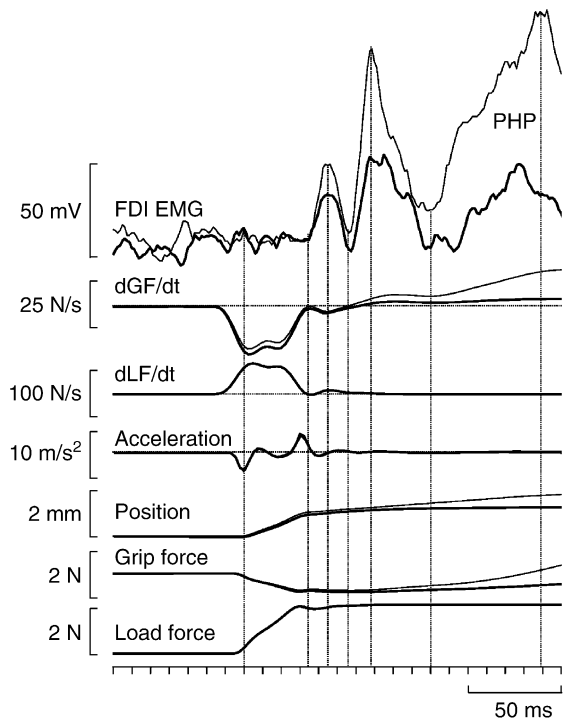
The first demonstration of a long latency reflex in humans came from studies by Hammond in 1954, who showed that forceful extension of the elbow causes a short-latency increase in EMG followed by a long-latency increase; later responses, which could be influenced by instructions to the subject (e.g. to pull hard or to let go on detecting the movement), occurred at volitional latencies. The first quantitative studies, performed by Marsden, Merton and Morton [1], examined the stretch reflex in flexor pollicis longus (FPL): brisk extension of the interphalangeal joint of the thumb causes a small short-latency response (SLR; M1) but a much larger long-latency response (LLR; M2); studies in patients with lesions of ascending sensory pathways in the spinal cord, or lesions in the sensorimotor cortex or capsular pathways, demonstrated that M2, but not M1, was abolished, thereby cementing the idea that M2 was truly a long-loop reflex [2]. Nevertheless, various counter arguments were presented, including fractionated discharge in the firing of ►muscle spindle primary endings or slow transmission of stretch-evoked activity in ►muscle spindle secondary endings: there is no doubt that the dynamically sensitive primary endings (►Ia afferents) are responsible for the early spinal reflex (M1), but it was postulated that the slower-conducting secondary muscle spindle afferents (►Group II afferents) could be responsible for the long-latency response - in other words, M2 was simply a spinal reflex generated by slower-conducting sensory inputs. An elegant experiment performed by Matthews, the proponent of the latter hypothesis, resulted in the hypothesis being by his own work: slowing nerve conduction by cooling the arm resulted in proportional delays in the M1 and M2 components (not the hypothesized greater slowing of M2), i.e. the two components were generated by the same class of muscle afferent [3]. The relative magnitudes of the M1 and M2 components to stretch of upper limb muscles vary according to the muscle: M1 is larger than M2 in biceps, but the reverse is true in FPL and first dorsal interosseous (FDI). Stretch of FDI causes a small short-latency response at 37 ± 2 ms and a larger long-latency response and 59 ± 1 ms [4].

### Cutaneous Reflexes

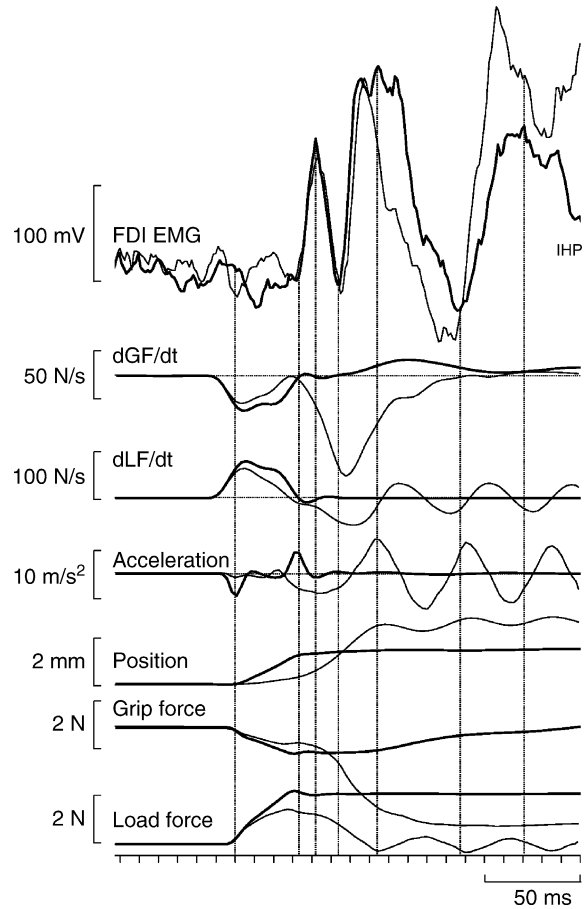
Electrical stimulation of the digital nerves of the index finger (which activates cutaneous and joint afferents), evokes in most subjects a short-latency (35 ± 1 ms) excitatory response (termed E1), subsequent inhibitory response (I1), and in all subjects a large long-latency response (E2; 58 ± 1 ms) in the first dorsal interosseous muscle (FDI) [5]. Natural stimulation of cutaneous afferents also evokes short- and long-latency excitatory responses. Unpredictable pulling forces applied to an object held between the index finger and thumb evoke reactive increases in grip force that serve to prevent escape of the object from the grasp. In most studies only a long-latency component is produced, but if the stimulus is brisk enough a smaller short-latency component can also be generated: the short- and long-latency responses to fast pulling loads (64 N/s) occur at 35 ± 1 ms and 59 ± 2 ms, respectively [6], latencies comparable to those produced by stretch of FDI [4]. Figure 1 shows records from one subject instructed to restrain a manipulandum using only his index finger and to prevent its escape: in one set of trials the manipulandum was covered with slippery material (rayon; thin lines) and in the other was attached to the subject's finger with double-sided tape (thick lines). Short- and long-latency responses, as well as responses at volitional latencies, occurred even when the manipulandum could not escape, indicating that it is the shear forces developed between the skin and the grasped object – rather than slips *per se* – that trigger these responses. It is known that tactile afferents bear sole responsibility for triggering the short- and long-latency responses to these types of stimuli (see ►Cutaneous mechanoreceptors, functional behavior).

### Higher Level Structures

While short-latency EMG responses can only be mediated by spinal pathways, it is believed that long loop reflexes can be mediated by pathways involving the cerebral cortex. Much of this comes from latency considerations: given that the average onset latency of the long-latency EMG response in muscles of the hand is ~60 ms, and it takes ~20 ms for a sensory volley to reach the sensorimotor cortex from a finger muscle and a similar delay for a cortico-motoneuronal volley to reach the muscle, some 20 ms is available for cortical processing of the afferent volley and generation of an appropriate response. There is considerable evidence in the monkey for rapid transmission of Ia afferent



**Long Loop Reflexes. Figure 1** Averaged records from one subject during application of 2-N pulling loads (64 N/s) to the pad of the index finger. Traces shown with thin lines were obtained in which the contact surface of the manipulandum was rayon (128 trials); traces shown with thick lines were obtained when the finger pad was stuck to the manipulandum with double-sided tape (128 trials), which prevented slips from occurring. Vertical lines refer to the rayon condition and indicate the following temporal events: stimulus onset, onset and peak of short latency response, onset and peak of long latency response, onset and peak of volitional responses (Reproduced from [6]).



**Long Loop Reflexes. Figure 2** Averaged records from one subject during application of 2-N pulling loads (64 N/s) to the pad of the index finger. The contact surface of the manipulandum was sandpaper. Traces shown with thick lines were obtained for trials ($n$ = 128) in which overt slips did not occur, and trials with slips ($n$ = 30) are represented by the traces with thin lines. For the latter the display gains of the acceleration and position records have been reduced to 50 m/s$^2$ and 20 mm, respectively, for clarity. Vertical lines refer to the non-slip condition and indicate temporal events as in Fig. 1 (Reproduced from [6]).

activity and modulation of the discharge of corticospinal motoneurones by muscle stretch. In addition to the studies of neurological lesions in patients referred to above [2], transcranial magnetic stimulation (TMS) provided further evidence for cortical involvement in the long-latency stretch reflex in humans: when brief stimuli were delivered to the motor cortex at a time coinciding with the long-latency response (but not the short-latency response) there was facilitation of the EMG that was greater than that produced by transcranial electrical stimulation (TES); based on the differential sites of action of TMS and TES this was interpreted as an increase in excitability of the motor cortex during the long-latency stretch reflex [7]. Interestingly, this same approach failed to demonstrate that long-latency responses to tactile stimulation were associated with an increase in motor cortex excitability (in the majority of subjects), suggesting that – unlike the long-latency responses to muscle stretch – these cutaneomotor reflexes are not mediated by a transcortical mechanism [4]. Nevertheless, neurological studies in patients do support the concept that – like the long-latency responses to muscle stretch – those to cutaneous stimulation do require integrity of the dorsal columns of the spinal cord, the sensorimotor cortex, and descending corticomotoneuronal pathways [8].

## Function

Given that long latency stretch reflexes, at least those acting on the hand, contribute to positional servo-assistance, it is generally accepted that these responses

are functionally significant. Indeed, they can be so effective that volitional responses may be absent: sensorimotor control is thereby delegated to an automatic mode of operation, one that requires no conscious oversight. This is particularly the case for the long-latency tactile reflexes, in which purposeful control of grip force – subserved by cutaneous afferents – can be achieved without volitional intervention. Figure 2 illustrates the responses to unexpected pulling loads that, in some trials, resulted in overt slips and escape of the manipulandum: it can be seen that the long-latency increases in EMG did contribute to the maintenance of an adequate grip force. Indeed, the short-latency responses are probably of negligible importance.

### Pathology

As noted above, long-latency – but not short-latency – responses are absent in patients with dorsal column lesions, or lesions within the sensorimotor cortex [2,8]. Mirror movements, in which a command to move one hand causes movements in the contralateral hand, are characteristic features of people with Klippel-Feil syndrome, in whom corticospinal projections are branched and innervate both sides of the body: stretch of FDI in a patient with this syndrome generated short- and long-latency responses on the ipsilateral side, but also a long-latency response on the contralateral side, lending support to the transcortical nature of this long loop reflex [9]. However, studies of cutaneous reflexes in patients with X-linked Kallmann's syndrome do not support a transcortical mechanism [10], a conclusion reached elsewhere [5].

## Longitudinal Fissure of Cerebrum

### Synonyms

Fissura longitudinalis cerebri; Longitudinal cerebral fissure

### Definition

Inter-hemisphere fissure.

It separates the two hemispheres from each other. Deep in the fissure is located the corpus callosum. Encountered here are the large fiber bundles exchanging information across the two hemispheres.

Tumor or hemorrhage in the longitudinal fissure of cerebrum generally triggers symptoms in both body halves. Accordingly, flaccid paralysis of both legs can be induced by a pathological event at the level of area 4. A tumor at the level of area 4 can cause complete blindness.

►Telencephalon

## Long-Lead Burst Neurons (LLBNs)

### Definition

On the basis of the time interval between the beginning of the burst and the onset of the saccade (latency), burst neurons can be subdivided into long-lead and medium-lead burst neurons. LLBNs have a longer latency than that of MLBNs and usually have an irregular prelude of activity that begins more than 100 ms before the saccade.

## Synonyms

Long-term memory storage; Recent and remote memory; Declarative and nondeclarative memory

## Definition

Long-term memory refers to information derived from one's lifelong experience, or system to store information occurred in the past.

## Characteristics

### Neuropsychology of Human Memory

#### *Amnesia*

Amnesia (isolated memory disorder) refers to a specific clinical condition in which there is impairment in the ability to learn new information despite normal attention and intact cognitive function such as perception, language and intelligence. Clinical studies of amnesics revealed that memory consisted of dissociable systems that accomplish different forms of learning and that are mediated by distinct neural networks. Namely, memory is not a single entity but entails a number of different aspects of mental faculty. Here, recent classifications of memory widely used along with neural substrates for individual memory systems and amnesia following cerebrovascular diseases and degenerative disease will be surveyed.

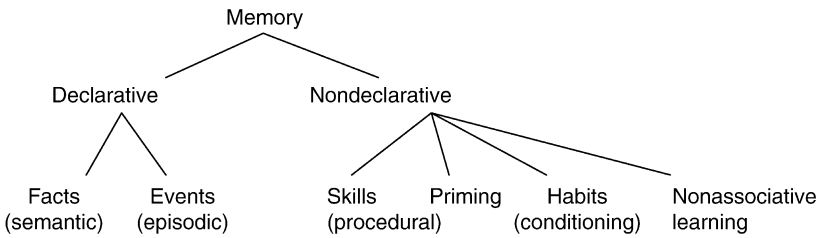
#### *Time Aspect of Memory*

The stages of memory processing are generally divided into encoding, storage and retrieval. With respect to the time span, clinicians have divided memory into the following three stages. *Immediate memory* that is usually evaluated by serial repetition as typified by the digit span verbally or by the block-tapping test nonverbally, has a time course measured in seconds. This corresponds to *short-term memory* used in the domain of psychology. Immediate memory is preserved in amnesic patients and its impairment suggests attention disorders as in confusional state or major cognitive deficits as in dementia. Working memory, that is another meaning of the short-term memory concept, refers to a system comprised of an executive component that guides goal-directed behaviors and short-term memory stores [1]. This memory is linked to the dorsolateral prefrontal cortex. *Recent memory* is evaluated by tests of the ability to learn new information (e.g., The Logical Memory subtest of Wechsler memory scale-revised [2]). *Remote memory* is assessed by tests of the ability to retrieve old, already learned information. Recent and remote memory is tested by free recall as well as recognition techniques. Thus, recent and remote memory refers to retention over longer periods of time and together encompasses the total of our remembered experiences. Recent and remote memory corresponds to long-term memory used in the domain of psychology. Recent memory loss is a main characteristic of amnesic patients.

There is another important distinction of memory about the time aspect. Anterograde amnesia refers to the inability to retain information encountered subsequent to the onset of amnesia, while retrograde amnesia refers to the inability to retrieve information learned prior to the onset of amnesia. Amnesic patients with vascular etiology usually exhibit a temporally limited retrograde amnesia with intact memory for very remote events in addition to anterograde amnesia.

### Kinds of Long-Term Memory

Most widely accepted classification in neuropsychology is dichotomy of declarative and nondeclarative memory (Fig. 1). Each memory has subordinate systems where distinctive learning and memory abilities are operated according to demanding situations. ►Declarative memory is mainly affected with brain lesions including



**Long-Term Memory. Figure 1** Components of long-term memory proposed by Squire and Zola-Morgan [3].

hippocampus and related structures causing amnesia while ►nondeclarative memory is spared.

Declarative memory is subdivided into episodic and semantic memory. These two subsystems are originally defined by Tulving [4]. Episodic memory refers to the system involved in recollecting past events in an individual's life. This system stores the cumulated experiences or episodes of one's life, an individual ►autobiographical memory, in which an event can be associated with a context. Hence episodic memory can be located in time and place. On the other hand, it doesn't need such contextual information to access more generalized knowledge as ►semantic memory. The most representative component of semantic memory is our knowledge of the meaning of words.

The distinction between declarative and ►procedural memory is based on the view that procedural learning represents the acquisition of skills, "learning how," while declarative learning involves the acquisition of facts, "learning what" [3]. ►Priming effects are mainly assessed using perceptual priming tasks such as word stem completion, in which words (e.g., motel) are presented and later cued by three-letter word stems (e.g., mot), and conceptual priming tasks such as word association techniques, in which words (e.g., patient) are presented and later asked to free associate to related words (e.g., hospital). According to learning theory, acquisition of ►habits is a result from conditioning. In classical conditioning a previously neutral stimulus such as a bell can cause unconditioned reflex as salivation if it is regularly paired with presentation of unconditioned stimulus as meat powder. In instrumental conditioning voluntary behavior is apt to maintain or reinforced if it leads to a reward.

In the domain of experimental psychology, distinction of explicit and ►implicit memory has also often been used. According to Schacter [5], this distinction depends on consciousness when retrieving information demanded by the memory task. Squire considers that declarative memory corresponds to ►explicit memory, while nondeclarative memory corresponds to implicit memory [3].

In amnesic patients, declarative memory is impaired, but nondeclarative memory is spared. Declarative memory, in particular episodic memory, depends on the integrity of brain structures and connections in the medial temporal lobe and the diencephalon. Amnesic patients can at least access to semantic memory, whereas they have great difficulty adding new knowledge to semantic memory. In recent years, selective semantic memory loss has been reported in patients with focal temporal lobe atrophy, in whom there are also little or no priming effects for words. Thus, lateral aspects of the temporal lobes are regarded as major importance for semantic memory [6].

Skill acquisition typically preserved in amnesic patients is impaired in patients with pathology in the basal ganglia such as Parkinson's disease and Huntington's disease. Recent studies revealed that basal ganglia and cerebellum plays a crucial role in the acquisition of procedural memory [1]. Thus, explicit and implicit memory is subserved by independent neural systems.

## Vascular Amnesic Syndromes

The medial temporal lobe and the diencephalon receive their blood supply from penetrating branches of the posterior cerebral artery. Bilateral damage to these structures causes persisting profound amnesia. Left hemispheric lesions principally affect memory for verbal material, while right hemispheric lesions memory for nonverbal material such as faces and spatial information.

### *Medial Temporal Amnesia*

Recent studies in humans and monkeys provide convergent evidence that the hippocampus and related structures such as the entorhinal and perirhinal cortices and the parahippocampal gyrus are responsible for the formation of new declarative memories [3]. Lesions confined to the medial temporal lobe structures produce pure amnesia, that is selective amnesia without other deficits such as loss of insight, confabulation and personality change. When the hippocampal formation is selectively damaged, amnesia is not so severe.

Additional damage to the above-mentioned surrounding cortical regions makes amnesia more severe [3].

### *Diencephalic Amnesia*

Diencephalic forms of amnesia arise following vascular accidents in the territories of the tuberothalamic or paramedian arteries. The lesion involves midline structures such as the mamillary bodies, the anterior nuclear group of the thalamus, the dorsomedial thalamic nucleus and two related fiber tracts (the mammillothalamic tract connecting the mamillary bodies with the anterior thalamic nuclei and the ventral amygdalofugal pathway connecting the amygdala with dorsomedial nucleus). Amnesic patients with diencephalic damage are often emotionally flat, apathetic, and without insight about their deficit. Confabulation is also frequently noted. These additional cognitive and personality disorders may be related to frontal lobe dysfunction presumably produced by damage to major link in a thalamo-frontal network [1]. Some authors suggest that diencephalic structures principally contribute to the acquisition of new information and are less involved in retrieval of previously learned knowledge [7]. However, it remains unclear that damage to diencephalic structures produces retrograde amnesia.

### *Basal Forebrain Amnesia*

Other than medial temporal and diencephalic structures, damage to basal forebrain may produce amnesia. The basal forebrain is thought to contribute to memory function by providing cholinergic innervation to the hippocampus. It is known that rupture of the anterior communicating artery causes amnesic syndromes with or without a change in personality, but the lesion usually encroaches not only basal forebrain but also adjacent structures such as striatum and ventral frontal cortex. Thus, it is controversial whether a focal basal forebrain lesion produces amnesia or not. Irle et al. suggested that discrete damage to the basal forebrain or striatum did not produce amnesia and combined lesions involving both the basal forebrain and striatum or ventral frontal cortex cause memory deficits [8]. The characteristic of this amnesia as well as the "cholinergic hypothesis" for the pathogenesis remains to be elucidated, even though Tranel and Damasio proposed the possibility that the basal forebrain contributes to the binding together of different modal components of a particular memory [7].

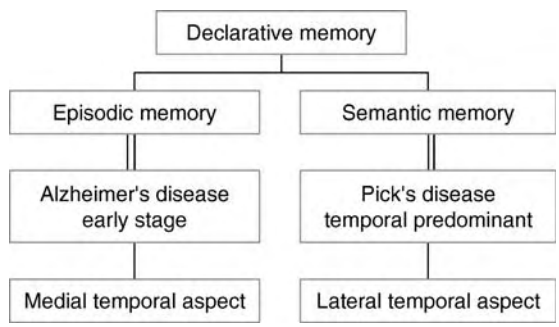
## Related Syndrome

### *Transient Global Amnesia (TGA)*

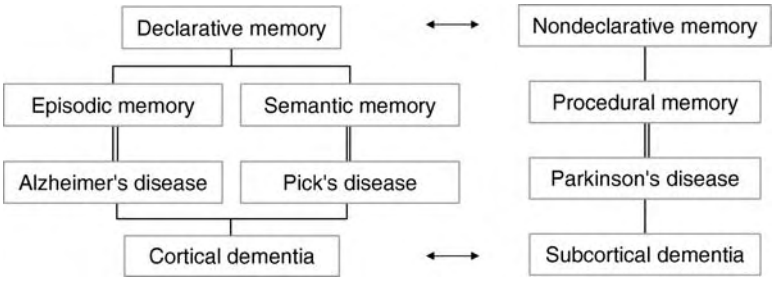
TGA is a well-recognized clinical entity characterized as follows [9]. Patients suffer sudden anterograde and retrograde memory loss without other neurological signs or symptoms. They retain personal identity and are able to carry on normal activities. However, they are unable to acquire any new information, namely they show complete anterograde amnesia. In addition, their inner world go back into a certain point of the past due to retrograde amnesia, while the outer world including their appearances are on the real time. As a result, various things incomprehensible to them develop in their immediate environment and situation. For example, one patient was astonished at a scar from a burn on her hand she had gotten 5 months before and asked her husband about the scar. Like this, the patients ask questions such as "What day is today?" and "Why am I here?" to try to grasp things incomprehensible to them or orient themselves into that particular situation. However, they cannot simultaneously retain answers due to the complete anterograde amnesia, so that they repeat the same questions despite repeated explanations. The retrograde memory loss, extending back for days, months or even years before the attack, gradually or quickly shrinks as the patients recover. No or only a brief period of permanent retrograde amnesia persists, but memory for events during the acute phase is permanently impaired. The amnesic episodes generally last several hours. Thus, the amnesic features of TGA closely resemble those of medial temporal amnesia. Actually, transient hypoperfusion limited to the medial temporal lobes has been demonstrated in SPECT images during the amnesic attack [10], although the pathogenesis remains unclear.

## Memory Impairment of Primary Degenerative Dementia

Memory deficits in the early stage of primary degenerative dementia were investigated in the light of the classification of memory systems from the standpoint of anatomo-clinical correlation. The results indicated the following.



**Long-Term Memory. Figure 2** Neural basis of declarative memory suggested by distinctive symptomatology of each cortical dementia. Alzheimer's disease typically causes episodic memory deficit associated with damage of medial temporal lobe involving the hippocampal area. While semantic memory is selectively affected with semantic dementia associated with lateral temporal lobe atrophy.



**Long-Term Memory. Figure 3** Relationship between memory systems and dementia. Declarative memory impairments caused by cortical dementia. Procedural memory (nondeclarative memory) impairment often occurs with subcortical dementia. *Double line* shows most closely and representatively affected memory system with each disease.

### *Cortical Dementia*

Declarative memory is affected in the context of preserved procedural memory, which is a kind of nondeclarative memory.

1. Alzheimer's disease
   Episodic memory is selectively involved without semantic memory loss. Nondeclarative memory is preserved. In atypical cases, progressive loss of episodic memory could remain the single most salient feature for some years.
2. Pick's disease
   In cases of lobar atrophy with temporal predominant type (semantic dementia), semantic memory is selectively affected without episodic memory loss. Involvement of the left temporal lobe results in semantic memory loss for words, while that of the right temporal lobe in semantic memory loss for faces. Neuroimaging studies on early cases of these diseases demonstrated that medial temporal lobe involving the hippocampal area is responsible for episodic memory loss, while lateral temporal lobe for semantic memory loss (Fig. 2).

### *Subcortical Dementia*

Procedural memory, a kind of nondeclarative memory, is affected in the context of preserved declarative memory. Involvement of subcortical nuclei such as caudate, putamen and substantia nigra is considered to be responsible for procedural memory loss. Hence, it is thought that striato-nigral systems are neuroanatomically important for procedural memory, while limbic systems including the hippocampal area for episodic memory. Furthermore, neurochemical findings obtained from diseases belonging to subcortical dementia such as Parkinson's disease, Huntington's disease and Progressive Supranuclear Palsy as well as Alzheimer's disease suggest the following; procedural memory is mainly subserved by noncholinergic systems such as dopaminergic systems and serotoninergic systems, while episodic memory by the cholinergic system. Thus, the distinct neuroanatomic and chemical substrates for the two memory systems may exist (Fig. 3).

# Long-Term Memory Storage

►Long-Term Memory

# Long-Term Potentiation (LTP)

Toshiya Manabe
Division of Neuronal Network, Department of Basic Medical Sciences, Institute of Medical Science, University of Tokyo, Tokyo

## Synonyms

Long-term synaptic potentiation; Long-term facilitation; LTP

## Definition

Long-lasting increase in the efficacy of synaptic transmission induced by special activation patterns of the synapse.

## Characteristics

### Quantitative Description

LTP is an activity-dependent synaptic modification, usually induced by high-frequency activation (e.g., 100 Hz for 1 s) or theta burst stimulation of afferent fibers, for instance, in the hippocampus [1]. The magnitude of LTP at excitatory synapses in the CA1 region of hippocampal slices is typically 140–180% of baseline synaptic responses (Fig. 1) and the potentiation lasts for more than an hour. LTP recorded in the living animal sometimes lasts more than a day [2].

### Higher Level Structures

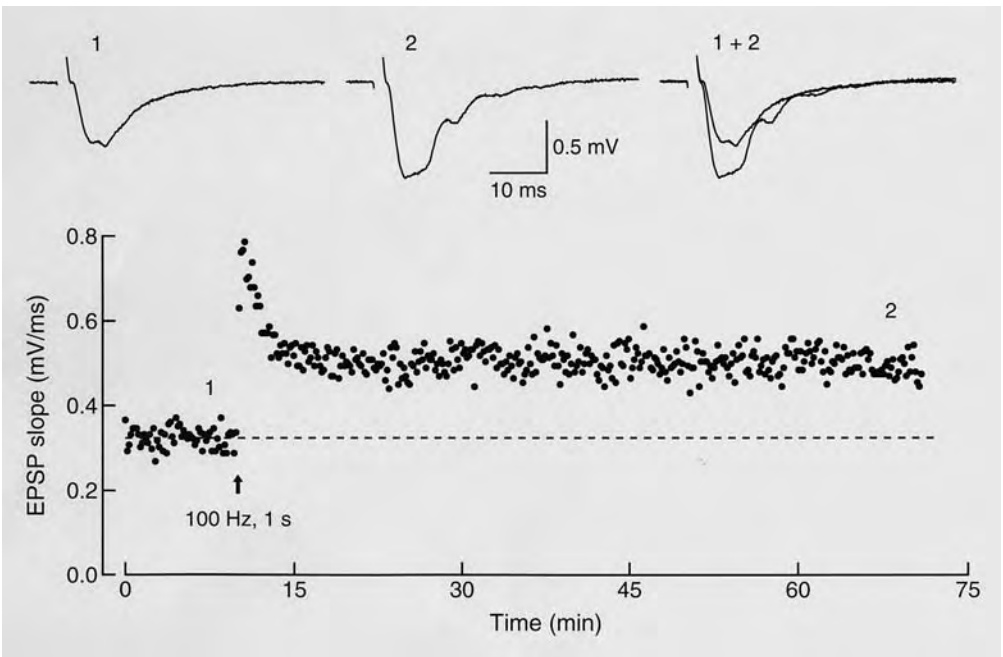
LTP can be observed in both excitatory and inhibitory synapses formed between neurons. LTP is most dramatically induced in the hippocampus; however, it is also observed in other brain regions, such as the cerebral cortex, amygdala, cerebellum, spinal cord and so on.

### Lower Level Components

LTP is a form of plasticity in synaptic transmission. It is evaluated by measuring the change in parameters recorded with electrophysiological methods, such as postsynaptic potentials, postsynaptic currents and population spikes.

### Higher Level Processes

LTP in the hippocampus is regarded as a cellular basis for certain kinds of learning and memory. Pharmacological interruption of LTP induction often results in impairment of memory, for instance the memory



**Long-Term Potentiation (LTP). Figure 1** An example of LTP in the CA1 region of the hippocampus. Excitatory postsynaptic potentials (EPSPs) were recorded with field potential recording techniques, and initial maximal slope values were measured and plotted. Baseline EPSPs were evoked at 0.1 Hz by stimulating Schaffer collaterals in the stratum radiatum. High-frequency stimulation (100 Hz, 1 s) was applied at time 0, and then EPSPs were again recorded at 0.1 Hz. Representative EPSP traces recorded at the times indicated by the numbers in the graph are shown on the *upper panel*.

concerning the space [3]. Furthermore, gene manipulations that affect LTP induction or expression in the hippocampus cause memory impairment [4].

## Lower Level Processes

The commonest types of LTP at the excitatory synapse can be divided into two classes [5]. One is NMDA receptor dependent, and the other, NMDA receptor independent.

### NMDA Receptor-Dependent LTP

This type of LTP is induced and expressed postsynaptically. High-frequency activity of synapses activates postsynaptic NMDA receptors in addition to AMPA receptors, which causes an increase in intracellular $Ca^{2+}$ concentrations by the influx of $Ca^{2+}$ through the NMDA receptor channel. Increased $Ca^{2+}$ then activates a series of biochemical processes that are $Ca^{2+}$ dependent, including calcium/calmodulin-dependent protein kinase II, which give rise to the insertion of active AMPA receptors to the postsynaptic membrane or the increase in the channel conductance of AMPA receptors preexisting on the postsynaptic membrane. This type of LTP is observed at Schaffer collateral-CA1 synapses or at perforant path-dentate gyrus synapses in the hippocampus.

### NMDA Receptor-Independent LTP

This type of LTP is induced and expressed presynaptically. High-frequency activity of the presynaptic terminal strongly activates presynaptic $Ca^{2+}$ channels, which causes an increase in $Ca^{2+}$ concentrations at the presynaptic terminal. The increased $Ca^{2+}$ then activates $Ca^{2+}$-dependent adenylate cyclase, which results in an increase in cAMP at the terminal. The resulting activation of protein kinase A is believed to be involved in the long-lasting enhancement of glutamate release from the presynaptic terminal. This type of LTP is observed at mossy fiber-CA3 synapses in the hippocampus or at parallel fiber-Purkinje cell synapses in the cerebellum.

## Process Regulation

### Frequency

The induction of LTP is regulated by a variety of factors. The frequency of synaptic activation is one of the most critical factors: in the standard in vitro conditions, LTP is induced when the activation frequency is higher than 10 Hz, while long-term depression (LTD) is induced when the activation frequency is less than 5 Hz.

### $Ca^{2+}$ Concentrations

It is generally believed that bidirectional regulation of synaptic efficacy is dependent on the level of postsynaptic $Ca^{2+}$ concentrations: a moderate increase in postsynaptic $Ca^{2+}$ concentrations preferentially activates protein phosphatases, resulting in LTD, and a large increase in postsynaptic $Ca^{2+}$ concentrations activates protein kinases, giving rise to LTP.

### Metaplasticity

Metaplasticity is a type of synaptic plasticity that is induced by some patterns of synaptic activation, which do not necessarily cause the change in normal synaptic transmission, and affects subsequently occurring synaptic plasticity such as LTP or LTD [6]. Modification of NMDA receptors may play a critical role in metaplasticity, as well as other molecules such as metabotropic glutamate receptors or other G-protein-coupled receptors that might also be involved in metaplasticity.

### Biochemical Processes

LTP lasting a few hours is mediated by modification of preexisting proteins such as $Ca^{2+}$/calmodulin-dependent protein kinases, tyrosine kinases, protein kinase C and so on, while a longer-lasting type of LTP is believed to involve synthesis of new proteins through gene expression [1]. Thus, LTP can be modified by the regulation of these biochemical processes.

## Function

When the hippocampus is damaged, certain kinds of learning and memory are severely impaired in experimental animals and humans. The hippocampus is a center of declarative memory and can store neural information for some duration. In 1973, Bliss and Lømo [2] published a comprehensive paper concerning long-lasting modification of excitatory synaptic transmission in the hippocampus of living rabbits. The reported phenomenon is now called LTP. Since the hippocampus plays a critical role in declarative memory, LTP, which is easily and dramatically induced in the hippocampus, was already regarded at that time as a cellular model of memory formation. When NMDA receptors are inhibited in the rat by D-AP5, an NMDA receptor antagonist, and thus LTP induction is blocked, the rat shows severe impairment in spatial learning [3]. In mutant mice lacking NR2A (GluRε1), a subunit of NMDA receptors, LTP is considerably reduced and spatial learning is severely impaired [7]. On the other hand, in mice overexpressing the NR2B (GluRε2) subunit, LTP as well as learning ability is enhanced [8]. Quite a number of papers have appeared reporting the relationship between LTP and learning ability, and it is likely that LTP is involved in memory formation in some way, although there still lacks definitive, direct evidence supporting the conclusion.

## Pathology

There are papers that report the impairment of LTP in aged mice and rats, Alzheimer's disease model mice and many kinds of mutant mice lacking functional molecules localized in the synapse [1].

# Low Back/Spine Pain

Nikolai Bogduk
University of Newcastle, Newcastle Bone and Joint Institute, Royal Newcastle Centre, Newcastle, NSW, Australia

## Synonyms

Backache; Lumbago; Lumbar spinal pain

## Definition

There is no universally accepted definition of low back pain. The term encompasses any combination of what the International Association for the Study of Pain (IASP) defines as lumbar spinal pain and sacral spinal pain [1]. Essentially this means pain perceived anywhere in a region bounded superiorly by first lumbar vertebra, inferiorly by the caudal end of the sacrum, and laterally by the lateral margins of the back muscles or the sacrum.

This definition is based on where the patient perceives their pain. It does not presuppose or imply that the source of pain lies in this region. Often it does, but sometimes the source can be from structures beyond the immediate vicinity of the lumbar spine.

## Characteristics

### Sources

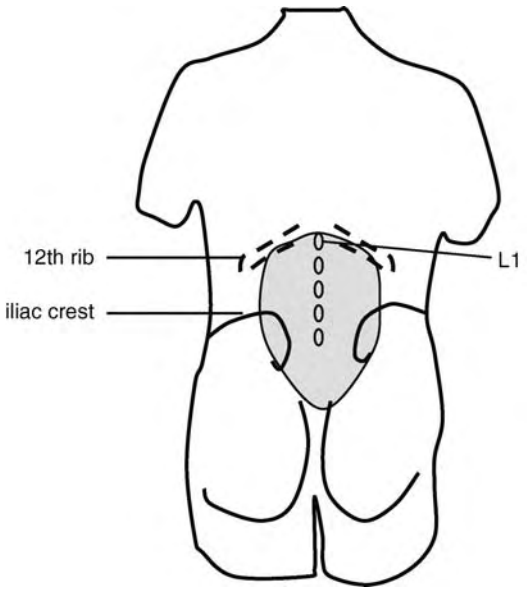
The possible sources of low back pain can be local or remote. The local sources are any of the components of

the lumbar spine that receive an innervation. Remote sources are vessels and viscera that are not part of the lumbar spine, but which share a similar segmental nerve supply with the lumbar or sacral spine.

The lumbar spine and sacral region are innervated by the dorsal rami, ventral rami, and sinuvertebral nerves of the L1–L5 spinal nerves and the upper two or three sacral spinal nerves [2]. These nerves innervate the muscles and fascia of the lumbar spine, the dura mater at lumbar and sacral levels, the ligaments of the lumbar spine and sacroiliac joint, the lumbar zygapophysial joints and intervertebral discs, and the sacroiliac joint. Any of these structures can, potentially, be a source of low back pain [2].

Remote sources include the abdominal aorta, the bladder and uterus, the uterine tubes, and the ovary. Viscera of the posterior abdominal wall may appear to be a source of back pain, but it is not evident if the pain arises from the organ itself or as a result of irritation of the anterior structures of the lumbar spine.

Experimental studies in normal volunteers and in patients with back pain have shown that back pain can be evoked, or reproduced, by noxious stimulation of the posterior back muscles, the interspinous ligaments, the lumbar zygapophysial joints, the lumbar intervertebral discs, and the sacroiliac joint [2,3].



**Low Back / Spine Pain. Figure 1** Low back pain is pain perceived anywhere in the region shaded.

## Referred Pain

Referred pain is pain perceived in the territory of a nerve other than the nerve that innervates the source of pain [1,3]. Typically the other nerve is another branch of the same spinal nerve that innervates the source.

Pain stemming from lumbar or sacral spinal structures can be referred into the gluteal region or groin, into the thigh, and even into the leg as far as the foot. Such distributions have been shown for pain stemming from the lumbar interspinous ligaments, the lumbar zygapophysial joints, the lower lumbar intervertebral discs, and the sacroiliac joint [3]. The patterns of distribution tend to be segmental, in so far as pain from higher spinal segments tends to be referred more proximally in the lower limb or lower limb girdle. However, there is considerable overlap between patterns from different segments, and considerable variation between individuals, which prevents patterns being diagnostic of the segmental source of pain.

Referred pain is perceived deeply, and is dull and aching in quality, or like an expanding internal pressure. It is distributed over relatively broad areas. These features distinguish referred pain from radicular pain, which is lancinating or shooting in quality and travels into the lower limb along narrow bands [3].

## Associated Features

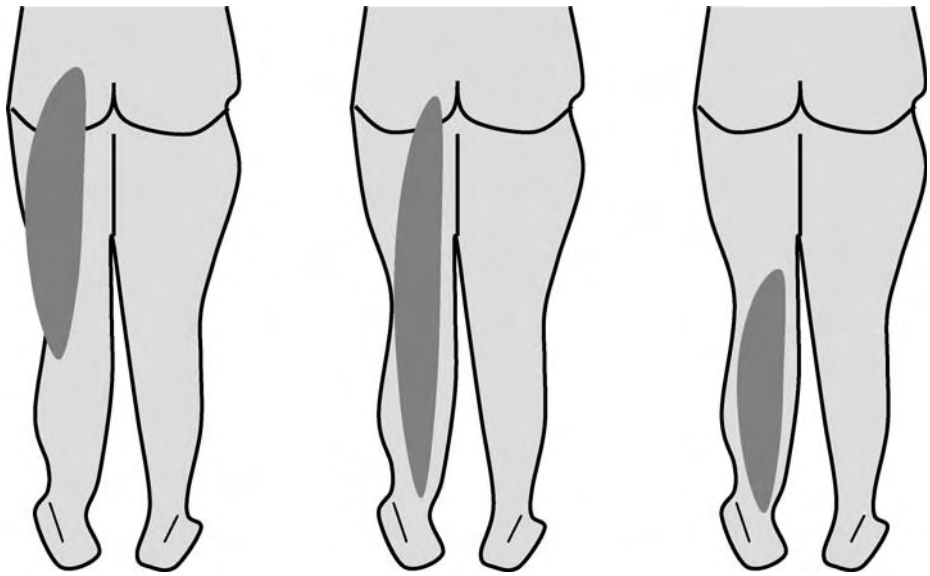
Low back pain can be associated with reflex activity in muscles. In experimental studies, this activity develops soon after the onset of pain, and typically lasts for as long as the pain is perceived. As a rule, it occurs in muscles with a segmental innervation similar to that of the source of pain. The muscles may be in the back (e.g., multifidus) or in the lower limb (e.g., gluteal muscles) or hamstrings [4] (Figs. 1 and 2).

## Causes

Although any innervated structure of the lumbar spine and sacrum can potentially be a source of back pain, evidence is limited as to what the actual sources and causes of pain are, either generally in populations or specifically in individual patients. At one time or another, during the last 100 years, virtually every structure of the lumbar spine has been invoked as the source of pain, and various conjectures have been raised as to its cause.

The International Association for the Study of Pain lists some 96 entities that could be causes of back pain [1]. However, the problem that has impeded progress in this field is the lack of reliable and valid diagnostic tests. Whereas various authorities have proposed various entities, they have not produced diagnostic tests that diagnose that entity and distinguish it from other possible causes of pain. Consequently, although the IASP provides diagnostic criteria for many entities, these criteria cannot be satisfied for lack of reliable and validated diagnostic tests.

Tumors and infections are accepted causes of low back pain, but they are rare. They account for fewer than 1% of cases of acute low back pain, and probably fewer than 5% of cases of chronic low back pain [3].



**Low Back/Spine Pain. Figure 2** Patterns of referred pain evoked by noxious stimulation of the lumbar zygapophysial joints, lumbar intervertebral discs, or the sacroiliac joint.

Likewise, fractures are rare causes of back pain, other than in patients who are at high risk of having sustained a fracture. Those risk factors are age, severe trauma, osteoporosis, and long-term use of corticosteroids [3].

Many practitioners believe that disorders of muscles can cause back pain. These have been described as trigger points, spasm, imbalance, and insufficiency. However, no reliable and valid test allows these conditions to be unequivocally diagnosed.

Some practitioners believe that ligament sprain can be a cause of low back pain, but there is only limited evidence for this contention. Injecting the affected ligament with local anaesthetic purportedly relieves this pain, but no controlled studies have demonstrated this. Therefore, a non-specific or placebo-effect has not been excluded.

Purportedly, pain from the dura mater can be diagnosed by a variety of so-called stretch tests, but no studies have shown that the pain that is aggravated by stretch tests specifically arises from the dura mater. No studies have provided evidence that back pain can arise from the fascia of the back.

For chronic low back pain, the strongest evidence to date incriminates the joints of the lumbar spine and sacrum as the most common sources of pain [3]. Equivalent data for acute low back pain are not available because the tests required to diagnose joint pain are not indicated, and have not been applied, in patients with acute pain.

Pain from the lumbar zygapophysial joints can be diagnosed using controlled blocks of the nerves that innervate these joints (medial branch blocks) [5]. Controlled blocks reduce the likelihood of a false-positive response. The prevalence of lumbar zygapophysial joint pain appears to differ with age. In younger, injured workers, zygapophysial joint pain accounts for fewer than 10% of cases [6]. In elderly patients, the prevalence may be as high as 40%. Still elusive, however, is the actual cause of lumbar zygapophysial joint pain. It is tempting to attribute the pain to osteoarthrosis, but radiological studies have found that back pain is not significantly more common in patients with radiographic osteoarthrosis.

In some 20% of patients with chronic low back pain, the source can be traced to the sacroiliac joint, using controlled diagnostic blocks [5]. The cause remains elusive, but is presumed to be some sort of injury to the joint, or excessive strain in its supporting ligaments.

Pain from the intervertebral discs is the most extensively studied basis for chronic low back pain. Discogenic pain can be diagnosed using disc stimulation. It accounts for some 40% of cases. The pathology is internal disruption of the disc [2,3]. Under repeated compression loading, fatigue failure of a vertebral endplate occurs in the form of a fracture. This precipitates a degradation of the nuclear matrix, and radial fissures develop into the outer anulus fibrosus. The capacity of the nucleus to bear compression loads becomes irregular and reduced, and greater than normal loads are borne by the posterior anulus. The presence of radial fissures, reduced nuclear stress, and increased anulus stress are each strongly associated with reproduction of pain when the affected disc is stimulated.

### Diagnosis

Serious causes of back pain can be suspected from key aspects of the history, such as a history of cancer, weight loss, cardiovascular risk factors, and risk factors for infection. They can be confirmed by magnetic resonance imaging [3].

Common causes of back pain defy diagnosis by history, physical examination, or imaging. The one exception is discogenic pain. Using McKenzie techniques, centralization of pain is reasonably predictive of a internal disc disruption being the cause of pain [7]. As well, some 30% of patients may exhibit, on magnetic resonance imaging, a high-intensity zone in the anulus fibrosus. This sign is strongly predictive of the affected disc being the source of pain [3].

For precision diagnosis of low back pain, invasive tests are required. Diagnostic blocks can be used to diagnose pain from synovial joints, and disc stimulation can be used to diagnose discogenic pain [5]. For these tests to be valid, they must be rigorously controlled. Diagnostic blocks must be performed in a single-blind, but preferably double-blind manner. Disc stimulation must be controlled for pressure of injection, and discs at adjacent segments must be shown to be asymptomatic [5].

### Treatment

Systematic and other reviews have shown that most of what has been used to treat back pain either lacks sufficient evidence of efficacy or is no more effective than sham therapy or no treatment [3,8,9].

For acute low back pain, the best evidence supports explanation, reassurance, and resuming activity as the mainstay of treatment. Passive treatments are not effective and should be avoided [3,8].

For chronic low back pain, the evidence is very limited. Intensive exercises, either alone or in the context of a multidisciplinary rehabilitation program are the mainstay of conservative management [9]. However, although they may reduce pain and improve function, they do not eliminate low back pain. Drug therapy does not eliminate back pain. Ironically, the most powerful agent shown to produce complete relief of back pain are injections of normal saline [10].

Zygapophysial joint pain can be treated by percutaneous radiofrequency neurotomy [3,9]. Discogenic pain can be treated by fusion, disc arthroplasty, or various intradiscal therapies. However, compelling evidence of efficacy is still lacking for these invasive interventions.

## Lower Motor Neuron Disease

### Definition

Lower motor neuron disease results from block or destruction of ►motoneurons in ►brainstem or ►spinal cord or of their axons in nerve roots or peripheral nerves, and may lead to paresis or paralysis of the innervated muscles depending on the site of lesion.

## Low-frequency Fatigue

### Definition

A type of fatigue that is prominent at low action potential (stimulation) frequencies (10–20 Hz) that

occurs when metabolites have recovered and in the presence of normal action potentials and that can take days to recover. Low-frequency fatigue is thought to be due primarily to impaired excitation-contraction coupling and reduced sarcoplasmic reticulum $Ca^{2+}$ release.

►Excitation-Contraction Coupling

## Low-Pass Filtering

### Definition

A filter that passes only those frequency components in the low end of the spectrum.

►Signals and Systems

## Low-Pass Filtering by Electrical Synapses

### Definition

A low-pass frequency filter is an electrical circuit (or biological equivalent thereof) containing resistive elements in series with reactive elements that progressively attenuates the transmission of high-frequency signals. Electrical synapses act as low-pass filters with passband attenuation as a consequence of the (resistive) electrical pathway provided by gap junction channels standing in series with the parallel electrical capacitance and resistance of the postsynaptic cell membrane.

►Electrical Synapses

►Tactile C Fibers

## Low-threshold Cutaneous Mechanoreceptors

►Cutaneous Mechanoreceptors, Functional Behavior

## Low-Threshold Mechanoreceptor

### Definition

A primary somatosensory neuron that detects and encodes information about innocuous mechanical deformation of its receptive field. These receptors are stimulated by very subtle degrees of mechanical deformation and contrast to high-threshold mechanoreceptors, which include receptors that detect and encode information about noxious mechanical deformation and damage of the tissues (i.e., nociceptors).

►Nociceptors and Characteristics
►Sensory Systems

## Low-threshold Spikes

### Definition

Membrane depolarizations generated by T-type $Ca^{2+}$ channels, which originate at low negative voltages and are favored by preceding membrane hyperpolarizations. Low-threshold spikes (LTS) drive neurons to the threshold of action potential generation and trigger all-or- none burst firings sustained by $Na^{+}$ channels. LTS are usually recorded in isolated neurons from a variety of brain nuclei, such as inferior olive, thalamic relay, hippocampus, subthalamic nucleus and thalamus.

## Mackintosh Model

### Definition

Developed to account for attentional phenomena (latent inhibition, perceptual learning), this model of classical conditioning views variations in the effectiveness of CS-US pairings in terms of variations in CS processing. The model asserts that attention to a CS is modifiable and it specifies rules for how CS processing is influenced by experience. Attention to a CS will decrease if it is a poor predictor of the US and increase if it is the best predictor of the US.

►Theory on Classical Conditioning

## Macrophages

### Definition

Macrophages are derived from circulating monocytes and differentiate into tissue macrophages (including microglia in the central nervous system (CNS) during development). Normally, macrophages are at a resting state. Upon infection, tissue injury or other disturbance in the tissue, macrophages can be activated and become more effective in eliminating damaged tissue, infected cells or tumor cells. Activated macrophages are characterized by increased phagocytosis, increased secretion of inflammatory mediators and cytotoxic substances, and increased ability to activate the adaptive immune response. Macrophage functions can be further enhanced or inhibited by certain cytokines.

## Macula Organs

### Definition

Epithelia of sensory cells covered by an otolithic structure (utricle, saccule, lagena) arranged in different spatial positions, forming an integral part of the peripheral vestibular sensory apparatus in the inner ear of all vertebrates. The detection of static and dynamic changes of the position of the otolith by the sensory cells makes this organ sensitive to linear head acceleration and constant changes of head position relative to gravity.

►Functional and Neurochemical Organization of Vestibulo Pathways

## Maculae

### Definition

Specific areas located in two regions (the sacculus and the utriculus) of the membranous labyrinth where labyrinthine (macular) receptors are located.

►Peripheral Vestibular Apparatus
►Vestibulo-Spinal Reflexes

# Macular Receptors

## Definition

Labyrinthine receptors located within the maculae of the utriculus and sacculus whose cilia are embedded in a gelatinous structure (the otolith membrane). The membrane contains crystals of calcium carbonate whose density is three times higher than that of endolymph. Linear accelerations imposed on the head or changes in head position with respect to the vertical axis displace the membrane and stimulate the receptors.

►Peripheral Vestibular Apparatus

## Synonyms

Magnetoreception; Magnetoperception; Magnetosensitivity; Magnetic orientation; Magnetotaxis; Magnetonavigation; Electroreception; Electric sensitivity; Electric orientation; Electrolocation; Electrocommunication

## Definition

Many animals use magnetic or ►electric fields to obtain information about their environment. Although the senses for both types of fields are discussed here in one chapter, the role of these physical features in animal behavior is fundamentally different. The magnetic field used is the ►geomagnetic field; it provides a reliable source of information utilized by the animals in numerous ways for orientation in space and possibly time. The electric information used by animals, on the other hand, is normally not provided by the ►physical environment, but comes from other animals or is produced by the user of the information for ►active electrolocation. The ►electroreceptor organs of marine elasmobranch fish, termed ►ampullae of Lorenzini, might additionally act as magnetoreceptors. At the same time, while the ecophysiology of magnetic and electric senses is generally known, at least in the most prominent animal groups studied, our knowledge about the neurobiological base differs greatly. The neurobiology of the electrical sense is comparatively well understood, and a prominent example of neurobiology, whereas our knowledge on the neurobiology of the magnetic senses is still rather limited; here, most of our knowledge comes from behavioral experiments.

## Magnetic Senses

For animals that are able to perceive magnetic parameters, the geomagnetic field provides an omnipresent source of navigational information. Its field lines exit the earth at the southern magnetic pole, run around the globe and reenter at the northern magnetic pole. This vector quality provides directional information to be used as a ►magnetic compass, whereas total ►intensity and/or ►inclination, showing a gradient from the poles to the equator, can provide positional information on a large-scale ►magnetic "map" to be used for navigation. The latter two magnetic parameters may also serve as "►sign posts" or triggers, marking specific locations or regions where they elicit specific responses. In a similar sense, even magnetic anomalies could serve to characterize a specific location. Furthermore, the daily variation of the geomagnetic field – in the temperate zones a decrease of magnetic intensity from sunrise to noon, followed by a corresponding increase – have been discussed as potential *Zeitgebers* for the circadian clock. In summary, in order to make optimal use of the wealth of information offered by the geomagnetic field, animals need sensors for magnetic direction as well as sensors for magnetic intensity or intensity changes.

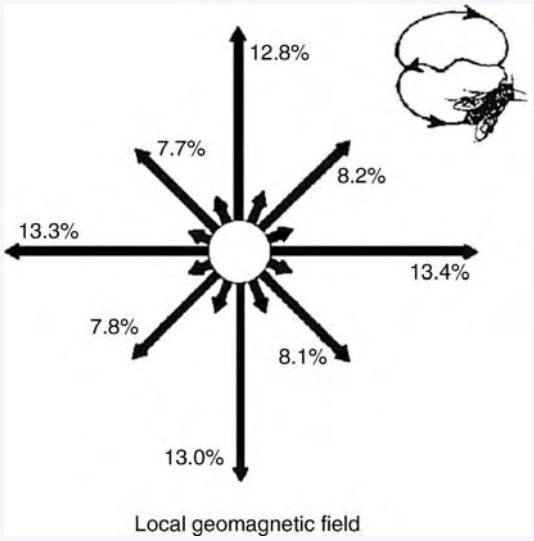
The use of the magnetic field for locating directions is rather widespread among animals. The associated behavior can be classified either as alignment responses or as a magnetic compass orientation. Alignment responses are characterized by an axial preference of the prominent magnetic directions, with the dances of honeybees on a horizontal comb being a classic example: without view of the sky, the largest activity is found along the magnetic N–S and the E–W axes (Fig. 1).

When, however, the magnetic field is used for compass orientation the animals can prefer any arbitrary direction with respect to the direction of the magnetic field. The behavioral context of the animal determines the specific angle relative to magnetic north. The selected course, or "set direction," of the compass can be of different origin: it can be innate, imprinted or learned.

The best studied examples for magnetic compass orientation is that of birds (Fig. 2).

It is a so-called "►inclination compass," as the birds do not use the polarity of the magnetic field, but the inclination of the magnetic field lines in space to derive directions. This type of compass response does not distinguish between magnetic North and South, but between "poleward," where the axis of the field lines forms the acute, and "equatorward," where it forms the

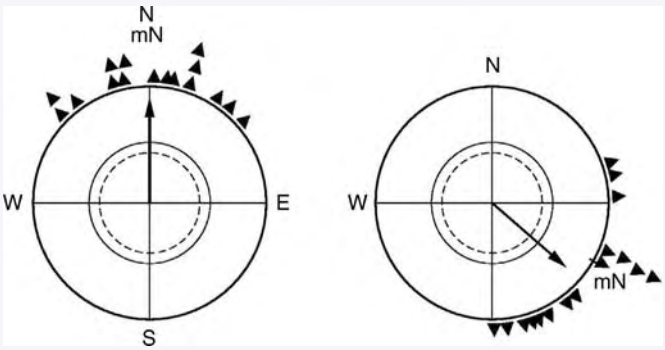
obtuse angle with gravity. At the same time, the avian magnetic compass functions only in a narrow ►intensity window; this functional window is finely tuned to the ambient magnetic intensity where the birds live. These findings from behavioral experiments imply specific characteristics of the receptors mediating magnetic compass orientation in birds. Various other animals are also able to perceive the direction of the magnetic field and use it as a magnetic compass. Two types of compass ►mechanisms have been described: marine turtles and amphibians have an inclination compass like birds, but mole rats, some fish and all invertebrates studied so far use a "►polarity compass" that is based on the polarity of the magnetic field lines, similar to our technical compass. This suggests the existence of at least two different receptor mechanisms among vertebrates [1].



**Magnetic and Electric Senses. Figure 1** Dancing directions of bees on a horizontal comb in the absence of directing visual stimuli under diffuse light in the natural geomagnetic field. 24,601 individual dances were recorded; the arrows are proportional to the percentage of dances in the various directions. For the main classes the percentage is given numerically. The results clearly demonstrate a spontaneous preference of the main-direction N, E, S, W and a still remarkable preference of the intermediate direction NE. SE, SW, NW (after [37]).

Birds use their magnetic compass for homing and for migration. Avian navigation is usually described as a two-step process: the direction to the goal is first determined as a compass course (= set direction); then, this course is located with a compass and converted into a heading for flight. Orientation within the home range and homing means that the compass course varies according to the position of the animal relative to home; it is determined by a navigation process or remembered from previous visits. For migration, the migratory direction as fixed set direction is innate; the respective course is genetically encoded and passed on from one generation to the next. Here, the geomagnetic field serves as external reference system and, together with celestial rotation, ensures that this genetic information is converted into the species-specific migratory direction [2]. In birds, the magnetic compass is also involved in establishing the directional relationship between sun azimuth and the circadian clock for the sun compass and in calibrating a stellar compass for nocturnal migrants. The biological significance of the avian magnetic compass lies in its role as a basic component of a complex navigational system (see [1]).

In non-avian species, magnetic compass orientation also provides a directional reference in various



**Magnetic and Electric Senses. Figure 2** Orientation behavior of 16 European Robins in spring, tested in the natural geomagnetic field (*left*) and in an experimental magnetic field with the horizontal component shifted to the SE (*right*). mN, magnetic North. The triangles at the periphery of the circle mark the headings of the individual birds. The arrows represent the mean vectors calculated from the 16 headings. The length of the vector is proportional to the radius of the circle. The two inner circles are the 5% (dashed) and the 1% significance levels of the Rayleigh test (after [35]).

M

behavioral situations. It is used by salmon fry that prefer innate directions to find their way in complex lake-river systems [3] and by hatchlings of sea turtles that use an imprinted magnetic course to head away from the shore to the open sea. Another famous example is the well-studied "y-axis"- orientation that is typical for animals living at the border of land and water, e.g., salamanders, beach hoppers and isopods: here, the animals move along a magnetic axis perpendicular to the shoreline toward water or land, depending on their physiological needs (Fig. 3; [4]).

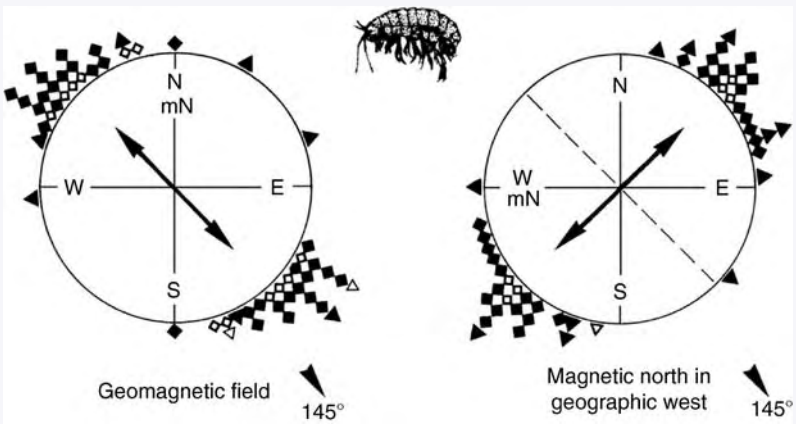
In birds as well as in other vertebrate species, the magnetic compass may be used in a navigational strategy called "path integration," based on directional information obtained during the outward journey. Recording the net direction of the displacement could be based on endogenous (idiothetic) cues alone, or on external (allothetic) factors. In very young pigeons, wood mice, box turtles and young alligators, the geomagnetic field was shown to provide the external reference for path integration (see [1]). Blind mole rats of the genus *Spalax* were shown to use idiothetic factors alone over short distances, but to turn to the magnetic field as external reference on more extended excursions [5].

A special case of directional orientation with the help of the magnetic field is found in ►magnetic bacteria. While all animals detect the direction of the magnetic field with specialized receptors and act according to this information, magnetic bacteria contain chains of tiny crystals of magnetic material. By the force of the geomagnetic field lines, they are passively rotated and aligned along the field lines by magnetic crystals; they then propel themselves along the field lines down into the mud (see [6]). Their orientation is thus fundamentally different from that of animals.

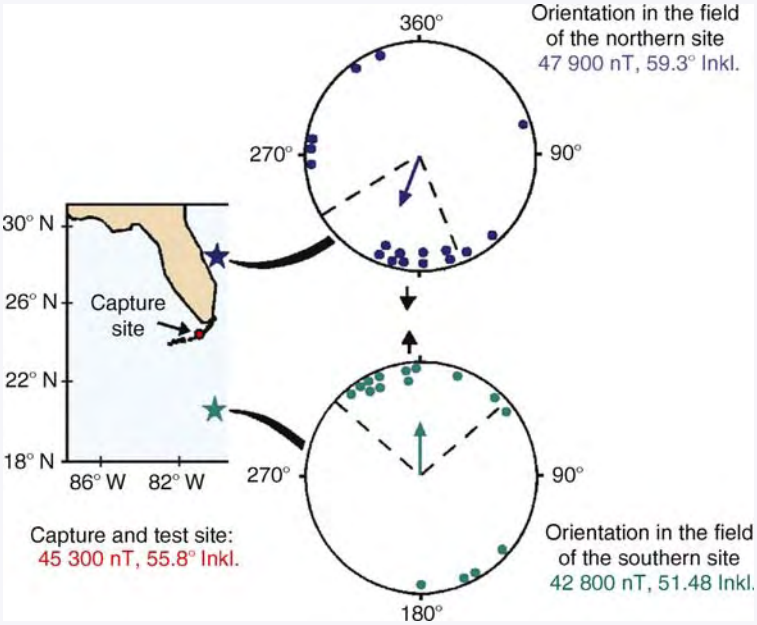
The geomagnetic field is not only used as a source of directional information. An increasing body of evidence suggests that non-directional features of the geomagnetic field are also utilized by animals. Because of the gradients running from the poles to the equator, magnetic intensity and/or inclination can serve as components in a potentially world-wide ►navigational map. The use of magnetic "map"-factors has been discussed for birds since the nineteenth century and is indicated by some findings with homing pigeons, other birds, marine turtles and alligators; Fig. 4 gives a recent example of navigation based on magnetic factors in an invertebrate for the first time.

Navigational "maps" are typical for territorial animals; their biological function is to ensure that the animals find back to their home territory after extended excursions or displacements. Such "maps" are established by experience, involving learning and memory. In these learning processes, the magnetic compass might be involved as reference system, allowing animals to record the regional directions in which navigational factors show a maximum change.

Aside from their role as components of the navigational "map," magnetic intensity and inclination or a combination of both may serve as "sign posts" or triggers to elicit specific preprogrammed responses in certain areas characterized by these magnetic features. A famous example is the responses observed in young sea-turtles from Florida that spend their first year of life



**Magnetic and Electric Senses. Figure 3** Orientation of the equatorial sandhopper *Talorchestia martensii* in the laboratory in a centrally lit arena. Test in the local geomagnetic field (*left*); test with magnetic North shifted 90° counterclockwise to geographic west (*right*). The theoretical escape direction to the sea of 145° is marked by the arrowhead outside the circle; the symbols at the periphery indicate the mean headings of individual sandhoppers: triangles unimodal behavior; diamonds axially bimodal behavior, with both ends of the axis indicated; solid symbols samples significant according to Rayleigh test; open symbols non-significant samples. The double-headed arrows represent the mean axes, the dashed diameter in the right diagram marks the axis of the respective controls (after [4]).



**Magnetic and Electric Senses. Figure 4** True navigation by magnetic parameters indicated in spiny lobsters. The lobsters were tested near their capture site in magnetic fields replicating the ones of two distant geographic locations (*marked with asterisks*). In the circular diagrams, the small arrows outside of the circle indicate the home directions from the simulated sites. Dots at the periphery of the circle mark the headings of single lobsters; the arrow represents the mean vector proportional to the radius of the circle, with the dashed radii indicating the 95% confidence interval of the mean direction (after [19]).

M

in the Atlantic gyre. When freshly hatched turtles were exposed in the laboratory to magnetic fields simulating those at the edge of the gyre, they altered their headings and chose directions that would have brought them toward the center of the gyre, thus helping them stay within suitable waters (see ►"Entry" Magnetic maps). Similar preprogrammed responses have also been described for migratory birds that change direction or respond physiologically by increasing their fat load when encountering specific magnetic conditions.

A further role of the magnetic field in orienting animal movements has been discussed for the extended migrations of whales between their polar feeding grounds and the temperate regions where they spend the winter; following magnetic contours was suggested as navigational strategy (see [1]).

Organisms like magnetic bacteria need no perception mechanism at all, as they are passively aligned by the force of the geomagnetic field. In contrast, animals that actively respond to magnetic parameters need to obtain information about the direction or the intensity of the geomagnetic field. By what kind of mechanism they detect these features is not yet entirely clear, however. Experiments with birds suggest that magnetic compass orientation requires a stable direction of the magnetic field, but would tolerate changes in intensity and inclination to a certain degree. For the magnetic components of the navigational "map," on the other hand, detecting minute changes in intensity is crucial, whereas the direction of the field appears not to be important. Considering the physical aspects of magnetoreception, three mechanisms have been suggested: induction, ►magnetite-based mechanisms and ►radical-pair processes.

Electric current induction through the Faraday Effect as primary process for magnetoreception is an option only for marine fish. It has been discussed for elasmobranch fish, because the ampullae of Lorenzini, the electroreceptor ►organs of sharks and rays (see below), are highly sensitive to electric fields. With a threshold of as low as 5 nV/cm, these receptor organs are, at least theoretically, sensitive enough to distinguish the voltage induced by the normal swimming speed when moving in different directions and thus provide the information required for magnetic compass orientation (see [1]).

►Magnetite is a specific form of $Fe_3O_4$, with its magnetic features depending on particle size. Small crystals of less than 40 nm are superparamagnetic (SPM), which means that they do not have a stable magnetic moment; their magnetic moment fluctuates due to thermal instability, but can be stabilized by static ambient magnetic fields like the geomagnetic field. Particles of an intermediate size of 40–120 nm form

so-called single domains (SD) and have a stable magnetic momentum; theoretically, they could align themselves along the magnetic field lines like minute compass needles. Larger particles above 120 nm become multi-domain and have no pronounced net magnetic moment, because the moments of the various domains largely cancel each other.

Considerations on ►magnetite-based magnetoreception usually favored single domains, and several models have been suggested how single domains could mediate magnetic information. E.g., attached to hair cells or specialized membranes, they would be able to transduce the magnetic torque to mechanical torque and thus act as a compass. By magnetic remanence measurements, single domain particles were indicated in the tissues of numerous animals (see [7]). In vertebrates, magnetite was found in the nasal and orbital region, a region which is innervated by the ophthalmic branch of the *nervus trigeminus*, from which electrophysiological responses to magnetic stimulation involving changes in intensity were recorded. Structures that may be candidates for a ►magnetite-based magnetoreceptor based on single domains have been described for fish (e.g. [8]). In the upper beak of homing pigeons a structure has been identified which contains clusters of superparamagnetic magnetite; it may serve as modified pressure receptor measuring magnetic intensity [9].

The radical-pair hypothesis postulates magnetoreception by specialized photopigments. By photon absorption, molecules are raised to the excited singlet state, where some of them undergo a transition into the excited triplet state. The probability to reach the triplet state, and with it, the triplet yield, depends on the alignment of the photopigments with respect to the magnetic field lines. In the spherical or hemispherical structure, the triplet yield would form a specific pattern that was centrally symmetric to the axis of the field lines, thus forming a ►chemical compass. By comparing the triplet yield in the various spatial directions, animals could obtain information on the direction of the magnetic field [10]. Because of their biochemical properties, cryptochromes are discussed as possible candidates for the photopigments underlying these processes. The radical-pair model is indirectly supported by behavioral findings indicating that the magnetic compass of salamanders and birds is ►light-dependent: short-wavelength monochromatic light allows normal orientation, whereas the use of long-wavelength light abolishes orientation behavior [11]. The recent observation that the magnetic compass of birds can be disrupted by high-frequency magnetic fields points directly to a radical-pair process underlying magnetoreception [12].

In salamanders, the receptors mediating compass information appear to be situated in the pineal, the ancestral "third eye" of vertebrates [13]. In birds, too, magnetosensitive cells have been found in the pineal; however, in two species of passerine birds, magnetoreception was shown to occur almost exclusively in the right eye [14]. Since the optic nerves of birds cross over almost completely, this means that magnetic information is processed predominantly in the left hemisphere of the brain. The tectofugal part of the visual system shows a marked anatomical lateralization, with the relevant pathways in the left hemisphere more pronounced than in the right [15] which might also be associated with processing magnetic compass information. Electrophysiological recordings from the *tectum opticum* and the nucleus of the basal optic root (nBor), a nucleus belonging to the tectofugal system, revealed units that were stimulated by changing the direction of the ambient magnetic field [16].

Altogether, the available findings on magnetoreception suggest a variety of mechanisms based on different principles. It seems plausible to assume that the magnetic compass and the magnetic part of the "map" require different types of magnetoreceptors, because they utilize different physical features of the magnetic field. This asks for different primary processes and different ways of neuronal processing. So far, evidence from birds suggests that a ►radical-pair mechanism in the right eye provides compass information, whereas magnetite-based receptors associated with the trigeminal system provides intensity information for the "map." A radical-pair mechanism is also discussed for the compass of salamanders, but what kind of mechanisms other animals might use is not yet known.

## Electric Senses

In contrast to the geomagnetic field, the electric field of the earth is highly variable. Its variability is caused by differences in the activity of thunderstorms and related phenomena, and the ►field intensity depends on many factors like air humidity, temperature and conductivity of the surface. The polarity of the electric field is directed vertically downward. In view of this, it is hard to see how the electric field could provide information that is useful to animals. Yet a number of animals were found to be electroreceptive. Only in the past 50 years, peculiar structures (sensory pores) in the skin of some aquatic vertebrates that had been known for a long time were identified as electroreceptor organs (see entry "Electroreceptor organ"). Such electroreceptor organs are found in all groups of lower aquatic vertebrates and in certain amphibians, while they are lacking in most of the modern fish (such as the Teleostei within the Neopterygii). In two, possibly three, not closely related lineages of Teleostei, they obviously reevolved independently, namely in the ►Mormyriformes from the Osteoglossomorph branch and the ►Siluriformes (catfish) and ►Gymnotiformes from the Neognath branch. Because of the insulating properties of air,

electroreceptor organs are generally lacking in terrestrial vertebrates such as reptiles, birds and mammals, the only exceptions being the ►Monotremata, the ►Echidna and the ►Platypus, where electroreceptor organs have been recently described (see entry "►Electroreception and Electrolocation in the platypus and the echidna").

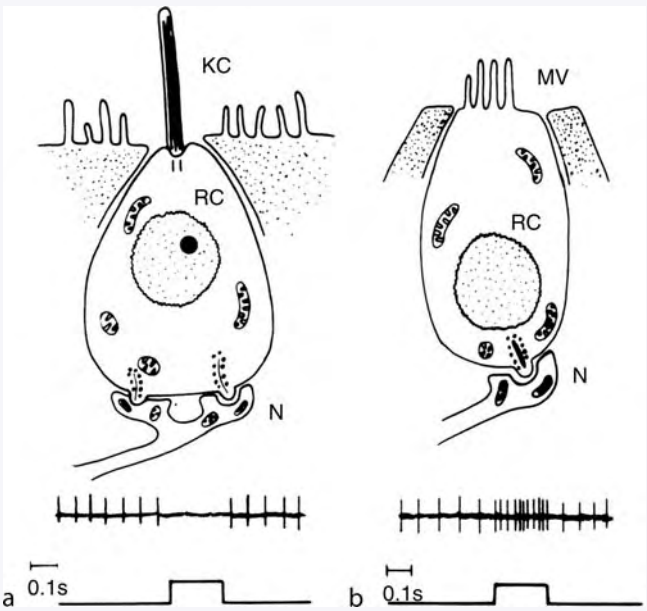
Electroreceptor organs are voltmeters; the receptor cells are modified hair cells and are part of the ►octavolateral sensory system that is responsible for hearing and the sense of equilibrium. Electroreceptor organs are contacted by sensory nerves only.

There are several types of electroreceptive organs. ►Ampullary electroreceptor organs are extremely sensitive to weak gradients of the electric field. The ampullae of Lorenzini of the marine elasmobranch fish have thresholds of about 5 nV/cm, the analogous "►ampullary" receptor organs of freshwater teleosts may reach 1–5 μV/cm maximum sensitivity. Reflecting their different origin, the structure of ampullary electroreceptor cells differs in the various groups: in non-teleosts, they bear a kinocilium, sometimes in addition to microvilli, whereas in electroreceptive teleosts, the secondarily evolved electroreceptor cells have only microvilli, but no kinocilium (Fig. 5).

The ampullary organs as a whole, as well as their teleost analogs, consist of a layer of receptor cells lining an ampulla which is embedded in the skin and connects to the outside by a canal. In marine fish, this canal is long, in fresh-water fish, it is short. The adequate stimulus is the voltage difference between the inside of the skin and the surface of the fish. The lumen of the ampulla and of the canal connecting to the surface is filled with a highly conductive jelly so that the electric potential at the lumenal surface of the receptor cells is almost identical with that on the outside of the skin. Because of the relatively high conductivity of the skin of marine fish, their ampullary canals must be longer than those of freshwater fish to achieve similar sensitivity. Also, whereas the ampullary organs of the ancestral forms of vertebrates are stimulated by negative voltages on the outer skin, those of teleosts are stimulated by positive voltages.

Animals with ampullary organs make use of their high sensitivity to detect minute changes in the ambient electric field, thereby locating prey by detecting the normal electric activity of living organisms, like prey buried in sand or active at night. The detection of electric fields that are produced by other organisms rather than the animal itself is called ►passive electrolocation. Orientation responses along local electric fields, even magnetoreception based on the voltage induced by moving in various directions with respect to the geomagnetic field have been described (see above).

Most ►Electrogenic fishes are not only sensitive to ambient electric fields, but also generate their own



**Magnetic and Electric Senses. Figure 5** Ampullary electroreceptor cells (*RC*) of nonteleosts (a) bear an apical kinocilium (*KC*), sometimes in addition to microvilli (*MV*), whereas electroreceptive teleosts (b) have only microvilli and no kinocilium. The spontaneously active, afferent nerve fibers (*N*) increase their firing rate when the electrical stimulus (in this case a square-wave pulse of 200 ms) is positive outside the ampulla in teleosts, while in nonteleosts a negative stimulus is required for a similar response (from [36] modified).

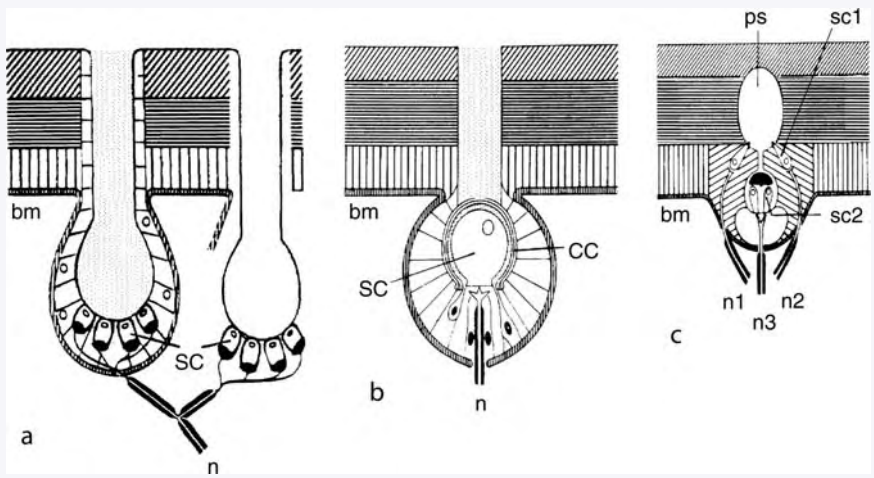
electric fields by specialized ►electric organs (see entry "Electric fish"). Any living tissue generates ►electric fields of low intensity by maintaining the ionic balance of its cells, and by field potentials from nerve and muscle activity; these fields' strength ranges from 0.5 mV to several mV (as measured between the body and a distant electrode). Electrogenic fish, however, possess electric organs consisting of orderly arranged, closely packed groups of modified muscle cells (nerve endings in one taxon). These fishes can discharge their electric organs in a controlled way; thereby producing electric fields ranging from a few mV up to 500 V. Electrogenic fish are found among both cartilaginous and bony fishes; prominent examples for species producing strong electric fields are the electric rays (genus *Torpedo*) and the electric eel (*Electrophorus electricus*).

The rhythmic discharge of electric organs (►EOD) generates species-characteristic electric signals that are highly stereotyped (see entry "►Electric organ discharge"). Among the teleosts, both gymnotiform and mormyriform fish have a second type of electrosensitive receptor organ besides the ampullary organs, namely ►tuberous electroreceptor organs. These receptor organs are specifically tuned to the frequency spectrum (15–20,000 Hz, depending on the species) generated by the discharge of their own electric organ.

The ►tuberous electroreceptor organs occur in two types: one acts as ►time marker unit of high sensitivity and short and constant latency, whereas the other type acts as ►amplitude coder that is relatively insensitive in absolute terms, but encodes minute changes in the intensity of the fishes' own electric organ discharges. Like ampullary receptor organs, ►tuberous receptor organs are located in the skin and form part of the ►lateral line system whose afferences project to the ►electrosensory lobe of the lateral line (ELL). With these tuberous electroreceptor organs, the fish detects impedance inhomogeneities in its environment by recording the associated modulations of their electric organ discharges in amplitude and phase. Thus, these fishes are capable of active electrolocation. Probably the predominant function of producing and perceiving electric fields is ►electrocommunication. With their electric organs, fishes produce signals either of the pulse- or the wave type that can be perceived and decoded by their neighbors (see entry "Electrocommunication and Electrolocation").

The tuberous electroreceptor organs of the African Mormyridae are the ►knollenorgane and the ►mormyromasts (Fig. 6).

Knollenorgane fire one action-potential per EOD pulse. As the mormyrid fish brain blanks the reafferences from self-generated electric organ discharges, only the pulses from other fish gain access to the higher centers of the brain. Knollenorgane thus serve electrocommunication. The second type of tuberous electroreceptor organ, the mormyromasts, has a higher threshold and therefore responds primarily to the fish's own EODs (those of other fish being centrally blanked); they appear to be primarily responsible for active electrolocation. Mormyromasts comprise two kinds of electroreceptor cell that are innervated separately. Mormyromasts are capable of coding for both resistive



**Magnetic and Electric Senses. Figure 6** Schematic electroreceptor organs in freshwater teleosts, located in invaginations (or ampullae) of the epidermis. (a) Small pit organ, the teleost equivalent of the ampullary electroreceptor organ of similar structure that is common to all classes of lower aquatic vertebrates (but lacking in neopterygians, including teleosts). (b) Knollenorgan, one kind of tuberous electroreceptor organ present in mormyrid fish. (c) Mormyromast, the other kind of tuberous electroreceptor organ in mormyrid fish [33].

and capacitive loads associated with nearby objects, and fish can discriminate between live and dead material by their difference in capacitive impedance.

The central-nervous processing of information from the various types of electric organ takes place in different structures of the brain; e.g., the input from mormyromasts and knollenorgane, involving active electrolocation and ►communication, are processed separately. In gymnotiform fishes, many of which generate discharges of the wave type, electrosensory reafferences are encoding time (phase) and amplitude (of the wave discharge envelope) by different receptor organs whose afferences are processed separately by different parts of the brain, analogous to the hearing system of other vertebrates. This separate neuronal processing of phase- and amplitude information is thought by one theory (theory I) to be important for the so-called "►jamming avoidance response" (JAR) that was mainly studied in the gymnotiform wave fish *Eigenmannia virescens.* A fish will tend to shift its own discharge frequency away from a stimulus too close in frequency such that the two signals beat against each other faster, in an attempt to restore its active electrolocation performance (according to theory I; see entry ►Temporal coding in electroreception). By contrast, theory II stresses that the jamming avoidance behavior has long been shown to be sexually dimorphic and to differ between juveniles and adults, and envisions its sensory mechanism and functional adaptation to be radically different (for aspects of theory II, see also entry ►Electric communication and electrolocation). For example, incompatible with theory I is the observation that the JAR threshold is identical to stimulus detection threshold, that is, it is defined by the more sensitive ►T receptor organs. Consequently, phase (timing) information (that is coded for by the ►T receptor organs) has been found to be both necessary and sufficient for evoking and guiding the JAR, and information on amplitude modulation of the beat envelope from the rather insensitive P receptor organs is not available in the threshold range and well above (as would be required by theory I, but not theory II; P receptor organs or probability coders report the amplitude modulation of the EOD by a stimulus of similar frequency only at sufficiently strong modulation depth, that is, sufficiently strong stimulus/EOD intensity ratios). Furthermore, the JAR may be evoked by a stimulus of exactly the fish's own frequency (that is, the frequency difference equals 0 Hz), even when maintained dynamically constant by a frequency clamp; an observation theory I cannot explain but which does not present a problem for theory II. According to theory II, by purely temporal analysis of beat features, the zero-crossings times of the individual oscillations within a beat wave that are reported by T receptor organs, the fish extracts (i) the strength of the stimulus signal harmonic closest to its own fundamental discharge frequency (only that stimulus harmonic is driving the JAR), (ii) the frequency difference and its sign, (iii) the waveform of the stimulus signal. The JAR is thought by theory I to support active electrolocation in the presence of "jamming" conspecifics in the near field (the reach of active electrolocation is limited to a few cm). Theory II, however, has demonstrated that the JAR supports electrocommunication and the detection of EOD waveforms generated by neighbors from a much greater distance (far field sensitivity). This discussion exemplifies the dual nature of the electric system that is adapted for both functions.

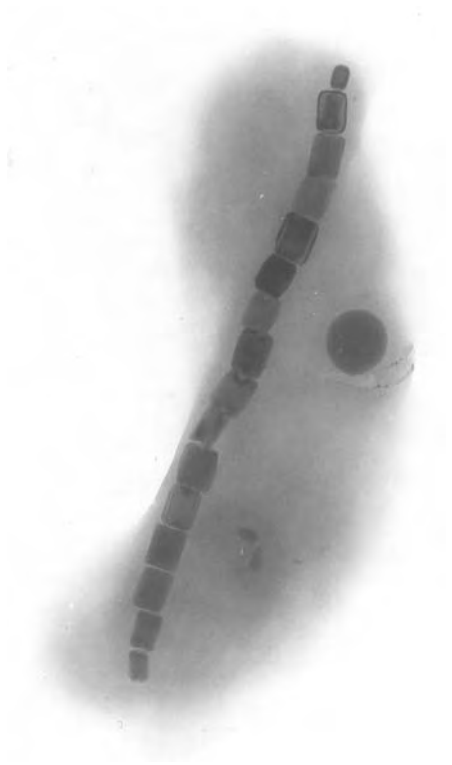
## Synonyms

Magnetotactic bacteria

## Definition

Magnetic bacteria are a morphologically and phylogenetically diverse group of motile Gram-negative prokaryotes. Their common feature is intra-cellular ►ferrimagnetic crystals, made of ►magnetite ($Fe_3O_4$) or ►greigite ($Fe_3S_4$), called magnetosomes. Rather than being ingested from food, magnetosomes are synthesized within the cell and are most often arranged in a single chain or two chains, apparently fixed within the cell (Fig. 1).

A chain of magnetosomes carries a permanent ►magnetic moment and thus acts as an internal compass needle, rotating the cell into alignment with the geomagnetic field axis. Due to this magnetic torque, magnetic bacteria are constrained to move along magnetic field lines when swimming. They are actively motile rather than being pulled or pushed by the magnetic field. Magnetic bacteria can move both parallel and antiparallel to the magnetic field, corresponding to downward (north seeking) and upward (south seeking) motions in the ►geomagnetic field, which has inclined lines of forces except at the magnetic equator, where field lines are horizontal. Their magnetically enforced one-dimensional locomotion, makes magnetic bacteria highly



**Magnetic Bacteria. Figure 1** Wildtype magnetic vibroid bacterium. The cell contains a linear chain of magnetite crystals, so-called magnetosomes. The chain length is 2 μm, the average length of the magnetosomes is 120 nm. Note that the magnetite crystals at the ends of the chain are smaller than average and therefore may represent nascent crystals. Courtesy of M. Hanzlik.

efficient at migrating to suitable chemical conditions in a vertically stratified water column or sediment, and so gives magnetic bacteria an advantage over their nonmagnetic counterparts that pursue purely chemotactic strategies such as run-and-tumble. The behaviour of magnetic bacteria is often referred to as ►magnetotaxis, which is misleading by implying motion as a *reflex* action to a magnetic field, and ignoring the fact that magnetic orientation in magnetic bacteria is a passive process. Stimuli to which magnetic bacteria react instead are high or low concentrations of free oxygen. It is therefore more appropriate to speak of magnetically assisted ►aerotaxis.

## Characteristics

Magnetic bacteria, discovered by Salvatore Bellini in the late 1950s, are widespread in both marine and freshwater habitats (see [1] for a review), and have even been identified in soils. They usually occur at zones where the gradients of oxygen or sulphide concentration are steepest, be it in the topmost few centimetres of lake sediments or deep-sea sediments, or be it at the oxic-anoxic-transition-zone (OATZ) within a chemically stratified water column as encountered in poorly ventilated marine environments.

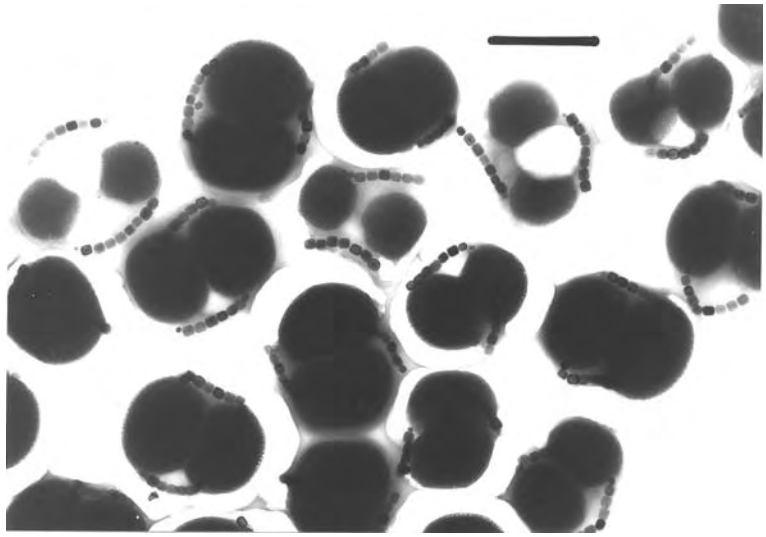
## Behaviour

The behaviour of magnetic bacteria from sedimentary habitats has not been accessible to *in situ* observations, and has had to be inferred from *in vitro* experiments under the light microscope. The easiest way to study magnetic bacteria is to place a wet sediment sample on a microscope slide and apply a horizontal magnetic field. Magnetic bacteria then swim out of the sediment and eventually collect at the edge of the sample. The swimming speed varies from one species to another, with magnetic coccoid cells (Fig. 2) being the fastest swimmers (around 100 mm/s). In samples taken from the northern hemisphere, the predominant swimming direction is towards the magnetic North Pole, in samples from the southern hemisphere, movement is towards the magnetic South Pole.

At the geomagnetic equator, where the magnetic field is horizontal, equal numbers of both polarities exist. Despite the hemispherical bias, a small percentage of magnetic bacteria can always be found that swim opposite to the prevailing direction.

The swimming behaviour observed under the light microscope was extrapolated to the natural environment, such that magnetic bacteria tend to swim downward along the downward- and upward-inclined geomagnetic field lines in the northern and southern hemisphere, respectively. This way, displaced magnetic bacteria (by bioturbation, wave action, etc.) are guided back into the sediment by persistently swimming downward until they reach their preferential position in the sediment. Such a unidirectional motility is usually referred to as magnetotaxis.

Other tactic responses may, however, override magnetotaxis. In particular, the notion of magnetotaxis needs to be revised when considering magnetic bacteria from aquatic habitats where the OATZ occurs within the water column. The vertical position of the OATZ in the water column may change seasonally, and magnetic bacteria have to migrate accordingly. To maintain position at the OATZ, magnetic bacteria must be capable of reversing their swimming direction once they have reached the border of their preferred chemical zone. Experimental evidence exists that bi-directional motility is coupled with an oxygen gradient: Spormann and Wolfe [2] observed the formation of a distinct band of actively motile cells (magnetic ►spirillum), with individual cells swimming back and forth within the band, parallel and antiparallel to the magnetic field B. It therefore depends on the oxygen concentration $[O_2]$ if cells swim parallel or antiparallel to B. The observed band was arc-shaped, roughly 60 mm across (cell length ~ 2 mm), and formed at a distance of ~100 mm from an air bubble trapped under the cover slide. The edge of the band nearer to the

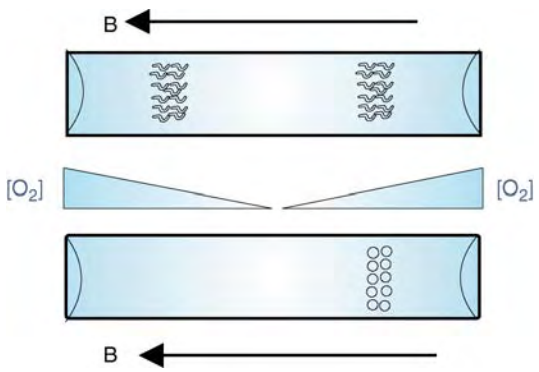


**Magnetic Bacteria. Figure 2** Cells of a wildtype magnetic ►coccus, the most abundant type of magnetic bacterium. A cell usually contains two linear chains of magnetosomes, lying at opposite sides within the cell. Cells have typical diameters of 1.5 µm. The average magnetosome dimensions are 100 nm by 80 nm. The dark globules are inclusions rich in phosphorous and sulphur. Courtesy of M. Hanzlik.

air bubble was more sharply demarcated than the far edge, implying that the tolerance of all cells reach an upper limit for tolerance of oxygen but individually varying lower limits. The role of the magnetic field here is to assist active aerotaxis. This behaviour, therefore, was later referred to as magnetically assisted aerotaxis, or briefly, ►magneto-aerotaxis [3].

A similar experiment by Frankel and co-workers [3] resulted in a further distinction between axial and polar aerotaxis and is summarized in Fig. 3.

In their standard essay, a magnetic field B is directed along a capillary tube, into which oxygen diffuses from the open ends, thereby building up an oxygen-concentration [$O_2$] gradient from the centre of the tube towards each end. While magnetic spirilla form aerotactic bands at both ends (axial magneto-aerotaxis), magnetic cocci from the northern hemisphere form only one band, located at that end of the tube where the [$O_2$] gradient is opposite to B (polar magneto-aerotaxis). While the band of spirilla remain intact after reversal of B, the band of cocci disperses. The reversed-field condition appears to impair their sensing mechanism for aerotaxis, which under normal field conditions triggers reversal in swimming direction.



**Magnetic Bacteria. Figure 3** Axial (*top*) and polar (*bottom*) magneto-aerotaxis. *Top*: Formation of aerotactic bands by spirilla is symmetrical and maps the two microoxic zones in the tube. *Bottom*: Band formation by cocci occurs only in that microoxic zone where the magnetic field direction is opposite to the oxygen-concentration [$O_2$] gradient (after ref. [3]).

## Behaviour and Ecology

The large majority of naturally occurring magnetic bacteria display polar magnetotaxis, with the advantage being that an oxygen gradient is not necessary for efficient orientation in the ►anoxic zone, thereby enabling a rapid return of the cell over large distances to the preferred ►microoxic conditions, without wasting energy by constant movement along gradients [4]. On the other hand, if greater than optimal oxygen concentrations are encountered, the cells - then in an "oxidized state" - will display the typical down-seeking response. Reversing the swimming direction can be accomplished by switching the rotational sense of the flagella. That the sense of flagellar rotation can be

regulated by an oxygen sensory system has been observed in other aerotactic bacteria.

By analogy with sulphide-oxidizing bacteria, it was suggested that magnetic bacteria perform excursions to the anoxic zones of their habitat in order to accumulate reduced sulphur compounds as an electron donor [4]. The bacteria, then in a "reduced state," would again reverse their swimming direction and move up to the microoxic zone where oxygen is available to them as an electron acceptor. In fact, many magnetic bacteria contain inclusions of sulphide (Fig. 2).

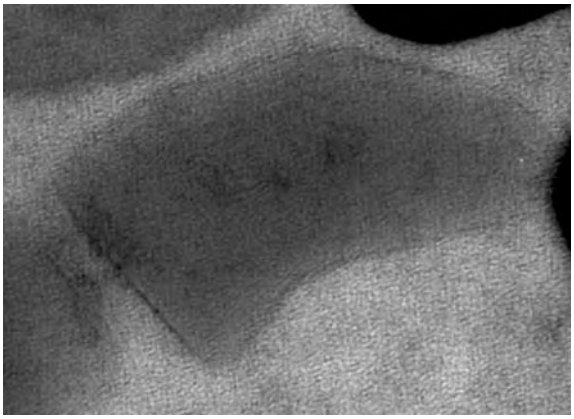
## Magnetosomes

The grain-size and crystal habits of magnetosomes as well as their arrangement within the cell may vary remarkably among the different morphological types of bacteria. Cells from a given strain, however, show little variation in crystal size, habit, and arrangement of chains. This implies that biomineralization of magnetosomes is genetically controlled. The biochemical details of magnetosome synthesis, however, remain elusive. It has been suggested that their biomineralization occurs in membrane vesicles [5], because magnetosomes in many species are enveloped by a bilayer membrane consisting of phospholipids and proteins, at least several of which appear to be unique to this membrane [6]. A vesicle would not only provide chemically stable conditions for magnetosome growth, but could also explain why magnetosomes do not grow above a certain maximum size. On the other hand, the hook-shaped magnetosomes of *Magnetobacterium bavaricum* (Inset in Fig. 4) do not appear to be surrounded by a membrane, and it is possible that magnetite crystals start growing from some template. From growth experiments monitored with Moessbauer spectroscopy [5], it was recently concluded that magentite precipitates directly in empty magnetosome vesciles. This is in contrast to greigite-producing magnetic bacteria, in which a series of non-magnetic phases of approximately FeS composition has been identified as crystalline precursors to ferrimagnetic greigite [7].

## Evolutionary Aspects

Interestingly, magnetite and greigite are the strongest ferrimagnetics of all the naturally occurring iron oxides and iron sulphides, respectively, and it is only these two phases that have consistently been identified in magnetic bacteria. Magnetotaxis obviously gives magnetic bacteria an edge over their nonmagnetic counterparts. If it were only for iron metabolism, there would be no need for the cells to sequester excess iron in a ferromagnetic form.

Not only are magnetosomes made of strong ferrimagnetics, they also appear to be magnetically optimised for the purpose of magnetotaxis: they are magnetic single domains (SD), that is, the magnetization within each magnetosome is uniform and so the magnetic moment of the particle assumes the maximum value attainable. Thus, the available magnetic material is used in the most efficient way.



**Magnetic Bacteria. Figure 4** Magnetobacterium bavaricum. A cell may contain up to a thousand magnetite crystals, which are arranged in several rope-shaped bundles of chains. Inset: The hook-shaped magnetosomes are characteristic of this unusual type of magnetic bacterium. The average magnetosome dimensions are 100 nm by 40 nm. A dark layer at the crystal base may represent a template from which the magnetite crystal may have nucleated. Courtesy of M. Hanzlik.

Magnetic bacteria achieve this magnetic optimisation by limiting the grain size of magnetosomes to values below ~150 nm, while it usually ranges between 40 nm and 120 nm. Above ~ 150 nm, non-uniform magnetization structures develop in magnetite crystals, resulting in lower magnetic moments. This means that magnetic material would be "wasted" by growing magnetosomes much larger than ~ 150 nm. If on the other hand the grain size were below some 30 nm, the particles would be in a ▶superparamagnetic (SP) state and could not carry a stable magnetic moment because of thermal fluctuations constantly buffeting the magnetization, leading to frequent spontaneous magnetization reversals within the particle. A magnetosome chain grows as new magnetosomes are synthesized at either end (see Fig. 1). A newly forming magnetosome has to go through the SP stage (provided that it has already transformed into a ferrimagnetic from the non-magnetic precursory phase), but grows in the magnetic stray field produced by the adjacent, mature magnetosome. As it grows further and eventually crosses the SP-SD threshold size (roughly 30 nm), its magnetization becomes locked in, and so has the same magnetic polarity as the mature magnetosome. By growing

this way, a magnetosome chain will always consist of individual magnetic dipoles pointing in the same direction. That the particles in a chain are all polarized in the same direction has been directly imaged by means of transmission electron holography [8]. In addition to the optimal grain-size range for magnetosomes, there is also a theoretical optimum for the number of magnetosomes per cell: Between 10 and 20 magnetosomes, with a typical grain size of 50 nm, are sufficient to constitute a permanent magnetic dipole strong enough to keep the cells aligned with the comparatively weak geomagnetic field. With the exception of the unusual *M. bavaricum*, which contains up to a thousand magnetosomes per cell (Fig. 4), this optimum is achieved in most types of magnetic bacteria. It is therefore fair to say that magnetic bacteria have evolved their peculiar traits under the influence of the Earth's magnetic field, which prompts the question of how magnetic bacteria adapt to periods of low geomagnetic field strength. In periods of reduced field strength, magnetic bacteria that produce more magnetosomes or grow larger magnetosomes than normal have an advantage. At present, such a scenario is to some extent realized in Rio de Janeiro, Brazil, where the field strength is anomalously low (0.25 G): The magnetosomes in one morphological type of bacterium had average dimensions of 120 nm in length and 110 nm in width, a volume nearly ten times greater than average [9]. Other bacteria from the same region, however, had rather averagely sized magnetosomes in usual numbers per cell. The field strength is obviously not low enough to cause a selection of magnetic bacteria with stronger magnetic moments. If, on the other hand, sediment samples that initially contained magnetic bacteria are kept in a *zero* magnetic field, the population of magnetic bacteria appears to decline rapidly, but it is not known whether magnetic bacteria become extinct or just stop producing magnetosomes, or whether non-magnetic mutants take over. Similar experiments with Northern-hemisphere sediments incubated in *reversed-field* conditions yielded an initial decrease in the population density of magnetic bacteria. With increasing duration of the experiment, South-seeking bacteria emerged in greater numbers and eventually supplanted North-seeking bacteria [10]. Thus, in the case of a geomagnetic field polarity reversal, the few cells in a natural population that have wrong polarity, (such as due to a malfunction in cell division) can take over and guarantee the survival of the species. That applies to polarily magnetoaerotactic bacteria, whereas "two-way swimmers" (axial magnetoaerotaxis) should remain unaffected. However, detailed paleomagnetic records and numerical geodynamo simulations strongly suggest that there is more to a geomagnetic polarity transition than a mere polarity flip. The global change in polarity is often foreshadowed by large directional variations and a period of decreasing field strength down to values of 10% of present-day values or even less, which may last thousands of years. The fossil magnetosome record in sediments analysed thus far is too scarce to clearly monitor adaptation of magnetic bacteria or evolutionary changes. Research is further complicated by the fact that bacterial magnetite, because of the small particle size, is prone to dissolve under increasingly reducing pore-water conditions with increasing burial.

# Magnetic Compass

## Definition

An animal with a magnetic compass has an ability to maintain a heading relative to the Earth's magnetic field (such as a course toward the north or the south).

►Magnetic Map

## Magnetic Displacement Experiments

### Definition

Experiments in which animals are subjected to the magnetic fields that exist in distant geographic areas, with a view toward determining if the animals possess a magnetic map.

►Magnetic Map

## Magnetic Field Inclination

### Definition

The angle formed between the field lines and the surface of the Earth, also known as dip angle.

►Magnetic Map

## Magnetic Map

Kenneth J. Lohmann,
Catherine M. F. Lohmann
Department of Biology, University of North Carolina, Chapel Hill, NC, USA

### Synonyms

Geomagnetic map; Geomagnetic positioning system; Magnetic positioning system; Magnetic position-finding

### Definition

A convenient, shorthand term used to indicate that an animal has the ability to derive positional (as opposed to directional) information from the Earth's magnetic field. The term is now increasingly used in a broad and metaphorical way.

### Characteristics

The Earth's magnetic field provides animals with two potential types of information. The simplest of these is directional or compass information, which enables an animal to maintain a consistent heading in a particular direction such as north or south. Magnetic compasses are phylogenetically widespread and exist in several invertebrate groups, as well as in all major groups of vertebrate animals.

Alone, a compass is often insufficient to guide an animal to a specific destination or to steer it reliably along a long and complex migratory route. For example, a sea turtle migrating through the ocean towards a distant target can be swept off course by currents, and a migratory bird's heading can be altered by wind. Navigation can therefore be enhanced by an ability to determine geographic position along a desired pathway of travel or relative to a destination. For today's humans, this need is usually met through a global positioning system (GPS), which provides users with their geographic position and can also continuously compute the direction to a goal. For some migratory animals, positional information inherent in the Earth's magnetic field provides a similar, although considerably less precise, way of assessing geographic location. Animals that can derive positional information from the Earth's field (as opposed to directional information) are often said to have a ►magnetic map.

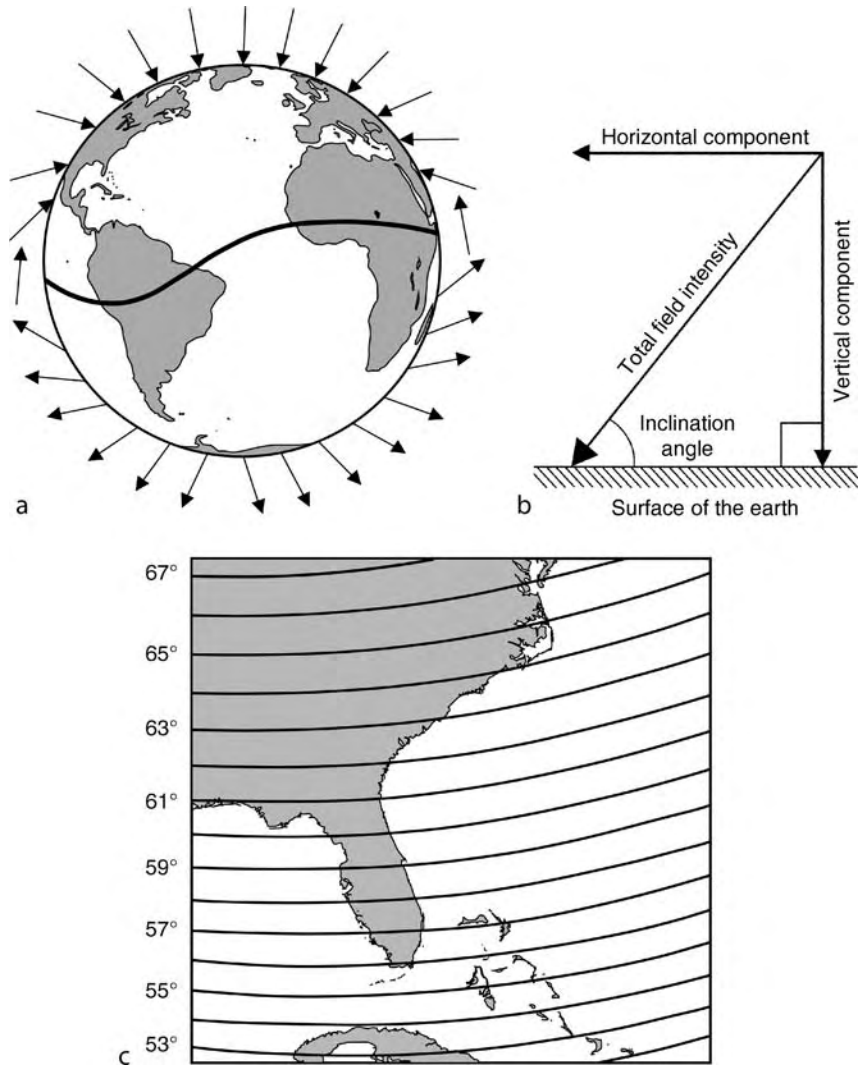
It is important to recognize that the term magnetic map is now increasingly used in a broad and metaphorical way [1,2]. The term does not imply that an animal necessarily has a detailed mental representation in its head equivalent to a human roadmap or high-resolution topographic map. Instead, the information in a magnetic map may be minimal and very general [1]. For example, it might simply tell the animal that it is approximately north or south of the area where it lives (possibly without encoding distance), or that the animal has arrived at a point in a migratory route where it should orient westward. Moreover, information from a magnetic map is often used in combination with other sensory information.

#### Positional Information in the Earth'S Magnetic Field

Several geomagnetic elements vary in a predictable way across the surface of the globe and might hypothetically be used in position-finding [3]. For example, at each location on the earth, the magnetic field lines intersect the earth's field at a specific angle of inclination (Fig. 1).

At the magnetic equator, the field lines are essentially parallel to the Earth's surface and the inclination angle is said to be 0°. The field lines become progressively steeper, however, as one moves toward the magnetic poles; at the poles themselves, the field lines are perpendicular to the Earth's surface. Thus, inclination angle varies predictably with latitude, and an animal able to detect this field element may be able to determine if it is north or south of a particular area.

In addition to inclination angle, at least three other magnetic field elements might hypothetically be used in assessing position. These include: (i) the intensity (strength) of the total field; (ii) the intensity of the horizontal field; (iii) the intensity of the vertical field.



**Magnetic Map. Figure 1** (a) Diagrammatic representation of the Earth's magnetic field illustrating how field lines (represented by *arrows*) intersect the Earth's surface, and how inclination angle (the angle formed between the field lines and the Earth) varies with latitude. At the magnetic equator (the curving line across the Earth), field lines are parallel to the Earth's surface and the inclination angle is 0°. The field lines become progressively steeper as one travels north toward the magnetic pole, where the field lines are directed straight down into the Earth and the inclination angle is 90°. (b) Diagram illustrating four elements of ►geomagnetic field vectors that might, in principle, provide animals with positional information. The field present at each location on Earth can be described in terms of a total field intensity and an inclination angle. The total intensity of the field can be resolved into two vector components: the horizontal field intensity and the vertical field intensity. (Whether animals are able to resolve the total field into vector components, however, is not known.) (c) Map of ►magnetic field inclination along the southeastern coast of the United States. The isolines represent isoclinics (lines of equal magnetic field inclination). In this part of the world the isoclinics trend east-west, while the coastline is aligned approximately north to south. As a result, each area of coastline along the eastern seaboard is marked by a unique inclination angle. A similar pattern exists for the isolines of total intensity. A sea turtle navigating along the east coast to a particular feeding or nesting area might thus hypothetically do so by detecting a single magnetic element such as inclination or intensity [1].

For animals that can perceive the direction of true geographic north (for example, by perceiving the area of the northern hemisphere night sky that does not rotate), additional magnetic parameters such as declination (the difference between true north and magnetic north) might also potentially be used.

The pattern of variation in magnetic field elements differs greatly in different geographic areas and may

thus influence what an animal can do with magnetic positional information in a given situation [1,4]. In some areas, the four magnetic elements listed above vary in similar directions over the surface of the earth. In others, such as the Indian Ocean, the gradients of inclination and intensity are oriented almost perpendicularly, so that each location is marked by a unique magnetic field. Thus, in some areas, an animal might be able to determine its position in only one dimension (for example, whether it is north or south of a goal). In others, bicoordinate magnetic navigation using two elements of the Earth's field might be possible. The matter is further complicated in some areas by the existence of magnetic anomalies arising from geological formations. Whether an animal can use a magnetic map to help solve a given navigational task, and the capabilities and limitations of such a system, may thus be influenced by a complex set of variables that differ among geographic settings.

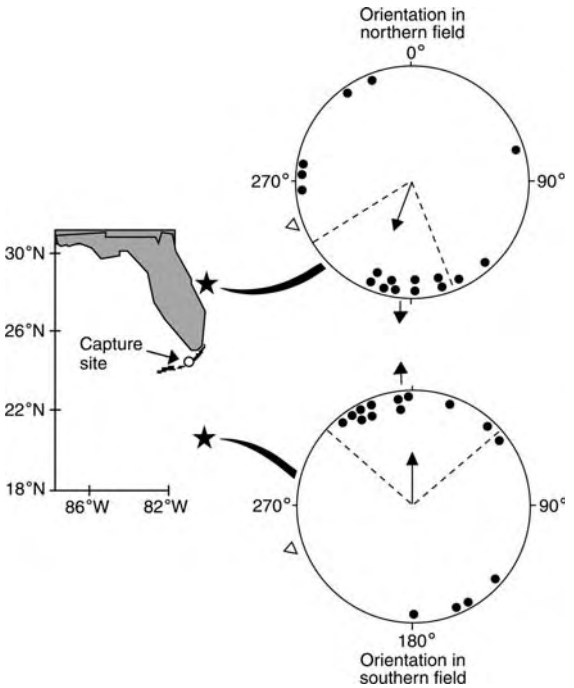
## Experimental Evidence for Magnetic Maps

The idea that animals derive positional information from the Earth's magnetic field was first proposed more than a century ago, but until recently, the concept remained controversial. Several early studies provided indirect correlative evidence consistent with the idea of magnetic maps. For instance, homing pigeons released in areas with slight magnetic anomalies appeared to have difficulty establishing a homeward course, and pigeon orientation was more dispersed on days when solar storms disrupted the Earth's field slightly – enough to potentially interfere with a magnetic map but not enough to affect a ►magnetic compass [3]. These findings generated much discussion, but it was not until researchers began exposing navigating animals to the actual magnetic fields found at different geographic locations that more definitive evidence began to emerge. These "►magnetic displacement experiments" provide a powerful tool for investigating magnetic maps because they do not involve physically displacing animals to new areas where numerous cues and factors may vary. Instead, animals can be tested under carefully controlled laboratory conditions in which only the magnetic field is altered.

Among animals that home to specific areas, the most compelling evidence for magnetic maps has come from studies with spiny lobsters [5], juvenile sea turtles [6], and newts [7]. Spiny lobsters inhabit dens in coral reefs and forage out from them at night, often returning to the same den before sunrise. These lobsters are capable of "true navigation," meaning that they can determine the direction to a capture site even if displaced to locations where they have never been. In one experiment [5], lobsters captured in their dens were taken to a nearby arena surrounded by a magnetic coil system that could be used to generate magnetic fields replicating those found in distant geographic locations. Lobsters exposed to a field that exists approximately 400 km north of the testing site oriented southward, whereas those exposed to a field that exists approximately 400 km south of the testing site oriented northward (Fig. 2).

In effect, the lobsters were apparently tricked into thinking that they were at distant locations when they encountered the magnetic fields that exist at those sites. These results provide strong evidence that lobsters have a magnetic positioning system that enables them, at a minimum, to determine if they are north or south of their goal.

Similar results have been obtained with juvenile green sea turtles [6]. After several years in the open ocean, these young turtles return to the southeastern



**Magnetic Map. Figure 2** Evidence for a magnetic map in spiny lobsters (*Panulirus argus*). Lobsters from the middle Florida Keys were subjected to magnetic fields that exist in locations north or south of the location where they were captured. Lobsters subjected to the field from the northern site oriented approximately southward, whereas those exposed to the field from the southern site crawled approximately north. The *open triangle* outside each orientation diagram indicates the actual direction to the capture site from the test site. In each case, lobsters responded as if they had been displaced to the locations marked by the stars rather than orienting in the direction that was actually toward the capture site. The *arrow* in the center of each circle represents the mean angle of the group. *Dashed lines* represent the 95% confidence interval for the mean angle. Figure is modified from [5].

M

coast of the United States to take up residence in feeding grounds. Turtles are known to return to these locations after experimental displacements and long seasonal migrations. In a recent experiment, turtles captured in their feeding grounds were tethered in an arena and exposed to magnetic fields that exist at locations north or south of their home areas. As with the lobsters, turtles exposed to a field that exists north of the capture site oriented southward, whereas those exposed to a field south of the capture site oriented northward. Thus, juvenile turtles evidently possess a magnetic map which permits an assessment of position relative to specific geographic destinations.

Sea turtles and spiny lobsters migrate over considerable distances, but a magnetic map may also exist in a kind of salamander that moves only over distances of about 1–3 km. Red-spotted newts exposed to an inclination angle found far north of their home area oriented southward, whereas those exposed to an inclination angle found south of their home area walked northward [7]. Although the fields used in these experiments did not precisely match those that exist in nature, these initial results are consistent with the hypothesis that newts, like lobsters and sea turtles, also have some type of magnetic map.

## Magnetic Maps and Migratory Pathways

Positional information in the Earth's magnetic field is also used by some animals during long-distance migrations that do not involve well-defined endpoints such as a particular home site. For example, young loggerhead sea turtles (*Caretta caretta*) from Florida, U.S.A., do not live in coastal feeding areas as older turtles do. Instead, they undertake a circular migration around a large region of the Atlantic Ocean. Newly hatched loggerheads, when exposed to magnetic fields replicating those found in three widely separated oceanic regions, responded by swimming in directions that would, in each case, facilitate movement along the migratory pathway [8]. Thus, young sea turtles appear to inherit responses that enable them, in effect, to exploit regional magnetic fields as navigational markers; such fields elicit changes in swimming direction at crucial geographic boundaries.

A similar use of magnetic positional information occurs in the pied flycatcher *Ficedula hypoleuca*, a migratory bird. Captive flycatchers exposed to a sequence of magnetic fields matching those they normally encounter while migrating shifted orientation in the same direction and at the same time as conspecifics during the natural migration [9]. Such shifts in orientation did not occur in birds maintained in the ambient field at the migration start point, or in birds maintained in a field replicating that at the migratory endpoint. Thus, for the pied flycatcher, the results suggest a complex interaction between an endogenous time program and magnetic parameters, in which the birds must apparently experience sequentially the fields of specific locations at the appropriate times in order to orient appropriately at each point in the migration.

In at least one species of bird, regional magnetic fields appear to act as a behavioral trigger of a different kind. The thrush nightingale *Luscinia luscinia* migrates south across the Saharan desert, a vast region over which food is seldom available. Birds held in Sweden but exposed to a sequence of regional fields along the migratory route, the last from a location just north of the desert, gained significantly more weight than control birds held under identical conditions but in the local Swedish field [10]. Thus, the results imply that a regional field just north of the Sahara, or perhaps a sequence of fields normally encountered during the migration, triggers changes in behavior and physiology that result in the birds accumulating fat needed for their trans-desert flight.

Given the phylogenetic distance between lobsters and the three vertebrate groups known to exploit positional information in the Earth's field, it appears likely that magnetic position-finding has evolved at least twice. Moreover, natural selection has apparently sculpted this ability for multiple uses in different animals, depending upon whether the animal needs to move along a migratory route, navigate to a specific home area, or store fat in preparation for a particularly difficult segment of a migration. The recent nature of these findings suggests that additional investigation will be fruitful, and that researchers have only begun to uncover the ways in which animals exploit magnetic maps.

## Magnetic Resonance Imaging

Peter Fransson
MR Research Center, Cognitive Neurophysiology, Department of Clinical Neuroscience, Karolinska Institute, Stockholm, Sweden

### Definition

Magnetic Resonance Imaging (►MRI) is an imaging method that is based on the principles and properties of water. It uses a combination of magnetic fields and radiofrequency electromagnetic pulses to produce images that show how water, or more precisely hydrogen, is distributed in the human body.

### Purpose

The medical usage of MRI is to locate and diagnose pathological changes in the human body. Recent advances in MRI technology have opened up the possibility of investigating physiological processes. Pertinent examples are measurements of macroscopic flow (MR angiography), in-vivo MR spectroscopy (MRS), perfusion, diffusion of water [►Diffusion weighted magnetic resonance imaging (DW-MRI)] and changes in cerebral hemodynamics related to changes in neuronal activity [►Functional magnetic resonance imaging (fMRI)].

### Principles

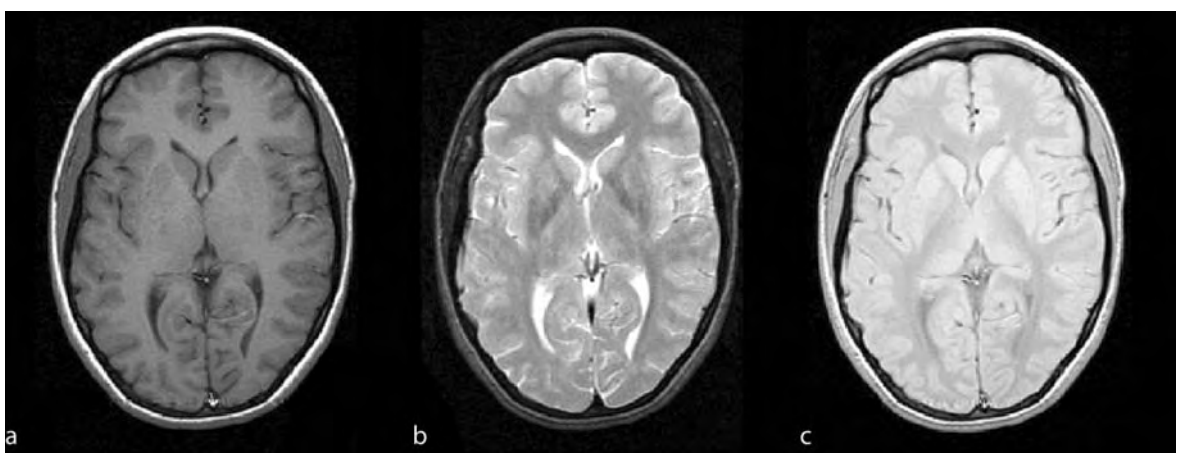
Magnetic Resonance Imaging (MRI) is founded on the same principles as ►Nuclear Magnetic Resonance (NMR), a technique that has been primarily used by chemists to study the three-dimensional structures of chemical compounds since the beginning of the 1950s [1,2]. It should be noted that the NMR phenomena occurs in different atom types, but since virtually all medical imaging is based on the magnetic properties of hydrogen atoms in the human body, this essay will only discuss hydrogen-based MRI.

The hydrogen nucleus consists of a single charged particle. In addition, the proton in the hydrogen nucleus possesses a nuclear magnetic spin, i.e. it spins around its own axis. Together, these properties of the proton entail that each proton behaves like a small magnet, much like a microscopic compass needle with a south and north pole. If protons are positioned in an external magnetic field, the protons will be aligned to the magnetic field, and start to precess around the external field with a precession frequency (►Lamor frequency) that is governed by the strength of the applied magnetic field. A field-strength of 1.5 Tesla, typical for clinical MR scanners, would imply a proton resonance frequency of approximately 63.87 MHz. In the presence of a magnetic field, the ensemble of protons split up into

two different energy levels, where the population of protons in the lower energy level is aligned parallel to the external magnetic field, whereas the population of protons in the high energy level is aligned anti-parallel to the external magnetic field. Subsequently, if a radiofrequency (RF) pulse is applied with a frequency that exactly matches the Lamor frequency of the precessing protons, a subpopulation of protons can be brought to jump from the low to the high energy level. This can be thought of as a process of energy absorption. The uptake of electromagnetic energy from the RF pulse is often called excitation, and it is said that the protons are at "resonance". After RF-excitation, the energy equilibrium between the two energy states is altered and the protons will again strive to reach an equilibrium state. A return to the equilibrium state is accomplished by an emission of energy in the form of a new radiofrequency pulse. This process, in which the protons jump back from the high to the low energy level, is termed relaxation in the MR literature. The emitted energy from the excited protons is subsequently detected as an induced current in a receiver coil, and this current is the basis for the MR signal.

The deciding factor for MR-image contrast between tissue types is the chemical environment for each excited proton. Immediately after RF-excitation, two relaxation processes start simultaneously. First, a net loss of magnetization, i.e. energy dissipation from the protons, is accomplished by a transportation of the extra energy to the surrounding tissue or "lattice" through spin-lattice relaxation (►T1-relaxation). Second, protons will feel the microscopic field from neighboring protons, which in turn causes an exchange of energy between protons. The exchange of energy between neighboring protons is called spin-spin relaxation or ►T2-relaxation. Protons residing in different tissue types have different T1 and T2-relaxation properties. For example, in white brain matter hydrogen is primarily found in the triglyceride chains of fat molecules due to the presence of myelin sheaths. The presence of fat will reduce the T1 and T2-relaxation times in white compared to grey brain matter. The local value of the T1 and T2-relaxation constants are, together with the local concentration of protons (proton density), the major factors that contribute to soft tissue contrast in MR images. The effect of different T1 and T2 relaxation times for the tissue types found in the human brain is shown in Fig. 1.

In order to spatially resolve the MR signal from the object being imaged, magnetic gradients are introduced during the image acquisition process [3]. Applying a magnetic gradient in an arbitrary direction in space implies that the magnetic field strength will vary spatially along the chosen direction. Since the proton precession frequency is proportional to the magnetic field strength, the proton precession (Lamor) frequency will increase or decrease depending on which direction we move along in the magnetic gradient. By applying linear gradients along all three dimensions in space during image acquisition, a spatial encoding is effectively enforced by the fact that the proton precession frequency is now uniquely dependent on its location in space. Hence, the raw data collected during the MRI acquisition takes the form of a sample of its discrete Fourier transform. The final step in the



**Magnetic Resonance Imaging. Figure 1** Images demonstrating the basic image contrast mechanisms available in MRI. Fig. 1a shows a T1-weighted, axial section of human brain where the MR signal is primarily governed by the local T1-relaxation times of the hydrogen atoms that reside in each voxel. Similarly, Fig. 1b shows the typical contrast achieved in a T2-weighted MR image, for the same section as in Fig. 1a, where the MR signal is dependent on the local T2-relaxation time of hydrogen. Note that the image contrast between gray and white brain matter is reversed for the T2-weighted image compared to the T1-weighted image. A proton-density-weighed image where the MR image signal intensity is proportional to the absolute concentration of hydrogen atoms in each voxel is shown in Fig. 1c.

MR image acquisition process is to translate the recorded frequencies to spatial information, and this is performed by reconstructing the images by using the two-dimensional Fourier transform. Virtually any image orientation is possible with MRI by employing pertinent linear combinations of magnetic gradients in the x, y and z-direction. The feasibility to set arbitrary slice orientation profiles is shown in Fig. 2, where a T1-weighted image of the human brain is shown in an axial, coronal and sagittal orientation.

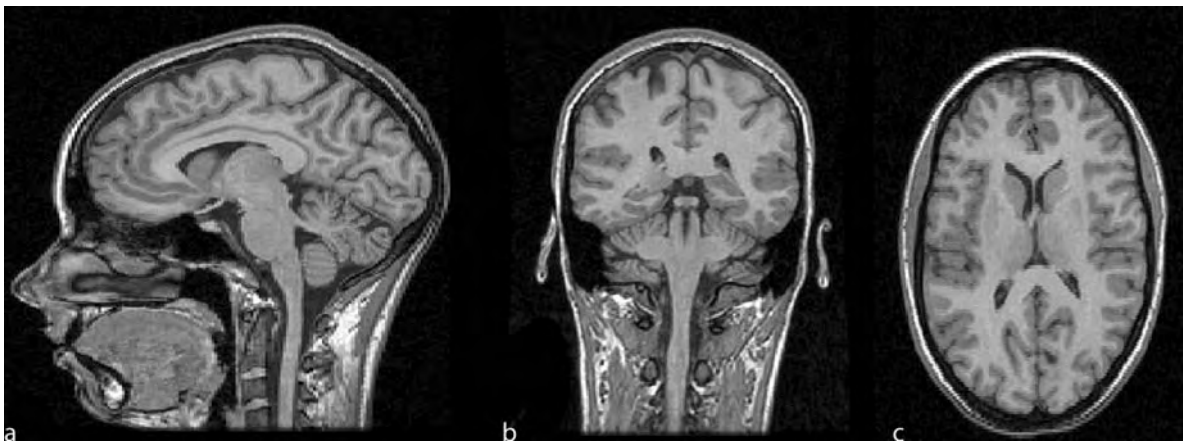
The workhorse in MR imaging is the so called spin-echo sequence [4], which by using two RF-pulses produces superior image contrast and spatial resolution with excellent diagnostic quality. However, conventional spin echo images typically take minutes to acquire. Consequently, throughout the history of Magnetic Resonance Imaging, numerous approaches have been developed to achieve increases in image acquisition speed. The rationale for this work has primarily been to relieve patient discomfort in the MR scanner by reducing scan time. More recently, a second motive for faster image acquisition has been the possibility of monitoring parameters such as perfusion, flow and diffusion. Methodological advances in image acquisition techniques in the mid-eighties such as the FLASH (Fast Low Angle Shot) gradient echo [5] and the RARE (Rapid Acquisition with Relaxation Enhancement) spin echo technique [6] decreased the scan time ten-fold. Ultra-rapid image acquisition schemes such as ►EPI (Echo-Planar Imaging), which allows single image acquisition in a tenth of a second, were conceived in 1977 [7] but it was not possible to make it available on a commercial scale until rather recently due to high demands on magnetic gradient hardware.

## Advantages and Disadvantages

During the last decades, MRI has expanded its usability to include the ability to examine and record physiological parameters in the brain. Two examples are given below:

### Functional MRI

MRI has recently become an important research tool in the field of cognitive neuroscience. In 1990, Seiji Ogawa and colleagues discovered the MR contrast mechanism that is commonly referred to as BOLD fMRI [8]. ►BOLD (Blood Oxygenation Level Dependent) imaging takes advantage of the fact that hemoglobin, which contains four iron ions, has different magnetic properties depending on whether it has an oxygen molecule attached to it or not. If oxygen is attached to an hemoglobin molecule, it is called oxy-hemoglobin and is slightly diamagnetically similar to the rest of the human body, and thus does not interact with an externally applied magnetic field. However, if the hemoglobin molecule has released its oxygen to the surrounding tissue, it is paramagnetic and called deoxy-hemoglobin. Consequently, a deoxy-hemoglobin molecule in the presence of a magnetic field will cause a local, microscopic inhomogeneity of the magnetic field. This inhomogeneity leads to a change in resonance frequency of the hydrogen atoms in the immediate vicinity of the deoxy-hemoglobin molecule. The deoxy-hemoglobin induced local change in resonance frequency will in turn lead to a reduction in the local MR signal intensity. However, since the increase in cerebral blood flow upon an increase in neuronal activity is much larger than the increase in oxygen consumption, the net result is an MR signal increase due to a wash-out of paramagnetic deoxy-hemoglobin. By employing fast



**Magnetic Resonance Imaging. Figure 2** High-resolution, T1-weighted MR images of a human brain in (a) sagittal, (b) coronal, and (c) axial slice orientations. An arbitrary spatial image orientation is possible in MRI through pertinent choices of linear combinations of magnetic gradients applied in the x, y and z-direction during image acquisition.

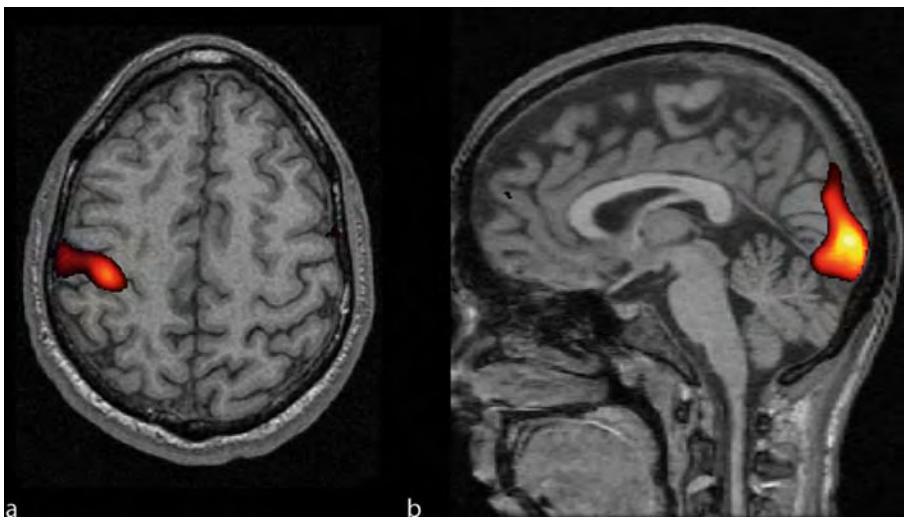
MR acquisition schemes such as echo-planar imaging [7], the whole brain can be scanned in 2–3 s with BOLD sensitivity. Thus, fMRI is usually performed by repeated echo-planar image acquisitions, which provide the possibility of detecting changes in hemodynamic activity that follow changes in external stimuli and/or cognitive processing. Examples of functional Magnetic Resonance Imaging for stimulation of the visual and motor systems in the human brain are given in Fig. 3.

## Diffusion Weighted Imaging and Diffusion Tensor Imaging

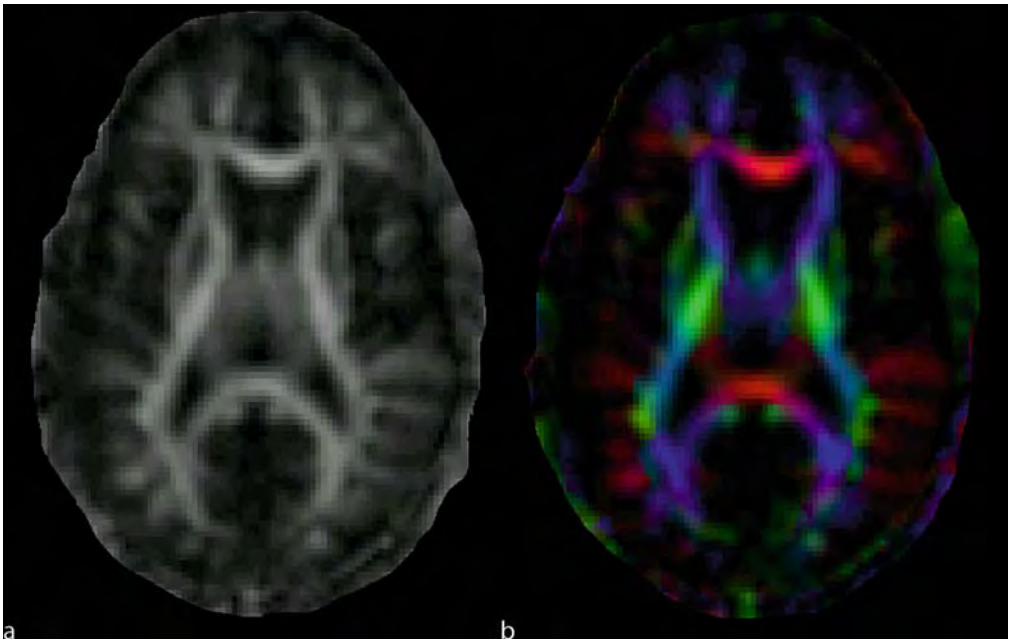
Another rather recent addition to the family of MRI techniques aimed at investigation of human physiology is diffusion-weighted MRI (DW-MRI) [9]. Image contrast in DW-MRI is based on differences in diffusivity of water molecules in the human body (random translational movement of molecules based on Brownian motion). For example, diffusional movement of water is relatively more restricted by cellular membranes in gray and white brain matter compared to cerebrospinal fluid. MR imaging sequences can be made sensitive to differences in diffusional movement by including additional magnetic gradients that encode for movement along an arbitrarily chosen spatial direction. Thus, the mechanism behind DW-MRI is that the MR signal from stationary hydrogen atoms is not affected by the additional gradients, whereas the MR signal from hydrogen atoms moving along the direction of the applied diffusion encoding gradient will be reduced. Moreover, the signal reduction for moving hydrogen is proportional to the speed of movement. If no preferred direction exists for diffusion of water, e.g. in cerebrospinal fluid, diffusion is said to be isotropic. That is, the size of diffusional movement is similar in all directions. However, water diffusion can also be anisotropic. This is the case for water in white matter tracts, where the movement of water is much less restricted along a line parallel to the fiber bundles compared to an orthogonal direction. A complete characterization of the spatial distributions of diffusional movement in each image voxel can be obtained by measuring the so-called ►diffusion tensor (DT-MRI). Diffusion tensor calculations require at least seven (six different directions and one image acquisition measurement without any diffusion gradients) separate MR image acquisitions. An average value of diffusion anisotropy based on diffusion tensor calculations is usually displayed using a scalar value such as the fractional anisotropy (FA) index, which shows the magnitude of the diffusion tensor that can be attributed to anisotropic diffusion (Fig. 4a). The spatial direction of the diffusion tensor can be indicated by using a color-coding scheme as depicted in Fig. 4b, where, for example, the color red indicates fibers running in the left-right direction (genu and splenum part of the corpus callosum).

## Limitations

Since the MRI technique is based on the usage of strong magnetic fields, caution must be exercised when bringing



**Magnetic Resonance Imaging. Figure 3** Color-coded statistical parametrical maps superimposed on anatomical T1-weighted MR images showing significant functional activation of the motor cortex (a) and the primary visual cortex (b) using the functional Magnetic Resonance Imaging (fMRI) technique. fMRI was used to record changes in neuronal activity as observed by local changes in blood oxygenation (Blood Oxygenation Level Dependent, BOLD) for either right hand finger-thumb opposition versus rest (a) or presentation of a visual, flickering checkerboard versus darkness (b).



**Magnetic Resonance Imaging. Figure 4** Water diffusion anisotropy in an axial section of the human brain measured with Diffusion Tensor Magnetic Resonance Imaging (DT-MRI). The mean degree of anisotropy is shown as an FA-map (Fractional Anisotropy) in Fig. 4a, where the white matter fiber tracts show a high degree of diffusional anisotropy due to the parallel arrangement of fiber bundles in white brain matter. The spatial orientation of the diffusion tensor for the same section is shown in Fig. 4b, where color represents the preferred direction of diffusion of water molecules, predominantly in white fiber tracts (red: left-right, blue: anterior-posterior, and green: inferior-superior). Courtesy of Zoltan Nagy.

metal objects into the MR scanner room. All ferromagnetic objects will experience both a translational force and a twisting force (torque) in the presence of the magnetic field created by the MR scanner. Moreover, the magnetic field may compromise the function of cardiac pacemakers. In addition, non-ferromagnetic metal objects will produce inhomogeneities in the vicinity of the magnetic field causing in-plane signal displacement and signal drop-out. These image artefacts are called susceptibility-induced image artifacts, and are also present in air-tissue interfaces, e.g. near the ear canals and the nasal cavities. This is a particular problem for functional MRI that is sensitive to macroscopic (tissue-air interfaces) as well as microscopic (deoxy-hemoglobin) magnetic field inhomogeneities.

## Definition

Magnetite is a ferrimagnetic mineral with chemical formula $Fe_3O_4$.

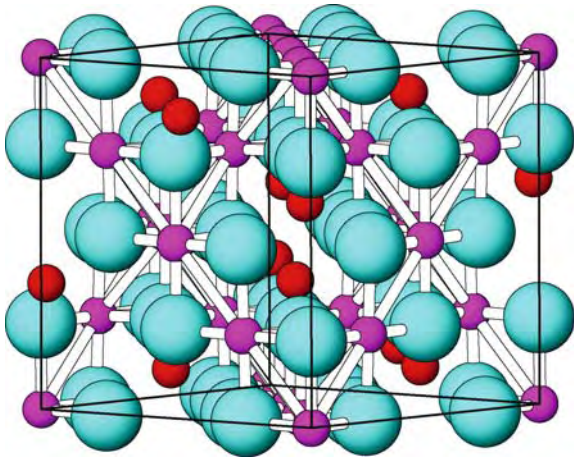
## Characteristics

### Occurrence

Magnetite (empirical formula $Fe_3O_4$) is the oldest magnetic mineral known to man. Being the most abundant magnetic mineral in terrestrial rocks of igneous and metamorphic origin, magnetite has helped paleomagnetists to reconstruct the ancient geomagnetic field from rocks, and with it, the past positions of the continents on the globe. As an ore, magnetite is economically valuable, containing 72 wt% of iron. In sediments, magnetite may be of detrital (inorganic) or biogenic origin. Magnetic bacteria, algae, and some higher organisms such as molluscs have been shown to synthesize magnetite of high chemical purity, although the biochemical pathways of biogenic magnetite formation remain to be elucidated. Magnetite may form the basis of a magnetic-field receptor in homing pigeons and migratory animals. Magnetite is also technically important in electrochemical applications (electrodes, catalysts) and magnetic storage media. Owing to its half-metallic character and high ►Curie temperature, magnetite is currently being considered for spintronic applications.

### Crystal Structure and Ferrimagnetism

The mixed-valence iron oxide magnetite (structural formula $FeO{\cdot}Fe_2O_3$) crystallizes in the inverse ►spinel structure, i.e., $(8\ Fe^{3+})^{[4]}[8\ Fe^{2+} + 8\ Fe^{3+}]^{[6]}\ 32\ O^{2-}$, with () and [] denoting tetrahedrally and octahedrally coordinated sites (A and B sites), respectively (Fig. 1).



**Magnetite. Figure 1** Lattice structure of magnetite. *Green*: Oxygen anions; *red*: tetrahedral sites; *pink*: octahedral sites (courtesy of Dr. R. Pentcheva). The cube defines the system of the crystallographical ⟨100⟩ axes.

The unit cell (edge length 8.396 Å) is a cubic-close packed lattice of 32 oxygen anions (8 formula units), which are slightly distorted toward the octahedral interstices to accommodate a third of the iron cations on tetrahedral interstices. The 16 B sites per unit cell (p.u.c.) are occupied by an equal number of randomly distributed $Fe^{2+}$ and $Fe^{3+}$ cations, and the remaining 8 $Fe^{3+}$ cations p.u.c. are on A sites. The A-site moments are aligned anti-parallel to the B-site moments, neutralizing the magnetic spin moment of the $Fe^{3+}$ cations in the B-sites. The net magnetic spin moment is therefore carried by the $Fe^{2+}$, resulting in a net magnetic spin moment of exactly 4 $\mu_B$ (►Bohr magneton) per formula unit $Fe_3O_4$. A small contribution from the orbital moments results in a total magnetic moment of 4.07 $\mu_B$ per formula unit $Fe_3O_4$ (value extrapolated to 0 K). This ferrimagnetic structure of magnetite was first suggested by Néel [1] and later confirmed by neutron scattering experiments.

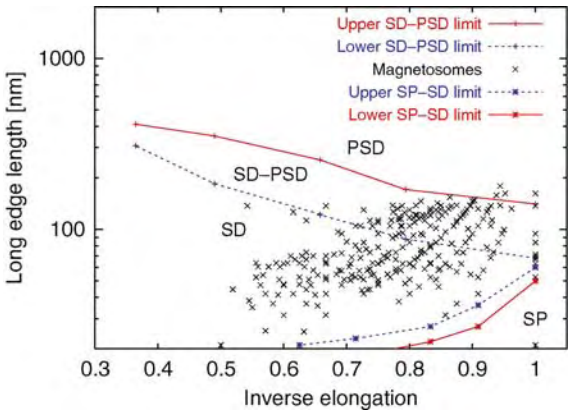
The ►ferrimagnetism of magnetite breaks down at a critical temperature of $T_C = 580°C$ (Curie temperature), above which magnetite is paramagnetic. At $T_V = 125$ K, magnetite undergoes a first-order phase transition, the so-called ►Verwey transition, below which the $Fe^{2+}$ and $Fe^{3+}$ cations on octahedral sites order, and so reduce the symmetry of the lattice from cubic to monoclinic. On warming through $T_V$, the electrical conductivity of magnetite increases by two orders of magnitude. The black color of magnetite, as well as its moderate electrical conductivity above $T_V$, is due to electron hopping between the $Fe^{2+}$ and $Fe^{3+}$ cations in the octahedral sites, that is, the cations exchange their valence between the +II (ferrous) and +III (ferric) oxidation states. The temperature of the Verwey

transition decreases with increasing oxidation parameter δ in $Fe_{3(1-\delta)}O_4$. The fully oxidized form of magnetite with δ = 1/9, called maghemite (formula unit $Fe_2O_3$), does not undergo a Verwey transition, but is an electrical insulator and roughly 10% less magnetic than stoichiometrically pure magnetite. The unit cell of maghemite has a defect spinel structure and can formally be written as $(8\ Fe^{3+})^{[4]}[40/3\ Fe^{3+} + 8/3\ ]^{[6]}\ 32O^{2-}$, where stands for a lattice vacancy. If ordered on a tetragonal superlattice, the vacancies in the maghemite lattice give rise to additional reflexes in X-ray diffraction (XRD), by which maghemite can be distinguished from stoichiometrically pure magnetite. However, not all maghemite crystals show vacancy ordering, and the unit-cell parameter reported in the literature ranges from 8.330 Å to 8.340 Å, reflecting differences in how the samples were synthesized or in the precursory minerals (magnetite or iron-oxyhydroxides, FeOOH) from which maghemite is naturally formed.

From the above, it is clear that discrimination between magnetite and maghemite may not always be straightforward by means of diffraction methods. The situation is even more complicated when it comes to identifying tiny amounts of magnetic material in tissue [2]. The amount of material in tissue is not sufficient for XRD (let alone spectroscopical techniques such as Moessbauer spectroscopy) and electron diffraction, as the only remaining crystallographical identification technique is not accurate enough to resolve the small differences in lattice spacing between magnetite and maghemite. Here, magnetometric measurements can be used to further constrain the nature of the magnetic material (see below).

## Domain State

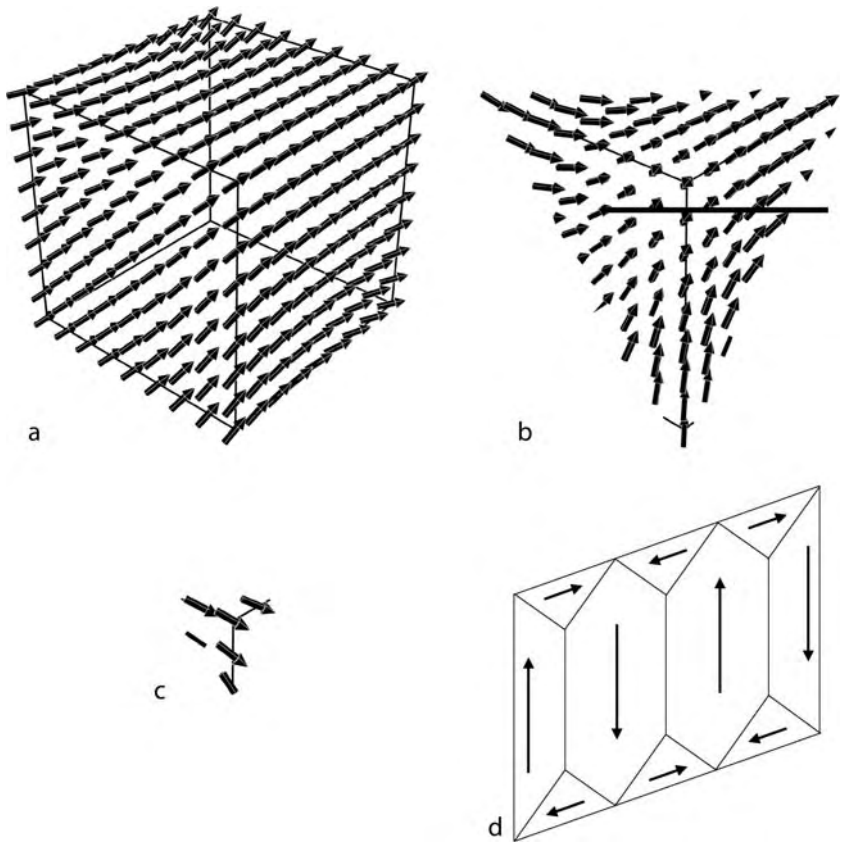
Magnetic properties of magnetite crystals such as ►magnetic remanence and coercive force are largely controlled by domain state, which in turn depends upon grain size and shape. Figure 2 shows a magnetic phase diagram for submicron-sized single crystals of magnetite as a function of grain size and axial ratio, calculated with a micromagnetic model [3,4]. Magnetite cubes with an edge length smaller than 68 nm are magnetic single domains (SD) and so have a nearly uniform magnetization structure (Fig. 3a). Departures from the uniform magnetization structure near the corners and edges of the cubes become larger with increasing grain size (Fig. 3a,b). As the grain size increases above 68 nm, however, SD magnetization states become energetically less favorable, but can still exist up to a threshold edge length of 140 nm (Fig. 2), where they finally give way to non-uniform magnetization structures such as magnetic vortices (Fig. 3c).



**Magnetite. Figure 2** Phase diagram for magnetic domain state in submicron-sized rectangular crystals of magnetite as a function of axial ratio (width/length) and long edge length calculated for room temperature (according to [3,4]). The upper two lines demarcate the stability of single domain (SD) magnetization states against pseudo-single-domain (PSD) states [3], the lower two lines against superparamagnetic behavior [4]. The crosses represent data from edge-length measurements on magnetite particles (magnetosomes) in magnetic bacteria [5]. With a few exceptions, magnetosomes fall into the stable SD field or in the field where SD states coexist with vortex states (SD–PSD field).

In a magnetic vortex, the magnetization structure is curling, thereby efficiently reducing the stray field outside the particle, however, at the expense of the magnetic moment. Particles containing such magnetic swirls are also referred to as pseudo-single-domain (PSD) particles. Magnetite crystals with grain sizes larger than 1 μm host several uniformly magnetized, lamellar domains (multi-domain, or "MD" particles) with adjacent domains in the interior having opposite polarity (see Fig. 3d).

While single-domain particles carry the maximum magnetic moment per particle volume (►saturation magnetization), the specific magnetic moment of a vortex decreases rapidly with grain size [3], and is nearly zero in MD particles. For the purpose of magnetotaxis, in magnetic bacteria it is therefore most efficient to have SD particles. This can be achieved by limiting the particle size to 140 nm and by increasing the particle elongation. It therefore comes as no surprise that magnetite crystals in magnetic bacteria, so-called magnetosomes, usually have grain sizes below 140 nm and are elongated [5]. It is true that vortex states are energetically more favorable in magnetite cubes with an edge length greater than 68 nm, but one has to bear in mind that the magnetization in growing magnetosomes already occupies a SD state, as the particle size exceeds the threshold of 68 nm.



**Magnetite. Figure 3** Domain state in submicron-sized cubes of magnetite as defined by the magnetization structure: (a) single-domain (SD) state with nearly uniform magnetization; (b) SD "flower" state; (c) pseudo-single-domain (PSD) state containing a spin-curling structure (vortex). For comparison (d) shows a cross section (viewing plane 110) through a multi-domain (MD) magnetite (grain size >1 μm), which contains lamellar magnetic domains and so-called closure domains near the surface to minimize magnetic pole density on the surface.

There are energy barriers preventing the (metastable) SD state from collapsing into a vortex, up to a critical size of 140 nm. That the magnetization in magnetosomes from the SD–PSD field is SD has convincingly been demonstrated by transmission electron holography [6]. Likewise, it is necessary to emphasize that the magnetic phase diagrams were calculated for isolated crystals in zero external field. Magnetosomes are usually arranged in chains, and so strongly magnetically interact. The interactions are such that the SD state will be stabilized.

## Superparamagnetism

If, on the other hand, the edge-length becomes less than some 50 nm, magnetite cubes cannot retain a temporally stable SD magnetization at room temperature because the magnetization structure is constantly buffeted by thermal fluctuations, leading to frequent spontaneous magnetization reversals in the particle. Such behavior is called Néel superparamagnetism. In a magnetic field, an assemblage of SP particles carries a magnetization, which will decay logarithmically with time after the magnetic field is switched off. Although ►superparamagnetism does not represent a true domain state but rather describes a thermal relaxation phenomenon, it is sensible to include it into the magnetic phase diagram, defining the lower end of SD stability (Fig. 2).

It is important to note that Néel superparamagnetism refers to the stability of magnetic remanence with respect to the coordinate system of the particle. If the particles are not embedded (as in a solid rock matrix), but dispersed in a fluid, then the magnetic remanence of an assemblage of particles will decay through Brownian motion in the fluid. Magnetically stable SD particles, which are able to rotate freely in a viscous medium, are therefore subject to the Brownian type of superparamagnetism. Using magnetic relaxometry, one can distinguish Néel and Brownian relaxation by their different relaxation time characteristics.

## Magnetic Measurements as a Diagnostic Tool

Thermomagnetic curves allowing for Curie-point determination are a widely used tool in rock magnetism for identifying different magnetic crystals with different

Curie temperatures. Due to the high Curie temperature of magnetite, this rock magnetic technique is not suitable in biomagnetism for detecting magnetite in tissue.

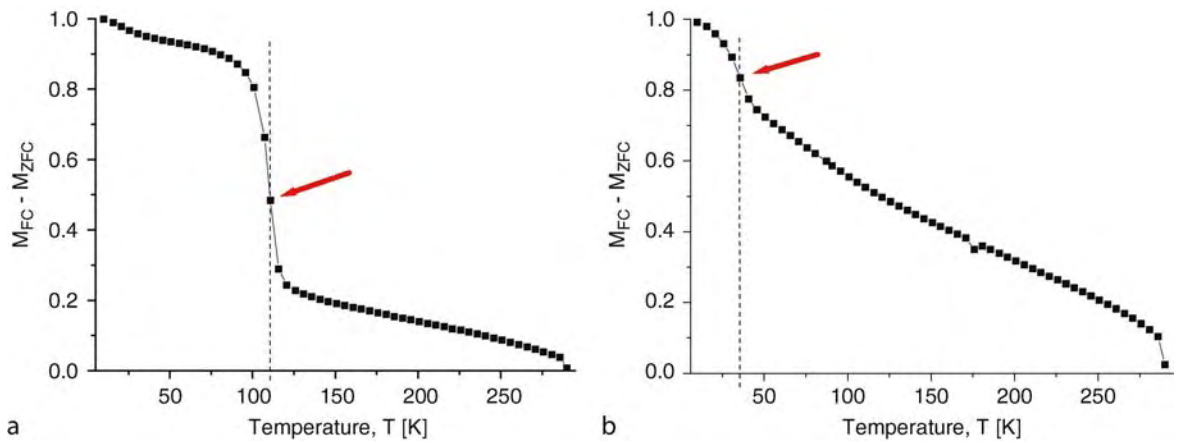
The electronic and structural changes at the Verwey transition are also accompanied by abrupt changes in magnetic properties, which can be used to identify magnetite by measuring magnetic properties at low temperatures (►ZFC–FC measurements). Figure 4a shows a conspicuous discontinuity in magnetic remanence associated with the Verwey transition. This is, however, not the case with magnetite particles smaller than some 30 nm (Fig. 4b).

With decreasing grain size, not only thermal fluctuations, but also surface effects become important and affect the (magnetic) Verwey transition, first by lowering the temperature of the Verwey transition, and eventually by suppressing it altogether. Magnetic relaxation may also obscure the Verwey transition in SP particles. Nevertheless, low-temperature magnetic measurements are an excellent tool to identify and characterize SP particles. With decreasing temperature, thermal fluctuations diminish and SP particles are able to retain a magnetic remanence. The temperature at which SP particles become stable SD particles is called the blocking temperature. On heating above the blocking temperature, the magnetic remanence acquired at temperatures below the blocking temperature becomes unblocked and relaxes (linear-logarithmic decay). The spectrum of blocking temperatures contains useful information on the SP particle-size spectrum (magnetic granulometry). Interpretation of low-temperature measurements may not be straightforward when additional phases are present that become magnetic at low temperatures (such as the iron-storage proteins ferritin or hemosiderin).

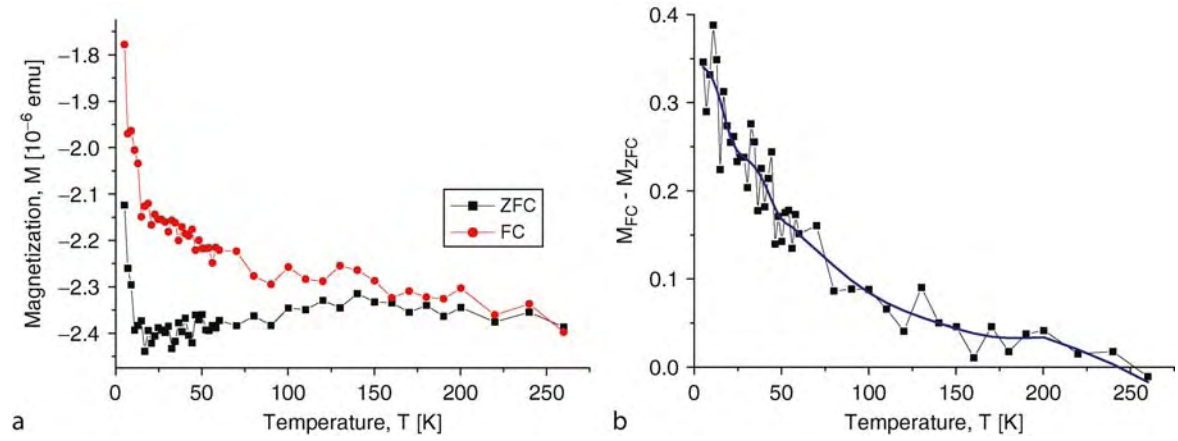
## Theory

### *Magnetoreception Based on SD Magnetite*

Following the example of magnetic bacteria, it was postulated that chains of SD magnetite particles might form an efficient basis for magnetoreception in animals [7]. A chain of magnetite particles would produce a torque in the geomagnetic field, which via mechanosensitive structures such as Pacinian corpuscles, hair cells, etc., could be transduced into a nerve signal. Despite the conceptual beauty of the model, a chain of magnetite particles has never been identified directly in animal tissue. It is true that SD crystals of magnetite have been extracted from brain tissue of bone fish, but the crucial questions have remained unanswered thus far, namely: (i) do the magnetite crystals have a physiological function and is it related to the magnetic sense? (ii) how had the magnetite crystals been arranged in situ before the tissue was dissolved and a magnetic extract made? (iii) what is the nature of the connection in the nervous system? In a more timely approach to unearth the elusive magnetic sense, iron-rich magnetic particles, probably SD magnetite, were detected by in-situ measurements on magnetically active nerve cells in the nose of trout [8]. Surprisingly, the particles detected were not arranged in a chain, but appeared to



**Magnetite. Figure 4** Low-temperature magnetic measurements on synthetic magnetite samples, (a) median grain-size 60 nm (interacting SD particles), and (b) median grain-size 20 nm (interacting SP particles). A magnetic remanence was acquired during ZFC–FC cycling in a field of 1 mT. The SD sample is characterized by a pronounced discontinuity at 110 K (*arrow*) associated with the Verwey transition. The SP sample on the other hand shows no apparent discontinuity, except for the change in curvature at 35 K (*arrow*). When it comes to identifying magnetic material in tissue, magnetization curves similar to the one on the left will make the case for magnetite, while curves resembling the one on the right can only be taken as evidence of very-fine grained material, however, not necessarily of magnetite (Winklhofer and Maher, unpublished data).



**Magnetite. Figure 5** Low-temperature magnetic measurements indicating the presence of SP crystals in the upper beak skin of homing pigeon [2]. (a) ZFC–FC cycling in a field of 5 mT. The mean concentration of magnetic material in the tissue is so little that the signal is dominated by the diamagnetic background and the variations in the signal are just above the noise level. (b) The resulting remanence curve (inset), obtained by subtracting the ZFC curve from the FC curve (raw data: squares; smoothed data: blue line), shows that most of the magnetic remanence is blocked well below 100 K. This is consistent with SP particles smaller than 10 nm grain size.

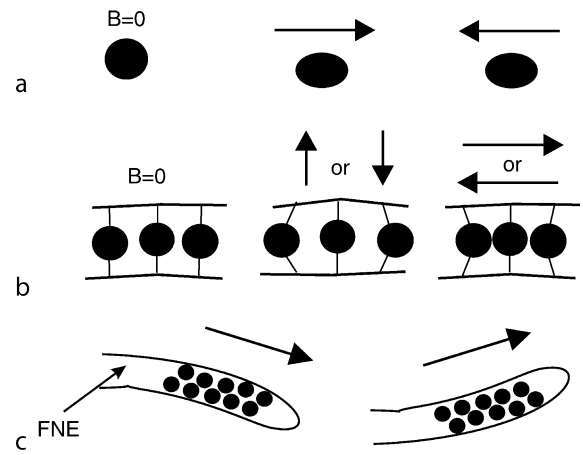
form an irregular cluster in the cell body of the neuron. Yet, the magnetic inclusions are a first structural candidate for the postulated magnetoreceptor in trout.

### *Magnetoreception Based on SP Magnetite*

Using an approach combining bulk magnetic measurements (Fig. 5), histological staining techniques and electron microscopy, it was possible to identify a putative magnetoreceptor in the beak skin of homing pigeons [2,9], namely clusters of SP crystals of magnetite (or maghemite) located in free nerve endings of the ophthalmic branch of the N. trigeminus.

Free nerve endings in the skin are sensitive to mechanical stimulation and so can convert, in principle, magnetic-field induced deformation into a nervous signal. There are several ways of producing mechanical deformation by SP clusters interacting with the magnetic field, as has been demonstrated theoretically and experimentally using droplets of magnetic fluids as a model system [10]. A single cluster of SP particles will assume a shape that depends upon the magnetic field direction and intensity (Fig. 6a).

The micrographs in [9,10] show that the clusters do not occur singly, but form coherent groups of some 20 clusters. The clusters will therefore be magnetically interacting [10], which opens new ways of producing mechanical deformation. If embodied in an elastic matrix (such as the cytoskeleton), adjacent clusters will attract or repel, depending on the relative orientation of the magnetic field axis to the (imaginary) axis connecting the clusters (Fig. 6b). This way, stress is produced on the cytoskeleton and can be measured using cellular mechanotransducers. If contained in a viscous medium, the clusters self-organize into a chain-like arrangement parallel to the magnetic field. Due to the shape anisotropy of the arrangement, a magnetic torque is produced when the relative orientation between the chain and field axis changes. The



**Magnetite. Figure 6** Possible ways of transforming a magnetic field into mechanical deformation based on SP clusters. (a) Single cluster in zero field (B = 0) and in an applied magnetic field. (b) Magnetically interacting SP clusters in an elastic matrix coupled to the membrane of the dendrite; the matrix is under dilatation (compression) if B is perpendicular (parallel) to the axis joining the clusters. (c) Magnetically interacting SP clusters in a viscous medium within a free nerve ending (FNE), which behave as a single mechanic unit. The magnetic field exerts a torque on the double chain of clusters, and by aligning the chain into the magnetic field, the FNE will be bent. Note that all the mechanisms are independent of the polarity of the magnetic field.

torque tries to realign the chain into the magnetic field axis and bends the free nerve ending (see Fig. 6c). In conclusion, there are several possibilities for transducing the magnetic field based on SP clusters. The theoretical predictions have been successfully confirmed by experiments on model systems, and it is about time to start in-situ experiments in order to find out which mechanism is realized.

## Synonyms

Magnetoencephalography; MEG

## Definition

Magnetoencephalography (MEG) encompasses a family of non-contact, non-invasive techniques for detecting the magnetic field generated by the electrical activity of the brain, for analyzing this MEG signal and for using the results to study brain function.

## Purpose

The overall purpose of MEG is to extract estimates of the spatiotemporal patterns of electrical activity in the brain from the measured magnetic field outside the head. The electrical activity in the brain is a manifestation of collective neuronal activity and to a large extent it is the currency of brain function. The estimates of brain activity derived from MEG can therefore be used to study mechanisms and processes that support normal brain function in humans and help us understand why, when and how they fail.

## Principles

### Basic Physical Principles

Brain function is expressed through electrical activity within and between *neurons*. The same neuronal generators responsible for the generation of the MEG signal are also responsible for changes in the electrical potential on the scalp that can also be measured non-invasively as the ►Electroencephalogram (EEG) by attaching electrodes to the scalp. The well-understood laws of electromagnetism define how electric currents in the brain generate EEG and MEG signals.

The determination of the EEG and MEG signal from the knowledge of the sources, the electrical properties of their biological environment and the configuration of the measuring devices is known as the forward problem. The estimation of generator strength, location and timecourse from the EEG and MEG signal and the knowledge of electrical properties of their biological environment and the configuration of the measuring devices is known as the inverse problem. The laws of electromagnetism define what can be asked of the data and how the forward and inverse problems should be tackled, in particular what *a priori* assumptions can be made about the generators. The basic elements of the hardware used for the detection of the MEG signal will first be described. The forward problem and then the inverse problem will then be considered, describing in each case the theoretical framework established by the laws of electromagnetism and its implications for useful MEG (and sometimes EEG) applications.

## Recording and Strength of MEG Signal

As will be described later the MEG signal is generated by the collective activity of a large number of neurons. Nevertheless, the strength of the MEG signal is extremely weak compared to typical terrestrial magnetic fields. The earth's magnetic field is about a billion times as strong, while the usual urban environment at frequency ranges that overlap the ones of interest in MEG is still many orders of magnitude higher than the strongest MEG signal from a normal human brain. A pre-requisite for useful MEG measurements is therefore the availability of sensors that can detect the weak magnetic fields generated by the brain. Also required are methods that can exclude the large ambient fields and tools that can separate out the signal of interest from any remaining interfering signals from the environment and other signals generated by the body of the subject that are often considerably stronger than the signal of interest.

The basic MEG measurement relies on the detection of the electrical current in a small loop of wire, typically about one centimeter across, induced by the change in the magnetic field component perpendicular to the loop surface. Measurement of the induced current determines the value of the change in the magnetic field. Usually a set of coils is used arranged as a ►gradiometer to emphasize nearby signals from the brain at the expense of distant sources. The detection of the minute magnetic field changes outside the head generated by electrical currents in the brain is measured by coupling the coil or gradiometer to an extremely sensitive "superconducting quantum interference devices" (►SQUID). ►SQUIDS as the name implies rely for their exquisite sensitivity on ►superconductivity and together with their sensing coils must be kept at extremely low temperatures, just a few degrees above absolute zero. To achieve this, sensing coils and SQUIDS are kept in a thermos-like container, the ►dewar, which under normal operating conditions is filled with liquid helium. In modern systems the bottom of the dewar is shaped into a helmet with well over one hundred, nowadays a few hundred sensing coils evenly distributed on its inner surface. Just a few millimeters away, on the other side of the insulating layer, at normal room temperature a subject can safely place his/her head inside the helmet. Each sensing coil samples the local magnetic field and the full set of sensing coils can be "scanned" a few thousand times a second. Each scan delivers an independent measurement of the instantaneous magnetic field just outside the head.

The second requirement, separating the signal of interest from the larger ambient background and other interfering signals is achieved by a combination of passive shielding, use of gradiometer design either in hardware for the sensing coils coupled to the SQUIDS or in software using additional reference channels. Other signal processing techniques, e.g. Independent Component Analysis (ICA) coupled to the use of information from auxiliary channels like the ►electro-oculogram (EOG) and electrocardiogram (ECG) can effectively eliminate biological and other artifacts. The combination of the exquisite SQUID sensitivity with these hardware and software methods allows the measurement of the magnetic field generated by the brain with little contamination.

In a modern MEG hardware typically a few hundred sensing coils, each coupled to its own SQUID, are housed at the bottom of the helmet-shaped dewar distributed so that they capture evenly the magnetic field just outside the head. The magnetic field for just one "timeslice" can be mapped by recording the signal from each sensor independently from, and for all practical purposes simultaneously with, the signal of each other sensor. In one second a few thousand such timeslices can be recorded so that successive timeslices provide a movie of the instantaneous change in the magnetic field just outside the head. Since, as we will shortly describe, the speed of propagation from the generators to the sensors is the speed of light, the MEG signal change corresponds to the instantaneous change of the electrical current density in the brain generated by neuronal activity. The peaks of the signal generated by the brain are about two orders of magnitude higher than the device noise level, so the map of the magnetic field not only has exquisite time resolution (a fraction of a millisecond) but is also a very clean map of the topography of the magnetic field just outside the head.

## The Forward Problem

It is useful to separate the full current density into two terms. In general we are interested in the first term,

known as impressed currents because they describe the active currents generated by energy-demanding neuronal activity. The remaining currents make up the second term; they describe the passive flow of currents that flows as a result of the impressed currents in the biological medium. Impressed currents of an individual neuron cannot be directly detectable by either MEG or EEG because they are too weak. Even under the most favorable conditions, a detectable signal can only be generated by the collective activity of many tens, possibly many hundreds of neurons spread over at least 1 $mm^2$ of cortex. At this spatial scale the appropriate terms that best separate the full current density into active and passive elements are referred to as primary current density and volume current or return current respectively. The primary current density depends on both intracellular currents and the local extracellular currents. The intracellular currents are closely related to the local impressed currents. Since these ionic flows are along axons and dendrites the net contribution from a single neuron is a sum of vectors each pointing along the long axis of the corresponding active dendrite or axon. The overall primary current density generated by intracellular currents is the vector sum of contributions from active neurons, which is therefore strongly dependent on the overall arrangement of neurons. The extracellular currents flow along the local conductivity gradients is determined mainly by cell membranes. For each focal neuronal activity, the local arrangement of cells determines the combined effect of both intracellular and extracellular currents and therefore shapes the resulting primary current density. The source space is a convenient label for the region of space where the primary current density can be non-zero, and it includes the entire brain. Primary currents can be thought of as the generators of the volume or return currents, i.e., the large-scale passive electrical current flowing in the "volume conductor," in the brain at large and bounded by the highly resistive skull. These large-scale passive electrical currents do not contribute to the magnetic field, except where they "twist" at boundaries with sharp changes in conductivity, especially the skull. In the special case that only concentric spherical boundaries of changes in conductivity are present, the magnetic field generated outside a conductor is given by an analytical expression [1]. Furthermore, the laws of electromagnetism and spherical symmetry define explicitly which generators can produce an external magnetic field and which are magnetically silent, i.e. they do not produce an external magnetic field no matter how strong they are. Specifically, radial components of the current density are magnetically ►silent sources. The non-zero contribution of tangential components of the current density can be written analytically in a form that depends on the center of the conducting sphere(s) and it does not depend on either the conductivities of the different compartments or the radii of the concentric shell(s), as long as the magnetic field is computed outside the conductor (last spherical shell). Finally the magnetic field in the *radial* direction depends only on the primary currents. The skull is smooth and nearly spherical so the convenient and relatively simple spherical model can provide an excellent estimate for the second term, except around openings like the eye sockets or parts of the skull that deviate substantially from the spherical model.

In contrast to the MEG forward problem the EEG forward problem poses real difficulties in practice. The computation of EEG signal is more complicated because it depends closely on details of the conductivity profile. The differences in the forward problem for MEG and EEG signals have two main consequences. First, the relationship between neuronal activity is easier to model for MEG. On the one hand the skull is transparent to magnetic fields and highly resistive to electrical currents (that must cross it to produce the scalp EEG) and on the other the effect of the conducting medium can be approximated by simple models for accurate computations of the magnetic field but have to be described in detail for the computation of the surface potential. Second, the EEG is influenced strongly by both radial and tangential electric currents while MEG is only sensitive to tangential sources.

The laws of electromagnetism endow both EEG and MEG signals with a direct relationship with the neuronal sources. Specifically, the electric and magnetic fields propagate from the (neuronal source) generator site with the speed of light. Since the sensors are just some centimeters away, for all practical purposes the effect is immediate: a change in the source electrical activity in the brain produces an immediate change in the MEG and EEG signal. This is in sharp contrast with other neuroimaging methods like ►positron emission tomography (PET) and ►functional magnetic resonance imaging (fMRI) that rely on changes in blood flow or content (*e.g.* radioactive labeling or oxygenation) and therefore produce indirect correlates of neuronal activity with delays that are at best a good fraction of a second in the case of fMRI and minutes in the case of PET.

Finally, the forward problem is linear as a direct consequence of the linearity of the laws of electromagnetism. In other words the electric and magnetic field generated by any combination of instantaneous current elements is simply the sum of individual contributions from each element. In the case of continuous primary current density, the instantaneous electric and magnetic field can be computed by integrating the contributions from each small volume element in the source space. In the case of a spherical model the source space for MEG includes only regions where neurons and possibly white matter exists, any intervening regions and boundaries

are not part of the source space as long as they do not generate primary currents.

### Inverse Problem

In contrast to the forward problem, the inverse problem has no unique solution, a mathematical fact that was already demonstrated over 150 years ago [2]. Simply stated, it is impossible to reconstruct uniquely the electrical current density inside the head from MEG and/or EEG measurements. Even if we knew exactly the electrical potential on the surface of the head and the magnetic field everywhere outside the head we would still be unable to determine the currents inside the head. In practice, non-uniqueness is much less of a problem than would appear from the dry mathematical statements. By definition silent sources cannot be recovered and noise and sparse sensor coverage further limit what can be reliably extracted about the non-silent part of the current density vector. Nevertheless what is often required of the data is to provide reliable estimates about which areas of the brain were preferentially activated by some stimuli or tasks and when. This limited objective is often satisfied with estimates of the timecourse of the non-silent part of the source configuration. The key question in practice is how accurately and reliably one can recover the non-silent part of the primary current density.

A unique solution of the biomagnetic inverse problem can be obtained by introducing constraints for the form of the generators. Two types of constraints are particularly popular [3]. The first assumes that the generators are one or more point-like sources, or current dipoles. ►Dipole source localization solutions are often interpreted as representatives for their neighborhood and are referred to as equivalent current dipoles (ECD). The second family of popular source localization methods assumes that the continuous current density can be written as a linear sum of (weighted) functions, each defining the sensitivity profile, or lead fields, of the sensors. These methods, known as ►minimum norm or weighted minimum norm solutions, are popular because they lead to a linear system of equations which allows standard pseudoinverse techniques to define the inverse operator that can then be applied directly to the data. Theoretical scrutiny of the mathematical foundation of the inverse problem shows that neither current dipoles nor linear solutions are adequate. Minimum norm is not appropriate for tomographic localization for a rather subtle reason; although the forward problem is linear the optimal algorithm for tackling the inverse problem cannot be linear [4]. The laws of electromagnetism provide no justification for expressing the full primary current density vector as a weighted sum of lead fields, only the direction of the primary current density can be so represented and this leads inevitably to a non-linear relationship between the measurements and the distribution of generators. This conclusion was reached first on the basis of simulation studies leading to the standard form of ►magnetic field tomography (MFT) [5]. In the last 10 years accurate MFT reconstructions have been demonstrated with many applications and extended to single timeslices of ►single trial data [6,7].

### Neural Mechanisms

A detectable MEG signal requires concerted action from many neurons numbering at a minimum many tens probably many hundreds. These neurons must be arranged in a similar way in space and they must be activated in near synchrony. The very presence of a good size MEG and EEG signal is evidence for dual organization of neurons: a spatial organization in the way they are grouped together in space and large scale synchrony in the way their activity is organized in time. It is generally believed that relatively slow changes in electrical activity associated with ►post-synaptic potentials (PSP) at the ►apical dendrites of large ►pyramidal neurons are the main contributors to the MEG signal. Large pyramidal neurons are prime candidate generators of MEG signals because their elongated shape is ideal for producing strong primary currents. Furthermore they are arranged in parallel in the cortex so the net impressed current from nearby large pyramidal neurons will tend to sum up constructively. It is very likely that a large part of the MEG signal is indeed due to slow PSPs in the apical dendrites of pyramidal neurons, especially at frequencies well below 100 Hz. For this standard mechanism, typical estimates require about a million *synapses* to be simultaneously active to produce a measurable MEG signal [3]. MEG activity at frequencies well above 100 Hz is likely to be produced by synchronous ►action potentials [7].

## Advantages and Disadvantages

### Advantages

MEG is a completely non-invasive method. With appropriate analysis methods it can provide simultaneously accurate localization of different brain regions and exceptional temporal resolution. The MEG signal depends weakly on the conductivity changes in the brain and simple models can provide accurate estimates of the magnetic field generated by a source in the brain. The insensitivity to radial sources adds to the discriminability of MEG, especially for sources in sulci.

### Disadvantages

The need for shielding and use of liquid helium makes MEG an expensive technology both in terms of the cost of hardware and the operating costs. Another disadvantage of MEG is the need for the subject to stay

motionless while data are collected. MEG is insensitivity to radial currents so generators close to the center of the head (e.g. ►thalamus) and at the crest of gyri are close to silent sources. The patterns of activity identified with MEG are not very meaningful on their own because they lack anatomical context. The background anatomy must be provided by other methods, usually ►MRI and the process of combining the background anatomy and the functional information requires considerable effort to ensure accurate coregistration between the two modalities for each subject and experiment.

►Magnetoencephalography

### Synonyms

Major depression; Endogenous depression; Unipolar depression; Melancholia

### Definition

Major depression is the most severe category of depression and is marked by a combination of symptoms that occur together and last for at least two weeks without significant improvement.

Symptoms from at least five of the following categories must be present for a major depression, although even a few of the symptom clusters are indicators of a depression, but perhaps not a major depression:

- Persistent depressed, sad, anxious, or empty mood
- Feeling worthless, helpless, or experiencing excessive or inappropriate guilt
- Hopeless about the future, excessive pessimistic feelings
- Loss of interest and pleasure in usual activities
- Decreased energy and chronic fatigue
- Loss of memory, difficulty making decisions or concentrating
- Irritability or restlessness or agitation
- Sleep disturbances, either difficulty sleeping, or sleeping too much
- Loss of appetite and interest in food, or overeating, with weight gain
- Recurring thoughts of death, or suicidal thoughts or actions

### Characteristics

#### History/Background

Descriptions of what is today known as depression or mood disorders appear in many ancient documents. About 400 BC Hippocrates used the terms mania and melancholia to describe mental disturbances. Around 30 AD, in his work "De re medicina" the Roman physician Celsus described melancholia (from the Greek "melan" meaning "black" and "chole" meaning "bile") as a depression caused by black bile.

In 1899, the German psychiatrist Emil Kraepelin, building on the ideas and theories of earlier French and German psychiatrists, described manic-depressive psychosis; according to Kraepelin, a dementing or deteriorating course in manic-depressive psychosis differentiated it from dementia praecox (as schizophrenia was then called). Kraepelin also described a depression that later came to be known as involutional melancholia as a form of depression beginning in late adulthood.

Epidemiological studies have shown that depressive disorders are more common and have a less favorable course than previously assumed. Concepts of diagnosis have also changed over time. The entity of endogenous depression, part of Kraepelin's systematic, triadic nosology (1913), was abandoned in favor of depressive episodes, as defined in ICD-10 (WHO 1992), and major depression as defined in DSM-IV (APA 1994). These became the new major diagnostic categories for depressive disorders. The heterogeneity of the depressive syndrome has resulted in a continuous demand for new attempts at classification. When the current DSM-IV and ICD-10 systems for the classification of depressive disorders are considered from the

controversial historical perspective, it becomes clear that the distinction between unipolar and bipolar disorders has prevailed and that classification on the sub-syndrome level has been taken up again, albeit in a somewhat modified form. The main change occurring in the transition from ICD-9 to ICD-10 was the abandonment of the distinction between endogenous and neurotic forms of depression: this distinction was considered to be too etiologically oriented, and could not be adequately validated on an empirical basis.

## Diagnostic Considerations

There is no general agreement about the best method of classifying depressive disorders. Three broad approaches have been made: first to base classification on etiology, second on symptoms and third on the course of the disorder.

Both ICD-10 and DSM-IV classify depressive episodes on the basis of severity and whether or not ►psychotic features are present. It is also possible to specify whether a depressive episode has ►melancholic (DSM-IV) or ►somatic (ICD-10) ►features. In DSM-IV, an episode of major depression with the appropriate clinical symptomatology can be specified as ►atypical depression. In ICD-10 atypical depression is classified separately under "other depressive episodes." Both ICD-10 and DSM-IV allow the diagnosis of ►recurrent brief depression. Nowadays it is argued that the phenomenologically-based concept of "major depression" has led to sterility in depression research and clinical practice, and that there is a need for a paradigm shift in modeling and classifying the depressive disorders [1].

## Epidemiology

Major depressive disorder is a common disorder, with a lifetime prevalence of about 15% and perhaps as high as 25% for women. The incidence of major depressive disorder is 10% in primary care patients and 15% in medical inpatients.

An almost universal observation, independent of country or culture, is that major depressive disorder is twice as prevalent in women than in men. Possible reasons for this are hormonal differences, the effects of childbirth, different psychosocial stressors for women than for men and behavioral models of learned helplessness.

The gender differences have been found in community samples and can thus not be accounted for by the fact that women are more likely to seek help than men. Race, education, income and marital status do not influence prevalence rates for major depressive disorder. Recent epidemiological data clearly indicate that the age of onset of major depressive disorder has decreased in recent years (the "birth cohort" effect) in many Western cultures [2].

The lifetime psychiatric co-morbidity rate for major depressive disorder can be as high as 43% [3], i.e., up to 43% of patients with major depressive disorder have a history of one or more non-mood psychiatric disorders. The one-month point prevalence for concurrent in contrast to lifetime psychiatric co-morbidity is 8%.

There is strong empirical evidence suggesting that psychosocial events or stressors may play a significant role in precipitating the first or second episode of major depressive disorder, but this becomes less important for the onset of subsequent episodes [4]. This means that for the recurrent forms of major depressive disorder, new episodes are less likely to involve a specific precipitant as the disorder becomes more firmly established.

## Course and Outcome

Periods of significantly increased risk for the onset of the illness include late adolescence and early adulthood, with a progressively increasing incidence up to the age of 45. The age of 30 is usually considered the typical age of onset, although more recent investigations have implied that the average age of onset is considerably earlier [5]. Contrary to the traditional clinical conception that the highest rates for depression are found in older persons, more recent studies have found the highest rates in younger age-groups [6]. More and more young patients are developing depression at an increasingly earlier age. It seems likely that the increased risk of depression in younger people is environmentally mediated, but the factors involved are unknown [7].

Major depression is 2.5 times more common in separated people living alone [5].

People who have been unemployed for at least 6 months of the 5 years preceding diagnosis are three times more likely to develop an episode of major depression.

Critical life events with respect to inter-personal relationships, particularly the death of a close friend of relative, and physical illness combined with poor social resources (e.g., inadequate social support) and personal resources (e.g., dysfunctional coping behavior) are found primarily in depressive cases [8]. An earlier onset of illness, a slower rather than an acute onset, the presence of dysthymia, the presence of chronic physical illness and above all the presence of a chronic anxiety disorder all significantly increase the risk of chronic depression.

The duration of the episodes varies, but several prospective studies have shown that affective disorders remit completely much more often than anxiety disorders (ratio: 32–46%).

The remission rate (defined as five years without relapse) is 42% for unipolar depressive illnesses.

For those who experience a first depressive episode, the risk of recurrence is 80–90%. About 50% of patients with major depressive disorder become chronic cases:

more than 20–30% do not respond to antidepressant medication, with up to 60% of primary care patients remaining depressed after 12 months and 20% of clinic patients remaining depressed for over two years despite pharmacological treatment. Further, one third of those initially responding to medication relapse within one year, with up to 75% relapsing within five years. Chronic depression leads to psychosocial deficits, which place a tremendous burden on both patients and society. It is not only associated with various somatic illnesses, but also entails massive economic costs. According to the WHO, it is predicted that depression will become the major burden on mental health services by the year 2020.

The risk of suicide has been estimated at 15% and is thus considerably higher than in the normal population. Co-morbid depressive episodes last significantly longer than non-co-morbid depression and have a considerably higher rate of relapse.

## Etiology

### Genetic Causes

Most family studies have shown that parents, siblings and children of severely depressed patients have a morbid risk of about 20% for mood disorders, as compared with about 7% for the relatives of controls. The concordance rates for manic depressive disorder were 69% for monozygotic twins reared together, 67% for monozygotic twins reared apart, and 13% for dizygotic twins.

### Neurodevelopment Factors

It has been proposed that stress-induced changes in the hippocampus may be central to the development of depression in genetically vulnerable individuals. New evidence implicates the pre-frontal cortex (PFC) in addition to the hippocampus as a site of neuropathology in depression. The PFC may be involved in stress-mediated neurotoxicity as stress alters PFC functions and glucocorticoid receptors, the PFC is directly interconnected with the hippocampus, and metabolic alterations can be seen in the PFC in depressed patients. Post-mortem studies in major depression provide preliminary evidence for specific neuronal and gliohistopathology in mood disorders. Three patterns of morphometric cellular changes are noted: cell loss (subgenual PFC), cell atrophy (dorsolateral PFC and orbitofrontal cortex) and increased numbers of cells (hypothalamus, dorsal raphe nucleus, cf. [9]).

### Neurotrophic Factors

Several neurotrophic factors (such as nerve growth factor, NGF, brain-derived neurotrophic factor, BDNF, and glio-derived neurotrophic factor, GDNP), as well as cytokines and insulin-like growth factor-1 (IGF-1) increase cell survival. The cAMP response element-binding protein (CREB) is a critical integrator of neuroplasticity that is responsive in a brain region-specific manner to a variety of environmental and pharmacological stimuli, including widely prescribed antidepressant medications. CREB is an ubiquitous key-element of intracellular signal transduction cascades that may contribute to symptoms of depression. The increase in CREB-phosphorylation might be a molecular state marker for the response to antidepressant treatment.

There is emerging evidence – primarily from post-mortem studies – supporting the role of abnormalities in neurotrophic signaling pathways in depression. Recent studies suggest that stress-induced atrophy and loss of hippocampal neurons may contribute to the pathophysiology of depression. At the cellular level, evidence has emerged indicating neuronal atrophy and cell loss in response to stress and in depression. At the molecular level, it has been suggested that these cellular deficiencies, mostly detected in the hippocampus, result from decreased expression of BDNF associated with elevation of glucocorticoids.

### Serotonergic Markers

Imipramine binding to blood platelets is generally decreased in depression, as indicated by decreased maximal binding capacity. Similarly, 5-HT-uptake in blood platelets is decreased. These findings correspond to a decreased maximal binding capacity of imipramine to brain tissue. Imipramine binding to platelets is a robust biological marker for depression.

### 5-HT-Receptors

Due to the efficacy of serotonergically acting drugs in major depression, some 5-HT-receptors have been extensively studied in major depression. Almost all the studies point to a decreased or unchanged expression of the 5-HT-1A-receptor. A trend towards decreased 5-HT-1A-receptor expression appears to be a robust finding in major depression.

### Biochemical Markers

Several studies have investigated lipids as biological markers for depression. Hypocholesterolemia has been associated with depression, suicide and affective disorders. Low or lowered cholesterol may be associated with increases of suicides and accidents. Cholesterol levels have been identified as a blood marker for depression and anxiety in a normal population in a primary care setting. A hypertriglyceridemia-driven metabolite cause of depression has also been demonstrated in controlled clinical trials, showing that trigylceride lowering alleviates the symptoms of depression. Recent evidence has suggested an important role for lipids in the etiology and treatment of depression. There is empirical evidence for the hypothesis that unipolar

depression may be associated with abnormalities in lipid-associated signaling systems.

### Vitamins: Folic Acid

Several cross-sectional studies have focused on the low blood folate levels in depression patients. In a large Finnish study, depressed patients in the general population with energy-adjusted folate intake below the median had a higher risk of being given the discharge diagnosis of depression during the follow-up period than those with a folate intake above the median. A low dietary intake of folate may be a risk factor for severe depression.

### Vitamins $B_6$ and $B_{12}$

A group of Danish investigators have suggested that a low level of vitamin $B_6$ is associated with symptoms of depression. A low plasma level of the vitamin $B_6$ derivate, puridoxal phosphate (POP), was significantly associated with the depression score. Higher vitamin $B_{12}$ levels were significantly associated with better outcome. Vitamin $B_{12}$ level may thus be positively associated with the probability of recovery from major depression.

### G-proteins

Abnormal signal transduction pathways have been implicated in the pathogenesis of major depression. G-proteins are key elements of these pathways in the regulation of cellular responses by transmission of signals from receptors to effector proteins. Several studies have reported altered levels and activities of G-protein subunits in depressive patients.

Although it is well established that depression is a major risk factor for the development of coronary artery disease and that cerebro-vascular disease can be a major contributing factor for the development of depression, the information interplay between the central nervous system and cardio-vascular disease is still limited. In an investigation of the G-protein beta-3-subunit C825T polymorphism and the angiotensine-1 converting enzyme (ACE) ID polymorphism, analysis of both genes showed that the combined actions of ACE and C825T genotypes accumulate in carriers of the ACE-D allele and C825T-TT nomozygates with IC/DD-TT carriers showing a more than fivefold increase in risk for major depression. Thus, the study reports that the same allelic combination of two genes that have been shown to increase the risk for myocardial infarction increase the vulnerability for depressive disorder. This finding strengthens the evidence for the involvement of G-protein-couple signal transduction in the pathogenesis of affective disorders.

### Hypothalamic Pituitary–Adrenal Axis

The HPA axis stimulating properties of higher ACE and consecutively higher angiotensine and lower substance peak concentrations may be crucial factors for the HPA system hyperactivity during major depressive episodes.

The corticotropin-releasing hormone binding protein gene is likely to be involved in the genetic vulnerability for major depression.

### Neural Imaging Markers

Positron emission tomography (PET) imaging studies have revealed multiple abnormalities in regional cerebral blood flow (CBF) and glucose metabolism in limbic structures and the prefrontal cortex (PFC) in mood disorders. In unmedicated subjects with major depression, regional CBF and metabolism are consistently increased in the amygdala, orbital cortex and medial thalamus, and decreased in the dorsomedial/dorsal anterolateral PFC and anterior cingulate cortex ventral to the genu of the corpus callosum (subgenual PFC), compared with healthy controls [10]. These abnormalities implicate limbic-thalamic-cortical and limbic-cortico-striato-pallidal-thalamic circuits involving the amygdala, orbital and medial PFC, and anatomically related parts of the striatum and thalamus in the pathophysiology of major depression. These circuits have also been implicated more generally in emotional behavior by the results of electrophysiological, lesion analysis and brain-mapping studies in humans and experimental animals. Structural imaging studies have demonstrated reduced greymatter volumes in areas of the orbital and medial PFC, ventral striatum and hippocampus, and enlargement of the third ventricle. It is not known whether these deficits constitute developmental abnormalities that may confer vulnerability to abnormal mood episodes, compensatory changes to other pathogenic processes, or the sequelae of recurrent affective episodes per se [9]. Taken together with other pre-clinical data regarding these structures' specific roles in emotional processing, the neuro-imaging and neuropathological abnormalities in major depression suggest that the illness is associated with the activation of regions that putatively mediate emotional and stress responses, whereas areas that appear to inhibit emotional expression (such as posterior orbital cortex) contain histological abnormalities that may interfere with the modulation of emotional or stress responses.

### Cognitive Deficits in Major Depression

There is growing evidence that several cognitive domains are significantly impaired in patients with major depression, including attention, memory and executive functioning. Patients with major depression manifest significant impairment in their ability to maintain attention in tasks requiring strenuous mental operations, i.e., tasks requiring selective and sustained attention or implying a large resource-allocation capacity.

Patients with major depression also have widespread executive dysfunction, including working memory, set-shifting and inhibition processes, even during the euthymic state.

It has been suggested that cognitive deficits in major depression may depend on age, severity of illness and psychotic or melancholic features. Cognitive deficits in depression may be associated with both trait and state factors and raise questions regarding the long-term cognitive functioning in patients with major depression. These deficits may be explained by structural or functional changes associated with the severity of illness, ageing effects or a possible cumulative pathologic effect of depression on brain structure and function across recurrent episodes of illness [9].

In summary, none of the biological and neuropsychological markers (see Fig. 1) have been shown to be sufficiently specific to allow inclusion in diagnostic manuals of major depression.

### *Sleep Abnormalities*

Problems sleeping – initial and terminal insomnia, multiple awakenings, hypersomnia – are common and classic symptoms of depression. The sleep electroencephalograms (EEGs) of many depressed persons show abnormalities. Common abnormalities are delayed sleep onset, shortened rapid eye movement (REM) latency (the time between falling asleep and the first REM period), a longer first REM period and abnormal delta sleep.

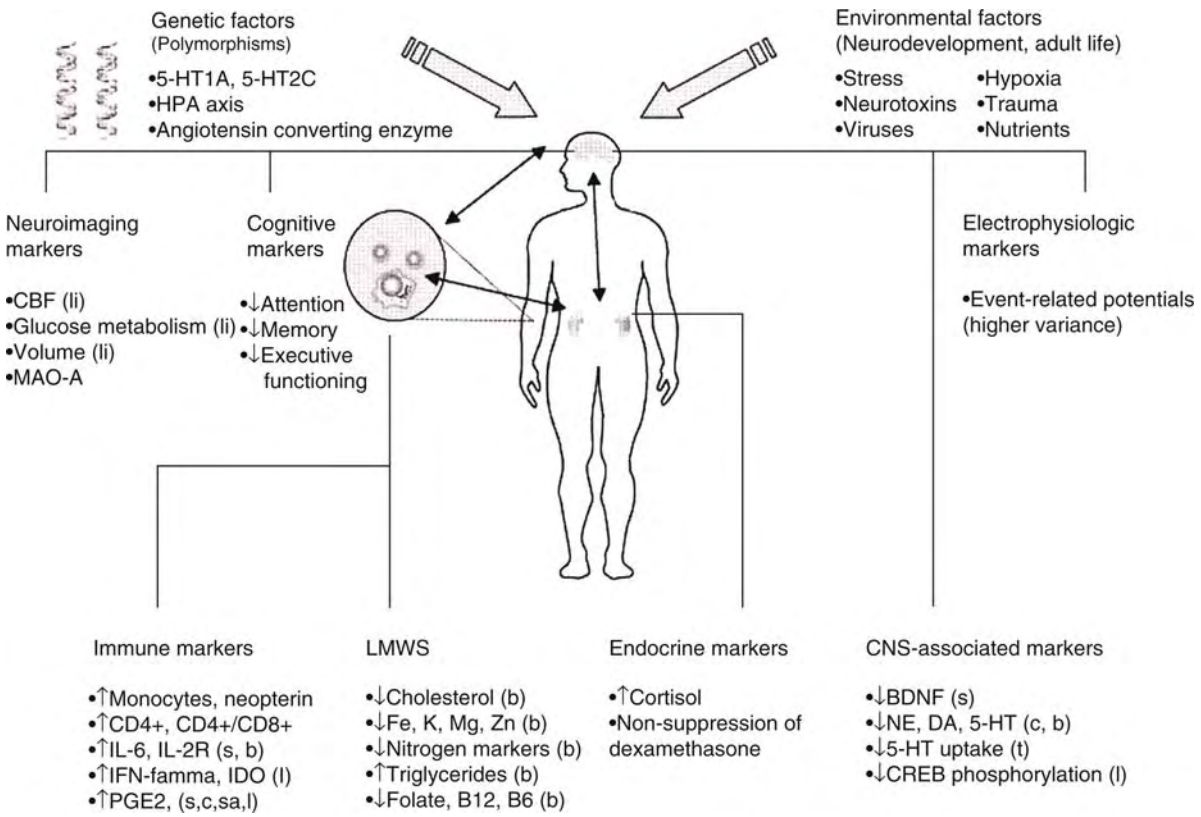
### *Circadian Rhythms*

The abnormalities in sleep architecture in depression and the transient clinical improvement associated with sleep deprivation have led to theories that depression reflects the abnormal regulation of circadian rhythms. Experimental studies with animals indicate that many of the standard antidepressant treatments are effective in changing the setting of internal biological clocks (endogenous zeitgebers).

## Psychosocial Factors

### *Life Events and Environmental Stress*

Stressful life events precede more often first rather than subsequent episodes of major depression. According to Post [4], the stress accompanying the first episode results in long-lasting changes in the brain's biology. These long-lasting changes may alter the functional states of various neurotransmitter and intra-neuronal signaling systems, and may even include the loss of neurons and an excessive reduction in synaptic



**Major Depressive Disorder. Figure 1** Biological markers of depression.

contacts. This greatly increases the risk of subsequent episodes of a mood disorder, even without an external stressor.

The most compelling data indicate that the life event most often associated with the development of depression is losing a parent before the age of 11. The environmental stressor most often associated with the onset of an episode of depression is the loss of a spouse. Another risk factor is unemployment: persons out of work are three times more likely to report symptoms of an episode of major depression than those working.

### Personality Factors

All humans, regardless of their personality pattern, can and do become depressed under appropriate circumstances. Persons with certain personality disorders – obsessive-compulsive, histrionic and borderline – may be at greater risk for depression than persons with antisocial or paranoid personality disorder. The latter can use projection and other externalizing defense mechanisms to protect themselves from their inner rage. Patients with dysthymic and cyclothymic disorder are at risk of developing major depression or bipolar I disorder later.

Stressors experienced by the patient as reflecting more negatively on his/her self-esteem are more likely to result in depression. What may seem to be a relatively mild stressor to outsiders may be devastating for the patient because of particular idiosyncratic meanings attached to the event.

### Pharmacotherapy

Since the introduction of the first tricyclic antidepressant, imipramine, in 1957, many new types of antidepressants have been developed. The classes of substances currently available differ little in their antidepressant effect; there is no convincing evidence that one particular class of antidepressant is more effective or has a more rapid onset of effect than the others. The newer antidepressants of the 1980s and 1990s generally have less serious side effects than the "classic" substance groups of the tricyclic agents and the irreversible monoamine oxydase (MAO) inhibitors. Approximately 30–40% of both in- and outpatients fail to respond adequately to an initial 4–6 week treatment with an antidepressant. As many as 10–15% of patients fail to improve sufficiently, even after several different treatment attempts. 12–15% of depressive patients are not yet asymptomatic two years after onset of the illness. The lack of success of antidepressant therapy is often due not to the illness itself, but to suboptimal treatment. If resistance to therapy remains intractable despite attempts at treatment optimization, the use of augmentative or combination therapy should be considered. Among augmentative therapies, the addition of lithium to traditional antidepressants, has been found useful. Combination therapy with various antidepressants has been tried with varying success, as has so-called pindolol augmentation, a combination of the beta-blocker pindolol with a serotonin-reuptake inhibitor (SSRI). The combination of a neuroleptic with an antidepressant has proven useful in the treatment of depression with psychotic features.

### Psychotherapy

The majority of patients with an episode of major depressive disorder respond to the first or second attempted treatment. In patients with mild or moderately severe episodes, treatment with antidepressant drugs and brief psychotherapies are adequate and equally effective. In those with severe episodes, antidepressant medication alone or a combination of medication and psychotherapy is recommended. The treatment of chronic depression and in particular of patients failing to respond to adequate drug treatment (approximately 20%) is more problematic. In addition, these patients have marked impairment in psychosocial functioning, incomplete remission even after two years and very high rates of use of healthcare resources. Furthermore, even if there is a partial remission, there remains a high risk of relapse (up to 80%).

Many studies indicate that a combination of psychotherapy (cognitive behavioral psychotherapy, psychodynamic psychotherapy, interpersonal psychotherapy) and pharmacotherapy is the most effective treatment for major depressive disorder. Some data suggest another view: either pharmacotherapy or psychotherapy alone is effective, at least in patients with mild major depressive episodes.

Three types of short-term psychotherapy (cognitive therapy, interpersonal therapy and psychodynamic psychotherapy) have been studied to determine their efficacy in the treatment of major depressive disorder.

# Major Histocompatibility Complex

Ernesto Salcedo, Diego Restrepo
University of Colorado at Denver and Health Sciences Center, Aurora, CO, USA

## Synonyms

Human leukocyte antigens (HLA – human); H-2 (mouse)

## Definition

A locus of highly polymorphic genes found on the short arm of human chromosome 6 and mouse chromosome 17 that encode proteins involved in the adaptive immune response (see Fig. 1), and certain aspects of brain function.

## Characteristics

### MHC Proteins

Genes in the MHC encode for proteins involved in the adaptive immune response. MHC proteins fall into two classes: I or II. Class I molecules (MHCI) consist of an MHC-encoded α heavy chain, and a smaller, non-MHC-encoded β chain (β2 microglobulin). Class II molecules (MHCII) are comprised of two MHC-encoded, non-covalently associated polypeptide chains, α and β (Fig. 1b). Both classes of MHC bind proteosomally degraded peptides (MHC peptides) in a binding cleft that is presented on the surface of the presenting cell. The entire MHC-peptide complex is then recognized by T cells as "self" or "non-self." The complex is considered "self" if the bound MHC peptide is a degraded product of an endogenous protein. If, however, the bound MHC peptide originated from an exogenous source, such as protein from bacteria, viruses, or from cells in a tissue graft, then the complex is recognized as "non-self" and the cell presenting the MHC complex is marked for destruction. MHCI molecules have been shown to be present on virtually all nucleated cells, whereas MHCII molecules expression is typically limited to a small subset of immune response cells such as B lymphocytes and macrophages [1].

### MHC Polymorphism

The unique collection of MHC alleles possessed by a given individual is known as the MHC haplotype (Fig. 1a). The MHC displays a high degree of polymorphism; alleles differ greatly from individual to individual within a species. The high degree of allelic variation in MHC is thought to be crucial to defeat attempts by foreign organisms to avoid detection by the immune system. In fact, all of the polymorphic residues found in encoded MHC proteins line the interior of the peptide binding cleft and directly interact with the anchor amino acid residues in the bound peptide (Fig. 1c) [1].

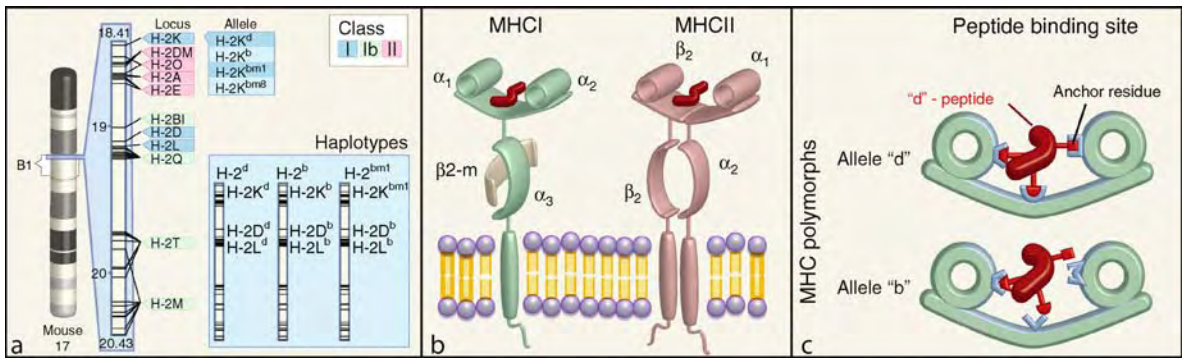
### Detection of MHC Haplotype by Smell

Mice and – to some extent – humans are able to detect differences in MHC haplotype between individuals [2]. In mice the detection of MHC identity by smell has been postulated to play a key role in social interactions involving individual recognition, such as mate selection and offspring recognition [3–5]. Indeed, mating preferences dependent on MHC type differences in seminatural populations of mice have been shown to be sufficient to account for much of the MHC genetic diversity [4].

Mice are able to discriminate among individuals with different MHC haplotypes through detection of differences in urine volatiles (these urine volatiles are often termed "odortypes"). The different odortypes elicit distinct maps of activity in the glomerular layer of the olfactory bulb that allow the mice to discriminate between MHC haplotypes [2–3]. In addition to volatiles, released MHC peptides can themselves also be detected by the main and accessory olfactory systems and appear to be involved in detection of MHC haplotype [2]. Intriguingly, MHCI molecules are expressed in the vomeronasal organ of mice and appear to directly interact with chemical receptors classically associated with the detection of pheromones [6].

### MHCI and Neuronal Plasticity

The unexpected discovery of activity-dependent MHCI expression in the developing visual system disproved the long held tenet that neurons in an uninjured brain were immune-privileged [7]. Subsequently, other well characterized members of the adaptive immune response have been shown to be expressed throughout



**Major Histocompatibility Complex. Figure 1** *The major histocompatibility complex (MHC) is a multigene cluster found on chromosome 17 in mice*. (a) Schematic representation of mouse chromosome 17 including the location and composition of the MHC gene cluster (also named the H-2 region in mice). The banding pattern of the chromosome is shown on the far left. To the right of the chromosomal representation is a partial list of MHC genes. Loci for Class I (*blue and green*) and Class II genes (*pink*) are clustered in the MHC located in the 17 B1 band between 18.41 and 20.43 cm. Each gene (locus) is identified by the prefix "H-2" followed by a capital letter (e.g. H-2K). Different alleles for each of these loci are denoted by a lower case superscript (e.g. H-2K$^b$). Listed in the two *dark blue panels* to the right of the H-2K locus are a selection of H-2K alleles. Haplotypes inset. Examples of three MHCI allele sets for three different mouse haplotypes: H-2$^d$, H-2$^b$, and H-2$^{bm1}$. (b) Renditions of an MHC class I (MHCI) and a class II (MHCII) transmembrane molecule. In MHCI, two homologous segments ($\alpha_1$ and $\alpha_2$) form the peptide-binding region, which consists of two parallel strands of α-helix supported by an eight-stranded β-pleated sheet. The non-MHC encoded β2-microglobulin (β2-m) chain is required for proper presentation of the molecule on the cell surface. In MHCII, the peptide binding region is formed by the interaction between the $\alpha_1$and $\beta_1$ subdomains of the two non-covalently associated MHC-encoded polypeptide chains. Polymorphic variation for a particular MHC locus is restricted almost entirely to amino-terminal domains that line the base of the binding cleft or are directed inward from the walls of the α-helices (indicated by blue shading) [1]. Contained within the binding site is an MHC peptide (*red*). (c) Example of the specificity of an MHC peptide to a particular MHC polymorph. "d"-peptide: a hypothetical MHC peptide that, due to its anchor amino acid residues, can only bind a hypothetical MHCI molecule encoded by a "d," but not a "b" allele. This specificity illustrates how MHC peptides, based solely on the configuration of their anchor residues and regardless of their primary amino acid sequence, can provide information on MHC haplotype.

the central nervous system during development and into adulthood. These molecules include the MHCI subunit, β2-microglobulin; the peptide loading enzyme transporter associated with antigen presentation (TAP); critical subunits of the T cell receptor, such as TCRβ or CD3ζ; and the Paired-immunoglobulin–like receptor, another MHCI receptor [7–8].

While the components of adaptive immunity are expressed in neuronal cells, the collective function of these molecules appears to have changed. Loss of MHCI or CD3ζ disrupts the activity-dependent structural reorganization of axons in the lateral geniculate nucleus and the hippocampus [7]. After lesion of the sciatic nerve, fewer neurons are able to regenerate axons in a deficient MHC background [9]. An in vitro examination of cultured hippocampal neurons revealed that MHCI sublocalizes to the soma and dendrites. Moreover, cultured neurons deficient in MHCI had changes indicative of a defect in homeostatic synaptic plasticity. Thus, MHCI molecules appear to function as components of a mechanism that regulates synaptic morphology and physiological function [10].

## Major Tranquilizer

►Antipsychotic Durgs

## Male Hypogonadism

### Definition

A clinical syndrome due to reduced levels of testosterone. Clinical hallmarks include absence or regression of secondary sex characteristics, reduced fertility (oligospermia, azoospermia), anemia, muscle wasting, reduced bone mass (and bone mineral density), and/or abdominal adiposity. This syndrome has a multifactorial etiology that includes genetic conditions, anatomic abnormalities, infection, tumor, and injury.

## Malignant Hyperthermia (MH)

### Definition

A pharmacogenetic disease of skeletal muscle with autosomal dominant inheritance that is manifested in humans as an acute hyperthermic reaction, arising from uncontrolled skeletal muscle $Ca^{2+}$ release and contraction, and usually triggered by potent inhalational anesthetics.

►Excitation-Contraction Coupling

## Mammalian Respiratory Rhythm Generators

►Respiratory Network Analysis, Isolated Respiratory Center Functions

## Mammillary Body

### Synonyms

Corpus mamillare

### Definition

The mammillary nuclei are located in the medial zone of the hypothalamus. Major afferents arrive via the fornix of hippocampus, while efferents pass largely via the mammillothalamic fasciculus, Vicq d'Azyr bundle to the anterior thalamic nucleus or via the dorsal longitudinal fasciculus (Schütz) to the visceral centers in the brainstem and spinal cord. Component of the Papez neuronal circuit. Involved in affective actions and learned processes.

Damage to the mammillary body, e.g. in the case of alcoholic encephalopathy, results in affective impairments and marked loss of perceptivity.

►Diencephalon

## Mammillary Nuclei

### Synonyms

►Nuclei mamillares; ►Nuclei of mammillary body

### Definition

A distinction is made between the following nuclei of the mammillary body:

- Mammillary body, medial nucleus
- Intermediate mammillary nucleus
- Mammillary body, lateral nucleus
- Posterior nucleus

The medial nuclear region is especially pronounced in humans and connected via the thalamus with the prefrontal cortex. Selective dysfunction of the mammillary body, medial nucleus results in Korsakoff syndrome (amnetic syndrome with anterograde and retrograde impaired memory, and diminished drive).

►Diencephalon

## Mania

►Bipolar Affective Disorder

## Manic-depressive Illness (MDI)

►Bipolar Affective Disorder

## MAP

**Definition**
Microtubule-associated Protein.

►Microtubule

## Map Refinement

**Definition**
The process by which the initial crude topographic map of a sensory surface to structures in the central nervous system, is refined later in development.

## MAPK

**Definition**
►Mitogen Activated Protein Kinase

## Mapping Study

**Definition**
An experimental procedure in which electrodes are placed into the cortex of a living brain to record the electrical activity of neurons in response to various stimuli.

►Evolution of Association Pallial Areas: Parietal Association Areas in Mammals

## Maps

**Definition**
Neurons may be arranged so that they represent the outside world in a systematic, topographic manner. Those arrangements are called neural maps. The most famous maps may be the representation of the body surface in the somatosensory cortex.

## Marburg's Variant

**Definition**
This is a fulminant, widespread demyelinating disease without remissions which is fatal within 1–2 years. Lesions in Marburg's multiple sclerosis (MS) are more destructive than those usually seen in MS with widespread myelin destruction, severe axonal loss, edema, massive macrophage infiltration and extensive necrosis. Lesions on magnetic resonance images (MRI) increase in size and become confluent reflecting large areas of demyelination.

►Multiple Sclerosis

## MARCM

►Mosaic Analysis with a Repressible Cell Marker

## Masking of Sounds

**Definition**
This refers to the increase in the level of a "target" sound (measured in dB) that is required to overcome effects produced by a second sound.

►Psychoacoustics

# Masking (Positive/Negative)

[2]Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, QC, Canada

## Synonyms

Disguising

## Definition

The attenuation (negative) or enhancement (positive) of a measure of the circadian master clock by an exogenous stimulus or factor.

## Characteristics

Masking is a term applied to a number of phenomena in circadian research, whereby some clock-controlled variable of interest is obscured, but not necessarily altered, by an exogenous factor. Masking can be superimposed on ►entrained or ►free-running rhythms, and can be identified by the sudden change in behavioral state that occurs with its onset or offset. Often the effectiveness of the masking stimulus is dependent on the circadian phase of the variable of interest. Masking can limit the interpretation of experimental results, which has necessitated the adoption of particular experimental protocols in order to reveal the endogenous circadian rhythm of the variable of interest. Two areas where masking has had a significant impact on experimental methodology are masking of locomotor activity by light in rodents and the masking of the core body temperature (CBT) rhythm by posture and sleep in humans.

### Photic Masking of Locomotor Activity

Photic masking is caused by the direct enhancement or inhibition of locomotor activity by light, and is mediated by the visual system, as it is abolished by orbital enucleation [1], but not by lesions of the master circadian clock, the ►suprachiasmatic nucleus (►SCN) [2]. Devising means of reducing masking effects has led to the development of special methodologies including the use of constant darkness, constant light, and skeleton photoperiods. In ►diurnal species like canaries, light produces positive masking, inducing or increasing locomotor activity, while darkness inhibits activity [3]. In ►nocturnal species, the effect of light is inhibitory, particularly when exposure occurs during the active phase, while darkness results in a release from inhibition or "unmasking" [4]. Positive masking by light has been observed in nocturnal rodents at very low light levels, inviting speculation that the utility of low light levels for successful foraging, compared to total darkness, can result in increased locomotion [1].

Interestingly, in rodents, positive and negative masking appear to be mediated by different aspects of the visual system. Negative masking is independent of the image-forming visual pathway, as suppression of locomotor activity was observed in mutant mice that have nearly total degeneration of both rods and cones [1]. In fact, negative masking appears to be mediated by melanopsin-expressing ►retinal ganglion cells, as melanopsin knock-out mice show an impaired masking response to light, compared to wild-type mice. Negative masking of activity occurs in melanopsin knock-outs during the first part of a 3 h light pulse, but activity gradually increases to darkness levels, despite the continued presence of light. In contrast, wild-type animals show negative masking throughout the three hour light pulse [5]. This suggests that melanopsin-expressing retinal ganglion cells are necessary for the maintenance of photic inhibition of locomotor behavior, but not for the initiation of masking. Interestingly, positive masking requires the classical ►photoreceptors. Positive masking is intact in wild-type mice and in melanopsin knock-out mice [5], but is absent in rodless mice [1].

### Masking of Circadian Core Body Temperature

Masking is a confounding variable in human circadian rhythms research because of the enormous difficulty of eliminating or even effectively modeling the effects of exogenous variables on the circadian core body temperature (CBT) rhythm. CBT is frequently used as a marker of the phase and amplitude of the circadian clock in humans because it is more readily measured in a continuous manner than circadian rhythms of ►melatonin or cortisol secretion, which must be sampled frequently via plasma, saliva, or urine. CBT is directly controlled by the SCN master clock, and easily measured with a rectal probe, but is influenced by a large number of exogenous variables including the ►light/dark cycle, sleep, activity, social interaction, posture, ambient temperature, and humidity [6]. Three methods have been used to control masking effects in humans: the ►constant routine (CR) procedure, the ►forced desynchrony procedure, and ►mathematical purification. The "gold standard" of these is the CR, which holds masking effects constant in order to reveal the CBT rhythm. After maintaining a regular sleep-wake schedule for several days to weeks, subjects enter a temperature, light, and humidity controlled laboratory where they remain awake in a semirecumbent posture throughout the 30–72 h assessment. Movements are kept to a minimum and meals are replaced by isocaloric

snacks at regular intervals. Using this technique, Czeisler and colleagues have been able to accurately determine the human phase response curve to light [7]. A major limitation of the CR is that effects of fatigue and sleep deprivation are not controlled. In contrast, a forced desynchrony protocol allows for the measurement of masking effects of sleep by placing subjects on a sleep-wake schedule either much longer, or much shorter than 24 h, to which the master ►circadian pacemaker is unable to entrain. In this way, the intrinsic circadian period of CBT is revealed and the effect of sleep can be observed at all circadian phases [8,9]. While both of these techniques are very powerful, they are limited by the necessity of being carried out in a laboratory over extended periods of days to weeks. In contrast, mathematical purification, which removes masking effects mathematically, can be performed on any data set, whether obtained in the laboratory under rigorous conditions, or in the field. Unfortunately, although purification is very powerful, it is limited by the availability of the data used to describe masking effects. For example, physical activity raises core body temperature. Therefore, to subtract the effect of activity from the endogenous CBT rhythm, the effect of that activity on temperature must be known. While some work has been done to measure the effects of posture and activity on temperature, normative values for a particular population of interest may not be available [6]. Also problematic is that many purification methods assume that exogenous factors affecting CBT are independent of each other and of the phase of CBT. If this assumption is violated, a purification model that was simply additive could potentially obscure changes in phase. Using a 90 min day protocol, Moul and colleagues [10] demonstrated that the masking effects of sleep and posture on CBT are not consistent across the day, but in fact also show circadian rhythms. The greatest rate of temperature decrease occurred several hours before the CBT minimum, while the subject was lying in bed awake, and gradually decreased after sleep onset. While a model for purification of CBT could certainly incorporate this type of data, rigorous testing and comparison with accepted laboratory based protocols like the CR will be necessary to determine the reliability and validity of any purification method, particularly when used with clinical populations, where observations about the phase relationships between CBT and masking variables may differ from that observed in normal subjects.

# Mast Cell

## Definition

Mast cells are a type of resident tissue leukocyte, widely distributed in a variety of tissues/organs. Mast cells have large numbers of cytoplasmic granules containing histamine, bradykinin, prostaglandins, and etc., which can be released upon mast cell activation (a process called degranulation). Many of these substances released have effects such as vasodilation and smooth muscle contraction. In an activated state, mast cells can also secret certain types of cytokines that shape further adaptive immune responses.

# Master-Slave Oscillators

## Definition

Master oscillators are those that set the phase and period of circadian rhythms by driving effectors for multiple

rhythmic processes, or by coordinating slave (secondary) oscillators that drive effectors. Slave oscillators drive local rhythms, and do not coordinate the phase of oscillators elsewhere.

►Internal Desynchrony

# Mastication

## Synonyms

Chewing; rhythmic jaw movements

## Definitions

The initial stage of digestion in which pieces of food are mechanically broken down and mixed with saliva by the rhythmical action of the teeth.

## Characteristics

### Quantitative Description

Humans and most other mammals except carnivores grind or chop food between their upper and lower teeth prior to swallowing. The incisor teeth are used to bite off pieces of food that are then transported back in a series of simple movements (Fig. 1a) by the tongue and facial muscles to the premolar and molar teeth, where reduction of the food takes place (Fig. 1b) during a series of repetitive movements of the mandible, at about 1.5 Hz in adult humans. The general form of each movement cycle depends on the type of food being eaten: brittle foods tend to be chopped, while tough foods are chewed with wider lateral strokes. As the size of the particles declines with successive cycles, the amplitude and velocity of the opening and closing movements of the jaw fall, and forces applied between the teeth drop. The tongue forms the food and intermixed saliva into a bolus during a pause in the opening phase of the cycles preceding swallowing (Fig. 1c).

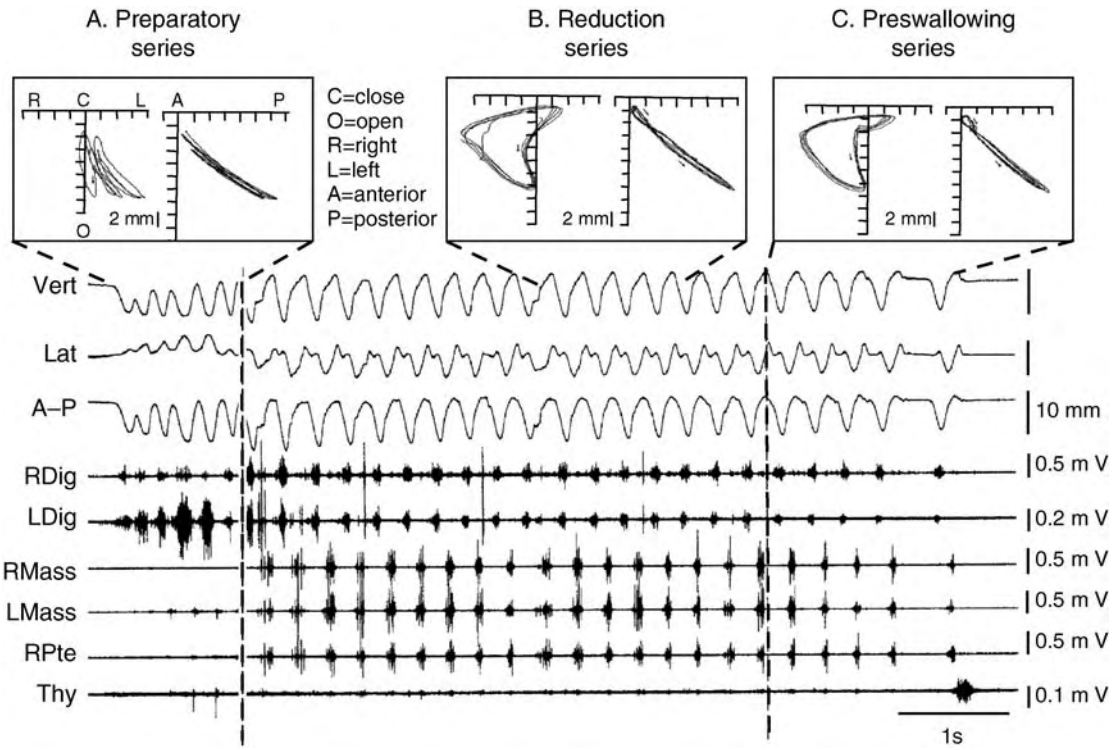
### Higher Level Structures

The essential circuits controlling mastication are located in the ►hindbrain, and the basic rhythmical alternation of jaw opening and closing movements can be produced by a hindbrain Central Pattern Generator (CPG) in the absence of sensory feedback [1–3]. However, when scientists began to use repetitive electrical pulses to stimulate the brain in the nineteenth century, they found that mastication was represented in the cerebral cortex of primitive mammals and in more evolved species, including humans [3,4]. In lower species, the various patterns of natural mastication are represented at distinct sites in an orderly fashion. In primates, the cortical masticatory area is found at the lateral end of the ►precentral gyrus, but it does overlap with the more medial representation of individual jaw, tongue and facial muscles in the primary motor cortex, and also extends into the adjacent sensory cortex in the ►postcentral gyrus [5]. Neurons in both the cortical masticatory and adjacent motor cortex receive inputs from orofacial sensory receptors, and lesions or cold block of both regions disrupt ingestion, mastication and swallowing.

### Lower Level Structures

The essential parts of the masticatory CPG lie between the rostral poles of the Vth (trigeminal) and VIIth (facial) cranial motor nuclei. There are two CPGs, one for each side, that are connected by axons that cross the midline. Each CPG is made up of many neurons. There are a large number in the lateral ►reticular formation (RF) that surrounds the Vth motor nucleus (Motor V), in the adjacent spinal trigeminal nucleus (Spinal V) and in the dorsal cap of the Vth main sensory nucleus (Main V), which change their pattern of firing during ►fictive mastication (Fig. 2).

Many of these neurons control V motoneurons directly [2]. Some fire tonically, but most of them fire rhythmical bursts of action potentials that coincide with either the jaw closing or jaw opening phases of the "fictive" masticatory cycle [6,7]. Most of the neurons receive inputs from oral mechanoreceptors or ►muscle spindles, and from the motor cortex [7]. The CPG also includes the central axons of muscles spindle afferents, which appear to transmit messages from their terminals in Spinal V and lateral RF backwards to their other terminals in Motor V [2]. The motor neurons in turn control the activity of four groups of muscles: one to open the jaws- the digastric, and three closers-the temporalis, masseter and pterygoid groups, and four groups of teeth (Incisors, Canines, Premolars, and Molars). The jaw closing groups are complex, multi-component muscle systems that are capable of moving the mandible in all three planes. All are innervated by the trigeminal nerve, except for a portion of the digastric muscle that is innervated by the facial nerve. The jaw closing groups are very powerful and also fatigue resistant. Mastication requires coordinated actions of the tongue and facial muscles. Saliva is mixed with the food during mastication, and salivary enzymes begin the first stage of chemical digestion. However, the main function of saliva is to provide lubrication during mastication and swallowing. Activation of ►periodontal pressoreceptors causes reflex salivation.



**Mastication. Figure 1** Records of movements of the lower incisor teeth of an awake rabbit and of jaw muscle electromyographic (EMG) activity during the mastication of a pellet of rabbit chow. The sequence of movements is divided into Preparatory, Reduction and Preswallowing series of cycles. The Preparatory cycles have only two phases, Opening and Closing; the Reduction series has a Slow Closing phase in which the food is ground up, and during the Preswallowing phase, the jaw pauses during opening to allow the bolus to be formed. Vert, Lat and A-P- movement of the teeth in the vertical, lateral and anterior-posterior directions. RDig, LDig- right and left digastric EMGs. RMass, LMass- right and left masseter EMGs. RPte- right medial pterygoid EMG. Thy- thyrohyoid muscle EMG (swallowing marker). In A, B and C, the output of two pairs of axes is combined to show movement of the teeth viewed from the front (left) and from the left side (right). Data from Schwartz G et al. (1989) Journal of Neurophysiology 62:273–287.

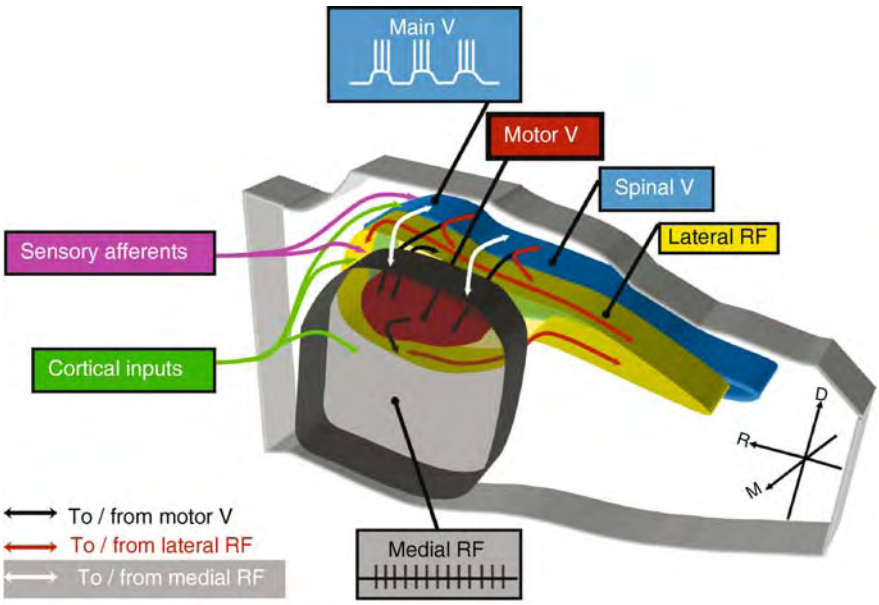
The medial RF at the level of Motor V also seems to be implicated in the control of mastication [3,8], but we do not know yet if it is an essential part of the CPG. This region does not project directly to V motoneurons, but it is reciprocally connected with the lateral subgroups [9]. It gets direct inputs from the motor cortex, but not from sensory afferents [8]. Many neurons in the dorsal half of the medial RF fire in either the jaw opening or the jaw closing phases, while most ventral neurons fire tonically. These tonic neurons appear to inhibit the lateral subgroups during mastication, while the phasic dorsal neurons have mixed effects [8].

## Higher Level Processing

The primary motor cortex has a primary role in coordinating the ingestion and the transport phase of mastication, while the masticatory cortex is more important in food reduction, preswallowing and swallowing [4, 5]. The corticobulbar pathways from these regions of the cortex innervate all of the brainstem masticatory cell groups bilaterally (Fig. 2), and the firing pattern of many brainstem neurons is modified by the short-latency inputs from the cortex during fictive mastication [4,5,7,8].

## Lower Level Processing

The motoneurons of the jaw closing muscles occupy the anterior and dorsal portions of Motor V, while the jaw opening motoneurons are confined to the ventral and caudal parts. During fictive mastication, the CPG causes jaw opening motoneurons to fire in very high frequency (up to 250 Hz) bursts, which are superimposed on slow rhythmical depolarizing potentials that return to resting levels during the jaw closing phase [3]. The slow rhythmical oscillations are mediated by excitatory amino acids. The jaw closing motoneurons are only weakly depolarized by similar slow potentials during the closing phase of fictive



**Mastication. Figure 2** A model of the hindbrain CPG for mastication and associated structures. The figure shows the right side of the brain viewed from the midline and slightly from behind. The Main sensory (blue-Main V) and Spinal trigeminal nuclei (blue- Spinal V)) and adjacent lateral reticular formation (yellow-lateral RF) receive direct inputs from sensory afferents and from the sensori-motor cortex that are capable of activating the CPG. The three regions are reciprocally connected, and all project directly to Motor V. Some neurons in Main V have the intrinsic ability to generate slow depolarizing potentials and bursts of spikes (Inset). The medial RF has direct inputs from the cortex, but not from sensory receptors. It is reciprocally connected with the lateral nuclei, but not with Motor V. Neurons in the middle of the nucleus can fire tonically even when isolated from other neurons. R-rostral, M-medial, D-dorsal.

mastication: however, they are much more active during jaw closing in real mastication, because of excitatory feedback from sensory receptors (see below). This feedback is cut off by strong glycinergic inhibition of the motoneurons during jaw opening [3]. Trigeminal motoneurons receive a dense serotoninergic innervation, and express several receptor subtypes. Serotonin has little effect on the activity of quiescent neurons, but it plays an important role by modulating firing generated by other transmitters. It also modifies the masticatory rhythm [2,3].

The CPG can be turned on by tonic stimulation of sensory receptors in the mouth and muscles [1], and during mastication, several groups of afferents provide feedback to motoneurons, the CPG and to higher centers (Fig. 2). The pattern of firing that emerges from the motoneurons is the result of these interactions. The effects of three groups of afferents (muscle spindles, periodontal pressoreceptors and nociceptors) have been well described.

There are no, or very few, muscle spindles in jaw opening muscles, but jaw closing muscles contain many. These provide monosynaptic excitatory glutamatergic feedback to jaw closing motoneurons, and to many interneurons in the trigeminal sensory nuclei and lateral RF [2,6,7]. During the jaw opening phase of mastication, these receptors are stretched, and they fire at high frequency [10]. This activity facilitates the CPG, but the monosynaptic excitation of the jaw closing motoneurons is prevented by hyperpolarization (see above). Many spindle afferents continue to fire as the jaw closing muscles shorten because the ►fusimotor neurons are driven strongly by the CPG. This muscle spindle input lengthens the jaw closing motoneuron bursts and greatly increases firing frequency [1,10].

Periodontal pressoreceptors are located in the ligament surrounding the roots of the teeth. They signal the direction and intensity of loads generated during mastication. Tapping on the teeth causes a bi-synaptic inhibition of the jaw closing muscles that is abolished by the glycine antagonist, strychnine, but heavy pressure on the teeth does not cause inhibition during mastication. Instead, these receptors cause the jaw closing phase to lengthen, and jaw closing motoneurons to fire at higher frequency. It appears that the CPG shuts the inhibitory pathway, and opens an excitatory one during mastication [1,10].

The CPG also modulates inputs from other oral mechanoreceptors and particularly from nociceptors (pain afferents). When nociceptors are stimulated during chewing (e.g., by biting the tongue), they strongly inhibit the jaw closing muscles [1].

### Process Regulation

Tonic stimulation of inputs to the CPG coming from sensory receptors, from the cortex and other forebrain and midbrain structures is converted into rhythmical mastication by the CPG [1–3]. It is not known how this happens, but there is evidence that special properties of the network and of individual neurons may be involved. For example, when the pattern of mastication changes, say from grinding on the left teeth to grinding on the right, about half of the active lateral RF and Spinal V neurons change their rhythmical firing pattern, while the others stop participating in the CPG [7]. This suggests that the CPG uses at least two methods to generate different patterns of mastication: addition and subtraction of its constituent neurons, and changes in firing frequency of active elements. There are extensive interconnections, both excitatory and inhibitory, between all of the lateral subgroups of the CPG [9] that must be important in this reorganization, and perhaps also in generating the rhythm. However, some CPG neurons seem capable of generating self-sustained membrane oscillations either spontaneously, or in response to tonic inputs, and this can lead to regular bursts of firing at about the masticatory frequency [6,9]. Most of these are in the dorsal cap of Main sensory V, which is the only region of the nucleus that seems to be part of the CPG [6]. Most of the interactions within these circuits involve amino-acid neurotransmitters. Excitatory synapses seem to release glutamate, while inhibitory inputs are either glycinergic or ►GABAergic [2,9].

### Function

The function of mastication is the mechanical breakdown of food to prepare it for digestion.

### Pathology

Disorders of mastication are not a frequent symptom of neurological disease, although strokes that cause lesions of the cortical masticatory area are associated with difficulty in initiating mastication and swallowing [5]. Abnormal orofacial movements, which sometimes resemble purposeless mastication, are a symptom of tardive ►dyskinesia, which is associated with damage to the striatum caused by long-term treatment with neuroleptic drugs.

Chronic pain of the jaw muscles and joints slows mastication and reduces chewing forces, and loss of salivary tissue (autoimmune disease, radiation) makes it hard to chew and swallow. Many millions of people throughout the world are handicapped because the ability to masticate falls as teeth are lost.

### Therapy

There is no effective treatment for tardive dyskinesia. Lost teeth can be replaced by prostheses.

# Matching to Sample

### Definition

Matching to sample discrimination (MTS) is a kind of conditional discrimination. In MTS training, a sample stimulus is given first, then two or more different choice stimuli are given to animal. One of the choice stimuli is the same as the sample stimulus and the animal has to choose that stimulus to get reward.

►Discrimination

## Material Body

### Definition
A continuous collection of material particles. Technically, such a collection is known as a material "continuum" or, more precisely, a differentiable manifold.

►Mechanics

## Material Evolution

### Definition
A concept used in theories of growth and remodeling, whereby certain phenomena (such as motion of dislocations, addition of matter or rearrangement thereof) take place in the material body, in addition to its deformation in space. An evolution law prescribes the time-evolution of the material isomorphisms of a body.

►Mechanics

## Material Frame Indifference

### Definition
A constitutive principle according to which the constitutive functionals are independent of the observer, whether it be inertial or not.

►Mechanics

## Material Isomorphism

### Definition
A map between the neighborhoods of two points bringing the material responses into exact coincidence. Also called a material transplant.

►Mechanics

## Material Symmetry

### Definition
A material isomorphism of a point with itself.

►Mechanics

## Material Time-Derivative

### Definition
The derivative of a field with respect to time while following a specific particle. In the Lagrangian description, the material time-derivative coincides with the partial derivative of the field with respect to time. In the Eulerian description an additional term needs to be added to take into consideration the fact that the particle is moving in space.

►Mechanics

## Materialism (Dialectical, Eliminative, Emergentist)

Jürgen Schröder
University of Karlsruhe, Heidelberg, Germany

### Synonyms
Materialist monism

### Definition
Materialism is a metaphysical doctrine opposed to idealism according to which everything that exists is material, i.e. there are only material but no spiritual substances. Angels, gods, incorporeal souls and spirits are denied. Secondly, materialism is a methodological attitude that is critical of tradition and authority. According to this attitude, explanations of mental phenomena should be given without reference to occult powers whose existence cannot be independently (from the facts to be explained) ascertained.

### Description of the Theory
#### Dialectical Materialism
Dialectical materialism is a doctrine that originated in the nineteenth century in the works of Marx and especially

Engels [1,2,3]. Both authors approved of Hegel's dialectical method but rejected his idealism. They held that matter is primary and that mind and consciousness are dependent on matter. Marx's materialism was empiricist in the sense that all real knowledge is based on sense experience, it was realist in that he believed in a mind-independent material world. Furthermore he rejected supernaturalism (the doctrine that some events like, for example, the plague are to be explained by the intervention of God or the Devil) and mind-body dualism.

The dialectical aspect of dialectical materialism was especially emphasized by Engels who understood dialectical materialism as superseding mechanical materialism as it was defended e.g. by Vogt, Büchner, or Moleschott. At the core of mechanical materialism is the idea that every phenomenon of nature, including life and mind, can be reduced to arrangements of the simple constituents of matter and explained by the laws of mechanics. As opposed to this sort of reductive materialism, dialectical materialism holds that there is real novelty in the development of the world and human history, e.g. new substances result from chemical combinations, life as a novel phenomenon results from the combination of a complex of chemical processes and minds result from the complex functioning of brains. Mechanical materialism turned out to be false because electromagnetic phenomena cannot be explained by the laws of mechanics. The underlying idea, however, that every phenomenon can be ultimately reduced to physical arrangements and physical laws has survived until today in the doctrine of physicalism.

Engels claimed that there were three fundamental dialectical laws of nature [3]: (i) The sudden change of qualities of phenomena when certain quantities in them reach a certain threshold, (ii) the law of the interpenetration of opposites, (iii) The law of the negation of the negation. Examples of the first law are the change from liquid to solid state when water is cooled down, the transformation of mechanical motion into heat, and the occurrence of a social revolution after the oppression of the people reaches a certain threshold. The interpenetration of opposites is an idea that Hegel used in order to explain how change and development are possible. For example, the movement of a body in space, Hegel thought, is only possible if the body is at one and the same instant at a certain place and at another place. For if it were at each instant at only one place then there would be only a series of stationary states but no movement. According to Engels (and Hegel) the opposites (the different places) have to interpenetrate one another if movement is to be possible.

The law of the negation of the negation is a law that applies especially to those changes in nature that give rise to novel phenomena and to progress in some sense. Examples of this law are the process in which a plant produces seeds giving rise to further plants, the process in which the early materialism of the Greeks was superseded by idealism which was superseded in turn by dialectical materialism, and the development of geological formations.

Of these three laws the second and the third seem to be unacceptable for different reasons. The second law amounts to the idea that there are contradictions in nature and to the idea that two sentences that contradict each other can both be true. From a contradiction, however, any sentence whatsoever can be logically derived and that means that the idea of truth, the idea that truth is a property only of *some* descriptive sentences and not of all, is abandoned. The third law suffers from a different defect. A law that is applicable to virtually everything and that accordingly cannot be refuted by any possible observation is cognitively useless. It is uninformative and its explanatory power is zero.

## Eliminative Materialism

Eliminative materialism shares the rejection of supernatural entities like gods and angels with dialectical materialism. It also rejects the existence of soul substances in addition to physical substances. Whereas dialectical materialism with its three laws and its emphasis on novelty and progress is a positive doctrine (although a poor one), eliminative materialism is a negative doctrine. It says that certain things are not what we take them to be. Furthermore, the scope of eliminative materialism is much narrower than the scope of dialectical materialism. Eliminative materialism is a thesis about a certain part of the mental, viz. the propositional attitudes and qualia. The thesis about propositional attitudes says that since they are posits of a folk theory, viz. folk psychology, and since every folk theory in the past was wrong, folk psychology will also be wrong. Besides, Churchland argues that folk psychology does not explain certain things (e.g. why we need sleep), that it has been in a state of stagnation for more than 2,000 years and that it is not reducible to the neurosciences (which is bad for folk psychology because the ontology of the latter is beyond any doubt) [4]. But – and this is the decisive move – if the theory (folk psychology) gets the properties of its posits quite wrong then the terms that are used in folk psychology like "belief," "fear," "hope," "desire" etc. do not refer. They do not designate any part of reality. They are empty. And their being empty means that propositional attitudes don't exist.

The corresponding thesis about qualia, viz. that they don't exist, is similarly argued for. Qualia, i.e. sensory qualities like tickles or color qualities, are supposed to have certain properties as e.g. that one cannot be wrong about one's own sensations. But there is nothing that has this property. So qualia *in the traditional sense* don't exist [5]. This line of attack on qualia is, however, easily rebutted by admitting that qualia *in this sense*

don't exist and by insisting that states with a characteristic feel and a subjective character do exist.

The basic strategy of eliminativists is, first, to say that propositional attitudes are posits of a theory with which we explain behavior and then to argue that this theory is quite probably false. The final step concludes from the alleged falsity of the theory to the emptiness of the terms of the theory and thereby to the non-existence of the entities those terms were supposed to refer to. This strategy can be criticized at every step.

First, as an alternative to the idea that we predict and explain the behavior of others by applying a theory (folk psychology) some theorists have urged that we run a simulation of the other's mental processes within ourselves, i.e. we take the information about the other person's situation in terms of her goals and beliefs and then ask ourselves what *we* would do in a similar situation [6]. In order to exclude the possibility that this simulation is done with an underlying theory of behavior, the proponents of the simulation approach point out that human behavior is very sensitive to slight changes in situations and that an incorporation of all the possible details of a situation into either the theory or the computational process of deriving conclusions would be just too complex a task.

Second, contrary to Paul Churchland's claim that our folk psychology (if we accept that we use a theory in the prediction of everyday behavior) is probably false, other theorists have insisted that it is a highly successful and deep theory without parallel in its domain (i.e. everyday behavior) [7].

Third, even if one takes folk psychology to be a false theory, it is far from clear what consequences its falsity has. A theory can be false in many ways. It may be that one peripheral claim of the theory is false or that many are. Or it may be that a central postulate has to be given up. The theory of electrons from 1900 ascribed trajectories to electrons, but the theory from 1934 rejected trajectories. Both theories, however, were about the same entities, viz. electrons. The term "electron" did not lose its reference by the fact that the theory from 1900 was found to be false. On the other hand, the theory of combustion before Lavoisier postulated a substance called "phlogiston" that was thought to be released in a combustion process. Oxygen, however, was thought to be absorbed by the burning material. In this case, the phlogiston theory of combustion was not only false, but the term "phlogiston" was said to refer to nothing. In order to adjudicate the plausibility of eliminative materialism it would be necessary to argue that folk psychology gets things so fundamentally wrong that the propositional attitudes will share the fate of phlogiston.

One way to argue for this conclusion takes its cue from cognitive science. There are certain models of cognitive processes like memory and inference according to which the information that is needed for various tasks is distributed over a network of nodes (connectionist models). In these networks there are just no entities to which the two characteristic properties of propositional attitudes, viz. a certain content and a certain causal role, can be ascribed. If connectionism with distributed representations turns out to be the best paradigm in cognitive science then this may be a decisive reason against the existence of propositional attitudes *thus* conceived (as distinct entities with a particular content and a particular causal role) [8].

On the other hand, propositional attitudes needn't be conceived in this way. They needn't be states with distinct causal roles, but may be rather like parallelograms of forces, i.e. devices that we use in order to make predictions but that do not themselves belong to the furniture of the world [9]. However, this move, viz. an instrumentalist conception of propositional attitudes, amounts to abandoning the reality of the attitudes altogether if one adopts a causal criterion of reality, i.e. that being real requires being causally efficacious.

A common objection to eliminative materialism urges that the eliminative materialist makes an assertion when expressing the thesis that there are no propositional attitudes. According to common sense assertions express beliefs. The eliminativist thus falls victim of the contradiction that he or she believes that there are no beliefs. Against this Patricia Churchland pointed out that we need a successor concept for the concept of belief [10]. Once we dispose of such a concept we can say that an assertion expresses a type of cognitive state T which is not a belief. Thus the contradiction would disappear. However, the problem with this answer is that nobody has any idea what such a successor concept would be like. So this answer does not seem to amount to much more than handwaiving.

## Emergentist Materialism

Emergentist materialism in the broad sense is the doctrine that although there are only material substances there are various types of such substances with properties that cannot be reduced to properties of their parts together with composition laws describing the interaction of the parts [11]. According to a weaker sense of "emergentist materialism" any materialism that acknowledges properties of wholes which are not properties of their parts is emergentist [12]. In the early 1920s, before the advent of quantum mechanics and quantum chemistry, C.D. Broad believed that certain properties of chemical compounds, in particular their chemical behavior, could not be predicted in principle from knowledge about the properties of the atoms and knowledge about how the atoms interact in a molecule. "In principle" meant that empirical regularities like "whenever atoms of type x, y, z etc. combine in proportion P, then the resulting compound will show behavior B in circumstances C" were disallowed for the

prediction. These regularities were also called "ultimate laws" because they were not reducible to or explainable by other facts. The British emergentists like Samuel Alexander and Convy Lloyd Morgan thought that predictions of chemical, biological, psychological or sociological properties could be made on the basis of such empirical laws but they also thought that these laws were brute facts that cannot be further explained. According to the British emergentists a property of a whole was emergent if and only if (i) it was not also a property of its parts and (ii) it was not deducible from the properties of the parts and general composition laws. If a property of a whole was only deducible from the properties of the parts and an ultimate law connecting these properties with the property of the whole then it was said to be emergent. The important point about composition laws was that they be general. In the case of chemistry this meant that they should be valid for all chemical compounds and not only for a certain kind of compound.

A prima facie strength of emergentist materialism was that it allowed to account for the major distinctions in our common sense picture of the world: the distinction between the living and non-living, and the distinction between organisms with a mind and organisms without a mind. Life and mind were considered to be major emergent properties.

A problem with emergentism thus construed is whether emergence is a property of reality itself or whether it is rather a property of our knowledge of reality. Certain properties that were considered to be emergent in the past such as the chemical properties of chemical compounds or the property of life with its more specific properties of growth, reproduction, metabolism etc. have turned out to be non-emergent according to Broad's criterion of non-deducibility. This fact supports the hypothesis that emergence has to do with our knowledge rather than with reality itself [13].

As far as the mind and the brain are concerned, emergentist materialism claims that among all properties of all things there is a certain class, viz. the qualities of sensations, which is not deducible from physical properties and furthermore that these qualities will remain undeducible and therefore emergent forever [14,15]. The more specific idea is that it will appear forever contingent that the special character of, for example, a visual sensation is connected with a particular brain process. It is claimed that we cannot give any reason why a visual sensation should be correlated with brain process A and another visual sensation with a brain process B instead of the reverse.

There is, however, an ambiguity as to the concept of qualia involved in this claim. The quality of an sensation can be described relationally by comparing it to other qualities of the same domain. Colors, for example, can be arranged in a circle such that any color that is on the opposite side of the circle is maximally dissimilar to a given color with respect to the other colors. All the relational properties of a sensory quality constitute its relational profile. It seems plausible that a state with a certain relational profile cannot be realized just by any brain state but only by such brain states that have enough structure in order to guarantee the relational profile of the respective sensory quality. Qualitative states with different relational profiles should accordingly be correlated with brain states that have different structures. If we identify a sensory quality with a certain relational profile there probably are explanations of sensory qualities that remove the impression of contingency that constitutes the so-called explanatory gap [16].

On the other hand, qualia may be taken non-relationally. One may conceive of a quale as a structureless property that has a certain intrinsic character. Even then qualia would not be completely without relations. But the only relations would be relations of difference without any specifications of greater or smaller difference. The emergentist claim would then be that with respect to these intrinsic, non-relational qualities any correlation with some brain process or other would be arbitrary, i.e. there would be no reason why the intrinsic quality of red should be correlated with brain process A instead of B.

According to this line of reasoning the only really emergent properties would be the intrinsic qualities of experience. But the underlying idea may also be used to show that any real property whatsoever is emergent relative to more fundamental properties. For, imagine any property, e.g. the property of being magnetic or the property of having some mass m. In order to characterize this property, you may specify a certain relational profile. You may say what the causal role of this property is and you may say how it differs from other properties in its domain. But you may also assume that this property has a certain intrinsic character over and above its relational profile. You may even assume that this intrinsic character is the bearer of the relational profile. In contrast with the case of qualia you don't know what this intrinsic character is like, you only think of it indirectly via its role of being the bearer of the relational profile. All the same, if you take any set of supposedly more fundamental properties and any composition rules there will be no reason why it is correlated with intrinsic character A instead of intrinsic character B. So the reason for the appearance of contingency of qualia relative to the brain states they are correlated with is their intrinsic character and not their being mental. Accordingly, every real property, i.e. every property with a distinct causal role is emergent relative to some set of more fundamental properties as it appears equally contingent that its intrinsic character is correlated with that set of more fundamental properties.

But if every real property is emergent then the concept of emergence does no useful work anymore, e.g. to demarcate the major layers of reality.

## Maze Learning

### Definition

A maze is a spatial puzzle. Mazes are typically two-dimensional and involve a player, termed a “traveler”, who attempts to move from a start location to a goal. A labyrinth is a particular type of maze with tortuous, walled alleyways and a single route from start to goal. Mazes have long been used as tests of learning, memory and intelligence. Common animal mazes include the T maze, the plus maze, Hebb-Williams mazes, the sunburst maze, the radial-arm maze, the water maze and the Barnes maze. Three important chapters in animal psychology involve mazes. Beginning in the 1920s Karl Lashley trained rats in labyrinths to explore their general learning capabilities. He found that no particular part of rat neocortex was necessary or sufficient to support maze learning and memory, and, from this observation, derived the principal of equipotentiality (also known as mass action). In the 1940s and 1950s two contentious groups (the behaviorists and the cognitivists) used a broad array of mazes to test whether rats learn about space by means of response learning or map learning. Finally, in recent years the radial-arm maze, the Barnes maze and the water maze have been used extensively to asses the role of the hippocampus in spatial learning and memory.

# M-channels

## Definition

M-channels (M for muscarine) are non-inactivating, voltage-sensitive $K^+$ channels that exist in many types of neuron in the central nervous system and in peripheral sympathetic neurons, and generate the only sustained current in the range of action potential initiation. In the absence of acetylcholine, M-channels open at resting membrane potential and dampen neuronal excitability. Acetylcholine inhibits M-channel activity by activation of the muscarinic $M_1$ receptors. The M-current can be modulated by various receptor types, either by suppression or enhancement. There are two main ways of modulation: receptor-mediated modulation and the control of current amplitude by intracellular $Ca^{2+}$.

# Meaning (Verification Theory)

Markus Schrenk Dphil
Research Fellow, Department Philosophy, University of Nottingham, University Park, Nottingham, UK

## Synonyms

Verificationist theory of meaning; Verification principle; Verification criterion; Verificationism

## Definition

The verification theory of meaning aims to characterize what it is for a sentence to be meaningful and also what kind of abstract object the ►meaning of a sentence is. A brief outline is given by Rudolf Carnap, one of the theory's most prominent defenders:

> If we knew what it would be for a given sentence to be found true then we would know what its meaning is. […] thus the meaning of a sentence is in a certain sense identical with the way we determine its truth or falsehood; and a sentence has meaning only if such a determination is possible. [1: 420]

In short, the verification theory of meaning claims that the meaning of a sentence is the method of its verification.

## Description of the Theory

Verificationism can only be fully appreciated in the larger context of the philosophical credo it emerged from, namely twentieth Century ►logical empiricism (also known as ►logical positivism) [2].

An empiricist subscribes at least to the following doctrine: intuition or pure reasoning, can reveal what the world is like. All *factual* ►knowledge has its sole source in sense experience. For example, if you want to understand how the human brain works, there is no other way to knowledge than via observation, especially via empirical experiments.

This *epistemic* doctrine (see ►epistemology) about the nature and source of factual knowledge had already been put forward by the ►classical empiricists in the seventeenth and eighteenth Centuries. The novelty of twentieth Century logical empiricism is a shift in focus from this doctrine about knowledge to a doctrine about (scientific) language. More exactly, the logical empiricists tried to underpin the validity of the doctrine about factual knowledge with a doctrine about sentence ►meaning. This is where the verification theory of meaning has its place.

Suppose we stipulate that the meaning of a ►statement (a sentence, a ►proposition) is given by the observations we have to make to find out if it is true. Or stronger, that a sentence has to be discarded as meaningless unless one can offer a description of what fact or state of affairs has to be observable so that this sentence can be said to be true or false. That is precisely what the verification theory of meaning demands: "The meaning of a proposition is the method of its verification." [3: 148]

Suppose furthermore, that all factual knowledge is expressed in meaningful sentences. Then, together with the verification theory of meaning, we arrive back at the epistemic doctrine from above: factual knowledge has its justification in observation. Thus, verificationism is the linguistic counterpart of the empiricists' doctrine about knowledge.

Both logical empiricism and the verification theory of meaning are, however, outdated theories. This is not because the general idea behind them – that empirical knowledge depends on sense experience – has been given up by philosophers. Rather, verificationism in its strongest form faced a few unsolvable technical difficulties. A closer look at the verification theory of meaning, as well as exemplary applications of the theory will unveil some of these problems.

### Verificationism and the Hierarchy of Language

*Historical Background.* The verificationist theory of meaning has a by-product: logical empiricists perceive language to be hierarchically structured. Observational terms are at the basis of that structure, and all other terms further down the hierarchy are translatable into

M

terms of this basis. ►Logic and ►conceptual analysis is the central tool to arrive at such translations of non-observational terms to observational terms. What does this mean?

Take a sentence like "This apple is red." The verification theory of meaning claims that it is meaningful if and only if we can describe which state of affairs has to be observable so that the sentence can be said to be true. In this case, the task seems to be rather easy: "This apple is red" is, indeed, a meaningful sentence – it is true just if the apple in front of us is really red, i.e. precisely if, under normal light conditions, it appears red to us, and false if not.

However, not every sentence contains terms that refer to directly observable features of easily observable objects. For those sentences it is difficult to see how the verificationist criterion can be met. For example, what kind of observation verifies sentences like "This fluid has a temperature of 100°C" or, worse, "The electron's mass is $m_e = 9.11 \times 10^{-31}$kg"?

For these sentences to meet the verificationist criterion of meaning, an intermediate step seems unavoidable: scientific terms which do not refer themselves to directly observable features of the world have to be analyzed or reduced to descriptive terms that do so (See ►operationalism). Those sentences that contain non-observational terms can, with the help of these analyses, be translated into sentences that are observational. Only then can the verification criterion of meaning be applied.

The following example illustrates what we mean: "object O has temperature T" can be analyzed into the phrase "if a mercury thermometer is placed into or nearby object O the mercury will rise (or fall) to mark T." With the help of this analysis we can translate "This fluid has a temperature of 100°C" into "if a mercury thermometer is placed into this fluid the mercury will rise (or fall) to mark 100." The latter sentence clearly indicates which possible observation would verify it. Hence, according to verificationism, the sentence has meaning.

The actual translation of all terms (or sentences) to observational terms (or sentences) is, of course, a utopian dream. In any case, the general possibility of such a reduction would suffice to support the empiricists' credo. Attempts to prove the general possibility have indeed been given [4].

*Verificationism and Metaphysics*. It is easy to see how both the conceptual analysis of terms and the verificationist doctrine about sentence meaning could be used as a tool to criticize or even ridicule metaphysical philosophy. Indeed, to try to show that metaphysics does not make any sense at all was part of the empiricists' programme. Terms like *god*, *nothingness*, or *meaning of life* are so the empiricists not suitable for analysis into observational terms and are, hence, not apt to figure in meaningful, verifiable sentences and philosophical research in general. They can, at best, be used to express a general attitude towards life, a *Lebensgefühl*, but they have no factual content [5].

*Verificationism and Behaviorism*. There is a close relation between verificationism and behaviorism (see ►behaviorism, ►logical). The aforementioned idea of a reduction of all scientific terms and sentences to observable terms and sentences means, too, that psychological terms, i.e., terms concerning the human ►mind, have to be translatable into observational language. This is precisely what behaviorism asks for: attributions of mental states to people (like "Agnes is happy") must be translated into statements about people's observable behavior or, at least, their dispositions to behave.

Take the sentence "Alfons desires a good bottle of wine." Such an ascription of a mental state to a person can only be admitted into scientific language if we can, according to the verificationist theory of meaning, describe the way we determine its truth or falsehood in observable terms. Hence, in order to give the meaning of that sentence we would have to say something along the following lines: "Alfons desires a good bootle of wine" is true if and only if (i) Alfons reaches for a bottle of wine when he sees one standing on the table, (ii) Alfons utters the words "Yes, please!" when someone offers him a glass of Riesling, (iii) Alfons seeks a wine shop when he has got the money and time, etc. This list amounts to a catalogue of observable stimulus and response connections (see ►testability). It thereby offers testing conditions and so gives the meaning of the initial sentence. In this way, statements about mental states are generally thought to be reduced to sentences about behavior (or dispositions to behave).

## Problems with Behaviorism and Verificationism

There are, however, severe problems for behaviorism and consequently for verificationism. For a start, note that the list given above seems to be endless. Wine lovers do various other things additional to those listed above. Yet, when can we stop and be sure to have reached the full meaning of the sentence which is to be analyzed? Is it not rather doubtful that there is a comprehensive catalogue of stimulus-response entries?

Furthermore, some wine lovers might not always be disposed to do the things listed: they might have interfering wishes, other preferences or they might obey certain prohibitions. Alfons could be a wine lover but he might not touch any alcohol for religious reasons. Hence, some sort of proviso will have to be added to the stimulus conditions: if Alfons sees a bottle of wine *and* no other wish or desire or prohibition or promise etc. prevents him from pouring himself a glass then he will do so. However, the verificationist is still not off

the hook, since the word *preventing*, which occurs in the proviso clause, is again an unobservable mental ►predicate (we were not talking about Alfons being observably chained to the chair but about other desires preventing him). In trying to reduce a statement about one mental state to observational language we had to use the non-observational mental terms, and it is questionable whether we can ever escape. (Kind of this vicious regress is already a danger for the analysis of non-mental non-observational terms).

## Verificationism and Physics: Further Problems

Aside from the realm of the mental, verificationism has difficulties with statements from the very ►science which should cause the least problems, namely physics. Consider a law hypothesis like "All masses attract each other." Which kind of observation would conclusively establish this sentence's truth and hence it's meaning? No doubt, this difficulty relates back to the traditional problems of ►induction of how to conclude from some observed events to all of them (including unobserved ones). In the guise of a puzzle about meaning, the problem of induction is, however, aggravated: not only is it difficult to define what would provide conclusive evidence for "All masses attract each other", for verificationism, the lack of such a characterization would mean that law hypotheses do not form meaningful sentences. Hence, they should be dropped from scientific language. And yet, this is unacceptable for general and universal hypotheses are, arguably, central to any scientific enterprise. Note that similar problems arise from sentences about past events for which observations are also in principle impossible.

There have been attempts to reformulate verificationism in weaker forms to avoid these consequences: observations should only be *somehow relevant* to the determination of the truth or falsehood of sentences [6,7: 18–19]. However, instead of going further into detail of those reformulations (which have anyway been unsuccessful in the end) it is worth turning to problems on a more abstract level. The first concerns the status of the verificationist doctrine itself. The second challenges tacit presuppositions of verificationism which turned out to be untenable.

## Verificationism Applied to Itself

Ironically, the verificationist doctrine itself falls short of its own high demands. Take the statement: "Sentences have meaning only in so far as they are empirically verifiable." Are there possible observations which could prove the truth of this very sentence? It seems not. But then the doctrine itself lacks meaning, i.e. it is a statement like metaphysical claims without any sensible content. The logical empiricists' response to this charge was to claim that the verification criterion is prescriptive rather than descriptive in character. It is meant to be a recommendation to scientists of what is best to be counted as proper scientific language; it is not meant to be a factual statement. Note inside that vertification is a similar answer have offered for other indispensable non-factual claims, like mathematical or logical statements, or sentences which state conceptual truths. (See ►necessity; ►necessity, conceptual).

## Verificationism and Meaning Holism

Still more problematic for verificationism is a thesis called *meaning* ►*holism*. Take again the sentence "if a mercury thermometer is placed into this fluid the mercury will rise (or fall) to mark 100." which is supposed to give the meaning of "The fluid is 100° C". Suppose your observation speaks against its truth. You place a thermometer into the fluid, Yet, the mercury does move only a little but not to 100. Unsurprisingly, it is possible to make, adjustments at various other points in our belief-system such that we could, in principle, nonetheless affirm to the sentence that the fluid is 100: we could, for example, doubt that the pressure is appropriate for the measurement and the pressure remains constant; we could suppose that the thermometer is broken; we could claim that thermometer's scale has been wrongly calibrated, etc.

The upshot of this ►thought experiment is that the verificationists' assumption that isolated sentences alone face the tribunal of observational evidence is not justified. It is always a whole bunch of interrelated sentences – a whole belief system – which is tested by observation. This is a thesis which came to be known as meaning ►holism and was argued for by W. V. O. Quine [8]. Single sentences are too small a unit to be verifiable by experience. Instead "the unit of empirical significance is the whole of science." [8: 42]. But if this is so, the verification theory of meaning which is defined for single sentences is false from the outset.

## Verificationism Rejected

The *prima facie* attractive verificationist doctrine proves to be untenable for various reasons: (i) It turned out to be difficult if not impossible to apply the verificationist theory of meaning in a concrete case: this has been shown in the example from behaviorism. Endless lists and regresses threaten the success of an analysis. (ii) It was necessary to rewrite the verificationist doctrine several times, as underlined by the example of law statements which would otherwise have to be discarded as being nonsense. (iii) The self-application of the doctrine reveals its own non-empirical status; and finally, (iv), the hidden presupposition that sentences are the units of observational verification had to be dropped, and so verificationism as a whole.

### The Remnants of Verificationism

It should be mentioned that some verificationist ideas still live on and are indeed worth pursuing. For philosophical theories of sentence meaning it is essential to hold on to the strong link between truth and meaning: some philosophers claim that giving the truth conditions of a sentence (not the *verification conditions* for its truth, though) is giving the meaning of that sentence [9]. The philosopher Michael Dummett even revived a verificationism which is, in some respects, akin to the logical empiricist's doctrine. As a result, Dummett had to adopt anti-realist positions (compare ►realism) when it comes, for example, to statements about laws of nature (►Law, Natural; ►Law, Lawfulness) or the past: he claims that statements whose truth cannot decisively be verified are neither true nor false [10].

### Synonyms

Optical techniques; Force; Acceleration; Sonomicrometry; Strain

### Definition

►Optical methods in biomechanical analyses include high-speed film and video. In the past decade, various motion analysis systems that track passive or active markers have become the preferred mode to capture human and animal movements.

"►Force" cannot be defined by itself. However, the effects of forces can be described. Most importantly, force is described by Newton's second law, which states that, for a particle system, the resultant force acting on a system is proportional to the acceleration of that system. Therefore, forces manifest themselves by accelerating but also by deforming systems.

►Acceleration is the second time derivative of displacement, or the first time derivative of velocity. Acceleration is an instantaneous vector quantity.

►Sonomicrometry is a technique that uses ultrasound transmission from one piezoelectric crystal to another to measure distances and strains. The principle of sonomicrometry rests on the idea that ultrasound pulses travel in a straight line and constant speed through a medium. Therefore, by measuring the time it takes the ultrasound signal to go from one crystal (transmitter) to another (receiver), the distance between the crystals can be calculated.

►Engineering strain is defined as the change in length of a material from its original reference length divided by the original reference length; that is:

$$(L - L_0/L_0)$$

Where: $L_0$ is the original reference length, and L is the current length of the material.

### Purpose

Optical methods in biomechanics are used to quantify the movements of the system of interest. These movements may be on the whole system level, for example human walking, or may be on the microscopic level and include cell motility and division, or the movements of a ►molecular motor protein (e.g. kinesin) on its motor track (microtubule). From movements, forces can often be calculated through the

so-called ►inverse dynamics approach [1], when direct ►force measurements are difficult or impossible.

Force measurements in biomechanics represent a basic tool to quantify the mechanics of a biological system. Forces in human locomotion provide insight into the loading of the musculoskeletal system and the workings and control of muscles. Forces obtained in micro scale systems may provide an understanding of basic life functions, such as cell division, muscle contraction, and ►ATP synthesis.

Acceleration measurements are often performed in situations where force measurements cannot be made. Accelerations of a system are proportional to the ►resultant external forces acting on the system, and therefore represent a valuable piece of information of the ►kinematics and ►kinetics of the target system.

Sonomicrometry has become an accepted tool for measuring deformations of soft tissues in vivo. For example, sonomicrometry is frequently used to measure deformations of the heart on a beat-by-beat basis, or to measure the strains in muscle fibers in freely moving animals.

►Strain measurements in biomechanics are fundamental to define the constitutive properties of hard and soft tissues. The ultimate strain defines the strain at which a material fails, while stress-strain measurements provide ►Young's modulus, a basic material property.

## Principles

Early optical methods for movement analysis in biomechanics include single shot photography, chronophotography, and stroboscopy. Photography has the distinct disadvantage that only a single picture of a movement is available, or in the case of multiple exposures, several photographs may be available, but typically with a poor time resolution.

Chronophotography uses a conventional photographic camera with a rotating disc shutter placed in front of the film. The shutter can be rotated typically at very high frequencies and the film is exposed every time the opening of the shutter is in front of the film. Thus, a movement is captured on a still photograph. The limitations of chronophotography include that the movement of interest must be in a given direction, so that exposures do not start to overlap in time, that the movement is relatively fast compared to the shutter speed, and that movements are best captured in an artificial environment where the background makes a very good contrast with the system of interest.

Stroboscopy is also based on multiple exposures of a still film. However, the exposures are obtained through pulsed flashes in an otherwise dark room, thus the system of interest is exposed each time the flash comes on, and is invisible when the flash is off. Stroboscopy, in principle, allows for very high frequencies of data collection. However, in practice, the same limitations as for the chronophotography apply. In addition, stroboscopy can only be performed in a laboratory setting and for movements that can be performed easily in partial darkness.

In the 1970s and 1980s, most biomechanical analyses of movements were performed with high-speed cameras. These cameras typically used 16mm film and were intermittent pin registered or rotating prism cameras. The intermittent pin registered cameras use a mechanical device to advance and then hold the film with pins that grab the holes on the side of the perforated film. When the film is held still, one frame is behind the lens and shutter and will be exposed during that time. This process is repeated frame by frame for a maximal time resolution of about 2 ms (i.e. 500 exposures per second).

In the rotating prism camera, light is focused through the lens onto a rotating prism that directs the light onto the continuously moving film. These cameras can reach time resolutions of about 0.1 ms (i.e. 10,000 frames/s).

Today, most movement analyses with optical methods are based on automated video systems that capture passive or active markers, and track them in three-dimensional space through multiple camera systems, and through software that is based on direct linear transformation [2]. These systems are commercially available (hardware and software), and typically operate at set frequencies, with a maximal time resolution of about 200 frames per second. Tracking of the markers is performed automatically, and the tester merely needs to interfere with manual corrections of the marker tracking system when markers start to overlap and cannot be identified uniquely by the tracking software, or when markers are not simultaneously observed by at least two cameras (for three-dimensional analyses).

In the past few years, high-speed digital cameras have also become available. These cameras allow data collection at rates of several kHz (i.e. several thousand frames per second), but because of memory limitations, can typically only operate for a few seconds at the highest sampling frequencies. The advantages of digital video cameras include that the movements can be directly viewed and displayed on a computer, and that the system can be configured such that very fast events may be captured after they have occurred. For example, a digital camera may be set to collect data continuously, but not store the data. Once the event of interest has occurred, data storage may be triggered to include events that occurred several seconds prior to the triggering of data storage, so that the event of interest is included.

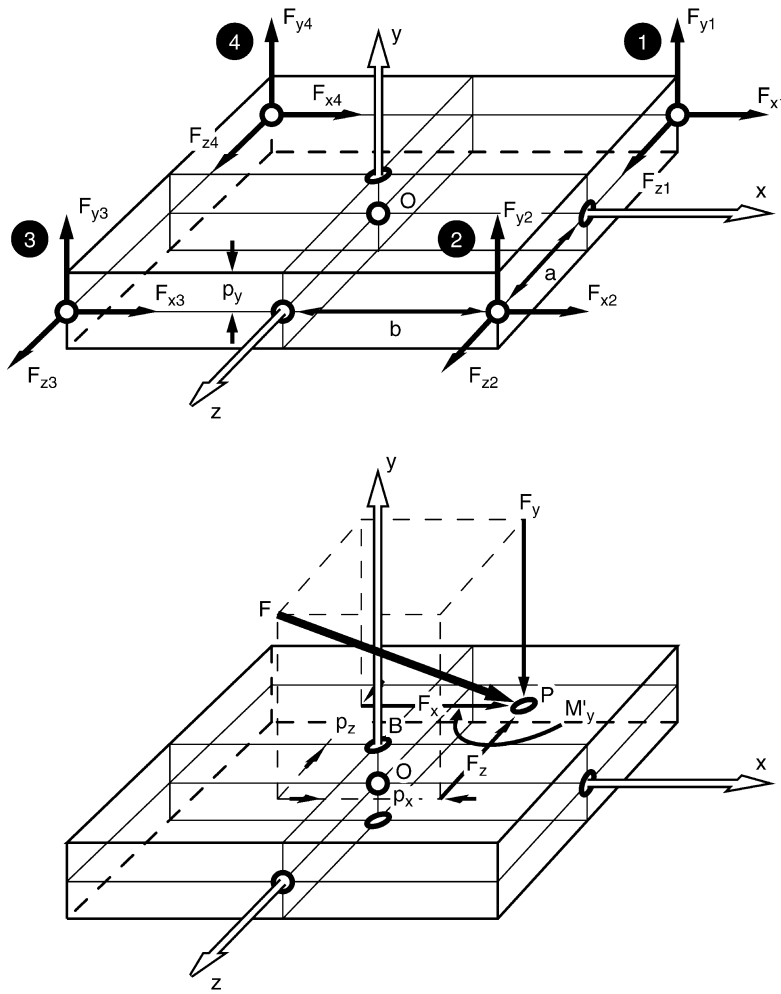
The principles of force measurements are virtually unlimited. They range from mechanical springs, to piezoelectric sensors, to ►optical trapping and atomic

force microscopy. Here, three examples of force measurement principles are given. The first is the ►force platform that is based on piezoelectric force sensors; the second is a strain gauge based ►tendon force transducer for muscle force measurements in freely moving animals and humans; and the third is an optical trapping method using lasers to measure the pico Newton forces in ►molecular motors and springs.

Force platforms have been used in biomechanical research for over a century and have been continuously refined for force and time resolution. Commercial platforms come in a variety of sizes and shapes, and they typically contain force sensors in four corners of a rectangular plate (Fig. 1, *top panel, labels 1–4*).

With this setup of sensors, it is possible to measure the three-dimensional forces and moments in an orthogonal reference system (x, y, z; Fig. 1), as well as the point of application of the force (P, Fig. 1, *lower panel*). Force platforms are typically based on piezoelectric or strain gauge sensors. The piezoelectric effect was discovered in the 1880s by the Curie brothers. Piezoelectric materials are based on non-conducting crystals that generate an electrical charge when strained. Quartz and ceramic materials have piezoelectric properties. For biomechanical applications, quartz crystals are typically cut into discs, and when subjected to forces they produce an electric charge that is proportional to the applied load. Piezoelectric sensors have the advantage that they can be used over a large range of forces. However, they have the disadvantage that the charge "leaks," and thus they are not well suited for long-term static force measurements.

Strain gauge based tendon force transducers have been used for many years to measure the muscle forces

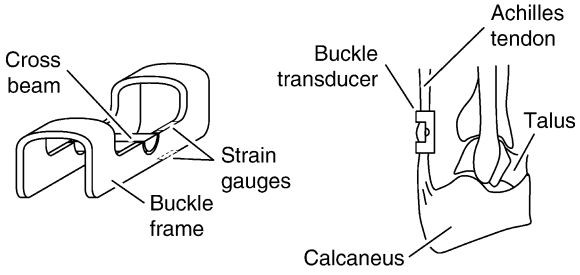


**Measurement Techniques (Biomechanics). Figure 1** Force platform with reference frame (x, y, z) and force sensors at each of the four corners (*top drawing*). Resultant force (F) applied to the force platform with the corresponding point of application (P), and force components ($F_x$, $F_y$, $F_z$) (*bottom drawing*).

in freely moving animals. Walmsley et al. [3] measured the forces in the cat medial gastrocnemius and soleus, and Herzog and Leonard [4] measured these same forces, plus the plantaris and tibialis anterior forces, for a variety of locomotor conditions. The tendon force transducers used in these experiments are of different shape and size depending on the tendon geometry. However, the principle of these tendon force measurements remains the same. A transducer element is either fixed externally (Fig. 2) or internally (Fig. 3) to the tendon.

Upon force production by the muscle, the transducer element is deformed, this deformation is measured with appropriately placed strain gauges, and the strain gauge output is then calibrated against known forces that are applied to the tendon in a terminal experiment. Measurements of this kind have been instrumental in identifying the forces acting on musculoskeletal structures, such as joints, (e.g. [5]) and in determining strategies of movement control (e.g. [3]).

Optical trapping was developed in the early 1970s by Arthur Ashkin. Optical trapping and the manipulation of small neutral particles is based on the forces of radiation pressure. These forces allow for trapping of a particle of the size of several nm to several μm in diameter at the centre of focus of a laser beam.



**Measurement Techniques (Biomechanics).**
**Figure 3** Schematic illustration of an implantable force transducer (*left*) and a possible arrangement in a patellar tendon (*right*). (From [7], with permission.)

Optical trapping has been used in atomic physics, but its use in biological applications is of primary interest here. Due to the virtually perfect control that can be exerted with optical traps, they have been used for a variety of biological applications: the unfolding and refolding of proteins and nucleic acids, testing of the strength of ligand to receptor bonding, and the study of a variety of molecular motor functions, and the corresponding forces and basic displacement steps.

Optical traps are perfectly suited to measure forces up to about 200 pN with sub-pico Newton resolution. When combined with adequate displacement sensors, nano metre steps of molecular motors can be detected (e.g. [8]). These techniques have resulted in great advances in our understanding of the basic forces and displacements produced by elementary cycles of a variety of molecular motors. For example, for the myosin II-actin motor associated with muscle contraction, single motor protein interactions are thought to produce forces in the 2–10 pN range, with single step sizes of 3–12 nm and the unbinding force of myosin II from actin in the absence of ATP has been measured as $9.2 \pm 4.4$ pN.

Accelerations in biomechanics are often determined using high-speed film or video for measuring displacements as a function of time, and then calculating acceleration through the second time derivative of the displacement data. However, this approach is not very accurate for situations where displacements are small and accelerations are high, and taking time derivatives of "noisy" displacement-time data using numerical approaches always introduces errors that are hard to quantify. Therefore, a number of sensors have been used for specific applications in biomechanics to measure accelerations directly rather than determining them numerically through displacement data.

Accelerometers work on the principle that a small inertial mass segment is moved within a sensor, that this movement is captured electronically and is converted, through appropriate calibration, into the corresponding acceleration. Often, accelerometers are built around a seismic mass element as shown in Fig. 4.

The cantilever is fixed to the base element, and the seismic mass is attached to the base through a weakened part in the beam design to allow for deformation of the element as the sensor is accelerated. The deformation is measured through strain gauge elements, as shown in Fig. 4 or piezoresistive elements.

Another principle underlying acceleration measurements is based on a mass element that is positioned between two coils that are attached to the accelerometer base (Fig. 5).

The mass is magnetically coupled between the coils, and when the mass is displaced by acceleration, the magnetic coupling is changed and the corresponding change in the inductive current is measured as a change

M

(Adapted from [9], with permission.)

in electrical output that can be related to the acceleration of the transducer. Accelerometers can be custom built for applications that require specific frequency and amplitude responses. Proper acceleration measurements are extremely difficult to perform and interpret because it is typically not trivial to attach the sensors rigidly to the target segment and to place them at the point of interest.

Sonomicrometry is a method based on ultrasound transmission between piezoelectric (ceramic) crystals for measurement of length and strain in tissues. For recording, a minimum of two crystal markers are attached to the target sites (for example, on arteries [10] or muscle fibers [11]). One of the crystals emits a short ultrasound pulse while the second crystal receives the pulse. From the known time between transmission and reception of the pulse, and the known speed of ultrasound transmission, the distance between the two markers can be measured continuously. Sonomicrometry can be used with at least 32 crystals, each acting simultaneously as a transmitter and a receiver for all the other crystal markers. Depending on the number of recording crystals, sonomicrometry signals can be measured with a time resolution of better than 1 ms (>1 kHz) and a spatial resolution of 12 μm.

Sonomicrometry has been used extensively to measure the behavior of single muscle fibers (cells) in cardiac and skeletal muscles. With this technique, it was first demonstrated that fiber length changes were not necessarily in concert with the corresponding length changes of the entire muscle (Fig. 6), a result that had great implications for the mechanics of whole muscle contraction, as well as the control of muscles through the ►muscle spindles [9]. Recently, measurements of the strains in vertebral arteries during high speed, low amplitude spinal manipulation of the neck have been instrumental in providing practice guidelines for these types of medical treatments [10].

Strain measurements are fundamental in biomechanics research. They are used to derive constitutive laws for biological tissues, to determine failure properties of materials, to determine stress distributions indirectly, to analyze interface compatibility between artificial and biological materials, and many other applications. Strain on hard tissues, where deformations are less than about 1% of specimen length, can be measured

readily and cheaply with today's technology. However, strain measurements on soft (hyperelastic) materials are much more difficult to measure, as strain transducers are typically hard to fix "rigidly" on soft specimens and might add to the force required to stretch the test specimen.

Strain gauges measure engineering strain (ε), which is defined as the change in length divided by the original length. There are a variety of possibilities of strain measurement and many of these have been used in biomechanical applications. These include electrical resistance strain gauges, extensometers, optical methods, Hall effect transducers, and many more. Strain gauges are used more often in biomechanics than any other strain-measuring device and they will be discussed briefly below.

Electrical resistance strain gauges rely on the general principle that the resistance of an electric conductor is a function of its dimensions and resistivity, or:

$$R = sL/A$$

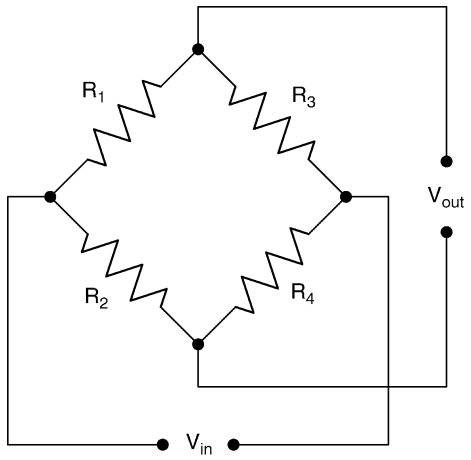
Where R is the electrical resistance, s is the resistivity, L is the length and A the cross-sectional area of the conductor. When a conductor is stretched, L increases and A decreases, and the change in resistance (ΔR) can be captured with the appropriate circuitry and related to the corresponding change in length of the conductor (ΔL):

$$R/R_0 = G_f(L/L_0)$$

Where $R_0$ is the electrical resistance of the unstrained material, $G_f$ is the gauge factor, and $L_0$ is the length of the unstrained material. Strain gauge signals are captured with a conditioning amplifier in a ¼, ½, or a full bridge configuration. In the ¼-bridge configuration, only one gauge will be active during testing (e.g. $R_1$ in Fig. 7). Two of the remaining gauges ($R_3$ and $R_4$) would be precision resistors of equal value inside the amplifier, while $R_2$ would be a dummy gauge.

In the unstrained condition, $R_2$ is adjusted to have the same resistance as the active gauge, $R_1$, and the circuit is balanced with a zero output. If $R_1$ experiences strain, $R_1$ changes by ΔR and the output, $V_{out}$ is non-zero and depends directly on ΔR. If $R_1$ and $R_2$ are active, we have a half-bridge configuration, which is particularly useful when one of the gauges is compressed while the other is stretched, as for example when they are attached to opposite sides of a deflecting beam. When all four gauges are active (Fig. 7), we have a full bridge configuration that maximizes the voltage output of the sensor.

There are two basic types of strain gauges: foil gauges and semiconductor gauges. Foil gauges consist of a thin layer of a metal conductor arranged in an array of connected parallel lines. These gauges are the most commonly used sensors in biomechanical applications. Semiconductor strain gauges are wafers of semiconductor doped to the form of a strain gauge. They have a higher gauge factor than the foil gauges, and thus, have a higher voltage output for a given strain and excitation voltage than the foil gauges. Semiconductor strain gauges can measure strains with a resolution of ~1 microstrain.



**Measurement Techniques (Biomechanics). Figure 7** Typical arrangement of four strain gauges with resistances $R_1$, $R_2$, $R_3$, and $R_4$, respectively, for strain measurements in biomechanics. Depending on the number of active cross-bridges, signals are captured with a conditioning amplifier in a ¼, ½ or a full bridge configuration (see text for details).

## Synonyms

Wavelet analysis; Time/frequency analysis; Windowed Fourier analysis

## Definitions

*Electromyogram (EMG):* EMG is the electrical signal in volts recorded by electrodes from a contracting muscle.
*Wavelets:* Wavelets are short oscillations that have a zero (0) integral, are defined in a limited time window and have a band limited power spectrum. Usually one has a "mother" wavelet and scales and shifts (translates) this wavelet appropriately to obtain a set of wavelets that cover the frequency and time range of the signal of interest.
*Tiling:* Subdivision of the time-frequency plane into time-frequency boxes covered by the scaled and shifted wavelets.
*Wavelet transform:* The mathematical method for obtaining the wavelet transformed EMG is a convolution of the EMG with different wavelets.
*Scalograms:* The intensity that is extracted from the signal by the wavelet transform is displayed in a scalogram as a function of time (abscissa) and scale (ordinate). Scalograms do not show the phase aspects of the wavelet transform (Fig. 1).

The intensity may be displayed in different ways, for example, as a gray scale, where intensity is represented in different shades of gray, black representing the highest intensity and white the lowest one. If colors are available, it is preferable to use color-coding to represent the intensities (e.g. rainbow colors). It has also become common practice to display constant intensities as contour lines similar to contour lines on geographical maps.

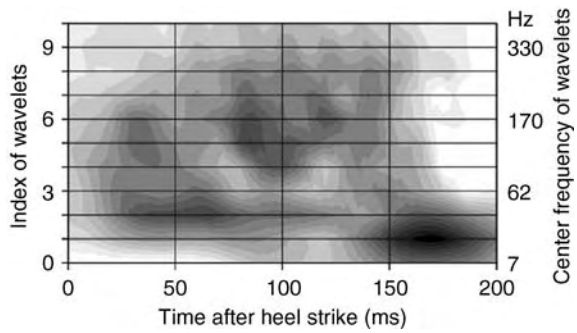
The time intervals on the abscissa are given by the tiling or by constant time increments in a time continuous wavelet transform.

The scale (ordinate) is used to represent the differently scaled wavelets. Frequently, the scale is represented by the actual scaling factor, but an index representing the different wavelets can also be used. If wavelets can be characterized by a center frequency, then the center frequencies can be displayed on the ordinate and thus the ordinate represents a measure of frequency in Hz. These scalograms are also called intensity patterns [1].

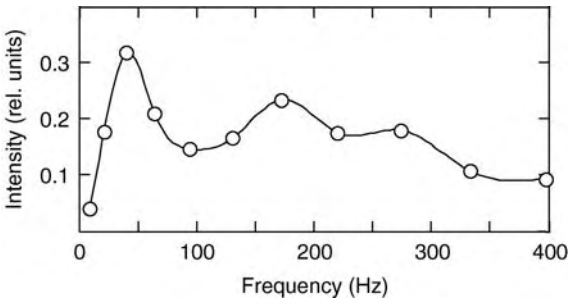
*Wavelet domain:* The wavelet domain contains the intensity of the EMG that is extracted by one wavelet and displayed over time (wavelet domains are represented as horizontal lines in an intensity pattern).

*Intensity spectrum:* The Wavelet transform decomposes the power of the EMG signal for each time point (small time window) into a limited set of frequency bands (Fig. 2). The intensity spectrum (wavelet spectrum) is the equivalent of a power spectrum for the Fourier transform. The intensities along a vertical line in an intensity pattern represent the wavelet spectra.

*Total intensity:* The sum of the intensities of the intensity spectrum is called the total intensity, and is assigned to the specific time point at which the intensity spectrum was measured. The total intensities represent a summation of the intensities across all



**Measurement Techniques (Electromyography). Figure 1** Scalogram (average over five trials) of EMGs of the gastrocnemius medialis for a person running at 4 m/s. The signal rises from lower frequencies at 50 ms to higher frequencies at 125 ms, and the high frequency components end at 150 ms. The drop in frequency seen after 150 ms leads to a muscular event that lasts about 50 ms and is typically seen when wearing shoes.



**Measurement Techniques (Electromyography).**
**Figure 2** Wavelet spectrum extracted from Fig. 1. The *dots* represent the intensities extracted by the wavelets 70 ms after heel strike. The dots are located at their respective center frequencies. The *solid line* represents an interpolation between the dots.

wavelet domains and form a one-dimensional time series. The square root of total intensities of this time series contains the same information as the root mean squared EMG signal [1].

*Heisenberg's uncertainty principle:* This principle states that the time resolution $\Delta t$ and the frequency resolution $\Delta f$ cannot simultaneously be infinitesimally small. The product $\Delta t \cdot \Delta f$ is constant and equals about 1. To exemplify this principle one can think of a sinusoidal signal of finite duration. If the duration is much shorter than the period of the sinusoidal wave one cannot accurately determine its frequency. On the other hand, if the signal duration is very long, and thus the time when the signal occurs is not known, then one can accurately measure its frequency.

*Frequency resolution:* Frequency is a property of a signal. If signals with distinctly different frequencies are superimposed, the difference can only be resolved if it is larger than the frequency resolution. The frequency resolution is a property of the wavelet and relates to the bandwidth of the wavelet. Scaling wavelets to make them shorter increases their frequency resolution.

*Time resolution:* Each wavelet has a frequency resolution, $\Delta f$, and, according to Heisenberg's uncertainty relationship, a corresponding time resolution, $\Delta t$. The time resolution is different for each wavelet domain and represents the shortest time separating two events that are located in the same wavelet domain. Time resolution relates to the finite width in time of the wavelet.

*Discrete versus continuous wavelet transforms:* Wavelet transforms require a discrete base set of wavelets to fully represent the information contained in an EMG signal. A discrete wavelet transform uses the smallest number of discretely scaled and discretely translated wavelets to transform the signal without loosing information about the original signal. Thus, discrete wavelet transforms require the smallest computational effort retaining the information for reconstructing the original signal. If we focus on the scaling and thus on the spectral aspect first we find that the spacing between the differently scaled wavelets can be so large that the resolution is too broad for projects that aim at a very fine frequency resolution. This handicap can be overcome by using a continuous wavelet transform in which the wavelets are scaled using very small, almost continuous changes of the scaling factors. The continuous wavelet transform is best used for getting a smooth wavelet spectrum, which allows for finding the maximum of the spectrum very accurately.

If two independent EMG signals are recorded, Heisenberg's uncertainty principle does not apply and one can resolve very small spectral differences; for example, differences in the position of the mean of the spectrum that are smaller than the frequency resolution. However, if one analyzes spectra that were recorded within a time interval in the order of the time resolution, then Heisenberg's uncertainty relationship becomes the limiting factor and one cannot have infinitely fine spectral resolution. In this case it does not make sense to use the continuous wavelet transform. Thus, when recording and analyzing movement related patterns of EMG intensities, the continuous wavelet transform is not appropriate.

The discrete wavelet transform is also discrete in time. The time intervals are given by the appropriate tiling. Thus, if one desires to see a smooth continuous development of the wavelet transformed signal in time, one will use almost continuously shifted (translated) wavelets to obtain a time continuous wavelet transform. A time continuous wavelet transform should be used if one is interested in observing the exact timing of muscular activities during a movement. If two EMG signals were separately recorded, for example, for two different external conditions, then the timing difference of muscular events can be measured with an accuracy that exceeds the time resolution imposed by Heisenberg's uncertainty relationship. However, if two muscular events occur in the same EMG recording then Heisenberg's uncertainty applies.

The decision of how "continuous" the wavelet transform should be depends on the desired frequency or time resolution. Unfortunately, one cannot have both simultaneously with great accuracy.

## Characteristics

### Purpose

The purpose of wavelet analysis of EMG signals is to decompose EMG signals into their frequency components in such a way that temporal aspects of the signal are conserved and resolved [1–3]. For practical cases of analyzing EMG signals, the purpose translates into decomposing the signal in such a way that conclusions about muscle physiological aspects can be drawn. Four

specific purposes relating to physiological aspects are mentioned below.

1. Muscles contain different fiber types that have type specific motor unit action potentials and conduction velocities. Short motor unit action potentials and fast conduction velocities generate high frequency contributions, and broad action potentials and slow conduction velocities generate low frequency contributions to an EMG. Decomposition of an EMG signal into the frequency bands covered by the wavelets provides information about the interplay of muscle fibers generating high or low frequency components in the EMG [4].
2. Muscles are typically only activated during parts of cyclic movements. Decomposition using wavelet analysis can resolve time-dependent muscle activities. Therefore, the time resolution can be selected such that it corresponds to physiological response times for activation and relaxation.
3. Assessment and evaluation of fatigue is a major field of muscle research. Evaluations are typically limited to steady-state recordings of EMG lasting at least 250 ms. Decomposition using wavelet analysis allows detection of the continuous decrease in frequency content that occurs with fatigue. Wavelet analysis is particularly useful when analyzing muscle fatigue for dynamic conditions such as isokinetic contractions [5].
4. Decomposition of EMG through wavelet analysis yields EMG intensity patterns representing the activity of one or multiple muscles at the same time. These patterns can be used as input to pattern recognition methods, which can reveal small differences in muscle activities governing a given movement. For example, male and female runners generate different EMG intensity patterns [6].

## Principles

An EMG signal is a recording of the potential generated by ionic fluxes in muscle fibers at the position of the electrode with reference to some other potential (reference potential). These potentials depend on tissue properties between the electrodes and the muscle fibers, and the recorded voltages depend on electrode configuration. The frequency of the EMG depends on the inter electrode distance and on the shape of the electrodes. Proper electrode placement is the key to obtaining high quality signals. The recorded EMG is a signal of the fiber action potentials as measured by "remote" electrodes. However, independent of the distortion of EMG signals as a result of electrode placement, any EMG contains information about the underlying physiological processes and structures.

The theory of wavelet analysis has greatly evolved in the last decade and has been well described by Mallat [7]. Various biomedical applications have emerged using this technology [8]. For time/frequency analyses of EMG signals, an appropriate set of base functions, or wavelets are required. Commercial software packages (MathCad™ or MatLab™) provide wavelets algorithms. There are commercial software packages that use a specific set of wavelets (Biomechanigg Research Inc.) designed for the analysis of EMGs. There are many different types of wavelets, and the selection of the wavelets depends on the purpose of the analysis. If one is mainly interested in frequency aspects, it is an advantage to select wavelets of a damped sinusoidal shape (Morley or Cauchy wavelets). For data compression, one might prefer Daubechies wavelets. The result of the transform depends on the wavelet selection, and there is no consensus as to which wavelets would be the most appropriate for a given situation. Selection is often guided by what is available in software packages, rather than by functionality. Once the wavelets have been selected, the wavelet transform is a straightforward mathematical operation of convolving the measured signal with the wavelets (Convolution, see Karniel in this Encyclopedic Reference). The magnitude of the wavelet-transformed signal (square root of the sum of the squared real and imaginary part) is called the intensity. Phase aspects are not used for the analysis of EMG signals.

## Advantages and Disadvantages

The main advantage of the wavelet transformed EMG signal is that physiological processes that change the frequency content of the EMG signal become visible simultaneously in the time and frequency domain. Thus, the classical separation of time- and frequency-domain can be overcome. Wavelet analysis is also an improvement over windowed Fourier transform because the time/frequency compromise is optimized.

Since researchers have used many different types of wavelets, it is difficult to compare results across studies. Nevertheless, wavelet analysis combined with pattern recognition algorithms will probably become the method of choice of EMG signals.

Stress

## Definitions

►*Stress/Pressure*: The force per unit area exerted on a material.

►*Diarthrodial Joint*: A joint encased in a ligamentous capsule including an articular cavity.

►*Spatial/Temporal Resolution*: A property of a measurement system that defines its ability to resolve measurements taken at two adjacent points in space or time. The closer the adjacent space or time points, the better the resolution is said to be.

## Characteristics

### Introduction

Pressure measurement techniques are currently utilized in several major biomechanical fields. For example, pressure sensitive mats and plates are used to measure the pressure distribution between different parts of the body (e.g. the foot or finger) and external surfaces (e.g. the floor, a shoe or a keyboard) [1]. Direct measurement of the contact pressure at articular interfaces within diarthrodial joints of the body (such as the femoral head and acetabulum in the hip joint) continues to remain a challenge in orthopedic biomechanics. Research in this particular field has enabled us to better understand the structure-function relationships of ►articular cartilage and other joint tissues in providing joint motion and the pathomechanical processes involved in joint diseases such as ►osteoarthritis. The main focus of this essay will be to give an overview of this latter area of application.

### Measurement Methods

#### *Pressure Sensitive Films*

Fuji prescale pressure-sensitive film (Fuji Photo Film Co. Ltd, Tokyo, Japan) is the most extensively used technique to measure contact pressures in diarthrodial joints. The film comes in grades, with each grade covering a different pressure range between 0.2 and 130 MPa (Table 1).

Except for the high-grade film, Fuji film consists of an A- and C-sheet [2]. The A-sheet contains randomly arranged fluid filled bubbles 2–25 μm in diameter. When pressure is applied, the bubbles burst, releasing their fluid content. The second C-sheet contains an active layer that reacts to the fluid to produce a red stain (Fig. 1) [2].

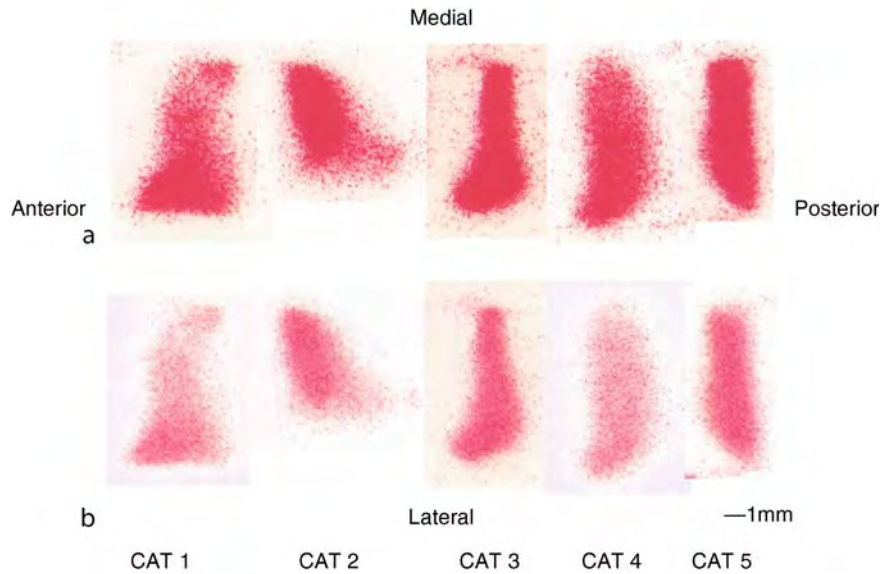
Since different sized bubbles break at different pressures, the amount of fluid released and thus the color density of the stain is dependent upon the pressure acting across that area (Fig. 1). The A- and C-sheets of the film are generally sandwiched between polyethylene layers to protect them from humidity. The film including the sealing materials is ~250 μm thick [2]. Thicker packets of film have been made by stacking films of different grades on top of one another [3]. This technique increases the sensitive range of the Fuji film packet. A much thinner Fuji film, 25–50 μm thick, has recently been introduced, though it has not yet been thoroughly assessed for biomechanical applications [4].

A second pressure sensitive film was developed and applied in the biomechanics field around the same time as Fuji film was first introduced. This sensor consisted of four layers with a total thickness of 285 μm [5]. A layer of fast-drying enamel paint sprayed onto an acetate film acted as a plastic material in this sensor. A nylon screen woven out of monofilament threads with 12 threads per millimetre lay on top of the paint layer with a mylar film on top of that to protect the

**Measurement Techniques (Pressure). Table 1** Grades of Fuji film and their pressure ranges [2]

| Film grade | Pressure range (MPa) |
|---|---|
| Ultra-super-low | 0.2–0.5 |
| Super-low | 0.5–2.5 |
| Low | 2.5–10 |
| Medium | 10–50 |
| High | 50–130 |

M



**Measurement Techniques (Pressure). Figure 1** Typical Fuji film stains from the patellofemoral joints of five cats under 300N of applied force on: (a) low- and (b) medium-grade film. Increasing pressures are associated with increasing stain darkness. sensor from moisture [5]. Pressure applied to the film pressed the threads of the nylon screen into the plastic paint material leaving a series of permanent micro-indentations. The depth of these micro-indentations were then evaluated and related to the magnitude of the applied pressure with ►calibration [5].

Most recently Iscan, an electric film for measuring pressure in joints, has been developed. The Iscan sensor (Tekscan Inc, South Boston, MA, USA) is 200 μm thick, has a sensing area of 56 $mm^2$, and can take measurements at up to 125 Hz [4]. Each sensor consists of two polyester sheets bonded together with a layer of semi-conductive ink between them. The polyester sheets have electrical conductors evenly distributed across them producing a sensing element at each point where the conductors on both sheets cross each other. As pressure is applied to the sensor, the semi-conductive ink is compressed, altering the resistance between the two polyester sheets [4]. This change in resistance is then related to the applied pressure by a calibration routine.

### Discrete Pressure Transducers

In addition to pressure sensitive films, a second major approach to measuring contact pressure in diarthrodial joints has been to place a number of small discrete ►transducers over the articulating surfaces. In the majority of cases, piezoelectric materials have been used to make transducers that are recessed into the superficial layer of the articular cartilage. In one series of studies, 24-flat-bottomed cylindrical wells, ~3.5 mm in diameter, were drilled into the articular surfaces of cadaver femoral condyles and femoral heads [6]. Miniature piezoresistive transducers 400 μm thick were then secured into the wells using cyanoacrylate adhesive. The depth of each well was adjusted so that the face of the transducer was palpably flush with the articulating surface. Two lead wires from each transducer passed across the cartilage surface to a signal-processing unit [6]. The transducers were made of a tightly packed granular piezoresistive material, contained and loaded in parallel through a silastic annular spacer. Transducer resistance changes due to the applied surface pressure were detected by output changes to a simple electronic circuit [6].

In a more recent study, a piezoelectric film replaced the piezoresistive material as the sensing element of these transducers [7]. Piezo film develops an electrical charge proportional to the mechanical stress or strain applied to it. The piezo film was sandwiched between two stainless steel electrodes and sealed in a water resistant capsule. Six of these transducers, 3 mm in diameter and ~300 μm thick, were embedded into the articular surface of cadaver patellae [7]. Wells were drilled into the cartilage as described above; however, an extra 1mm diameter hole was drilled in each well through the subchondral bone to allow the wires to pass through to the other side of the patella [7].

In contrast to these piezoelectric transducers, pressure pipes (1.5 mm in diameter) inserted into holes drilled through the articular cartilage and subchondral bone have also been used as discrete pressure transducers [8]. Physiological saline was utilized as a pressure medium within the pipes and the pipe pressure was measured using a transistor pressure transducer and pressure gauges. This set up was used to measure instantaneous contact pressures between cadaver femoral condyle and tibial articular surfaces [8].

#### *Instrumented Prosthesis*

Among the earliest attempts to measure contact pressures in diarthrodial joints was an instrumented femoral hip ►prosthesis [9]. A number of small pressure transducers were introduced in the hollow sphere at the end of the prosthesis to be positioned in the hip joint in contact with the cartilage in the socket. A hole (4 mm diameter) was machined into the inside of the hollow hemisphere leaving a thin diaphragm 445 μm thick. This diaphragm was deflected slightly (0.28 μm/MPa) by the contact pressure with the acetabular cartilage [9]. The displacement of the centre of the diaphragm was detected and measured by a strain-gauged, silicon crystal cantilever beam transducer. Fourteen pressure transducers were evenly distributed across the sphere of the prosthesis. Each transducer was switched on serially and the output sent to a remote data collection station using a radio transmitter and receiver [9]. The transducers were sampled at 253 Hz and the electronics were powered using an induction arrangement involving a pair of magnetically coupled concentric coils. The primary coil circled the upper thigh and was coupled with a smaller secondary coil located on the tip of the stem of the prosthesis inside the femur. The prosthesis was therefore completely self-contained and used no batteries [9].

### Advantages and Disadvantages

#### *Disruption of Joint Contact Mechanics*

Introducing a pressure sensitive film between two contacting surfaces alters the very pressure distribution that is being measured. This error is primarily caused by the stiffness and thickness of the film. The softer and thinner the film is, the smaller the errors will be. The magnitude of this problem has been evaluated for Fuji film using a theoretical approach [10]. The pressure distribution in the feline patellofemoral joint was calculated for given loading conditions with and without the pressure sensitive film. The film, including sealing materials, was defined as 250 μm thick with a stiffness of about 200 times the stiffness of the articular cartilage. The results of this case indicated that introducing the Fuji film into the joint caused an underestimation of the true pressure distribution by about 10% [10]. Along similar lines, pressures recorded by an instrumented prosthesis are likely to be quite different from those in a natural joint due to the metal on cartilage as opposed to the cartilage on cartilage interface [9].

With discrete pressure transducers, the cylindrical defects made in the articular cartilage and the different elastic moduli of the transducer relative to the surrounding cartilage may alter the local load transmission processes and therefore the pressures being measured [7]. Slight differences in the amount of cement used at the base of each transducer and differences in the congruity match at the cartilage surface may also influence local pressures [7]. While drilling holes through the bone to allow leads to pass out of the joint will keep the leads from disrupting joint contact, it may also cause greater disruption to the fluid flow within the cartilage and between the cartilage and bone in the vicinity of the defect.

When an instrumented prosthesis is implanted, roughly half of the cartilage in the joint is lost [9]. This will almost certainly affect the distribution and quantity of ►synovial fluid between the joint surfaces [9]. The significance of any variation in pressure distribution caused by this redistribution of synovial fluid is currently unknown.

#### *Spatial Resolution of Pressure Measurements*

One of the major advantages of pressure sensitive films is that they can record the pressure distribution over the entire contact area within a given joint. In contrast, discrete transducers only record local pressure values from certain points in the joint from which the corresponding whole contact stress patterns must then be reconstructed [6]. In particular, the reported peak local stress values reflect the highest single transducer reading, which may not coincide with the most highly stressed point on the contact surface. Increasing the number of transducers in a joint would improve the spatial resolution of this method, although would also lead to more severe disruption of joint mechanics as discussed above.

#### *Temporal Resolution of Pressure Measurements*

The viscoelastic deformational characteristics of articular cartilage suggest that static measurements may not be ideal for estimating the transient pressure distribution that occurs in diarthrodial joints in vivo. One of the major advantages of the pressure measurement techniques that utilize electronics, the pressure pipes or the instrumented prosthesis is that they have the potential to record virtually continuous pressures during joint loading. For example, an Iscan sensor can record measurements at 125 Hz [4] and an instrumented prosthesis at 253 Hz [9]. Pressure films similar to the Iscan, however, have demonstrated drift; a significant time-dependent response to load which may lead to large errors during measurements of dynamic activities

[4]. Fuji film and the film introduced by Ahmed do not allow such time resolution of pressure measurements [5,10,2]. Both of these films record maximal pressures. Therefore, either of these films inside a joint will record the local peak pressures occurring during a loading period rather than any actual pressure distribution or the time history of the pressure distribution.

### *Other Potential Sources of Artifact*

The complex and often multidimensional curvature in many diarthrodial joints is a potential cause of artifacts in pressure measurements. Studies using Fuji film have described artifacts as the film has crinkled while negotiating the curvatures in a joint [10,2]. While not wrinkling, the accuracy of the Iscan sensor may be affected by joint curvature, though it is not clear by how much [4]. Clearly, discrete pressure transducers are not affected as significantly by the curvature of a joint.

The majority of the pressure transducers outlined above are sensitive to things other than pressure. These include temperature, humidity, electromagnetic interference and crosstalk. It is important, therefore, that these variables are either eliminated (e.g. by sealing transducers in water resistant coating), minimized (e.g. by limiting the number of connecting wires routed through a joint) and/or held constant throughout loading and calibration routines.

### *Adaptability of Technique for In-Vivo Measurements*

Ultimately, in trying to understand the in vivo structure-function relationships of joints it is most desirable to conduct experiments that resemble the in vivo situation as closely as possible. Use of the instrumented prosthesis, for example, has enabled pressure measurements to be made in humans during a wide range of daily activities such as riding a bike and using a bedpan. The Iscan sensor has also been inserted into the medial compartment of knees during routine arthroscopic examination. It was used to measure the effects of braces on patient knee loading during normal stance.

# Mechanical Impedance

## Definition

A dynamic operator that specifies the forces that a mechanical system generates in response to imposed motions. It is normally represented as the transfer function relating the velocity of the system (input) to the force (output). Inertia, damping and stiffness can be identified from the phase relation between output force and imposed velocity. Admittance is the inverse of impedance: an operator specifying a motion in response to imposed forces. Muscle-environment interaction is fundamentally two-way; since the muscle is coupled to the skeleton, which tends to impose motions, muscle is usually best regarded as providing impedance. In the context of vertebrate motion, mechanical impedance determines how the forces applied to a body segment will be transformed into motion.

►Impedance Control

# Mechanical Obstruction (or Ileus)

►Bowel Disorders

## Mechanically Skinned Fiber

### Definition

An isolated single muscle fiber preparation that involves physically peeling or rolling back the sarcolemma (plasma membrane) leaving the other structures relatively unaltered. Upon skinning, the transverse-tubular system seals off which makes it possible to study the normal excitation-contraction coupling process in these fibers (i.e. depolarization-induced $Ca^{2+}$ release).

### Definition

The science that studies the motion of material bodies and its relation with the forces acting on them.

### Description of the Theory

As the science of motion and ►deformation of ►material bodies, ►mechanics plays an essential part in the study of those aspects of biological systems that underlie the functioning of living tissues and organs regardless of the fact that they are alive. In biomechanics therefore, mechanics and physiology are complementary disciplines. The barriers between these two main components of biomechanics are not however sharply defined. A chemical reaction involving long, geometrically complex molecules may require a mechanical description of the relative motion of the molecules, while a proper understanding of the macroscopic deformation of an organ may need the incorporation of chemical reactions in the continuum model. In broad terms, mechanics can be divided into two main branches, classical mechanics of particles and rigid bodies and continuum mechanics of deformable media. Both are of relevance to biomechanics. For instance, the description of many physical activities and sports, such as diving or running, can be undertaken fairly faithfully by ignoring the deformability of the tissues involved and considering the human or animal body as an assembly of rigid members joined together by means of ideal hinges and articulations. Models developed under such assumptions fall within the realm of classical rigid body mechanics. The description of the functioning of the heart, on the other hand, is a typical example in which the methods of continuum mechanics are called for. Intermediate between these two realms lies the domain of the so-called rheological models, which represent an attempt at describing deformable systems as if they were made of a discrete array of a small number of idealized deformable elements (such as ►springs and ►dampers).

## Mechanoelectric Transduction

►Mechanosensory Transduction

## Mechanoreceptor Mechanism

►Mechanosensory Transduction

## Mechanoreceptors

### Definition

A class of sensory receptors whose adequate stimulus is a physical change in the position of a body part or surface, including the various mechanoreceptors in the skin, the auditory and vestibular hair cells of the inner ear, and the stretch receptors in skeletal muscle. The mechanical deformation causes an electrical change within the receptor cell (i.e., the generator or receptor potential), and eventually an action potential in the nerve fiber(s) connected to the receptor organ.

►Sensory Systems

# Mechanosensation

## Definition

The sensation of a mechanical event (e.g., contact, deformation, stretch or displacement) involving a somatic tissue, such as the skin, oral mucosa, muscle or joint.

## Synonyms

Mechanoelectric transduction; Mechanoreceptor mechanism; Mechanosensitive ion channels; Mechanically-gated ion channels

## Definition

Low mechanical energy is received at cutaneous mechanoreceptors and converted into electrical energy in the form of receptor potential. Mechanoreceptors work as sensory transducers to transform mechanical energy to electrical energy. Receptor potential is then converted into a series of impulses at a spike generating site, the first Ranvier node of sensory nerve fibers innervating. Different structures of mechanoreceptors may be suitable to receive different forms of mechanical energy. Comments are also made on the mechanical filter of lamella of corpuscles, the possible functional role of Merkel cells in the Merkel cell-►neurite complex, which yield receptor potentials in response to mechanical stimulator mechanosensitive ion channels.

## Characteristics

### Quantitative Description

Receptor potentials in response to mechanical stimulation were first discovered at Pacinian corpuscles isolated from the mesentery in cats [1]. Receptor potentials to mechanical stimulation were also recorded from the muscle spindle of frog [2] and from stretch receptors of muscles in crayfish. Receptor potentials are generated locally at the non-myelinated nerve terminals (or at the dendrites of muscle stretch receptor cells), and ►graded depending on the strength of mechanical stimulus. Receptor potentials from the Pacinian corpuscle are rapidly adapting or ►phasic in time course, generated at the onset and offset of mechanical pulses applied (Fig. 1c), whereas those from muscle spindles and stretch receptors are tonic, lasting during the application of muscle stretch.

Thus, it is believed that receptor potentials are phasic in rapidly adapting mechanoreceptors, such as lamellated corpuscles or Meissner corpuscles, but they are tonic in slowly adapting mechanoreceptors, such as Merkel cell-neurite complexes or Ruffini endings, although receptor potentials have not been recorded from most of the cutaneous mechanoreceptors. The size of receptor potentials are dependent on the sodium concentration in the solution bathing the isolated Pacinian corpuscles. Therefore, mechanical forces increase ►membrane conductance, probably by gating the ionic channels permeable sodium ions [3] which have not yet been identified. ►Tetrodotoxin and local anesthetics affect receptor potentials, however, the effects of amiloride which affect Deg/ENaC, mechanosensitive ion channels in *C. elegans* (see below), have not been investigated.

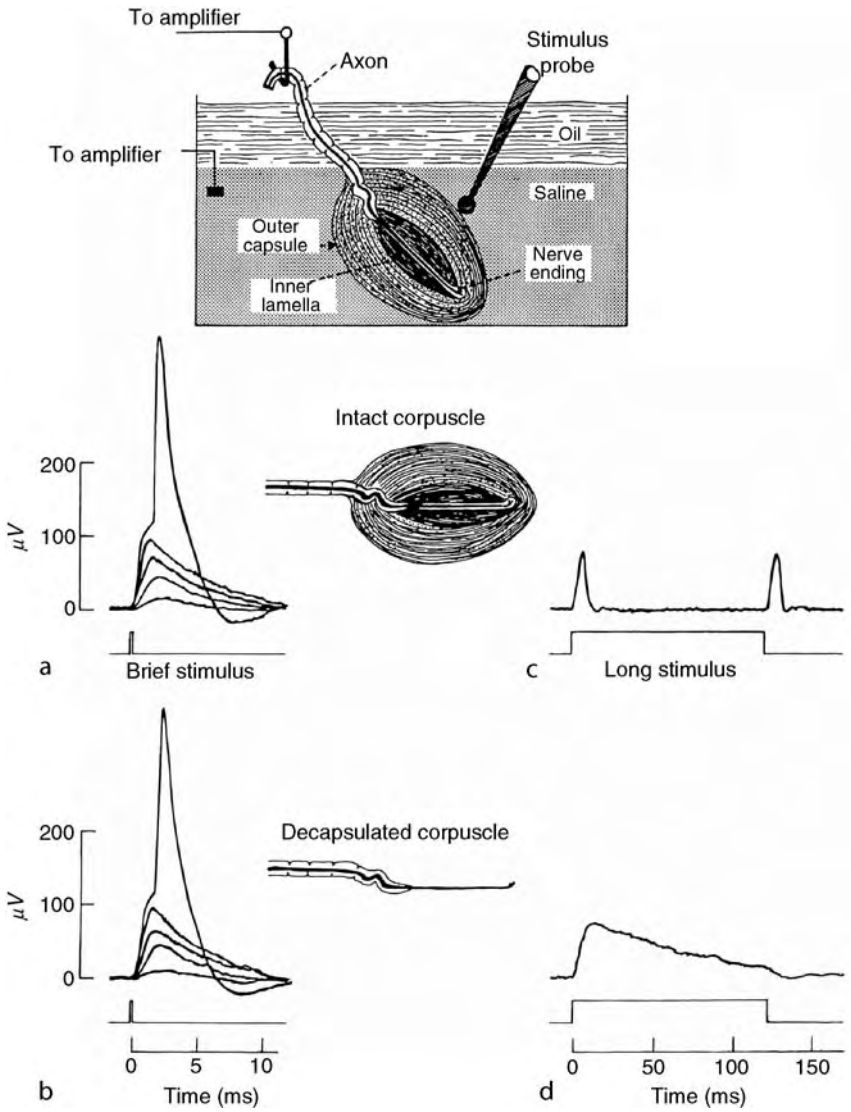
Receptor potentials increase in a graded manner in response to the increased strength of mechanical pulses. The magnitude of the receptor potential is proportional to the strength of mechanical stimulation [1] (Fig. 2).

Receptor potentials spread electrotonically [►Electrotonus, electrotonic (ally)] to the spike generation site, the first Ranvier node, and are recorded as generator potentials. Generator potentials are now converted into spikes when they exceed the threshold for the firing spike. As far as generator potentials exceed the firing threshold, spikes are generated successively, although adaptation at the spike generation sites is different with different mechanoreceptors. The number of spikes generated in a unit time is proportional to the receptor potential height as well as to the mechanical stimulus applied.

Further study of the mechanosensory transduction mechanism may exceed the limit of electrophysiological technique, and may proceed with collaboration of both electrophysiology and molecular biology (see mechanosensitive ion channel).

#### *Lamellate Structure Works as a Mechanical Filter*

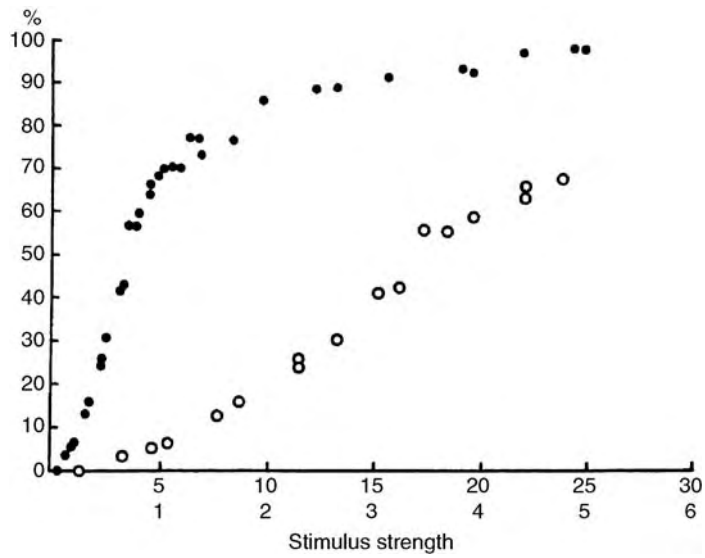
Lamellated corpuscles work as a mechanical filter and transmit a transient change of mechanical forces applied to the unmyelinated nerve terminal in the central core [3]. Application of short mechanical pulses to the



**Mechanosensory Transduction. Figure 1** Responses of intact and decapsulated Pacinian corpuscles (PC) to brief and prolonged mechanical stimulation. The upper part of the figure illustrates the gross morphology of an intact PC and the method to stimulate and record from it. A, B; Responses to evoked by graded brief mechanical stimuli at both intact and decapsulated Pacinian corpuscles (A, B). The strongest stimulus evoked a response that exceeded threshold for generation an action potential. C. An intact PC produced a phasic receptor potential at the onset and offset of a prolonged stimulus. D. A decapsulated PC produced a sustained receptor potential. (Reproduced and modified from PB Detwiler 'Sensory transduction', In: HD Patton et al. (eds) Textbook of Physiology, 21st Edition, vol. 1, Excitable Cells and Neurophysiology, WB Saunders Company, Philadelphia 1986, pp 98–129, Fig. 5–9).

outer lamella in the Pacinian corpuscle generates both transient and static phases of mechanical displacement at the outer part of the lamella. But the static phase of the displacement is rapidly decreased as the displacement is transmitted further down to the inner core, and finally only the transient phase of displacement is transmitted to the non-myelinated nerve terminal. Such a mechanical filter action has theoretically also been analyzed. Resection of the outer lamella from the Pacinian corpuscle changes the adaptation of receptor potentials from phasic to tonic form; now, receptor potentials last during the period of mechanical stimulation (Fig. 1b). Thus, the lamella works as a mechanical filter to pass only the high frequency component of mechanical forces to the nerve terminals.

Generation of the RP at offset as well as at onset of mechanical compression is explained by the oval form of nerve terminals [3]. The unmyelinated nerve terminal



**Mechanosensory Transduction. Figure 2** Relationship between the stimulus strength applied to crystal or an electromechanical transducer (in voltage) and receptor potential relative to the maximum amplitude (%) in a PaC. Filled circles, relationship in the range of 0~30 volts; open circles, in the range of 0~6 volts. (Reproduced and modified from JAB Gray and M Sato (1952) 'Properties of the Receptor Potential in Pacinian Corpuscles', J. Physiol. 122:610–636, Fig. 8).

is oval in shape, and the longer transverse axis is aligned with the cleft of the inner lamella. The application of mechanical displacement to the shorter axis depolarizes the nerve terminal but the stimulation of the longer axis hyperpolarizes it. Application of mechanical forces displaces the lamella at the onset to increase the pressure inside the lamella, depolarizing the nerve terminal at the shorter axis. When mechanical distortion is over, the lamella return to the original sphere and the pressure inside the lamella is decreased as a whole, which depolarizes the nerve terminal at the longer axis.

This mechanical filter hypothesis is applicable to all lamellated corpuscles, since all sensory units innervating lamellated corpuscles are rapidly adapting to generate both on and off discharges in response to mechanical pulses.

### *Functional Role of Merkel Cells at Merkel Cell-Neurite Complexes*

Since F Merkel (1875) discovered Tastzellen (Merkel cells) in various vertebrates, it has been known that they are located at the position of the skin to readily receive mechanical deformation or force to the skin from the outside; under the touch dome in hairy skin or under the papillary ridges in glabrous skin. However, there is long-lasting controversy over the issue of whether Merkel cells are receptor cells, merely accessory cells to transmit mechanical forces to the associated nerve terminals or to induce their innervation of the skin during development [4]. Among affirmative evidence for the mechanotransduction hypothesis, included are phototoxic or chemical destruction of Merkel cells to abolish the tonic phase of discharges, chemical or gaseous manipulation of the circulating blood supply or bathing solutions for Merkel cells in situ or in vitro to modify the discharge patterns, and tonic discharges to anodal DC stimulation [4–6]. Among the negative evidence against the hypothesis, however, the failure by phototoxic destruction of Merkel cells to abolish discharges in response to short mechanical stimulations, the capability of Merkel cell-►neurite complex afferents to follow high frequent sinusoidal stimulation, possibly denying the function of synapse between Merkel cells and nerve terminals, and the survival of slowly adapting afferent discharges of irregular form (a specific feature of mechanoreceptor afferents innervating Merkel cell-neurite complexes) in spite of almost all loss of Merkel cells in mice lacking some neurotrophin [4,7]. To compromise the two parties, two-mechanotransduction site hypotheses have been submitted [4] (Fig. 3); Merkel cells are receptor sites for both phasic and tonic transduction and nerve terminals those for phasic transduction.

### *Mechanosensitive Ion Channels*

Application of mechanical forces to mechanoreceptors open mechanosensitive ion channels which is reflected as an increase in membrane conductance, to generate receptor potentials. By using techniques

M

of both electrophysiology and molecular biology, mechanosensitive ion channels have been extensively studied in nematode (*Caenorhabditis elegans*) and arthropod (*Drosophila*), and some correspondence in mammals has also been studied. However, ion channels gated by low mechanical stimulation have not yet been identified in mammals.

In both *C. elegans* and *Drosophila*, ion channels of two gene families, degenerin/epithelial Na channel (Deg/ENaC) and transient receptor potential (TRP) superfamily, are proposed as the candidates for mechanosensitive ion channels to mechanically gate in a short latency. Corresponding genes in are also found.

*Deg/ENaC superfamily* [8] have two transmembrane domains with a large extracellular loop for receiving physical stimuli from outside and the N and C terminals facing intracellular space. Among the superfamily, MEC-4 complexes have been identified as a mechanotransduction in *C. elegans*; the assembly is composed of Deg/ENaC subunits MEC-4 and MEC-10 and the accessory subunits MEC-2 and MEC-6. The MEC-4 complex is thought to associate with the extracellular matrix. ►Null mutation in MEC-4, MEC-2 and MEC-6 abolish mechanotransduction in body touch neurons. Since mammalian correspondence, β-ENaC and γ-ENaC, localize at lanceolate nerve endings in the vibrissae, Merkel cells and lamellated corpuscles in the food pad of the rat, they are assumed to act as a mechanotransduction channel. However, the function remains to be studied because of failure in their mutation study.

Three members of the acid-sensing ion channels (ASICs), a related subfamily of Deg/ENaC, are tested for a possible mechanotransduction channel. Na current through the channel is blocked by amiloride and facilitated by an acid lower than pH 5 and Zn. Knockout of respective genes in mice has been carried out to elucidate their involvement. Knockout of ASIC1 did not affect cutaneous touch, but did affect visceral mechanical afferents. Since both ASIC 2 and ASIC 3 are expressed at various mechanoreceptor afferent terminals, such as Meissner's corpuscles, Merkel cell-neurite complex, and hair follicles, several research groups knocked out ASIC 2 and 3 to see the influence on cutaneous mechanoreception. One group found that knockout of either ACIC 2 or ASIC 3 reduced in ►firing rates of rapidly adapting afferents in hairy skin but not in other types of mechanoreceptor afferents. Other groups, however, did not find any disruption of mechanoreceptor afferent activities by knockout of ASIC2 and/or ASIC3.

*TRP family* [8,9] is comprised of seven families. They are generally nonselective cation channels, having a molecular architecture similar to that of voltage-gated ion channels: subunits have six transmembrane domains with

a putative pore region, and are arranged to form a tetrameric channel. Almost all TRP families are expressed at ciliated structures, such as hair cells in the inner ear, and the vaniloid receptor TRP subfamily (TRPVs) is probably involved in mechanotransduction in vertebrates. TRPV4 are expressed at cutaneous nerve terminals, including Meissner corpuscle, Merkel-cell neurite complex, and Ruffini endings, but not in hair follicle palisade, however, its knockout did not impair mechanotransduction in low threshold mechanoreceptors but did in high threshold pressure receptors or mechanical nociceptors. TRPV4 is also activated by osmotic stimuli which cause cell to swell to regulate osmotic pressure in the brain. Since TRPV4 are usually activated by a second messenger in response to chemicals or temperature, a real mechanosensor is suggested in an upstream element even if it is involved in mechanosensory transduction. Isolated Merkel cells increased intracellular Ca in response to hyposmotic stimuli [10] and Merkel cells have lots of cytoplasmic processes probably corresponding to cilia of hair cells (see Mechanoreceptor, Anatomy in this Encyclopedia). However, it is not known whether TRP is involved in mechanotransduction of Merkel cells.

In spite of efforts, no mechanosensitive ion channels have so far been identified for low threshold cutaneous mechanoreceptors. Attempts to record mechanically-gated ionic currents from dorsal root ganglion (DRG) cells with genes of possible candidates for mechanosensitive ion channels have resulted in vain, probably because mechanosensors are not expressed at the membrane of DRG cells but at the nerve terminals.

# Mechanotransduction

## Definition

The sensing of mechanical stimuli by specialized mechanoreceptor cells, which transduce the stimuli into membrane potential changes (receptor potentials).

►Sensory Systems

# Medial Diencephalic Disorder

## Definition

Frequently referred to as ‘diencephalic amnesia’, medial diencephalic disorder is a type of amnestic disorder linked to lesions in the medial diencephalic region of the brain. The specific structures and connections in this region that must be damaged to cause memory impairment continue to be investigated. Two structures most frequently implicated include the medio-dorsal thalamic nucleus and mammillary nuclei. The presentation of diencephalic amnesia is similar to medial temporal lobe amnesia, with the usual occurrence of both anterograde and temporally graded retrograde amnesia.

## Synonyms

Auditory thalamus; Medial Geniculate Nuclei

## Definition

The medial geniculate body is the thalamic processing centre of the auditory pathway. It receives projections from several nuclei in the auditory brainstem and midbrain (predominantly the inferior colliculus), the auditory cortex, and the thalamic reticular nucleus (TRN). The projections of the MGB include regions of the auditory cortex, the TRN, and the lateral nucleus of the amygdala. The MGB comprises several subnuclei, each of which has distinct structural and functional properties. As well as being important for sound recognition and localization, it also plays a role in the emotional responses to sounds and auditory attention.

## Characteristics

### Introduction

The innervation of the MGB provides compelling evidence that sound perception depends on more than the upward sweep of sensory information from cochlea to cortex. Although the MGB receives ascending inputs chiefly, but not exclusively, from auditory centers in the brainstem, these are greatly outweighed by the descending inputs it receives from cortical sources. Indeed, the thalamic and cortical centers are so closely interconnected they are often referred to conjointly as the thalamo-cortical loop. Although we know little about the function of these connections, it seems likely they enable prior experience and stimulus history to influence sensory inflow to the cortex. But as well as projecting to the cortex, the MGB also targets the limbic system, a region of the brain involved in controlling emotions, and other subcortical targets such as the auditory sector of the thalamic reticular nucleus (TRN). Thus, the MGB not only has an essential role in auditory perception, but also contributes to learning, memory and attention in the auditory domain.

Our knowledge of the MGB is based on anatomical studies in a variety of mammals from rodents to humans, and physiological studies principally in cat, rat, guinea pig and primate. Species differences exist, but for the sake of clarity the emphasis here will be on the common features.

### Location and Subdivisions

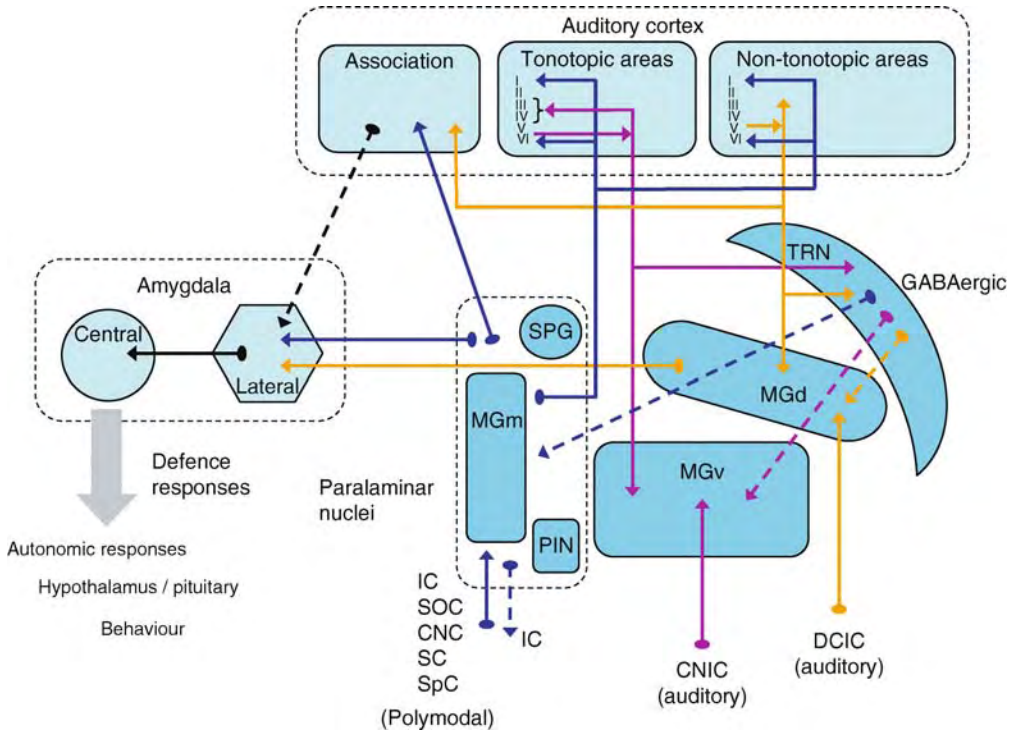
The paired MGBs are the most caudal thalamic nuclei, and are visible as rounded eminences on the lateral edges of the diencephalon at its junction with the mesencephalon. Caudal to each MGB is the superior colliculus, while dorsally and laterally is the lateral geniculate body: the principal visual nucleus of the thalamus.

The MGB is not a single uniform structure, but consists of three divisions, or nuclei: ventral (MGv), dorsal (MGd) and medial (MGm). Within these divisions further subdivisions have been recognized by their distinct cytoarchitecture, connections, and functional properties [1]. In contrast to some structures in the auditory brainstem, the two MGBs are not directly interconnected.

MGv, the largest of the three divisions, is overlain by the flatter dorsal division (MGd), while the narrow MGm lies medial to them. Of the three divisions MGv appears to be primarily sensory. It receives the major ascending (lemniscal) input from the ►inferior colliculus in the auditory midbrain, and sends outputs to the frequency mapped (tonotopic) subdivisions of the auditory cortex on the ipsilateral side, which in turn project back to MGv. MGd receives its inputs primarily from the dorsal cortex of the inferior colliculus and projects predominantly to nontonotopic, or extra-lemniscal, auditory fields and to the limbic system. MGm is characterized by polymodal inputs, and outputs that project to both tonotopic and non-tonotopic regions of auditory cortex. It also targets non-cortical structures including the lateral ►amygdala in the limbic system, and is involved in emotional responses to sound and auditory learning. The TRN comprises a shell of GABAergic neurons enveloping the thalamus laterally and rostrally; the auditory sector being most caudal part of the nucleus. It receives collateral inputs from excitatory thalamo-cortical and cortico-thalamic synapses, while delivering inhibitory feedback to the MGB via $GABA_A$ and $GABA_B$ fibers. Thus, under the influence of these feed forward and feedback connections, TRN modulates information flow from thalamus to cortex. The connections of the MGB are summarized in Fig. 1.

### Ventral Nucleus (MGv)

The major ascending input to MGv is from the midbrain, chiefly the central nucleus of the inferior colliculus on the ipsilateral side. Although this projection is predominantly excitatory, there is also a significant GABAergic, inhibitory projection, at least in rat and cat. As with other nuclei in the lemniscal division of the auditory pathway, the incoming fibers are arranged systematically within MGv according to their ►best frequency (BF), so giving rise to a topographic representation of sound frequency (a ►tonotopic map) that reflects the spatial analysis of frequency on the basilar membrane in the cochlea.



**Medial Geniculate Body. Figure 1** Connections to and from the medial geniculate body. *Double-headed arrows* indicate bi-directional connections. *Arrows* in the area enclosed by the *dashed line* labeled "paralaminar nuclei" represent connections of all nuclei in this group. Key: CNC, cochlear nucleus complex; CNIC, central nucleus of the inferior colliculus; DCIC, dorsal cortex of the inferior colliculus; IC, inferior colliculus; MGv, MGd, MGm, ventral, dorsal and medial nuclei of MGB, respectively; PIN, Posterior intralaminar nucleus; TRN, thalamic reticular nucleus; SC, superior colliculus; SOC, superior olivary complex; SpC, spinal cord; SPG, suprageniculate nucleus.

The neural substrate underlying this organization is an arrangement of large principal neurons whose flattened, tufted dendrites align with the incoming fibers. In the lateral part of MGv in cat, the species investigated most intensively, the cells and fibers are arranged in curved sheets or laminae orientated approximately dorsal to ventral and rostral to caudal. Neurons responding best to low-frequency sounds are encountered in the most lateral laminae and those with high frequency BFs occur medially. The sequence changes in the neighboring pars ovoidea; a region named for the laminae's distinctive concentric arrangement. The tonotopic mapping reflects this structure with neurons tuned to low frequency in the centre [2]. The tonotopy continues into the lateral part of the Posterior Group of the thalamus, a nucleus that abuts the MGv on its lateral, rostral and medial borders. The similarity of the auditory representation in the posterior group to that in MGv has led to its inclusion as a lemniscal component of the auditory pathway [2]. The tonotopic organization of MGv is reportedly less precise in lightly, or unanesthetized animals.

Other parameters of sounds are distributed across the two dimensional surface of each frequency lamina in MGv. Specific regions of the laminae represent different binaural interactions, e.g., bands of neurons that are excited by sound at either ear are separated by neurons that are excited by sound presented to the contralateral ear and inhibited by sound in the ipsilateral ear.

In cat and primate, MGv has an abundance of small inhibitory (GABAergic) interneurons distributed amongst the lamina-forming principal cells. These neurons form complex nests of connections with the principal cells called glomeruli. In marked contrast, GABAergic neurons are virtually absent in the rat, indicating differences of function across species [1].

In general, neurons in MGv are selective, or tuned, for sound frequency, with the majority showing the same or sharper tuning compared to that of auditory nerve fibers. A variety of different firing patterns to tonal stimuli have also been described including onset (the majority), tonic and off responses [3]. These patterns may reflect the distinct response properties of different units, but they may also be influenced by different functional states of the thalamus. Cells in the MGB, like many in the other thalamic nuclei, are capable of switching between two different modes of firing, "tonic" and "burst," depending on the state of a voltage-sensitive calcium conductance.

Bursts occur when this ion channel is activated by hyperpolarization of the neuron's membrane potential, presumably as consequence of the abundant inhibition derived from intrinsic and extrinsic sources in the MGB. Suggestions for the possible functional relevance of bursting include enhancing sensitivity to weak stimuli, and more effective driving of cortical target neurons. In MGv there is a greater tendency for bursts to fire when the stimulus is near the neuron's best frequency, thus perhaps generating a more robust representation of such sounds.

A caveat to any discussion about the functional role of these different modes of firing is the influence of the animal's conscious state. Membrane potential hyperpolarization appears to be prominent under anesthesia and slow-wave sleep, whereas MGB neurons are more depolarized in awake animals. Recordings in unanesthetized preparations are thus essential to reveal the true physiological response patterns of MGB neurons.

Outputs of MGv project to the tonotopic areas of the auditory cortex; these include A1 and AAF in cat, and the equivalent areas in primates identified as the "core" areas (AI and R, the area rostral to AI). These projections terminate predominantly in layers III–IV; the main input layers of the cortex. The ventral nucleus receives a heavy projection from the same areas of cortex particularly from cells in layer VI, but these patterns of connections are complex, and not simply reciprocal to the sources of input [4]. Collaterals of thalamo-cortical fibers from the MGv terminate in TRN which sends projections back to MGv and the other subdivisions.

We still know little about the functional role of the cortico-thalamic projection, although several studies have demonstrated changes in the tuning and firing rates of thalamic neurons following manipulation of the cortical activity [5]. It seems likely that cortico-thalamic projections mediate the feed-forward as well as feedback of cortical information to the MGB.

## Dorsal Nucleus (MGd)

The dorsal nucleus of the MGB has been subdivided into as many as five heterogeneous subdivisions. Like the ventral nucleus, the inputs to MGd originate from excitatory and inhibitory (GABAergic) neurons in the inferior colliculus, but in this case mainly from the dorsal cortex and the nearby lateral tegmental area rather than the central nucleus.

Generally, MGd neurons are not particularly selective for sound frequency and have broad or complex tuning curves; consequently there is little evidence of tonotopic organization in this nucleus, except in the deep dorsal division where neurons with more sharply tuned frequency responses have been recorded [3].

A particular property of MGd neurons is that many fail to respond to simple acoustic stimuli, and their responses habituate to repeated presentation of the same stimulus. Some authors have also reported the preference of MGd neurons for sounds that are spectrally and temporally complex, particularly animal calls and vocalizations [3].

The outputs of MGd are predominantly to the auditory cortex, but they are distributed more diffusely than those of MGv and directed mainly to the non-tonotopic, non-primary areas. For example, in cat there is a particularly strong input to the second auditory area AII, and in primates the strongest projections are to the belt regions surrounding the primary core areas of auditory cortex. The fibers' terminals are more widely distributed within the cortical layers with endings in all six layers [4]. Projections from MGd also go to the insular cortex and to the lateral nucleus of the amygdala indicating that it contributes to emotional responses to sound. MGd receives reciprocal projections from the auditory cortex, particularly from layer V cells, from the perirhinal cortex, the caudate and the putamen. As is the case with MGv, collaterals of MGd output fibers project to the TRN which, in turn, sends projections back to MGd.

## Medial Nucleus (MGm)

The medial nucleus of the MGB lies within the paralaminar group of nuclei found medial to the rest of the MGB. The group includes MGm, the suprageniculate nucleus (SPG; included in MGd in some classifications) and the posterior intralaminar nucleus (PIN). Functionally, these nuclei have many features in common and may be parts of the same entity [6].

MGm is a multimodal nucleus; in addition to its auditory input it also receives connections from other sensory pathways including the visual (superior colliculus), vestibular (vestibular nuclei) and ▶somatosensory (spinal cord) systems. Its auditory afferents originate chiefly from the extra-lemniscal external cortex of the inferior colliculus, but it also receives axons from the central nucleus of the inferior colliculus, and auditory centers peripheral to the midbrain including the superior olivary complex and the cochlear nucleus.

Consistent with the input it receives from lemniscal as well as extra-lemniscal divisions of the IC, some neurons in MGm have properties rather like those in MGv, namely relatively sharp tuning and short response latencies. But in general the frequency tuning of MGm neurons is broad, and some have distinctive multi-peaked tuning curves. Tonotopic organization is similarly relatively weak in MGm, although more apparent in the rostral part of the nucleus [3]. Responses are often more labile than those in the MGv, and, like neurons in MGd, often show habituation to repeated stimulus presentation. An important functional difference between neurons in MGm and those in other subdivisions of MGB is the reduced or absent expression of the calcium conductance responsible for the burst mode of firing [6].

A subset of MGm neurons are amongst the largest found in the MGB. An asymmetry in the size and number of these magnocellular neurons has been reported in the brains of dyslexic subjects at post mortem [7]. Compared with controls there was a deficit in the number and size of the neurons in the left MGm. Some assert this finding supports a general magnocellular theory of ►dyslexia. This posits that dyslexia results from a general deficit in magnocellular neurons leading to impaired processing of rapidly changing visual and auditory signals in the thalamus. However, while auditory deficits in processing dynamic stimuli have been reported in dyslexics, they are not always most pronounced for sounds with the most rapid fluctuations of frequency or amplitude. Furthermore, MGm does not appear to be homologous in input or function to the magnocellular layers in the visual thalamus.

The outputs of MGm project widely in the auditory cortex and target both primary, (tonotopic) and secondary (nontonotopic) areas. In contrast to the cortical projections of the other subdivisions, axons from MGm terminate primarily in the most superficial and deepest cortical layers (I and VI). Such a distribution is consistent with evidence that inputs to the cortex from MGm and other paralaminar nuclei contribute to cortical mechanisms mediating the formation of auditory memories, perceptual binding and aspects of attention. Electrical stimulation of the PIN enhances 40 Hz ►gamma oscillations in the cortex in rat, whereas they are attenuated by stimulation of MGv and MGd. These oscillations are hypothesized to reflect the binding of the different sensory representations of an object into a single percept [8]. Similarly, stimulation of TRN also increases cortical gamma oscillations suggesting that the paralaminar group and TRN are part of the same circuit.

Another important role of MGm is its contribution to the circuit mediating ►fear conditioning to acoustic stimuli. In this behavioral paradigm studied in rat, a neutral conditioned stimulus, e.g., a tone, is paired with a fear inducing unconditioned stimulus (mild footshock). After several such pairings, and consequent to the neural plasticity they induce, presentation of the conditioned stimulus alone is sufficient to elicit the fear response. The MGm and other paralaminar nuclei send direct projections to the lateral nucleus of the amygdala in the limbic system, the centre responsible for activating the behavioral and autonomic changes associated with fear responses [9]. The importance of such mechanisms for survival may explain the existence of a direct, and therefore fast, connection between the cochlear nucleus, (the first nucleus of the auditory pathway) and the MGm. An fMRI study in human has reported a correlation between activity in the amygdala and thalamus during conditioning.

There is no dispute that MGm is a source of auditory input to the fear conditioning circuit, but there is disagreement about where the conditioned and unconditioned stimuli become associated. The combined auditory and somatosensory input to MGm could provide a necessary substrate for such an interaction. Receptive field plasticity has been reported for MGm neurons in the form of an enhanced response and selectivity for the frequency of the conditioned stimulus [10]. These changes are persistent and occur with appetitive as well as fear conditioning. Others argue that the association between the conditioned and unconditioned stimulus first occurs in the lateral amygdala, and changes in MGm reflect feedback from the amygdala – although the necessary feedback connection has not been described. Alternatively, plasticity could of course occur at both sites, and differences in the properties of the plasticity observed in the two nuclei are consistent with this possibility.

Information from the MGB also reaches the amygdala via a second (albeit slower) indirect projection from both the dorsal and medial nuclei via the cortex. Other projections of MGm include the basal ganglia and feedback connections to the inferior colliculus.

## Medial Lemniscus

### Synonyms
Lemniscus med.

### Definition
The medial lemniscus arises from the union of the spinothalamic tract (anterior column of the spinal cord, protopathic sensibility), the bulbothalamic tract (gracile nucleus and cuneate nucleus, epicritic sensibility), the trigeminal lemniscus (face) and afferents of the solitary nucleus (gustatory sensibility). Hence it is also called the somatosensory tract. The fibers terminate in the corresponding thalamic nuclei,

which in turn project to the somatosensory cortex.

►Somatosensory Projections to the Central Nervous System

## Medial Longitudinal Fasciculus

### Synonyms
Fasciculus longitudinalis med.

### Definition
A nerve fiber bundle running rostrally to caudally in the brainstem, a little laterally to the midline and below the oculomotor complex (rostrally) and the surface of the fourth ventricle caudally. The riMLF (rostral interstitial nucleus of the MLF) is the rostralmost of the nuclei and is reticulated by the interspersed fibers of the MLF. It borders caudally with a second interstitial nucleus of the MLF, the interstitial nucleus of Cajal from which it is separated by the dorsal to ventral running fibers of the tractus retroflexus. Also, dorsally and medially it is demarcated by the thalamo-subthalamic paramedian artery. The medial longitudinal fasciculus is composed of two fiber components:

- Vestibular component: conducts efferents of the vestibular nuclei to the nuclei for controlling eye and cervical muscles, thus coordinating organ of equilibrium with eye and head movements
- Internuclear component: it coordinates motor cranial nerve nuclei and provides for synchronous eye movement and coordination of pharyngeal muscles while speaking and swallowing

The following tracts course here:

- Interstitiospinal tract
- Reticulospinal tract
- Tectospinal tract
- Lateral vestibulospinal tract
- Medial vestibulospinal tract

## Medial Preoptic Nucleus

### Synonyms
POML; Nucl. preopticus med.

### Definition
Lies in the preoptic area, involved in thermoregulation, hypovolemic thirst, male sexual behavior, brood care, modulation of go nadotropin secretion. Larger afferents from the amygdala, subiculum, interstitial nucleus of the stria terminalis, lateral septal nucleus, insula. Efferents to the diagonal band, septum, substan-tia innominata, interstitial nucleus, amygdaloid body, brainstem. Has numerous cells with receptors for gonadal steroids. Disruption of this nucleus induces ongoing hypothermia, while stimulation results in hyperthermia.

The menstruation cycle is also interrupted in the event of dysfunctioning of this area.

►Diencephalon

## Medial Rectus Muscle

### Definition
Medial rectus is one of the six eye muscles.

►Eye Orbital Mechanics

## Medial Reticular Formation

### Definition
The magnocellular, medial region of the RF stretches across the entire brainstem and enables the following sections to be distinguished:

- Gigantocellular reticular nucleus
- Caudal pontine reticular nucleus
- Oral pontine reticular nucleus

Belonging here are also the mesencephalic nuclei: cuneiform nucleus, subcuneiform nucleus and central medulla oblongata nucleus. This region of the RF is involved in motor and sensory tasks.

## Medium Spiny Neuron

### Definition

A type of central nervous neuron comprising more than 95% of the neurons in basal ganglia input structures, such as the caudate nucleus, putamen, nucleus accumbens and striatal districts in the olfactory tubercle. The cell body has a diameter in a range between 15 and 18 μm and gives rise to three to five primary dendrites that are aspiny proximally, but densely spiny beginning at about the first branch point.

The dendrites are extensively branched, producing approximately spherical dendritic fields with diameters of 200–300 μm. Medium spiny neurons utilize γ-amino butyric acid (GABA) as an inhibitory neurotransmitter and may co-express a number of peptide neuromodulators, such as enkephalin, substance P, dynorphin and neurotensin. They express dopamine and glutamate receptors and their activities are robustly modulated by dopaminergic projections arising in the midbrain and glutamatergic projections from a variety of sources, including the cortex and intralaminar thalamic nuclei.

The axons of medium spiny neurons give rise to dense terminations characteristic of the striatopallidal and striatonigral projections. Medium spiny neurons are also found in certain other of the deep telencephalic nuclei, such as the central and medial nuclei of the amygdala, bed nucleus of stria terminalis and lateral septum.

►Basal Ganglia
►Ventral Striatopallidum

## Medium-Lead Burst Neurons in Eye Movement (MLBNs)

### Definition

Neurons that exhibit a burst of spikes beginning no more than 15 ms before the onset of saccades in a preferred direction, but are silent or nearly silent during

fixation or slow eye movements. These include excitatory and inhibitory burst neurons.

►Brainstem Burst Generator
►Saccade, Saccadic Eye Movement

# Medulla Oblongata

## Definition

The medulla (Latin for marrow) is the caudal most part of the brainstem. Its rostral border is immediately caudal to the caudal edge of the pontine nuclei and its caudal border is marked by the top of the spinal cord just caudal to the pyramidal decussation and the cuneate and gracile nuclei.

## Definition

Effect of medullary serotonin (5-HT) neurons on motor output from the brainstem respiratory network.

In the accompanying essay of this Encyclopedia, we discuss the effects of medullary 5-HT neurons on the control of breathing. By releasing 5-HT, substance P (SP) and thyrotropin releasing hormone (TRH), they are thought to modulate respiratory output in a sleep state dependent manner, are required for ►hypoxia induced plasticity, and contribute to the stimulation of respiratory output by high $CO_2$ and/or low pH.

## Characteristics

### Anatomy

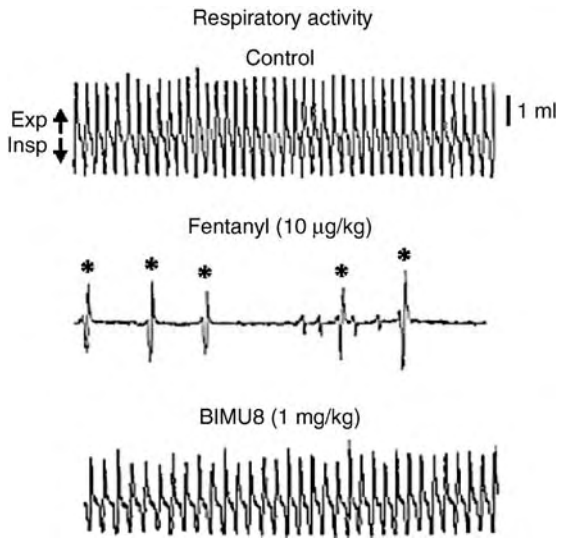
There is a caudal group of 5-HT neurons found in four locations in the caudal pons and medulla: the raphé pallidus, raphé obscurus, raphé magnus and parapyramidal region (►caudal raphé). Using tract tracing methods combined with immunohistochemistry for 5-HT or tryptophan hydroxylase (TPH), caudal 5-HT neurons have been found to project widely to nuclei containing respiratory neurons, including the nucleus ambiguus, nucleus tractus solitarius (NTS), hypoglossal motor nucleus and phrenic motor nucleus [1]. A variety of 5-HT receptor subtypes have been identified within these respiratory nuclei, including 5-$HT_{1a}$, 5-$HT_{1b}$, and 5-$HT_{4a}$ [1].

### Effect of 5-HT on Breathing in vivo

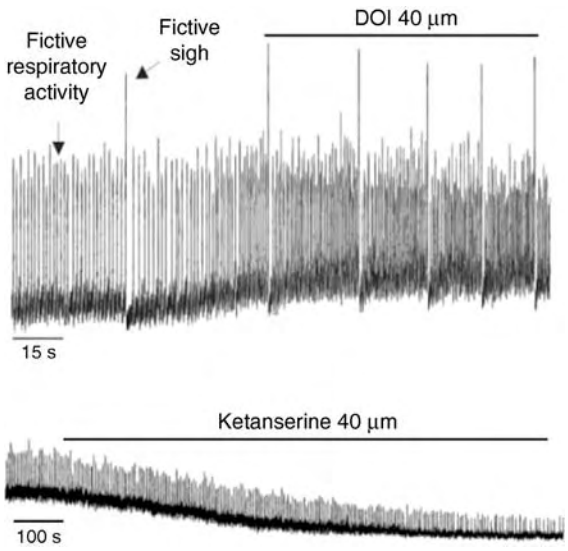
5-HT has a variety of modulatory effects on respiratory output and respiratory neurons *in vivo* [1]. Early experiments showed that blockade of 5-HT synthesis induced an increase in ventilation, suggesting that 5-HT inhibits breathing. Later it was found that stimulation of neurons within the medullary raphé nuclei causes release of 5-HT into the NTS and phrenic motor nucleus, and this could either stimulate or inhibit breathing depending upon where the electrode is placed. In contrast, selective agonists for 5-$HT_{1a}$, 5-$HT_{2a/1c}$ and 5-$HT_{4a}$ receptors stimulate ventilation (Fig. 1) [1,2]. The precise role of 5-HT and serotonergic neurons remains unclear, because it has been difficult to determine how endogenous release of 5-HT influences breathing *in vivo* under physiological conditions. This has been particularly problematic due to confounding effects of arousal state, separation of the effects of different receptor subtypes, and the interaction with other neuromodulatory inputs (e.g., norepinephrine, acetylcholine, histamine, SP and TRH). However, the consensus is that 5-HT has a primarily excitatory effect on respiratory motor output under most conditions.

### Co-localized Neuropeptides

Many 5-HT neurons in the medulla are also immunoreactive for neuropeptides, including SP and TRH. These neuropeptides are co-released by 5-HT neurons, and there are receptors for them on respiratory neurons. For example, neurokinin 1 (NK1) receptors for SP are localized in high concentration within the pre-Bötzinger Complex (pre-BötC) [3]. When administered *in vivo*, SP and TRH both have effects on breathing that are often stronger than 5-HT itself, and are uniformly stimulatory [1]. For example, studies in a variety of species have shown that TRH reverses respiratory depression induced by anesthetics. The relative importance of TRH in mediating the respiratory effects of 5-HT neurons has been difficult to determine, because there are not good antagonists of TRH receptors, but



**Medullary Raphe Nuclei and Respiratory Control. Figure 1** 5-$HT_{4a}$ receptor activation stimulates breathing *in vivo*. Data is from a rat *in vivo*. Each trace is a recording of lung ventilation. Under control conditions there is regular breathing. Fentanyl leads to severe apnea that required ventilatory support to prevent the animal from dying. Breathing was restored with the 5-$HT_{4a}$ receptor agonist BIMU8. (From Manzke et al, Science, 301:226, 2003).



**Medullary Raphe Nuclei and Respiratory Control. Figure 2** 5-$HT_{2a}$ receptor activation stimulates respiratory activity *in vitro*. Shown is activity recorded from the pre-Bötzinger Complex in a brain slice from the rostral rat medulla. Fictive respiratory activity is recorded as regular bursts of action potentials (shown here as an "integrated" recording). Application of the 5-$HT_{2a}$ agonist DOI increases the frequency of respiratory output (top trace). Application of the 5-$HT_{2a}$ antagonist ketanserine abolishes respiratory output (bottom trace), due to blockade of the effect of endogenously released 5-HT. (From Pena & Ramirez, J Neurosci, 22:11055, 2002.)

there is some evidence that TRH and SP are released primarily as the firing rate of 5-HT neurons increases to higher levels.

## Effects of 5-HT, SP and TRH on Respiratory Neurons in vitro

Compared with *in vivo* experiments, *in vitro* work has more consistently shown that 5-HT, and 5-HT neurons, stimulate the respiratory network. For example, spontaneous respiratory output generated by the pre-BötC in brain slices is stimulated via 5-$HT_{2a}$ (Fig. 2) and NK1 receptors [4,5]. In slices, 5-HT induces ectopic bursting activity in non-pacemaker neurons of the pre-BötC, and TRH induces bursting pacemaker activity in neurons within the respiratory portion of the NTS [1]. 5-HT, SP and TRH also have excitatory effects in the *in vitro* brainstem spinal cord preparation and perfused brain preparations. It is not clear why there are different results from *in vitro* preparations compared to *in vivo*, but it may be related to the more reduced nature of these preparations in which there is less influence of inputs from the periphery and other brain regions.

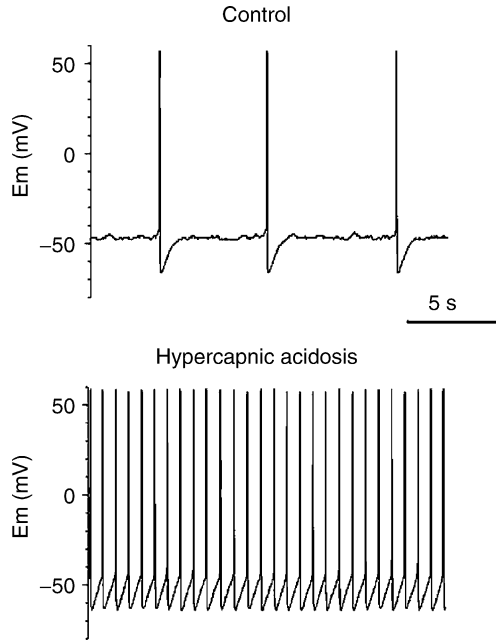
## $CO_2$/pH Chemoreception by 5-HT Neurons

5-HT neurons are normally tonically active *in vivo*, with greater activity during wakefulness and less during sleep, but are relatively unresponsive to most other perturbations and afferent inputs *in vivo*. Two exceptions are that they increase their firing rate *in vivo* in response to inhalation of $CO_2$ and during repetitive motor activities. This has been shown using extracellular recordings from medullary raphé neurons in behaving cats [6], as well as c-*fos* staining in rats. Interestingly, the response of these neurons to $CO_2$ is depressed during sleep, in tandem with a decrease in the ►hypercapnic ventilatory response.

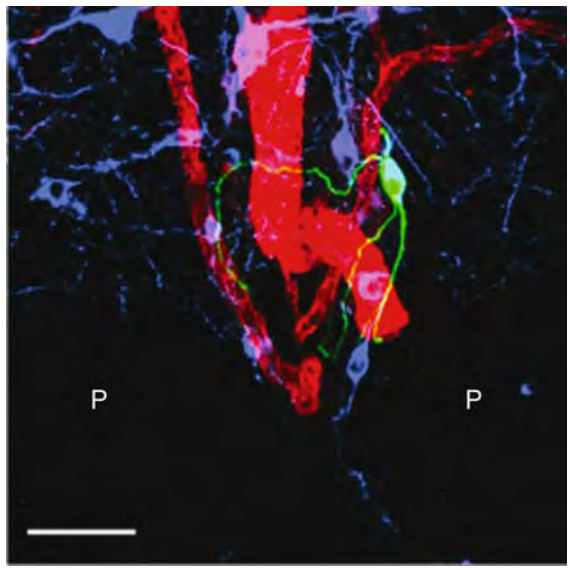
5-HT neurons are intrinsically chemosensitive to $CO_2$. After chemical or physical isolation from other neurons in brain slices and in cell culture, they respond to ►hypercapnia with an increase in firing rate (Fig. 3) [1]. This response is indirectly due to the decrease in pH induced by increased $PCO_2$. Based on these and other data, serotonin neurons are thought to be ►central respiratory chemoreceptors (CCRs), i.e., sensors of blood $CO_2$ that stimulate respiratory output in response to hypercapnic acidosis. This response lowers $PCO_2$, thus maintaining pH homeostasis.

5-HT neurons in rats have anatomy that suggests they are specialized to detect changes in blood $PCO_2$. Many 5-HT neurons are located in the midline medulla, which is highly perfused by large arteries, and they have

M



**Medullary Raphe Nuclei and Respiratory Control.**
**Figure 3** 5-HT neurons are intrinsically sensitive to acidosis. Shown is the membrane potential of a 5-HT neuron from the medullary raphé grown in cell culture. A decrease in pH from 7.4 to 7.2 induces an increase in firing rate. (From Wang et al, J Physiol, 540:951, 2002.)



**Medullary Raphe Nuclei and Respiratory Control.**
**Figure 4** Serotonin neurons are closely associated with large midline arteries in the medullary raphé and ventrolateral medulla. Shown is a brain slice after recording from a neuron that was stimulated by acidosis. The neuron was identified by filling with biocytin (green). Immunohistochemistry for tryptophan hydroxylase (blue) revealed that it was serotonergic. This neuron had dendrites that were closely associated with large penetrating arteries stained with an antibody for α-smooth muscle actin (red). P – pyramidal tract. Bar – 50 μm. (From Bradley et al, Nature Neurosci, 5: 401, 2002.)

dendrites and cell bodies that are closely apposed to these arteries (Fig. 4). The $PCO_2$ of arterial blood is inversely proportional to gas exchange in the lungs. This location would avoid confounding effects of changes in local brain metabolism or cerebral blood flow that would influence the $PCO_2$ near venous blood or brain capillaries, and would thus allow a relatively greater selectivity for monitoring lung ventilation.

5-HT neurons play a role in the increased ventilation induced by hypercapnic acidosis. In slices of the medulla, focal application of acidic solution into the raphé nuclei leads to an increase in frequency of respiratory rhythm generated by the pre-BötC. In rats and goats *in vivo*, focal acidosis in the medullary raphé leads to an increase in ventilation [3]. Specific lesions of 5-HT neurons with the neurotoxin 5,7-dihydroxytryptamine, or genetic deletion of 5-HT neurons, leads to blunting of the hypercapnic ventilatory response *in vivo*. The relative importance of 5-HT neurons in central respiratory chemoreception *in vivo*, compared to other putative chemoreceptors in the brain, has not been determined. However, some data suggest that as much as 50% of the central chemoreceptor response is dependent upon 5-HT in mice. Current work is aimed at defining the relative importance of each of the candidates for central chemoreceptors, and whether this varies under different conditions, such as sleep or disease states.

## 5-HT and Plasticity of Respiratory Output

Respiratory output is generally considered to be hard-wired, but it has recently been shown to undergo considerable plasticity [3]. For example, after three episodes of mild hypoxia of 5 minutes each, ventilation slowly increases over the next hour despite withdrawal of the hypoxic stimulus. This "long term facilitation" of respiratory motor output is due to strengthening of the synaptic drive to respiratory motor neurons from the medullary respiratory centers, and requires protein synthesis. It has recently been found that this LTF is blocked by 5-HT antagonists [3]. Elucidation of the serotonergic mechanisms involved in LTF may provide new avenues for treatments to strengthen respiratory drive in patients with respiratory weakness, such as that due to incomplete spinal cord injury.

## 5-HT Neurons and Breathing in Disease

5-HT neurons of the midbrain (dorsal and median raphé) are central to many psychiatric diseases. Those

within the medulla are now known to be involved in the pathophysiology of diseases in which there are breathing abnormalities.

►Sudden infant death syndrome (SIDS) is defined as the "sudden death of an infant under one year of age, that remains unexplained after a complete clinical review, autopsy, and death scene investigation." SIDS is a heterogeneous disorder, including a small subset due to genetic cardiac defects. However, a large percentage of SIDS cases are believed to occur when a developmental defect in the brainstem of otherwise normal infants makes them vulnerable to an exogenous stressor such as obstruction of the airway, a mild infection, or variations in ambient temperature. The stressor can then lead to a decrease in ventilation, hypoxia and hypercapnia, and ultimately death.

Recent neuropathological studies of infants that died of SIDS have found abnormalities in serotonin receptors, the serotonin transporter and the number and morphology of serotonin neurons in the medulla [7]. Genetic studies have also linked SIDS to polymorphisms in the promoter for the serotonin transporter. It is now believed that a large percentage (> 50%) of SIDS cases are due to a developmental defect in 5-HT neurons. This defect can be genetically influenced or induced by environmental factors such as cigarette smoking.

Animal experiments have provided insight into mechanisms by which a defect in the 5-HT system could lead to vulnerability to an exogenous stressor. Selective deletion of 5-HT neurons by genetic methods or neurotoxins in rodents leads to blunted $CO_2$ chemoreception and impaired thermoregulation in adults. There is also irregular breathing and an increase in mortality in neonatal mice [8]. These abnormalities in mice are reminiscent of defects proposed to exist in SIDS cases. Although the pathological changes in these mouse models are not the same as those in human SIDS, current research is aimed at determining whether the physiological changes are similar, if a test can be developed to identify infants at highest risk, and if preventive treatments are possible.

►Sleep apnea occurs in 4% of adult males in the US, and is most commonly due to obstruction of the upper airway from withdrawal of muscle tone during sleep, particularly during REM. Many patients are apneic more than 15 times per hour, each time becoming hypoxia. This can lead to a variety of consequences including daytime sleepiness, difficulty concentrating, hypertension, right sided heart failure and stroke.

One of the factors that contributes to airway obstruction during sleep is the withdrawal of 5-HT input onto motor neurons that innervate upper airway muscles. Hypoglossal neurons, which have been studied the most intensively, are depolarized *in vitro* by 5-HT, SP and TRH, each of which inhibit leak $K^+$ channels. During sleep, the firing rate of 5-HT neurons decreases, with almost complete cessation during REM. The decrease in excitatory neuromodulation of motor neurons is thought to play an important role in the decrease in upper airway tone during sleep.

►Multi-System Atrophy (MSA) is a neurodegenerative disorder that involves degeneration of dopamine and autonomic neurons in the brain. Patients have symptoms similar to Parkinson's disease, but also have autonomic dysfunction. It has recently been found that there is also degeneration of 5-HT neurons in some of these patients [9]. This may explain why sleep apnea can be an early manifestation of MSA, because of impairment of central respiratory chemoreception and/or greater reduction in 5-HT tone during sleep.

►Panic attacks are discrete periods of fear or discomfort in which there is rapid development of symptoms such as a feeling of air hunger, choking and/or palpitations. They often include hyperventilation. These episodes can occur spontaneously or can be induced by situational triggers. They can also be induced by breathing $CO_2$. Selective serotonin reuptake blockers are highly effect for treatment. A widely held theory is that panic attacks are an inappropriate triggering of a reflex that can be activated in normal people by hypercapnia, and which is designed to restore normal blood $CO_2$ levels. This "false suffocation alarm" has been proposed to be due to a defect in 5-HT neurons [10].

## Synonyms

Meissner's corpuscle; Wagner's corpuscle; Corpusculum tactus; Tactile lamellar corpuscle; Digital lamellated corpuscle

## Definition

A rapidly-adapting mechanoreceptor for touch sensation, situated at the top of the dermal papillae of the skin. The corpuscle consists of thin sheets of lamellar cells densely piled around axon terminals.

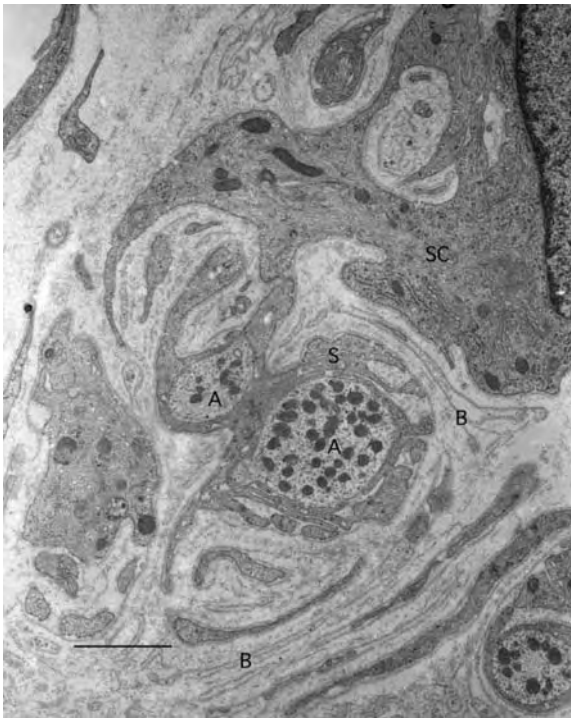
## Characteristics

### Structure

The corpuscle is oval in shape, with a long axis of ca. 100–300 μm. The corpuscle is usually situated with the apical end pointing towards the base of the epithelium of the dermal papillae. Generally, one or sometimes two to three nerve fibers innervate the corpuscle, ending as enlarged terminals after branching within. The axon terminals are characterized by containing numerous mitochondria and clear vesicles, and are sandwiched by thin lamellar cell processes (ca. 0.5 μm in width) in the basal-apical direction of the corpuscle [1]. Lamellar cells are specialized Schwann cells, extending thin sheet-like cytoplasmic processes with characteristically numerous caveolae on the cell surface membrane [2]. Lamellar cell processes are interposed with neighboring ones by narrow connective tissue spaces, being covered by basal laminae at the connective tissue surface. Lamellar cells secrete the enzyme cholinesterase into the interlamellar spaces [3], and have TGF-beta immunoreactivity [4]. The corpuscle lacks the perineurial sheath.

### Regeneration

When an innervating nerve is cut, its axon terminals disappear, and concomitantly the surrounding lamellar cells become atrophic. The atrophic corpuscle then persists for an extended time. When regenerating axons enter the atrophic corpuscle, the lamellar cells retain their original "active" form. Some trophic factors available from axons are needed for lamellar cells to maintain their active form [5]. Meissner corpuscles are reinnervated by host axons in the allograft skin [6], or ectopically grafted digital skin [7]. Meissner corpuscles can regenerate in an acellular environment. When the skin is freeze-treated with liquid nitrogen, all cellular components including lamellar cells are killed and only connective tissues including basal laminae constituting the corpuscle remain in their original condition. Reinnervating axons first enter such an acellular environment, followed by Schwann cells. The Schwann cells then gradually develop into lamellar cells with a small number of thin cytoplasmic processes (Fig. 1). Innervating axons are enlarged at their ends as in the original Meissner corpuscle. Although the patterns of lamellar cells are incomplete compared to the original normal corpuscle, the overall structures are those of normal Meissner corpuscles, and thus can be called an atypical Meissner corpuscle [8]. The extracellular matrix of the Meissner corpuscle has the ability to develop new Meissner corpuscles after re-innervation. A new corpuscle can never develop in an acellular site other than that of the original corpuscle. Similarly, there is no evidence of Meissner corpuscle



**Meissner Corpuscle Regeneration. Figure 1** The rat toe skin was freeze-treated to kill the cellular components of tactile digital corpuscles in the toe pad. The extracellular matrix of the corpuscle remained in loco after the cellular components had been removed. About 1 week after treatment, regenerating axons (A) accompanied by immature Schwann cells (SC) entered the acellular matrix of the corpuscle. It is noted that immature Schwann cells with regenerating axons begin to develop into digital corpuscles by extending cellular processes (S) through the basal lamina scaffolds (B), mimicking the formation processes during digital corpuscle development. Axons end in axon terminals associated with layers of Schwann cell lamellae. Thus, the new digital corpuscle, although atypical in cellular organization, can be formed in the acellular matrix of the old corpuscle. Scale bar: 2 μm.

regeneration de novo in nerve fascicular repair [9]. There is no tactile lamellar corpuscle regeneration when developing corpuscles are denervated before postnatal day 5 in the rat [10].

# Melanin and Neuromelanin in the Nervous System

William H. Tolleson
Division of Biochemical Toxicology,
National Center for Toxicological Research,
US Food and Drug Administration, Jefferson,
AR, USA

## Synonyms

Neuromelanin; Melanin; Eumelanin; Pheomelanin

## Definition

►Melanins are naturally occurring polymeric pigments produced from L-tyrosine and L-cysteine by catecholaminergic neurons and ►melanocytes. Melanin subcategories occurring in humans include ►neuromelanin, ►eumelanin and ►pheomelanin.

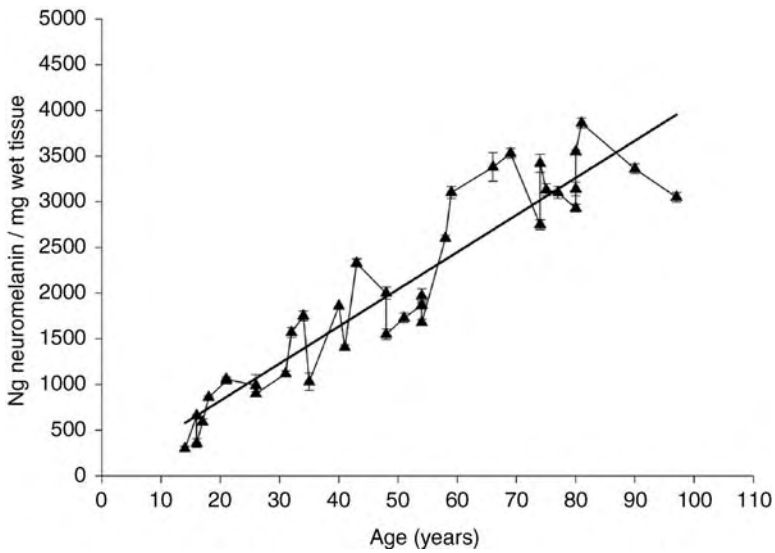
## Characteristics

### Quantitative Description

In humans, melanin pigments are distributed among anatomic sites harboring melanocytic cells or dopaminergic and noradrenergic neurons. Melanocytes residing in hair follicles and the interfollicular epidermis produce eumelanin and pheomelanin pigments that are responsible for natural individual variations in external pigmentation. Other major populations of melanocytes are present in the: (i) uveal tract in the posterior portion of the eye, (ii) stria vascularis within the scala media of the cochlea, and (iii) meninges covering the brain [1].

Neuromelanin is produced by dopamine- and norepinephrine-synthesizing neurons, but not those producing epinephrine. It is generally believed that ►catecholamine neurotransmitters are the major biochemical precursors of human neuromelanin, although definitive chemical analysis of neuromelanin has been impeded by its low abundance. Elucidating the chemical structure and origin of neuromelanin is a matter of active research.

Dopaminergic neurons of the substantia nigra lack neuromelanin at birth; it is detectable as intracellular granules within the substantia nigra pars compacta by 3 years of age and becomes increasingly abundant throughout life [2]. The substantia nigra pars compacta of normal brains (mean age 61 years) contain approximately 1 mg of neuromelanin, or about 2.5 μg neuromelanin per mg wet tissue (Fig. 1).



**Melanin and Neuromelanin in the Nervous System. Figure 1** Neuromelanin content within the substantia nigra increases steadily throughout life. Regression analysis of the relationship between neuromelanin content in the substantia nigra (ng/mg tissue) and age of normal male and female subjects, ages 14–97 years. (By permission, Zecca et al. [2]; copyright (2004) National Academy of Sciences, USA.) Similar concentrations of neuromelanin accumulate within the locus coeruleus.

The major population of noradrenergic neurons located in the locus coeruleus of the brain stem also contains neuromelanin granules. Although greater inter-individual variation is apparent, neuromelanin levels in the locus coeruleus also increase with age and are comparable to the amounts found in the substantia nigra of the same individuals (~2.5 μg/mg wet tissue at 61 years) [2].

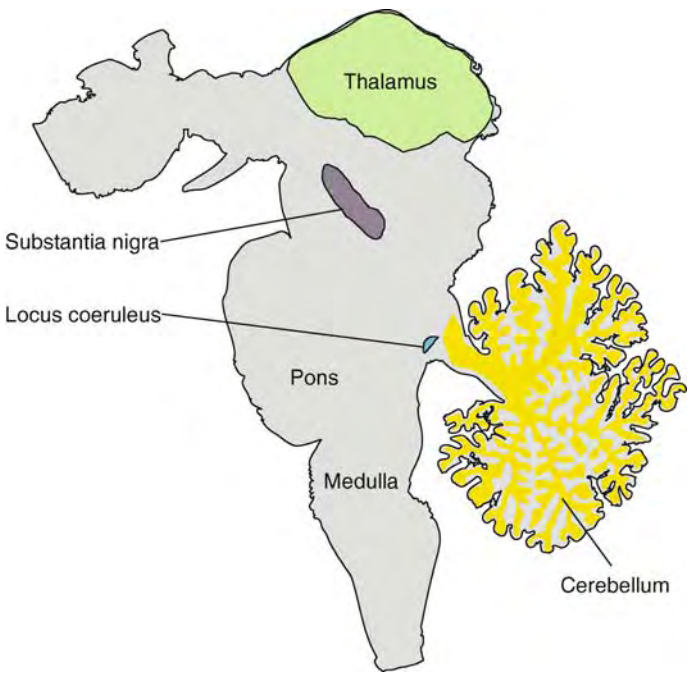
## Higher Level Structures

### *Pigmented Dopaminergic Neurons of the Substantia Nigra Pars Compacta*

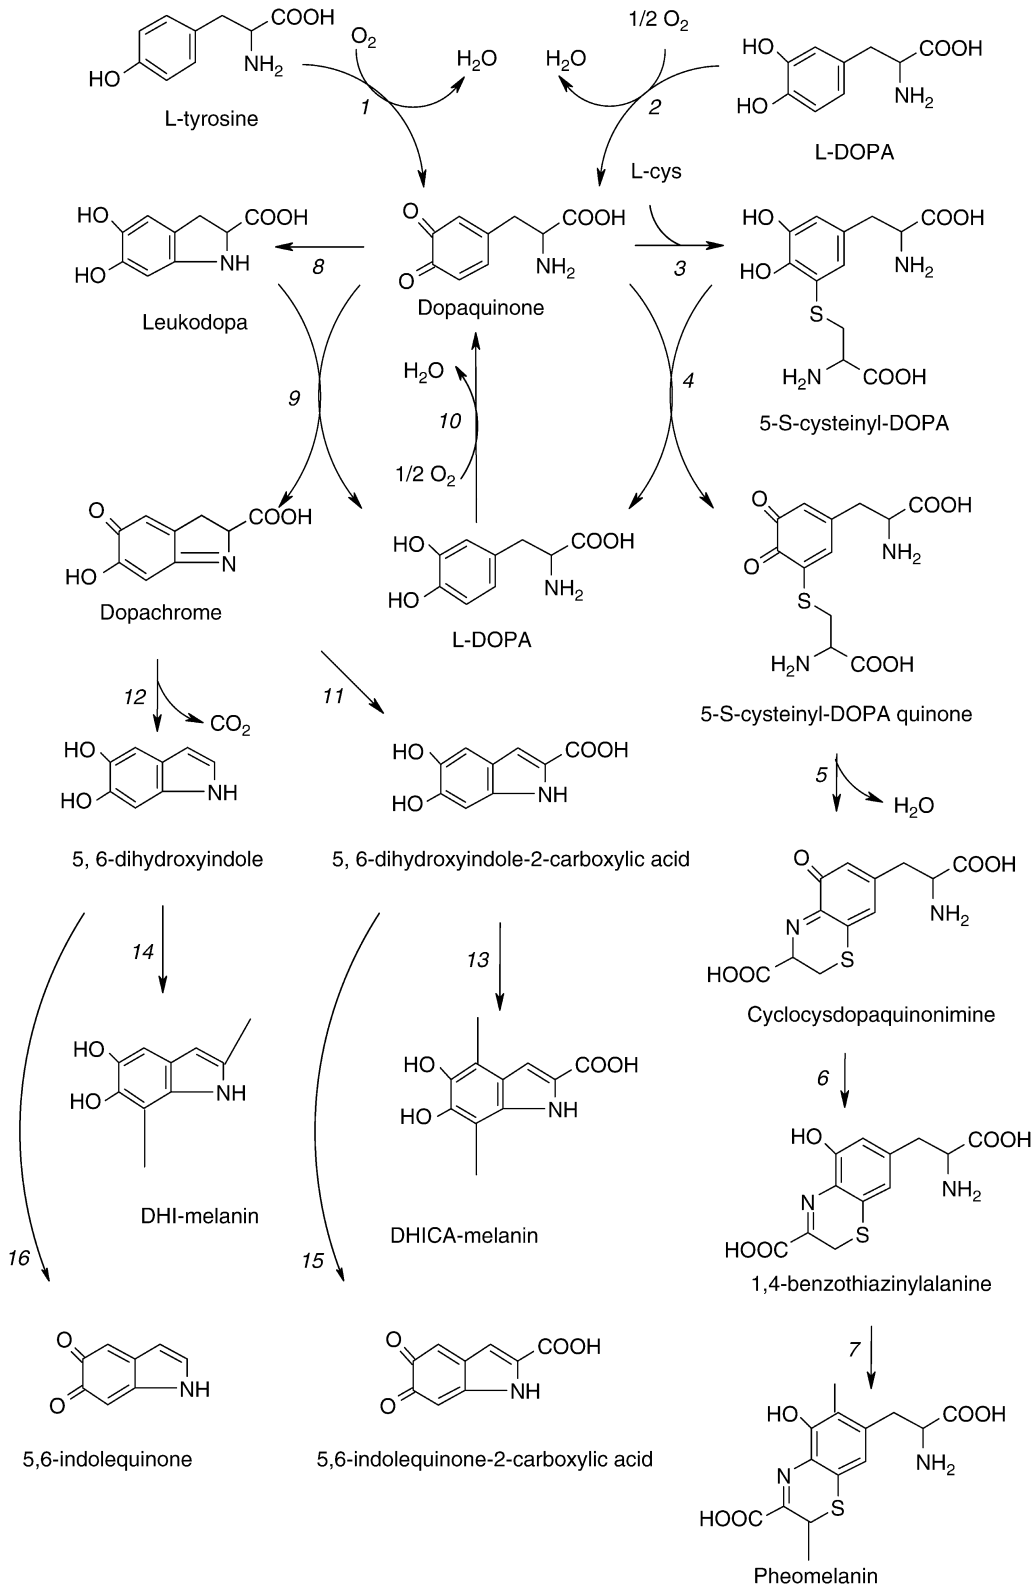
The largest nuclear mass of the mesencephalon is the substantia nigra (Fig. 2), divided into two sections by the interpeduncular fossa and interpeduncular nucleus [3]. The substantia nigra extends caudally from the rostral mesencephalon to the pons. The substantia nigra can be subdivided into its dorsal neuromelanin pigmented portion, designated the substantia nigra pars compacta, and the ventral substantia nigra pars reticularis. The substantia nigra pars compacta includes closely packed, pyramidal or polymorphic neurons containing neuromelanin. The substantia nigra pars reticularis, also called the stratum intermedium, containing polymorphic GABAnergic neurons, is positioned ventrally to the substantia nigra pars compacta and dorsally to the crus cerebri. Cells of the substantia nigra pars reticulum lack neuromelanin but contain abundant iron, which imparts a reddish color to this region. Dopaminergic axons from the substantia nigra pars compacta project anteriorly to the striatum, constituting the nigrostriatal neural pathway that regulates muscle control. A minor number of pigmented dopaminergic neurons innervate the nucleus accumbens and cerebrum. These neurons originate from the ventral tegmentum area, which is ventral to the red nucleus, medial to the substantia nigra and dorsal to the interpeduncular nucleus.

### *Pigmented Noradrenergic Neurons of the Locus Coeruleus*

Noradrenergic neurons are aggregated in the locus coeruleus (Fig. 2) [3,4]. The tightly packed, pigmented, polygonal cells of the locus coeruleus communicate with diverse regions of the CNS. The locus coeruleus receives inputs from the hypothalamus, amygdala, cingulate gyrus, raphe nuclei, and cerebellum. Efferent fibers from the locus coeruleus innervate the spinal cord, cerebellum, hypothalamus, amygdala, cerebral cortex, and the basal telencephalon.



**Melanin and Neuromelanin in the Nervous System. Figure 2** Primary neuromelanin-containing regions of the human brain. The majority of neuromelanin-containing dopaminergic neurons are found in the substantia nigra located in the mesencephalon. Another major cluster of neuromelanin-containing cells are found within the locus coeruleus in the anterior pons adjacent to the superior cerebellar peduncle. Dopaminergic axons from the substantia nigra pars compacta, ventral tegmentum area, and arcuate nucleus of the mediobasal hypothalamus project to the striatum, nucleus accumbens, cerebrum, and the hypothalamic median eminence. Noradrenergic neurons innervate the spinal cord, cerebellum, hypothalamus, amygdala, cerebral cortex, and the basal telencephalon.



**Melanin and Neuromelanin in the Nervous System. Figure 3** Synthesis of eumelanins and pheomelanins. Tyrosinase (EC 1.14.18.1), a copper-containing monooxygenase, catalyzes the first steps of melanogenesis (reactions 1, 2, and 10) – the formation of dopaquinone by hydroxylation and oxidation of L-tyrosine. Dopaquinone is a key intermediate essential for synthesis of both pheomelanins and eumelanins. Pheomelanin synthesis is initiated

### Dopamine Neural Pathways

Four dopamine neural pathways exist: (i) nigrostriatal, (ii) mesocortical, (iii) mesolimbic, and (iv) tuberoinfundibular. The nigrostriatal is the largest of the four dopamine pathways and it connects the substantia nigra pars compacta and striatum to facilitate muscle control. The mesocortical pathway regulates emotional responses and connects the ventral tegmentum area of the midbrain to the cerebrum. The mesolimbic pathway connects the ventral tegmentum area to the nucleus accumbens, the reward/desire center of the brain. The tuberoinfundubular pathway connects the arcuate nucleus of the mediobasal hypothalamus to the hypothalamic median eminence, and regulates the release of prolactin. Neuromelanin granules have been detected within dopaminergic neurons in each of the four pathways, but are the most abundant and consistently evident in the substantia nigra pars compacta of the nigrostriatal pathway.

### Melanocytes Associated with the Nervous System

Three major populations of extracutaneous melanocytes provide accessory functions for the nervous system [1]. A large number of highly pigmented melanocytes can be found within the posterior choroid and cilliary body of the uveal tract, separated from the neural retina by the retinal pigment epithelium and Bruch's membrane. Melanin of the pigment epithelium and uveal tract prevents photodynamic damage in the very highly perfused choriocapillaris of the uveal tract and improves visual acuity by absorbing stray light. Specialized melanocytes, termed intermediate cells, are found in the stria vascularis of the scala media in the inner ear. These cells play a critical role in maintenance of the endocochlear potential, essential for hearing, by regulating potassium transport into the endolymph. Scattered melanocytes can be found throughout the meninges but are most apparent within the ventrolateral leptomeninges overlying the pons and medulla. Melanin produced by these melanocyte populations is believed to scavenge toxic materials, including organic and inorganic cations and reactive oxygen species, providing a defense/protective function.

## Lower Level Components

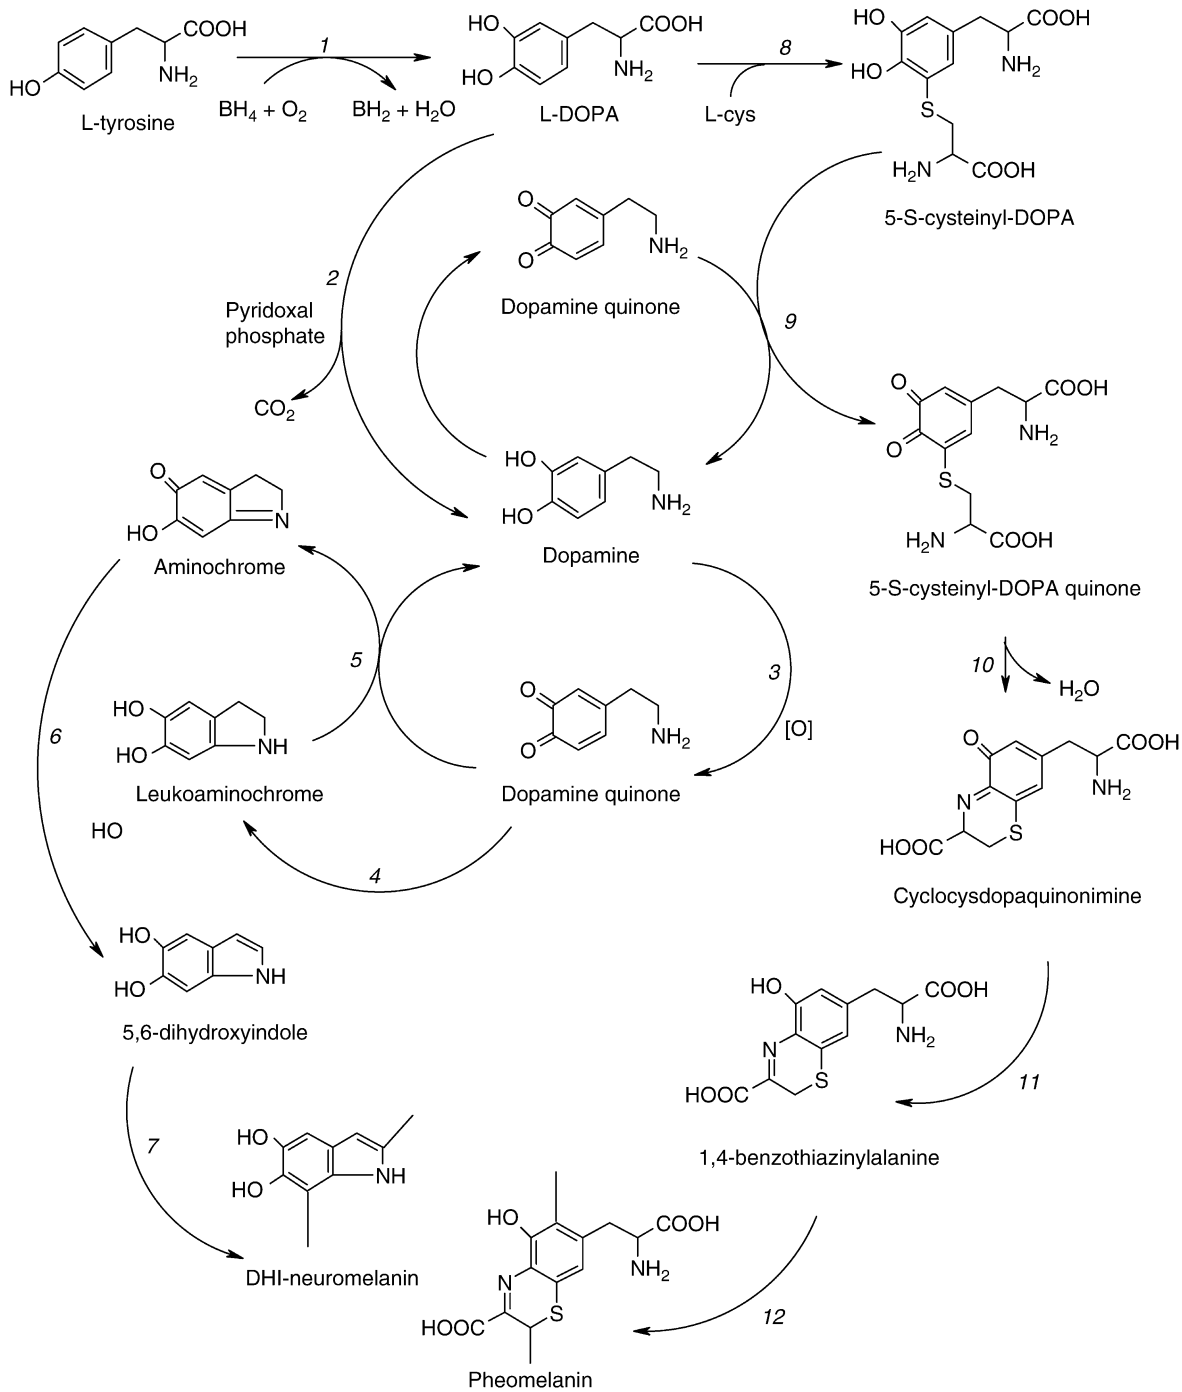
### Synthesis of Melanin, Pheomelanin, and Neuromelanin

Eumelanin and pheomelanin biosynthesis from L-tyrosine and L-cysteine sequestered within melanosomes, the specialized cytoplasmic organelles related to lysosomes and unique to melanocytes, is well understood (see Fig. 3) [1]. The levels of these two amino acids within melanosomes, along with intramelanosomal pH and the relative expression of melanin-producing enzymes, influence the forms of melanin ultimately produced. By contrast, less is known concerning neuromelanin synthesis (see Fig. 4). Within melanosomes, tyrosine is converted to L-DOPA by tyrosinase followed by oxidation to dopaquinone (Fig. 3, reactions 1, 2). Dopaquinone may react spontaneously with L-cysteine in the first committed step towards pheomelanogenesis (Fig. 3, reaction 3) or experience intramolecular cyclization to form leukodopa, which leads to the eumelanogenesis pathway (Fig. 3, reaction 8). The cytoplasmic enzyme tyrosine hydroxylase catalyzes formation of L-DOPA from L-tyrosine in neurons (Fig. 4, reaction 1) followed by decarboxylation to form dopamine in a reaction catalyzed by aromatic amino acid decarboxylase (Fig. 4, reaction 2). Dopamine is readily oxidized to the neuromelanin precursor dopamine quinone within dopaminergic neurons (Fig. 4, reaction 3). In noradrenergic neurons, dopamine is converted to norepinephrine by dopamine β-hydroxylase, which is also subject to oxidation to its analogous quinone, noradrenoquinone, believed to be another neuromelanin precursor.

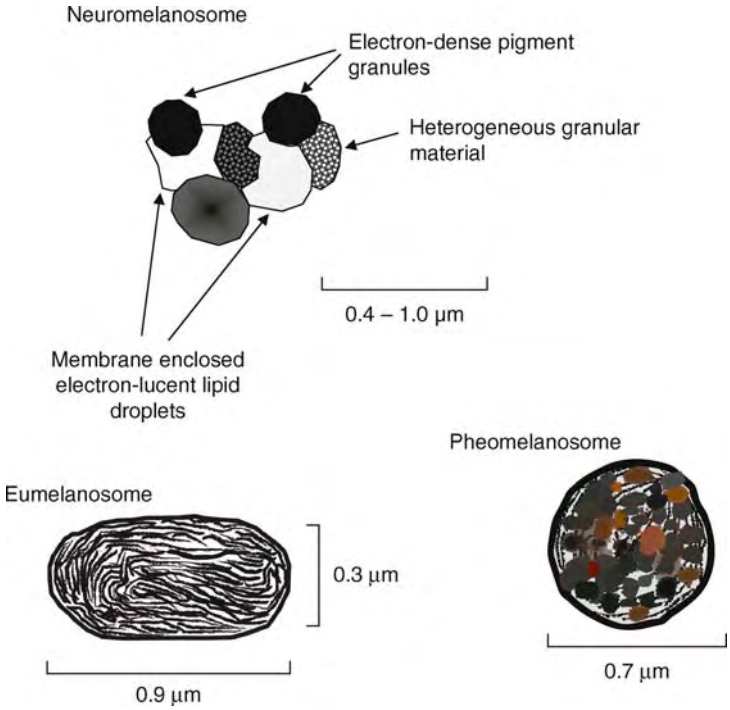
### Melanosome Structure

The processes of melanin synthesis and melanosome assembly (divided into Stages I–IV) are coordinated in human melanocytes. Mature human Stage IV ►eumelanosomes are membrane-enclosed ellipsoidal

when L-cysteine reacts spontaneously with dopaquinone to form 5-*S*-cysteinyl DOPA (reaction 3). Excess dopaquinone or other oxidants convert 5-*S*-cysteinyl-DOPA to 5-*S*-cysteinyl-dopaquinone nonenzymatically (reaction 4). Elimination of water from 5-cysteinyl-dopaquinone yields cyclocysdopaquinonimine (reaction 5), which isomerizes spontaneously to form 1,4-benzothiazinylalanine (reaction 6). Polymerization of 1,4-benzothiazinylalanine monomers yields pheomelanin (reaction 7). Synthesis of eumelanins begin with the spontaneous cyclization of dopaquinone to produce leukodopa (cyclodopa; reaction 8) followed by its oxidation to form dopachrome via a recycling reaction that regenerates L-DOPA from excess dopaquinone (reactions 9, 10). Dopachrome tautomerase (tyrosinase-related protein-2, TRP-2, EC 5.3.3.12) converts dopachrome to 5,6-dihydroxyindole-2-carboxylic acid (reaction 11). Spontaneous decarboxylation of dopachrome may occur at a reduced rate in the absence of TRP2 enzyme activity to yield 5,6-dihydroxyindole (reaction 12). Polymerization of 5,6-dihydroxyindole-2-carboxylic acid (reaction 13) yields a lighter colored pigment than does polymerization of 5,6-dihydroxyindole (reaction 14). Tyrosinase (in humans) or tyrosinase-related protein 1 (TRP-1, catalase B) catalyze oxidation of 5,6-dihydroxyindole-2-carboxylic acid or 5,6-dihydroxyindole to their respective *o*-quinones (reactions 15 and 16, respectively), which polymerize spontaneously to form eumelanins.



**Melanin and Neuromelanin in the Nervous System. Figure 4** Neuromelanin synthesis. Neuromelanin synthesis begins with hydroxylation of L-tyrosine to produce L-DOPA (reaction 1), catalyzed in catecholaminergic neurons by tyrosine hydroxylase (EC 1.14.16.2), a nonheme Fe-containing monooxygenase that utilizes tetrahydrobiopterin ($BH_4$) as a cofactor. Aromatic amino acid decarboxylase (EC 4.1.1.28) utilizes pyridoxal phosphate as a coenzyme to produce dopamine via L-DOPA decarboxylation (reaction 2). Dopamine is easily oxidized nonenzymatically at physiological pH to generate dopamine *o*-quinone (reaction 3). Cyclization of dopamine *o*-quinone (reaction 4) to form leukoaminochrome occurs more slowly at physiological pH than in acidic conditions. Leukoaminochrome can be oxidized to aminochrome by dopamine *o*-quinone (reaction 5). Aminochrome rearranges to generate 5,6-dihydroxyindole (reaction 6) that polymerizes to form neuromelanin (reaction 7). Tyrosine hydroxylase also possesses an L-DOPA: L-cysteine conjugating activity that generates 5-*S*-cysteinyl-DOPA (reaction 8). Excess dopa (amine) quinone converts 5-*S*-cysteinyl-DOPA to its *o*-quinone (reaction 9), which can form pheomelanin by the



**Melanin and Neuromelanin in the Nervous System. Figure 5** Melanosome structure. Mature Neuromelanosomes found within catecholaminergic neurons may exhibit a distinct lipid bilayer enclosing aggregates of electron dense pigment granules associated with electron lucent lipid and heterogeneous granular material. Eumelanosomes and pheomelanosomes are found within melanocytes – or may be taken up by adjacent cells. A eumelanosome (Stage III) and a pheomelanosome (Stage IV) are depicted here. Stage II–III melanosomes exhibit a striated proteinaceous network that imparts a characteristic "fingerprint" appearance that is often obscured by pigment deposits in Stage IV melanosomes.

M

structures 0.3 μm × 0.9 μm that contain eumelanin pigment deposited in, or on, a fibrillar proteinaceous network that may be partially visible or completely obscured by pigment. Human Stage IV ►pheomelanosomes are spherical membrane-bound organelles 0.7 μm in diameter that contain pheomelanin pigment (Fig. 5).

Melanosome development begins with budding of spherical Stage I melanosomes from the endoplasmic reticulum. Stage I melanosomes (premelanosomes) accumulate their major melanosomal scaffolding protein, Pmel17, which is organized to form the characteristic "fingerprint" network pattern via proteolytic processing. Stage II eumelanosomes begin to adopt their typical ellipsoidal shape and acquire tyrosinase via endosome sorting vesicles. Pigment synthesis begins in Stage III melanosomes and Stage IV melanosomes are fully pigmented.

### *Neuromelanosome Structure*

Mature ►neuromelanosomes examined by electron microscopy vary in size from 0.5 μm to 2.5 μm and appear as aggregates of electron dense pigment granules combined with electron lucent lipid bodies and heterogeneous granular material [5]. A lipid bilayer can sometimes be detected. Proteomic analysis of purified human neuromelanosomes identified 72 proteins and over half were characteristic of lysosomes (29), endosomes or sorting vesicles (9), or endoplasmic reticulum (4), supporting the hypothesis that these

same mechanism as in melanocytes (Fig. 3, reactions 5–7 and Fig. 4, reactions 10–12). Neuromelanogenesis in noradrenergic neurons begins similarly with 3-hydroxylation of L-tyrosine via tyrosine hydroxylase to form L-DOPA, followed by decarboxylation catalyzed by aromatic amino acid decarboxylase to produce dopamine. Norepinephrine is formed from dopamine via dopamine β-hydroxylase (EC 1.14.17.1), a Cu-containing oxidoreductase that utilizes ascorbate and molecular oxygen as cosubstrates. In a process analogous to that described for incorporation of dopamine into neuromelanin, norepinephrine is oxidized to noradrenoquinone, which then cyclizes and rearranges to generate noradrenochrome. Tautomerization converts noradrenochrome to 3,4,6-trihydroxyindole, a neuromelanin monomer.

structures are derived from a lysosomal-endosomal lineage [6].

### Process Regulation

Melanin synthesis by melanocytes is stimulated by α-melanocyte stimulating hormone, stem cell factor, endothelins, histamine, eicosanoids, estrogen, and vitamin D [7]. Neuromelanin synthesis is driven by cytoplasmic dopamine or norepinephrine levels that exceed their capacity for removal. In addition to consumption to form neuromelanin, the other principal mechanisms for cytoplasmic clearance of neurotransmitters include: (i) vesicular monoamine transporter (VMAT2)-dependent packaging into secretory vesicles, (ii) conversion to DOPAC by monoamine oxidase, and (iii) methylation via catechol *O*-methyltransferase.

### Function

Excessive cytoplasmic catecholamine levels generate dangerous quinone and semiquinone species [1,2,5,8,9]. Polymerization of reactive intermediates to form neuromelanin provides an effective cellular defense mechanism.

Hydrogen peroxide can be converted to much more reactive and dangerous hydroxyl radicals via the ►Fenton reaction. Melanins bind copious amounts of metal ions via abundant hydroxyl and amine functional groups which block these metal ions from participating in hydroxyl radical formation [1,8]. Chemical analysis of eu- and pheomelanosomes isolated from human hair reveal that metal ions represent 4.0% and 1.6% of the total mass, respectively [10]. Similar metal ion binding properties have been determined for neuromelanin [8]. The toxicity of a variety of chemicals and drugs, such as paraquat, chlorpromazine, haloperidol, amphetamine, and imipramine, can be modulated through sequestration by melanins [1,8].

Melanins are characterized as sinks for reactive oxygen species and diffusible alkoxy (RO·) and peroxy (ROO·) radicals. Electron spin resonance spectroscopy shows that melanins (including neuromelanins) exist as stable free radicals; a typical free radical content is one radical per 2,000 polymer unit [2,9]. The uniquely stable combination of quinone, hydroquinone, and radical groups present in melanin allows it to participate as electron donor or acceptor in one- and two-electron transfer reactions. Thus, melanins contribute to cellular antioxidant defenses by consuming a spectrum of toxic oxidizing agents.

## Melanocyte

### Definition

Melanocyte is a cell located in the bottom layer of the skin's epidermis and in the middle layer of the eye, the uvea. Through a process called melanogenesis, these cells produce melanin, a pigment in the skin, eyes, and hair. There are both basal and activated levels of melanogenesis; lighter-skinned people generally have low basal levels of melanogenesis, and exposure to ultraviolet (UV) radiation generally causes increased melanogenesis (see MSH).

## Synonyms

Opn4; OPN4

## Definition

The opsin-based ►photopigment that confers photosensitivity upon ►intrinsically photosensitive retinal ganglion cells (ipRGCs). In non-mammalian vertebrates, it is also present in other photoreceptive cells such as melanophores and pinealocytes.

## Characteristics

### Discovery

Melanopsin was originally identified in the dermal melanophores of the African clawed frog *Xenopus laevis*. Melanophores darken in response to light and this photosensitivity is maintained in culture. Darkening is dependent upon the presence of retinoids, thereby suggesting that an opsin-based photopigment initiates this response. The search for such a photopigment in these cells eventually led to the discovery of melanopsin which was achieved through low-stringency screening of a melanophore cDNA library using probes based on the nucleotide sequences of the known opsin-based photopigments of *Xenopus*. Overexpression of melanopsin in these cells causes hyperphotosensitivity indicating a prominent role for this photopigment in darkening [1].

Melanopsin's deduced amino acid sequence shows highest homology to members of the opsin superfamily of G protein-coupled receptors. A lysine residue is present in the predicted seventh transmembrane domain, a hallmark of all opsins and a required site for retinoid chromophore attachment. Melanopsin possesses an unusually long intracellular carboxy-terminus tail containing many putative phosphorylation sites. Despite being identified in a vertebrate, melanopsin shares greater sequence homology to the rhabdomeric opsins that are typically found in invertebrate ►photoreceptors rather than the ciliary opsins of vertebrate ►rods and ►cones [2].

In addition to amphibians, melanopsin homologs have been characterized in cephalochordates, fish, reptiles, birds, and mammals. Non-mammalian vertebrates possess at least two melanopsin genes designated "x" and "m." The "x" genes are orthologs of the original gene identified in *Xenopus*, and the "m" genes are orthologs of the original homolog identified in mouse. The "x" melanopsin gene was lost in mammals prior to the eutherian/metatherian split [3].

### Localization

Like all opsin-based photopigments, mature melanopsin resides in the plasma membrane. However, unlike ciliary or rhabdomeric photoreceptors, the cells that contain melanopsin do not possess a photopigment-dense organelle specialized for light capture such as the outer segments of rods and cones or the rhabdomeres of invertebrate photoreceptors. Rather, melanopsin is found throughout the plasma membrane of most of the cell including the membranes of the cell soma, dendrites, and proximal axon [1].

In mammals, melanopsin is only expressed in a small subset of ►retinal ganglion cells that are intrinsically photosensitive (ipRGCs) [4]. At least three morphologically distinct subclasses of ipRGCs exist. The first subclass has dendrites that reside within the OFF sublamina of the inner plexiform layer (IPL) of the ►retina. The second subclass has dendrites that stratify within the ON sublamina of the IPL. The third subclass ramifies dendrites in the ON and OFF sublaminae of the IPL [5]. The primary central projections of these cells are to the ►suprachiasmatic nucleus (SCN), ►intergeniculate leaflet, ►olivary pretectal nucleus, and lateral habenula. Other areas of the forebrain and midbrain receive less prominent projections [6].

In non-mammalian vertebrates, melanopsin is expressed in a range of cell types previously believed to be photoreceptive. For example, in *Xenopus* a high level of melanopsin is expressed in iridial myocytes, suggesting that melanopsin is likely to be responsible for the photosensitivity observed in the isolated amphibian iris. Non-mammalian vertebrates also exhibit melanopsin expression in the pineal gland and areas of the brain believed to harbor encephalic photoreceptors. In lower vertebrates and birds, inner retinal cells, in addition to a small number of retinal ganglion cells, also express melanopsin. The pattern of retinal expression varies across the classes of vertebrates, with birds demonstrating the most expansive pattern of retinal melanopsin expression. Finally, melanopsin has been identified in amphioxus (*Branchiostoma* spp.), the closest living relative to modern-day vertebrates. In these animals, melanopsin is found in the rhabdomeric Joseph and Hesse photoreceptor cells but not the frontal eye that contains ciliary photoreceptors [1].

## Spectral Sensitivity

The pupillary light reflex and ►entrainment of behavioral ►circadian rhythms to the ambient ►light:dark cycle are both examples of light-regulated physiology that does not require the construction of images. Accordingly, they can be considered non-visual responses to light. Previous action spectra studies on such responses in mice lacking functional rods and cones revealed a sensitivity in the blue wavelengths that peaked around 480 nm. At the time of these studies, the photoreceptor cells and their respective photopigments responsible for this blue sensitivity were not known. It is now firmly established that melanopsin-expressing ipRGCs mediate these non-visual photoresponses in blind mice. Consistent with this is the finding that the peak spectral sensitivity of light-induced membrane depolarization in ipRGCs is 484 nm. This value correlates well with photoresponses measured in *Xenopus* oocytes and HEK293 cells heterologously expressing mouse melanopsin. The peak sensitivities observed in these systems were 480 and 479 nm, respectively. Heterologously expressed amphioxus melanopsin absorbs maximally at 485 nm and behaves as a bistable photopigment much like Rh1 opsin of *Drosophila* [1,3,4,6–8].

## Signal Transduction

Metazoan opsin-based photopigments can be classified as rhabdomeric (r-opsins) or ciliary (c-opsins) according to the photoreceptor type in which they reside. Typically, ciliary photoreceptors electrically hyperpolarize their cell membrane in response to illumination while rhabdomeric photoreceptors depolarize the membrane. The characteristic that correlates most closely with the rhabdomeric/ciliary classification scheme of opsins is the second messenger system that these photopigments initiate; r-opsins activate a $G_q\alpha$-mediated transduction cascade while c-opsins activate a $G_t\alpha$-mediated pathway. As mentioned, melanopsin, at the amino acid level, shows greater sequence homology to r-opsins than c-opsins [2]. Additionally, all melanopsin-bearing cells studied to date depolarize in response to light. These features strongly suggest that melanopsin initiates a $G_q\alpha$-based cascade [4].

Studies in cultured amphibian melanophores have shown that inhibitors of phospholipase C (PLC) and protein kinase C (PKC) block photoresponses. Furthermore, chelation of intracellular calcium renders melanophores photically insensitive. Moreover, a small cohort of proteins is phosphorylated in a PKC-dependent manner after melanophores are exposed to light. Taken together, these data also suggest that a $G_q\alpha$-based transduction cascade is initiated by melanopsin [1]. Several studies employing heterologous expression in cells not typically photoreceptive have concluded that melanopsin likely signals through a rhabdomeric $G_q\alpha$-mediated pathway [6]. The details of such a transduction mechanism remain unknown. For example, the terminal effector of this cascade that directly results in membrane depolarization is yet to be elucidated. Because of the similarities between melanopsin-based signaling and the canonical insect ►phototransduction cascade, it has been proposed that the melanopsin-initiated cascade is likely to regulate the gating of an ion channel in the *transient receptor potential* channel superfamily [4]. The kinases potentially involved in regulating or modulating the terminal effector also remain to be determined. Interestingly, PKCζ colocalizes with melanopsin in ipRGCs, and mice null for PKCζ are behavioral phenocopies of mice null for melanopsin [3,7].

## Function

In mammals, non-visual responses to light persist in the absence of rod and cone photoreceptors. Surgical removal of the eyes, however, abolishes these responses. These findings suggested the presence of an ocular non-rod, non-cone class of photoreceptor. The identification of melanopsin and the subsequent discovery of the ipRGCs that express this photopigment provided an explanation for the paradox that mammals lacking visual photoreceptors continue to respond to light. Mice null for melanopsin show some attenuated non-visual responses to light. Interestingly, they retain residual photoresponses that are mediated by rods and/or cones. Consequently, mice null for melanopsin and lacking rods and cones display no responses to light; they behave as animals do when bilaterally enucleated [1,3,7,9].

Among the non-visual photoresponses shown to be at least partially dependent upon melanopsin-based signaling are the photoentrainment of circadian locomotor rhythms, the acute photic regulation of pineal melatonin synthesis, the acute light-induced suppression of nocturnal activity, and the pupillary light reflex. The central targets of ipRGCs also provide insight into other potential forms of non-visual photophysiology that may be influenced by this newly discovered photosensory system. For example, a projection to the ventrolateral preoptic area suggests a role in the photic regulation of sleep. Likewise, a minor projection to the supraoptic nucleus of the hypothalamus implicates ipRGCs in the light-mediated regulation of neuroendrocrine output. The previously described sparse retinal inputs to the lateral hypothalamus now appear to be derived almost exclusively from ipRGCs, suggesting that information from these cells may converge with olfactory inputs to regulate the reproductive axis. Other targets too numerous to detail here indicate a broad role for the melanopsin-expressing ipRGCs in the photic regulation of physiology [10].

Several human responses to light are maximally sensitive to blue wavelengths, consistent with the involvement of melanopsin. Acute photosuppression of serum melatonin, photic control of alertness and vigilance, light regulation of sleep architecture, and light mediated changes in heart rate all show maximal

sensitivity in the blue wavelengths thereby implicating the melanopsin-based photoreceptive system. In addition, some humans, despite being cognitively blind, continue to suppress serum melatonin levels in response to illumination. Taken together, these responses should give pause to clinicians who recommend enucleation of blind patients to minimize ocular complications such as recurrent infections. Although these patients may not be capable of forming images (vision), their eyes may still be serving them to regulate the multiple emerging examples of physiology regulated by light via the melanopsin-based ipRGC photoreceptors.

# Melatonin

Josephine Arendt
Centre for Chronobiology, Faculty of Health and Medical Sciences, University of Surrey, Guildford, Surrey, UK

## Synonyms

N-acetyl-5-methoxytryptamine; mel (abbreviation); MT (abbreviation); Pineal hormone; Darkness hormone

## Definition

An indolic hormone derived from the amino-acid tryptophan, via the tryptophan metabolite serotonin (5-hydroxytryptamine).

## Characteristics

### Synthesis

The primary site of melatonin synthesis is the ►pineal gland (*epiphysis cerebri*), a small, unpaired central structure, essentially an appendage of the brain. In humans the pineal weighs around 100–150 mg. Melatonin is synthesized within pinealocytes – cell types derived from ►photoreceptors – via the pathway shown in Fig. 1. In virtually all species studied to date, whether ►nocturnal or diurnal, melatonin is synthesised and secreted during the dark phase of the day. Melatonin production is clearly a highly evolutionarily conserved phenomenon. In most circumstances the rate-limiting enzyme is serotonin-*N*-acetyltransferase (arylalkylamine N-acetyltransferase [AA-NAT] commonly abbreviated as NAT). Control in mammals is via sympathetic innervation from the superior cervical ganglia terminating in adrenergic receptors within the pineal gland. The rhythm of production is endogenous in that, like other circadian rhythms, it is generated in the ►suprachiasmatic nucleus (SCN), the major central rhythm-generating system in mammals (the pineal itself is a self-sustaining "clock" in some, if not all, lower vertebrates) [1]. Other sites of synthesis exist, notably the ►retina, however pinealectomy abolishes the rhythm of circulating melatonin in mammals. Within the rodent retina a self-sustaining "clock" maintains rhythmic production of melatonin *in vitro* as it does in some lower vertebrates [2]. Whether this pattern is true in humans remains to be seen.

Melatonin synthesis is both entrained and suppressed by light of suitable intensity and spectral composition such that the duration of night time secretion reflects the length of the night [3]. The most effective wavelengths for melatonin suppression and ►phase shifting lie in the 460–480 nm area [4]. Rapid decline in activity with light treatment at night appears to depend on proteasomal proteolysis of NAT following dephosphorylation and removal of a protective 14–3–3 protein [5].

### Metabolism

Melatonin is metabolized primarily within the liver by 6-hydroxylation, followed by sulphate and/or glucuronide conjugation. 6-sulphatoxymelatonin (aMT6s) is the principle metabolite in humans, accounting for 50–80% of melatonin produced. A number of minor metabolites are also formed through ring splitting, cyclization of the side chain, or demethylation. In humans and rodents, exogenous oral or intravenous melatonin has a short metabolic half-life (20–60 min, depending on the author and species), with a large

**Melatonin. hepatic first-pass effect and a biphasic elimination pattern. In ruminants, longer half-lives are seen after oral administration [3].

## A Photoneuroendocrine Transducer

When seasonal functions are primarily timed by day length, species are referred to as being photoperiodic. Moreover photoperiod is often critical for the timing of pubertal development. In photoperiodic mammals and marsupials, an intact innervated pineal gland is essential for the perception of photoperiodic change. The critical signal is the changing duration of melatonin secretion in response to daylength. Long-duration melatonin is equivalent to short days, and short-duration melatonin is equivalent to long days. Interpretation of the signal, as with day length, depends on the physiology (for example, long- or short-day breeder) of the species in question [6]. The mechanism of action of melatonin with regard to seasonal variation in reproductive competence and the timing of puberty in animals is thought to involve an influence of melatonin on steroid feedback mechanisms in the brain, together with a direct influence on the pituitary gland via melatonin receptors. There is recent evidence that melatonin

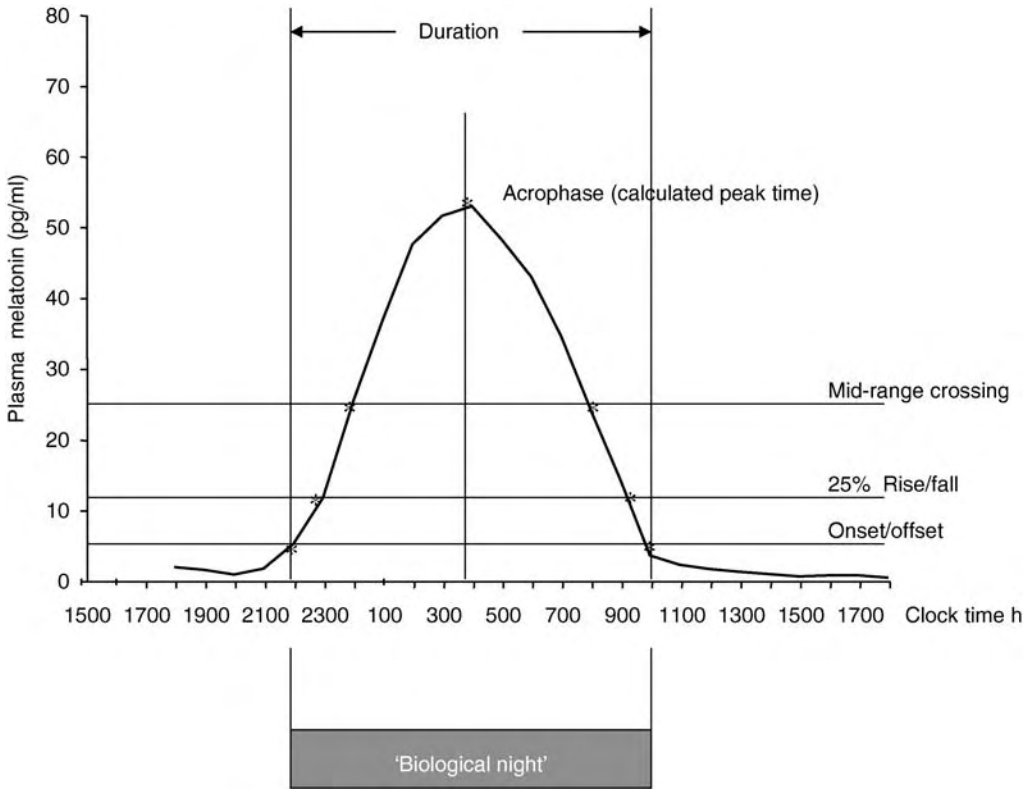
acts directly on peripheral ►clock genes to convey information about photoperiod. Melatonin treatment has been commercialised for the purpose of changing the time of the breeding season (and other seasonal functions) in domestic species such as sheep and goats. In appropriate experimental conditions humans show a duration change in response to daylength changes, like animals [4].

## A Hand of the Clock

The secretion of melatonin from the pineal is probably the most direct peripheral link to the central circadian clock. In healthy individuals, the timing, amplitude, and even the details of the profile can be highly reproducible from day to day and from week to week, rather like a hormonal fingerprint even without strictly controlled sampling conditions. The very large interindividual variations have been ascribed to the size of the pineal gland rather than to variations in enzymic activity. No consistent gender differences have been found and a small number of apparently normal individuals have no detectable melatonin in plasma at all times of day. Diurnal preference (morningness) and short ►free-running circadian ►period are associated with earlier melatonin phase. There are seasonal variations in human melatonin (and aMT6s), with an earlier phase in summer and, according to some reports, increased levels and duration of secretion in winter in high latitudes. Plasma melatonin declines during development and with age [4].

For clinical assessments of possible circadian abnormality, the use of melatonin "onset" – the start of the evening rise – in plasma or saliva has been used as a phase marker of the internal clock, as it avoids overnight sampling [4]. There is some evidence that two ►oscillators usually known as M and E (for ►morning/evening oscillators) are concerned with the generation of the melatonin rhythm. The rise is theoretically associated with E, and the fall with M [4]. Differential effects on the rise and fall, and even on the details of the overnight profile, may well be clinically important (Fig. 2). There is extensive evidence for good correlations in both timing and amplitude between the rhythms of plasma and saliva melatonin and the urinary metabolite aMT6s.

A variety of observations in disease states indicate that the amplitude and sometimes the timing of the rhythm may be modified. It is hard to draw any general



**Melatonin. Figure 2** Diagram of the markers used to characterize melatonin and aMT6s (6-sulphatoxymelatonin) rhythms. Area under the curve or total 24-h excretion (aMT6s) is used to assess total secretion. At present, there is no standard definition of onset-offset (and hence duration). Redrawn from: Arendt, J. & Skene, D. J. Melatonin as a chronobiotic. *Sleep Med Rev*, 2005, 9:25–39.

conclusions, and it is rare for such clinical studies to control for all known masking factors.

The timing and duration of melatonin secretion are its critical features with regard to physiological functions. The relevance of small changes in melatonin amplitude remains obscure, particularly in view of the enormous individual variation between normal healthy subjects.

## Role of Melatonin in the Circadian System

In some lower vertebrates and birds melatonin has a major role in the organisation of circadian rhythms. In mammals this role is hierarchically less important and until quite recently, opinion was that the pineal did not have an important role in the mammalian circadian system. Some strains of (healthy, prolific) laboratory mice have virtually no detectable melatonin. Pinealectomised rats show no obvious circadian abnormalities unless 'challenged'. However, in rats, pinealectomy increases the rate of re-►entrainment to forced phase shifts of the light-dark cycle, and pinealectomy of hamsters in constant light leads to major disruption of the circadian system [3]. In rodents, maternal melatonin can influence the circadian timing of the foetus [7]. In humans it is likely that the phase shifting effects of light do not depend on melatonin suppression, but that the presence of endogenous or exogenous melatonin can in some circumstances modulate the effects of light on the circadian system. Melatonin has received much attention as a 'sleep hormone'. However it is quite possible to sleep out of phase with melatonin (although sleep is somewhat compromised). Essentially the presence of melatonin secretion appropriately timed, at night, reinforces physiological events that occur at night, for example sleep and the decline in core body temperature. Most evidence for a circadian role of melatonin derives from timed administration.

## Effects of Exogenous Melatonin on Sleep and Circadian Rhythms

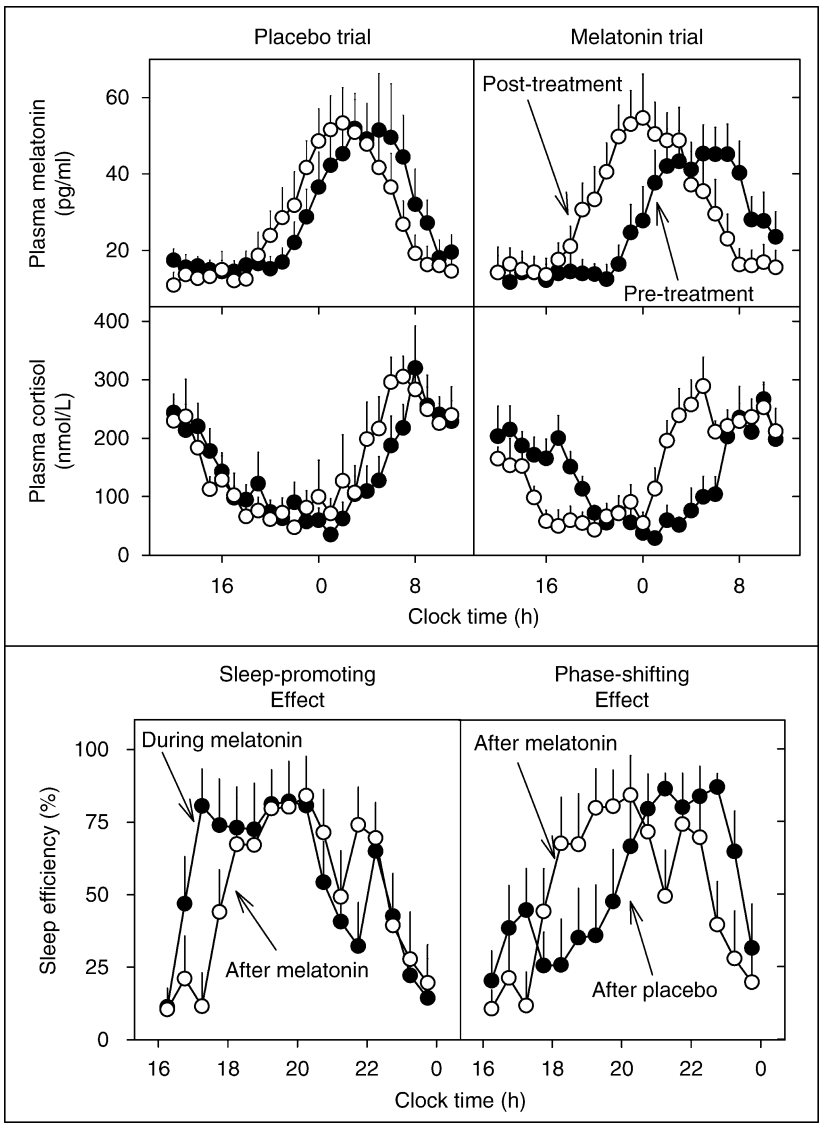
Aaron Lerner discovered melatonin. He was the first person to show, 40 years ago, that melatonin had sleep-inducing effects. Now it is clear that low (0.1–10 mg) doses of melatonin during the "biological day," that is, when endogenous melatonin levels are low, can induce transient sleepiness or sleep, and lower core body temperature, in suitably controlled circumstances (posture is important; the greatest effects are seen with recumbent subjects in very dim light). These effects are opposite to the acute effects of bright light given at night. A substantial body of literature has described effects on sleep and sleep structure comparable to but not identical with benzodiazepines [8]. There is little evidence to suggest that it has important effects in normal sleepers if given at habitual bedtime.

Melatonin can shift the timing of SCN activity in vitro: clear evidence that it affects the central circadian clock [9]. In the dose range 0.05–10 mg melatonin is able to shift circadian timing to both later and earlier times when administration is appropriately timed. ►Phase advances (and possibly ►phase delays) are dose-dependent using a single dose in the range 0.05 to 5 mg. As for light, appropriate timing of treatment to delay or advance the circadian system can in principle be predicted from a ►phase-response curvea (PRC) in subjects whose body clock phase is known [10]. The reported PRCs to melatonin are essentially the reverse of that to light. In controlled experiments melatonin can shift all circadian rhythms observed to date. It is possible to differentiate the acute sleep-inducing and circadian phase shifting effects and in these circumstances it is evident that melatonin changes the timing and distribution of sleep but not total sleep time in healthy subjects (Fig. 3). In subjects whose sleep is suboptimal due to misalignment of circadian rhythms the ability of melatonin to optimise circadian phase relative to sleep and to induce sleep during biological day mean that it has therapeutic properties in circadian rhythm sleep disorder.

The phase shifting properties of melatonin mean that in principle it can entrain free running rhythms. This property was initially demonstrated in rats. However it was only 15–20 years later that full entrainment was shown in humans. There is no doubt that timed melatonin administration (0.5–5 mg at 24-h intervals, usually at desired bedtime) can entrain (or synchronize) the free-running circadian rhythms of most blind subjects, with a consequent improvement in sleep and daytime alertness (even without entrainment, sleep is improved). Interestingly, if entrainment does not occur, shortening of circadian period is seen in the blind. It is possible that one action of melatonin is to shorten period, to the extent that entrainment is possible by other time cues if present [10].

## Treatment of Circadian Rhythm Sleep Disorders

Melatonin has been employed to treat various circadian rhythm disorders, including ►delayed sleep phase syndrome (DSPS), free run (non-24 h sleep wake cycles, common in blind people with no light perception at all), and desynchrony due to ►jet lag and ►shift work. Most success has been obtained in DSPS and in blind free-run [10]. Various factors may influence the ability of melatonin to entrain and or phase shift both blind and sighted humans including dose, formulation, individual pharmacokinetics, free-running period, receptor sensitivity, and behavior. In sighted subjects, unknown circadian phase, unpredictable light exposure, and self-selected sleep times are probably the reason for some inconsistency in the clinical trials of melatonin in shift work and jet lag.



**Melatonin. Figure 3** The direct and circadian effects of melatonin. (a) Melatonin administration (at 16h) phase-advances endogenous melatonin and cortisol rhythms in healthy volunteers (n = 8) exposed to a phase-advanced, extended sleep opportunity (16.00 h, daily for 8 days). Data are mean ± SEM) for placebo trial (*left*) and melatonin (*right*), pre-treatment (*closed circles*) and post-treatment (*open circles*). Melatonin reinforced the phases advances seen with placebo ($P < 0.05$). Redrawn from Rajaratnam, S. W., Dijk, D. J., Middleton, B., Stone, B. M. & Arendt, J. Artificially prolonged melatonin profile phase-shifts human circadian rhythms without altering the duration of endogenous melatonin secretion, daytime sleepiness, mood or the 24h production of reproductive hormones. *J Clin Endocrinol Metab*, 2003, 88:4303–9. (b) Sleep-promoting and phase-shifting effects of melatonin. Sleep efficiency (% per hour, mean ± SEM, polysomnography) from the study in Fig. 3a. The direct, sleep-promoting effect of melatonin (*left panel*) is seen by comparison of the last day of melatonin treatment (*closed circles*) and the first post-treatment day, open circles). Increased sleep efficiency is observed for the first 2 to 3 h during melatonin treatment (*grey shaded*). The phase-shifting effect of melatonin on sleep (*right panel*) is seen when comparing data (melatonin, closed circles, placebo open circles) from the first post-treatment day. A shift in the distribution of sleep can be observed after melatonin treatment. Redrawn with permission from Rajaratnam, SM.W., Middleton, B., Stone, B.M., Arendt, J. & Dijk, D-J. Melatonin advances the circadian timing of EEG sleep and directly facilitates sleep without altering its duration in extended sleep opportunities. *J Physiol*, 2004, 561:339–351.

### Melatonin and Cancer

This subject is included here since there is evidence that pinealectomy, photoperiod per se and forced phase shifts of the light dark cycle can influence growth of tumors. In vivo, it has also been reported that melatonin may increase or decrease tumor growth, depending on ►photoperiod, in hamsters. It has been proposed that light at night during night shift work suppresses melatonin and that this loss of melatonin "activity" is responsible for the possible increased cancer risk. However, to attribute any detrimental effects directly to loss of melatonin is overspeculative. Light at night has numerous other effects. The mere fact of frequent disruption of all circadian rhythms, not just melatonin, is effectively a physiological insult [4].

### Summary

The rhythm of melatonin production provides information on daylength for the organisation of biological rhythms. It appears to be the only solidly established humoral method of signaling time of day and time of year to other physiological systems. The rhythm in plasma or saliva provides the best available measure of the timing of the internal circadian clock. Melatonin is not only a "hand of the clock"; endogenous melatonin acts to reinforce the functioning of the mammalian circadian system. Most is known in humans about its relationship to sleep and the decline in core body temperature and ►alertness at night. Melatonin clearly has the ability to induce sleepiness and lower core body temperature during "biological day" and to change the timing of human rhythms when treatment is appropriately timed. It can entrain free-running rhythms and maintain entrainment in most blind and some sighted people. Used therapeutically it has proved a successful treatment for circadian rhythm disorder, particularly the non-24-h sleep wake disorder of the blind. Numerous other clinical applications are under investigation. In normal subjects endogenous melatonin and light may act in concert to help maintain synchrony with the 24 h day. Threads of evidence indicate an involvement in timing mechanisms throughout life. For therapeutic purposes a combination of timed melatonin and exposure to bright light promises much for the future.

# Melatonin Receptors

Josephine Arendt
Centre for Chronobiology, Faculty of Health and Medical Sciences, University of Surrey, Guildford, Surrey, UK

### Synonyms

MT1, Mel1a, MTNR1A; MT2, Mel1b, MTNR1B

### Definition

A seven transmembrane domain, G protein-coupled receptor (GPCR) which binds melatonin.

### Characteristics

#### Melatonin Binding Sites

Melatonin G protein-coupled membrane receptors are considered to mediate the effects of this hormone on numerous physiological systems and notably its influence on seasonal and circadian rhythms. The development of 2-$^{125}$I-iodomelatonin as a high-specific activity ligand permitted the identification of high-affinity, saturable, specific, and reversible ►melatonin binding to cell membranes in the central nervous system, initially in the central circadian clock, the ►suprachiasmatic nucleus (►SCN), and the *pars tuberalis* (PT) of the pituitary, [1–4] and subsequently in many brain and other areas, including cells of the immune system, a number of cancer cell lines, the gonads, the kidney, and the cardiovascular system. The SCN shows clear binding in human postmortem tissue [3]. Species

variation of melatonin-binding sites in the brain is apparent. The most consistent (but not universal) binding site between mammalian species is the *pars tuberalis*, primarily implicated in transduction of the effects of ►photoperiod, via melatonin, on seasonal variations in prolactin secretion in ruminants [5].

A functional melatonin receptor exists in rabbit and chicken ►retina (inhibition of calcium-dependent dopamine release) and is localized in dopamine-containing amacrine cells in the inner plexiform, in the outer and inner segments in mice, and possibly in the pigmented layer in some mammals [4].

The interaction of melatonin with nuclear receptors (RZR/ROR alpha and RZR beta) and intracellular proteins, such as calmodulin or tubulin-associated proteins has also been reported. The transcription factor RZR/ROR alpha may mediate a direct gene regulatory action of the hormone. It has been hypothesized that while the effects of melatonin on circadian and seasonal rhythms appear to use the membrane receptors, peripheral effects of melatonin (such as immunomodulatory effects) may largely be mediated by RZR/ROR alpha [6].

## Melatonin Receptor Pharmacology

Melatonin-induced pigment aggregation in amphibian melanophores provided an early model for investigation of melatonin receptor pharmacology. It is a pertussis toxin-sensitive system and melatonin inhibits forskolin-activated cAMP formation. Inhibition of cAMP production may be a general feature of melatonin receptors. Intensive investigation of the properties of the *pars tuberalis*-binding site has revealed that physiologic doses of melatonin inhibit forskolin-activated cAMP production *in vitro* in a time- and dose-related manner [2]. Guanosine triphosphate analogues, which interfere with the regeneration of $G_1$-coupled receptors, decrease the affinity and sometimes the capacity of $^{125}$I-melatonin binding in reptiles, birds, and mammals.

Melatonin receptors have been cloned, and three subtypes were initially named Mel-1a, Mel-1b, and Mel-1c [3]. The Mel 1a receptor gene has been mapped to human chromosome 4q35.1. Its primary expression is in the *pars tuberalis* of the pituitary and the SCN. Mel 1b has been mapped to chromosome 11q21–22 and its main expression is in the retina and the brain. Mel 1c is not found in mammals. Two cloned mammalian receptors (Mel 1a, Mel 1b) have now been renamed MT1 and MT2 [4]. They are a new family of G protein coupled receptors (GPCRs), have high affinity (Kd 20–175 picomolar) and inhibit forskolin-stimulated cyclic AMP formation. The so-called MT3 receptor is an enzyme, quinone reductase, concerned with detoxification mechanisms. This may be at least a partial explanation for some of the free-radical scavenging/antioxidant properties of high dose melatonin (not to be considered here).

The two cloned receptors, MT1 and MT2, are of particular importance with regard to rhythm physiology and pharmacology. Using gene knockout technology in mice and pharmacological manipulations, initially the MT1 receptor, most studied in the SCN and the *pars tuberalis* of the pituitary, and the MT2 receptor (also found in the SCN) were thought to have different functions, with ►phase shifting rhythms attributed to MT2 and suppression of SCN activity (countering the "wake" signal of the SCN) attributed to MT1. However more recently it appears that there is redundancy between these two receptors [7]. They can also form heterodimers which differ in properties from the monomeric forms [8].

MT1 has important actions within the *pars tuberalis* controlling seasonal prolactin variations in ruminants [5]. The hypothalamic receptor(s) concerned with seasonal and circadian variations in gonadotrophins has not been unequivocally identified, however melatonin regulation of reproductive functions in sheep is mediated by action in the premammillary hypothalamus [9].

Genetic polymorphism has been identified within melatonin membrane receptors, and further investigation of these polymorphisms in relation to photoperioidism, human disease, sensitivity to melatonin, and so on, is ongoing.

Probably the most interesting development in the effects of melatonin concerns its influence on peripheral gene expression in the *pars tuberalis* [5]. In rodent *pars tuberalis* cells, rhythmic expression of the ►clock gene *per1* appears to be dependent on sensitization of adenosine A2b receptors, which in turn depend on melatonin activation of MT1 receptors [10]. Clearly it is possible that the melatonin signal is a widespread humoral mechanism related to biological timing, acting through modification of peripheral clock gene expression. The effects of melatonin on peripheral, as well as central, clock gene expression are likely to be a rich field of enquiry.

## Melatonin Analogues

In view of the properties of melatonin (see section "Melatonin") there has been much effort directed to the synthesis and evaluation of indolic and non-indolic analogues specific for either or both of the MT1 and MT2 receptors. Both agonists and antagonists with varying specificity have been described. Human trials of sleep promoting, circadian phase-shifting and anti-depressant effects are ongoing. Most information is available for three agonists (agomelatine/valdoxan/S20098, *N*-[2-(7-methoxynaphthalen-1yl)ethyl]acetamide, ramelteon TAK-375 rozerem (*S*)-*N*-[2-(1,6,7,8-tetrahydro-2*H*-indeno-[5,4-*b*]furan-8-yl)ethyl]propionamide and VEC-162 (1R-*trans*)-*N*-[[2-(2,3-dihydro-4-benzofuranyl) cyclopropyl] methyl] propanamide). All appear to be selective for the MT1 and MT2 receptors with little

M

affinity for other receptors. Agomelatine in addition has 5-HT2c antagonist activity and in view of this the emphasis of clinical work has shifted to its anxiolytic and anti-depressant activity. It effectively targets both depressive disorders, in particular major depressive disease, and circadian rhythm sleep disorders. Ramelteon has received marketing authorization for insomnia. VEC-162 shows promise with respect to its ability to phase shift the circadian system and to regulate sleep [11].

Development of melatonin agonists and antagonists, with varying affinities to MT1 and MT2, and possibly to other, yet to be reported, melatonin receptors, may elucidate the mechanisms of melatonin action, and further enhance the therapeutic potential of "melatoninergic" drugs.

## Introduction

At a cellular level, information transmission and processing must occur within the cell, between its different parts, and with the extracellular environment at the cell surface. Internal membranes that delineate compartments, and the surface cell membrane (►plasmalemma or ►sarcolemma) play prominent roles in organizing cellular life. They serve to preserve the semi-autonomy of the cell, with two competing aspects: cell ►homeostasis (maintenance and preservation of a fairly constant internal milieu) by incapsulation on the one hand, and exchange with the environment through a continual flux of matter, energy and information on the other. Membranes provide and organize means to subserve both aspects. In particular, information transmission must be securely put on a molecular basis. The cell membrane should thus provide the following:

- Mobility of cell wall constituents
- Selective permeability for compounds, implying a reconnaissance function
- Asymmetry between internal and external sides
- Electrical insulator function because the cell membrane must also separate ions and, hence, electric charges (see below)

The information exchange process has two aspects: acquisition and delivery of information. Acquisition involves reception of signals related to many different facets of the environment. Delivery implies executive acts, be they motor, excretory or the like. In single-celled organisms (protozoa) such as *Paramecia*, the same cell carries out both processes and for the most part they take place at cell surface membranes. In highly developed metazoa, cells have specialized functions, certain groups being "receivers" and others "executors" of information, but most in fact are both. Executors include muscle, glandular and other cells because motor

acts and glandular functions transmit information to the environment or other cells.

In the following sections, we will be primarily concerned with information transmission in metazoa. To receive information, metazoa have developed specialized "►receptor cells" (or often, for brevity, ►receptors). As is intuitively clear, metazoa need to collect information about many different aspects of their internal and external environments (►Sensory systems).

Information is an abstract entity that needs to be encoded in a signal to be transmitted and processed. Signals in turn are generated by some material substrate or carrier that may engage one or the other mechanism to produce a signal. This chapter will deal with the following questions:

- What are the signals used by the nervous system to encode information?
- What are the structures carrying them?
- How are the signals generated, by what mechanisms?
- How are the signals transmitted over some distance?
- How is information encoded and decoded again?
- How can information be quantified?

The first problem to be solved by evolving cellular organisms is to find a suitable signal and a carrier. The signal should be:

- Easily implemented with biological structures at hand: molecules and their aggregates
- Reproduced into what can be called a resting state
- Able to propagate over long distances
- Fast (within the scope of biological "time")
- Energy-efficient
- Versatile
- Modifiable

In processing information, protozoa and multi-celled organisms have the same interest. It is therefore intuitively appealing to think that the basic structures and mechanisms involved in information transfer have evolved early on and been preserved fairly well throughout evolution. The signal and its supporting physical structure should then be common to most animals. Communication of a unicellular organism and of an individual cell within a metazoon must occur at their cell surfaces, hence signals must be generated, propagated and processed at cell membranes.

*Historical Notes.* The study of cell physiology was launched in the seventeenth century with the use of microscopes by M. Malpighi (1627–1694) and A. von Leeuwenhoek (1632–1723). Neurophysiology took off in the eighteenth century after electricity had become amenable to experimentation (Leyden flask). Seminal experiments were performed by A. Galvani (1737–1798) who noted that frog muscles contracted whenever a contact was made with a Leyden flask. He demonstrated that no external source was needed if different metals were used in the frog experiments: contractions also occurred when the brass wire in contact with the spinal cord touched the iron support on which the frog was lying. He concluded that electricity was an intrinsic property of the muscle. Galvani's interpretations were criticized by A. Volta (1745–1827) because he was able to produce electrical batteries from different metals and salt solutions. Volta was correct in saying that Galvani had used external electrical stimulation. Nonetheless, Galvani's idea of the existence of intrinsic electricity turned out to be right in the end. Further important contributions came from, among others, J. Müller (1801–1858), T. Schwann (1810–1882), C. Matteucci (1811–1868), E. du Bois-Reymond (1818–1896), H. von Helmholtz (1821–1894), A. Fick (1829–1901), L. A. Ranvier (1835–1922), W. Kühne (1835–1900), L. Hermann (1838–1914), J. Bernstein (1839–1917), J. von Kries (1853–1928) [1]. In the twentieth century, the field exploded, and a number of achievements were rewarded with the Noble Prize (NP) for Medicine or Physiology, among the prize winners being: E. D. Adrian (1889–1977; NP 1932), J. Erlanger (1874–1965; NP 1944), H. S. Gasser (1888–1963; NP 1944), J. C. Eccles (1903–1997; NP 1963), A. H. Hodgkin (1914–1998; NP 1963), A. F. Huxley (*1917; NP 1963); B. Katz (1911–2003; NP 1970), E. Neher (*1944; NP 1991), B. Sakmann (*1942; NP 1991).

## Nerve Cell Membrane

### Membrane Structure

The nerve cell membrane (►Cell membrane – components and functions) is a microscopically thin membrane that separates the cell cytoplasm and intracellular organelles from the extracellular milieu. Its chemical composition and structural features allow free passage of most lipids, and selective passage of ions, sugars and amino acids. The membrane, in addition, contains the molecular machinery for cell-to-cell chemical and electrical communication (below) and immune responsiveness (►Neuroimmunology).

### Anatomy and Chemical Makeup of the Nerve Cell Membrane

The unit membrane of the nerve cell is, on average, about 50 nm thick and comprised of various types of phospholipids, proteins and carbohydrates. Proteins, being the largest molecules, make up the greatest membrane mass but the smaller phospholipids are the largest in number and carbohydrate molecules are the fewest. The molecules making up the membrane proper, or attached to it, are mobile, interactive and in many cases functionally interdependent. They are replaced by intracellular biosynthesis, and turned over by a process called membrane trafficking.

### Membrane Phospholipids

Membrane lipids are arranged in a bilayer with the glycerol phosphates facing the extracellular and intracellular fluids, and the fatty acid chains arranged in rows side by side in the membrane. Phospholipid molecules have a high degree of lateral mobility in the bilayer, which facilitates movement of small non-polar molecules across the cell membrane. Fluidity of cell membrane phospholipids also facilitates ►transport processes and enzyme activities. Less frequently, phospholipid molecules will "flip-flop," i.e., migrate from a monolayer on one side to that on the other.

Functions of membrane phospholipids include:

- Insulation and barrier properties
- Intracellular signaling
- Electrical properties

The extremely thin, expansive lipid bilayer of the nerve cell membrane has a ►membrane capacitance on the order of 1 μF/cm$^2$ that produces a charge of about $8 \times 10^{-9}$ coulombs/cm$^2$ at a resting membrane potential (below; ►Membrane potential – basics) of –80 mV, or approximately $5 \times 10^{11}$ monovalent ions/cm$^2$.

*Cholesterol.* The nerve cell membrane contains large amounts of ►cholesterol, which enhances the permeability-barrier property of the lipid bilayer. This renders the lipid bilayer less permeable to small water-soluble molecules.

*Glycolipids.* These lipids contain carbohydrate groups and are found only on the extracellular side of the cell membrane. ►Glycolipids are believed to be involved in cell-cell interactions. Five to ten percent of the total lipid mass consists of a particular type of glycolipid called a ►ganglioside. Gangliosides are thought to alter the electrical field across the cell membrane, as well as the concentration of $Ca^{2+}$ ions along the external surface of the cell membrane. They may also be involved in cell–cell recognition at the extracellular matrix that promotes cell aggregation.

### Membrane Proteins

The membrane contains a large group of membrane proteins, not all of which have been identified. ►Integral proteins completely traverse the cell membrane, whereas ►peripheral proteins are anchored to either the cytoplasmic or extracellular side. Membrane proteins exhibit function-dependent polarity. Cell membrane proteins are also stored in membranous cisterns in dendrites and axons, where they play important roles in ►synaptic plasticity and ►axon growth.

The locations of different types of proteins in the cell membrane serve as general predictors of how they function in the nerve cell.

Integral membrane proteins serve as:

- ►Ion pumps (below), moving ions against a concentration gradient, using energy derived from adenosine triphosphate (ATP)
- ►Ion channels (below), allowing flow of ions and water across the cell membrane down an electrochemical gradient
- ►Transporters of sugars and amino acids
- Cell–cell recognition sites

Peripheral proteins function as:

- Receptors for ►neurotransmitters, ►neuromodulators, ►hormones and other chemical messengers that trigger membrane ion permeability changes
- Enzymes that catalyze intracellular signal cascades
- Immunoreactive elements (Neuroimmunology)
- Membrane structural support proteins
- Mediators of neurite outgrowth and axon bundling
- Intermediaries in membrane trafficking

## Membrane Potential

Membrane potential denotes the electrical potential difference (►voltage, V) across the cell membrane of all living cells, which is produced by an unequal net distribution of positive and negative charges on either side of the cell membrane. The potential in the intracellular milieu is normally negative with respect to the extracellular milieu, reference set to zero (Membrane potential – basics).

Resting membrane potentials can be measured in all living cells. They vary in magnitude, but are negative inside vs. outside. It is assumed, on well-established physico-chemical grounds, that they originate from concentration differences across the cell membrane of ions that carry electric charges. Generally, the concentrations of $Na^+$ and $Cl^-$ are high extracellularly and low intracellularly, thus establishing a strong inward concentration gradient across the cell membrane. The situation is opposite for $K^+$. Another ion that is unequally distributed is $Ca^{2+}$, with a high extracellular and a normally very low intracellular concentration.

### Membrane Potential and Ion Concentration Gradients

In 1902, Julius Bernstein [2] hypothetized that the resting membrane potential, V, is a diffusion potential determined exclusively by $K^+$. According to the ►Nernst equation, V should then be the $K^+$ equilibrium potential, $E_K$:

$$V = E_K = \frac{R.T}{F} \times \ln \frac{[K^+]_0}{[K^+]_i}$$

where $[K^+]_o$ is the external and $[K^+]_i$ the internal $K^+$ concentration.

However, later measurements showed that Bernstein's hypothesis could not fully account for the real

situation because, in addition to $K^+$, other ions can permeate the membrane even under resting conditions, giving rise to deviations of the membrane potential from $E_K$. A most important ion is $Na^+$, whose equilibrium potential is opposite in sign to that of $K^+$. In most cells, the resting membrane potential is much closer to $E_K$ than to $E_{Na}$, however, because under resting conditions the membrane permeability for $K^+$ is much larger than that for $Na^+$. Also, $Ca^{2+}$ with its positive charge and inwardly directed concentration gradient has, like $Na^+$, a positive equilibrium potential. Chloride with its negative charge and inwardly directed concentration gradient has a negative equilibrium potential (Membrane potential – basics).

## Ion Pumps

As outlined above, even under steady-state or resting conditions, membrane channels, including some $K^+$ and $Na^+$ channels, stay open and generate a "►leak conductance" [3]. In effect, what results is a leaky RC circuit, with a specific membrane resistance of about 1,000 $\Omega cm^2$ [4]. The RC circuit properties have functional consequences. In the resting state, the net movement of $K^+$ ions down its concentration gradient through leak channels will leave behind impermeant cytoplasmic organic anions that accumulate on the inner side of the cell membrane and an accumulation of cations on the extracellular side [5], which accounts for the potential difference (V) of about −80 mV across the cell membrane (Membrane potential – basics).

Because the membrane is permeable to several ions that flow passively down electrochemical gradients, unrestricted ion flow would eventually abolish concentration differences between the inside and outside of the cell and, in consequence, the equilibrium and membrane potentials. In order to prevent this, the cell invests much energy in so-called ion pumps that transport the leaking ions back to where they come from, against their respective gradients (►Ion transport). Such pumps need

- Metabolic energy, ultimately supplied by adenosine triphosphate (ATP)
- Regulation mechanisms, including the sensitivity for particular ions and their concentrations (e.g., inside for $Na^+$)

The action of the $Na^+$ pump that expels $Na^+$ from a cell was first demonstrated by Hodgkin and Keynes [6], who showed that the metabolic poison dinitrophenol (DNP), which deprives energy sources for the $Na^+/K^+$ pump, depresses cellular extrusion of $Na^+$. Since then, other laboratories have demonstrated the active role of ion pumps that maintain steady state membrane potential by regulating intracellular $Na^+$, $Cl^-$, $K^+$ and $Ca^{2+}$ concentration.

## Spread of Local Potentials

Local potential changes (►receptor potential, ►synaptic potential) originating anywhere on the cell surface must ultimately be conveyed to other regions of the cell or, more generally, the nervous system, where a response to the stimulus begins to be formulated. However, passive electrical properties, resistive and capacitive, reduce the size and alter the shape of the receptor potential as it moves transversely through the cell's soma and fibrous, cable-like processes (►Cable theory). Passive cable properties that affect the receptor potential are also present in dendrites and axons of nerve cells, and thin elongated muscle fibers such as frog sartorius muscle [5]. In the latter preparation, a rectangular current pulse depolarizes membrane potential with a near-exponential time course, declines in amplitude with distance along the fiber and changes shape due to temporal filtering. The pulse-evoked response is an approximate simulation of the receptor potential, and attributable to the cable properties of an ►equivalent electrical circuit that consists of a membrane ►capacitor ($C_m$) and a resistor ($R_m$) arranged in parallel. In the RC circuit of a biological membrane, $C_m$ is a leaky capacitor that allows ionic charge to accumulate and dissipate through $R_m$. The time-related change of voltage during discharging of an RC circuit is described by the relationship:

$$V(t) = V_0[\exp(-t/\tau)] \quad (1)$$

Where $V_0$ is the membrane potential at the cessation of applied current, V(t) is the membrane potential at a corresponding time after termination of the applied current, and $\tau$ is the time constant, where $\tau = R_m C_m$. In neurons, time constants $\tau$ are of the order of 0.5–5 ms [7].

Current flowing from the receptor region through the longitudinal resistances of the cytoplasm and extracellular fluid form current circuit loops. Current gets progressively smaller with distance. A constant fraction per unit length is diverted through ion leak channels, and falls off exponentially with distance from the region where the stimulus has originated:

$$\Delta V(d) = \Delta V_0.\exp(-d/\lambda), \quad (2)$$

where the length (space) constant $\lambda$ is $\sqrt{(R_m/R_i)}$, defining the distance at which the original voltage change drops to a fraction of $1/e \approx 0.37$.

The principles illustrated in these simple reduced preparations provide only a relatively primitive explanation for some of the basic properties of sensory transduction. Nonetheless, two important conclusions are evident:

- The passive or ►electrotonic spread of local membrane potential changes (receptor and synaptic potentials) across a cell membrane is no means for transmitting information over long distances.

M

- A process of ►encoding, is necessary to transform the receptor potential from a wave form to a discharge of ►*action potentials* that reach sites of sensory integration, and that reflects the magnitude and duration of the waveform and thus the applied stimulus.

## Action Potential

The action potential is the active electrical response of an excitable cell membrane to a stimulus, reflected in a fairly stereotyped change in membrane potential from a resting value (negative inside) to a depolarized (positive inside) value and back (Action potential). The durations of action potentials range from a few milliseconds in neurons to hundreds of milliseconds in cardiac and smooth muscle cells. The underlying mechanisms include time- and voltage-dependent changes in ion conductances.

### Ion Currents Underlying the Squid-Axon Action Potential

Early, simple experiments by a number of investigators led Bernstein [2] to propose that the action potential represented a sudden transition from a selective $K^+$ permeability at rest to a generalized, i.e. non-selective increase of membrane ion permeability. On this basis, one would predict a value of 0 mV at the peak of an action potential. However, Bernard Katz's measurements with conventional ►intracellular recording in the 1940's (reviewed in [4,8]) showed that membrane potential at the peak of a shock-evoked action potential was on the order of +50 mV. From Nernstian considerations, this implicates a cation species such as $Na^+$, which Katz proved by showing that the amplitude of the action potential changed by about 58 mV for a 10-fold change of extracellular $Na^+$ concentration. But the peak depolarization was rapidly followed by repolarization and ►hyperpolarization that momentarily exceeded the resting value, indicating that a secondary, selective ion permeability change had occurred. It was previously shown that in frog muscle fibers, resting membrane potential changed in approximate conformation with the Nernst equation when external $K^+$ concentration was varied. Moreover, Keynes [9] was able to measure shock-evoked efflux of radioactive $K^+$ from Sepia giant axons.

The superposition of various time-varying currents was difficult to disentangle using the more conventional methods of the time. The invention of the ►voltage-clamp technique (Action potential; Intracellular recording), a by-product of advances in electronics pioneered by K. S. Cole in 1949 [10] and used by A. F. Hodgkin and A. L. Huxley in the 1950's [11], made it possible to separate and analyze voltage-and time-dependent properties of the action potential (Action potential). The giant axon of the squid turned out to be a favorable structure because its size (diameter 0.5–1 mm) and robustness allowed it to be removed from the animal, placed in a bath and subjected to varying extracellular compositions. Its size allowed insertion of relatively bulky longitudinal electrodes, and because of membrane durability it was possible to squeeze out the intracellular content and replace it with solutions of varying composition (Intracellular recording).

The squid-axon experiments showed that the action potential is brought about by voltage-dependent opening of $Na^+$, $Ca^{2+}$ and $K^+$ channels. The action potential is initially depolarizing due to opening of $Na^+$ (►Sodium channels) and/or $Ca^{2+}$ channels (►Calcium channels – an overview), and subsequently repolarizing due to delayed opening of $K^+$ channels (►Neuronal potassium channels).

*$Na^+$ Inactivation.* The fall of the action potential from its peak is promoted not only by $K^+$-channel opening, but also by inactivation of the $Na^+$ conductance, which has a slower time course than activation. The $Na^+$ system recovers from inactivation with an approximately exponential time course and a time constant on the order of 5 ms, with the time constant depending on the holding potential imposed experimentally [2]. The period of reduced $Na^+$ channel reactivity characterizes the ►refractory period. The impact of membrane depolarization on both activation and inactivation of $Na^+$ conductance has profound functional consequences. The sequence of $Na^+$ activation and inactivation (i) limits action potential rate (below); (ii) controls the direction of ►action potential propagation (Action potential propagation); (iii) leads to accommodation; (iv) has clinical implications (Action potential).

*Single-Channel Currents.* In 1976, Neher and Sakmann [12] introduced the breakthrough ►patch-clamp technique, through which it became possible to voltage-clamp small patches of cell membrane and record ►single-channel currents (Intracellular recording).

### Action Potentials in Central Neurons

The squid axon is a simple system devoted to conducting action potentials along the axon (Action potential propagation). Individual central neurons, however, typically express several subtypes of voltage-dependent ►$Na^+$ channels, voltage-dependent $Ca^{2+}$ channels (Calcium channels – an overview), voltage-dependent $K^+$ channels (Neuronal ►potassium channels), $Ca^{2+}$-activated $K^+$ channels (Neuronal potassium channels), ►hyperpolarization-activated, ►non-selective cation channels (►HCN channels), and more. The different combinations of channels enable diverse action potential amplitudes, shapes and firing patterns [13].

*Sodium ($Na^+$) Currents.* In central neurons, the rising phase of the action potential is generated by very fast activation and inactivation of ►voltage-dependent $Na^+$ channels [13] (Action potential propagation).

*Calcium ($Ca^{2+}$) Currents.* Inward $Ca^{2+}$ currents (Calcium channels – an overview) contribute little to

the action potential upstroke, but initiate intracellular signaling pathways, influence action-potential shape and firing patterns, and – at presynaptic terminals the amount of neurotransmitter released [13] (Action potential propagation).

*Potassium ($K^+$) Currents.* Central neurons express a wide range of ►Voltage-gated (or –dependent) $K^+$ channels (Kv; Neuronal potassium channels), only a fraction of which activate appreciably during the action potential. Significant contributions to action potential repolarization are commonly made by Kv3 family and Kv4 family channels mediating the ►A-type $K^+$ current ($I_A$). Large-conductance $Ca^{2+}$-activated $K^+$ channels (►BK channels) promote membrane repolarization. Small-conductance $Ca^{2+}$-activated $K^+$ channels (SK channels) contribute to the following ►afterhyperpolarization [13] (Action potential propagation; Neuronal potassium channels). Furthermore, ►$Na^{\pm}$-activated $K^{\pm}$ channels (K(Na) channels) may modulate action-potential shape, and contribute to slow afterhyperpolarization after repetitive firing [14] (Action potential).

*Afterdepolarization.* In many neurons, the fast phase of action potential repolarization is followed by a delayed depolarization, whose origins may be passive and/or active, i.e., mediated by an electrotonic mechanism or amplified and supported by active $Na^+$, $Ca^{2+}$ and ►non-selective cation currents (Action potential propagation).

*Afterhyperpolarization (AHP).* Afterhyperpolarizations in mammalian central neurons may be complex, often showing different phases and being due to different $K^+$ currents. BK-channel-mediated afterhyperpolarizations are usually brief, while SK-channel-mediated ones can last up to seconds [13] (Action potential propagation). ►$Na^+$-activated $K^+$ channels (K(Na) channels) may contribute to slow afterhyperpolarization after repetitive firing [14] (Action potential).

*Repetitive Firing.* Many central neurons discharge over a wide range of rates and with various patterns, to which many factors may contribute, including various $Na^+$, $K^+$, $Ca^{2+}$ and HCN channel currents. Many central neurons fire spontaneously and fairly regularly, and are called "►pacemakers" [13] (Action potential propagation).

Fast-Spiking Neurons. Neurons capable of firing at high rates for prolonged periods often possess voltage-gated $K^+$ channels or special "resurgent" $Na^+$ current, which activates transiently upon repolarization after inactivation due to strong depolarization and is sensitive to ►tetrodotoxin (TTX) [13] (Action potential propagation).

## Action Potential Propagation

### Propagation along Muscle and Nerve Fibers

The action potential propagates over long distances. Propagation along a nerve or muscle fiber occurs automatically as a consequence of the axonal cable structure (Cable theory; Action potential propagation).

In a muscle or nerve fiber, the ring of membrane that is just being depolarized during the action potential's rise experiences a strong influx of positive charges ($Na^+$) that distribute internally in both forward and backward directions. The local currents reaching out in the action potential's propagation direction unload the capacitor of the advanced membrane regions and depolarize them. This depolarization increases the $Na^+$ conductance and elicits the inward $Na^+$ current in the adjacent membrane segment until threshold is reached for action potential generation at this site. Since charging or discharging of a capacitor takes some time, expressed in the time constant, the substantial depolarization-induced ionic ($Na^+$) currents are delayed.

In a muscle fiber or an unmyelinated axon, action potentials propagate in feed-forward fashion, regenerating progressively with passage in small increments of membrane. In myelinated nerve fibers, the conduction mechanism is different. The ►myelin sheath is a good insulator. When a ►node of Ranvier between internodes (stretches of myelin sheath) is depolarized during an action potential, local circuit currents depolarize the next one ahead, without discharging the internodal region. The excitation thus leaps from node to node, a process called ►saltatory conduction. This type of conduction confers several advantages: (i) economy of space; (ii) economy of energy expenditure; (iii) high safety factor for conduction (Action potential propagation).

Myelination has notable disadvantages, namely limits to ►regeneration after injury and involvement in various neurological diseases. Functional recovery following injury differs dramatically in the peripheral and the central nervous system (Regeneration).

Demyelination disorders are numerous and are exemplified by the ►Guillain-Barré syndrome and ►Multiple sclerosis.

### Back-propagation of Action Potentials

In many neurons, action potentials originate close to the axon's juncture with the cell soma (the initial segment), from where they travel down the efferent axon, but may also "back-propagate" into the dendritic tree (Action potential propagation). These back-propagating action potentials are supported by active, tetrodotoxin-sensitive, voltage-dependent Na+ channels and possibly ►$Ca^{2\pm}$ channels. The extent of this decremental back-progagation varies widely between different types of central neurons, different specimens of the same sort, and possibly different dendritic branches of individual cells. Back-propagation depends on cell morphology and densities of dendritic ion channels, as well as adaptive influences provided by excitatory and inhibitory inputs and neuromodulators. Back-propagating action potentials have been implicated in

short-term and long-term changes in ►synaptic efficacy involving increases in $Ca^{2+}$ influx [15] (Action potential propagation).

## More Ion Channels and their Functions

A wide range of channels affect additional cellular functions in addition to control of excitability.

### Cyclic Nucleotide-regulated Cation Channels

►Cyclic nucleotide-regulated cation channels are activated by intracellular binding of cyclic AMP (cAMP) or cyclic GMP (cGMP) to a cyclic nucleotide-binding domain (CNBD) in the channel protein, thereby translating intracellular changes in signaling molecules to changes in membrane potential. Two families of channels, both exhibiting a high sequence similarity to voltage-gated $K^+$ (Kv) channels (Neuronal potassium channels) and regulated by cyclic nucleotides, have been identified, the *cyclic nucleotide-gated (CNG) channels* and the *hyperpolarization-activated ►cyclic nucleotide-gated channels (HCN) channels*. CNG channels require the obligatory binding of a cyclic nucleotide in order to be activated. In contrast, HCN channels are activated by membrane hyperpolarization and modulated by cyclic nucleotides [16]. Cyclic nucleotides enhance HCN channel activity by affecting the voltage-dependence of channel activation.

### Hyperpolarization-activated Cyclic Nucleotide-regulated Channels

The HCN1–4 channel gene family encodes HCN channels. They are slowly activated by membrane hyperpolarization and by intracellular cAMP or cGMP, and give rise to depolarizing inward ionic currents termed *Ih*, *If* ("f" for "funny") or *Iq*. They were first discovered in cardiac pacemaker cells, but are widely distributed in various excitable cells including CNS neurons, retinal ►photoreceptors and ►taste buds. HCN channels are structurally similar to voltage-gated $K^+$ (Kv) channels (Neuronal potassium channels), but much (> or = 25 times) less selective than Kv channels [17]. They are involved in a range of functions, including the setting of resting membrane potential (Membrane potential – basics), ►input conductance and ►length constants, dendritic integration, cardiac and neuronal pacemaker activity, and the regulation of presynaptic release of neurotransmitter [18]. Deficits in the HCN1 gene impair motor learning but enhance spatial learning and memory. Deletion of HCN2 plays a role in ►absence epilepsy, ►ataxia and sinus node dysfunction [19].

### Non-selective Cation Channels

Non-selective cation channels are macromolecular pores in the cell membrane that form an aqueous pathway. In distinction to selective ion channels, non-selective cation channels enable cations such as $Na^+$, $K^+$ or $Ca^{2+}$ to flow rapidly, as determined by their electrochemical driving force, at roughly equal rates ($>10^7$ cations per channel pore and per second). One of them is the ►nicotinic acetylcholine receptor (►nAChR); others include the ►ionotropic glutamate receptors, ►capsaicin receptors, cyclic nucleotide-gated (CNG) cation channels, and ►TRP channels.

### Transient Receptor Potential (TRP) Channels

Non-selective cation channels of the *transient receptor potential* (TRP) superfamily (TRP channels) display a great variety of activation mechanisms and sensitivities and are thus involved in multifarious functions. TRP proteins are assigned to distinct subfamilies based on sequence similarities to *Drosophila* TRP or structural and functional features. The ion-permeating pores mostly allow the permeation of monovalent and divalent cations through all channels and of $Ca^{2+}$ ions through all but two channels [20]. TRP channels make significant contributions to ►olfaction, taste, ►hearing, ►vision, ►thermosensation, ►touch, ►osmosensation, and ►nociception [21]. As to thermosensation, at least six different TRP channels cover the spectrum of relevant temperatures for our body. As mechanosensors, TRP channels are involved in functions ranging from *Drosophila* hearing to nematode touch to mouse mechanical pain [22]). Other TRP channels are essential for the $Ca^{2+}$ and $Mg^{2+}$ homeostasis in our body.

### Anion Channels

Chloride channels (►Chloride channels and transporters) are membrane proteins that allow for the passive flow of anions across biological membranes. As $Cl^-$ is the most abundant anion under physiological conditions, these channels are often called "$Cl^-$ channels" instead of "anion channels", although other anions (such as iodide or nitrate) may permeate more easily. In mammals, the CLC gene family encodes nine different $Cl^-$ channels in the plasma membrane or intracelluar organelles such as vesicles. These diverse channels are involved in the control of membrane potential in muscle and nerve cells, in the regulation of cell volume, in the acidification and ionic homeostasis of endosomes and synaptic vesicles, in the transepithelial transport of salt and water, and in the degradation of bone by osteoclasts. Mutations of human CLC channels cause diseases such as myotonia, neurodegeneration and possibly epilepsy, cystic fibrosis, Bartter syndrome (renal salt loss) with or without deafness, Dent's disease (kidney stones and proteinuria), osteopetrosis. The CLC from Escherichia coli functions as a $Cl^-/H+$ exchanger [23]. Some $Cl^-$ channels are activated by intracellular $Ca^{2+}$ ($Ca^{2+}$-activated $Cl^-$-channels) [24].

## Ion Channel Development

The distribution patterns and properties of ligand- and voltage-gated ion channels in developing nerve and muscle cells differ profoundly from those of mature cells (►Ion channel development). At early developmental stages, these specific patterns determine the timing and waveform of spontaneous electrical activity, which is required for the normal maturation of excitability and synaptic connections and for $Ca^{2+}$ influx triggering activity-dependent developmental programs [25].

## Channelopathies

Rapid advances in genetics, molecular biology and neurophysiology have enabled unraveling and characterization of the molecular bases of a number of neurological and other diseases, among which ►channelopathies comprise a class of diseases caused by ion channel dysfunctions. They can be due to autoimmune and paraneoplastic [26] processes and drug, toxic or genetic mechanisms that affect all kinds of channels: $Ca^{2+}$, $Cl^{-}$, $K^{+}$, $Na^{+}$, HCN, TRP channels etc. Mutations in genes encoding ion channel proteins that alter channel function are common mechanisms underlying channelopathies. Examples are plentiful (see Calcium channels – an overview; ►Calcium channelopathies; ►Epilepsy [27]; ►Episodic ataxia [28]; ►Familial periodic paralyses and ►Non-dystrophic myotonias [29]; ►Migraine; ►Neuromyelitis optica; Non-dystrophic myotonias). Channelopathies may also affect internal cell membranes, e.g., of the mitochondria [30].

## Prospects

There has been a rapid progression of new concepts related to membrane structure and function, so much so that we seem to have merely touched the surface in our understanding of cell membranes. As we go forward with new techniques that provide more accurate spatial and temporal resolution of membrane dynamics, it seems likely that molecular conformational changes involving channel proteins and lipids will be visualized with optical methods and other techniques as they occur. Gene-gene interactions and the impact of environmental perturbations may also be fruitfully investigated, leading to treatments directed at channelopathies, synaptic dysfunction and correction of myelin disorders.

## Membrane Capacitance

### Definition

The membrane capacitance is the stored charge of ions across the cell membrane. The cell membrane serves as an insulator of the membrane potential generated by the disequilibrium of ionic charge on either side of the membrane. The membrane capacitance (C) is a function of the stored charge divided by the potential difference across the membrane. As a result, any potential difference change generates a capacitance transient. Membrane capacitance is directly proportional to surface area, so biophysicists often use membrane capacitance as a measure of the changes to membrane surface area.

### Synonyms

Transmembrane voltage

### Definition

The electrical potential difference (►voltage) across the cell membrane (►plasmalemma or ►sarcolemma) of all living cells that is produced by an unequal net distribution of positive and negative charges on either

side of the cell membrane. The potential in the intracellular milieu is normally negative with respect to the extracellular milieu, reference set to zero.

## Characteristics

Even phylogenetically ancient unicellular organisms such as Paramecium need to exchange matter and information with their environment. In multicellular organisms, the exchange must be organized across different cellular and body parts. Information is an abstract entity that needs to be encoded in a signal to be generated, transmitted and processed. Signals in turn are generated by mechanisms bound to some material substrate or carrier. The basic structure for information exchange is the cell membrane, and the signals required are generated by physico-chemical mechanisms. Here, we describe a fundamental type of signal: the membrane potential. To understand how it is generated, it is instructive to start from two basic principles.

### Ion Concentrations Differ in the Internal and External Solutions of Cells

The first principle is that the concentrations of some basic sorts of ions, which characteristically are abundant on the earth's surface, are different in the internal and external milieus of cells. Table 1 lists concentrations of some pertinent ions in the frog muscle fiber and in the giant axon of the squid.

The respective ion concentrations are higher in the squid axon than in the frog muscle fiber, because the squid lives in seawater with higher ion concentrations. For both types of cells, the concentrations of $Na^+$ and $Cl^-$ are high extracellularly and low intracellularly, thus establishing a strong inward ►concentration gradient across the cell membrane. The situation is opposite for $K^+$. Another ion that is unequally distributed is $Ca^{2+}$, with a high extracellular and a normally very low intracellular free concentration.

**Membrane Potential: Basics. Table 1** Extra vs. intracellular concentrations of several types of ion in mM/l (Data from [1])

| Ion | Extra | Intra | Ratio extra/intra |
|---|---|---|---|
| (A) Frog muscle fiber | | | |
| $K^+$ | 2.5 | 140 | 0.018 |
| Organic anions | 40 | 86 | 0.465 |
| $Na^+$ | 120 | 10 | 12 |
| $Cl^-$ | 77.5 | 1.5 | 51.667 |
| (B) Giant axon of squid | | | |
| $K^+$ | 10 | 400 | 0.025 |
| Organic anions | | 360 | |
| $Na^+$ | 460 | 50 | 9.2 |
| $Cl^-$ | 540 | 40–100 | 5.4–13.5 |

### Cells Exhibit a Resting Membrane Potential

This second principle is apparent from the experimental measurement illustrated in Fig. 1a. A long skeletal muscle fiber is isolated and put in a medium representing the extracellular milieu. Two sets of electrodes measure the electrical potential differences and apply electrical stimuli. To do the former, a large electrode (so-called indifferent, or reference electrode) is placed in the extracellular milieu, and another movable electrode with a very fine tip is also situated initially in the extracellular fluid. Both electrodes are connected to an amplifier that leads the potential difference to a voltmeter (►Intracellular recording). As long as the movable electrode remains in the homogeneous extracellular milieu, there is no potential difference (Fig. 1b, left), but once the fine electrode penetrates the membrane and enters the interior, a potential difference of about −90 mV is measured (Fig. 1b, right). This steady-state voltage is called the ►*resting membrane potential*. A value of roughly 0.1 V across a membrane 50–100 Å thick corresponds to an electrical field strength of $1–2 \times 10^5$ V $cm^{-1}$ [2].

Resting membrane potentials can be measured in all living cells. They vary in magnitude, but are negative inside vs. outside. It is assumed, on well-established physico-chemical grounds, that they originate from concentration differences across the cell membrane of ions that carry electric charges.

### Relation Between Ion Concentration Gradients and Membrane Potential

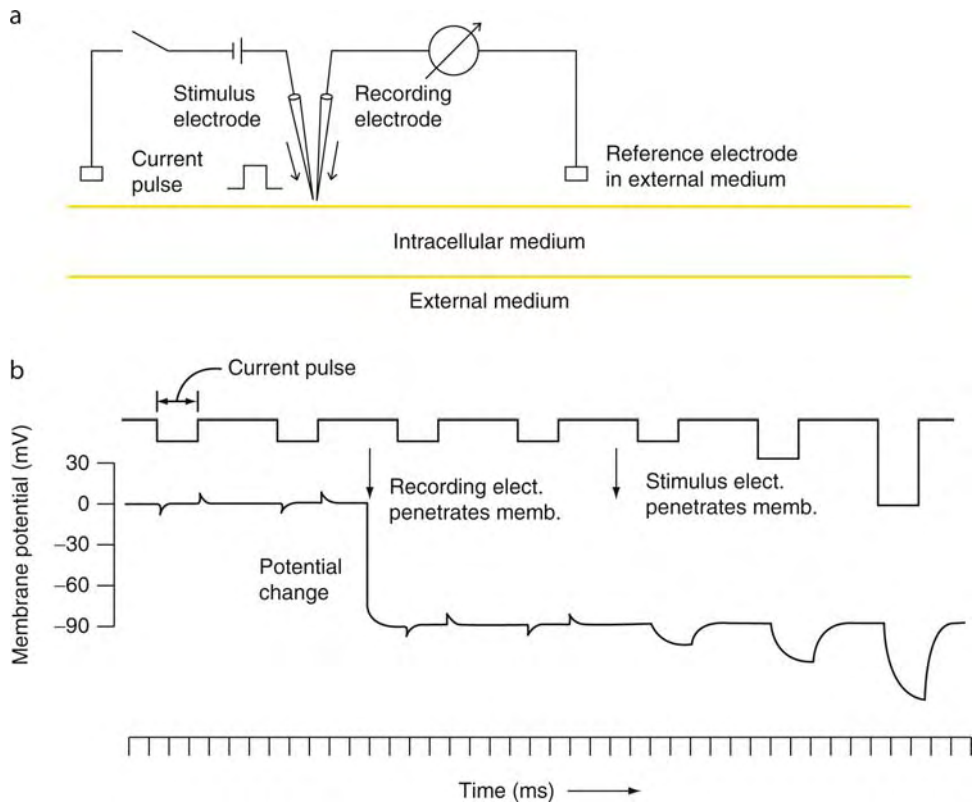
In order to understand this relation, consider some fundamental phenomena in aqueous salt solutions.

#### *Diffusion*

Imagine a container made up of two compartments separated by a thin membrane. Both compartments contain a solution of two types of electrically uncharged molecules, one of relatively high molecular weight and the other small. The concentrations are low in the left compartment ($c_2$) and high in the right compartment ($c_1 = 10.c_2$). If a step-like change in concentration occurs right at the membrane and the membrane is removed, diffusion occurs because of the statistical thermal movement of the particles. The diffusion process follows the following physico-chemical rules:

1. Net flux of both particles proceeds from higher (right) to lower (left) concentrations because, on the average, there are more particles on the right moving leftward than particles on the left moving rightward.
2. Concentration gradients, initially step-like, flatten with progressing diffusion until equilibrium (homogeneous particle concentration) is reached.

M



**Membrane Potential: Basics. Figure 1** (a–b) Recording from, and stimulation of, an isolated skeletal muscle fiber (*yellow lines*). (a): Two microelectrodes (micro-pipettes filled with an electrolyte solution) are connected to a battery (*left*) or voltmeter (*right*), and are referenced to large indifferent electrodes in the external medium. (b): As long as the recording electrode tip remains in the external medium, it measures a zero potential difference relative to the large indifferent electrode (*left lower trace*). When the recording electrode tip enters the internal medium of the muscle fiber (*first vertical arrow*), the potential difference jumps to a negative value of ca. −90 mV, corresponding to the so-called resting membrane potential. As long as the stimulus electrode tip remains in the external medium, rectangular current pulses passed through it (*upper trace*) elicit only small smoothed voltage changes picked up by the recording electrode whether extra- or intracellular (*left upper trace*). When the stimulus electrode tip enters the muscle fiber (*second vertical arrow*), the recording electrode measures deviations from the resting potential corresponding to low-pass filtered versions of the current pulses (Adapted from [7]).

3. Velocity of diffusion depends quantitatively on: Concentration gradient at any time and site: the shallower the gradient, the slower the diffusion. Velocity is faster for the small than the large particles because the former meet less friction in solution than do the latter, therefore the diffusion fronts of both particles will separate over time (this difference being eliminated in equilibrium). The higher the temperature, the faster are the particles' motions, thus diffusion is faster.

### Diffusion Potential

The above model considers uncharged particles. What happens when we are dealing with ions? Assume, for example, that the small particles are potassium ions ($K^+$) and the large particles are organic anions ($A^-$) such as isethionate, glutamate, aspartate and organic phosphates with a net negative charge. Initially, when the membrane is still in place, there are equal numbers of oppositely charged particles in each compartment, providing electro-neutrality.

After removal of the membrane, diffusion will again set in from right to left, with the small (positive) particles tending to rush away from the large (negative) particles, as long as there is a concentration gradient. However, the two types of particle are not moving independently of each other because positive and negative charges attract each other. There is thus a competition between opposing forces. The concentration gradient tends to separate small from large particles, while the ensuing charge separation tends to re-unite particles in the opposite direction. These two forces create an ►electrochemical equilibrium. (In case the two opposite forces are not of equal magnitude, they create an ►electrochemical gradient).

The two particle types will therefore separate only partially, building up a potential difference between their diffusion fronts; specifically, a ►diffusion potential. It is a vector force, with a direction and a magnitude. The direction is from left (positive) to right (negative), because $K^+$ ions rush away leftward from the anions.

The diffusion potential has the following characteristics:

1. ►Equilibrium potential. It is an equilibrium potential because it equalizes the chemical force originating in the concentration gradient and acting in opposite direction.
2. Dependence on concentration gradient. The equilibrium potential's magnitude naturally depends on the concentration gradients, it thus disappears when diffusion stops (in thermodynamic equilibrium).
3. Dependence on the difference of ion mobilities. The equilibrium potential's magnitude depends on the difference of ion mobilities in watery solution, $u_+$ and $u_-$. If there is no mobility difference, as is the case with $K^+$ and $Cl^-$, there is no diffusion potential.

Quantitatively, the last two dependencies are formalized as follows. The magnitude of the diffusion potential, $E_D$, depends on the concentration gradient as expressed in the ratio $c_1/c_2$, and on the difference of ion mobilities, $u_+$-$u_-$, according to the formula [2]:

$$E_D = \frac{R.T}{z.F} \times \frac{u_+ - u_-}{u_+ + u_-} \times \ln(c_1/c_2), \qquad (1)$$

where R is the general gas constant (1.987 cal $K^{-1}$ $mol^{-1}$ = 8.315 J $K^{-1}$ $mol^{-1}$), T the absolute temperature in Kelvin (K), z the number of elementary electric charges per molecule (e.g., z = 1 for $K^+$), and F the Faraday constant (9.648 × $10^4$ C $mol^{-1}$).

In the special case where one ion, say the large anion, cannot diffuse at all, i.e., that its mobility is zero and $u_- = 0$, (1) simplifies to:

$$E_D = \frac{R.T}{z.F} \times \ln(c_1/c_2) \qquad (2)$$

This is the famous *Nernst equation* (named after Walther Nernst, Nobel Prize in Chemistry 1920), which describes the situation of a single sort of ion in free solution. (For a derivation from thermodynamic principles see, e.g., [2,3]. Could it describe a real situation?

### Semi-Permeable Membranes

In the container model (above), the two compartments are initially separated by a membrane that cannot be passed by either sort of ion. Now assume that the membrane contains pores, through which only the small $K^+$ ions, but not the large anions can pass. The $K^+$ ions will then diffuse through the pores from right to left, but separate from the anions left behind only as much as the evolving diffusion potential allows them to do. This diffusion potential is the equilibrium potential for $K^+$, $E_K$. This is a physical situation described by the Nernst equation (2).

The membrane described above is semi-permeable, which has important consequences:

1. The concentration differences are maintained because the large anions cannot diffuse through the membrane and thus, through the diffusion potential, also prevent the small permeable ions from equalizing their concentrations.
2. The diffusion potential is maintained because the concentration differences stay the same.

Semi-permeability can be generated by several mechanisms: Pores (more often called channels) with different diameters let ions pass or not pass, according to their (hydratized) diameters. Electric charges within in the channels prevent the passage of ions of the same charge.

### Bernstein's Hypothesis

In 1902, Julius Bernstein [4] proposed that the resting membrane potential, V (Fig. 1b), is a diffusion potential that is determined exclusively by $K^+$. According to the Nernst equation, V should then be equal to the $K^+$ equilibrium potential, $E_K$:

$$V = E_K = \frac{R.T}{F} \times \ln \frac{[K^+]_o}{[K^+]_i}, \qquad (3)$$

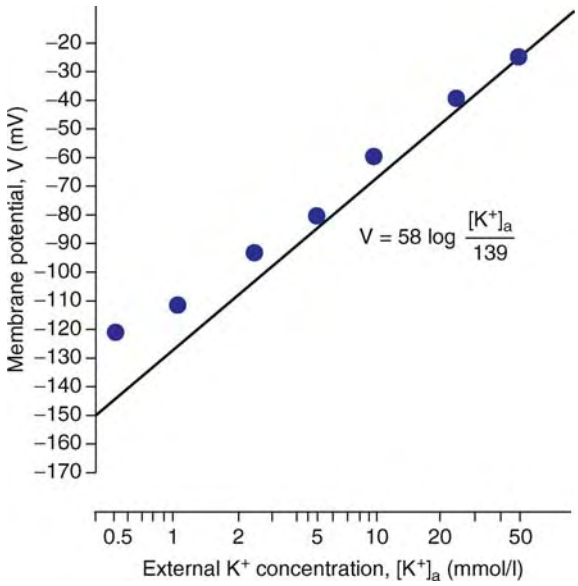
where $[K^+]_o$ is the external and $[K^+]_i$ the internal $K^+$ concentration.

Bernstein was not able to test his hypothesis experimentally because the required techniques including ►intracellular recording and the related electronics were not yet available. A more recent test [5] is shown in Fig. 2. It was conducted at the frog muscle fiber at a temperature of T = 20° C = 293 K. Inserting values for R and F, and with ln a = 2.3 $\log_{10}$ a, (3) becomes

$$V = E_K = 58 \log_{10} [K_o/K_i] (\text{in mV}). \qquad (4)$$

While the internal $K^+$ concentration $[K^+]_i$ remains constant at about 140 mM $l^{-1}$, the external $K^+$ concentration $[K^+]_o$ can easily be changed, and the resultant theoretical dependence of V on $[K^+]_o$ according to (4) is depicted in Fig. 2 as the solid straight line. The values actually measured experimentally are given as dots. Note that, since the external $K^+$ concentrations are lower than the internal concentrations, the resultant membrane potentials are negative. At high external $K^+$ concentrations, the measured resting membrane potentials are fairly well fitted by the solid line, in agreement with Bernstein's hypothesis, but the measurements deviate from the prediction to more positive values at low $K^+$ concentrations.

M



**Membrane Potential: Basics. Figure 2** Dependence of resting membrane potential on extracellular $K^+$ concentration. Frog sartorius muscle fiber. The resting membrane potential is plotted on the ordinate (in linear coordinates) as a function of extracellular $K^+$ concentration in logarithmic units on the abscissa. The *straight solid line* shows the theoretical relation according to the Nernst equation, assuming that only $K^+$ passes through the membrane; the *blue dots* are experimental measurements (Adapted from [5]).

### *Resting Membrane Potential: Weighted Average of Equilibrium Potentials*

The discrepancies between theory and measurement in Fig. 2 suggest that Bernstein's hypothesis cannot fully account for the real situation, and invite an inquiry into the underlying reasons. The starting point of course is to question the central assumption in the hypothesis, which is that $K^+$ is the only ion able to diffuse through the membrane.

What happens if – in addition to $K^+$ ions – other ions can diffuse through the membrane as well? First consider another major cation, namely $Na^+$. The resulting situation can be captured by two limiting cases:

1. Limiting case 1: Membrane permeable solely to $K^+$ ions $\Rightarrow V = E_K$, as assumed by Bernstein: This makes the cell interior negative with respect to the outside, according to the Nernst equation; in nerve cells $E_K$ is around −70 mV, in muscle cells around −90 mV.
2. Limiting case 2: Membrane permeable solely to $Na^+$ ions $\Rightarrow V = E_{Na}$; this makes the cell interior positive with respect to the exterior because $Na^+$ ions would tend to diffuse inward and thus impose their positive charge onto the inside: $E_{Na}$ is around +50 mV.

If, however, the membrane is permeable to both $K^+$ and $Na^+$ ions, membrane potential V must lie somewhere between $E_K$ and $E_{Na}$, which as extreme cases constitute the limits for V: $E_K < V < E_{Na}$. This could account for the positive deviation of the experimentally measured V values (circles) from the theoretical $E_K$s (straight line) in Fig. 2.

If the membrane is permeable to both $K^+$ and $Na^+$ ions, no cation is at its equilibrium. This has important consequences, as illustrated in Fig. 3. The left column (a–b) explains the situation for $K^+$ ions and the right column (c–d) for $Na^+$ ions.

Figure 3a depicts limiting case 1, where $V = E_K$. $K^+$ is at its equilibrium, and there is thus no net $K^+$ flow through the membrane. In Fig. 3b, $E_K < V$, implying that the electrical potential does not compensate for the $K^+$ concentration gradient. Hence, $K^+$ ions flow out of the cell, following the surplus electrochemical gradient directed outward.

Figure 3c depicts limiting case 2, where $V = E_{Na}$. $Na^+$ is at its equilibrium, and there is thus no net $Na^+$ flow through the membrane. In Fig. 3d, $V < E_{Na}$, implying that the electrical potential does not compensate for the $Na^+$ concentration gradient. Hence, $Na^+$ ions flow into the cell, following the electrochemical gradient directed inward.

In general, therefore, when $E_K < V < E_{Na}$, there will be net ion currents flowing through the membrane, outward $K^+$ and inward $Na^+$ currents.

These qualitative points can be formulated quantitatively. According to ►Ohm's law, the amount of current I carried by each ion through the membrane is proportional to the electric ►conductance g (in units of $\Omega^{-1}$ $cm^{-2}$) of each ion and the ►driving potential, which is the difference between the actual membrane potential V and the equilibrium potential for each ion, as follows:

$$I_{Na} = g_{Na}(V - E_{Na}), \tag{5a}$$

$$I_K = g_K(V - E_K). \tag{5b}$$

Whenever the membrane potential V remains constant during steady state, no net current flows through the membrane. Hence, the two currents $I_{Na}$ and $I_K$ must cancel each other:

$$I_{Na} = -I_K \text{ or } I_{Na} + I_K = 0$$

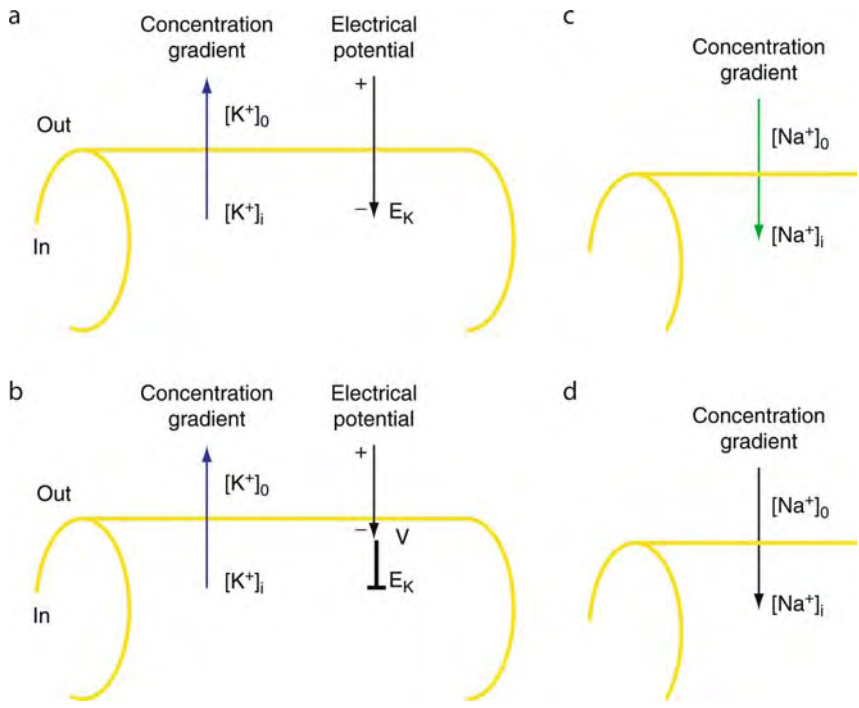
$$g_{Na}(V - E_{Na}) + g_K(V - E_K) = 0$$

Solving for V yields

$$V = \frac{g_{Na}\, E_{Na} + g_K\, E_K}{g_{Na} + g_K} \tag{6}$$

In the extreme,

1. Limiting case 1: for $g_{Na} = 0 \Rightarrow V = E_K$



**Membrane Potential: Basics. Figure 3** (a–d) Origin of passive net $K^+$ and $Na^+$ ion flows across the cell membrane. The left column (a–b) explains the situation for $K^+$ ions and the right column (c–d) for $Na^+$ ions. (a): Situation at $V = E_K$: There is no net $K^+$ flow because the outward concentration gradient (*left blue arrow headed upward*) is balanced by the inward electrical potential (*right arrow headed downward*) corresponding to the $K^+$ equilibrium potential, $E_K$. (b): Situation for $E_K < V$: $K^+$ ions flow out of the cell, following the surplus electrochemical gradient directed outward. (c): Situation at $V = E_{Na}$. There is no net $Na^+$ flow because the inward concentration gradient for $Na^+$ (*left green arrow headed downward*) is balanced by the outward electrical potential difference (*right arrow headed upward*). (d): Situation for $V < E_{Na}$. $Na^+$ ions flow into the cell, following the huge electrochemical gradient directed inward (Adapted from [6]).

M

2. Limiting case 2: for $g_K = 0 \Rightarrow V = E_{Na}$

In this $Na^+$-$K^+$ system (with conductances for all other ions being zero), the two equilibrium potentials determine the limits, within which the membrane potential V can move.

## Other Ions

Equation 6 can be extended to other sets of ions, e.g., by including additional conductances, such as, e.g., for $Ca^{2+}$ and $Cl^-$. $Ca^{2+}$ with its positive charge and inwardly directed concentration gradient has, like $Na^+$, a positive equilibrium potential. Chloride with its negative charge and inwardly directed concentration gradient has a negative equilibrium potential. Including $Cl^-$ with $Na^+$ and $K^+$ in (6) would yield:

$$V = \frac{g_{Na}\, E_{Na} + g_K E_K + g_{Cl}\, E_{Cl}}{g_{Na} + g_K + g_{Cl}} \qquad (7)$$

## Constant Field Equation

The formulations in (6) and (7) use electrical variables, i.e., conductances and potentials, which are related to chemical variables, albeit not in a simple way. The equilibrium potentials are related to concentration gradients via the Nernst equation, and the conductances to permeabilities (in units of cm/s) of the membrane to certain ions [2].

These relationships are expressed in the ▶Goldman-Hodgkin-Katz equation (Alan Hodgkin and Bernard Katz, Nobel Prizes in Physiology or Medicine 1963 and 1970, respectively) or ▶constant field equation, which has the form of a generalized Nernst equation (generalized to several permeant ions) (see, e.g., refs. [2,3,7,8]):

$$V = \frac{R.T}{F} \times \ln \frac{P_K[K^+]_o + P_{Na}[Na^+]_o + P_{Cl}[Cl^-]_i}{P_K[K^+]_i + P_{Na}[Na^+]_i + P_{Cl}[Cl^-]_o}, \qquad (8)$$

where $P_K$ is the membrane permeability for $K^+$ etc. Note that, in the strict sense, the common habit of using the terms conductance and permeability as synonyms is not correct [2].

## Conductances as Weighting Factors

Equations (6) and (7) reveal the role of the different ion conductances as weighting factors: Increasing any one

of them drags the membrane potential V closer to the equilibrium potential of the respective ion, and vice versa. V is thus an average of the relevant equilibrium potentials weighted by the conductances.

In most cells, the resting membrane potential is much closer to $E_K$ than to $E_{Na}$ because under resting conditions $g_K$ is much larger than $g_{Na}$ (by a factor of 10–75 in different cells, the latter value applying to frog muscle fibers; see ref. [2]).

### Ion Pumps

Because the membrane is permeable to several ions that flow passively down electrochemical gradients, unrestricted ion flow would eventually abolish concentration differences between the inside and outside of the cell and, in consequence, the equilibrium and membrane potentials. In order to prevent this, the cell invests much energy in so-called ►ion pumps that transport the leaking ions back to where they come from, against their respective gradients (►Ion Transport). Such pumps need:

1. Metabolic energy, ultimately supplied by adenosine triphosphate (ATP).
2. Regulation mechanisms, including the sensitivity for particular ions and their concentrations (e.g., inside for $Na^+$).

The action of the $Na^+$ pump that expels $Na^+$ from a cell was first demonstrated by Hodgkin and Keynes [9], who showed that the metabolic poison dinitrophenol (DNP), which deprives energy sources for the $Na^+/K^+$ pump, depresses cellular extrusion of $Na^+$. Since then, other laboratories have demonstrated the active role of ion pumps that maintain steady state membrane potential by regulating intracellular $Na^+$, $Cl^-$, $K^+$ and $Ca^{2+}$ concentrations [10].

### Sub threshold Membrane Potential Transients are Shaped by cable Properties

Membrane potential changes is response to transmembrane current flow are low-pass filtered as illustrated in Fig. 1, (right side). As long as the stimulus electrode tip remains in the external medium, rectangular current pulses passed through it (upper trace) elicit only small smoothed voltage changes picked up by the recording electrode whether extra- or intracellular (left upper trace). When the stimulus electrode tip enters the axon (second vertical arrow), the recording electrode measures deviations from the resting potential corresponding to low-pass filtered versions of the current pulses. The low-pass filtering is due to cable properties of the nerve or muscle fiber (►Cable Theory).

# Membrane Properties

►Intrinsic Properties of Auditory Neurons

# Membrane Resistance

### Definition

The membrane resistance is a measure of the impediment to the transmembrane flow of ions. The membrane resistance is infinite in the absence of ionic channels and transporters in the membrane. The membrane resistance decreases as the number of ion channels and transporters increase in the membrane, which permit the transmembrane flux of ions under the driving force of electrochemical gradients.

## Definition

Formation of certain kinds of memory (declarative memory) requires functional activation of the hippocampus. Synaptic plasticity of excitatory synaptic transmission, represented by long-term potentiation (LTP), has been regarded as a cellular and molecular model of learning and memory. LTP in the hippocampal CA1 region is induced by the activation of the ►NMDA receptor, which is one type of the ►ionotropic glutamate receptors, and is expressed by the enhancement of basal synaptic transmission mediated by the ►AMPA receptor, which is another type of the ionotropic glutamate receptors. NMDA receptor activation regulates intracellular biochemical processes, resulting in long-lasting modification of synaptic transmission, which has been thought to be a molecular mechanism of memory.

## Characteristics

### Hippocampal LTP

Fast excitatory synaptic transmission in the central nervous system is mediated mainly by the two ionotropic glutamate receptors, the AMPA receptor and NMDA receptor [1]. Basal synaptic transmission in the pyramidal cell at a membrane potential around the resting membrane potential is mostly mediated by AMPA receptors. When the neurotransmitter glutamate is released from the presynaptic terminal and binds to the AMPA receptor, the receptor channel opens regardless of the membrane potential and permeates monovalent cations. Because the ionic concentration of $Na^+$ is higher outside the cell, the ionic concentration of $K^+$ is higher inside the cell, and the membrane potential of the cell is negative at rest, mainly $Na^+$ ions enter the cell through AMPA receptors, resulting in the depolarization of the cell.

On the other hand, NMDA receptors fail to open at a membrane potential around the resting membrane potential even if glutamate binds to the receptor, because external $Mg^{2+}$ ions block the ionic channel of the receptor ($Mg^{2+}$ block). However, when the synapse is repetitively activated at high frequencies and the postsynaptic cell sufficiently depolarizes, the $Mg^{2+}$ block is released and $Ca^{2+}$ ions as well as $Na^+$ ions enter the postsynaptic cell through the NMDA receptor channel [1]. Thus, the NMDA receptor functions as a coincidence detector for presynaptic and postsynaptic activities.

The increased intracellular $Ca^{2+}$ then activates $Ca^{2+}$-dependent biochemical processes such as the calcium/calmodulin-dependent protein kinase II (CaMKII) and protein kinase C cascades, which further promotes the process of LTP expression. The final expression mechanism for LTP is thought to involve an insertion of active intracellular AMPA receptors into the synaptic site and/or a long-lasting increase in the conductance of AMPA receptor channels [2].

### LTP and Memory

LTP has been thought to be involved in memory formation. In Morris water maze task, in which the ability of spatial memory in rats and mice can be assessed, the blockade of LTP by intraventricular injection of an NMDA receptor antagonist impairs the spatial learning in the rat [3]. It has also been reported that the genetic deletion of the NR2A subunit of NMDA receptors in the mouse causes the reduction of hippocampal LTP and the impairment of learning abilities in Morris water maze task [4]. Furthermore, overexpression of the NR2B subunit has been reported to enhance learning and memory in the mouse [5]. Thus, the NMDA receptor, which is essential for LTP induction, plays a pivotal role in memory formation.

There are many reports showing the involvement of various intracellular signaling molecules downstream of NMDA receptor activation in learning and memory. The first papers in which LTP of knockout mice is examined suggest that CaMKII is essential for LTP induction in the hippocampal CA1 region [6] and that spatial memory of the mutant mice is severely impaired [7]. So far, many intracellular signaling molecules, such as protein kinase C, mitogen-activated protein kinase and protein kinase A, have been shown to be involved in both LTP and memory formation.

# Memory, Short-term

## Definition

►Short-term Memory

# Memory: Eidetic, Photographic

## Definition

The ability to store perceived events. Eidetic memory refers to motor programs that help to orient in familiar environments even when no sensory input is present (people may find light switches in familiar dark rooms). If the storage results in a representation of space similar as in a photograph, the term photographic memory is used.

# Memory and Dementia

Murray Grossman
Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

## Definition

Memory is the acquisition and mental representation of information. ►Dementia is a progressive neurodegenerative disease that compromises neurologic functioning in individuals who have attained adult levels of intact cognition. There are many kinds of memory, and each of these has a different fate in patients with the most common form of dementia, ►Alzheimer's disease (AD). The distinct ways in which these different forms of memory are compromised depends in large part on the neuroanatomic distribution of disease in AD.

## Characteristics

►Episodic memory is the ability to learn a new event consciously and then to recall this specific event purposefully and at will [1]. This form of memory depends on the hippocampus and intimately related structures in the medial temporal lobe. The earliest evidence of histopathologic disease in AD is the accumulation of neuritic plaques composed of amyloid and neurofibrillary tangles consisting of paired helical filaments of tau in the hippocampus, and the earliest clinical feature of AD thus is impaired episodic memory. Indeed, a prodromal Alzheimer's condition known as amnestic Mild Cognitive Impairment (aMCI) is defined clinically as an isolated deficit of episodic memory.

Impaired episodic memory is commonly demonstrated by a list-learning task. On this task, a supraspan list of words (a list of 10–15 words that is longer than can be repeated in one try) is presented for learning, and as many words as possible are repeated by the patient. This sequence of list presentation and repetition is repeated for several learning trials. Subsequently, a brief period filled with another task is administered to prevent rehearsal of the words, then the list is recalled. Although we do not fully understand how the hippocampus and medial temporal structures accomplish this task, one important theory proposes that a to-be-remembered event is bound to its context or other associated attributes of the event. On a list-learning task, this is the specific list of words bound to its recent presentation as part of the memory test. Healthy adults typically demonstrate learning by repeating a longer list on each successive learning trial. Moreover, despite the filled period that prevents rehearsing the list, healthy adults can recall most of the stimulus words. In AD, by comparison, there is impaired learning and impaired recall. AD patients may repeat only three or four words during a learning trial, and they do not show learning by repeating more words on subsequent trials. Moreover, AD patients typically recall no words following the brief delay. Patients with aMCI and mild AD may be able to recognize some of the words in a multiple-choice format. A similar pattern of findings is evident regardless of the stimulus modality (e.g. aural or visual) or material (e.g. words or geometric designs). Imaging studies directly relate this episodic memory deficit to hippocampal atrophy or reduced hippocampal metabolism in AD through correlation studies, while functional imaging that monitors brain activity during episodic memory shows reduced hippocampal activation in AD patients compared to healthy adults [2].

►Remote Memory is the long-term representation of information that was learned months to years earlier [3]. This may include factual knowledge or personal autobiographical knowledge. It often seems that remote memory is relatively preserved in AD, since these patients frequently enjoy reminiscing about events that occurred in their early years. However, careful examination demonstrates that remote memory also may be impaired in AD [4]. These are at least two possible explanations for this deficit. One account, paralleling the mechanism for episodic memory mediated by the hippocampus, suggests that impaired remote memory involves difficulty retrieving facts bound to a specific, remote period of time. However, functional neuroimaging studies of healthy adults suggest that the hippocampus may not be activated to retrieve information from remote memory. An alternate possibility is that the neural representation of remote memories is degraded as the disease in AD spreads from the hippocampus to other cortical areas in the temporal lobe and the frontal lobe.

►Semantic Memory is the representation of the meaning of words, objects, actions, thoughts, and the like [5]. Semantic memory is also impaired in up to 50% of patients with AD. Like episodic memory and remote memory, one theory of semantic memory difficulty in AD is that hippocampal disease interferes with this form of memory. This may be because the hippocampus is necessary for binding features into a meaningful category of knowledge, or the hippocampus mediates retrieving semantic information form its long-term cortical representation. However, these accounts would not explain the dissociation between episodic memory difficulties present in virtually all patients with AD, and the semantic memory deficit that is present only in a subset of these patients. An alternate possibility is related to the frequent correlation of impaired semantic memory with cortical atrophy in the posterolateral temporal and dorsolateral frontal lobe. It is unlikely that temporal and frontal regions are the neural repository for all semantic knowledge. Instead, the semantic memory deficit associated with temporal and frontal disease may be related to a categorization process that assembles information that is widely represented throughout the cortex into a meaningful concept. Consistent with this possibility, the temporal and frontal regions consist of multimodal association cortex, where there is a connectivity pattern involving reciprocal projections with all unimodal association cortices. Functional neuroimaging studies of semantic categorization in healthy adults show activation of these areas, and this activation is reduced in AD [6].

►Working Memory is a form of short-term memory that may supplement many of the other forms of memory described above [7]. For example, retrieval from episodic, remote or semantic memory may benefit from working memory that maintains the to-be-remembered target in an active mental state during searches and decision-making components of these forms of memory. Working memory also may contribute to other processes such as understanding a long and grammatically complex sentence, or weighing all relevant facts during mental reasoning tasks. Much evidence indicates that working memory is impaired in AD. This appears to be related to disease in prefrontal cortex and inferior parietal cortex, according to correlation studies of cortical atrophy in AD.

►Implicit Memory is another form of memory for acquiring new information [8]. Unlike the kinds of memory described above, implicit memory occurs without conscious awareness. This may take the form of a habit that is acquired through repeated performance of a particular activity, or repeated exposure to a category of similar materials that subsequently biases an individual towards accepting similar appearing materials as members of the same category. Implicit memory appears to be relatively preserved in AD [9]. Thus, patients with AD are able to learn a new habit and a new perceptual category such as a dot array when presented implicitly. Recent work also suggests that AD patients can learn a meaningful category when presented implicitly. Functional neuroimaging studies in healthy adults suggest that implicit memory tasks involve the caudate as well as other cortical association regions. Functional neuroimaging studies of patients with AD during implicit memory challenges show some activation of caudate and cortical association regions. The hippocampus is not activated in AD, ad this may account for the minor deficit in implicit memory tasks in AD relative to age-matched controls.

Memory difficulty in non-Alzheimer's forms of dementia is also well documented [10]. In semantic dementia, for example, there is profound impairment of semantic memory. In this condition, comprehension of words, objects, actions and abstract concepts is significantly compromised. This is related to their temporal lobe disease. In frontotemporal dementia presenting with a disorder of social comportment and personality, working memory is regularly compromised. This appears to be due to their prefrontal disease. In Parkinson's dementia, habit learning is impaired due to disease affecting the caudate.

Multiple forms of memory difficulty are evident in AD. While we typically think of an episodic memory deficit as the *sine qua non* of AD, difficulty with remote memory, semantic memory, and working memory also are regularly compromised in AD. More surprisingly, it appears that some forms of memory are relatively preserved in patients with AD, including habit learning and implicit memory.

# Memory and Sleep

Shigenobu Shibata
Division of Physiology and Pharmacology, School of Science and Engineering, Waseda University, Tokyo, Japan

## Definition

Memory and sleep refer to the role of sleep in memory processing

## Characteristics

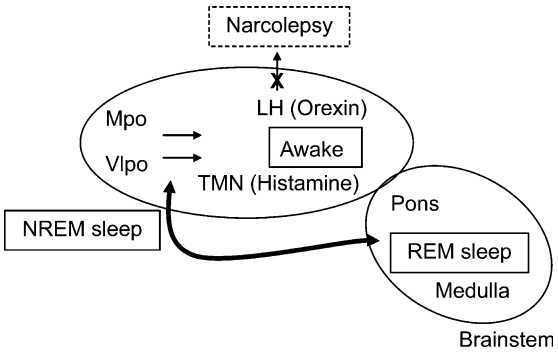
A large number of studies offer substantial evidence supporting the role of sleep in what is becoming known as sleep-dependent memory processing [1]. Many reports, ranging from studies on cellular and molecular processes in animals to behavioral studies in humans, have provided a wealth of converging evidence that sleep-dependent mechanisms of neural plasticity lead to the consolidation of learning and memory across a range of animal species. There are a number of stages of memory consolidation, and each stage uses distinct brain processes to perform separate functions. When combined with multiple memory systems such as procedural or declarative memory and the different stages of sleep such as ►REM or ►NREM sleep, one is faced with a truly staggering number of possible ways that ►sleep cycle might affect memory consolidation. Recent findings show that sleep deprivation can impair learning and memory for both motor procedural and declarative memory systems. It is only by asking whether a specific stage of sleep affects a particular aspect of memory processing for a given type of memory that one can begin to ask scientifically answerable questions concerning sleep-dependent memory processing. There remain numerous important and unanswered questions regarding sleep-dependent memory consolidation. While procedural learning, both perceptual and motor, is clearly enhanced by post-training sleep, the forms of declarative memory that are similarly affected are uncertain. Contribution of sleep to the processes of memory stabilization, enhancement, reconsolidation, integration, translocation, and active erasure require further elucidation. The actual processes within sleep that effect consolidation are almost completely unknown; however, many papers allow us to draw conclusions. Both REM and NREM sleep seem necessary for learning and memory: thus, for efficient consolidation of both (declarative) knowledge and (procedural) skills, the biggest risk can come from sleep loss or fragmentation.

### Different Sleep Stages: REM and NREM Sleep

Sleep can be defined as a state of immobility and greatly reduced responsiveness distinguishable from coma or anesthesia by its rapid reversibility. An additional defining characteristic of sleep is that when it is prevented, the body tries to recover the lost amount, termed "rebound." Sleep is the state of natural rest observed in humans and throughout the animal kingdom in all mammals and birds, and in many reptiles, amphibians, and fish. Two types of sleep have been defined based on the measurement of eye movement during slumber: rapid eye movement (REM) and non-rapid eye movement (NREM). Each type has a distinct set of associated physiological, neurological, and psychological features.

In NREM sleep, the body is active and the brain inactive, and there is relatively little dreaming. NREM is comprised of four stages according to the "The American Academy of Sleep Medicine (AASM)"; stages1 and 2 are considered the light sleep stages, and 3 and 4 the deep sleep stages, differentiated solely by electroencephalography (EEG). NREM accounts for 75–80% of total sleep time in normal human adults.

Sleep-activated neurons, which have been discovered in the preoptic and basal forebrain regions [2], are maximally active during NREM sleep. When



**Memory and Sleep. Figure 1** Schema of sleep-regulating neuronal populations. Mpo, median preoptic area; Vlpo, ventrolateral preoptic area; LH, lateral hypothalamus; PH, posterior hypothalamus; NREM sleep, non-rapid eye movement sleep; REM sleep, rapid eye movement sleep.

stimulated, these cells will induce the NREM state. In contrast, damage to these regions greatly reduces sleep. The neurons in these brain regions give inhibitory projections to aminergic, cholinergic, and orexinergic neurons in the forebrain and brainstem. GABAergic inhibitory projections from preoptic regions might be important in inhibiting orexin neurons, which are thought to be involved in sleep regulation, during sleep (Fig. 1).

In humans, the duration of REM sleep episodes progressively increases throughout the sleep period and is maximal just prior to the expected time of awakening. For example, the initial REM sleep period may last only 5–10 min, whereas the last REM period before awakening may last for more than 25 min. REM amounts are maximal near the nadir of the brain and the core body temperature cycles. REM sleep phenomena can be generated by the isolated brainstem region, in particular the pons and adjacent midbrain [2]. Although an animal in REM sleep is behaviorally asleep, brain metabolic and neuronal activity are high, respiration and heart rate are variable, rapid eye movement and twitches of the extremities occur, and males frequently develop erections. Several theories have suggested that REM state, and its associated ►periodic brain activation, plays a role in localized recuperative processes and in emotional regulation during sleep. The brain areas where REM sleep neural activity is higher than wakefulness consist of the anterior cingulated cortex, the amygdala and the limbic-paralimbic regions, and the associated visual areas [3].

Each sleep cycle (NREM sleep + REM sleep) lasts about 90 min. Most people repeat this cycle four times a night, for a total of approximately 6–8 h of sleep. REM sleep time elongates with each repeating cycle, and a comfortable wake-up is best just after the end of a REM sleep period. The alternation between NREM and REM sleep is the outcome of a balanced action based on the cyclic function of the brainstem and forebrain structures.

## Sleep and the Different Memory Systems: Declarative and Non-Declarative Procedural Memory

Human memory has been subjected to several different classification schemes, the most popular being based on the distinction between declarative and non-declarative (procedural) memory. Non-declarative memory includes procedural memory ("knowing how") learning of actions, habits, and skills, as well as implicit learning. This type of memory system appears to be less dependent on medial temporal lobe structures. Declarative memory is comprised of the consciously accessible memories of fact-based information. Current neural models of declarative memory formation emphasize the critical importance of structures in the medial temporal lobe, including the hippocampus, a structure that is thought to form a temporally ordered retrieval code for neocortically-stored information.

The evidence for sleep-dependent consolidation of declarative memories is less consistent. Many earlier experiments investigated the effects of classic tests of declarative memory (verbal learning tasks) on REM sleep changes following training. More recently, verbal (recall of paired–associated word lists) and non-verbal declarative memory were investigated through a subject's ability to recall spatial locations in memory rotation tasks, and findings showed improved recall spanning the early sleep interval, rather than late sleep interval, and the corresponding intervals of wakefulness. While the results were taken to mean that in addition to REM sleep, NREM also exerted a selective facilitation of declarative memory consolidation in humans, they may actually just reflect the nature of the word pairs used: unrelated word pairs such as dog-leaf for earlier and related pairs such as dog-bone for later. Other findings on declarative memory suggest that following initial practice of a numeric sequence problem-solving task, a night of sleep can trigger insight into a hidden rule(?) and thus improve performance strategy the following morning.

In contrast to the declarative memory system, there have been robust and consistent findings that across a wide variety of functional domains, including visual, auditory and motor systems, procedural memory relies on sleep. The results from many reports seem to support the hypothesis of sequential processing of memories during sleep stages, suggesting that memory formation is promoted by NREM and then consolidated by REM sleep. Accordingly, the amount of sleep-dependent improvement on a perceptual learning task is linearly correlated with the amount of NREM during the first quarter of the night and with the amount of REM sleep in the last quarter.

The beneficial effect of sleep on procedural memory has also been investigated through motor skill learning tasks. A night of sleep can trigger significant performance improvements in speed and accuracy on a sequential finger-tapping task, while equivalent periods of awake time provide no significant benefit. These sleep-dependent benefits appear to be specific to both the motor sequence learned and the hand used to perform the task. Furthermore, overnight learning gains seem to correlate with the amount of stage 2 NREM sleep. A complex procedural motor adaptation task requiring hand–eye coordination was introduced. The extent of the local parietal lobe increase in slow-wave activity in the first 90 min of sleep strongly correlated with subsequent performance enhancement (learning) observed the next day, showing a close relationship between local EEG activity and subsequent regional slow-wave activity homeostasis.

It has been shown that periods of awake time following training on a synthetic speech recognition task result in a degradation of task performance, while a subsequent night of sleep can restore performance to post-training levels. Hence, it appears that there is a process of sleep-dependent consolidation capable of reestablishing previously learned complex auditory skill memories. Faced with such consistent and reproducible findings on sleep-dependent visual, auditory, and motor skill learning, it seems difficult to refute the claim that sleep is necessary for the consolidation of human procedural skills, the restoring of previously decayed memory traces, and the triggering of additional learning.

On the whole, recent findings have generally been interpreted as supportive of the notion that early night NREM and late night REM play a fundamental role in the consolidation of procedural memories in humans, while NREM-rich sleep seems to have facilitating effects for declarative memories.

Studies with monoamine oxidase inhibitors and other REM suppressing antidepressants have proven that REM sleep plays no role in memory consolidation, and thus the argument arose that such REM suppressants could be taken for years with no deleterious effects on memory. However, there are some arguments for the reemergence of REM sleep with chronic drug treatment and REM rebound with drug withdrawal.

## Sleep-Dependent Brain Plasticity

Memory formation depends on brain plasticity-lasting structural and/or functional neuronal changes in response to stimuli from an individual's experiences. If sleep is to be considered a critical mediator of memory consolidation, then evidence of sleep-dependent plasticity would greatly strengthen this claim. Indeed, there is now a wealth of data describing sleep-dependent brain plasticity at a variety of different levels thanks to neuron-imaging studies, electrophysiological studies, and cellular molecular studies in both animals and humans, complementing evidence of sleep-dependent changes in behavior. Findings of sleep-dependent plasticity in the visual cortex of the rat suggest that REM sleep, in conjunction with visual stimuli, modulates the initial course of visual cortex maturation. At the molecular level, administration of protein synthesis inhibitors to rats during REM sleep windows, a time thought to be critical to consolidation, prevents behavioral improvement following the sleep period. Thus, learning and memory are dependent on processes of brain plasticity, the same processes that must also mediate sleep-dependent learning and memory consolidation. Many examples of such plasticity during sleep have now been reported, several of which were specifically induced by experiences that took place during awake time.

## Sleep and Academic Performance

As sleep has a relevant role in facilitating learning and memory processes, and since sleep deprivation and/or fragmentation usually impair these functions, the effect of sleep patterns and schedules on academic performance is an area of interest. In terms of an indirect link between sleep and academic performance, it was shown that students with more regular sleep-wake patterns (shorter sleep latency, fewer night awakenings, later school rise times, earlier rise times on weekends) reported a higher grade point average, whereas students with lower grades reported increased daytime sleepiness, also as a consequence of less sleep at night [4].

## Orexins, Narcolepsy and Memory

Endogenous ►orexin, also referred to as hypocretin, may be involved in multiple functions including arousal, the sleep-wake cycle, sleep disorders, and learning and memory. Orexin is the common name given to a pair of highly excitatory neuropeptide hormones. The two related peptides (orexin A and B), are produced by cleavage of a single precursor protein. Although these peptides are produced by a very small population of cells in the lateral hypothalamus [5], they send projections throughout almost the entire brain. The orexin system was initially suggested to be involved in the stimulation of food intake, and later in sleep regulation because of dysfunctional orexin and its association with the sleep disorder ►narcolepsy. Orexin neurons strongly excite various brain nuclei with roles in wakefulness and the dopamine, norepinephrine, histamine, and acetylcholine systems.

Orexin A enhances normal long-term potentials (LTP) in medial perforant path – dentate granule cell synapse in the hippocampus. Given the well-documented involvement of monoaminergic and cholinergic neurotransmitter systems over a wide range of memory processes,

memory impairments might accompany the sleep symptoms seen in narcolepsy.

The main characteristic of narcolepsy is an overwhelming excessive daytime sleepiness, even after an adequate night of sleep. A person with narcolepsy is likely to become drowsy or fall asleep, often at inappropriate times and places. Daytime naps can occur several times a day. Drowsiness may persist for prolonged periods of time, and nighttime sleep may be fragmented by frequent awakening.

In narcolepsy, the order and length of NREM and REM sleep periods are disturbed, with REM sleep occurring at sleep onset instead of after a period of NREM sleep. Thus, narcolepsy is a disorder in which REM sleep appears at an abnormal time. When narcolepsy patients were compared to matched control subjects on a range of tasks that measured attention, memory and executive control, impairments were only observed during the attention and executive function tasks, which involved higher demands on inhibition or task management abilities. The relatively routine memory and attention tasks yielded intact performances in the narcolepsy patients. Thus, the overall pattern of results indicates an executive control deficit that occurs with narcolepsy that might be related to a reduction of available cognitive processing resources because of the need for continuous allocation of resources toward monitoring and maintaining vigilance.

## Memory Distortion

Daniel M. Bernstein[1], Elizabeth F. Loftus[2]
[1]Department of Psychology, Kwantlen University College, Surrey, BC, Canada
[2]Departments of Psychology and Social Behavior, Criminology, Law and Society, Cognitive Sciences, University of California, Irvine, Irvine, CA, USA

### Synonyms

False memory; Memory illusions

### Definition

Memory distortion refers to a memory report that differs from what actually occurred.

### Characteristics

Memory's fate is determined by factors present at encoding (when the memory is first recorded), storage (how and where the memory is represented in the brain), and retrieval (when the memory is reported). The level of attention paid to the original event, the time that passes after the original encoding, the match between encoding and retrieval contexts, and the presence of competing and interfering information in memory are but a few of the factors that determine memory accuracy. Memory records experiences. The recording includes sensory information like sight, sound and touch, as well as emotions, thoughts, and feelings about the experience. These details are stored in a distributed fashion throughout the brain, making it difficult if not impossible to localize any particular memory trace in the brain [1].

The British psychologist, Sir Fredrick Bartlett [2] demonstrated the constructive nature of memory. Bartlett examined the fate of memory, and concluded that memory undergoes typical transformation over time including omissions, deletions and distortions. In one of Bartlett's most famous experiments, British subjects read a Native American folktale called the War of the Ghosts in which a battle occurs between two warring tribes. Using a

method called serial reproduction (akin to the child game called "telephone"), one subject would recall the story in as much detail as possible. Another subject would read the first subject's account of the story and then try to recall it, followed by additional subjects reading the account of their immediate predecessor and trying to recall it. This method revealed that memory for the original story undergoes massive distortion after very few repetitions.

## Memory Distortion Techniques

Many techniques have been shown to distort memory. A partial list of techniques includes misinformation, outcome information, semantic relatedness, suggestion, imagination, and more subtle manipulations such as subliminal repetition and unscrambling. Each of these techniques reveals the inherent fallibility of memory.

In the early 1970s, researchers began to explore the effects of misleading post-event information on memory for events. In one study, subjects viewed a simulated vehicle-pedestrian accident. Some subjects watched as a car approached an intersection and stopped at a stop sign. The car then turned right and hit a pedestrian who was crossing the street. After viewing the accident, some subjects were asked a question that suggested it was a yield sign. Later subjects had to report on the sign they had actually seen, and many subjects who received the misinformation incorrectly recalled seeing the opposite sign. In related work, researchers showed how the wording of a question during an eyewitness interview affects memory for what was seen. For example, subjects who viewed an accident on film and were asked, "About how fast were the cars going when they smashed into each other?" reported greater speed than did subjects who were asked, "About how fast were the cars going when they hit each other?" Additionally, those who were asked the "smashed" question were more likely to report having seen broken glass than subjects who were asked the "hit" question, even though no broken glass had appeared. Thus, simple word choices can distort memory for details of an event [3].

In a related paradigm involving post-event information, subjects predicted the outcome of an event that had not yet occurred. After finding out the true outcome, they were asked to remember what they originally predicted. For example, prior to Nixon's 1972 visit to China and the Soviet Union, subjects were asked to provide probability estimates for various outcomes: President Nixon will meet Chairman Mao; President Nixon will declare the trip a success. Even when told to ignore the true outcome, most subjects adjusted their original estimates to concur with the actual outcome, thereby claiming that they "knew it all along." This hindsight bias has been demonstrated using a variety of materials and sensory modalities, including verbal, visual, and even gustatory judgments [4]. Like the misinformation effect, hindsight bias is a form of memory distortion that is influenced by outcome information that conflicts directly with one's original memory.

Other techniques show how easy it is to distort memory for details of prior experience. For example, consider the following set of words: bed, rest, awake, tired, dream, wake, night, blanket, pillow. Most people who hear or read a similar list will mistakenly recall hearing or seeing the word, "sleep" in the original list. The fact that the words in the list are all semantically related to the critical word, "sleep" causes the vast majority of people to misremember [5]. Semantic relatedness also underlies another common form of memory distortion called ►conjunction errors. These errors occur when people fuse together in memory aspects of an event or experience. For example, subjects who read the words, blackboard and jailbird often mistakenly remember having read the conjunction word, blackbird. Again, these examples demonstrate how easy it is to distort people's memory for details of a prior experience [6].

But is it possible to distort memory in a larger way, namely by making people believe that they experienced a whole event in the past that never occurred? The answer is, "yes." Simply by suggesting to adults that they had experienced a particular event in their childhood, like being lost in a shopping mall for an extended period of time or being hospitalized overnight for an ear infection, investigators have created ►false memories for whole events in their subjects' minds. In such studies, researchers often use a form of strong suggestion where they might tell a subject that a family member reported the event in question or that the subject's dreams suggest that she had a particular unpleasant experience as a child. For instance, researchers might tell the subject that "most" people under the age of five have been attacked by a dog. The purpose of such suggestive techniques is to increase the plausibility of the false event. Researchers might also ask their subjects to imagine the false event in detail: "Even if you do not recall the event, just try to imagine what it was like. Where were you when the event occurred? Who were you with? What were you doing? How did it make you feel?" Imagination serves to imbue the false memory with sensory details, and often leads people to adopt the false memory as part of their autobiography [3].

In contrast to the more obvious forms of suggestion that distort memory for the past, memory can be distorted by more subtle means. Consider the phenomenon called unconscious plagiarism, in which a person inadvertently claims ownership of an idea that belongs to someone else. There are numerous examples of unconscious plagiarism, including cases of accusations against high-profile individuals like the writer, Helen Keller and the singer, George Harrison. Unconscious plagiarism relates to priming in that the information or idea, once heard or read from another source, may return to one's memory

later without the person realizing that the information was encountered before. Another related form of memory distortion, called unconscious transference, occurs when an eyewitness to a crime adamantly declares that a certain person was the "one" who committed the crime simply because this certain person looks familiar. For example, the memory researcher, Donald Thomson, was accused of rape after appearing on live television in Australia. The victim in this case was raped while watching the television program featuring Dr. Thomson. Thus, the fact that the victim had seen Thomson's face before, albeit in another context that was linked to the rape, was enough to lead her to believe that Thomson was the rapist.

Given the variety of memory distortions that have been observed and created in laboratory experiments, what is the evidence that memory distortion also happens in the real world? Unfortunately, all-too-meaningful therapists, seeking to help a client, may encourage their client to plumb the depths of memory for clues that might help explain the client's problems. Although potentially therapeutic, this tactic sometimes backfires: Therapists have been known to implant false memories in their clients, often using many of the techniques that we have discussed here, like suggestion and imagination. These implanted false memories have resulted in innocent people being sent to prison, and have caused lasting and irrevocable damage to family unity and trust. Related to this issue of false memory, is the issue of repressed memory. ►Repressed memory refers to the hypothesized notion that the mind banishes traumatic experiences from conscious awareness due to the memory's threatening nature. This memory, once repressed, may return to consciousness at some later point in a person's life. The resulting memories are thought to be accurate in detail, and the processes involved different from ordinary forgetting and remembering. Although there is clear experimental evidence that false memories exist, there is at present no direct experimental evidence for repressed memories.

By now, it should be clear that memory is malleable. Given the variety of techniques that can and have been used to distort memory, one might ask how these techniques work.

## Proposed Mechanisms

Several theories have been proposed to explain the formation of false memories and memory distortion. We focus here on three of these theories. According to the *Source Monitoring Framework*, people routinely monitor their memory for accuracy. ►True memories tend to elicit more sensory and contextual detail, for example, "It was a rainy afternoon when I saw the accident. I remember that my jacket was drenched and my shoes squished when I walked. The car turned at the intersection and hit the pedestrian in the crosswalk." False memories, however, can also contain sensory detail. This makes it particularly difficult to distinguish between true and false memories. The Source Monitoring Framework argues that techniques such as imagination serve to create memory traces that sometimes can be distinguished from actual experiences stored in memory. The problem is that over time it becomes harder to monitor the origin of information coming from different sources like imagination, perception and action, resulting in source monitoring errors and false memories [7].

Another theory, related to source monitoring, involves what is called *Familiarity Misattribution*. According to this theory, techniques like suggestion, imagination, repetition and unscrambling serve to increase the fluency with which a person processes an event or experience. By fluency, we mean that the experience is processed more quickly. Consider imagination and repetition. Both techniques serve to prime an individual to process an event or experience more quickly. After imagining an event in detail, the event will be processed more quickly and fluently when the person subsequently thinks about it. In this way, the event seems to "spring" to mind. Similarly, repetition speeds subsequent processing. For example, if I present the word "window" to you, and then sometime later ask if you ever broke a window as a child, you will process the word "window" more quickly the second time you see it. This means that you will read and understand the word "window" faster than if you had not seen that word presented earlier. Just like with imagination, we tend to interpret the enhanced processing fluency as familiarity. So, the event, "broke a window" might now feel somehow familiar to you. If you fail to realize that the event feels familiar because you saw the word, "window" earlier, then you may mistakenly claim that you broke a window as a child [8].

One final theory that we discuss, called *Fuzzy-trace theory,* divides memory into two types of traces. Verbatim traces store sensory information, while gist traces store semantic information. Verbatim-based memory relates to detailed recollection of past experience, while gist-based memory relates to familiarity for past experiences [9]. Both types of memory traces can produce true and false memory; however, true memory is more often associated with verbatim traces, while false memory is more often associated with gist traces. Returning to our memory-distortion techniques, the suggestion that one was lost in the mall as a child leads to many different associations with malls. The person receiving this suggestion might begin to think about different, actual experiences that she did have in malls as a child. She might even think about how she would feel if she were lost in the mall. These associations, thoughts, and emotions would be stored as gist-based memory traces. When later asked about the event in question "were you ever lost in the mall as a child," the event will likely feel familiar. If our imaginary subject fails to realize the source of this familiarity – that

last week the experimenter told her that she had been lost in the mall as a child – she will mistakenly come to believe that the event actually occurred.

Thus, source monitoring, familiarity misattribution and fuzzy trace theory all posit that people routinely monitor their memory for accuracy. Failure to distinguish among potential sources (e.g., I imagined the broken glass, I saw the broken glass, I only heard the broken glass) can result in memory distortion.

### Memory Distortion and Brain

Much work over the past decade has focused on the neural regions supporting true and false memory. In search of a neural signature of true and false memories, researchers have employed a variety of neuropsychological, neuroimaging, and electrophysiological techniques. These include lesion studies, Positron Emission Tomography (PET), functional Magnetic Resonance Imaging (fMRI), electroencephalogram (EEG), event-related potentials (ERPs), and more recently transcranial stimulation, and near-infrared spectroscopy. A consensus is beginning to emerge that true and false memories activate different brain regions, leading some investigators to claim that they have located a neural signature of false memories. Specifically, the medial temporal lobe has been implicated in false recognition, while the prefrontal cortex has been implicated in memory monitoring errors [7,10]. Despite these advances, some studies have also found that true and false memories activate similar brain regions, including prefrontal cortex, parietal cortex and medial temporal lobe. There is at present growing excitement in the field of cognitive neuroscience. As this field advances, it should soon be possible to distinguish true from false memories reliably and consistently by observing brain activation. Someday it may even be possible to determine the veridicality of one's memory for an individual event simply by looking at the person's overall pattern of brain activity.

# Memory Dysfunction

►Amnesia

# Memory-guided Saccade Task

### Definition

A task in which a target is briefly presented at the same time that the subject continues to look at a fixation point. The subject is not allowed to make a saccade to the target until after the fixation point is extinguished, usually 0.5–3 s after the target disappears. Thus the subject must make a saccade to the remembered location of the target.

►Saccade, Saccadic Eye Movement

# Memory-guided Saccades

### Definition

A type of saccadic eye movement that is directed to a remembered target. The target position is indicated while the subject is fixating at the center and then the subject is required to make a saccade to the remembered position.

►Saccade, Saccadic Eye Movement

# Memory Illusions

►Memory Distortion

# Memory Impairment

►Amnesia

# Memory Improvement

## Synonyms

Cognition enhancement

## Definition

Memory improvement refers to the enhancement of cognitive functions such as attention, learning and memory without affecting other physiologic functions in subjects with cognitive deficits as well as in healthy subjects.

## Characteristics

### Conditions

Learning is the acquisition of new information or knowledge. Memory is the retention of learned information. Certain diseases and injuries to the brain cause a serious impairment of learning and memory, the condition known as amnesia. Amnesia following brain trauma has two different forms; ►anterograde amnesia and ►retrograde amnesia. Transient global amnesia is an inability to form new memories (anterograde amnesia), which lasts less than 24 h, and is not associated with other focal neurological signs or symptoms. This type of amnesia can be induced by brief cerebral ischemia, in which the blood supply to the brain is temporarily reduced, or concussion to the head from trauma such as a car accident. There is also retrograde amnesia for recent events before the attack. ►Anxiolytic agents such as benzodiazepines, muscarinic acetylcholine (ACh) receptor antagonists such as scopolamine, and N-methyl-D-aspartate (NMDA) receptor antagonists are known to induce memory impairment in humans and experimental animals. Some neuropsychiatric diseases, including Alzheimer's disease, mild cognitive impairment, vascular dementia, and schizophrenia, are accompanied by memory impairment or loss.

### Alzheimer's Disease

Alzheimer's disease is the most common cause of senile dementia, which is characterized by the presence of numerous senile plaques, neurofibrillary tangels accompanied by neuronal loss. The cholinergic neurons that project from the medial septal nuclei and basal nucleus of Meynert to the hippocampus and cerebral cortex, respectively, play an important role in learning and memory. Degeneration of the basal forebrain cholinergic neurons is correlated with cognitive deficits in Alzheimer's disease. The so-called "cholinergic hypothesis" proposed in the early 1980s essentially states that a loss of cholinergic function in the central nervous system contributes significantly to the cognitive deficits associated with aging and Alzheimer's disease [1]. Based on the hypothesis, agents that can enhance cholinergic function have been developed to improve memory deficits in Alzheimer's disease. An alternative hypothesis regarding the mechanism of Alzheimer's disease is that excessive activation of glutamate receptors may be responsible for the neuronal loss observed in those with the disease. Although it is unlikely that glutamate-mediated excitotoxicity is the primary etiopathological factor in Alzheimer's disease, it may partly contribute to the neurodegeneration. Supporting this idea, memantine, an uncompetitive NMDA receptor antagonist with moderate affinity, has been approved in Europe and USA for the treatment of moderate to severe Alzheimer's disease. In addition, various ►neuroprotective agents with diverse mechanisms of action have been proposed for treating Alzheimer's disease [2]. The dominant hypothesis regarding the etiology and pathogenesis of Alzheimer's disease is the "amyloid cascade hypothesis": Amyloid β produced by the amyloidogenic processing of amyloid β precursor protein triggers a neurotoxic cascade, thereby causing neurodegeneration and Alzheimer's disease [3]. According to the amyloid cascade hypothesis, there are several possible molecular targets for treating Alzheimer's disease [2].

### Mild Cognitive Impairment (MCI)

Mild cognitive impairment is regarded as a transition phase between healthy cognitive ageing and dementia. Accordingly, clinical studies of elderly individuals with memory impairment reveal a rapid rate of conversion to Alzheimer's disease, reaching as high as 15% per year. Recognition that MCI may represent a transition phase between normal cognitive decline by ageing and dementia will provide a possible early diagnosis and potential treatment with the aim of delaying the onset or preventing dementia [4].

### Vascular Dementia and Stroke

Vascular dementia, the second most common form of dementia, is a term currently used to define any

type of dementia resulting from cerebral blood vessel disease. The classification of vascular dementia is based on the following main diagnostic points: cognitive deficits, a history of stroke and/or focal vascular neurological deficits, neuroimaging showing neurovascular focal or diffuse lesions, and a temporal association between stroke and the onset of dementia. Among the risk factors for vascular dementia, hypertension has a major role. An elevated blood pressure measured in midlife increases the risk of dementia or accelerates age-related cognitive decline. Clinical studies have demonstrated that donepezil, an acetylcholinesterase (AChE) inhibitor, has significant effects on the cognitive deficits of vascular dementia [5]. In stroke victims, the ischemic vascular bed is composed of a core area where cerebral blood flow (CBF) is severely decreased and a more distal penumbra with less severely affected CBF. The penumbra is the focus of new therapeutic targets because it may be salvaged with restored circulation, and prevention of cell death may be possible with neuroprotective agents. Several compounds such as NMDA receptor antagonists, calcium channel blockers, radial scavengers, and antioxidants have shown neuroprotective effects in animal models, but have failed to be effective in human clinical trials [6].

## Schizophrenia

Schizophrenia is a chronic mental disorder characterized by psychosis (e.g., hallucinations and delusions), flattened emotions, and impaired cognitive function. There are no drugs that can effectively treat the cognitive dysfunction in patients with schizophrenia. The areas of impaired function are verbal learning and memory, working memory, visual learning and memory, speed of processing, reasoning and problem solving, attention and vigilance, and social learning [7]. The "NMDA receptor hypofunction hypothesis" has been proposed for schizophrenia because NMDA receptor antagonists such as phencyclidine and ketamine induce a schizophrenia-like spectrum of symptoms in healthy subjects and exacerbate symptoms in patients with schizophrenia. Hypofunctioning of NMDA receptors contributes to the pathophysiology of schizophrenia, especially those symptoms associated with the endophenotype such as cognitive impairment and negative symptoms [8]. According to the hypothesis, agents that enhance NMDA receptor function may ameliorate the cognitive impairment and negative symptoms in patients with schizophrenia. Because an excessive activation of NMDA receptors could lead to excitotoxicity and neuronal degeneration, an indirect enhancement of NMDA receptor function with agonists acting at the glycine modulatory site on NMDA receptors would be required for the treatment of schizophrenia [8]. Ampakines that bind to a site on the AMPA receptor and stabilize the receptor in its channel-open state following the binding of glutamate are also promising candidates for agents to treat cognitive dysfunction [9]. Furthermore, there are possible molecular targets for treating cognition in schizophrenia such as dopamine $D_1$ receptors, serotonin 5-$HT_{1A}$, 5-$HT_{2A,}$ and 5-$HT_6$ receptors, muscarinic and nicotinic ACh receptors, and GABA receptors [7].

## Cognitive Enhancers

Various agents with different chemical structures and diverse mechanisms of action are currently being investigated as a ►cognitive enhancer or ►anti-amnesic agent to improve cognitive functions such as learning and memory. They include AChE inhibitors, and muscarinic and nicotinic ACh receptor agonists. Alternatively, agents that directly or indirectly activate the glycine modulatory site on the NMDA receptor complex, ampakines, and ►sigma-1 receptor ligands may provide memory improvement in those with cognitive disorders. Furthermore, neuroprotective agents that can protect neurons from various neurotoxic substances including glutamate, amyloid β, and free radicals may afford memory improvement in cases where cognitive deficits are associated with neurodegenerative diseases, such as Alzheimer's disease and cerebral ischemia.

## AChE Inhibitors

The cholinergic system in the cerebral cortex and hippocampus plays an important role in learning and memory. Degeneration of the basal forebrain cholinergic neurons is correlated with cognitive deficits in Alzheimer's disease. Therefore, enhancement of cholinergic function would lead to an improvement of memory deficits in those with Alzheimer's disease. One of the pharmacologic strategies used to enhance cholinergic function is to inhibit the decomposition of ACh into choline and acetic acid, which is catalyzed by AChE. Four AChE inhibitors (tacrine, donepezil, rivastigmine and galantamine) have been approved so far for the treatment of Alzheimer's disease [2].

## Muscarinic ACh Receptor Agonists

The direct activation of muscarinic ACh receptors is supposed to improve cognitive deficits in Alzheimer's disease as well as other neuropsychiatric diseases. Muscarinic M1 receptors are predominantly present in the frontal cortex and hippocampus, while M2 and M3 receptors predominate peripherally where they mediate effects on cardiovascular, respiratory, and secretory systems. Accordingly, specific M1 receptor agonists are supposed to ameliorate cognition impairment with few peripheral side effects associated with the stimulation of M2 and M3 receptors. However, no muscarinic M1 receptor agonists have been approved so far because of their side effects [2,7].

### Nicotinic ACh Receptor Agonists

The activation of nicotinic ACh receptors with selective agonists may have some beneficial effects on the cognitive deficits in patients with Alzheimer's disease and/or schizophrenia. Nicotinic ACh receptors are ligand-gated cation channels, the neuronal subtypes of which (α7 and α4β2) are highly permeable to $Ca^{2+}$. Thus, nicotinic ACh receptors modulate neurotransmitter release and synaptic plasticity, and thereby improve cognition. Moreover, accumulated evidence demonstrates that nicotine and subtype selective nicotinic ACh receptor agonists have neuroprotective effects in the brain. For instance, nicotine provides neuroprotective effects against glutamate and amyloid β toxicity via α7 nicotinic ACh receptors. Galantamine, a weak AChE inhibitor, allosterically modulates nicotinic ACh receptors and improves Alzheimer's disease [2,7].

### Ampakines

Ampakines bind to a site on the AMPA-type glutamate receptor, and stabilize the receptor in its channel-open state following the binding of the neurotransmitter glutamate, with no agonistic or antagonistic effects. Thus, ampakines prolong current flow through AMPA receptors and enhance synaptic responses. Ampakines accelerate learning, reduce age-related memory impairments, and suppress symptoms in models of schizophrenia, attention-deficit hyperactivity disorder, and depression [9].

### Glycine Modulatory Site Agonists

NMDA receptors play an important role in the synaptic plasticity associated with learning and memory. The activation of NMDA receptors requires the binding of L-glutamate to the NR2 subunit and a co-agonist (D-serine or glycine) at the glycine modulatory site on the NR1 subunit. D-serine is abundant in the forebrain and the expression is correlated with that of NMDA receptors. The glycine modulatory site is not saturated so that the activation could potentially modulate responses of the NMDA receptors. According to the NMDA receptor hypofunction hypothesis, enhancement of NMDA receptor function with agonists at the glycine modulatory site could have benefits in the treatment of schizophrenia. The results of clinical trials are encouraging with D-serine having a beneficial effect on the positive, negative, and cognitive domains of schizophrenia [8].

### Sigma-1 Receptor Ligands

Sigma receptors are widely distributed in the mammalian brain, and recognize a diverse array of compounds, including opiates, antipsychotics, antidepressants, phencyclidine-related compounds, and neurosteroids. Two sigma receptor subtypes have been identified, and the sigma-1 receptors have been cloned. Sigma-1 receptors regulate NMDA receptor function and the release of neurotransmitters such as ACh and dopamine. Accordingly, selective sigma-1 receptor ligands have been suggested to represent a new class of therapeutic agents for neuropsychiatric disorders [10].

## Meningism

### Definition

A syndrome of headache and neck stiffness with flexion indicative of meningeal irritation. This syndrome may be found with viral or bacterial meningitis or subarachnoid hemorrhage.

►Headache

## Meningitis

### Definition

An inflammation of the membranes (dura mater, arachnoid mater and pia mater) covering the brain and spinal cord due to infectious, immune-related or paraneoplastic (associated with cancer) causes, injury or medication. Infectious causes of meningitis include bacteria, viruses, fungi, parasites and protozoa. Symptoms typically begin with non-specific flu-like symptoms: fever, headache, eye pain, back pain, malaise, myalgias and sometimes a rash, then proceed to stiffness and pain of the neck (meningismus), change in mental status or coma, and at times weakness, cranial nerve dysfunction, or seizures. Diagnosis is confirmed by demonstration of increased number of white blood cells in the cerebrospinal fluid (pleocytosis) or contrast enhancement of the meninges on computerized tomography or magnetic resonance imaging.

## Meningoencephalitis

### Definition

Inflammation of the brain and meninges. Also called cerebromeningitis, encephalomeningitis, and meningocerebritis.

.

## Meningoencephalomyelitis

### Definition

Inflammation of the meninges, brain, and spinal cord.

.

## Meningovascular Syphilis

### Definition

Meningovascular syphilis manifest itself ca. 2 years after the primary infection and presents with cerebrovascular accidents, cranial nerve palsies, and often convulsions.

## Mental Causation

### Definition

"*Mental causation*" is a term for the causal interaction between mental and physical phenomena. Although it applies to physical-to-mental causation and mental-tomental causation no less than to mental-to-physical causation, it is customarily reserved for instances of mental-to-physical causation, as when a sharp pain makes one wince, fear makes the heart beat faster, remembering an embarrassing situation makes one blush, and Fred's desire for beer and his belief that there is beer in the fridge cause him to go to the fridge.

►Epiphenomenalism

## Mental Development

### Definition

Cognitive development. Changes with age in human ontogeny in mental processes and abilities, that is, the development of higher mental processes such as problem solving, reasoning, conceptualizing, classifying, and planning, as well as more basic processes such as perception and language.

►Cognitive Development

## Mental Models

Verena Gottschling
Department for Philosophy, York University, Toronto, ON, Canada

### Definitions

Kenneth Craik was the first to introduce the term "mental model." He contends that humans translate external events into internal mental models and that ►reasoning takes place by manipulating these models. Then, either the resulting symbols are in turn translated into actions, or recognition of a correspondence between these symbols and an external event occurs. Hence, for Craik a mental model is mainly a simulation of the world; this simulation also has a structure similar to that of the simulated process.

Subsequently, various mental model accounts have been introduced. Apart from their labels, these accounts have little in common other than the fact that internal representations are involved. Indeed, the term "mental model" is sometimes used as a synonym for "►mental representation."

In our days, the term "mental model" is used mainly to refer to Philip Johnson-Laird's mental models account. According to Johnson-Laird, a mental model is a special kind of mental representation – either long-term or short-term knowledge – whose structure is isomorphic to the structure of the situation it represents, and in which no free variables are found.

### Characteristics

#### Description of the Theory

Mental models are thought to be the result of several cognitive processes, and they are assumed to play a role in central cognitive processes like comprehension, reasoning, and discourse. [1] They are internally generated models of situations, scenes, or objects and can play a role in very different situations. But besides this, it turns out to be surprisingly difficult to determine precisely what mental models are. As we will see, mental models can be short-term or long-term representations, conscious or unconscious representations, and they can be voluntarily or spontaneously generated. We can distinguish mental models in discourse, in perception, and in reasoning processes. I will consider them in turn. A further tricky issue is to determine the role mental models play in another cognitive capacity, namely visual imagination and mental imagery.

#### Mental Models in Discourse

Mental models are considered to be representations that can be constructed during verbal discourse. Descriptions of complex situations lead us to construct a mental model of the situation and read out information that is only implicitly contained in the description. For example, by using a mental model in working memory we envisage the setting of a verbal description. Consider: "Watson enters the kitchen from the right door, at the opposite end Holmes was kneeling beside the crying victim, whereby the glistering sunshine from the window nearby threw light on the scene, even if the rest of the kitchen was relatively dark." This assertion establishes a relation between several entities, Holmes, Watson, and other elements of the scene, the door, and the window. We can infer that the victim is at the left side of the kitchen on the basis of a mental model we construct. This mental model is isomorphic to the situation described, and contains at least three mental tokens, corresponding to Watson, the unnamed victim, and Holmes. Furthermore, these tokens are interrelated

in a way that corresponds to the spatial relation between them. According to Johnson-Laird, these discourse models make explicit the structure of situations as we perceive or imagine them.

## Mental Models in Perception

Mental models are also supposed to play a role in perception, especially in vision. Vision is characterized as a multi-stage process. It is accomplished in three separable and successive processing states often referred to as low-level, intermediate-level and high-level vision.[1] Cognitive neuropsychologists distinguish successive states in vision roughly corresponding to David Marr's levels, together with three different levels of perceptual representations mentioned before [2].

Johnson-Laird's mental models have often been identified with high-level representations, that is, with viewpoint independent, three-dimensional models of the spatial relations between objects. Correspondingly, the most appropriate candidates for their neural correlates seem to be regions in the inferior-temporal cortex (IT) in the ventral system.

In contrast to high-level representations, the experienced percept, a viewpoint-dependent representation is typically identified either with low-level or intermediate representations. These representations are not object-centered, but strongly bound to knowledge about visual appearances – information that resides in the 3D representation described above. Therefore, images and percepts are restricted to a particular point of view; they are instances of categories stored in the conceptual system and generated from knowledge contained in 3D models.

Ray Jackendoff [3] proposes a related but different view. He sees the conceptualized world as divided between the "cognitive structure," which is approximately propositional, and the "spatial structure," which is geometric, but is nonetheless not restricted to a particular point of view, and more abstract than experienced images and percepts. In the cognitive structure, knowledge, like category memberships and properties, is encoded. The spatial structure[2], by contrast, is identified with Marr's 3D sketch and Johnson-Laird's mental models. Here, knowledge about visual appearance is encoded; these representations are 3D representations, which are roughly understood as images of prototypic instances of categories. Thus, they are imagistic, but no longer strictly visual. Additionally, they are abstract and support visual object categorization and identification. They are image-schemas, abstract structures from which a variety of different images can be generated and to which a variety of percepts and images can be compared. These representations are conceptual, they specify the configuration of the object's parts relative to one another, and encode possible shape variations of objects. But for Jackendoff, this structure is, to some degree, modality-independent[3]. Thus, elements in the spatial structure including mental models are not perceptual representations, but part of central cognition. The spatial structure is concerned with judgments and inferences having to do with shapes and locations and necessary for visual object categorization and identification. This structure includes all parts of the object, including hidden parts. It is not a simple three-dimensional object but a complex hierarchy of representations, which encode how objects can be regarded as assemblages of parts.

## Mental Models and Visual Images

Other authors do not distinguish between theories of visual imagery and mental model theories. They identify mental models and visual mental images. Pictorialist theories of visual imagery understand images as mental representations that function in the way pictures do, whereas the most important relations to be discussed are spatial relations. During the last years, participants in this debate moved away from an emphasis of pictorial representation and more towards perceptual representations. [4] The mental spatial representations they focus on are identical with perceptual representations, and are also thought to play an important role in reasoning and learning. But as in the case of identification with perceptual representations, the relation between mental models and visual images is controversial. Their possible relations can be summarized as follows:

1. Images and mental models are assumed to be different terms for the same entities.
2. Images are a subclass of mental models, very rich mental models within perception. "Mental models" is the more general term, though [5] mental models can take many forms and serve many purposes. A model can be a "physical" model and consist of elements corresponding only to perceptible entities, in which case it may be realized as an image, either perceptual or imaginary. Alternatively it can contain elements corresponding to abstract notions; in this case it would be a "conceptual" model.
3. According to Johnson-Laird's "triple-code" hypothesis [6], mental models are a different and more abstract format of mental representations than images. Images differ from mental models and need distinct processes, although they often function like models. But both sorts of representations are more closely related than the third kind of mental representations, namely propositional representations. Both mental

[1] They can be roughly identified with David Marr's three levels, the primary sketch, the 2.5D-ketch, and the 3D-sketch.
[2] Jackendoff's spatial structure makes use of Marr's 3D sketch and understands Biederman's geons as an extension.
[3] In contrast to Marr, who saw it as a part of vision, as the "perceptual front end."

models and visual images can be used in reasoning processes, but under some circumstances visual imagery can in fact impede reasoning [1,7]. There is a structural isomorphism between the represented situation and the representations in both cases. Both mental models and visual images are isomorphic, but differ with respect to the relations and properties that make up this structural isomorphism. In contrast to images, mental models are pure spatial representations. In mental models, visual characteristics like color, texture, and form can be neglected. Mental models are not restricted to a specific modality, they can contain symbols, and there may be only a minimal degree of analogical structure. Even tokens representing abstract concepts like negation, which are hard to visualize, are accredited. However, mental models can also be used to generate visual images. These images are assumed to be necessarily restricted to two dimensions, are conscious, and contain visual information.

All three views understand mental models as representations in working memory, in contrast to theories described above, which identify them only with the structures used to generate these representations. The situation is even worse: Imagery theorists describe the relation between visual images and mental models differently. The focus in the imagery debate lies in spatial relations as well. With regard to other typically "pictorial" properties the theories are more or less silent; it is not always assumed that images can only be two dimensional. It is controversial how strongly they are bound to concepts, as well as whether they have to be pictorial in a literal sense [4,8,9], and whether they are to be identified with patterns of activation in the visual system, and if so, which level this is. Sometimes image properties (such as color and texture) are assumed to be represented elsewhere in a more abstract format, and are connected by pointers to specific parts of the depictive representation. The main proponent of pictorialism, Steven Kosslyn, is sympathetic to these hybrid accounts. A related claim is that images are symbolic representations, but nonetheless modality-specific; they consist of a subset of neural activity associated with the corresponding visual perception. [10] Thus, images are basically representations using a spatial layout. In addition, images are not to be identified with the experience of having them. The imagery debate is rather about the format of the mental representations that come along with this experience. In other words, it seems we run into a similar problem than the one we already encountered: The term "image" is used in the same broad sense as "mental model."

## Reasoning in Mental Models

Mental model theory as a model-theoretical method is an alternative view to formal rule theories. Formal rule theories posit that deduction depends on formal rules of inference. In contrast, the main idea in the mental model theory of deduction uses the idea that instead of rules we use a special kind of mental representation in reasoning. We construct a model, or a set of models, based on such things as relevant background knowledge, meaning of the premises, and perceptual information. We then formulate a conclusion by describing a relation in the models that was not explicitly asserted in the premises. Finally, we check whether there are alternative models that comply with the premises but are incompatible with the conclusion. The conclusion is valid and necessary if the conclusion holds in all models of the premises. In cases of connectives like "if," "and," and "or" we construct a set of models in which each model represents a different possibility. The complete set of mental models describes exactly the cases where the compositional statement is true. Deductions that depend on quantifiers like "all" or "some" call for the construction of models containing sets of tokens, in which each token represents an individual. Again, we generate as many mental models as possible and check whether the conclusion is true. If we fail to find a mental model in which the conclusion is false, the composed statement is taken to be true. The underlying idea in mental model theory is again that the model or set of models represents the relation between the elements by isomorphism. Drawing the inference, then, is reading out the information that is implicitly contained.

An important advantage of mental model theory is that it covers not only deductive reasoning, but also probabilistic and ►modal logic. In probabilistic and modal cases, we need to adjust the description above: We do not talk about true or false statements, but about possible or impossible circumstances, propositions that might be true or false etc. A conclusion is impossible if it holds in no mental model; possible if it holds in at least one mental model; probable if it holds in most mental models; and necessary if it is valid in all mental models.

Furthermore, mental model theory gives us explanations for several systematically invalid conclusions people typically draw, i.e. they explain performance errors reasoners frequently make. These conclusions tend to correspond to just a single model instead of all possible models. Reasoners seem to fail to realize what is common in those multiple models. Mental model theory even predicts that reasoners will commit certain systematic fallacies. In the case of complex models, they construct models that are too simple and neglect some aspects. Content effects are to be expected as well. Logically untrained reasoners do not use formal rules, but rather, rely on their ability to understand the premises. Their models mirror their understanding of the situation, along with their background knowledge. The conclusions they draw are true with respect to their

models. Other systematic invalid conclusions are illusory inferences in probabilistic reasoning. Naïve individuals assume that each constructed model is equally probable, and wrongly infer the probability of an event from the proportion of models in which this event occurs.

For all these reasons, mental model theory in deduction can be seen as a strong alternative to formal rule reasoning.

## Mental Models and Central Cognition: Meta-Reasoning, Mindreading, and Theories of Concepts

In addition to reasoning associated with logical conclusions, mental models are assumed to play an important role in other central cognitive capacities such as meta-reasoning, i.e. reasoning about what other individuals have reasoned. Mental models are also thought to play a role in mindreading, our ability to understand and predict the mental states of our conspecifics. More precisely, they are assumed to play a role in developing central concepts for mindreading: In order to attribute mental states or to reason about other people's reasoning, I need to understand how a situation is represented from the perspective of other subjects. It is assumed that we use mental models during these processes.

In addition, the value of mental models for theories of concepts has recently been discussed. According to exemplar theories, concepts are stored instances of individual categories; they are perceptually derived mental representations. These stored representations can be activated in working memory to represent a category. Prototype theories and proxytype theories are related versions, which see concepts either as generated from perceptually derived individual representations (prototypes) or sets of prototypes (proxytypes). Again, mental models are frequently mentioned as paradigm examples for these representations. Since concepts play a role in almost all cognitive processes, these accounts would assign mental models a central role in cognition in general.

Let us take stock. According to the majority of mental model accounts, these representations are short-term representations. They are generated during reasoning processes, during discourse or in mental imagery, or as the result of visual perception. Sometimes the concept "mental model" is used for long-term representations as well, for example if mental models are identified with the underlying information used to generate short-term representations. Even if the term "mental model" is used for representations stored in long-term memory, these representations are assumed to have a similar structure to the representations used in working memory. Examples are accounts that treat mental models as schemas or stored prototypes of spatial representation, or accounts of concepts holding that they are long-term memory networks of perceptual representations. These accounts do justice to Johnson-Laird's central idea that mental models may be a central structure of cognition: "It is now plausible to suppose that mental models play a central and unifying role in representing objects, states of affairs, sequences of events, the way the world is, and the social and psychological actions of daily life." [5, p. 397]

## Problems With Mental Models

### *Mental Models: A Variety of Connected Concepts*

The most pressing problem in the debate is that the notion of a mental model is unclear and that proponents do not us the same characterization of "mental model." In other words, the central term is used both vaguely and ambiguously. Moreover, the term "mental model" is often used as an umbrella term covering all sorts of spatial representations. Researchers in Artificial Intelligence, linguistics, and psychology often seem to use mental models in this broad sense as well. Mental models are spatial representations of any kind. Moreover, authors who use the term in a stricter sense use it either for long-term representations or short-term representations. Different authors also explicitly use different characterizations. Unfortunately, these characterizations are probably incompatible. The term is used not only in different ways, but also in mutually exclusive ways.

### *Ockham's Razor*

The postulation of a special format of mental representations characterized by structural isomorphism is frequently accused of being unnecessary. The reason is that alternative explanations exist which postulate symbolic representations only. According to Ockham's Razor, entities must not be multiplied beyond necessity. As a result, the postulation of mental model is not warranted, or so the argument goes.

A standard reply is that the legitimacy of a postulated entity does not only depend on Ockham's Razor. More factors play a role, and Ockham's Razor is only warranted if the alternative explanations and predictions are comparable. Other criteria, such as physiological evidence, optimality, plausibility, and efficiency, give us additional constraints, and they help us to decide between theories that posit different kinds of representations. Consequently, advocates of mental models could argue, for example, by presenting empirical evidence for spatial representations in high-level vision and intermediate-level vision. They can also argue that mental models explain performance errors in reasoning, and systematic invalid conclusions people typically draw, in a more plausible way than rule-based reasoning theories.

### *Confusing Levels of Explanation? Properties of the Underlying Representations*

Related to the former two issues, another group of objections is frequently mentioned: We witness a confusion of levels in mental model theory. Mental models are supposed to be high-level representations, representations at the "representational level" (Marr). At this level we postulate *representations of different formats and algorithms*. We deal with representations of the input and output as well as an algorithm, which transforms one into the other. Another level of analysis is the implementation or *hardware level*, dealing with the physical realization of these algorithms and representations. According to the theory we outlined, mental models are representations which play an important role for explanatory projects at the representational level. It seems hasty to simply identify them with neural representations in the brain, representations postulated as elements within a different explanatory project. A related objection states that we should not identify these representations with the experiences we have during events of reasoning. For it is not clear that the experience during, for example, mental imagery, helps us to learn something about the properties of the representations used in these processes. This takes us to the classical interface problem: how do explanations at different levels (in the different disciplines) relate to one another? This is a question about the connection between the different explanatory projects and of the theoretical postulates at different levels. In other words, what does a successful inter-theoretical reduction look like? What are the requirements a theory has to fulfill in order to give an explanation for phenomena at a higher level? Unfortunately, the term "explanatory level" is not clear, nor do unambiguous criteria exist for distinguishing particular levels, or for specifying the notion of an explanatory (or analytical) level. It is clear though that the personal level and sub-personal levels of analysis should be distinguished. The former level of explanation deals with the explanation and prediction of behavior of the thinking and acting person, whereas lower levels of analysis explain the mind at sub-personal levels. If consciously experienced images (personal level) are identified with mental models (sub-personal level), or even specific retinotopic areas in the brain (a lower sub-personal level), it is tempting to suspect that we witness a confusion of levels. Another question is how the theoretical postulates in different accounts are related. Far from uncontroversial though, according to the classical view, the structure of "higher levels" of a system should not be assumed to be isomorphic, or even similar, to the structure of "lower levels" of a system. The same holds for the explanatory projects at these levels. Since the term "mental model" is used for structures at different levels, it invites confusion, to put it moderately.

But to say that the concept of mental models is an umbrella concept, and that some of the characterizations are even incompatible, does not imply that it is out of the question to develop a consistent explanatory account. Rather, a refinement and improvement of this concept is required.

# Mental Representation

## Definition

A theoretical construct of cognitive science. It is a basic concept of the Computational Theory of Mind, according to which cognitive states and processes are constituted by the occurrence, transformation and storage (in the mind/brain) of information-bearing structures (representations) of one kind or another. More broadly construed, a mental representation is a mental object with semantic properties, which need not be understood only in computational terms, but as a vehicle that refers to or denotes something, or as the relation between a thing and the object or state of affairs that it stands for.

►Mental Models

# Mental Rotation

## Definition

A particular type of mental image transformation abilities. The ability to mentally rotate representations

of two-dimensional or three-dimensional objects is conceived to be analogous to a physical rotation. Research showed that reaction times are linearly proportional to the difference in angle between two items when participants decide whether they are the same or not (i.e. a mirror image).

►Action Representation

## Mental States (States of Mind)

### Definition

The perceptions, beliefs, desires, hopes, fears and intentions of an individual.

►Theory Theory (Simulation Theory, Theory of Mind)

## Mentalizing, Mind-Reading

### Definition

The ability to attribute mental states to oneself and others in order to predict and explain thoughts, feelings and behavior.

## Merkel Cell-Neurite Complex Regeneration

Tamiko Tachibana[1], Chizuka Ide[2,3]
[1]Department of Oral Anatomy, Iwate Medical University School of Dentistry, Uchimaru, Morioka, Japan
[2]Department of Anatomy and Neurobiology, Kyoto University Graduate School of Medicine, Yoshidakonoe-cho, Sakyo-ku, Kyoto, Japan
[3]Department of Occupational Therapy, Aino University, Faculty of Nursing and Rehabilitation, Shigashiohta, Ibaragi, Osaka, Japan

### Synonyms

Merkel's corpuscle

### Definition

The Merkel cell-neurite complex is a slowly adapting type I mechanoreceptor that recognizes punctate pressure stimuli applied to the surface of the skin or oral mucosa.

The corpuscle is composed of a specific epithelial cell, the Merkel cell, discovered by F. S. Merkel in 1875, and an afferent axon terminal.

### Characteristics

#### Structure and Distribution

Merkel cell-neurite complexes are usually localized in the basal layer of the epithelium of the skin and oral mucosa. They are mainly distributed in areas of high touch sensitivity, including the digital pads, the vermilion border of the lip, ►touch domes of hairy skin, hair follicles, ►sinus hair, ►Eimer's organ and the epithelia of masticating oral mucosa [1].

Merkel cells are less electron-dense with scanty tonofilaments than epidermal cells, extending spur-like projections (1–2 μm long and ca. 0.2 μm wide) into the intercellular spaces between neighboring epithelial cells. An axon terminal containing numerous mitochondria and clear vesicles attaches to the Merkel cell like a disc at the basal surface, i.e., the side towards the basal lamina. Merkel cells contain many dense-cored granules of ca. 100 nm in diameter, which deviate in the cytoplasm towards the associated axon terminal. These granules contain bioactive substances such as neuropeptides, ATP, serotonin and glutamate [1]. Although the function of Merkel cells is still unclear, it has been proposed that Merkel cells serve as mechanoreceptors by the exocytotic release of neurotransmitters or neuromodulators from granules [1,2].

#### Regeneration

Following transection of the nerve innervating Merkel cell-neurite complexes, most Merkel cells (60–80%) disappear, while some survive without any contact with axons for an extended period [3,4]. Regenerating axons, after penetrating the basal lamina, make contact with those surviving Merkel cells. Although the number of Merkel cells decreases immediately after denervation, the original population of Merkel's corpuscles can be retained following re-innervation [4]. There are usually nerve-free Merkel cells in varying proportions in normal skin and oral mucosa. Approximately 4% of the total Merkel cells have no contact with axon terminals in the adult rabbit labial mucosa, in which the population of Merkel cells is estimated to be ca. 1,000 per 1 $mm^2$ [5]. A touch dome in the adult rat contains between 80–100 Merkel cells, of which only 50% or fewer are innervated [6]. It is considered that Merkel cells are targets of regenerating axons [6].

Merkel cells can newly differentiate in the epithelium of labial mucosa during wound healing in adult rabbits. These Merkel cells make contact with the regenerating

axons, and finally develop into structurally normal Merkel cell-neurite complexes [5].

It appears that Merkel cells probably develop from epithelial cells bordering the wound. On the other hand, a recent study has reported that Merkel cells are derived from the neural crest [7]. Interestingly, Merkel cells do not develop in the absence of neurotrophin-3 [8].

## Mesencephalic

### Definition

Related to the midbrain (mesencephalon).

## Mesencephalic Locomotor Area

### Definition

Mesencephalic nuclear region that can coordinate simple step movements. Corresponds to the pedunculopontine tegmental nucleus, pars compacta.

►Mesencephalon

## Mesencephalic Reticular Formation (MRF)

### Definition

A neuronal structure located in the core of the brain stem whose caudal boundary is the crossing of the superior cerebellar peduncle (brachium conjunctivum) and extends rostrally to the thalamic reticular nucleus. It is reciprocally interconnected with the superior colliculus. Original function was defined as part of the reticular activating system (RAS). Clear evidence now that there are subgroups of cells that participate in the control of saccadic and vergence eye movements. The MRF has two major subdivisions. The posterior commissure in the subhuman primate serves to separate the MRF into rostral and caudal regions. The cells of the rostral portion of the MRF are associated with the control of vertical eye movements, while neurons in the caudal region also termed the central MRF (cMRF) are more closely associated with the control of horizontal eye movements.

►The Central Mesencephalic Reticular Formation – Role in Eye Movements

## Mesencephalon

### Definition

Midbrain. The most rostral portion of the brainstem. Three parts:

1. The cerebral peduncles contain large fiber bundles from the cerebrum.
2. The tegmentum area contains substantia nigra, red nucleus, cranial nerve nuclei and parts of the reticular formation.
3. The tectum is formed from the quadrigeminal plate (inferior and superior colliculi). Tasks: eye movement, fine motor control, sensory-motor coupling, effector movement, synaptic center.

## Mesenchymal Stem Cell

### Definition

Mesenchymal stem cells are derived from various tissues including bone marrow, skin, adipose tissue, synovium, periosteum, skeletal muscle, placenta and thymus. They proliferate *in vitro*, and have the pluripotent capacity of differentiating into a broad range of cells such as osteocytes, chondrocytes, tenocytes, adipocytes, and smooth and cardiac muscle cells. Mesenchymal stem cells express CD 13, CD 29, CD 44, CD 90, CD 105, and HLA-ABC.

## Mesopontine Tegmentum

Philip Winn
School of Psychology, University of St Andrews, Fife, UK

### Definition

The mesopontine tegmentum sits between the midbrain (also called the *mesencephalon* and therefore *meso*) and the anterior pons (and therefore *pontine*). The term *tegmentum* is a generic one that translates directly from Latin as "a cover". The mesopontine tegmentum is therefore the upper area at the junction of pons and midbrain; it is a region of brain rather than a clearly delineated structure. It sits above the underlying pontine tissue (principally the pontine nuclei and the nuclei of the pontine reticular formation) and the fibers of the superior cerebellar peduncle, which marks an approximate border between the mesopontine tegmentum and these nuclei. Laterally, both the pontine nuclei and mesopontine tegmentum are bordered by the fibers of the lemniscal system. Medial to the mesopontine tegmentum is the central gray and in the dorsal part of the area is the inferior colliculus, though this is a structure better understood in conjunction with the superior colliculus in the midbrain proper. In comparative terms, the mesopontine tegmentum differs little across vertebrate species, suggesting that whatever its functions are, they evolved early and have been preserved. What differentiates the region across species most clearly is the density of the fiber systems that cross the area rather than its structural or morphological identity.

Within the mesopontine tegmentum are two small nuclei with uncertain functions, the microcellular tegmental nucleus and the deep mesencephalic nucleus. These are identifiable by the aggregation of neurons of similar morphology, separable from the surrounding structures. In addition there is the cuneiform nucleus and three nuclei – the parabigeminal nucleus, the laterodorsal tegmental nucleus (LDTg) and the pedunculopontine tegmental nucleus (PPTg PPT or PPN). The pedunculopontine tegmental nucleus can also be referred to as the pedunculopontine nucleus, the tegmental pedunculopontine nucleus (TPP) or the nucleus tegmenti pedunculopontinus (NTPP). Pedunculopontine tegmental nucleus (PPTg) is preferred, being used by the major stereotaxic atlases. These nuclei, all of which contain large, deeply pigmented neurons whose principal neurotransmitter is acetylcholine, are undoubtedly the most prominent in the mesopontine tegmentum and are thought to be part of the ascending reticular activating system ARAS), an organized network of neurons in the hind- and mid-brain that regulate neural

functions throughout the entire CNS. However, while the cholinergic neurons of the PPTg and LDTg fulfill the criteria for inclusion in this system, it is important to recognize that different elements of the ARAS have different functions. Using this one generalized term to describe a number of structures collectively carries the danger that one obscures the specific functions of each one.

## Characteristics

### Neurodevelopment

The neurodevelopmental literature refers to a structure not recognized in the adult brain, called the isthmus. It sits between the midbrain and hindbrain – the area that in the adult brain includes the mesopontine tegmentum. This primordial tissue contains what is known as the "isthmic organizer", responsible for the proper development of midbrain and hindbrain tissue from the tectum to the cerebellum. The critical molecule involved in this, as demonstrated by a range of transplantation techniques, appears to be Fgf8, though a variety of other transcription factors are also involved [1].

The developmental history of the large cholinergic neurons that are the most prominent cells of the mesopontine tegmentum has been specifically studied. In rats, similar histories have been described for both PPTg and LDTg cholinergic neurons. The final adult number and morphology are achieved by postnatal day 21, but their development is not linear. The numbers of what will become cholinergic neurons (identifiable by morphology, location and the use of antibodies for choline acetyltransferase [ChAT] and the vesicular acetylcholine transporter [VAChT]) *declines* over postnatal days 1–3 but *increases* progressively thereafter, with ChAT and VAChT activity developing during postnatal days 7–14. Neuronal size is relatively large during this time, with later shrinkage to the adult form. This developmental time course appears to parallel changes in sleep, from the juvenile active sleep (which does not involve muscle atonia) through to the adult rapid eye movement (or paradoxical) sleep, in which muscle atonia is a prominent feature [2].

### Principal Structures

The cuneiform nuclei – so called because of their wedge (cuneiform) shape – receive inputs from the superior colliculus and send projections to the medulla and spinal cord. They function as relay stations for collicular motor output and have been suggested to be involved in rapid "fight or flight" activities. For example, local chemical manipulation of the cuneiform nuclei produces behavioral freezing or darting movements. The cuneiform nuclei are also part of the mesencephalic locomotor region (MLR), a region defined functionally rather than anatomically. In pre-collicular – post-mamillary transected animals, electrical stimulation of the MLR elicits co-ordinated walking. This is a robust and reliable effect, but one whose significance can be misinterpreted. In otherwise intact animals, bilateral ▶excitotoxic lesions of the cuneiform do not impair locomotion and similar lesions of the PPTg (similarly suggested to be in the MLR) also leave locomotion intact. The MLR's existence should not be taken as showing that the primary function of this part of the brain is locomotor control. Rather, it might better be taken to demonstrate that in the absence of descending inhibitory control from the forebrain, these low level systems are capable of generating organized responses.

The pedunculopontine tegmental, laterodorsal tegmental and parabigeminal nuclei are nuclei that each contain a population of cholinergic neurons, designated (using the classification of Marek Marsel-Mesulam) Ch5, Ch6 and Ch8 respectively. The Ch8 neurons of the parabigeminal nuclei sit in an isolated cluster and innervate principally the geniculate nuclei of the thalamus. Ch5 and Ch6 however are closely coupled, forming a continuous chain of cholinergic neurons – called the caudal cholinergic column when first identified – that stretches (in rodents) from the caudal pole of the substantia nigra back as far as the locus coeruleus. These cholinergic neurons are thought in addition to contain a variety of other neurotransmitters (including neuropeptides and neuroactive amino acids) and neuromodulators (including nitric oxide – nitric oxide synthase is present in virtually all mesopontine cholinergic neurons). Receptors for a very wide variety of signaling molecules are present on these neurons, including those for acetylcholine; there appears to be strong intercommunication between PPTg and LDTg. Both also contain populations of non-cholinergic neurons, identified by morphology, electrophysiology and the absence of cholinergic markers. Precisely which neurotransmitters characterize these neurons is not clear, though recent evidence from immunohistochemical and *in situ* hybridization studies strongly suggests that many of them contain GABA.

### Mesopontine Connections with the Limbic System, Basal Ganglia, Sensory and Motor Systems

The mesopontine tegmentum is a point of convergence for a variety of information. Visual, auditory and somatosensory data are all processed through here and some of this processing is very fast, PPTg neurons for example fire in response to auditory signals with a mean latency of only ~8 ms. Complementing this sensory input, several structures in the mesopontine tegmentum have output to sites of motor control in (for example) the pontine and medullary reticular formation, the trigeminal complex and spinal cord. As well as these sensory inputs and motor outputs, there is substantial descending (mostly inhibitory) control from the forebrain, with convergence of information from both basal ganglia and limbic system. Indeed, the description

"►limbic-motor interface" which was applied to the nucleus accumbens in the forebrain might better be used in relation to the mesopontine tegmentum. All of this connectivity is well illustrated by considering in particular the most closely studied mesopontine structures, the PPTg and LDTg.

## The Pedunculopontine and Laterodorsal Tegmental Nuclei

The cholinergic neurons of the PPTg and LDTg project widely through the brain. These neurons are both heavily collateralized and, in many instances, have ascending and descending connections. They innervate the thalamus *en masse*, as well as midbrain dopamine (DA)-containing neurons (which they excite) and elements of the basal ganglia, the colliculi, hypothalamic and basal forebrain sites of non-specific cortical input and multiple motor structures in the brainstem and spinal cord. As well as these cholinergic neurons, both PPTg and LDTg contain non-cholinergic neurons that project widely, though not to quite the same extent as the cholinergic neurons. What controls the activity of these neurons appears to be two types of information: (i) basic sensory information from midbrain and brainstem visual, auditory and somatosensory systems and (ii) descending control from limbic structures (such as the amygdala, extended amygdala and hypothalamus) and from various parts of the basal ganglia (including the prefrontal and motor cortex). These various connections can be made sense of if brain systems are considered to be organized hierarchically in a form of layered architecture. The PPTg and LDTg receive primary sensory data and can generate output aimed at motor systems – this represents a simple system aimed at producing rapid responses to imperative signals. In addition to this, it can activate systems at a higher level, aiding more detailed processing. However, descending forebrain output, nearly all of which is GABA-mediated inhibition, allows for modification of both the ascending signals from PPTg and the rapid motor response generation to be effectively regulated by neural systems at higher levels of the architecture [3]. Note that this organization is consistent with the effects described above in relation to the MLR; loss of descending inhibition does not impair the ability of the PPTg to organize locomotion.

At the single unit level, the characteristic firing patterns of individual neurons in the PPTg and LDTg have been used to discriminate putative cholinergic and non-cholinergic neurons (see [4] for a brief review). More globally, mesopontine cholinergic neurons have been known for many years to be involved in regulating the electrical activity of the thalamus and through this, the cerebral cortex. Cholinergic activity in the thalamus has a complex action on the thalamic reticular nucleus and thalamic relay nuclei, with the outcome that increased cholinergic activity is associated with effective corticothalamic transmission, while decreased cholinergic activity inhibits traffic. These two states are differentiated in ►behavioral state control processes – increased cholinergic activity is associated with the waking state and REM sleep, while decreased activity is associated with slow wave (or paradoxical) sleep [5].

The traditional view has been very much that structures at this level of the brain are associated with basic mechanisms of behavioral state control and the regulation of locomotion. However, recent studies have revealed that more complex processing is represented here as well. There is no doubt that PPTg and LDTg neurons are differentially active at different stages of the sleep wake cycle, and as such play a role in behavioral state control. However, bilateral excitotoxic lesions of the PPTg do not prevent rats from exhibiting normal patterns of sleep and wakefulness, indicating that while the PPTg is important in the sleep wake cycle, it is not critical; it is not some form of master switch for sleep. As noted above, the PPTg is a part of the brain described previously as part of the MLR. Likewise, bilateral excitotoxic lesions do not impair locomotion, indicating that the essential function of this area is not just the production of movement. Indeed, a variety of studies from many labs worldwide have shown that bilateral excitotoxic lesions of the entire PPTg do not impair locomotion, feeding, drinking, grooming or any other basic activity; in their home cages, such lesioned rats are indistinguishable from controls. However, when challenged in a variety of tests involving more complex processes relating to ►reward and reinforcement, attention, learning and memory, lesioned rats are strikingly impaired [4]. In a recent attempt to aggregate these various deficits into a theoretical framework, Alderson and Winn [6] argued that the essential deficit present in PPTg lesioned rats is an inability to properly associate actions and outcomes. It is a significant move away from considering tissue at this level of the neuraxis as being only involved in automatic regulatory processes, one that moves toward a different account of the relationships between processes such as learning and memory and widely distributed brain systems.

One final point of interest is that the PPTg has been linked to neurodegenerative brainstem disorders such as Parkinson's disease and progressive supranuclear palsy [4]. In this context it is important to note that outflow from the basal ganglia to a focused part of the PPTg (termed the midbrain extrapyramidal region by David Rye and his colleagues) is disturbed in Parkinsonism. Very recently, several groups have shown that deep brain stimulation in the region of the PPTg can provide relief from some of the motor symptoms of this disorder. What the longer-term consequences of

this are – and whether there are any non-motor effects – remains unclear, but this is nevertheless an exciting new therapeutic development.

New ideas about the role of this part of the brain in both neurological disorders and more complex psychological processing than had previously been expected suggest that it might be exposed to more detailed study in the near future.

## Messenger RNA (mRNA)

### Definition

Messenger RNA (mRNA) is the mature RNA, processed from the single stranded pre-mRNA transcribed from DNA, which is translated into protein.

## Metabolic Coupling

### Definition

The term metabolic coupling refers to the ability of many gap junctions to coordinate the metabolic and/or signaling state of multiple cells trough the exchange of small intracellular messenger molecules and metabolites.

►Electrical Synapses
►Gap Junctions

## Metabolic Encephalopathy

### Definition

One form of encephalopathy.

►Encephalopathy (or Acute Organic Brain Syndrome)

## Metabotropic

### Definition

An influence on ion channel activity mediated indirectly by the binding of a neurotransmitter or hormone to its receptor. Commonly, receptor binding activates one or more second messenger systems within the target cell, which ultimately causes relatively long-lasting changes in the activity of voltage-dependent ion channels. This is a relatively long-latency, long-lasting event.

## Metabotropic Glutamate Receptors (mGluRs)

### Definition

G-protein-coupled receptors activated by glutamate made up of three groups: I, II, and III. Group I mGluRs trigger phospholipase C (PLC) hydrolysis of phosphatidyl inositol (4,5)-bisphosphate ($PIP_2$), whereas groups II and III trigger adenylyl cyclase synthesis of cyclic adenosine monophosphate (cAMP).

►Associative Long-Term Potentiation (LTP)
►Long-Term Potentiation (LTP)

# Metachromatic Leukodystrophy (MLD)

## Definition

Rare, autosomal recessive, lysosomal storage disorder characterized by severe and progressive ►demyelination. It is caused by a deficiency of the lysosomal enzyme arylsulfatase A (ARSA), which leads to the accumulation of galactosylceramide-3-O-sulfate (sulfatide) in the central and peripheral nervous systems. In the late-infantile form (50% of the patients), which manifests in the second year of life and for which no efficient therapy exists, death occurs within a few years. There are also juvenile forms (onset between 4 and 12 years) and adult forms (onset after 12 years). Allogeneic hematopoietic cell transplantation may ameliorate the condition of selected patients with juvenile or adult forms.

## Definition

Metacognition is, in a narrow sense, defined as cognition about and emotion for one's own cognitive states and processes, but in a broader sense, the self-regulatory process of cognitive processes while engaging in the task, or even more simply cognition and cognition (which is based upon the view underlying those definitions that "humans are reflective thinking agents who are actively monitoring, regulating, and reflecting upon their own cognitive processes while engaging, in order to achieve certain set goals").

## Characteristics

In the accompanying essay, we shall discuss (i) components, (ii) characteristics of research, and (iii) new directions.

### Two Components of Metacognition

The first component includes declarative, procedural, and conditional (if-then) knowledge and strategies, and beliefs on human cognitive processes and states (e.g., ►self-appraisal). It could be called as a set of beliefs or as naïve theories of human cognitive functioning.

The second component constitutes the online control process that monitors and guides underlying cognitive processes, or the dynamic executive system (e.g., ►self-management) that actively guides the processes generating cognitions. It consists of the four functions: (i) to know what the problem is, (ii) to plan and activate strategies appropriate for engaging in and solving the problem, (iii) to predict and direct performance, and (iv) to monitor and regulate ongoing cognitive activities [1,2]. Those functions are closely intertwined and are recurrently deployed until achieving set goals satisfactorily.

### Five Research Areas: What Aspects of Metacognition have been Focused upon?
