The following hypotheses on the evolution of the *Dianthovirus* genus are based exclusively on analysis of the extent of similarity of the amino acid sequence of the various viral gene products. The replicases of all known and sequenced positive strand RNA viruses have been placed into three distinct phylogenetic supergroups. The dianthovirus replicase belongs in supergroup II along with the tombus-, carmo-, necro-, a subset of the luteoviruses, pestiviruses, hepatitis C virus, flaviviruses and the positive strand RNA coliphages (notably Qβ) and the related yeast dsRNA elements. It is generally assumed that the replicase from all of these viruses evolved from a common progenitor and was subsequently dispersed by modular evolution. The dianthovirus capsid protein fits into a rather large group of icosahedral-shaped viruses whose capsid protein(s) possess a conserved structural element termed the 'jelly roll' confirmation. It is suspected that this type of capsid protein has evolved only once. All genera within the *Tombusviridae* have capsid proteins that fit into this group. *Dianthovirus* capsid proteins possess an additional structural feature termed the protruding domain. Tombus- and carmoviruses share this feature. The movement protein gene is unique to plant viruses (**Table 3**). It is hypothesized that this gene was

recruited by the virus from the plant as viruses evolved to adapt to plant hosts.

Future

Since a putative dianthovirus (FNSV) has recently been identified from the tropics, it is possible that additional species within the *Dianthovirus* genus exist and will be discovered. However, with the possible exception of the tropical regions of the world, it is unlikely that any members of this genus will become a major disease problem. RCNMV is clearly the best studied member of the genus. RCNMV is being used as a model system in several research laboratories to study plant–virus interactions, movement, and replication. RCNMV is a convenient model system because of the extreme simplicity of the genome, it does not require a biological vector for infection, and clones from which infectious RNA transcribed are derived are available.

ECHOVIRUSES (*PICORNAVIRIDAE*)

Helena Kopecka, CNRS, Institut Pasteur, Paris, France

History

Echoviruses (echo for *e*nteric *c*ytopathogenic *h*uman *o*rphan) were defined initially in 1955 as a group of nonpoliomyelitis viruses that are nonpathogenic for newborn mice. They were thus distinguished from coxsackieviruses, another subgroup of enteroviruses pathogenic for newborn mice. Although the echoviruses are the most frequently isolated enteroviruses, they remain the least well known and characterized subgroup.

Taxonomy and Classification

Echoviruses are members of the *Enterovirus* genus of the *Picornaviridae* family. Enterovirus classification relies mainly on neutralization assays using specific antibodies raised against the prototype strains. The subgroup of echoviruses consists of 31 types: types 1–9, 11–27, 29–33. On the basis of recent evidence from cell culture and from molecular organization, echovirus types 22 and 23 constitute a new enterovirus genus, *Parechovirus*.

Geographic and Seasonal Distribution

Echoviruses circulate worldwide in all geographical areas. They are isolated primarily during the summer and early autumn months, usually as cyclic epidemics over comparatively short periods of time in temperate climates. In tropical and semitropical areas circulation tends to be endemic, produced throughout the year with longer periods of prevalence, often associated with the rainy season.

Host Range and Virus Propagation

The important primary determinants of virus cell tropism and host range are cell surface molecules that act as receptors. The subunits α_2 and β_1 of the integrin VLA-2, the adhesion molecule, have been identified as receptors for echovirus types 1 and 8 (**Fig. 1**). Human decay accelerating factor (DAF), or CD55, was shown to be a cellular receptor for echoviruses types 7, 13, 21, 29 and 33.

Echovirus multiplication *in vivo* is limited to primates, although certain strains can infect mice and eventually induce paralysis in suckling mice (e.g. echovirus type 9, strain Barty). Two cases of endomyocarditis with histological lesions were observed in newborn mice inoculated with echovirus type 25.

The *in vitro* propagation of echoviruses in cell culture gives apparent cytopathic effect (with exception of types 22 and 23). Most echoviruses shut off host cell protein synthesis after infection. Primary monkey and human cells and primate tissue culture are the most appropriate systems for echovirus isolation. These include Buffalo green monkey kidney (BGM), rhesus monkey kidney (MK) cells or Vero cells, human embryonic kidney (HEK) cells, human diploid fibroblasts (MRC-5), human amniotic cells or human rhabdosarcoma (RD) cells. Other continuous

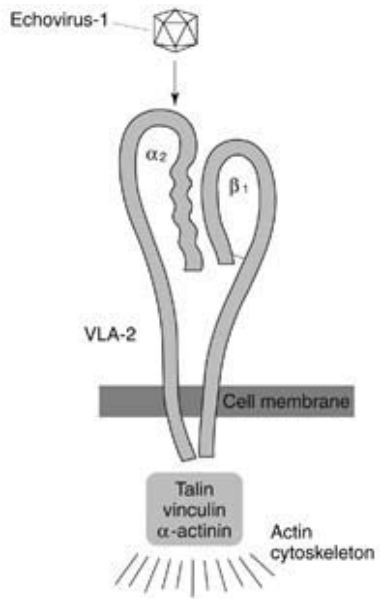

Figure 1 Echovirus types 1 and 8 receptor – the integrin VLA-2. (Reproduced with permission from Bergelson *et al* (1993).)

cell lines (HeLa, KB, HEp-2) are usually less sensitive, although different cells vary in their susceptibility to different echoviruses. Thus, the use of multiple cell lines increases yield and enhances the chance and speed of virus isolation.

Genetics

Echoviruses are typical members of the *Enterovirus* genus and share many of its characteristics. Echoviruses are small nonenveloped viruses; their capsid is formed from 60 copies of four nonglycosylated proteins, organized in an icosahedron (VP1, VP2, VP3 and the relatively unstructured and wholly internal protein VP4). The genome is a monocistronic single-stranded RNA molecule of plus polarity, about 7500 nucleotides long, covalently linked on the 5′ extremity to a small, virus-encoded protein (VPg). It has a long untranslated sequence in the 5′ region with highly conserved structures important for replication and translation initiation. A single large open reading frame encodes a polyprotein of about 250 kDa, proteolytically processed by virus-encoded proteases to yield structural and nonstructural proteins. On the 3′ end is located a short (70–100 nucleotides long) untranslated region (UTR), forming a pseudoknot structure. The 3′ terminal is polyadenylated; the mean length of the poly(A) tail is 60 nucleotides and it plays a role in RNA stability and infectivity of the virus.

The genome sequences of several echoviruses have been determined (types 6, 9, 11, 12, 22 and 23). Sequence comparisons with other enteroviruses revealed a strong overall amino acid identity of echovirus type 9 to types 11 and 12. The echovirus

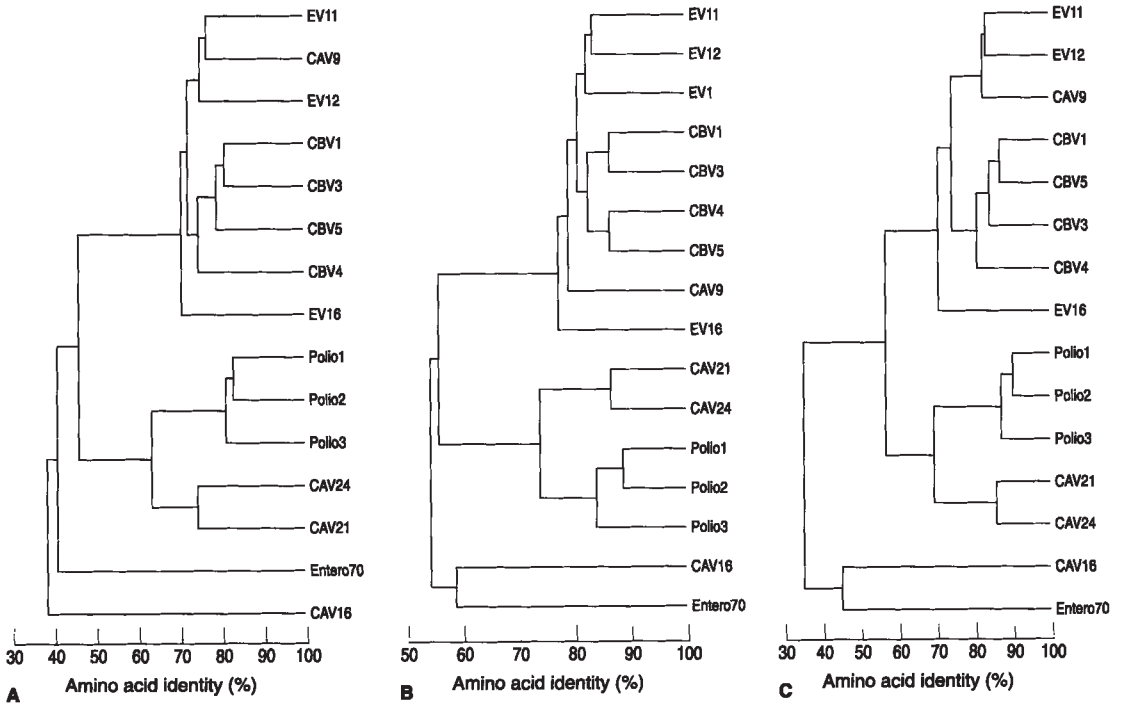

Figure 2 Dendrograms generated using sequences of the major capsid proteins. (A) VP1; (B) VP2; (C) VP3. (Reproduced with permission from Huttunen et al (1996).)

type 11 also showed a remarkable similarity with coxsackievirus A9. These viruses have insertion sequences at the C-terminus of VP1 polypeptide. The organization of the 5′ untranslated region resembles that of other enteroviruses, but also contains a long poly(U) stretch not seen in any other enteroviruses sequenced to date.

Echovirus types 22 and 23 have particular structural, genomic and biological properties when compared with other echoviruses. Their major capsid protein (VP0) is an uncleaved form in the mature virion. In addition, an N-terminal basic extension was determined in VP3. In contrast to the overall low degree of sequence identity with other enteroviruses, a number of sequences in the 5′ untranslated region are shared with the cardiovirus encephalomyocarditis virus. Moreover the incomplete cytopathic effect in cell culture and the absence of shutoff of host cell protein synthesis in infected cells, properties distinctive in both molecular and biological terms, justify their classification in a new genus in the *Picornaviridae* family.

The study of genomic relations in the *Enterovirus* genus has shown that echoviruses are closely related to the coxsackie B virus group (**Fig. 2**).

Evolution

Most echovirus infections of a single serotype contain a heterologous population of viruses that constitutes a quasi-species.

Echoviruses, like other enteroviruses, demonstrate reasonable genome stability in some situations, but can evolve extensively upon replication in the human gut, as is reflected in their rapid evolution during outbreaks in human host populations. They may well be the most variable enteroviruses, with 31 different types discriminated with polyclonal sera. Echoviruses, represented by a very heterologous population of viruses, allow great adaptability and rapid evolution of their genomes. The rate of evolution of continuously replicating RNA viruses is 10^{-3}–10^{-4} substitutions per site per year. In addition to stepwise evolution due to the accumulation of point mutations, RNA recombination between different viruses may also contribute to variation; this event has been demonstrated for polioviruses, but has not yet been described for echoviruses.

Serologic Relationships and Variability

Identification of echovirus serotypes is based on the profile of seroneutralization with monospecific sera raised against the prototype virus, usually the first isolate. There is a general problem of antigenic variation in enteroviruses. It seems that the impact of the variations in echoviruses is greater than in other enteroviruses. One possible explanation may be that echoviruses occur widely in human populations and persist in nature, although their presence is probably underestimated because they give rise to a wide range of clinical symptoms and the majority of infections are asymptomatic. The major problem encountered with human sera often relates to their crossreactivity with other serotypes. Because of the antigenic variation observed within the serotype, the selection of one prototype strain for the production of antiserum for diagnostic purposes is unsatisfactory. It is clear that the panel of prototype antisera is not broad enough antigenically for virus diagnosis by this method. This statement is supported by the observation that many antigenic variants of the same serotype are frequently isolated from clinical specimens; about 10% escape identification using sera raised against the prototype strain. Antigenic variants of echoviruses were isolated rapidly after description of prototype strains; the intratypic variations were observed in echovirus type 1 and type 8 at the same time as the antigenic relations between these two types and also have been documented with echovirus type 4, 12 and 29. Similar antigenic relations were observed between echovirus type 6 and 30. Despite antigenic differences, the prototype strains and the variants of echovirus types 4, 9, 18, 19 and 25 also present variations in their structural capsid proteins VP1, VP2 and VP3. Considerable biological and antigenic variations of natural isolates of echovirus type 25 were observed when compared with the prototype strain JV-4. Antigenic heterogeneity of echovirus type 30 was used to divide these variants in different, but overlapping, antigenic subgroups. The genomic variations in this serotype have been located in the 5′ UTR and in the VP2 and VP4 coding sequence.

Epidemiology

Outbreaks of infection with echoviruses occur frequently in widely separated areas of the world, in various climates, conditions and at different time intervals. Global figures from 1975 to 1983 published by the World Health Organization showed prevalence of 64% for echoviruses in a total of nearly 60000 nonpolio enterovirus reports. Echoviruses clearly continue to be an important cause of significant morbidity and mortality worldwide. The prevalent serotypes have changed since 1983; several outbreaks of echovirus type 30 spread in the United States, in Canada and in Japan between 1990 and 1992. The outbreak of echovirus type 3 in China in 1985, which was never isolated in this country, affected 20% of the

population in the Guizhon province, with a case fatality of 12%. The retrospective epidemiological studies of echovirus type 22 infections from 1966 to 1990 revealed a peak in 1986, with the predominance in infants under 1 year old. In Jamaica in 1986 there was an outbreak of echovirus 22, with several cases of flaccid paralysis, two deaths and a case of aseptic meningitis. Why particular serotypes appear and disappear and the factors dictating endemic versus epidemic behavior are not well understood. One theory is that some epidemic strains, such as echovirus 9, may spread rapidly and exhaust susceptible individuals in the population, whereas those strains appearing endemically over several years may be less contagious.

The study of enteroviral epidemiology has been enhanced recently by the application of molecular genetics methods, such as two-dimensional oligonucleotide gel electrophoresis of viral RNA, hybridization with specific subgenomic probes, amplification and identification of defined RNA sequences using reverse transcription and polymerase chain reaction and nucleotide sequencing. These methods have been used to trace the routes of spread and to determine the degree of relatedness among epidemiologically distinct isolates. The nucleotide sequences in the 5′ UTR of 60 isolates of echovirus type 30 from the recent outbreak of meningitis in Canada compared to prototype strains showed a difference of 11–15%, whereas all isolates originated from seven different provinces shared 99% or greater sequence identity. These approaches can be utilized to rapidly identify enteroviral strains associated with particular outbreaks and distinguish them from other strains and serotypes.

Transmission and Tissue Tropism

Humans are the only known reservoir for echoviruses and therefore close human contact appears to be the primary route of spread. The limited replication of echoviruses takes place in the oropharynx, followed by transit through the stomach and implantation in the lower intestinal tract, where they undergo more extensive multiplication. Virus can be recovered from the oropharynx and intestine of individuals with apparent or inapparent infection. Viruses are generally shed for periods ranging from one to many months in stools; their concentration is highest early in infection. In rare cases of persistent infection, viruses can be shed for several years.

Besides fecal–oral transmission, other routes to be considered are water, food, inoculation, blood and vertical transmission from mother to fetus. Waterborne transmission can be considered as an extension of fecal–oral transmission in which the intermediate vector is water. Indeed the viruses can survive for prolonged periods in favorable environmental conditions (low temperature, neutral pH, presence of organic matter). Echoviruses can be found in surface and ground waters, and in swimming pools, even after chlorination. They can be isolated from raw or partly cooked mollusks and crustacea and their overlying waters. Shellfish rapidly concentrate many viruses, including enteroviruses, which may survive for several weeks, and their consumption may be the route of infection. Soil and crops also provide conditions favorable to echovirus transmission.

Although most neonatal echovirus infections are acquired directly from the mother, some infections are transmitted nosocomially; this type of transmission, typical in newborn nurseries, has been well documented. The incidence and severity of perinatally acquired infections from an infected mother reflect the occurrence of infection, usually in the enterovirus season. Clusters of vertically transmitted neonatal infection have been recorded during community outbreaks. Airborne transmission is probably not significant in echovirus infections.

Echoviruses, like other enteroviruses, multiply throughout the alimentary tract, the primary site of colonization. The virus is translocated from the oropharynx and from the intestine to other organs. Enteroviral replication in ileal lymphoid tissue is detectable 1–3 days after ingestion of virus. After multiplication in submucosal lymphatic tissues, the viruses pass to regional lymph nodes and give rise to a transitional minor viremia. The major viremia results in dissemination to target organs, such as meninges, heart and skin. In these tissues, necrosis and inflammatory lesions are observed, whereas histopathologic lesions are generally not seen in the gut and lymphoid tissues during the earlier replicative events.

Pathogenicity

Most enterovirus infections are characterized by subclinical manifestations; however, they can also cause a wide spectrum of more or less several clinical diseases, including aseptic meningitis, encephalitis, flaccid motor paralysis, exanthema, herpangina, myocarditis, pleurodynia, hepatitis, upper respiratory symptoms, etc.

The genetic heterogeneity of the virus population and selective pressure can lead to the evolution of variants with altered pathogenic properties such as virulence, tissue specificity and host range, which may increase virulence and cause syndromes not ordinarily associated with the prototype virus. Alternatively, an attenuated virus variant can emerge from the adapted

Table 1 Clinical spectrum of infections with echoviruses[a]

Asymptomatic infection	Most echoviruses
Aseptic meningitis	All types (except 24, 26, 29, 32)
Encephalitis	Types 2, 3, 4, 6, 7, 9, 11, 14, 17, 18, 19, 25
Paralysis	Types 2, 4, 6, 7, 9, 11, 14, 16, 30
Exanthema	Especially types 9 and 16 but also several other types
Myopericarditis	Types 9, 22
Generalized disease of newborn	Types 4, 6, 7, 9, 11, 12, 14, 19, 21, 25, 31
Neonatal diarrhea	Types 11, 14, 18
Diarrhea	Several types
Hemolytic-uremic syndrome	Type 22
Myositis	Types 9, 11
Guillain–Barré syndrome	Types 6, 22
Chronic meningoencephalitis in agammaglobulinemic patients	Types 2, 3, 5, 9, 11, 19, 24, 25, 30, 33
Infectious lymphocytosis	Type 25

[a] According to Modlin.

subpopulation. Attenuated variants of echovirus type 2 and type 12 have been isolated. Echovirus type 6 can cause persistent infection *in vitro* and *in vivo*. In immunodepressed individuals with congenital agammaglobulinemia, echovirus types 5, 11 and 25 were detected in the central nervous system.

Most echoviruses lack the property of mouse pathogenicity. However, different strains can produce variants that exibit paralytogenic activity in newborn mice. The analysed sequences of the nonpathogenic prototype strain Hill and the mouse virulent strain Barty of the echovirus type 9 differ, particularly in an insertion coding for an RGD motif at the C-terminus of the capsid protein VP1 in the genome of the strain Barty. It is suggested that this motif is an important determinant for pathogenicity of newborn mice.

Clinical Features and Infection

The majority of echovirus infections are asymptomatic or result in undifferentiated febrile illness. When disease occurs, the spectrum and severity of clinical manifestations vary with the age and immune status of the host and with the serotype and even the intratypic viral strain. While a variety of distinct clinical syndromes are caused by infection with echoviruses some manifestations are associated with many echovirus serotypes (**Table 1**).

Echoviruses together with coxsackieviruses cause more than 90% of cases of aseptic meningitis. Infants under 3 months of age have the highest rates of recognized aseptic meningitis. Pharyngitis and other symptoms of upper respiratory tract infections are often present during the meningitis. Symptoms of encephalitis sometimes complicate the course of aseptic meningitis. In perinatally acquired echovirus infection, encephalitis may be one manifestation of generalized viral infection. Most patients with echovirus encephalitis beyond the neonatal period recover fully; however, one fatal case of echovirus type 9 encephalitis has been reported. Sporadic cases of flaccid motor paralysis have been associated with several echovirus types, most often types 2, 6, 7, 9, 11 and 16. The disease is generally milder than poliomyelitis; paralysis is not usually permanent. The Guillain–Barré syndrome has been reported in a small number of patients infected with echovirus types 6 and 22.

Echoviruses cause a variety of exanthems; they cause little morbidity, but are important sentinels of the prevalence of echoviruses in the community. Summer outbreaks of herpangina have been associated with infection by echovirus types 3, 6, 9, 16, 17, 25 and 30, but other types have been also isolated from persons with herpangina. Echovirus types 1, 6, 9, 16 and 19 are sometimes implicated in pleurodynia. During the summer, disease of the upper respiratory tract is often associated with echovirus type 11 infection.

Direct evidence linking echovirus types 9 and 22 with myopericarditis has been demonstrated by the presence of the infectious viruses or viral antigens in myocardium or pericardial fluid. There is less substantive evidence for echovirus types 1–4, 6–8, 11, 14, 19, 25 and 30; these serotypes have been recovered from noncardiac sources during the episode of acute myopericarditis.

Human neonates are uniquely susceptible to echovirus and coxsackievirus diseases. Echovirus 11 is most frequently associated with overwhelming, systemic neonatal infection. Generalized enterovirus disease in the newborn usually occurs with myo-

carditis or fulminant hepatitis. The serotype 11 is responsible for most cases of fulminant hepatitis but other serotypes (4, 6, 7, 9, 12, 14, 19, 21 and 31) are also responsible for severe hepatitis in neonates. There are several reports of cases of fatal pneumonia occurring in the first few days of life caused by echovirus types 6, 9 and 11. Most cases of persistent, sometimes fatal, infection of the central nervous system in children with hereditary or acquired agammaglobulinemia are mainly associated with echovirus type 11, but other types have also been detected in these patients.

Pathology and Histopathology

Echoviruses have found clinical expression mainly in injury to the central nervous system; occasionally peripheral neuropathies, hepatoneuronal dysfunction, orchitis, pleurodynia or carditis may intervene during infections with several serotypes.

Neonatal myocarditis, which is usually accompanied by encephalitis, is mostly the manifestation of coxsackie B virus infection, and less commonly echovirus 11 infection. Infants dying of myocarditis have enlarged, dilated hearts, extensive myonecrosis and a variable degree of cardiac inflammation. Lymphocytic infiltration of the brain, meninges, lungs, liver, pancreas and adrenal glands may also be found.

Neonatal echovirus encephalitis with white matter sclerosis has been documented. A fatal case of echovirus type 7 infection in a neonate, which was probably acquired from the symptomatic mother, exhibited extensive hemorrhagic necrosis of brain, liver, adrenal glands and kidneys and disseminated intravascular coagulation.

Clinical and pathological findings in a fatal case of disseminated echovirus infection complicating bone marrow transplantation, in which the patient developed noncardiogenic pulmonary edema, has been reported. Viral cultures of the pericardiocentesis were positive for echovirus type 11, and the virus was isolated post mortem from the brain, cerebrospinal fluid, spleen and heart. The virus isolated was probably a variant of echovirus type 11, according to the neutralization titers of the variant versus prototype virus.

Fulminant hepatitis presents with hypotension, profuse hemorrhage and multiple organ failure; the major pathologic findings for infants dying of hepatitis are massive hepatic necrosis and extensive hemorrhage into the cerebral ventricles, renal medullae and interstitial spaces of solid organs. Inflammation is commonly found in the liver and adrenal glands.

Several cases of spontaneous abortion and stillbirth associated with echovirus types 11, 17, 19, 27, and 33 infection have been reported.

Acute renal failure due to rhabdomyolisis has been associated with echovirus type 9 infection.

Echovirus type 4, classically associated with acute lytic infection, appears to have the potential to persist in β cells or perinsular tissue, causing autoimmunity and impairment of insulin secretion without massive β cell lysis.

Echoviruses may be at the origin of symptoms mimicking bulbospinal poliomeningitis. Bilateral limb paralysis in children, and in one adult, was associated with echovirus types 4, 9, 14 and 30.

Immune Response

Neutralizing type-specific humoral antibodies appear as a consequence of infection with echoviruses; they develop shortly after infection and persist for many months or years, depending upon the severity of infection. Immunity to infection is type specific and disease relates not only to the presence, but also to the concentration, of specific humoral antibodies.

In the serum, both IgM and IgG humoral antibodies are produced as early as 1–3 days after echovirus infection. IgM antibodies predominate during the first month and gradually disappear; neutralizing IgG antibodies in serum persist for life after natural infection with these viruses. There are indications that macrophage function may also be a critical component in the immune response to enterovirus infection. Antibody-mediated immune mechanisms operate both in the alimentary tract to prevent the implantation of the virus and in blood to prevent dissemination to the target organs. While antibodies, either passively or actively acquired, may modulate the course of infection, they may not prevent infection. Serologic cross-relationship between echoviruses or other members of the human enteroviruses may be a problem in the control of echovirus infection.

Echovirus infections are high risk for persons with deficiencies in their humoral or cell-mediated immunity. A number of persistent or fatal infections of immunodeficient persons by echoviruses have been reported. In most of the patients the main deficit was in the B cell functions associated with humoral immunity. The majority of the subjects were unable to eradicate the virus from their central nervous system.

Prevention and Control

Echoviruses are the most frequently represented enteroviruses in severe or less severe pathologies of

young children. Despite the frequency and severity of their infection, these viruses are the least understood of the picornaviruses. The only enterovirus vaccines available at present are those against the three poliovirus serotypes. Their application for almost 40 years has resulted in the goal of eradication of poliomyelitis in the world becoming a reality. However, there are no vaccines against other enteroviruses. In view of the large number of different serotypes of echoviruses, it is difficult to design vaccines against them all. A better understanding of their genomic organization and function, as well as the mechanisms of their rapid evolution and variability, would be a great help in the design of antiviral components, where the essential functions of the virus would be a target. The studies of cell receptors are of great importance for the understanding of the interactions of a virus with its host cell, and thus the possible inhibition of virus–cell interaction. A better understanding of the localization and structural configuration of epitopes is necessary for the development of recombinant vaccines. The application of rapid, sensitive and specific diagnostic molecular biology tools for echovirus detection in clinical specimens and in environmental samples is important for epidemiological control. Surveillance of newly isolated strains is also of great importance, as viruses with new pathologies, such as neurotropism and cardiotropism, may emerge. The study of the resistance of echoviruses in the environment in general, and in the clinical environment in particular, is important for epidemiology and for the risk of severe pathologies in immunodepressed persons. The coming years will surely lead to new and important information regarding the potential of the echoviruses to trigger autoimmunity and/or cause chronic infection.

Eradication of poliomyelitis by vaccination is an objective of WHO. However, a number of cases of infection-associated paralysis and meningoencephalitis due to enteroviruses other than polioviruses will still exist. The exact diagnosis of such infections is imperative in order to obtain the correct epidemiological data to demonstrate the role of viruses other than polioviruses in these clinical manifestations.

Future Perspectives

A knowledge of genomic composition and organization will simplify the classification of the enterovirus group and may well mean the reclassification of some echoviruses into the different subgroups. More information on the properties, ecological variations and natural history of isolates of echoviruses will shed further light on this important group of enteroviruses. We have to be concerned about the future occupation by other enteroviruses, and mainly by echoviruses, of the ecological niches liberated by the polioviruses after their eradication.

EMERGING AND RE-EMERGING VIRUS DISEASES

Frederick A Murphy, School of Veterinary Medicine, University of California Davis, Davis, California, USA

Introduction

Many elements can contribute to the emergence of a new viral disease; these include *viral determinants* (such as mutation, recombination, natural selection, evolution), *natural determinants* (such as ecologic and environmental determinants) and *determinants pertaining to human activity* (such as behavioral, societal, transport, commercial and medical care activities). In general, there is no way to predict when or where the next important new viral pathogen will emerge; nor is there any way to predict the ultimate importance of a virus as it first emerges. Given this reality, initial investigation at the first sign of the emergence of a new viral disease must focus on characteristics such as mortality, severity of disease, transmissibility and remote spread, all of which are important predictors of epidemic potential and societal threat. Clinical observations, pathologic examinations and preliminary identification and characterization of the virus often provide early clues because new, emerging viruses often resemble their closest genetic relatives in regard to their epidemiologic and pathogenic characteristics. The elements of disease control and prevention programs include surveillance, diagnostics and communications, linked to a professional response network. This network, actually a web of many national, state and local networks with only modest international links, must be flexible; capable, for example, in one instance of emphasizing local resources as the basis for actions, and in the next of emphasizing global epidemic aid. Given the nature and magnitude of the threats represented by the many new and emerging viral diseases, the importance of all the elements of the global network seems clear.

The Emergence of New Viral Diseases is Inevitable yet Unpredictable

New or previously unrecognized viruses are constantly being identified. New diseases emerge as the cause of geographically limited curiosities, as the cause of intermittent disease outbreaks and as the cause of new epidemics. No one would have predicted the emergence a new rodent-borne hantavirus as the cause of a severe acute respiratory distress syndrome in the southwestern region of the USA in 1993 and certainly no one would have predicted the epidemic emergence of human immunodeficiency virus (HIV) as the cause of acquired immune deficiency syndrome (AIDS) before the initial description of the disease in the early 1980s.

New viral diseases appear to be emerging with increasing frequency, as suggested by published reports of cases, outbreaks and epidemics, and by the rate of identification of new pathogenic viruses. The list of newly emergent viruses of humans and animals is impressive, indeed, and is seemingly prophetic of more to come in the future (**Tables 1–3**). There are several reasons why emergence of new viral diseases seems to be accelerating. The global human and domestic animal populations have continued to grow inexorably, bringing increasingly larger numbers of people and animals into close contact. There have been successive revolutions in transportation of humans and animals, making it possible to circumnavigate the globe in less than the incubation period of most viral diseases. Ecological changes brought about by human activity are occurring at a rapidly accelerating rate.

When a new viral disease is suspected, it must be characterized (by the work of clinicians and pathologists), and assessed in regard to its impact on populations at risk (by the work of epidemiologists). When a new virus is suspected, it must be isolated, identified and characterized and methods must be developed for diagnosis and field investigation. All these activities must be integrated to construct a comprehensive view of the immediate problem at hand. Today, this kind of integrated investigative problem-solving activity is usually thought to be the sole responsibility of governmental agencies, but in fact, many professionals from throughout the human and animal health sectors have played central roles in recent episodes. As it turns out, assessing risk and guiding intervention involve quite diverse activities; for example, in some cases complex field studies of the incidence of infection in the general population or in a selected subpopulation are necessary to determine risk factors for infection, mode of transmission, targets for intervention, etc., while in other cases, studies of the pathogenetic mechanisms underpinning the clinical presentation in the individual human or animal patient might hold the key. Today, in nearly every instance, important clues lie in characterizing the molecular structure and replication strategy of the virus and the cellular pathobiology of the infection.

Table 1 Some of the most important emerging and re-emerging human viruses

- *Crimean-Congo hemorrhagic fever virus** (tick-borne; severe human disease with 10% mortality; widespread across Africa, Middle East and Asia)
- *Dengue viruses** (mosquito-borne; the cause of millions of cases of febrile disease in the tropics and dengue hemorrhagic fever, a life-threatening disease, especially in children)
- *Ebola** *and Marburg** *viruses* (natural reservoirs unknown, the cause of the most lethal hemorrhagic fevers known)
- *Guanarito virus** (rodent-borne; the cause of Venezuelan hemorrhagic fever)
- *Hantaviruses** (rodent-borne; the cause of important rodent-borne hemorrhagic fever in Asia and Europe and severe, often fatal acute respiratory distress syndrome in the USA and elsewhere in the western hemisphere)
- *Hepatitis C virus* (the cause of much severe chronic liver disease worldwide)
- *Hepatitis E virus* (the cause of epidemic hepatitis, especially in Asia and along the USA/Mexico border; the infection has a high mortality rate in pregnant women)
- *Human herpesviruses 6 and 7* (the cause of febrile disease in children)
- *Human immunodeficiency viruses, HIV-1 and HIV-2* (the cause of AIDS, still emerging in many parts of the world)
- *Human papillomaviruses* (over 70 viruses, some associated with cervical, esophageal and rectal cancers)
- *Human T-lymphotropic viruses, HTLV-1 and HTLV-2* (the cause of adult leukemia and neurologic disease, especially in the tropics)
- *Influenza viruses* (the cause of thousands of deaths every winter in the elderly; the cause of the single most deadly epidemic ever recorded – the worldwide epidemic of 1918, in which 25–40 million people died)
- *Japanese encephalitis virus* (mosquito-borne; severe, lethal encephalitis; now extending across southeast Asia; great epidemic potential)
- *Junin virus** (rodent-borne; the cause of Argentine hemorrhagic fever)
- *Lassa virus** (rodent-borne; the cause of severe disease in West Africa)
- *Machupo virus** (rodent-borne; the cause of Bolivian hemorrhagic fever)
- *Measles virus* (still the cause of more than 1 million deaths per year in children, mostly in the tropics)
- *New-variant Creutzfeldt–Jakob disease* (prion disease, zoonotic, transmitted to humans from cattle with bovine spongiform encephalopathy)
- *Norwalk and related viruses* (major causes of outbreaks of severe diarrhea)
- *Polioviruses* (still an important problem in some developing countries; targeted by the World Health Organization for worldwide eradication by the year 2002)
- *Rabies virus* (transmitted by the bite of rabid animals; still the cause of 25 000–50 000 human deaths per year, mostly in developing countries)
- *Rift Valley fever virus** (mosquito-borne; the cause of explosive epidemics in Africa)
- *Ross River virus* (mosquito-borne; the cause of epidemic arthritis that has moved across the Pacific region several times)
- *Rotaviruses* (rotavirus enteric disease is the second leading cause of death among infants in the world)
- *Sabiá virus* (rodent-borne; the cause of hemorrhagic fever in Brazil and two laboratory-acquired cases)
- *Venezuelan encephalitis virus* (mosquito-borne; great potential for causing explosive epidemics in humans and horses in Central and South America)
- *Yellow fever virus** (mosquito-borne; one of the most deadly diseases in history)

* The viruses that cause hemorrhagic fevers in humans.

Of course, the immediate goal of such enterprise is to invent and guide prevention and control measures as these become necessary.

Variation and Evolution of Viruses

Variation in the genome of viruses, altering any of many characters that affect their pathogenicity and transmissibility, can increase their potential for emerging incrementally. For this reason, the great breakthroughs in viral molecular and cellular biology have had great value in dealing with emergent viral diseases. All of the many mechanisms that drive viral evolution must be evaluated in trying to predict the future course of a disease; first, there is the high frequency of *viral mutation* during replication, especially with RNA viruses, especially with the greatly expanded number of viral replication cycles that occurs early in an epidemic. Second, there is the opportunity for *recombination or reassortment* of genes that is afforded in the same circumstances. Finally, there is the long-term risk of viral recombination with genetic elements of host cells, the ultimate risk whereby retroviruses acquire new genes.

Classical examples of such viral variation and evolution include the definition many years ago of smallpox variants, variola major (Indian subcontinent and Europe, mortality up to 30%) and variola

Table 2 Some of the most important emerging and re-emerging viruses of animals

- *African horsesickness viruses* (mosquito-borne; a historic problem in southern Africa; now becoming entrenched in the Iberian peninsula; a major threat to horses worldwide)
- *African swine fever virus* (tick-borne and also spread by contact; an extremely pathogenic virus; recently present in Europe and South America)
- *Australian bat lyssavirus* (new rabies-like virus in fruit bats in Australia, one human death)
- *Avian influenza viruses* (spread by wild birds; a major threat to poultry industries globally)
- *Bluetongue viruses* (*Culicoides*-borne; the isolation of several strains in Australia became an important nontariff trade barrier issue)
- *Bovine spongiform encephalopathy prion* (the cause of a major epidemic in cattle in the UK, resulting in major economic loss and trade embargo)
- *Canine parvovirus* (the cause of a pandemic of severe disease in dogs that rapidly swept around the world; a new virus, having mutated from feline panleukopenia virus)
- *Chronic wasting disease of deer and elk prion* (spongiform encephalopathy of unknown source, discovered in captive breeding herds in the USA)
- *Feline immunodeficiency virus* (important cause of AIDS-like disease in cats globally)
- *Foot-and-mouth-disease viruses* (still considered the most dangerous exotic viruses of animals in the world because of their capacity for rapid transmission and great economic loss; still entrenched in Africa and Asia)
- *Australian equine morbillivirus* (new virus causing lethal respiratory disease in horses and humans; reservoir host recently found to be fruit bats)
- *Lelystad virus (porcine respiratory and reproductive disease virus)* (the cause of an important new disease in swine in Europe and the USA)
- *Malignant catarrhal fever virus* (an exotic, lethal herpesvirus of cattle; an important nontariff trade barrier issue throughout the world)
- *Rabbit hemorrhagic disease virus* (being used to control rabbits in Australia, with great success)
- *Rinderpest virus* (still considered very dangerous, with potential for causing great economic loss in Africa and Asia)

minor (South America, mortality about 1%) and naturally occurring attenuated poliovirus variants, some of which inspired the development of Sabin live-attenuated polio vaccines.

There are several other kinds of change that can contribute to the emergence of new viral diseases. A *change in host range* can permit a virus to spread into a new species with devastating consequences (e.g. following minimal mutations a feline parvovirus evolved into canine parvovirus 2, which then caused a global pandemic in dogs). An *increase in virulence* can convert a nonpathogenic virus into an important pathogen (e.g. following minimal mutations temperate endemic Venezuelan equine encephalitis viruses

Table 3 The special case of emerging and re-emerging viruses in endangered/threatened species

- *Callitrichid arenavirus in tamarins (LCM/marmoset hepatitis)* (lethal disease; a major problem in the golden lion-tamarin, an endangered species)
- *Canine distemper virus in the black-footed ferret* (lethal disease; its control is crucial to the survival of this endangered North American species; being controlled by vaccination)
- *Canine parvovirus in the red wolf* (severe disease in endangered wolf pups reintroduced into the Great Smoky Mountains National Park; being controlled by annual vaccination)
- *Eastern equine encephalitis virus in the whooping crane* (lethal disease; its control is crucial to the survival of this endangered North American species; being controlled by annual vaccination)
- *Feline infectious peritonitis virus in the cheetah* (lethal disease; its control is crucial to the survival of this endangered African species)
- *Dolphin, porpoise and phocine (seal) morbilliviruses and related viruses* (newly recognized; a complex of lethal diseases in several species of seals, sea lions, dolphins and porpoises, caused by several related morbilliviruses; control is crucial to the survival of several endangered/threatened species, worldwide)
- *Rabies in endangered free-living wild canid species* (lethal disease; its control is crucial to the survival of several endangered wild canid species)
- *Rinderpest virus in endangered free-living ruminant species* (several wild ungulate species of Africa serve as reservoir hosts of this virus, the source of virus causing epidemics in cattle; control is crucial to the acceptance of cohabitation of domestic and wild animals in large areas of Africa)

have evolved into lethal epidemic pathogens). A *change in antigenic signature* can permit a virus to infect a population already immune to parental strains of the same virus (e.g. human influenza viruses undergo 'drift' and 'shift', in many instances resulting in new epidemic emergence).

In some instances, a new viral disease is the consequence of the appearance of a virus which is truly new to its host. The most dramatic instance of this phenomenon is the global pandemic caused by HIV-1 and HIV-2, each of which evolved in nonhuman primates from viral ancestors resembling simian immunodeficiency viruses. In this instance, the human population had no background immunity nor any resistance derived from long-term genetic selection. Without such natural barriers to dissemination, international spread and a global pandemic followed.

Epidemiologic Considerations in the Emergence of Viral Diseases

Epidemics are classically divided according to their means of spread into two major categories, propagated and common source. *Propagated epidemics* depend upon spread from host to host; they continue to expand as long as each infection gives rise to more than one new infection. *Common source epidemics* occur when a virus is disseminated from a single focus; they usually result from contamination of air, food, water, drugs, medical devices, or the like.

Propagated epidemics

The epidemic potential of newly emerging acute viral diseases varies depending upon the mode of transmission, the immunological and genetic susceptibility of the host population and the size of the population at risk. Epidemic potential is greatest for a virus which is readily transmitted from host to host, particularly via the respiratory route. Conversely, zoonotic agents and arthropod-borne agents are usually limited in their geographic range, although the latter are certainly not limited in their capacity for causing very large epidemics.

Continuing evolution of a virus which is already present in a population can cause what appears to be re-emergence of epidemic disease. For example, the evolution of influenza viruses is accompanied by variances in virulence, with some variants being responsible for greatly increased mortality. The greatest example of this phenomenon is the global influenza pandemic of 1918, in which 25–40 million people died.

On occasion, a virus may emerge in epidemic form simply because of an alteration in the ecology of its host. An example of historic importance is the emergence of epidemic poliomyelitis in the mid-nineteenth century. This was not due to any change in the properties of the virus, as epidemiological studies strongly suggest that the same virus strains could be simultaneously associated with both pathogenic and nonpathogenic infection. Rather, this was due to an improvement in public sanitation and personal hygiene, which led to a delay in the acquisition of enteric virus infection from infancy to childhood. Since infants were protected by maternal antibody, they usually underwent silent immunizing infections, whereas when older children were infected they more often suffered paralytic poliomyelitis.

Common source epidemics

If a virus is introduced from a common source into a large population, disease can emerge on an epidemic scale. A recent example is the ongoing epidemic of bovine spongiform encephalopathy in the UK. In this instance it appears that the scrapie prion of sheep contaminated meat-and-bone meal which was fed to cattle. This resulted in the apparent adaptation of the prion to cattle, and the emergence of a devastating new cattle disease. When the prion associated with bovine spongiform encephalopathy emerged as the cause of new-variant Creutzfeldt–Jakob disease in humans, the ultimate risk of a common source contagion became manifest.

Persistent infections, long incubation periods and emerging diseases

The dynamics of emergence of a new viral disease can vary greatly, depending upon the incubation period, whether the infection is acute or persistent, and whether the resulting disease (and shedding pattern) is acute or chronic. When associated with a short incubation period and acute disease, emergence can be a dramatic event. An example is hantavirus-associated respiratory distress syndrome, which first came to attention in 1993. However, when the emerging agent is associated with a long incubation period, the resulting epidemic may rise over a period of years, its presence obscured by a failure to appreciate its entrenchment in the population. Of course, the example *par excellence* is AIDS: first, the length of its incubation period (as long as 8–10 years) led to underestimates of its potential epidemic potential and case–fatality rate; next, its initial epidemic behavior led to misjudgments of its shedding and transmissibility patterns; finally, misconceptions about its clinical course led to gross underestimates of its burden on the health care systems of developed countries.

New recognition of previously unrecognized diseases

In some instances, a long-existing viral disease may appear to emerge simply as a matter of recognition – the occurrence of a notable outbreak and intensified investigation, the isolation of the virus and the development of diagnostics, etc. New diseases that are clinically unique are more likely to be recognized early than diseases that closely resemble well-established clinical entities, such as hepatitis, diarrhea or encephalitis. One example of 'delayed emergence' due to late recognition is California encephalitis, caused by La Crosse virus. The virus was first isolated in 1964; using an isolate as a source of antigen, retrospective serological surveys showed that the virus has been an important endemic cause of encephalitis in children for many years in midwestern USA.

Nature of Ecological and Zoonotic Factors in Regard to Emerging and Re-emerging Viral Diseases

One set of factors contributing to the emergence of new viruses relates to their capacity to adapt to extremely diverse and changing econiches. One of the most complex sets of adaptive characteristics concerns the transmission of viruses by arthropods. The arthropod-borne viruses are examples *par excellence* where emergence and re-emergence follow upon human environmental manipulation:

- Population movements and the intrusion of humans and domestic animals into new arthropod habitats have resulted in many new emergent disease episodes. The classic example of this was the emergence of yellow fever during the building of the Panama Canal; there are many contemporary examples as well.
- Ecologic factors pertaining to unique environments have contributed to emergent disease episodes. Remote econiches, such as islands, free of particular species of reservoir hosts and vectors, are often particularly vulnerable to an introduced virus. For example, the initial Pacific 'island-hopping' of Ross River virus in the 1980s from its original niche in Australia, caused 'virgin-soil' epidemics of arthritis–myalgia syndrome in Fiji and Samoa – this virus will surely re-emerge in a similar way again.
- Deforestation has been the key to the exposure of farmers and domestic animals to new arthropods. The occurrence of Mayaro virus disease in Brazilian woodcutters as they cleared the Amazonian forest in recent years is a case in point.
- Increased long-distance travel facilitates the carriage of exotic arthropod vectors around the world. The carriage of the Asian mosquito, *Aedes albopictus*, a proven vector for dengue, yellow fever and California encephalitis viruses, into the USA in the water contained in imported used tires represents an unsolved problem of this kind.
- Increased long-distance livestock transportation facilitates the carriage of viruses and arthropods (especially ticks) around the world. The introduction of the tick-borne virus, African swine fever virus, from Africa into Portugal (1957), Spain (1960) and South America (1960s and 1970s) is thought to have occurred in this way – it is just a matter of time until this virus makes further international forays.
- New routings of long-distance bird migrations, brought about by new manmade water impoundments, represent an important yet still untested new risk of introduction of arboviruses into new areas. This may be one key to the movement of Japanese encephalitis virus into new areas of Asia.
- Ecologic factors pertaining to environmental pollution and uncontrolled urbanization are contributing to many new, emergent disease episodes. Arthropod vectors breeding in accumulations of water (tin cans, old tires, etc.) and sewage-laden water are a worldwide problem. Environmental chemical toxicants (herbicides, pesticides, residues) can also affect vector–virus relationships directly or indirectly.
- Ecologic factors pertaining to water usage – that is, increasing irrigation and the expanding reuse of water – are becoming important factors in viral disease emergence. The problem with primitive water and irrigation systems, which are developed without attention to arthropod control, is exemplified in the emergence of Japanese encephalitis in new areas of Southeast Asia.
- Global warming, affecting sea level, estuarine wetlands, swamps and human habitation patterns, may be affecting arthropod vector relationships throughout the tropics; however, specific data are scarce because such long-term trends are involved.

Nature of Behavioral and Societal Factors

There are diverse behavioral, commercial, societal and iatrogenic factors that lead to the emergence of new diseases or new viral disease patterns. In many countries these represent overarching societal health problems:

- Sexually transmitted viral diseases are increasing in incidence in many populations. After widespread personal behavioral changes made in the wake of the global AIDS pandemic, prevention programs based upon public education seem to be burning out.
- Virus transmission associated with daycare has become recognized as the most important factor in community and family spread of many respiratory and enteric viruses. Daycare-acquired infection is also important in the spread of viruses, such as hepatitis A virus, that usually cause only subclinical infection in children but which cause serious disease when transmitted to parents and staff.
- The re-emergence of childhood viral diseases transmitted in the community is often a sentinel of the condition of all public health disease prevention programs. When the incidence of these diseases increases it is usually because of inadequate vaccine coverage.
- Viral diseases associated with agriculture and food processing and distribution systems are increasing in incidence as the sources, scale and technologies involved are driven to change by economic forces. Foods are produced by fewer but larger processors, resulting in increasing numbers of large regional outbreaks of disease. The centralization of the food industry also means that a single contaminated ingredient may appear in many different end-products. The USA now imports 30 billion tons of food a year, including meat, fruit, vegetables and seafoods; such foods, representing an increasing proportion of the diet, often come from developing countries where hygiene and sanitary conditions are less than adequate. In such circumstances, hepatitis A virus has become an important food-borne pathogen.
- Several viral diseases associated with medical care have increased in incidence in recent years, partly because of the wider use of advanced invasive medical technologies. Viral diseases have been associated with immunosuppressive therapy, organ transplantation, dialysis and blood transfusion. Hepatitis B, hepatitis C, human cytomegalovirus and AIDS are notable in these regards, but so are less common diseases such as Crimean–Congo hemorrhagic fever, Lassa fever and Ebola hemorrhagic fever.

Prevention and Control

The world faces immediate and urgent problems in regard to emerging and re-emerging viral diseases. Health systems are being challenged by these diseases, each of which seems to have qualities that defy established conventional prevention and control strategies. Innovative strategies based upon agent-specific epidemiologic and virologic research must address several distinct needs: (1) a global disease surveillance system, (2) a global diagnostics system, (3) a global integral research base, (4) a global communications system, (5) a global technology transfer system, (6) a global emergency response system, (7) a global training program, and (8) a stable global funding base.

International organization is the key to many of these elements. There would be value in designing a single overarching global organization to deal with the emerging and re-emerging viral disease problems of humans and the similar problems of interest in animal agriculture (the many viral diseases of livestock, poultry, fish and shellfish), crop agriculture (the many viral diseases of commercially grown food and fiber plants) and national and international security and law enforcement agencies (the viral diseases involved in biological warfare threats from rogue governments and bioterrorism from the same sources as well as amateur groups).

ENCEPHALITIS VIRUSES (*FLAVIVIRIDAE*)

Contents

Encephalitis Viruses and Related Viruses causing Hemorrhagic Disease

James S Porterfield, Barnstaple, Devon, UK

History

'Brain fevers' such as rabies and poliomyelitis have been known since ancient times, and early in this century it was recognized that these two diseases were of viral origin. In the 1930s and 1940s it became clear that a number of other neurotropic viral infections occurring in different parts of the world differed from rabies and poliomyelitis in that they were transmitted by mosquitoes or ticks; these became known as the arthropod-borne encephalitides. Later, when it was found that some diseases not associated with encephalitis were caused by viruses serologically related to those responsible for the arthropod-borne encephalitides, the more general collective term 'the arthropod-borne viruses' or 'arboviruses', was introduced. In the 1950s arboviruses were divided into a number of serological groups, A, B, C and others, and this serological division formed the basis upon which these viruses were later placed within genera and families recognized by the International Committee for the Taxonomy of Viruses, group A arboviruses becoming the genus *Alphavirus* and group B arboviruses the genus *Flavivirus*, both initially within the family *Togaviridae* (but see Taxonomy and Classification, below). Encephalitic alphaviruses are considered in separate entries elsewhere in the Encyclopedia: this entry is concerned with flaviviruses that cause encephalitis and/or hemorrhagic disease (see **Table 1**). A chronological account of the recognition of these viruses and their associated diseases now follows.

Outbreaks of summer encephalitis were recognized in Japan as early as 1873, but no virus was isolated until 1935. Japanese encephalitis virus (JEV) is described in greater detail elsewhere in the Encyclopedia and is not considered further here, except to note that it is another flavivirus.

In the Australian summer of 1917–18 epidemic encephalitis, at first diagnosed as poliomyelitis, affected 134 people, half of them children under 5 years of age; the mortality rate approached 70%. Brain tissue from fatal cases yielded an agent that was passaged through rhesus monkeys, some of which developed a fatal meningoencephalitis, and other animal species were also infected. Unfortunately, this agent was lost before its nature could be established. Lesser outbreaks of what came to be known as Australian X disease followed in the summers of 1922, 1925 and 1926, after which no further cases were recognized until another outbreak of encephalitis struck the Murray and Darling River areas of Victoria and New South Wales in 1951. A virus that became known as Murray Valley encephalitis virus (MVEV) was isolated from a fatal case and was successfully propagated. Other isolates were made from mosquitoes. An examination of sera from survivors of Australian X disease made it very likely that the earlier Australian outbreaks were also due to MVEV.

In the summer of 1932 separate outbreaks of encephalitis were recorded in the USA, at Paris, Illinois, and in far eastern regions of the former USSR. The following summer encephalitis again struck the USA, this time in St Louis and Kansas City. The intracerebral inoculation of rhesus monkeys and albino mice yielded strains of a virus that became known as St Louis Encephalitis virus (SLEV). Subsequent studies showed that the infection was transmitted by mosquitoes.

In 1937 a virus was isolated from blood collected in the West Nile district of Uganda from an African woman suffering from a mild fever; it became known as West Nile virus (WNV). Although antibodies against WNV are commonly found in Africa, association with human disease was not at first apparent. The same virus was later (1951) isolated in Egypt from healthy children and also from wild birds, mosquitoes and from the brain of a horse with encephalitis. An association with encephalitis was demonstrated in elderly human subjects in Israel, and more recently in Europe.

Meanwhile, cases of encephalitis continued to occur in the eastern USSR, and in 1937 Russian spring summer encephalitis virus (RSSEV) was isolated. By 1940 it was established that RSSEV was transmitted by the tick *Ixodes persulcatus*, and that a second, closely related virus could be recovered from *Ixodes ricinus* ticks collected in western regions of the former USSR where it also produced encephalitis;

Table 1 Principal features of the seven flaviviruses

Virus	*First isolated*	*Geographic distribution*	*Host range*	*Principal vector*	*Clinical disease*
Murray Valley encephalitis virus	(1917)[a] 1951	Australia, New Guinea	Birds, humans	Mosquito	Encephalitis
St Louis encephalitis virus	1933	Epidemic USA and Canada, endemic South America	Rodents, humans	Mosquito	Encephalitis
West Nile virus	1937	Africa, Mediterranean, France, Portugal, Cyprus, Romania, Bulgaria, CIS, Asia.	Birds, humans	Mosquito (tick)	Mild fever, rarely rash, arthralgia, encephalitis
Russian spring–summer encephalitis virus	1937	Eastern CIS	Rodents, humans	Ticks	Encephalitis
Central European encephalitis virus	1940	Europe, from Scandinavia in north to Greece in south	Rodents, humans	Ticks	Encephalitis
Omsk HF virus	1947	Central CIS	Muskrats, humans	Ticks	Gastrointestinal symptoms, hemorrhagic fever
Kyasanur Forest disease virus	1957	India (Mysore)	Monkeys, humans	Ticks	Hemorrhagic fever

[a]The agent isolated in 1917 was lost before its identity was established.

these two agents are sometimes described as the Eastern and Western subtypes of tick-borne encephalitis virus (TBEV). The next two decades established that the second virus was not confined to the western USSR, but was also responsible for many cases of encephalitis in Central Europe and in Scandinavia, where the vector was also *I. ricinus*; this virus, the western subtype of TBEV, is also known as Central European Encephalitis virus (CEEV).

In 1947 a third tick-transmitted virus was isolated in the Omsk region of central USSR. This virus is transmitted by *Dermacentor marginatus* and *Dermacentor pictus* ticks, and is responsible for a diphasic fever with gastrointestinal symptoms and hemorrhagic manifestations, but with little involvement of the central nervous system; it is known as Omsk Haemorrhagic Fever virus (OHFV).

In 1957 large numbers of monkeys were reported to have died in the forested region of Shimoga District, Mysore (now Karnataka) State, India, and severe, sometimes fatal disease also affected the human population of the area. A virus, now known as Kyasanur Forest disease virus (KFDV), was isolated from monkeys, humans and from a variety of ixodid ticks. KFDV is antigenically distinct from the tick-borne viruses mentioned above, although crossreactions can be demonstrated by sensitive methods.

Taxonomy and Classification

The seven viruses named above were first categorized as Group B arboviruses and were later placed in the genus *Flavivirus* (named after the type species yellow fever virus, from the Latin *flavus*, 'yellow') within the family *Togaviridae*. In 1985 the large (>70) genus *Flavivirus* was moved to the newly established family *Flaviviridae*.

Properties of the Virion

Virus particles are roughly spherical, 40–50 nm in diameter overall, and contain a 20–30 nm core. The genome contains single-stranded, positive sense RNA with a molecular weight of about 4×10^6. The three structural proteins: capsid (C), membrane (M), and envelope (E), are all encoded by the viral genome. For further details see entries under yellow fever virus and Japanese encephalitis virus.

Properties of the Genome

The complete genomic sequences are now known for WNV, SLEV, MVEV, CEEV and RSSEV, and partial sequence data are available for KFDV and OHFV. Genome lengths vary from 10 644 to 10 976 nucleotides. As with all other flaviviruses replication involves a single molecule of RNA which encodes a single open reading frame which directs the synthesis of a large polyprotein which is subsequently cleaved to form both structural and nonstructural proteins. Details of flavivirus replication are more thoroughly discussed in the entry for yellow fever virus.

Geographic and Seasonal Distribution

WNV has the widest geographic distribution, virus strains having been isolated in Africa (from Tunisia and Egypt in the north, through West, Central and East Africa to South Africa and Mozambique), in Europe (the Mediterranean area, Portugal, southern France, Cyprus, and western parts of the former USSR, and most recently (1996) Romania and Bulgaria) and in Asia (the Middle East, India, Borneo and Asiatic parts of CIS). WNV antibodies have also been found in Australia, Thailand and Malaysia, but these probably represent crossreactions from other closely related flaviviruses, notably Kunjin virus in Australia, and Japanese encephalitis virus in Malaysia and Thailand.

SLEV is responsible for epidemic disease in the USA and Canada, but is also endemic in Mexico, Panama, Trinidad and Jamaica, Surinam, French Guiana, Brazil and as far south as Argentina.

MVEV is confined to Australia and New Guinea.

RSSEV is endemic over a large area of the CIS corresponding to the distribution of *I. persulcatus*. OHFV is limited to the Omsk and Novosibirsk Oblasts of the CIS.

CEEV is something of a misnomer since it is now established that the virus is endemic in foci which provide a habitat suitable for the maintenance of the vector *I. ricinus* in virtually every country in Europe with the exception of the British Isles. There, *I. ricinus* ticks support the maintenance and transmission of a closely related flavivirus that is responsible for louping ill, a neurotropic disease affecting principally sheep, but also cattle, horses, deer, birds, notably grouse, and very occasionally, humans.

KFDV originally appeared to be confined to the Shimoga District of Mysore (now Karnataka) State, India, but the virus has more recently produced disease in a wider area of western coastal India.

The spring–summer seasonal incidence of disease recognized in the name 'Russian spring summer encephalitis', also applies to the other infections, whether these are tick-borne or mosquito-borne.

Host Range and Virus Propagation

All seven viruses are arboviruses, which, by definition, infect both vertebrate and invertebrate hosts.

The maintenance of an arbovirus in nature depends on the vertebrate host developing a sufficiently high level of viremia to infect a blood-sucking arthropod that can function as a permissive host for that particular arbovirus. All seven arboviruses under consideration are capable of infecting humans, and usually a wide range of other vertebrate species, but the principal vertebrate hosts responsible for virus maintenance are birds for WNV and MVEV, and small rodents for the others. The invertebrate hosts, which serve as vectors for the transmission of the viruses to vertebrates (including humans), are mosquitoes for SLEV, MVEV and WNV and ticks for RSSEV, CEEV, OHFV and KFDV. WNV is exceptional in that although normally mosquito-borne it is tick-transmitted between birds in arctic regions of the CIS. A single isolation of SLEV from ticks has been reported, but ticks play no role in the natural transmission cycle of this virus.

The properties of the seven viruses are similar to those of all other flaviviruses (*see* **Yellow fever virus**).

Genetics

Flavivirus susceptibility of laboratory mice has been shown to be genetically controlled, and although there is no firm evidence of a flavivirus-susceptibility gene in humans, the possibility cannot be dismissed. Genetic factors may also affect the susceptibility of mosquitoes or ticks, with consequent effects on the epidemiology of different viruses.

Regarding genetic variation in individual viruses, WNV has been shown to exist in at least two major antigenic types, one found in Africa, Europe and Central Pakistan and the other in India. However, studies with monoclonal antibodies have revealed antigenic drift within African strains, but also stability within strains isolated many years apart. Variant strains may be introduced into new areas by migratory birds.

Six different topotypes have been reported within strains of SLEV, four from within the USA and two from Central and South America. Topotype 1 occurs in western states and is of intermediate virulence for laboratory animals and probably also for humans; topotype 2 isolates are found in eastern and central states, and are of high virulence; topotypes 3 and 4 are limited to Florida, where one occurs in epidemics and has high virulence whereas the other occurs endemically and is of low virulence. The topotypes from Central and South America have variable virulence characteristics. Genetic drift has been detected within SLEV strains, and as with WNV, variants may be transported into new areas by migratory birds.

Analysis of MVEV strains has shown that isolates from the Australian mainland are generally similar and are distinguishable from strains from New Guinea. The earlier suggestion that Australian disease outbreaks were due to importations of virus from New Guinea now seems unlikely.

Tick-borne flaviviruses appear to be inherently more stable than mosquito-borne viruses. Analysis by peptide mapping of the envelope glycoproteins of a number of different strains of RSSEV and CEEV showed only insignificant differences; OHFV and KFDV have not been subjected to such detailed study.

Evolution

The high degree of conservation found within the nucleotide sequences of those flaviviruses that have been studied strongly suggests that they all evolved from a common, primitive precursor, possibly a virus infecting arthropods rather than vertebrates in the first instance, with involvement of vertebrates being a later step in the continuing process. Evolutionary links with certain insect viruses have been reported and it has been suggested that the cell fusing agent (CFA), a virus isolated from *Aedes aegypti* cells, may be the present day survivor of the primeval flavivirus. It is of note that about one-quarter of all flaviviruses now known appear not to depend on an arthropod for their maintenance in nature, but this subset has yet to be subjected to detailed molecular study. There is some evidence that the flaviviruses originated in the old world, perhaps as recently as within the past 10 000–20 000 years, and that the rate of evolution has been gradual for tick-borne viruses, and much more rapid for mosquito-borne members. WNV is unusual in its ability to replicate in both mosquitoes and in ticks; it may have originated in Africa and be the most ancient of the mosquito-borne flaviviruses, SLEV, JEV, MVEV and other Australian flaviviruses having evolved from it in different parts of the world. Future studies may throw more light on the phylogeny of this large and important family.

Serologic Relationships and Variability

Crossreactions between flaviviruses are most readily detected by hemagglutination–inhibition (HI) tests, followed by complement fixation (CF) tests; neutralization tests (NT) show the greatest specificity. Nevertheless, more closely related flaviviruses, such as WNV, SLEV and MVEV can be shown to crossreact by neutralization tests, particularly when antibodies prepared by multiple inoculations of viruses are used. Such crossreactions may result in difficulties in the interpretation of the results of

serological tests carried out on specimens collected in areas where two or more different flaviviruses co-exist.

As already mentioned under Genetics, considerable strain variation is apparent within the mosquito-borne viruses, but this is less evident with the tick-borne flaviviruses.

The envelope glycoprotein E is the dominant antigen in HI and NT, whereas the core protein C plays the major role in CF tests. Of the different viral antigens, the NS1 protein appears to be the most highly conserved between different viruses.

Epidemiology

These seven viruses are maintained in nature by complex cycles involving the principal vertebrate host and the arthropod vector that feeds upon that vertebrate. Infection of humans is a dead-end event as far as the virus is concerned and does not in any way contribute to the maintenance of the virus in nature.

Probably more is known about the epidemiology of SLEV than of any of the other viruses with which this section is concerned. With this virus, completely different mosquitoes have been shown to be involved in different parts of the USA. *Culex tarsalis* is the principal vector in the western USA, *Culex pipiens* dominates in northern and eastern parts of the USA, and in the southern parts of the country *Culex quinquefasciatus* is the most important species. In addition to these three species, *Culex nigripalpus, C. restuans, C. salinarius* and others also contribute to virus transmission. The virus remains endemic in many areas, and produces epidemics of human disease when environmental conditions permit the build-up of a substantial population of vector mosquitoes. Water accumulations in artificial containers, such as automobile tires, and natural containers, such as tree holes, are important in this respect. Vertical (transovarial) transmission of SLEV virus has been demonstrated under laboratory conditions, and virus has been recovered from overwintering female *C. pipiens* mosquitoes.

The epidemiology of the tick-borne flaviviruses is even more complex than that of the mosquito-borne viruses, since ticks serve as reservoirs of infection as well as acting as vectors. Virus can be transmitted both transtadially and transovarially within ticks, and infected male ticks are also capable of infecting vertebrates, although they are less efficient vectors than females, probably because the levels of virus found in salivary glands are lower in males. In addition to tick transmission, RSSEV and CEEV are both capable of causing infection in humans following the ingestion of milk from a virus-infected animal, usually a goat, but sometimes a cow.

The epidemiology of OHFV is not fully established, but it is clear that in addition to the role played by the ticks *Dermacentor pictus* and *Dermacentor marginatus*, which are responsible for most human infections, water-borne transmission occurs between muskrats, *Ondatra zibethica*, the principal vertebrate hosts in nature. However, the complete natural cycle probably involves rodents, birds and mosquitoes as well as musk-rats and ticks.

Transmission and Tissue Tropism

All seven viruses are vector transmitted, mosquitoes being responsible for the transmission of MVEV, SLEV and WNV and ticks for RSSEV, CEEV, OHFV and KFDV. As already noted, WNV is unusual in being transmitted in nature by both mosquitoes and ticks.

Five viruses, MVEV, SLEV, WNV, RSSEV, and CEEV have a marked tropism for the central nervous system, whereas OHFV and KFDV have tropism for vascular endothelial cells.

Pathogenicity

Of the neurotropic viruses, WNV is the least pathogenic, the majority of human infections being subclinical, and RSSEV is the most pathogenic, carrying a mortality of up to 5%, with CEEV, SLEV and MVEV being between these two extremes.

OHFV carries a mortality of up to 2.5% and that of KFDV is between 5 and 10%.

Clinical Features of Infection

Most infections with each of the seven viruses under consideration are entirely subclinical, and are diagnosed only on the basis of the detection of specific antiviral antibodies.

WNV is unusual in that it may be associated with a dengue-like rash and with arthralgia; more exceptionally, liver involvement with overt jaundice has been reported in Africa, where the condition may be confused with yellow fever. Meningitis or meningoencephalitis may occur, particularly in the elderly, as clearly seen in the 1996 outbreak in Romania.

Clinically overt St Louis encephalitis cases usually have encephalitis, but may also present as an aseptic meningitis or as a benign febrile headache. Manifest disease is rare in children, and fatalities in children are unknown. The onset is usually sudden, with fever, headache and a stiff neck. There is frequently mental confusion, and patients develop tremors, but remain

quiet and somnolent unless aroused. Convulsions are rare, but are indicative of a possible fatal outcome.

Unlike St Louis encephalitis, Murray Valley encephalitis affects children much more frequently than adults, and males more commonly than females in the proportion of about 2:1.

Russian spring summer encephalitis usually starts with a sudden onset of fever, severe headache, nausea and vomiting and severe back pains. The fever may be biphasic. Infection of the brain and spinal cord may result in signs of meningeal irritation, or there may be a focal, paralytic response, most frequently affecting muscles of the neck or the proximal regions of the arms.

Central European encephalitis may present as an influenza-like fever, which may be followed by a biphasic fever associated with meningitis, usually benign, but occasionally leading to a shoulder-girdle type of paralysis. A few patients may die with paralysis of all four limbs.

Hemorrhagic manifestations are prominent in both Omsk hemorrhagic fever and Kyasanur Forest disease, although they are more severe in the latter, occurring into the skin, the mouth, the gastrointestinal tract and the uterus. Central nervous system (CNS) involvement is uncommon in Kyasanur Forest disease, but there may be signs of meningeal irritation and neck rigidity.

Pathology and Histopathology

Experimental studies in mice and hamsters infected with WNV and SLEV have provided a substantial pool of information concerning the pathology of infection within the central nervous system. Prominent features seen by microscopy include neuronal necrosis, neuronophagia and perivascular cuffing, with infiltrations of mononuclear cells and the formation of microgleal nodules. In St Louis encephalitis, lesions may be found in the substantia nigra, the basal ganglia, brainstem, thalamus, spinal cord and cerebellum; the cerebral cortex is usually less heavily damaged. In hamsters infected with SLEV, other organs such as the liver and heart may show extensive damage, but such lesions are rare in human St Louis encephalitis infections. Interstitial myocarditis has been reported in humans and horses infected with WNV, and the same virus has also been responsible for a small number of cases of fatal hepatitis in humans, with the development of lesions very similar to those seen in the liver of fatal cases of yellow fever.

Laboratory studies show a pronounced effect of age, with neonatal mice and hamsters being highly susceptible to fatal encephalitis, whereas older animals become resistant to infection by peripheral routes, but retain a degree of susceptibility to intracerebral infection. The reverse pattern is seen in humans, severe encephalitis due to WNV, SLEV and tick-borne viruses being more common in the elderly than in children, except in the case of MVEV infections, where children have more serious disease. The reasons for the differences are unknown.

Immune Response

All seven viruses provoke a brisk immune response in humans, converting the great majority of infections into subclinical attacks. There is evidence that, whereas humoral antibodies are predominant in resistance to infection, both humoral and cell-mediated immune responses contribute to recovery from infection. Intracerebrally produced antibodies are found only when virus has invaded the CNS, and such antibodies are able, in some cases, to protect the patient from severe encephalitic disease. Passively transferred antibody can confer protection in experimental infections, even when given after as long as six days after peripheral inoculation of WNV, at which time the brain was already infected.

The prime antigen involved in the humoral immune response is the envelope glycoprotein, E, but antibodies are also produced against the matrix protein or its precursor, and against the nonstructural protein, NS1. Antibodies against the latter also contribute to protective immunity.

Prevention and Control

These may be divided into measures directed to limit exposure to the vector, and measures directed against the causative virus.

A highly efficacious inactivated vaccine is available against CEEV. In Austria, where around 500 cases used to occur each year, extensive use of this vaccine almost eliminated the disease. The same vaccine also confers protection against Russian spring summer encephalitis, but both eastern and western viruses still present a significant problem in the CIS.

A number of experimental vaccines have been prepared against KFDV, but no satisfactory vaccine is yet available. No vaccines are available against WNV, SLEV or MVEV.

Future Perspectives

Increasing knowledge of the molecular biology of the viruses under consideration and of the epitopes involved in protective immunity brings the prospect of improved vaccines, possibly based on noninfectious genetically engineered products.

Tick-Borne Encephalitis and Wesselsbron Viruses

EA Gould, Institute of Virology and Environmental Microbiology, Mansfield Road, Oxford, UK

History, Taxonomy and Classification

The classical clinical picture of yellow fever (YF), tick-borne encephalitis (TBE), dengue (DEN) fever and the close association of these diseases with mosquitoes or ticks have been recognized since the early part of the twentieth century. However, these diseases were accurately described hundreds of years previously. The first flaviviruses were isolated in the late 1920s and originally classified as group B *ar*thropod-*b*orne viruses (arboviruses) to distinguish them from other serologically unrelated arboviruses in groups A and C. There are approximately 70 recognized viruses in the genus *Flavivirus* (family *Flaviviridae*), of which about 20% are assigned to the TBE virus complex. Wesselsbron (WSL) virus is included amongst the 60% of flaviviruses transmitted by mosquitoes. Currently, there are no recognized invertebrate vectors for the remaining 20% of viruses in the genus. In contrast to encephalitis, which is the characteristic clinical picture induced in humans by most of the TBE complex viruses, Omsk hemorrhagic fever (OHF) and Kyasanur Forest disease (KFD) viruses usually cause haemorrhagic fever; nevertheless, they are firmly established both serologically and genetically as TBE complex viruses.

Subgrouping on the basis of serological cross-reactivity essentially confirms the close antigenic relationships between the TBE complex viruses and shows they are distinct from the mosquito-borne and nonvectored viruses. This is further supported by molecular phylogenetic analysis of flaviviruses in which the tick-borne, mosquito-borne and nonvectored flaviviruses form distinct phylogenetic groups which have evolved from a common ancestral virus. At the time of writing, there are insufficient data to demonstrate conclusively which group represents the ancestral line, although antigenic comparisons with monoclonal antibodies and limited sequence data imply that the nonvectored viruses have the most ancient lineage.

WSL virus is transmitted to vertebrate hosts by *Aedes* spp. mosquitoes which become infected when they take a bloodmeal from other infected animals. The virus is found in Southern and Central Africa in regions which provide sufficient vegetation to sustain farmed animals such as sheep and cattle. Humans, working with or associated with the animals, also frequently become infected but usually present with a mild febrile illness. WSL virus is antigenically closely related to YF, Zika and Uganda S (UGS) virus and immunity to WSL virus is believed to provide cross-protection against these other viruses.

Properties of the Virion

Virions are about 50 nm in diameter, spherical, with a single capsid (C) protein and a lipid envelope. Infectious virions contain two membrane-associated proteins: the envelope (E) and the membrane (M) protein. Intracellular virions are immature and contain a presursor membrane (prM) protein which is proteolytically cleaved at the end of the infectious cycle. The E protein forms a dimer which is orientated parallel to the membrane. The E and the C proteins probably form icosahedral structures. The virion M_r is about 6×10^7; mature virions sediment at about 200S and have a buoyant density of $1.19\,g\,ml^{-1}$ in sucrose. Viruses are stable at pH 8.0 but are readily inactivated at acidic pH, temperatures above 40°C, by ultraviolet light and gamma-irradiation. The genome of flaviviruses is a positive-sense single-stranded RNA of approximately 11 kb. The 5′ end of the genome possesses a type 1 cap followed by the conserved dinucleotide AG. The 3′ end lacks a terminal poly(A)

Tick-Borne Encephalitis and Wesselsbron Viruses

EA Gould, Institute of Virology and Environmental Microbiology, Mansfield Road, Oxford, UK

History, Taxonomy and Classification

The classical clinical picture of yellow fever (YF), tick-borne encephalitis (TBE), dengue (DEN) fever and the close association of these diseases with mosquitoes or ticks have been recognized since the early part of the twentieth century. However, these diseases were accurately described hundreds of years previously. The first flaviviruses were isolated in the late 1920s and originally classified as group B *ar*thropod-*bo*rne viruses (arboviruses) to distinguish them from other serologically unrelated arboviruses in groups A and C. There are approximately 70 recognized viruses in the genus *Flavivirus* (family *Flaviviridae*), of which about 20% are assigned to the TBE virus complex. Wesselsbron (WSL) virus is included amongst the 60% of flaviviruses transmitted by mosquitoes. Currently, there are no recognized invertebrate vectors for the remaining 20% of viruses in the genus. In contrast to encephalitis, which is the characteristic clinical picture induced in humans by most of the TBE complex viruses, Omsk hemorrhagic fever (OHF) and Kyasanur Forest disease (KFD) viruses usually cause haemorrhagic fever; nevertheless, they are firmly established both serologically and genetically as TBE complex viruses.

Subgrouping on the basis of serological cross-reactivity essentially confirms the close antigenic relationships between the TBE complex viruses and shows they are distinct from the mosquito-borne and nonvectored viruses. This is further supported by molecular phylogenetic analysis of flaviviruses in which the tick-borne, mosquito-borne and nonvectored flaviviruses form distinct phylogenetic groups which have evolved from a common ancestral virus. At the time of writing, there are insufficient data to demonstrate conclusively which group represents the ancestral line, although antigenic comparisons with monoclonal antibodies and limited sequence data imply that the nonvectored viruses have the most ancient lineage.

WSL virus is transmitted to vertebrate hosts by *Aedes* spp. mosquitoes which become infected when they take a bloodmeal from other infected animals. The virus is found in Southern and Central Africa in regions which provide sufficient vegetation to sustain farmed animals such as sheep and cattle. Humans, working with or associated with the animals, also frequently become infected but usually present with a mild febrile illness. WSL virus is antigenically closely related to YF, Zika and Uganda S (UGS) virus and immunity to WSL virus is believed to provide cross-protection against these other viruses.

Properties of the Virion

Virions are about 50 nm in diameter, spherical, with a single capsid (C) protein and a lipid envelope. Infectious virions contain two membrane-associated proteins: the envelope (E) and the membrane (M) protein. Intracellular virions are immature and contain a presursor membrane (prM) protein which is proteolytically cleaved at the end of the infectious cycle. The E protein forms a dimer which is orientated parallel to the membrane. The E and the C proteins probably form icosahedral structures. The virion M_r is about 6×10^7; mature virions sediment at about 200S and have a buoyant density of $1.19\,g\,ml^{-1}$ in sucrose. Viruses are stable at pH 8.0 but are readily inactivated at acidic pH, temperatures above 40°C, by ultraviolet light and gamma-irradiation. The genome of flaviviruses is a positive-sense single-stranded RNA of approximately 11 kb. The 5′ end of the genome possesses a type 1 cap followed by the conserved dinucleotide AG. The 3′ end lacks a terminal poly(A)

tract and terminates with the conserved dinucleotide CU. The E protein hemagglutinates red blood cells and mediates receptor binding and acid pH-dependent fusion activity. Seven nonstructural (NS) proteins are synthesized in infected cells: NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5. The N-terminal one-third of the NS3 protein forms the viral serine proteinase complex together with NS2B which is involved in proteolytic cleavage of the polyprotein. The C-terminal portion of NS3 contains an RNA helicase domain involved in RNA replication and RNA triphosphatase activity that is probably involved in formation of the 5′-terminal cap structure of the viral RNA. NS5 protein is the RNA-dependent RNA polymerase and probably encodes the methyltransferase activity necessary for methylation of the 5′ cap structure. Virions contain about 17% lipid by weight, which is derived from host cell membranes, and about 9% carbohydrate by weight; their composition and structure are dependent on the vertebrate or invertebrate host cell. *N*-glycosylation sites are present in the M, E and NS1 proteins.

Genome Organization and Replication

The genome RNA is the viral messenger RNA and is infectious when introduced into cells using either electroporesis or membrane-fusing agents such as lipofectin. The RNA consists of a long open reading frame of more than 10 000 bases encoding all structural and nonstructural proteins which is flanked by short untranslated regions (UTRs). About 300 nucleotides at the terminal part of the 3′ UTR show sequence divergence but conserved secondary structures among different flaviviruses. The 3′ UTR may contain internal poly(A) tracts. Virus particles attach to as yet unidentified receptors on the cell surface and are engulfed as virions in endocytoplasmic vesicles, where the slightly lower pH conditions induce conformational changes in the E protein and the viral envelope fuses with the membrane of the vesicle, thus releasing the RNA. This incoming messenger RNA is translated and RNA replication begins with synthesis of complementary negative strands which serve as templates for genome-length positive-stranded molecules. This process appears to occur on the membranes of the perinuclear endoplasmic reticulum by formation of replicative intermediates and replicative forms. A polyprotein is synthesized from the messenger RNA and is immediately processed by cellular proteases and the viral serine protease (NS2A–NS3), giving rise to the structural and nonstructural viral proteins. Immature virus particles appear in the rough endoplasmic reticulum, where they are probably assembled and transported as immature particles through the membrane systems of the secretory pathway to the cell surface where exocytosis occurs. Immediately before release from the cell, mature virions are generated by a furin-like cellular protease which cleaves the precursor premembrane (prM) protein.

Geographic Distribution and Evolution

Viruses in the TBE serocomplex are geographically widely dispersed. If we assume an African origin, their subsequent evolution and dispersal during the past 5000–10 000 years may have occurred as depicted in **Fig. 1**. It is possible that infected seabirds, or alternatively infected ticks, dispersed the viruses from Africa, across southeast Asia as far afield as the South Pacific Ocean and they then gradually dispersed and evolved in a northerly direction to far-east Asia and Canada in the northern hemisphere. During the past 2000–3000 years the more recently dispersed TBE complex viruses appear to have evolved in a westerly direction through the forests of Asia and Europe until, in the past 200–400 years, they reached the British Isles. This gradual evolutionary pattern takes the form of a cline showing a distinct correlation between geographic and genetic distance, as estimated from the most recently emerged virus, louping ill (LI), at the most westerly geographic location, i.e. the British Isles. The determining factor for the clinal distribution of the TBE complex viruses is probably the tick vector (primarily *Ixodes ricinus* and *I. persulcatus*), which has a very long (3–5 years) life cycle, feeding only once at each stage of the life cycle and moving only locally when carried by forest animals on which it feeds. The virus probably spends most of its time replicating or persisting in ticks rather than vertebrate hosts (i.e. rodents, deer, horses, etc.), which, in the wild, rarely develop significant viremia.

In contrast to the TBE complex viruses, WSL virus is found in south and central Africa. Serological evidence suggests that WSL virus may also be present in Thailand but it is not yet entirely clear if the Thai virus represents an antigenically closely related virus. WSL virus infections occur most frequently amongst sheep and the associated *Aedes* spp. mosquitoes that increase in density and feeding activity during rainy seasons. Recent molecular phylogenetic data support the results obtained using serology, showing that WSL virus is genetically most closely related to YF virus, which is also widespread throughout central Africa but, in contrast to WSL virus, has retained a sylvatic existence with periodic escapes from the jungle environment to cause human epidemics in rural and urban areas.

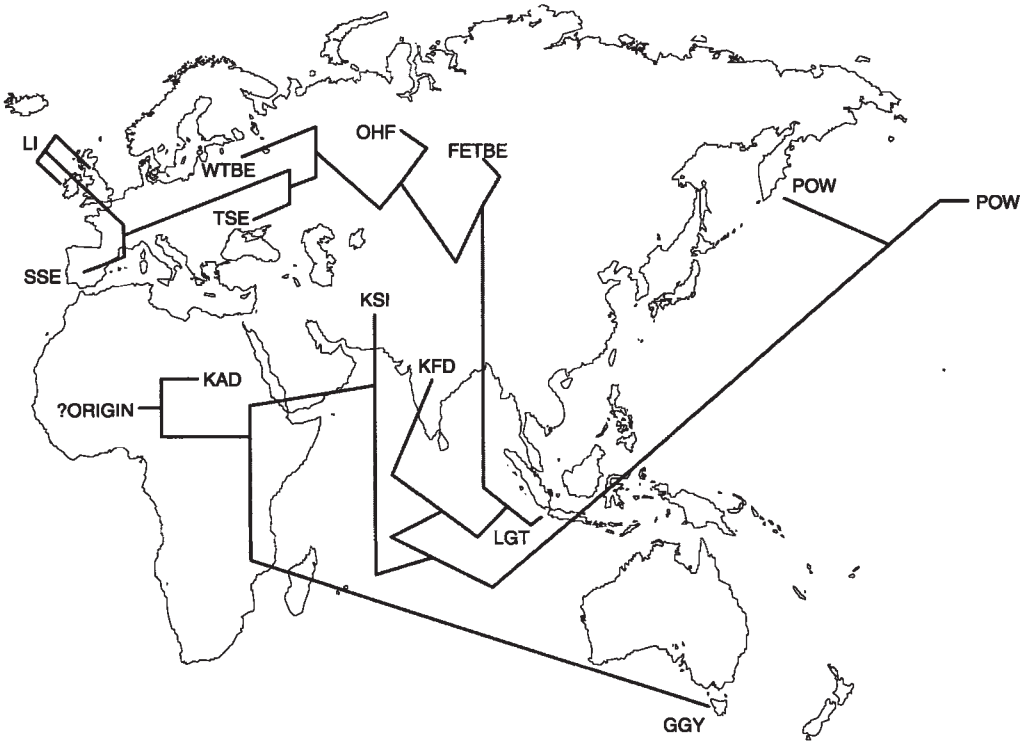

Figure 1 Predicted geographic dispersal pattern of the TBE virus complex during the past 5000–10 000 years. The illustration presumes an African origin for these viruses. The viruses can be identified from **Table 1**.

Host Range and Virus Propagation

Viruses in the TBE complex infect humans and a wide range of tick (*I. ornithodorus, Haemaphysalis, Dermacentor*) and wildlife vertebrate species, particularly forest rodents and birds. In many cases, indigenous vertebrates do not show clinical disease but produce antibodies in response to infection; however, severe disease often occurs in humans or animals encountering these viruses for the first time, such as livestock or domesticated animals. Louping ill disease first appeared as an epizootic sheep and grouse encephalomyelitis on the uplands of the British Isles, about 200–300 years ago when sheep and grouse were introduced on to the moors. Similar epizootics in sheep were observed on the Spanish, Turkish and Greek uplands, again following the introduction of sheep. The uplands, with their moist grassy undergrowth, provide an ideal environment for *I. ricinus* survival, and young nonimmune sheep provide a susceptible and readily available host for the tick. Tourists, hill-walkers, accompanying dogs and horses, etc. are all susceptible to infection if they encounter infected ticks.

WSL virus is found most commonly in sheep, to which it is transmitted by *Aedes* spp. mosquitoes. Cattle, goats and camels are also susceptible to infection when exposed. Human infections, obtained as an occupational disease, usually result in a febrile illness with rash. Seasonality of the disease is determined by the activity of the mosquitoes.

Propagation of TBE complex viruses or WSL virus can be achieved readily in the brains of newborn and young mice or hamsters and a wide range of vertebrate cell cultures, including Vero, LLC-MK2, BHK-21 and PS cells.

Genetics

Flavivirus genetic variability is constrained by the different structural and functional requirements of the two-host system, i.e. vertebrate and invertebrate. Amongst the seven nonstructural and three structural genes, NS5 is considered to be the most conserved, whereas the viral envelope (E) gene is believed to be one of the more variable genes, at least in part because of immune selection pressure. Nevertheless, phylogenetic trees constructed from sequence data based on any flavivirus gene are virtually identical, implying similar selective constraints on all flavivirus genes. The impact of the invertebrate host and its life cycle on evolutionary rates is revealed by the observation that mosquito-borne flaviviruses appear to be

evolving at more than twice the rate of tick-borne flaviviruses.

The genetic determinants of flavivirus pathogenicity remain to be identified but their complexity is evident from the fact that both single and multiple nucleotide substitutions or deletions may result in attenuation of virus virulence. Whether or not genetic recombination contributes to virus virulence is not known but dual infections with different flaviviruses have been recorded, thus providing the potential for genetic interchange.

An interesting and practical application of comparative amino acid sequence analysis is the ability to diagnose viruses on the basis of genetic marker sequences. The E gene of flaviviruses possesses at least three characteristic domains which categorize the viruses. A hexapeptide sequence (EHLPTA for most TBE complex viruses) at amino acid position 207–212 is unique to the TBE viruses. A pentapeptide sequence (DSGHD) at amino acid position 320–332 (for the TBE virus complex) identifies TBE virus and other serotypes, whereas a unique tripeptide (position 232–234) identifies individual viruses (NPH for LI virus).

Serologic Relationships and Antigenic Variability

High titer hyperimmune antiserum against any individual flavivirus crossreacts, in sensitive serologic tests, with any other flavivirus. On the other hand, monoclonal antibodies show panflavivirus, subgroup or species-specific reactivity. These serologic properties formed the basis of flavivirus classification prior to the construction of phylogenies based on sequence data, and although there are inherent weaknesses in the serogroupings, the essential distinctions have proved to be quite robust. The TBE serocomplex comprises about 12 antigenically closely related viruses. An additional group of three tick-borne viruses (Tyuleniy, Meaban and Saumarez Reef) is associated with seabirds. These viruses crossreact in complement fixation tests. The mosquito-borne and nonvectored viruses were subdivided into a further six or seven antigenic groups, depending on the serological methods and other criteria employed. An updated scheme of classification for the flaviviruses, based on available serological and molecular sequence data, is presented in **Table 1**.

Antigenic variability of flaviviruses is most often detected in the E gene in the form of neutralization escape mutants that can be selected in the laboratory using neutralizing antibodies. Naturally occurring antibody escape mutants of LI virus have also been isolated from field samples collected in parts of the UK where vaccine was used to protect sheep from LI virus infection, implying that immune selection pressure could operate in the natural environment. Many of these and the experimentally selected escape mutants show attenuated virulence for mice.

Epidemiology

Flavivirus epidemics arise when large numbers of susceptible vertebrates encounter high densities of active infected invertebrates. Epidemics of TBE are seen characteristically in the European, Siberian and Asian forests during spring and early autumn, when ticks quest in order to obtain a bloodmeal. Forest workers, soldiers, local residents or tourists enter these tick-infested areas, are bitten and subsequently may become infected. In the spring, forest animals become active following hibernation and increase their likelihood of exposure to the questing infected ticks. In contrast to TBE in the forests, LI epidemics occur as encephalomyelitis in sheep grazing on the moist coarse grasses of the moorlands in Britain. The high moisture content of the grasses on the moorlands is essential for tick survival. Sheep are an abundant source of blood for *I. ricinus* which parasitize immunologically naive sheep and transmit the virus as the bloodmeal is imbibed. In Ireland, the situation is different because of the higher moisture levels in the grasses at lower elevations. Louping ill is therefore frequently seen in pigs, cattle and horses which graze on the tick-infested pastures. Epidemic OHF in Siberia is another example of the influence of environmental perturbation on disease incidence. Muskrats imported from Canada were introduced on to farmlands in Siberia, where OHF virus is known to circulate amongst the rodent population. In contrast to the local rodents, the introduced muskrats were highly susceptible to OHF virus. Epidemics amongst farm workers hunting the muskrats, and the families of the farm workers, were also observed. A different epidemiological picture was observed in the Shimoga district of Mysore in India. Hemorrhagic disease was first reported in 1957 in monkeys found dead in the Kyasanur Forest. Subsequent investigations revealed that *Hemaphysalis* spp. ticks had transmitted KFD virus to the monkeys when they came down from the trees to forage for food scraps left by local workers as they were clearing the edges of the forest for urbanization projects. Humans became infected when they entered the edges of the forest and were exposed to infected ticks.

WSL virus epidemics occur widely in regions of Africa where immunologically naive sheep are available at times when *Aedes* spp. are abundant. The factors that determine the dispersal of viruses such as

WSL are not fully understood but, in addition to the need for an environment that can sustain farm animals and the associated mosquitoes, immunological crossreactivity with other flaviviruses is probably also significant in restricting WSL virus to particular geographic regions. Moreover, as climate change impacts on the world, the dispersal of WSL and other viruses may be altered.

Transmission and Tissue Tropism

The main invertebrate vectors of TBE complex viruses are ixodid ticks. *I. ricinus* transmits LI virus and European strains of TBE virus, whereas *I. persulcatus* is usually associated with TBE complex viruses further east across the former Soviet Union. KFD virus, on the other hand, has been isolated from a variety of ixodid ticks, and Powassan (POW) virus also seems to have a catholic invertebrate host range. The virus has been isolated from *Dermacentor andersoni*, various *Ixodes* ticks and even mosquitoes. The classic picture of transmission to vertebrates involves larvae, nymphs or adults transmitting the virus during the feeding process or becoming infected as they take a bloodmeal from viremic animals. Replete ticks then drop off and molt to the next stage of their life cycle before taking another bloodmeal. Virus replicates and survives in the ticks through the trans-stadial phases of their life cycle. Thus, ticks that became infected at the larval (or nymphal) stage could potentially transmit the virus when feeding at the nymphal (or adult) stage. An alternative mechanism has been proposed to explain transmission on nonviremic animals. It has been shown in the laboratory that infected ticks can transmit the virus to noninfected ticks as they cofeed in clusters on animals which do not develop viremia. Saliva produced by the cofeeding ticks enhances the efficiency of nonviremic transmission. Nonvectored transmission of TBE complex viruses has also been reported. For example, biphasic milk fever has been seen in humans as the result of drinking milk from infected animals such as goats. Moreover, grouse chicks can develop fatal encephalitis from eating infected ticks. There is also evidence of vertical transmission of TBE complex viruses, albeit it at low frequency. It has been shown that the virus can survive in tick eggs and then be transmitted to vertebrates at the subsequent stages of development during the life cycle.

Virus enters the vertebrate host following the bite of an infected tick and probably replicates locally before being transported to lymph nodes via Langerhans and other cells. Further replication takes place in extraneural tissues and a viremia becomes detectable. When encephalitis develops, the major target of TBE complex viruses is the central nervous system. Viruses within the complex may target different but specific neuronal cells and, depending on the particular virus, the disease may be seen as an encephalitis or an encephalomyelitis. Viruses such as OHF and KFD may show a preference for vascular tissues in the final stages of the infection. WSL virus is transmitted by a variety of *Aedes* spp. which become infected when they feed on animals with a high viremia. Replication of the virus in the mosquito occurs rapidly to produce a high titre which can then be transmitted to susceptible animals such as sheep when the mosquito takes a second bloodmeal, usually within a few weeks. WSL infections involve the liver and skin, and in more severe cases the central nervous system.

Pathogenicity

There are significant differences in pathogenicity between viruses of the TBE complex, ranging from those which have not been shown to cause overt disease, such as Gadget's Gully virus, to those which cause encephalitis and/or hemorrhagic fever. In addition, differences in virulence for mice between strains of a virus are often seen; for example, highly virulent strains and almost totally avirulent strains of LI virus have been isolated. Human cases of encephalitis involve cerebral and cerebellar cortex, brainstem, basal ganglia and spinal cord. In general, the case fatality ratio of TBE is higher in the eastern and far eastern part of Russia than it is in western Europe but the reasons for these differences in neurovirulence have not been adequately explained. There is accumulating evidence, based on serology and virus isolation, of chronic progressive human encephalitis caused by TBE complex viruses that are sequestered in neuronal tissues, and this is supported by experimental evidence of chronic encephalitis in monkeys. WSL virus is not known to have caused fatal infections in humans; however, it causes abortion and death of newborn lambs and pregnant ewes.

Clinical Features

Tick-borne encephalitis in western and central Europe tends to take a milder form than that seen in eastern and far eastern Russia. The milder disease is often biphasic. The onset, 3–7 days after infection, is influenza-like with headache, mild fever and myalgia. There is then an asymptomatic (or recovery) period lasting 5–8 days before a proportion of those affected develop the second phase, which involves the central nervous system. Up to 2–3% of cases may be fatal, the fatality rate being higher in adults. Up to 20% of severe cases have long-lasting neuropsychiatric symp-

toms. The more severe eastern form of TBE presents a significantly different clinical picture. It has a higher case fatality rate (20%) and a gradual onset, with fever, headache, anorexia, vomiting and photophobia. This is followed by a severe deterioration to paralysis and convulsions. Deaths occur usually within a week of onset. The disease is more severe in children than in adults and neurologic sequelae are seen in 30–60% of survivors. WSL virus in humans has an incubation period of 2–4 days, followed by a sudden onset of fever, chills, myalgia, hyperesthesia of the skin and hepatosplenomegaly and maculopapular rash. Involvement of the central nervous system has been observed in severe cases of human infection. In sheep and goats the disease is severe, usually leading to death in newborn lambs and abortion and maternal death in pregnant ewes. A mild and usually nonfatal febrile disease occurs in cows.

Pathology and Histopathology

Severe infections by TBE complex viruses show swelling, congestion and petechial hemorrhages. Monkeys infected intracerebrally show degenerative spongiform lesions and astrocytic proliferation. Histopathologic alterations in humans include meningeal and perivascular inflammation, neuronal degeneration and necrosis, neuronophagia and glial nodule formation involving cerebral and cerebellar cortex, brainstem, basal ganglia and spinal cord. Kyasanur Forest disease in humans causes parenchymal degeneration of the liver and kidneys, hemorrhagic pneumonitis and an increase in reticuloendothelial tissue in liver and spleen, with marked erythrophagocytosis.

Immune Response

Infection with a TBE complex virus stimulates antibodies against each of the recognized structural and nonstructural proteins. The predominant protective antibodies are those stimulated by the E and NS1 proteins. Antibodies against the E protein neutralize virus infectivity, inhibit virus hemagglutination and are generally crossreactive with TBE complex and other flaviviruses in nonfunctional tests such as ELISA or immunofluorescence microscopy. NS1-specific antibodies are less broadly crossreactive with non-TBE complex flaviviruses. Nonfatal infections by TBE complex viruses induce long-lasting immunity to reinfection with TBE complex-related viruses but there is insufficient information to predict the extent to which crossprotection occurs amongst more distantly related mosquito-transmitted flaviviruses. Conventionally, immune animals are not thought to be hosts for virus transmission by infected vectors; however, there is experimental evidence of TBE virus transmission by ticks cofeeding on immune rodents.

Prevention and Control

Immunization with an inactivated vaccine prepared in Austria and derived from a strain of western European TBE virus affords good protection against many of the TBE complex viruses when tested under experimental conditions in laboratory mice. This vaccine has shown good efficacy in Austria and neighbouring European countries, where the incidence of encephalitis due to western European TBE virus has dropped significantly following intensive immunization programs. The immunization schedule recommends three doses within the first few months, followed by a booster immunization every 3–4 years. An inactivated virus vaccine is also available for protection of sheep against LI virus infection. While its efficacy is undoubtedly good, LI virus persistence in areas of Scotland where the vaccine has been correctly used demonstrates that sheep are not the only significant hosts for maintenance of the virus in the environment. Recent evidence has shown that virus transmission between ticks cofeeding on mountain hares may also contribute to virus persistence. Apart from vaccination, control strategies for TBE complex viruses are based on avoidance of exposure to infected ticks when they are actively questing during the spring and summer/autumn. Most of the TBE complex viruses are associated with forest environments, whereas LI virus occurs on the sheep-rearing uplands in the British Isles, Spain, Greece, Turkey and Bulgaria and can therefore be avoided accordingly.

There are no recognized vaccines for WSL virus and control of the disease is difficult in areas of Africa where mosquito populations increase during rainy seasons.

Future Perspectives

Current research associated with the TBE complex viruses is focused on the development of new, improved broad-spectrum vaccines based on the E and NS1 proteins using molecular biological techniques. Other major areas of research include the NS1, NS3, NS5 proteins and the untranslated regions of the viral genome. The major questions being addressed are the role of these proteins in virus replication and virus virulence. Understanding these complex characteristics of the viruses will ultimately lead to the development of antivirals. Nucleotide and amino acid sequencing is providing the basis for detailed molecular epidemiological and evolutionary

studies which will explain the origin and dispersal of these viruses.

ENDOGENOUS VIRUSES

Bernhard F. Benkel, Agriculture and Agri-Food Canada, Lethbridge Research Centre, Livestock Sciences Section, Lethbridge, Alberta, Canada

Introduction

Endogenous proviruses are commonly described as prehistoric sequences or retroviral fossils that are derived from ancient infections of germline cells. They may be considered intimate partners in long-term relationships. In contrast to their exogenous counterparts, endogenous viral loci are inherited as stable mendelian genetic elements, i.e. transmitted vertically from parents to offspring. Many endogenous proviral elements contain defective or incomplete viral genomes and are noninfective, and replication-incompetent. There is mounting evidence, however, that a small number of endogenous proviruses are complete and able to direct the production of infectious viral particles that spread by normal means of transmission. In this entry, the terms 'complete' or 'functional' are used to differentiate those endogenous proviruses that encode infectious virus from the bulk of endogenous viral loci, which are defective and/or transcriptionally silent.

The distribution limits of endogenous retroviruses remain to be established. However, to date endogenous viral sequences have been reported in all but the most primitive vertebrate taxa. In addition, the genomes of several invertebrate species have been shown to contain genetic elements that are remarkably retrovirus-like. Thus, it is conceivable that endogenous retroviruses are ubiquitous among eukaryotes.

In higher vertebrates, endogenous proviruses represent a truly prolific class of genetic elements. For example, it has been estimated that up to 2% of the human genome consists of retrovirus-derived sequences. This state of affairs has prompted some researchers to declare that humans are 'descended from viruses as well as from apes'. Since the available data suggest that infections of germline cells by retroviruses are rare events, the large number of some of these elements in higher vertebrate genomes is generally interpreted as evidence that endogenous proviruses are effective at intragenomic spread, i.e. RNA-mediated retrotransposition within the host genome. The intimate association between endogenous proviruses and their hosts over long periods of evolutionary time has resulted in complex patterns of interrelationships, many of which are still poorly understood.

The literature on endogenous retroviruses has been growing at an exponential rate during the past few years. In fact, there are currently close to a thousand reports pertaining to endogenous viruses in the human genome alone. The existence of such a wealth of information means that an all-inclusive review of the field is no longer practical. Instead, this review will focus on three topical themes in endogenous retrovirology: (1) patterns of evolution within endogenous proviral families; (2) the interactions of endogenous elements with their host genomes and their role in modulating physiological processes in the host; and (3) endogenous proviruses and their significance to viral transmission and disease.

Taxonomy and Classification

Retroviruses are currently classified as part of a large array of *retroid* elements, which also includes the elements known as long interspersed elements (LINEs), and short interspersed elements (SINEs).

studies which will explain the origin and dispersal of these viruses.

ENDOGENOUS VIRUSES

Bernhard F. Benkel, Agriculture and Agri-Food Canada, Lethbridge Research Centre, Livestock Sciences Section, Lethbridge, Alberta, Canada

Introduction

Endogenous proviruses are commonly described as prehistoric sequences or retroviral fossils that are derived from ancient infections of germline cells. They may be considered intimate partners in long-term relationships. In contrast to their exogenous counterparts, endogenous viral loci are inherited as stable mendelian genetic elements, i.e. transmitted vertically from parents to offspring. Many endogenous proviral elements contain defective or incomplete viral genomes and are noninfective, and replication-incompetent. There is mounting evidence, however, that a small number of endogenous proviruses are complete and able to direct the production of infectious viral particles that spread by normal means of transmission. In this entry, the terms 'complete' or 'functional' are used to differentiate those endogenous proviruses that encode infectious virus from the bulk of endogenous viral loci, which are defective and/or transcriptionally silent.

The distribution limits of endogenous retroviruses remain to be established. However, to date endogenous viral sequences have been reported in all but the most primitive vertebrate taxa. In addition, the genomes of several invertebrate species have been shown to contain genetic elements that are remarkably retrovirus-like. Thus, it is conceivable that endogenous retroviruses are ubiquitous among eukaryotes.

In higher vertebrates, endogenous proviruses represent a truly prolific class of genetic elements. For example, it has been estimated that up to 2% of the human genome consists of retrovirus-derived sequences. This state of affairs has prompted some researchers to declare that humans are 'descended from viruses as well as from apes'. Since the available data suggest that infections of germline cells by retroviruses are rare events, the large number of some of these elements in higher vertebrate genomes is generally interpreted as evidence that endogenous proviruses are effective at intragenomic spread, i.e. RNA-mediated retrotransposition within the host genome. The intimate association between endogenous proviruses and their hosts over long periods of evolutionary time has resulted in complex patterns of interrelationships, many of which are still poorly understood.

The literature on endogenous retroviruses has been growing at an exponential rate during the past few years. In fact, there are currently close to a thousand reports pertaining to endogenous viruses in the human genome alone. The existence of such a wealth of information means that an all-inclusive review of the field is no longer practical. Instead, this review will focus on three topical themes in endogenous retrovirology: (1) patterns of evolution within endogenous proviral families; (2) the interactions of endogenous elements with their host genomes and their role in modulating physiological processes in the host; and (3) endogenous proviruses and their significance to viral transmission and disease.

Taxonomy and Classification

Retroviruses are currently classified as part of a large array of *retroid* elements, which also includes the elements known as long interspersed elements (LINEs), and short interspersed elements (SINEs).

Table 1 Characteristics of retroid elements

Retroid element	*No. per genome*	*Size (bp)*	*Components*
SINE	Up to 1 million	100s	pro, polyA
LINE	Up to 100 000	1000s	pro, pol, polyA
Retrovirus	Up to 1000s	1000s	pro, gag, pol, env, LTR

pro, promoter; polyA, poly(A) tail; pol, polymerase; gag, group-specific antigen; env, envelope; LTR, long terminal repeat.

Table 1 compares the structures of prototypes of the major classes of eukaryote retroid elements, and gives estimates of the abundances of these elements within the genome of a typical higher eukaryote. The prototypes for both the long terminal repeat (LTR) elements and the LINE elements encode a reverse transcriptase enzyme. The prolific SINE elements lack such a coding region, and SINE element replication is dependent upon reverse transcriptase activity encoded elsewhere within the host genome.

Complete retroviruses are distinguished from LINEs and SINEs by their genetic structure and their ability to direct the production of infectious viral particles. Unlike complete retroviruses, which can spread horizontally from host to host, the non-LTR LINEs and SINEs are intracellular retroids that spread mainly by colonization of noncarrier chromosomes during sexual reproduction.

The established classification system divides retroviruses, both exogenous and endogenous members of the *Retroviridae*, into seven genera: avian leukosis viruses, human T cell leukemia viruses, lentiviruses, mammalian type B viruses, murine leukemia-type viruses, spumaviruses and type D viruses. A recent report on retroviral distribution provides general support for these groupings, but also strongly suggests that a number of new groupings constituting highly divergent groups of retroviruses, especially spumavirus-like and murine leukemia virus-related endogenous retroviruses, will emerge as more detailed information on these viruses is gathered.

The standardization of the nomenclature used to describe endogenous viral elements is an issue that has yet to be resolved. For exogenous viruses, the situation is somewhat simpler and the descriptors have frequently included information on the discoverer of the strain, the associated type of disease, and the common host species, e.g. mouse mammary tumor virus or Rous sarcoma virus. Endogenous viruses frequently lack a direct association with any particular pathological condition, and the global distribution patterns of families of endogenous elements are in many cases still unclear. In addition, for many endogenous viruses, only fragments of genomic sequence are known, resulting in phylogenetic assignments that are tentative at best. Also, although there are some notable exceptions, most endogenous proviral families lack exogenous, disease-inducing counterparts. For these reasons, the nomenclature applied to endogenous retroviruses can perhaps best be described as colourful. For example, *ev* is still commonly used to designate *a*vian *l*eukosis *v*irus-type (ALV) elements found in chickens, both *Mtv* and endogenous MMTV are used to describe *m*urine *m*ammary *t*umor *v*irus-related (MuMTV) proviruses in mice, whereas RD-114 has been used to describe a feline viral element family. For human endogenous viruses a variety of naming systems has been employed in the past, e.g. *h*uman *T* cell *l*eukemia *v*irus-like (HTLV-like).

Against this background, the recent trend towards adopting a common four-letter descriptor, e.g. HERV for *h*uman *e*ndogenous *r*etro*v*irus, followed by a letter representing the tRNA primer type, is a welcome improvement. However, as more information becomes available on individual loci, this descriptor will need to be extended in order to identify individual elements within proviral families (see below). For some of the more prolific proviral families, such as the HERV-H family which may contain as many as 10 000 members, the typing and classification of individual loci represents a huge undertaking. Furthermore, some elements are shared between humans and other primates, and this information is lost through the assignment of an HERV designation.

Another area where the taxonomy of endogenous viruses can be confusing is the designation of elements within a family. The first and most extensively characterized family of endogenous viral elements consists of the avian leukosis subgroup E proviruses in chickens, originally called *ev* genes (for *e*ndogenous *v*iral genes). At the time of their discovery, the all encompassing descriptor of *ev* genes may have seemed appropriate. However the characterization of at least three other families of endogenous viral elements (EAV), in addition to the ALV-type proviruses, has necessitated a revision of the nomenclature. Poultry researchers have recently adopted a four-letter designation modelled on the human system; in this case with an embedded descriptor identifying the element family, e.g. *ALVE-#*, where the # refers to a specific *ALVE* element.

The *ALVE* proviral family is a particularly informative example of the problematic nature of endogenous virus taxonomy. Although a total of roughly 50 different *ALVE* elements are known to

exist within the *Gallus* gene pool, the small number of elements per chicken (typically 1–12) and the ability to breed lines of chickens carrying a single element have allowed *ALVE* proviruses to be studied in great detail. Based on extensive characterization of *ALVE* elements, it has become clear that a complete description of an endogenous provirus must include information on both the proviral genome and the insertion site within the host genome (also known as the unoccupied site or the flanking sequences).

A case in point is the element *ALVE*21 of 'late feathering' chickens, a complete endogenous element that produces infective subgroup E viral particles. Chickens of the Nunukan line, which display a 'very-late feathering' phenotype, carry a proviral insert at a location identical to that of *ALVE*21; however, the 5′ half of the provirus plus about 650 bp of host DNA at the upstream flank of the insertion site are deleted in Nunukan chickens. A further complication is that the insertion site of the *ALVE*21 element is part of a large duplication on the Z chromosome of the chicken genome. Thus, there are two potential insertion sites for *ALVE*21 in female chickens and four in males.

Substantial polymorphisms within the genomes of endogenous proviruses at identical locations in the host genome have also been described in primates. For example, sequence variability has been described for the ERV-3 envelope gene, and a deletion in the HERV-K gag gene is evident in hominids. Such variations in proviral genomic sequences can be crucial elements in determining the effect of a particular endogenous element on host physiology. A definitive description of each element of a proviral family is a daunting task with current technologies, even for a family with relatively few members such as *ALVE*, and it becomes much more difficult for families with large numbers of members. However, new methodologies are becoming available that can dramatically speed up molecular typing and should help tremendously in providing the analytical power necessary to generate endogenous element profiles quickly and inexpensively (see Prevention and Control).

Evolution

At some point in time, the ancestors of endogenous viral elements of many of the classes that we recognize today were fully functioning, infectious exogenous retroviruses. Most extant proviruses, however, contain incomplete genomes and are no longer capable of coding for infectious viral particles. Thus, the evolutionary history and the biphasic lifestyle of functional endogenous retroviruses (infectious horizontal spread versus intragenomic retrotransposition) are reflected in current host distribution patterns as well as the structure and sequence composition of proviral families and their individual endogenous element members.

When a novel endogenous retrovirus arises (novel in the sense that it uses a cellular receptor that is different from those recognized by existing viruses in a particular host), the virus has an essentially unlimited supply of target host individuals. During the initial stages of the colonization of a species, therefore, the typical 'exogenous' form of spread involving horizontal transmission of infectious virus is likely to be the predominant factor in host conversion. However, as the colonization of the host population proceeds, the number of host individuals carrying at least one insert of the novel viral class increases. Viral interference, i.e. the inability of retrovirus to superinfect cells already carrying provirus of a related family, will begin to limit the efficiency of horizontal spread. Consequently, intragenomic spread through genome colonization during meiosis will become the dominant mode of viral replication.

Along with this switch in lifestyle to intragenomic replication and vertical transmission comes a major change in the selective pressures operating on the proviral genome. The 'hit and run' lifestyle of the exogenous virus, which depends on its ability to produce a large number of complete, infectious particles quickly, is replaced by an intimate, long-term association between the pathogen and its host. For its persistence, the endogenous virus becomes crucially dependent upon its host, and viral loci that have negative effects on host survival will tend to be evolutionarily unstable.

The factors limiting the intragenomic expansion of retroviral families are not understood at this time. Selection for attenuation in order to minimize the genetic load exerted on the host due to insertional mutagenesis is part of the explanation. However, the somewhat perplexing observation that some families of virus are able to amplify to thousands of copies, while others appear as single inserts within the same host genome, suggests that there are as yet unidentified factors at work. In parallel with intragenomic colonization, selection for completeness and the capacity to produce infectious particles diminishes, and proviral loci accumulate defects in the form of point mutations and small deletions, as well as sizable internal deletions. The result is the emergence of families of virus where most member proviruses are defective. Theoretically, given a sufficiently long period of evolutionary time, this process of sequence erosion would eventually obliterate the recognizable features of the endogenous provirus family. At this

point, novel viruses, even ones employing the same receptor as the obliterated elements, could begin the process of genome colonization afresh.

Expression and Effect on Host Immune Response

Each endogenous provirus has the capacity to affect the outcome of a viral infection of the host by related classes of virus in at least two ways: (1) by programming the immune response of the host organism; and (2) by providing a barrier to superinfection through receptor blocking. Definitive experimental evidence for programming of the immune response of the host comes from the avian leukosis system in chickens – the only system for which selected lines carrying single, defined endogenous elements are currently available. The results, however, have broad-ranging implications.

A number of studies using both semicongenic lines and commercial birds of defined genetic backgrounds have provided clear evidence that certain endogenous elements modulate the response of the carrier individuals to infection by exogenous retroviruses in a predictable manner. The endogenous *ALVE* elements that mediate this effect are structurally complete and express functional viral particles. The nature of the effect is a generally diminished host immune response to exogenous virus that includes a delayed-onset, low-level antibody response to exogenous *ALV* subgroup A, as well as increased shedding of exogenous ALV particles into the oviduct resulting in an increase in congenital infections. The basis for the modulation of the immune response is that peptides encoded by endogenous proviruses can take part in the programming of the host's immune system. Thus, individuals carrying expressed endogenous proviral elements typically recognize virus-encoded peptides as self. The result is the lack of an effective immune response to incoming virus with similar antigenic determinants.

At the other extreme of the spectrum are endogenous elements that, instead of predisposing their hosts to chronic infections, actually provide protection against related strains of incoming virus. A prime example of this effect is the transgenic line of chickens carrying the defective ALV subgroup A provirus, *alv6*. *Alv6* expresses the ALV subgroup A envelope proteins only, and provides resistance to infection from exogenous ALV subgroup A virus by blocking the relevant cell surface receptors. Receptor blocking also appears to be responsible for resistance to infection by endogenous ALV in chickens carrying the provirus *ALVE6*, and in Fv-4 mice carrying the Fv-4r resistance allele. Receptor blocking is not the only mechanism by which endogenous viral elements can afford a measure of protection against infection upon their hosts. The *Fv1* gene in mice encodes a *gag*-like protein that restricts murine leukemia virus replication after viral entry but before proviral integration.

The nature of the effect that any particular endogenous virus will have on a carrier individual depends on the structure and expression of the proviral genome. Many proviruses are defective and retain the capacity to code for only a portion of the peptides necessary to produce an infectious viral particle. Some apparently complete proviruses are not expressed, presumably due to the silencing effect of host DNA at the proviral integration site. Thus, each proviral element needs to be assessed individually for its effect on host physiology, and accurate diagnostics are essential for predicting host–virus interactions.

Pathogenicity

Endogenous proviruses typically show low levels of transcriptional activity and/or aberrant patterns of RNA and protein expression, which are often ascribed to the accumulation of mutations and deletions in proviral genomes as well as hypermethylation of viral genes. As a result, the effects on host physiology of endogenous viral elements typically stem from the action of viral LTRs on adjacent host DNA, e.g. proto-oncogenes, as well as from a host immune response directed toward viral-encoded peptides. Both of these mechanisms can lead to the progression of disease states in the host species and recent evidence has implicated endogenous viruses in a number of conditions in humans including breast cancer, multiple sclerosis and lupus erythematosus.

The pathogenicity of endogenous viruses has also become a prime concern in the field of xenotransplantation. Although it is true that the majority of extant endogenous proviruses are nonfunctional and noninfective, there is a short but expanding list of examples where, either through the expression of intact viral loci or by complementation between defective endogenous proviral elements, vertebrate cells have been shown to produce infectious viral particles. Examples of this phenomenon include several porcine PERVs, the chicken *ALVE* prototype RAV-0, endogenous murine leukemia virus and human RTLV-H. The plasticity of the retroviral genome and the proven ability of some endogenous retroviral strains to cross species boundaries, especially under the chronic high level exposure conditions afforded by xenotransplantation, should provide ample motivation for the development of endogenous virus-free donor cells.

Prevention and Control

Due to their intimate association with the germplasm of their hosts, the control of endogenous viral elements poses a unique set of problems. Obviously, although eradication has worked well for eliminating exogenous retroviruses from some experimental and commercial populations of animals, there is little chance of selectively breeding out the thousands of endogenous viral elements in the typical animal genome. Central to the issue of control, therefore, are the enabling tools of rapid diagnostics and a large database on the physiological roles of individual proviral elements. In terms of rapid diagnostics, the development of DNA chip technology has resulted in a massive increase in DNA-typing ability over previously available methods. Whereas in the past, establishing the profiles of endogenous elements was a painstakingly slow process, DNA chip technology has the potential to facilitate data acquisition at an unprecedented speed. Thus, it may soon be feasible to establish the complete genetic profile for endogenous viral elements in any individual on a routine basis. Rapid diagnostics will also aid the process of defining the interrelationships between individual endogenous proviruses and their hosts.

The potential benefit for endogenous viral profiling in humans lies in the identification of carriers of the particular endogenous elements that are associated with morbidity states. Once such genetic risk factors have been determined, lifestyle adjustments can be made to avoid environmental factors that might compound the risks, and available treatment programs can be fine tuned to address specific disease potentials. For applications in other areas, such as farm animal health, molecular profiling of endogenous viral elements can be integrated with existing selection programs to reduce viral particle prevalence in food products, and to increase natural resistance to viral infection.

ENTERIC VIRUSES

Ruth F Bishop, Department of Gastroenterology and Clinical Nutrition, Royal Children's Hospital, Parkville, Victoria, Australia

Introduction

Viruses are amongst the first microorganisms to colonize the germ-free intestine after birth, where they encounter conditions ideal for growth, including warmth, an abundant supply of nutrients and continual replenishment of susceptible cells. Many viruses identified in feces, including reoviruses, adenoviruses and enteroviruses, have the capacity to replicate in the intestine without causing clinical symptoms. Other viruses detected in feces may be derived from swallowed secretions originating in the respiratory tract, from plant viruses ingested in food, or from phages released after bacterial lysis. Many viruses use the gastrointestinal tract as a portal of entry and may replicate there before initiating systemic disease (e.g. poliovirus, hepatitis A and E). A diverse group of viruses (rotaviruses, adenoviruses, caliciviruses, astroviruses, coronaviruses) replicate in the epithelial cells lining the small intestine, causing sufficient destruction to result in the symptoms of enteric infection, including diarrhea, vomiting, fever and dehydration. A further group of viruses of systemic origin (e.g. measles virus, cytomegalovirus

Prevention and Control

Due to their intimate association with the germplasm of their hosts, the control of endogenous viral elements poses a unique set of problems. Obviously, although eradication has worked well for eliminating exogenous retroviruses from some experimental and commercial populations of animals, there is little chance of selectively breeding out the thousands of endogenous viral elements in the typical animal genome. Central to the issue of control, therefore, are the enabling tools of rapid diagnostics and a large database on the physiological roles of individual proviral elements. In terms of rapid diagnostics, the development of DNA chip technology has resulted in a massive increase in DNA-typing ability over previously available methods. Whereas in the past, establishing the profiles of endogenous elements was a painstakingly slow process, DNA chip technology has the potential to facilitate data acquisition at an unprecedented speed. Thus, it may soon be feasible to establish the complete genetic profile for endogenous viral elements in any individual on a routine basis. Rapid diagnostics will also aid the process of defining the interrelationships between individual endogenous proviruses and their hosts.

The potential benefit for endogenous viral profiling in humans lies in the identification of carriers of the particular endogenous elements that are associated with morbidity states. Once such genetic risk factors have been determined, lifestyle adjustments can be made to avoid environmental factors that might compound the risks, and available treatment programs can be fine tuned to address specific disease potentials. For applications in other areas, such as farm animal health, molecular profiling of endogenous viral elements can be integrated with existing selection programs to reduce viral particle prevalence in food products, and to increase natural resistance to viral infection.

ENTERIC VIRUSES

Ruth F Bishop, Department of Gastroenterology and Clinical Nutrition, Royal Children's Hospital, Parkville, Victoria, Australia

Introduction

Viruses are amongst the first microorganisms to colonize the germ-free intestine after birth, where they encounter conditions ideal for growth, including warmth, an abundant supply of nutrients and continual replenishment of susceptible cells. Many viruses identified in feces, including reoviruses, adenoviruses and enteroviruses, have the capacity to replicate in the intestine without causing clinical symptoms. Other viruses detected in feces may be derived from swallowed secretions originating in the respiratory tract, from plant viruses ingested in food, or from phages released after bacterial lysis. Many viruses use the gastrointestinal tract as a portal of entry and may replicate there before initiating systemic disease (e.g. poliovirus, hepatitis A and E). A diverse group of viruses (rotaviruses, adenoviruses, caliciviruses, astroviruses, coronaviruses) replicate in the epithelial cells lining the small intestine, causing sufficient destruction to result in the symptoms of enteric infection, including diarrhea, vomiting, fever and dehydration. A further group of viruses of systemic origin (e.g. measles virus, cytomegalovirus

ds, Double-stranded; ss, single-stranded. The role of the virus as an etiological agent of diarrhea is not proven in the species in parentheses.

(CMV), human immunodeficiency virus (HIV)) may multiply in gut-related cells, again causing symptoms of enteritis.

The diversity of viruses excreted in feces confused the interpretation of initial tissue culture-based surveys aimed at detecting etiological agents of acute nonbacterial gastroenteritis. It was only after electron microscopy revealed noncultivable viruses in diarrheal stools and not in control specimens that many viruses causing acute enteritis could be identified and studied in detail. Viruses belonging to at least seven different genera have now been implicated in the etiology of acute enteritis in animals, avian species and humans (**Table 1**).

History

The symptoms of acute diarrhea were described in the earliest medical writings, long before the concept of infectious agents was considered. Reports of viral enteritis are impossible to identify with accuracy because of the nonspecific nature of the symptoms resulting from injury to intestinal epithelial cells. However, nineteenth and early twentieth century accounts of 'pseudocholera infantum', as a severe watery diarrhea in young children during winter months, make it likely that rotavirus infection may have been implicated in this often fatal disease.

In 1943 a filtrate of stools from infants with diarrhea induced diarrhea in young calves. Many years later, rotaviruses were identified in calf feces obtained at the time. Similar experiments in the 1960s induced diarrhea in a proportion of human volunteers, giving evidence for involvement of an 'ultrafilterable agent' (presumed to be a virus) in the etiology of epidemic gastroenteritis. Eventually in 1972 the 27 nm Norwalk virus was identified, by immunoelectron microscopy, as a cause of gastroenteritis in older children and adults. In 1973 the 70 nm human rotavirus was identified by electron microscopy in duodenal tissue and stools from young children admitted to hospital for treatment of acute diarrhea. Similar particles had been described in 1963 as a cause of epidemic diarrhea of infant mice, and in 1967 as a cause of diarrhea in calves. Electron microscopy (**Fig. 1**) then revealed a great variety of other noncultivable viruses in stools, some of which have been shown to be etiological agents of acute enteritis in animals and humans, and others for which evidence of an etiological role is still not proven.

Rotaviruses (*Reoviridae*)

Rotaviruses are approximately 70 nm in diameter with a wheel-like appearance (*rota* is Latin for wheel) (**Fig. 2**). The genome is composed of double-stranded

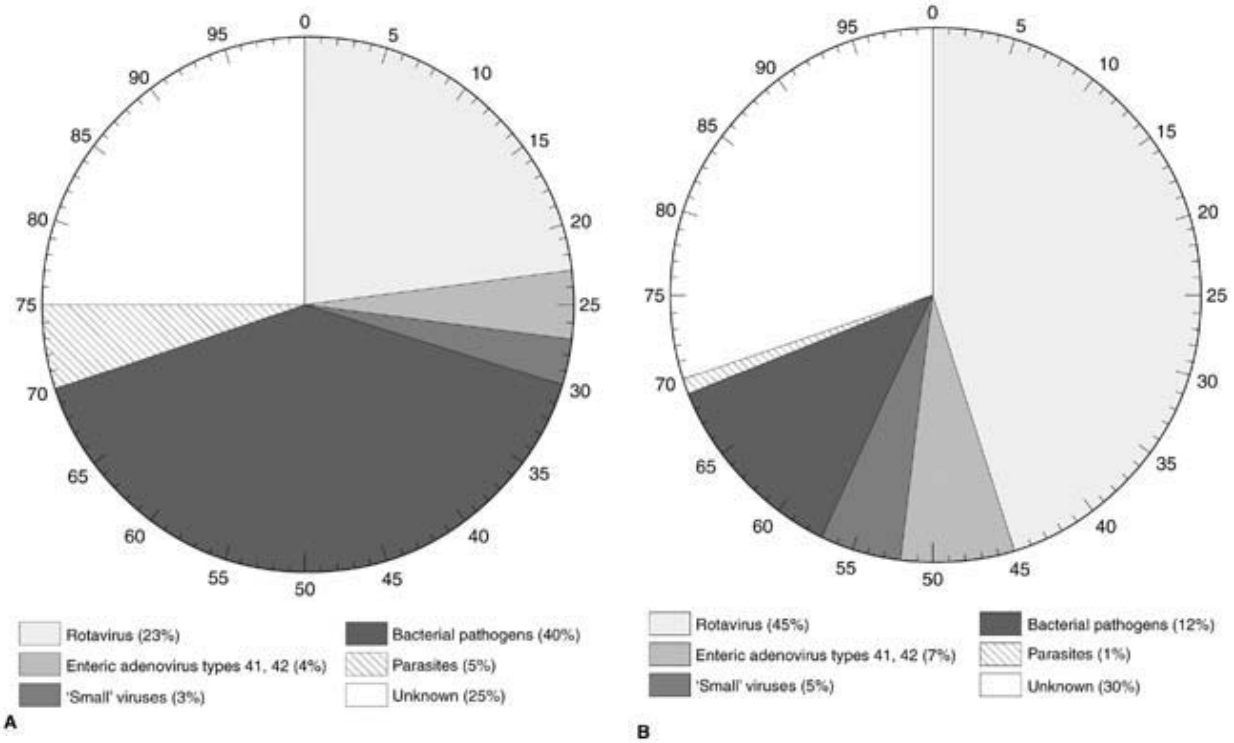

Figure 1 Etiology of severe acute diarrhea in young children in (**A**) developing and (**B**) developed countries (data compiled from published surveys).

RNA which can be separated into 11 segments (genes) by polyacrylamide gel electrophoresis. The inner capsid protein bears non-neutralizing antigenic epitopes that allow serological subdivision of the strains into groups A–F. The majority of human infections studied to date are caused by group A rotaviruses.

Group A rotaviruses

These are ubiquitous in nature and infect the young of all mammalian and avian species. They cause life-threatening diarrhea, predominantly in young children aged 6–24 months, and epidemics of mild to severe diarrhea in newborn animals and birds. Newborn babies are susceptible to infection, but this is often asymptomatic, either because rotaviruses adapted to growth in the neonatal intestine are naturally attenuated and/or because maternally derived antibody reduces the severity of symptoms. Reinfections occur regularly thoughout life. Group A rotaviruses have a worldwide distribution and cause 20–45% of disease in children admitted to hospital. Seasonal epidemics occur in children during the colder months of the year. Infection is endemic throughout the year in tropical countries. Group A rotaviruses present an almost limitless spectrum of genetic variation, but antigenic variation appears more restricted. Rotaviruses are species-specific, although cross-species infections can be induced under experimental conditions. When this occurs, rotavirus replication is minimal, thus reducing the likelihood of horizontal transmission of infection. Occasional zoonotic infections have occurred in humans. There is

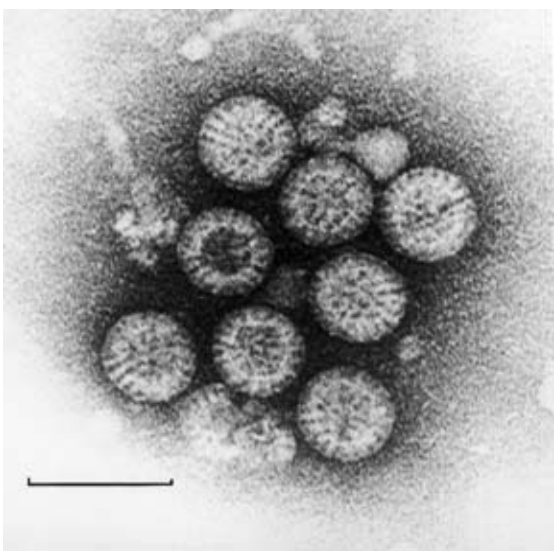

Figure 2 Electron microscopic appearance of negatively stained rotavirus particles. Bar = 100 nm.

a potential for human and animal strains to reassort in nature. During natural group A rotavirus infections, as many as 10^{10} particles ml^{-1} are shed in feces. The virus is highly infectious, spreads rapidly to contacts, and can retain infectivity for several months in the environment, and in sewage.

Group A rotaviruses are divided into serotypes by identification of neutralizing antigens on the two outer capsid proteins VP7 (G-type) and V4 (P-type). To date 14 G-types and 20 P-types have been identified. G1P1A[8] infections have been overwhelmingly predominant in humans worldwide during the past two decades.

The non-group A rotaviruses

Also referred to as 'novel' rotaviruses, pararotaviruses or atypical rotaviruses, these are morphologically identical with group A rotaviruses, although some disintegrate more readily and appear in negatively stained preparations as thin-walled featureless core particles. They show differing patterns of mobility of the 11 genome segments, and to date all have lacked the 7-8-9 gene triplet characteristic of group A rotaviruses. They do not react serologically in assays to identify group A rotaviruses. Attempts to produce reassortants between group A and non-group A rotavirus *in vitro* have been unsuccessful. All appear to be species-specific. All have been difficult to adapt to cell culture, with limited success using swine kidney cells (group B), swine testicular cells and CaCO-2 cells (group C).

Non-group A rotaviruses can be subdivided into serogroups B–G. Group B rotaviruses have been identified in pigs, cattle, sheep, rats and humans. Infections in farm animals may often be asymptomatic or cause only mild symptoms. The numbers of particles shed during infection appear to be less than in group A infections. Their distribution worldwide is uncertain. Serum surveys indicate a moderate prevalence (10–20%) of antibodies to group B rotaviruses in humans in China, the USA and Australia, and group B rotaviruses caused a large epidemic of severe enteritis in older children and adults in China in 1982–1983.

Group C rotavirus infections have been recorded in pigs, ferrets and humans. Infection is thought to be relatively common in pigs in the UK and USA (as judged by serum surveys) but severe disease may be comparatively rare. A similar situation may occur with humans. Antibodies have been detected in 43% of sera from humans (0–75 years), with the highest incidence (60%) in the 71–75 year age group, but severe infections are rare (<2% of children admitted to hospital worldwide). Most symptomatic infections have been associated with family or community outbreaks. Infection with group C rotaviruses has been suggested as a cause of biliary atresia in infant humans.

Groups D, F and G have been identified frequently in chickens, pheasants and turkeys in the UK and USA, where they appear to be more common than group A infections. Group E rotaviruses have been identified in pigs.

The importance of non-group A rotavirus infections in animals and humans will be debatable until suitable diagnostic tests are developed and used widely.

'Enteric' Adenoviruses (*Adenoviridae*)

Adenoviruses are nonenveloped icosahedral particles of 75–80 nm in diameter (**Fig. 3**). The virion contains a genome composed of double-stranded DNA coding for 10 different structural polypeptides. Human adenoviruses are classified into six subgenera, A–F (with different trophisms), each containing one or more serotypes. 'Enteric' adenoviruses causing disease in humans belong to subgenus F, serotypes 40 (Ad40) or 41 (Ad41). Restriction enzyme analysis indicates heterogeneity within both serotypes. Neither replicate in conventional cell culture but can

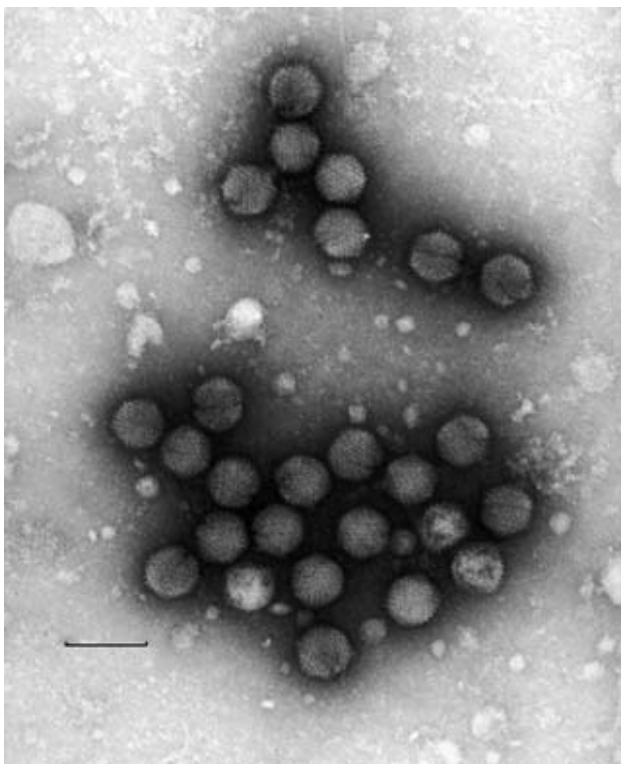

Figure 3 Enteric adenoviruses. Bar = 100 nm.

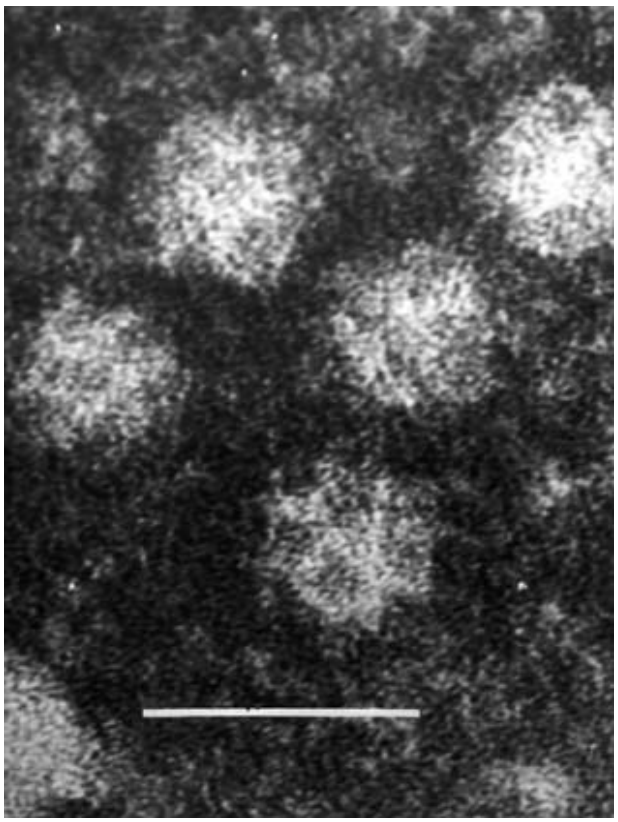

Figure 4 Caliciviruses (HuCV). Bar = 50 nm.

be coaxed to grow in Graham 293 cells (transfected with regions of Ad5).

Enteric adenoviruses (Ad40, Ad41) have been identified worldwide as a cause of severe diarrhea in 7–17% of children admitted to hospital. The relative incidence of Ad40 has declined since 1981, and Ad41 infections have shown a rapid rise in prevalence in North America, Europe and Australia. Enteric adenoviruses are a common cause of nosocomial infection, with an incubation period of 7–8 days. Diarrhea is often protracted, lasting up to 12 days, and viral excretion can be prolonged. Immunodeficiency may enhance enteric adenovirus infections because these viruses have been found more frequently than other enteric viruses in bone marrow transplant patients, and in patients with HIV-associated diarrhea. They cause fatal enteritis in immunodeficient foals.

Adenoviruses (of other serotypes) have been reported to cause hemorrhagic enteritis in turkeys, enteritis in mice and mild diarrhea in weaned piglets. Infections in calves or lambs are rare. 'Nonenteric' adenoviruses are common in human feces, perhaps derived from swallowed respiratory secretions. The ability of adenovirus 7 to colonize the human intestine asymptomatically has led to its suggested use as an oral vaccine vector.

Caliciviruses (*Caliciviridae*)

These are small (35–40 nm) single stranded RNA viruses (**Fig. 4**) 'Classical' caliciviruses show characteristic surface cup-shape indentations (calices), but many other members of this family are described as small round structureless viruses (SRSV) with an amorphous surface structure and a feathery ragged outline. Some of the size variations noted by electron microscopy and/or the relative scarcity of particles detected in feces may be due to proteolytic degradation of particles shed in feces. Caliciviruses possess only a single major structural polypeptide and comprise at least five genogroups. Caliciviruses associated with enteritis appear to be highly species-specific, and have been described in cattle (Newbury agent), pigs, chickens, dogs and humans.

The disease due to human caliciviruses (HuCV) was initially studied in adult volunteers using oral administration of fecal filtrates, leading to the discovery of Norwalk virus in 1972 by immune electron microscopy. This was followed by the description of many other small viruses implicated in gastroenteritis outbreaks. Most of these viruses were named after their geographical origin, e.g. Hawaii agent, Snow Mountain virus, Sapporo virus, Mexico virus, but now are known to have worldwide distribution. Identification and classification within HuCV took an enormous leap forward with the development of reverse transcriptase polymerase chain reaction primer-based hybridization assays, and enzyme immunoassays using recombinant antigens. Preliminary genetically based classification now recognizes three HuCV genogroups represented by Norwalk virus (NV), Snow Mountain agent (SMA) and Sapporo virus. The Sapporo virus genogroup has been detected in 0.5–6.6% of sporadic gastroenteritis in hospitalized children. The NV and SMA genogroups have predominantly caused outbreaks of diarrhea (in all age groups) as a result of ingestion of contaminated food/fluids. Etiological surveys undertaken in the USA have shown that approximately 65% of outbreaks of gastroenteritis in camps, cruise ships, nursing homes, schools and families have been associated with excretion of HuCV. HuCV are still recalcitrant to growth *in vitro*, and these viruses have not been visualized in intestinal tissue, despite repeated attempts.

Astroviruses (*Astroviridae*)

These viruses have a diameter of 28–30 nm and possess a positive-strand RNA genome coding for four structural polypeptides. A surface structure with a five- or six-pointed star-like appearance (hence

astrovirus) can be seen by electron microscopy on 5–10% of particles (**Fig. 5**). These viruses were first described in association with an outbreak of mild diarrhea in newborn infants. Strains have been identified in many animals including calf, lamb, pig, cat, dog, duck and turkey. Experimental infections are usually asymptomatic or produce only mild symptoms, although infected ducklings can develop fatal hepatitis. Infections appear to be host-specific. Seven human serotypes that are serologically distinct from animal strains have been described. Serotype 1 has been responsible for >50% of all human astrovirus infections described to date.

Human astrovirus infections occur worldwide, with peak incidence in winter/spring in temperate climates. Illness is usually mild, with an incubation period of 3–4 days, and is accompanied by seroconversion. Symptomatic astrovirus infection is mainly restricted to young children and can account for severe diarrhea in ≤5% of hospitalized children. Outbreaks of astrovirus gastroenteritis have been observed in nursing homes for the elderly (Marin county agent), among military recruits, and in immunocompromised patients. An enzyme immunoassay incorporating monoclonal antibodies and an RNA probe hybridization assay have been developed recently to facilitate diagnosis. Antibody prevalence surveys show that 65% of 3–4-year-old children and 87% of 5–10-year-old children possess serum antibody. The virus can be propagated in human embryo kidney cells in the presence of trypsin, and in human colonic carcinoma cell lines (CaC02, HT-29).

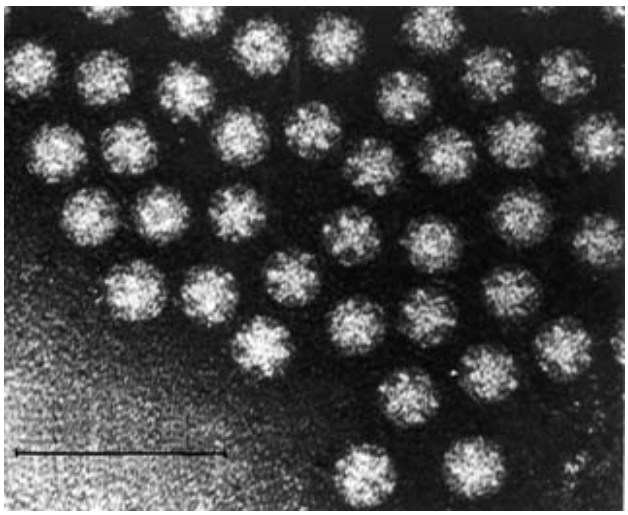

Figure 5 Astroviruses. Bar = 100 nm.

Parvoviruses (*Parvoviridae*)

These are small structureless single-stranded DNA viruses of 18–26 nm diameter. Some have caused severe acute gastroenteritis in cats, dogs, mink and calves. Pathogenesis clearly differs from most other enteric infections, as primary virus replication after ingestion occurs in lymphoid tissues, followed by viremia. Secondary replication (within a few days) occurs within the intestinal epithelium, where infection of crypt cells is widespread. No equivalent infectious agents have been described in humans. A heterogeneous collection of small round featureless viral particles of similar size has been described in diarrheal feces from humans. The particles have a size range of 22–26 nm diameter, with no discernible surface features and no sharply delineated outer edge. They resemble parvoviruses in morphology, size and buoyant density. These particles (Ditchling, W, Paramatta 'cockle agents') have been detected in stools of patients involved in approximately one-third of outbreaks of gastroenteritis attributed to ingestion of shellfish or cold foods. There has been frequent dual infection with other viruses confirmed as etiological agents of enteritis. No serological evidence of infection with these small viruses has been demonstrated. It is possible that these parvovirus-like particles are endemic 'intestinal' viruses that replicate to low titer in crypt cells, and that infection by other enteric viruses stimulates replication of crypt cells, favoring increased replication and fecal shedding of these particles.

Coronavirus/Coronavirus-like Particles (*Coronaviridae*)

Coronaviruses are enveloped single-stranded RNA viruses, visible in feces by electron microscopy as large pleomorphic particles (80–120 nm diameter) with a characteristic corona (crown) projecting as a single or double fringe of 10–20 nm length (**Fig. 6**). Coronaviruses are undisputed causes of epidemic diarrhea in newborn piglets *t*ransmissible gastro*e*nteritis *v*irus (TGEV), calves, foals, mice, rabbits, turkeys, dogs and cats. Large pleomorphic fringed particles resembling coronaviruses have been identified in humans in outbreaks of gastroenteritis among army personnel and hospital nurses, and in newborn babies with bloody diarrhea and necrotizing enterocolitis. Pleomorphic particles resembling coronaviruses have frequently been observed in symptomatic and asymptomatic adults and children living in crowded unhygienic conditions. The significance of many of the fringed particles seen in human feces in relation to enteric symptoms is controversial. In some circumstances, the particles may arise from degenerate fragments of intestinal tissue or they may be

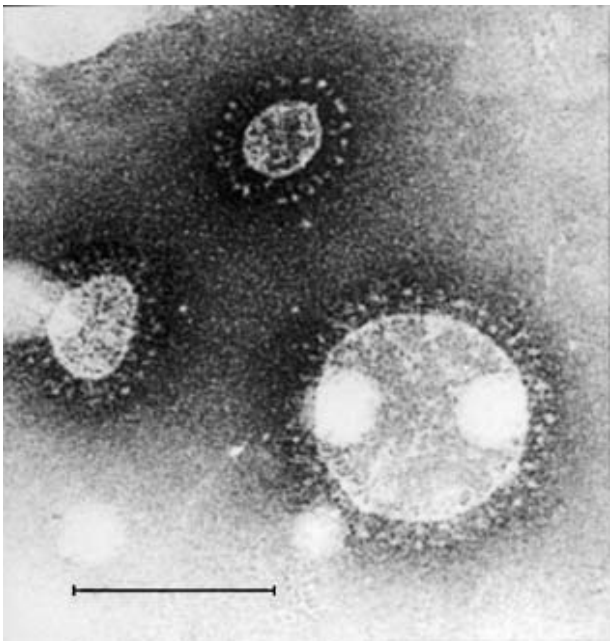

Figure 6 Coronavirus-like particle. Bar = 100 nm.

immunologically related to human respiratory coronaviruses. However, coronavirus-like particles shed in feces by babies with necrotizing enterocolitis replicated in human fetal intestinal organ culture, and homologous seroconversions were demonstrated in paired sera from these infants. Recognition and identification of human enteric coronaviruses requires development of specific diagnostic techniques. Only then will their importance in human infections be resolved.

Toroviruses (*Coronaviridae*)

These are positive-strand RNA viruses classified as a genus within the family *Coronaviridae*. They are visible by electron microscopy of feces as 100–140 nm pleomorphic fringed particles (spherical, kidney-shaped or elongated) with 10–20 nm long peplomers. These viruses infect a number of animal species but appear to be most common in horses (Berne virus) and calves (Breda viruses). Equine infections appear to be asymptomatic. Diarrhea due to Breda viruses has been reproduced experimentally in gnotobiotic calves. With the exception of Berne virus (successfully cultivated in equine dermal cells), none have been adapted to growth *in vitro*. Serum antibody surveys indicate that torovirus infection, but not disease, is widespread among cattle in the UK, Europe and the USA. Antibody has been detected in humans, goats, sheep, pigs, laboratory rabbits and wild mice. Toroviruses have been identified as a cause of diarrhea in humans (including children) in the UK, France, the USA and Canada. Etiological and epidemiological studies require improved methods for detection, and strict criteria to differentiate toroviruses from other 'fringed particles' seen in feces. These viruses may prove to be widespread and of low pathogenicity in the intestinal tract.

'Picobirnaviruses'

These are double-stranded RNA viruses (assumed to be members of the family *Birnaviridae*) initially detected by polyacrylamide gel electrophoresis (PAGE) in 14 of 3134 fecal samples from Brazilian patients with acute gastroenteritis. The 32–35 nm particles resemble viruses found in intestinal contents of rats, calves, pigs, hamsters and guinea pigs. Similar particles have since been reported in approximately 10% of humans (aged 3–70 years) in the UK, and in 10% of HIV-infected patients in the USA. 'Picobirnaviruses' appear to be widespread in humans but their role in human disease is not known.

Enteroviruses/Reoviruses

Routine cell culture of human feces will frequently show reoviruses and enteroviruses (including poliovirus, echoviruses, coxsackieviruses) excreted by patients with and without diarrhea. Most are coincidental infections, unrelated to an etiology of diarrhea, but there is evidence implicating group A coxsackieviruses and echoviruses types 11 and 18 as causes of diarrhea in normal and in immunodeficient patients. Reoviruses can produce diarrhea in animals, including mice, where the intestine is a portal of entry for systemic infection.

Other Viruses

Diarrhea is associated with a variety of other viruses that more characteristically produce systemic infections. Viremia can result in infection of gut epithelium or of cells in the lamina propria. For example, diarrhea is a common and severe complication of *measles* infection in children in tropical countries. CMV infection (in patients with HIV infection or immunoincompetence due to other causes) produces changes ranging from mild inflammation to ulceration and necrosis at all levels of the intestinal tract, associated with gastrointestinal symptoms relative to the level of gut infected. HIV may directly cause an enteropathy, with symptoms of weight loss, diarrhea, vomiting and abdominal pain.

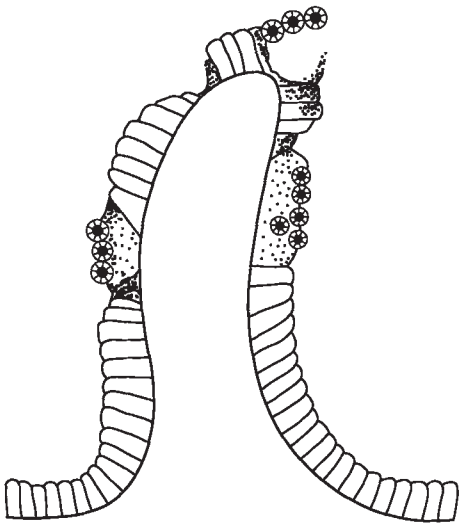

Figure 7 Small intestinal villus infected with rotavirus.

Clinical Features of Enteric Infection

Clinical features of viral enteric infection (regardless of agent) include an abrupt onset of vomiting, fever and diarrhea. Infections in adult humans (particularly with caliciviruses) predominantly involve nausea and vomiting. Profuse watery diarrhea in young children (and other young animals) can lead to dehydration, acidosis and electrolyte imbalance. Feces do not contain blood, white cells or mucus. Abdominal cramps occur but are much less frequent than with bacterial infections. Respiratory symptoms are present in 20–40% of children but may be coincidental. Vomiting usually persists for 24–48 h, and diarrhea for 2–7 days. Depression of mucosal disaccharidase activity leads to lactose malabsorption in a proportion of young children, and may persist and require dietary modification.

Pathology and Histopathology

Most enteric viruses implicated in the etiology of acute diarrhea replicate only in the mature absorptive epithelial cells of the villi of the small intestine (**Fig. 7**). The inability of these cells to undergo further replication *in vitro* has been the main barrier to adaptation of many enteric viruses to cell culture. *In vivo* replication in these cells produces similar histopathological changes in the intestine of animals and humans. Rotaviruses, Norwalk viruses, astroviruses and caliciviruses preferentially infect the upper small intestine, whereas adenoviruses, toroviruses and coronaviruses commonly infect the lower small intestine. Toroviruses also infect the colon. Most enteric viruses have been detected in M cells overlying lymphoid tissue, but do not appear to replicate in lamina propria or lymph nodes. Parvoviruses (and Breda viruses) also infect crypt cells. Only parvoviruses have been conclusively shown to have a viremic phase.

Histological changes observed in gut mucosa at all levels are similar. Initially, epithelial cells (infected and uninfected) are stripped from the sides and tips of villi, which may be denuded. Villi become stunted, and are covered with nonabsorptive cells derived from mitosis of crypt cells. The intestine is rapidly repopulated by mitosis of crypt cells, resulting in restitution of normal villus architecture covered by new mature absorptive villus cells. Crypt cell hyperplasia may be mediated via the hormone enteroglucagon, levels of which are raised in calves after enteric virus infections. The availability of newly regenerated absorptive cells may lead to a brief second wave of viral replication.

Treatment

Treatment consists of replacement of fluid losses, usually by administration of oral fluids containing glucose and electrolytes. Early resumption of normal feeding is encouraged, particularly in malnourished children. Breast-feeding can usually be continued throughout the illness. Lactose malabsorption may be a problem in a proportion of young children: reduction of lactose content in feeds may be required. There is no place for use of antibiotics or antiperistaltic agents in treatment of viral enteritis.

Immune Responses

The humoral immune response has been analyzed in great detail for human rotavirus infection. Specific antibodies detectable in intestinal contents and feces (of immunoglobulin IgA, IgM class) and serum antibodies (IgG, IgA, IgM class) appear during the first week after onset of infection. Serum antibody levels cannot be used as predictors of immunity to reinfection. The level of ingested or persisting antibody in the intestinal lumen can be predictive of immunity. Longitudinal studies of rotavirus infection in children (in developed and developing countries) show that primary infection (symptomatic or asymptomatic) does not confer immunity to reinfections, which are frequent, but does result in clinical immunity to development of severe symptoms during reinfection (**Fig. 8**). Immunity to caliciviruses following infection appears to be influenced by the infecting agent. Sporadic pediatric infections (due to Sapporo viruses) are associated with long-lived immunity. However, immunity to HuCV after epidemic out-

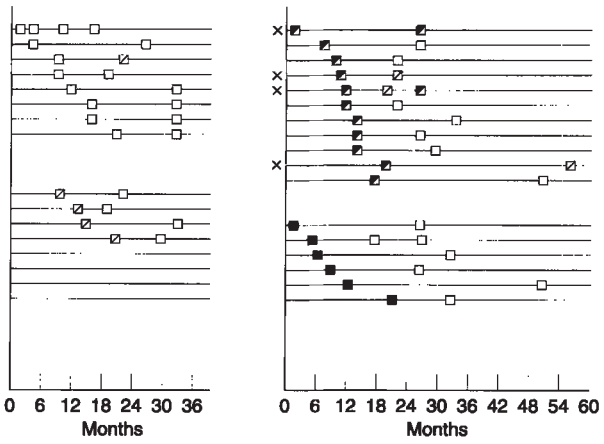

Figure 8 Longitudinal serological surveillance of rotavirus infection in 29 children recruited at birth and studied for 36–60 months (each line represents one child). □, Asymptomatic seroconversion; ▨, mild diarrhea on seroconversion; ◩, moderate diarrhea on seroconversion; ■, severe diarrhea on seroconversion; ×, children with more than one symptomatic infection.

breaks (in older age groups) is short-lived with no apparent protection against reinfection with the same viruses. Adult volunteers given Norwalk virus orally on more than one occasion were either repeatedly ill or persistently well. Volunteer studies with Norwalk virus show that approximately 50% of adults have an inherent resistance to infection (and disease) that has no detectable immunological basis. Cell-mediated immune responses have been demonstrated after rotavirus infection, and are important for cessation of virus excretion. Their role in long-term immunity is not known.

Prevention and Control

Some viral enteric infections, e.g. epidemics of waterborne or food-borne disease, could be controlled by improved sanitation and hygiene. Public health departments need to remain on the alert to monitor outbreaks and identify sources of infection. Infections where fecal/oral person-to-person spread is common are less likely to be controlled by improvements in sanitation. Implementation of strict crossinfection control measures could limit nosocomial spread of some infectious agents in hospitals, daycare centers, etc. However, the development of vaccines, particularly against rotavirus infection, is likely to have the greatest impact in both animals and humans on reduction of morbidity and mortality resulting from enteric viral infections.

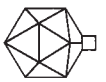
ENTEROBACTERIA PHAGE N4 (*PODOVIRIDAE*)



Lucia B Rothman-Denes, Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, Illinois, USA

Introduction

Coliphage N4 is a lytic phage specific for *Escherichia coli* K12 with a linear double-stranded genome 72 kb in length. The phage, originally isolated from the sewers of Genoa by G. C. Schito, displays several unique features, which include the sequential use of three different DNA-dependent RNA polymerases to transcribe its genome, a virion-encapsulated RNA polymerase which is injected into the host cell along with the phage DNA upon infection, the use of single-stranded DNA-binding proteins as transcriptional activators, and the presence of 3′ extensions at the ends of its linear genome.

Taxonomy and Classification

The phages of Enterobacteriaceae are classified with the *Podoviridae* in the family containing the T7-like phages. Phage N4 is assigned to the same genus, 'T7-like viruses' as the better-studied T7, based upon the size of its icosahedral head and short noncontractile tail. P22 has recently been assigned to a separate genus, 'P22-like viruses'.

Virion Structure

Electron microscopy of negatively stained N4 virions reveals particles with an icosahedral head 70 nm in diameter, a base plate, a small noncontractile tail, and short tail fibers originating at the neck. The particle weight is about 83×10^6, half of which is contributed by DNA. Virions contain at least 11 proteins, ranging in denatured molecular mass from 350 kDa to 16.5 kDa. The major capsid protein, which makes up 65% of the total protein of the virion, is 48 kDa.

The genome is a linear double-stranded DNA molecule approximately 72 kb in length with terminal direct repeats varying in length from 390 to 440 bp. The left and is relatively unique with the 5- or 6-base 3′ protruding sequences 3′-CATAA or 3′-CATAAA. In contrast, at least six discrete families are present at the right-hand end, differing in length by 10 bp and giving rise to the variability in the length of the terminal repeats. Each of these ends exhibits 1- to 3-base 3′ extensions.

Growth Cycle/Morphogenesis

Upon adsorption, the phage injects its DNA and a virion-encapsulated, DNA-dependent RNA polymerase which transcribes the early region of the genome. Synthesis of N4 middle transcripts, which appear 3 min after infection, requires the activities of three early proteins (p4, p7 and p17). Middle transcripts encode, in part, proteins required for N4 DNA replication. N4 DNA synthesis begins approximately 7 min after infection. Late RNA synthesis requires the activity of the *E. coli* RNA polymerase and begins 13–15 min after infection. A middle gene product, the N4 single-stranded DNA-binding protein (N4SSB), activates the host polymerase to initiate transcription at late promoters. Late RNAs code for morphogenetic proteins, including the virion RNA polymerase. Approximately 30 min after infection, the first progeny appear. N4-infected cells are lysis-inhibited, with up to 3000 N4 particles per infected cell accumulating intracellularly over a 3 h period. Enlarged cells filled with paracrystalline arrays of virions are observed under the electron microscope.

Gene Expression

N4 transcription is regulated in a hierarchical manner, with phage transcripts falling into three classes (early, middle and late) based on their time of appearance following infection. Early and middle transcription occur at the left half of the genome and proceed with a rightward polarity, whereas late transcription occurs at the right half of the genome with a leftward polarity.

Early transcription

Phage with temperature-sensitive mutations in the virion RNA polymerase are defective in early transcription, indicating a requirement for the virion RNA polymerase in this process. The virion RNA polymerase, which consists of a single, 3244 amino acid polypeptide, has been purified to homogeneity from N4 virions, where it is present in 1–2 copies. *In vitro,* virion RNA polymerase uses denatured N4 DNA as a template and exhibits little activity on native N4 DNA or heterologous denatured or native DNAs. Initiation of transcription on denatured N4

DNA occurs at unique sites which coincide with the sites of *in vivo* early transcription initiation. N4 virion RNA polymerase utilizes these sites efficiently and specifically when present on single-stranded vectors, indicating unequivocally that all the determinants of RNA polymerase–promoter interaction are present on the template DNA strand.

The three N4 early promoters share two features: interrupted sequence homology between −18 and +1 with the longest region being a GC-rich heptamer centered at −12, and a set of 5–7 base inverted repeats composed of both conserved and nonconserved bases, also centered at −12. Templates containing mutations at conserved positions have reduced *in vitro* activity, demonstrating that these bases are required for RNA polymerase recognition. Templates containing mutations that disrupt the inverted repeats at the nonconserved positions also have reduced activity, indicating that template single-strandedness is required for the formation of a stem–loop structure (hairpin) at the inverted repeats and that this hairpin and specific bases are required for productive RNA polymerase–promoter recognition.

However, single-stranded DNA is not the *in vivo* template for virion RNA polymerase. *In vivo,* early transcription requires the activity of two host gene products, *E. coli* DNA gyrase and *E. coli* single-stranded DNA binding protein (*Eco* SSB). *In vitro, Eco* SSB activates transcription on double-stranded, supercoiled but not on relaxed DNA templates. Transcriptional activation by *Eco* SSB is specific, as other single-stranded DNA binding proteins (i.e. T7 gene 2.5 protein, T4 gene 32 protein and N4SSB) cannot activate. These observations led to a model for virion RNA polymerase–promoter recognition whereby supercoiling elicits hairpin formation at the promoter region. *Eco* SSB subsequently activates by stabilizing a single-stranded region and allowing virion RNA polymerase to recognize the hairpin and specific bases at the promoters. This model predicts that the promoter hairpin must extrude in a supercoil-dependent manner and that *Eco* SSB must interact without destabilization of the extruded hairpin. Results from recent experiments indicate that both predictions are fulfilled. Contrary to certain theoretical predictions, hairpin extrusion at the promoters occurs at physiological superhelical densities in a Mg^{2+}-dependent manner. Specific sequences on the template strand, which define unusually stable DNA hairpins, are required for hairpin extrusion. In addition, DNA footprinting indicates that *Eco* SSB stabilizes the template-strand hairpin while the non-template strand hairpin is destabilized. Other single-stranded DNA binding proteins destabilize the template hairpin, explaining the specificity of *Eco* SSB activation. Therefore, *Eco* SSB acts as an activator of transcription by providing the appropriate DNA structure at the promoter required for N4 virion RNA polymerase binding.

The availability of an *in vitro* transcription system which recognizes the promoters on a double-stranded template allowed the identification of transcription termination sites for the N4 virion RNA polymerase. Sequencing of the template at the site of termination revealed a nine-base palindrome separated by five bases, followed by a row of five thymidines. These results suggest that the sequence determinants for N4 virion RNA polymerase termination may be similar to those for eubacterial factor-independent termination.

Middle transcription

N4 middle RNA synthesis requires the activity of three N4 early gene products. Two of these gene products, p4 (40 kDa) and p7 (30 kDa), are soluble, have been purified to homogeneity using an *in vitro* complementation assay, and constitute a heterodimeric, rifampicin-resistant RNA polymerase (N4 RNA polymerase II). This enzyme, although composed of two polypeptides, shares sequence homology with the single-subunit phage T7–T3 and the yeast mitochondrial RNA polymerases. However, purified N4 RNA polymerase II does not transcribe N4 DNA with *in vivo* specificity.

Conserved regions at seven sites of middle transcription initiation share the sequence 3′-t/aAAAT-5′ at the +1 region while the sequence 3′-Tt/aCTGGA-Ca/t-5′ is present 14–21 nucleotides upstream. *In vitro* utilization of these sites is dependent on purified N4 RNA polymerase II and a DNA-membrane salt-wash complex from N4-infected cells containing p17 (15 kDa), the third protein required for N4 middle RNA synthesis. However, purified p17 does not allow N4 RNA polymerase II to utilize middle promoters specifically, indicating that an additional factor is required for promoter recognition.

Late transcription

N4 late transcription is catalyzed by the host σ70-RNA polymerase. Indeed, temperature-sensitive *E. coli* mutants in the σ, β, or β' subunits of RNA polymerase are able to support N4 growth at the permissive but not the restrictive temperature. Late N4 transcripts appear about 8 min after N4 DNA replication has started, but their synthesis is not dependent on concurrent or previous N4 DNA replication. N4 mutants defective in the N4-coded DNA polymerase (*dnp*) or in *dns,* another N4 gene required for replication, are able to produce late transcripts.

Interestingly, N4 mutants defective in N4SSB are defective not only in N4 DNA replication but also in late transcription. Sites of late N4 transcription initiation have been identified by S1-nuclease mapping. The sequences of five such regions show weak homology to the *E. coli* promoter consensus sequence at the −10 and −35 regions. No strong sequence homology is shared by the late promoters at the −10 or −35 regions. A conserved sequence (5′AGTCGGTT3′) is present around the site of transcription initiation but its function is unknown. *In vitro* utilization of these sites by *E. coli* RNA polymerase requires the presence of N4SSB, demonstrating that N4SSB is a transcriptional activator.

N4SSB does not detectably bind double-stranded DNA. Therefore, the mechanism of N4SSB transcriptional activation must involve its single-stranded DNA-binding activity (for example, to facilitate isomerization from closed complex to open complex), or protein–protein interactions with *E. coli* RNA polymerase, or both. The isolation of N4SSB mutants defective in single-stranded DNA binding (and therefore in recombination and DNA replication), but proficient in transcriptional activation indicates that the single-stranded DNA binding activity of N4SSB is not required for transcription activation. In contrast, certain carboxy-terminal N4SSB mutants proficient in single-stranded DNA binding, recombination and replication are deficient in transcription activation, indicating that the carboxy-terminus of N4SSB comprises part or all of an 'activating region' that makes direct protein–protein contacts with RNA polymerase. Results of affinity chromatography experiments utilizing immobilized *E. coli* RNA polymerase indicate that N4SSB interacts specifically (activation-defective mutants do not interact) with both RNA polymerase core and holoenzyme.

N4 late transcription is blocked in an *E. coli* mutant that lacks the carboxy-terminal 52 amino acids of β' and has in their place 23 nonnative amino acids, indicating that the extreme carboxy-terminal region of β' plays a specific role in transcriptional activation by N4SSB. Results of site-specific protein–protein photocrosslinking showed that the interaction between N4SSB and *E. coli* RNA polymerase occurs exclusively within the carboxy-terminal 111 amino acids of the β' subunit. This region contains region H, which is conserved in sequence, followed by a negatively charged segment, which is conserved in charge, in the largest subunits of procaryotic RNA polymerase and eucaryotic RNA polymerase II. Since both these regions of the largest subunit of eucaryotic RNA polymerase II interact with transcription activators, it will be interesting to determine whether activation involving this region of the largest subunits of both procaryotic and eucaryotic RNA polymerases has similar mechanistic consequences.

The finding that N4SSB activates *E. coli* RNA polymerase through direct protein–protein interactions in the absence of DNA binding raises two questions. How does N4SSB achieve sufficient occupancy at target promoters? DNA binding to achieve occupancy might not be required since N4SSB is produced at very high levels ($\sim 10^{-5}$ M) during N4 infection. How does N4SSB achieve specificity for target promoters? It is possible that specificity is achieved through 'indirect readout' of promoter sequence, with N4SSB preferentially recognizing a specific conformation that RNA polymerase adopts only at N4SSB-dependent promoters. Alternatively, the specificity might be achieved kinetically, with N4SSB affecting a step in transcription initiation that is limiting only at N4SSB-dependent promoters. Finally, N4SSB might have only a limited specificity for target promoters; although limited specificity would be unsuitable for most activators, it might be suitable for a late-phase, lytic-viral activator.

Recombination

Very high levels of recombination have prevented the generation of an N4 linkage map. Recombination is independent of host recombination genes, suggesting that N4 encodes its own recombination functions. N4SSB is required for recombination.

Mutants/Genetic and Physical Map

The availability of cloned N4 fragments allowed the mapping of a large collection of suppressor-sensitive and temperature-sensitive mutants by marker rescue. The genes for the components of the N4 middle transcription apparatus, the N4 DNA polymerase, N4SSB and the N4 virion RNA polymerase have been mapped. The gene for the N4 virion RNA polymerase, which is part of the phage particle, is located with other morphogenetic proteins in the late region of the genome.

The isolation of heat- and citrate-induced deletions defined a 6 kb nonessential region in the middle transcriptional region. The ability to isolate heat- and citrate-resistant N4 phage implies that N4 does not encapsidate its DNA by full-head packaging but through the recognition of specific sequences at both ends of the genome. This is corroborated by the finding that deleted phages have wild-type terminal sequences.

The recent development of a method for constructing gene replacements, disruptions and deletions on the N4 chromosome by means of site-specific recom-

bination, analogous to the two-step gene replacement method in yeast, will be useful in investigating the role of N4 open reading frames of unknown function.

Effect on Host Cell

Immediately after infection, an as of yet unidentified early gene product inhibits host DNA replication. The host chromosome is not degraded and its transcription remains unaffected except for the shut-off of cAMP-dependent operons.

Replication

The functions of three host genes, *dnaF* (ribonucleotide reductase), *lig* (DNA ligase) and *gyrB* (DNA gyrase), are required for N4 replication. Cells defective in the polymerization activity of DNA polymerase I (*polA1*) support N4 growth; however, the 5′–3′ exonuclease activity of DNA polymerase I is required for processing of N4 Okazaki fragments. The functions of the *dnaA, dnaB, dnaC, dnaE* and *dnaG* genes of *E. coli* are not required for N4 DNA synthesis, suggesting that the phage must code for functions required for initiation, priming, polymerization and strand-displacement during replication.

Five phage-encoded functions involved in N4 replication, the N4 DNA polymerase (*dnp*), a single-stranded DNA binding protein (*dbp*), a 5′–3′ exonuclease (*exo*), the virion-encapsulated RNA polymerase and an unknown function (*dns*), have been identified through the isolation of phage containing amber- and temperature-sensitive mutations in each of these genes. Besides the virion-encapsulated RNA polymerase (see Early transcription), the N4 DNA polymerase, the single-stranded DNA binding protein and the 5′–3′ exonuclease have been purified to apparent homogeneity. The DNA polymerase (87 kDa) catalyzes accurate DNA synthesis due to an active 3′–5′ exonuclease activity. As with other replicative polymerases, the N4 enzyme lacks 5′–3′ exonuclease activity, cannot strand-displace and is nonprocessive. These results suggest that a processivity factor(s) and helicase activities must be N4-encoded. N4 DNA polymerase activity is greatly stimulated by N4SSB (32 kDa), which binds with moderate cooperativity to single-stranded DNA, covering 10 bp per protein monomer. The 5′–3′ N4-coded exonuclease (a 45 kDa polypeptide) exists as a dimer. Its preferred substrate is duplex DNA containing 3′ extensions (i.e. N4 DNA), which it degrades by a distributive mechanism. It is inactive on nicks or gaps. These properties suggest that the 5′–3′ exonuclease might play a role in recombination or replication of the ends of the N4 genome.

An *in vitro* replication system has been developed, which shows a marked preference for double-stranded N4 DNA as a template with little activity on heterologous or denatured templates. The system uses extracts from N4-infected *polA1* cells. Extracts from mutant N4-infected cells demonstrated that the *dnp, dbp* and *exo* gene products, but not the *dns* gene product, are required in the *in vitro* replication system. The *in vitro* system, therefore, does not possess all the properties of *in vivo* N4 replication. Replication in the *in vitro* system initiates at the ends of the N4 genome and proceeds towards the center. This is in agreement with electron microscopic analysis of *in vivo* replicating N4 DNA molecules, which shows Y-shaped molecules and molecules with single-stranded tails rather than replication bubbles, suggesting that origins of replication are located near the ends of the genome. Two-dimensional gel electrophoresis of the terminal restriction fragments from *in vitro* replicating N4 DNA molecules suggests that initiation occurs through hairpin priming of the single-stranded ends. Since the *in vivo* origin of N4 replication is not yet known, the relevance of the *in vitro* mode of initiation remains to be determined.

The utilization of an RNA primer has not been ruled out, and indeed the role that the N4 virion RNA polymerase plays in replication has not been elucidated. A possible role of this enzyme in replication initiation is suggested by the structure of 'activated' N4 virion RNA polymerase promoters, which is reminiscent of activated origins of replication. The accumulation of Okazaki-like fragments after infection of *polAex1* or *lig* mutants suggests discontinuous DNA synthesis and it is possible that the virion RNA polymerase synthesizes primers for this process as well.

The 3′ extensions of the N4 genome are unusual and, as all known DNA polymerases synthesize in a 5′ to 3′ direction, N4 must have a novel mechanism for replicating these sequences. Analysis of restriction products of intracellular N4 DNA detects a restriction fragment containing one copy of the terminal redundancy flanked by the right and left ends of the genome (joint fragment). Furthermore, *in vivo* pulse-chase experiments show that label accumulates in the joint fragment and chases into both the right and left genome ends. We have not yet identified the *in vivo* structure that contains the joint fragment but it is likely that this fragment originates through homologous recombination at the direct terminal repeats. Moreover, analysis of *in vivo* replicating N4 DNA by electron microscopy reveals longer than unit length molecules, suggesting concatemer formation. The enzyme or enzymes and the mechanism responsible for the generation of N4 DNA ends from processing of concatemers are unknown.

Host Range

The N4 genome is resistant to cleavage by a wide range of restriction endonucleases including *Ava*I, *BamH*I, *Ban*I, *Ban*II, *Cla*I, *Eco*RI, *Eco*RV, *Hind*III, *Kpn*I, *Nae*I, *Nar*I, *Nco*I, *Pst*I, *Pvu*I, *Pvu*II, *Sal*I, *Sma*I, *Sph*I, *Sst*I and *Sst*II, and *Xho*II, *Hae*II, *Mlu*I and *Nru*I cleave the 72 kb genome only once. Fragments of N4 cloned into *E. coli* vectors remain resistant to these restriction enzymes, indicating that resistance is due to the absence of enzyme recognition sequences and not to phage-induced base modifications or an N4-encoded antirestriction activity. The resistance of the N4 genome to restriction enzymes present in enterobacteria might reflect the host range of N4 in nature.

N4 infection is initiated by the attachment of the phage to, at most, five sites per bacterium. To characterize the N4 receptor, we have isolated and mapped mutations in *E. coli* that prevent adsorption of bacteriophage N4. The mutations map to four loci designated *nfrA, nfrB, nfrC* and *nfrD*. *NfrA* and *nfrB* map at 12′ on the *E. coli* map. Both genes have been cloned and sequenced. *NfrA* encodes a 96 kDa outer membrane protein which is presumed to be the bacteriophage receptor. The neighboring *nfrB* gene encodes a 70 kDa inner membrane protein whose exact role in N4 adsorption remains to be defined. We speculate that it may form a multicomponent receptor complex with the *nfrA* gene product or may serve as a channel through which the N4 genome and virion-encapsulated RNA polymerase pass during infection. The discovery of these genes has explained the restricted N4 host range. *E. coli* B is naturally N4-resistant because it lacks *nfrA* and *nfrB*. When a plasmid carrying these genes is introduced into *E. coli* B, it becomes sensitive to N4 infection.

The *nfrC* gene, which maps between *cya* and *ilv*, has been cloned and sequenced; maxicell experiments show that it encodes a 40 kDa polypeptide with UDP-*N*-acetylglucosamine-2-epimerase activity. *NfrD* maps to 50′ on the *E. coli* linkage map. The roles of these proteins in N4 adsorption and DNA and virion RNA polymerase injection remain to be elucidated.

Future Perspectives

N4 is unique among the lytic phages. The study of its transcription has provided novel mechanisms for RNA polymerase–promoter recognition, activation and the supercoil-dependent generation of noncanonical DNA structures. N4 RNA polymerase II is the smallest DNA-dependent RNA polymerase described to date and an excellent candidate for structure–function studies. The discovery of single-stranded DNA binding proteins behaving as transcriptional activators has endowed these proteins with a novel activity beyond their role in replication and recombination.

Little is known about the injection of proteins into bacterial cells. The study of the localization of the RNA polymerase in the virion and its injection into the host will provide clues as to the mechanism of this process. The generation of the 3′ single-stranded ends present on mature N4 DNA cannot be explained easily using known mechanisms of replication of linear genomes. Identification of the *in vivo* origin of N4 DNA replication and further characterization of *in vivo* replication intermediates will allow delineation of what could be a novel pathway for replicating linear genomes.

Finally, the imminent availability of the complete sequence of the N4 genome will provide clues as to its evolutionary origins.

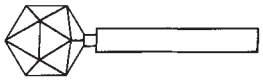
ENTEROBACTERIA PHAGE P1 (*MYOVIRIDAE*)



Hansjörg Lehnherr, University of Odense, Institute for Molecular Biology, Odense, Denmark

Jürg Meyer, University of Basel, Dental Center, Basel, Switzerland

History

Bacteriophage P1 was one of three phages isolated in 1951 by Bertani from the lysogenic *Escherichia coli* strain of Lisbonne and Carrère. The phages, called P1, P2 and P3, had different plaque sizes on a particular strain of *Shigella dysenteriae* and were serologically distinguishable. P1 did not attract much attention until Lennox discovered the P1-mediated generalized transduction of chromosomal markers between strains of *E. coli* and *Shigella*. Furthermore, Lennox isolated a mutant, P1*kc*, which produced slightly larger (but still rather small) plaques, from which the strains studied later were derived.

P1 gained tremendous practical importance as a transducing phage and is still extensively exploited in bacterial research. It also has served as a model system for the study of several fundamental aspects of bacterial and phage biology:

- P1 specifies its own DNA-restriction-modification system, which was extensively studied by Arber and provided first insights into the biology of such systems. Thus, P1 was at the root of genetic engineering.
- The P1 genome encodes two site-specific recombination systems, which play important roles in its life cycle. In addition, P1 DNA carries a copy of the insertion element IS1. These systems contribute to the formation of specialized transducing phages and may be involved in generalized transduction.
- The P1 prophage exists extrachromosomally as a stably maintained low copy number plasmid. Studies of replication, partition, incompatibility and plasmid addiction (postsegregational host killing) have been fruitful for the understanding of the plasmid way of (prophage) life.
- P1 specifies a complex immunity system, intricately balancing the decision between lytic and lysogenic growth. Important elements of the immunity systems have been revealed by comparison to P7 (originally called ϕAmp), a heteroimmune phage which is otherwise closely related to P1.

Classification

P1 is in the genus 'P1-like viruses' of the *Myoviridae* family.

Virion Structure and Proteins

Three phage particles with similar tails, but with icosahedral heads of different diameters, are present in P1 lysates: B (big) 85 nm, S (small) 65 nm and M (minute) 47 nm. The inflexible tail is composed of a head–neck connector, a tail tube and a contractile sheath, and ends in a baseplate with six kinked tail fibers (**Fig. 1**). The proportion of the three head variants in a population of P1 virions depends on the P1 genotype and on the host (for P1 wild-type in *E. coli* K12 P1B 70–94%, P1S 6–27%, P1M 0.2–4%). All three phage particles can adsorb to host cells and infect their DNA, but only P1B particles are infectious because they contain the entire P1 genome. They hold slightly more than 100 kb of double-stranded linear DNA, which is circularly permuted with a terminal redundancy of about 10%. P1S particles contain about 36–40 kb of circularly permuted P1 DNA. At high multiplicities of infection, P1S virions can be infectious, due to recombination to a complete genome.

The phage head is composed of one major and 14 auxiliary proteins, while two major and seven auxiliary proteins contribute to the tail structure. The location of four additional virion proteins has not been assigned so far.

Genome Structure and Organization

Phage P1 has a genome of about 100 kb, thus having a coding capacity of about 100 genes. Fewer than 50 have been identified by genetic analyses. Interestingly, the genetic map based on recombination frequencies is linear, even though the phage DNA circularizes upon infection and the prophage is a plasmid. This discontinuity comes about by the action of the P1 *lox-cre* site-specific recombination system. The re-

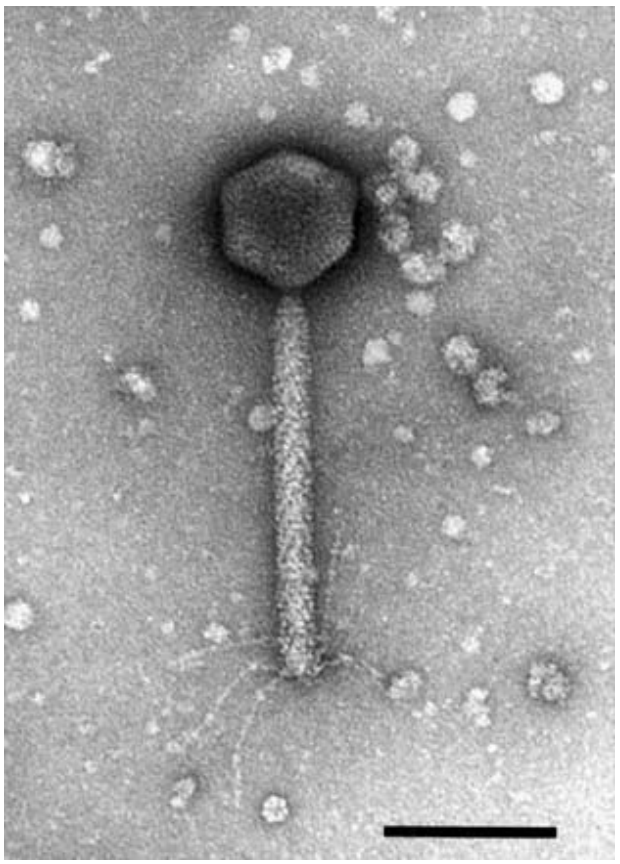


Figure 1 Electron micrograph of a phage P1 particle. Bar=100 nm. (Kindly supplied by Dr Michel Wurtz.)

combinational hot spot (*loxP*) marks the end of the genetic map (**Fig. 2**).

Packaging of P1 is initiated at the *pac* site, which is located about 5 kb from *loxP*, and proceeds in this direction. If a P1B particle results from the first round of headful packaging, it will contain two *loxP* sites in the terminally redundant DNA.

P1 DNA contains a 4.2 kb invertible segment, which is composed of 3 kb of unique sequence, flanked by 0.62 kb of inverted repeats. This segment, called the C-segment, encodes two sets of tail fiber functions and provides P1 with two alternative host ranges by changing its orientation in the prophage.

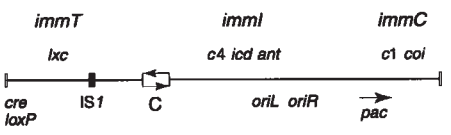

Figure 2 Simplified genome map of phage P1. The regions and functions shown are discussed in the text. The boxes at the termini represent *loxP*. The arrow above *pac* indicates the direction of DNA packaging.

Related functions are scattered on the P1 genome. Immunity determinants are found in three well-separated regions. Similarly, head and tail genes are each located in at least three distinct regions. This dispersion is reminiscent of the genome organization of the T-even phages.

Replication Cycle

The lytic cycle of phage P1 in *E. coli* and *S. dysenteriae* hosts takes about 60 min and yields 100–200 progeny phages per bacterium.

Phage P1 attaches by its tail fibers to its receptors, which have been postulated to be a terminal or subterminal glucose or galactose moiety of the lipopolysaccharide core of the bacterial outer membrane. How the linear DNA is injected into the host cell has not been studied; however, within a few minutes it is converted into a closed circular form.

Presumably, this rapid circularization is important to protect the DNA against degradation by cellular nucleases, e.g. the RecBCD enzyme, against which P1 perhaps expresses some activity, as has been established for other phages. The cyclization of P1 DNA is mediated efficiently by the *lox-cre* system. The Cre recombinase mediates a site-specific recombination reaction between two 34 bp *loxP* sites. It functions *in vivo* and *in vitro* without requiring any accessory factors. The *lox-cre* system can be replaced by other recombination systems dependent on the host *recA* function, which might be stimulated by the P1 function *ref* and/or by DNA ends. It is interesting to note that phage P7 DNA is circularized efficiently in a *recA* host, even though its terminal redundancy is less than 1 kb, and is unlikely to contain two *loxP* sites.

Replication of P1 DNA can be detected as early as 5 min after infection, and by 30 min reaches a level of about 95% of bacterial DNA synthesis. While in the early phase, σ forms and θ forms are found with equal frequencies, σ forms are found almost exclusively in the late phase, as was revealed by electron microscopy of replication intermediates. The σ forms appear to result from rolling circle replication, rather than from recombination, and they produce concatemeric DNA. Thus, like λ, P1 seems to be able to replicate by two different modes.

The σ and θ replication are predominantly initiated at *oriL*. However, vegetative DNA replication is clearly independent of the plasmid replication system, *oriR*, used in the prophage state. There are P1 mutants defective for vegetative replication, which are unaffected in their plasmid replication. Conversely, there are others with intact vegetative growth, but no plasmid replication. Furthermore, vegetative

and plasmid replication are affected differently by mutations of host functions (e.g. *recA* or *dnaA*). *oriL* encodes one essential protein, RepL, and is activated by transcription from the upstream promoter Pr53. This promoter is negatively regulated by the major repressor protein C1 and by a 180 bp antisense RNA, which is expressed from Pr53as, initiating transcription in opposite and convergent direction to Pr53.

The morphogenetic pathways have not been studied extensively. Only a few head genes have been identified, and the function of most of them remains to be determined. Head morphogenesis proceeds via a prohead and requires a maturation protease, involved in the processing of phage proteins. A nonessential gene, *vad,* modulates the ratio of P1B to P1S particles. Most of the tail genes have probably been identified by mutation, but their interactions during the assembly process have yet to be clarified.

Detailed information has been obtained on the phage-specific DNA-recognition and cleavage functions, *pac,* mediating the packaging of viral DNA into proheads. Mature P1B and P1S particles appear to result from 'headful' packaging, starting from the same concatemeric DNA. Filling of the first head starts at the *pac* site and proceeds unidirectionally. Three to four 'headfuls' were estimated to be processed sequentially, but the number may be two to three times higher, depending on the length of the P1 concatemer substrate.

The *pac* cleavage site is located within the 5′ part of *pacA,* which together with the adjacent gene, *pacB,* specifies the *pac* endonuclease. Almost symmetrically located around the major cleavage site are eight copies of the hexanucleotide sequence 5′-TGATCA(G), seven of which are contained in the 162 bp minimal *pac* segment. They are the binding sites for the *pac* endonuclease. The actual cleavage termini are distributed nonrandomly around one helical turn of DNA. Preferred cleavage sites on the two strands are staggered by 2 bp. The hexanucleotides also contain DNA adenine methyltransferase (*dam*) methylation sites (5′-GATC). As *pac* endonuclease activity is found as early as 10 min after initiation of the lytic growth cycle, expressed first from the *c*1-regulated promoter Pr94 and later from the late stage-specific promoter LPr95, further regulation of *pac* cleavage occurs via adenine methylation. Methylated *pac* sites are cleavable, whereas unmethylated sites are not. These *dam* methylation sites are not only a substrate for the host chromosomal enzyme, but also for a P1-encoded adenine methylase, the expression of which is regulated by the *c*1 repressor.

Host cell lysis is dependent on three genes, *lydA, lydB* and gene *17.* The last specifies a T4-like lysozyme and is essential for cell lysis, while the first two are dispensable. The product of *lydA* is a holin, thought to provide the lysozyme with improved access to the bacterial cell wall. The product of *lydB* antagonizes the holin, thus fine tuning the timing of cell lysis.

Mutations

By 1980 two collections of about 100 amber mutations which affect P1 plaque formation had been assigned to 18 and 31 complementation groups, respectively, and many have been mapped genetically. The two nonessential genes *res* and *mod* specifying the P1 restriction-modification system have been mapped by transposon mutagenesis. Thus, of the estimated coding capacity of the P1 genome of about 100 genes, less than half are defined by mutation. A project to determine the complete sequence of the P1 genome is near completion. It is expected to reveal a wealth of new genes, the functions of which have yet to be determined.

Lysogeny and Immunity

Phage P1 encodes a tripartite immunity system composed of the *immC, immI* and *immT* regions (**Fig. 2**). The *immC* region encodes the *c*1 repressor and the C1 inactivator function *coi.* The major repressor protein C1 is responsible for maintaining the lysogenic state. It binds to at least 17 operator sequences, which show a 17 bp asymmetrical consensus sequence and are scattered widely over the P1 genome. Upon infection both C1 and Coi are expressed simultaneously. To establish lysogeny C1 has to repress the expression of Coi by binding to an operator sequence located in the *coi* promoter. Coi, in turn, promotes lytic growth by inactivating C1 upon the formation of a 1:1 complex with C1.

To maintain the lysogenic state the major repressor C1 is assisted by the auxiliary repressor protein Lxc (*l*owers e*x*pression of *c*1, formerly called Bof), encoded in the *immT* region. Lxc interacts directly with C1 and increases the binding activity of C1 for all operator sequences. However, as C1 autoregulates its own expression and the interaction with Lxc results in increased autorepression, the total concentration of C1 in the cell is reduced. This lower C1 concentration in turn results in decreased repression of several *c*1-controlled genes. Having these two antagonistic effects Lxc modulates C1 activity, stabilizing the lysogenic state, but keeping the repression level low and thus facilitating a potential shift to the lytic mode of growth.

The three functions *c*4, *icd* and *ant,* located in the *immI* region, are coexpressed from two promoters, the strong *c*1-regulated promoter Pr51a and the

weaker, constitutive promoter Pr51b. The product of the *c*4 gene is a 77 bp antisense RNA, acting as a translational repressor of the adjacent *icd* gene and indirectly also of the *ant* gene, as *icd* and *ant* are translationally coupled. This blockage of *icd-ant* translation also leads to premature termination of *icd-ant* transcription, via a *rho*-dependent transcriptional terminator. The *c*4 RNA is synthesized as a precursor and needs to be processed by RNaseP in order to be functional. C4 is essential for establishing lysogeny and is solely responsible for the heteroimmunity of P1 and P7. Only in the absence of functional C4 are *icd* and *ant* synthesized. The Icd product interferes with host cell division and eventually leads to cell death, but *per se* is not required for *ant* expression. The functional antirepressor molecule, Ant, is a heterodimer composed of Ant1 and Ant2, the latter being initiated at an in-frame start codon in the *ant* gene. Ant in 2–4-fold molar excess forms a complex with and precipitates C1, thereby inactivating it. Differences between P1 and P7 indicate that a phage-specific loading site, called *sas* (for *s*ite of *a*nt *s*pecificity) might be essential for Ant to interact with DNA-bound C1 repressor molecules.

P1 is inducible by UV irradiation and other agents causing DNA damage, but the induction is not mediated by *recA*-assisted cleavage of an immunity repressor. It remains an enigma why bacteriophage P1 maintains such a complex immunity system in order to regulate the choice between lytic and lysogenic growth.

Plasmid Replication and Partition

P1 prophages replicate autonomously as plasmids and regulate their copy number at 1–2 copies per host chromosome. Like other plasmids with low copy number, P1 carries functions which ensure reliable partition of prophages to the daughter cells. Two P1 prophages cannot stably coexist in the same host cell, that is, they display – like plasmids in general – incompatibility behavior.

Two incompatibility determinants, *incA* and *incB*, were identified in separate regions of the P1 genome (**Fig. 3**). Either one is sufficient to destabilize P1, but only *incA* also destabilizes P7, and thus represents the incompatibility determinant of the IncY plasmids. Based on the fact that incompatibility determinants are involved in the replication and/or partition of plasmids, these P1 genome regions were searched for stable plasmid replicons. Between *incB* and the *imml* region, the L-replicon (*oriL*) was found, which is under *c*1 control and is used for lytic replication. As repression is incomplete, the lytic replicon may occasionally act as an auxiliary in plasmid maintenance.

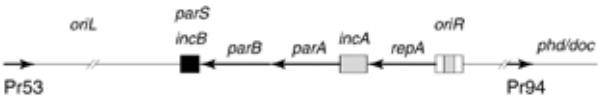

Figure 3 Organization of the replication and partition region of P1. See text for details.

On a 1.5 kb DNA segment including *incA*, the R-replicon was identified. This replicon is sufficient for P1 plasmid replication, because it replicates with the same low copy number as intact P1. The R-replicon consists of an origin (*oriR*) of not more than 245 bp, a gene (*repA*) encoding an essential replication initiator protein, and the control element *incA* of 285 bp, which is dispensable for DNA replication. The R-replicon also contains recognition sequences for the *E. coli* DnaA initiator protein, which is required for *oriR* replication together with several other host proteins (DnaB helicase, DnaC, DNA gyrase, RNA polymerase). Plasmid replication is also modulated by DNA methylation. Several *dam* methylation sites (5′-GATC) are located in *oriR* and the host-encoded protein SeqA binds the hemimethylated form of the origin, exerting negative control (preventing premature reinitiation) by sequestration.

The *repA* promoter located within *oriR* straddles one of the five directly repeated copies of a 19 bp sequence called 'iterons', to which RepA protein binds, resulting in autoregulation of *repA* expression. Nine additional iterons constitute *incA*, located at the 3′ end of the *repA* gene. According to a current model of replication control, involving protein-mediated DNA looping (handcuffing), RepA mediates the binding of *incA* to *oriR* so as to sterically block initiation of DNA replication at *oriR*.

Analysis of *in vitro* P1 DNA replication showed that RepA monomers efficiently bind *oriR* and *incA*, while RepA dimers are inactive. The *E. coli* heat shock proteins DnaJ, DnaK and GrpE stimulate RepA binding by monomerization of RepA dimers. The three heat shock proteins act coordinately as molecular chaperones in an ATP- and temperature-dependent reaction in the absence of *oriR* DNA.

The P1 prophage is rarely lost from its host cell (about 10^{-5} per generation). Several mechanisms contribute to this high stability. The site-specific *lox-cre* recombination system efficiently resolves plasmid dimers, ensuring that monomeric plasmid copies are present at the moment of cell division. Mutations in the partition functions *par* may lead to about a 100-fold increase in loss rate. The *par* region is located adjacent to *incA* and contains a promoter

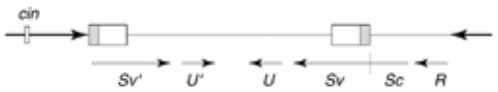

Figure 4 Organization of the DNA inversion system of P1. The *cin* recombinase gene contains the recombinational enhancer sequence (blank rectangle). The large boxes represent the 0.62 kb inverted repeats carrying the recombination sites *cix* (hatched part) at the termini. Arrows indicate the direction of transcription of the genes, the synthesis of which is controlled by DNA inversion. In the opposite orientation Sc is fused to *Sv'* resulting in *S'*.

expressing two genes, *parA* and *parB*, and the *cis*-acting (centromere-like) site, *parS*, which coincides with *incB*. The formation of a functional partition complex requires binding of the ParB protein to *parS*, a reaction which is assisted by the host protein IHF (*i*ntegration *h*ost *f*actor). The *parS* site contains a 13 bp inverted repeat sequence, which overlaps with the heptamer and hexamer sequences defining ParB-binding sites.

While the plasmid replication functions of P1 are interchangeable with P7, the partition functions are not, although they are clearly related. The organization of the *rep-par* region of P1 is very similar to that of the functional homologue of the F plasmid, but the DNA sequences are considerably divergent. In addition to the *par* functions, P1 also encodes a postsegregational host killing system, stabilizing the prophage by killing plasmid-free cells. Two small proteins, called Phd and Doc, are expressed from an autoregulated promoter. Phd is an antidote, forming a neutralizing complex with the cell toxin, Doc. Phd is slowly degraded by the host encoded protease ClpXP, while Doc is stable. Upon loss of P1 the antidote protein is degraded and the toxin is able to kill the plasmid-free cell.

Gene Expression

The few studies of gene expression indicate that some genome segments of the prophage are transcribed and are thus not repressed by the *c*1 repressor. According to a model proposed by Sternberg, early phage functions may be activated by replicative induction: at low concentration of *c*1 repressor, the lytic origin *oriL* is expressed from the strong *c*1-controlled promoter Pr53, and lytic DNA replication is initiated. Expression of the genes required for the lytic cycle is stimulated on one hand by an increased gene dosage; on the other hand transient undermethylation may increase the strength of some promoters, as has been shown for the *cre* promoter.

The host core RNA polymerase is probably used throughout the replication cycle. A single phage encoded gene, *lpa* (*l*ate *p*romoter *a*ctivator), mediates the transition from early to late gene expression. The *lpa* gene is *c*1-regulated and is expressed as soon as the C1 concentration in the cell drops below a certain threshold level. Lpa then activates transcription from P1-specific late promoter sequences, which, in common with the operator sequences, are scattered over the entire genome. The late promoters show a conserved *E. coli*-like −10 region and a 9 bp palindromic sequence centered around position −22, but they lack homology to the *E. coli* −35 region. Whether Lpa is a DNA-binding activator or modifies the host RNA polymerase remains to be determined.

DNA-Restriction-Modification and Antirestriction Systems

Phages P1 and P7 encode the type III restriction-modification enzyme *Eco*P1, which is composed of two subunits, the products of the *res* and *mod* genes. The Mod protein is responsible for both recognition of the specific DNA sequence 5′-AGACC and its modification methylation (A becomes N^6-methyladenine). It forms a complex with the Res protein which cuts DNA about 25 bp to the 3′ side of the recognition sequence. The *Eco*P1 enzyme displays both restriction and modification activities simultaneously so that unmodified DNA is not completely restricted as a result of modification of some sites. Because of the asymmetry of the recognition sequence, a fully modified site contains a methyl group in one strand only. The totally unmodified recognition sequence in newly synthesized DNA escapes restriction, because restriction requires two unmodified sites in inverse orientation (all of the nonmodified sites in newly replicated DNA are in the same orientation).

The two genes, *mod* and *res*, are organized in one operon. One would expect that, after P1 infection, the *mod* function would be expressed before the *res* function, in order to protect the host chromosome. Indeed, modification activity can be detected within a few minutes after infection, while the restriction function is fully developed only after 3–4 hours. How this regulation is achieved is at present still unclear, but the regulation is not at the transcriptional level, because by 30 min after infection both Mod and Res proteins can be detected.

Phage P1 also encodes an antirestriction function, which protects P1 DNA against type I restriction enzymes, i.e. the chromosomally encoded restriction endonucleases of the *Enterobacteriaceae*. It is based on the action *in cis* of two phage proteins, DarA and

DarB, which are incorporated into the phage head and then injected into host cells along with the phage genome.

Control of Host Range by DNA Inversion

Inversion of the 4.2 kb C-segment of the P1 genome (**Fig. 4**), leads to the expression of alternative tail fiber genes (*R, S, U* or *R, S′, U′*) and thus to (mixed) populations of two different phage particles with different host ranges. The C-segment is largely homologous to the smaller G-segment of phage Mu, and by analogy its orientation is indicated as C(+) or C(−). The correlation of type of tail fiber with host bacterium has not been studied as extensively as for phage Mu, but P1-C(+) particles infect *E. coli* K-12, while P1-C(−) virions do not; both phages form plaques on an *E. coli* C mutant. The receptors for both particles are the lipopolysaccharides of the outer membrane. Phages derived from infection carry the C-segment predominantly (>99%) in the original orientation, while, after induction of lysogens, both orientations are represented with equal frequency.

Recombination occurs between 26 bp imperfect inverted repeat sequences, *cix*, which flank the C-segment, and is mediated by the phage Cin protein, a site-specific recombinase acting as DNA invertase. The *cin* gene is located immediately adjacent to the inverted repeats flanking the C-segment and contains an approximately 75 bp DNA sequence, which stimulates the DNA inversion reaction *in cis* and controls the topology of the reaction. This recombinational enhancer sequence contains two binding sites for the host factor FIS (*f*actor for *i*nversion *s*timulation). Recombination sites and DNA invertase are nearly identical between P1 and P7 and also closely related to those of phage Mu and the multiple inversion system of the P1-related plasmid p15B. The different invertases complement each other.

Occasional Integration of P1 into the Host Chromosome: Significance for Transduction

The P1 and P7 prophages can integrate into the host chromosome, although with low probability. This integration is documented by the fact that P1 and P7 can suppress the replication defect of some *E. coli dnaA*ts mutants. This phenomenon is known as integrative suppression. Under nonpermissive conditions, the bacterial chromosome can be replicated from an integrated prophage origin. This implies that *oriR* replication is less sensitive to the impaired DnaA function than the chromosomal origin and/or that replication initiates from a *dnaA*-independent origin, (e.g. *oriL*). Another consequence of prophage integration may be the production of specialized transducing phage particles.

The integration is mediated in most cases by the *lox-cre* system and occurs at a distinct site, *loxB*, of the host chromosome, which has a high degree of homology to *loxP*. Also the other site-specific recombination system, *cin-cix*, can lead to integrative recombination. Furthermore, co-integrate formation with the host chromosome – or with other plasmids – can result from the activity of the IS*1* element of P1. Homologous recombination between different copies of IS*1* is more frequently observed than integration mediated by the transposition functions of IS*1*. Subsequent IS*1*-mediated recombination events may result in specialized transducing P1 genomes (e.g. P1*argF*, P1*raf*, P1Cm), which carry the host DNA flanked by IS*1* elements. The Tn*902* element of P7 may be implicated in similar processes.

Generalized transducing P1 particles contain very little, if any, phage DNA and the cellular DNA encapsidated appears to represent all genome regions equivalently. This suggests that packaging is not exclusively initiated at *pac* sites of integrated prophages or at pseudo-*pac* sites in the bacterial chromosome, but might start at additional sites. For a long time P1 transduction has been applied to fine-structure genetic mapping in *E. coli* and other enterobacteria.

Applications in Genetic Engineering

A DNA cloning system based on phage P1 has been developed, which is capable of accepting inserts of up to 100 kb. The vectors have a size of about 13 kb and are composed of a P1 *pac* site for *in vitro* packaging of recombinant DNA into phage particles, two P1 *loxP* sites for circularization of the recombinant DNA upon injection into an *E. coli* expressing the P1 *cre* recombinase gene, a P1 plasmid replicon for stable maintenance, a kanamycin-resistance gene for selection and a P1 lytic replicon under the control of the Lac repressor for inducible amplification of recombinant DNA before isolation and *in vitro* packaging. The system yields up to 10^5 clones carrying large inserts per microgram of vector DNA.

The *lox-cre* recombination system has also been combined with λ cloning vectors, which *in vivo* automatically lead to the conversion of recombinant phages to plasmid subclones. Furthermore, it has been used for manipulating DNA, i.e. producing deletions, inversions and co-integrates, in plant and animal cells, for example in the genetic engineering of 'knockout' mice.

ENTEROVIRUSES (*PICORNAVIRIDAE*)

Contents

Animal and Related Viruses

Elizabeth M Hoey and **Samuel J Martin**, School of Biology and Biochemistry, The Queen's University of Belfast, Belfast, UK

Introduction

This entry deals with animal viruses that up to recently have been referred to as enteroviruses. However, as discussed below, the taxonomic status of some of them remains to be determined. This is particularly true of the avian viruses that will be considered, and such viruses will be referred to as enterovirus-related viruses.

History

Over the past 70 years a number of diseases caused by animal enteroviruses and enterovirus-like agents have been described in the literature. For example, the virulent form of pig polioencephalomyelitis (Teschen disease) was first reported in 1929 in Czechoslovakia and avian encephalomyelitis was first recorded in the USA in 1932. It is probable that the viruses causing these and other diseases had been circulating in animal populations for considerable lengths of time. However, with the advent of more intense farming practices their disease-causing potential has become more apparent and their spread facilitated. With the introduction of tissue culture and egg culture techniques it has been possible to isolate and biologically characterize some of these viruses but few, as yet, have been biochemically characterized.

Classification

Bovine enteroviruses (BEVs), porcine enteroviruses (PEVs), simian enteroviruses (SEVs) and swine vesicular disease virus (SVDV) are currently classified as belonging to the genus *Enterovirus* of the family *Picornaviridae*. Such viruses are small in size (25–30 nm), resistant to ether and are relatively stable over a wide pH range (3.0–10.0). They have a buoyant density of 1.30–1.34 g ml^{-1} in caesium chloride gradients. Mature virus particles are nonenveloped and possess icosahedral symmetry. Empty protein shells are sometimes observed. These enteroviruses have been categorized further into serotypes.

Avian encephalomyelitis virus (AEV), avian nephritis virus (ANV), duck hepatitis virus (DHV) and

Animal and Related Viruses

Elizabeth M Hoey and **Samuel J Martin**, School of Biology and Biochemistry, The Queen's University of Belfast, Belfast, UK

Introduction

This entry deals with animal viruses that up to recently have been referred to as enteroviruses. However, as discussed below, the taxonomic status of some of them remains to be determined. This is particularly true of the avian viruses that will be considered, and such viruses will be referred to as enterovirus-related viruses.

History

Over the past 70 years a number of diseases caused by animal enteroviruses and enterovirus-like agents have been described in the literature. For example, the virulent form of pig polioencephalomyelitis (Teschen disease) was first reported in 1929 in Czechoslovakia and avian encephalomyelitis was first recorded in the USA in 1932. It is probable that the viruses causing these and other diseases had been circulating in animal populations for considerable lengths of time. However, with the advent of more intense farming practices their disease-causing potential has become more apparent and their spread facilitated. With the introduction of tissue culture and egg culture techniques it has been possible to isolate and biologically characterize some of these viruses but few, as yet, have been biochemically characterized.

Classification

Bovine enteroviruses (BEVs), porcine enteroviruses (PEVs), simian enteroviruses (SEVs) and swine vesicular disease virus (SVDV) are currently classified as belonging to the genus *Enterovirus* of the family *Picornaviridae*. Such viruses are small in size (25–30 nm), resistant to ether and are relatively stable over a wide pH range (3.0–10.0). They have a buoyant density of 1.30–1.34 g ml^{-1} in caesium chloride gradients. Mature virus particles are nonenveloped and possess icosahedral symmetry. Empty protein shells are sometimes observed. These enteroviruses have been categorized further into serotypes.

Avian encephalomyelitis virus (AEV), avian nephritis virus (ANV), duck hepatitis virus (DHV) and

turkey hepatitis virus (THV) have previously been referred to as enteroviruses because they share some of the above features. However, the genome sequence is not available for any of them as yet and little is known about their biochemical properties. Thus the ICTV currently have not assigned them to any genus of the family *Picornaviridae*. Indeed, although at present all 13 serotypes of porcine enteroviruses are classified as belonging to the genus *Enterovirus*, evidence is emerging in our laboratory that at least one of these serotypes may be misclassified.

Properties of the Virion

The animal enteroviruses belong to the family *Picornaviridae*. Virions are nonenveloped and exhibit icosahedral symmetry (pseudo $T = 3$). Reported sizes vary but most estimates are 25–30 nm in diameter. They show little surface morphology. All enteroviruses so far examined are comprised of a single-stranded positive-sense RNA genome surrounded by a protein shell. This is made up of 60 structural units (protomers), the majority of which contain one copy of the four virus-encoded structural polypeptides (VP1–4). The consistent presence of a small proportion of VP0 in purified BEV preparations suggests that in a few structural units this polypeptide, which normally gives rise to VP2 and VP4, remains uncleaved.

The avian viruses are of similar size and purified AEV particles have been reported to contain three polypeptides.

Properties of the Genome

Few molecular studies have been performed with the majority of these viruses; however, the characterization of the genomes of those studied (BEVs, SVDV and a few PEV serotypes) indicates that they are closely related to the human enteroviruses. The genome consists of a single species of single-stranded positive-sense RNA of approximately 7–8 kb. The 3′ end is polyadenylated. The 'A' tract is heterogeneous in length and is genetically encoded. The 5′ end is covalently linked to a small virus-encoded protein, VPg. The naked RNA of BEV is infectious when transfected into tissue culture cells. The genome contains a single open reading frame (ORF) from which the various virus-encoded proteins are derived. This is preceded by a long 5′ untranslated region (UTR). In the SVDV genome this is of approximately the same length as in the human enteroviruses (750 bases). However, in four sequenced BEV strains it is longer (818–821 bases). This region shows high sequence conservation when comparisons are made between the human and animal enteroviruses, and analyses of sequences indicate that it assumes an extensive secondary conformation. The ORF is followed by another shorter noncoding region (70–100 bases). This shows little sequence conservation between viruses. The ORF is approximately 6500 bases in length, potentially giving rise to a polyprotein of 230 kDa. The generation of the various virus proteins from this and their functions are described below.

The detailed structures of the avian virus genomes have not as yet been assessed.

Properties of the Viral Proteins

The genome layout of the animal enteroviruses so far examined is essentially the same as that of the human enteroviruses. The four structural capsid proteins VP1–4 are derived from the P1 coding region at the 5′ end of the ORF. These have been alternatively called proteins 1A (VP4), 1B (VP2), 1C (VP3) and 1D (VP1) and are encoded in this order in the genome. VP4 and VP2 arise from the cleavage of a precursor protein VP0. Proteins VP1, 2 and 3 are the major structural proteins and have molecular masses of 25–33 kDa. The minor structural protein VP4 is about 7 kDa. This protein has been shown to have a myristic acid molecule covalently attached to it in BEV. The VP1 amino acid sequence is the most variable when comparisons are made between the proteins of animal and human enteroviruses. Purified AEV particles have been reported to contain three structural polypeptides with molecular masses of 35, 30 and 26 kDa; however, the sequence of these has not been determined. Three nonstructural proteins (2A, 2B and 2C) are derived from the P2 coding region in the central part of the genome and four (3A, 3B, 3C and 3D) from the P3 coding regions at the 3′ end of the ORF. Although very little investigative work has been performed on these proteins, because of the high levels of sequence identity at the amino acid level it is assumed that they perform the same function as their human enterovirus counterparts. Thus there would appear to be two virus proteases, 2A and 3C, and a polymerase protein, 3D. Prior to cleavage the protein 3CD may be involved in a number of proteolytic processing events. In poliovirus, this protein has also been shown to bind to the cloverleaf structure formed by the first 95 bases of the genome. The protein 3B is the small genome-linked protein VPg and is linked to the replicative complex by 3A prior to being donated to the genome. The precise function of the 2B protein remains to be fully elucidated; 2C is involved in replication processes.

A high-resolution structure is available for a serotype 1 strain of BEV. This indicates that the three virus proteins assume the same basic conformation as those of other picornaviruses, with each protein having an eight-stranded antiparallel β-barrel core. However, there are few protrusions emanating from the capsid shell, giving the virion a smooth appearance. The minor structural protein, VP4, is internally situated in the virion. The canyon, which surrounds the pentameric axes, is partially filled in when compared to the other enteroviruses and rhinoviruses for which crystal structures have been determined. This feature lies at the junction between the three major structural proteins and it has been suggested that this is the receptor-binding site. The hydrophobic pocket below it is occupied by a pocket factor which has been modeled to be myristic acid.

Physical Properties

The molecular weights of animal enteroviruses are $8–9 \times 10^6$. They have a sedimentation coefficient of 145–165S and a buoyant density in caesium chloride of approximately 1.34 g ml^{-1}. Viruses are stable over a wide pH range (3–10) and are insensitive to ether, chloroform and nonionic detergents. They can be stabilized against heat inactivation by divalent cations.

The buoyant density of AEV has been reported to be 1.31 g ml^{-1}. It is stable at pH 2.8 but the titer drops when the virus is incubated at pH 9–10. The sedimentation coefficient is 160S. It can be stabilized against heat inactivation by magnesium ions.

Replication

To replicate, viruses need to attach to their cellular receptor, penetrate into the cell and uncoat their genome. Translation of this is necessary to provide the proteins involved in replication processes. Little is known about the receptors to which animal enteroviruses bind. However, as with other picornaviruses, the binding site is thought to be the canyon area in BEV. It is assumed that the animal enteroviruses enter the cell and uncoat their genome in a similar manner to poliovirus, which has been studied in much more depth. Three species of viral RNA can be extracted from BEV infected cells. The first is single-stranded RNA, which is identical in sequence to the RNA found in mature virions. The second is replicative intermediate, which has a double-stranded core with nascent single strands growing from it. The third is the completely double-stranded replicative form. The enzyme responsible for replication of the genome is the virus encoded protein 3D, which functions as an RNA-dependent RNA polymerase. Synthesis of a negative-sense complementary strand is initiated at the 3′ end of the genome. The completed negative strand acts as template for progeny viral RNA. The rates of initiation may allow more of this to be formed relative to the minus strands. The progeny positive-sense molecules are either translated by polysomes or are encapsidated. It is likely that the other viral agents replicate their genomes in a similar way; however, further molecular studies will be necessary to confirm this.

Characterization of Translation

Like other picornaviruses, analyses of the available enterovirus sequences indicate that they contain a single large ORF. This is preceded by the long 5′ UTR described above. With poliovirus, part of this region has been shown to contain an internal ribosome entry site (IRES), to which ribosomes attach directly. This is in contrast to the situation with other eucaryotic mRNAs where ribosomes attach at the 5′ end and scan the sequence until the first AUG in the proper context is met, signifying the translation start site. The sequence similarities between the 5′ UTR of SVDV, BEV and the polioviruses indicate that these two animal viruses also contain IRES sequences. Preliminary translation studies with one strain of BEV suggest that this is the case. Translation starts at the AUG following the 5′ noncoding region, although with both viruses this is not the first AUG in the genome sequence. The long ORF frame covers about 85% of the genome. During BEV infection, translation of host mRNAs is shut off and viral RNA is translated preferentially. This facilitates analysis of virus-induced protein products following labeling of infected cells with radioactive amino acid(s). These are considered below.

Post-Translational Processing

Post-translational processing of the long polypeptide occurs *in situ* and has been demonstrated in BEV-infected cells using pulse chase experiments. The enzymes responsible are probably the two virus-encoded proteases 2A and 3C, although 3CD may play a role in the cleavage of the structural region. 2A is responsible for cleaving between VP1 and P2A at a T/G site in SVDV and at a Y/G or A/G site in BEV serotype 1 or 2 strains, respectively. 3C or 3CD are responsible for all but one of the remaining cleavages, which are mainly at Q/G sites in both viruses. Exceptions are the cleavage sites between 2B and 2C, which is Q/N in SVDV and Q/S in BEV, and the VP1/VP3 cleavage site in BEV which has not

accurately been determined. Sequence alignments indicate that it is either between Q/N or Q/T. The final cleavage event occurs on maturation of the virion when RNA enters the viral particle. VP0 is cleaved to generate VP2 and VP4 at an N/S bond in SVDV and a K/S bond in BEV. None of the virus proteins are glycosylated post-translationally; however, it has been shown that the N-terminal residue of VP4 of BEV is modified with a myristic acid moiety.

Assembly Site, Uptake, Release, Cytopathology

Few studies have been performed on the assembly and release of any of the animal viruses discussed here but it is likely that the mechanisms used are similar to those occurring in poliovirus-infected cells. The reader is referred to the entry dealing with this virus.

Most of the animal enteroviruses, which grow in cell cultures, produce marked cytopathic effect. Following BEV infection, BHK cells round up and eventually shrivel. The 13 serotypes of PEV have been divided into three groups, each of which produce a different type of cytopathic effects on pig kidney cell lines. Group I consists of serotypes 1–7, 11–13 and produces rounded refractile cells. Serotype 8 strains are the only members of group 2 and produce granular cells with cytoplasmic protrusions. Group III contains serotypes 9 and 10 and produces a cytopathic effect typical of SVDV and the coxsackieviruses. Group 1 viruses grow only in pig kidney cell lines, while group II strains are also cytopathogenic in the BHK21 cell line and type III are cytopathogenic in BHK21, Vero and HeLa cell lines.

Geographic and Seasonal Distribution

Many animal enteroviruses occur worldwide and may be endemic where host populations are sufficient to sustain them. However, the virulent serotype 1 PEV strain, Teschen disease virus, appears to be geographically restricted to parts of Africa and Eastern Europe, whereas the less virulent serotype 1 strains have a global distribution. Swine vesicular disease was first observed in Italy in 1966, since when outbreaks have been reported in most European countries and in Malta, Hong Kong and Japan. The continents of Africa, America and Australia have remained free of the disease. Most outbreaks have occurred in Great Britain, where they have been reported to peak in December and January. Avian encephalomyelitis was first identified in New England in 1932 and the disease has since been confirmed in many countries of the world. Duck virus hepatitis was initially reported in the USA in 1945 and then again in 1949. Since then the disease has spread to many countries in Europe, Asia, North Africa and America. The first reports of turkey virus hepatitis came from Canada and Massachusetts. It has since been reported in Italy. The true incidence of the disease is not known because it tends to be subclinical in nature. In many other instances it has not proved possible to link enteroviruses and related agents to defined disease symptoms; evidence of such infections have therefore come from serological conversion studies.

Host Range and Virus Propagation

Enteroviruses and enterovirus-like viruses have been isolated from a large variety of animal and avian species. Some animal enteroviruses only infect the species, or closely related species, to that from which they were isolated. A notable exception to this is SVDV which is antigenically similar to the human coxsackievirus B5 and has been shown to have infected laboratory personnel, causing a coxsackievirus-like illness. However, coxsackievirus B5 infection of pigs does not cause clinical signs of disease. SVDV also causes a progressive neurological disease in infected experimental newborn mice. Antibodies, which neutralize some BEV and PEV strains, have been demonstrated in human sera, although this may be a nonspecific reaction. In addition, some BEVs belonging to serotype 1 have been isolated from a variety of other animals, including goats and sheep; serotype 2 viruses have only been isolated from domestic cattle. Chickens, turkeys, pheasants and Japanese quail are the natural hosts of AEV but ducklings, pigeons and guinea fowl can be experimentally infected. ANV infects mainly chickens. Ducks are the natural hosts of the two DHV picornaviruses but experimental infection of other avian species has been achieved. THV infection has only been observed in turkeys.

Most animal enteroviruses can be propagated in primary kidney cell lines from the host species of origin. Many PEVs can be grown in established pig kidney cell lines although they may need to be isolated and adapted on primary cultures. They have been divided into three groups on the basis of the different types of cytopathic effect they produce in established pig kidney cultures. Viruses from group I and II are isolated more frequently from feces than from epithelium cells, whereas with group III viruses the reverse is the case. The majority of BEV strains grow in a range of primary kidney cell lines and also in a variety of established cell lines such as BHK-21, HeLa, Vero and L cells. Few avian enteroviruses grow well on primary avian cell cultures. Growth of ANV has been demonstrated in chicken kidney and embryo

liver cultures and two antigenically related viruses have also been shown to grow in chicken kidney cells, forming irregular plaques and giving rise to a cytopathic effect untypical of enteroviruses. In most cases propagation of avian viruses can be achieved by inoculation of chick embryos via the yolk sacs of eggs. AEV isolates have also been propagated by intracerebral inoculation of day-old chicks.

Genetics

No studies have been made of mutation rates in animal enteroviruses; however, as these are RNA viruses, the polymerases of which are error prone, it is likely that the mutation rate is high. In addition, picornavirus genomes undergo recombination events leading to variability.

Evolution

The genomes of only a few animal enteroviruses have been sequenced. Those that have show considerable homology to the human enteroviruses, suggesting that these viruses may have arisen from a common ancestor. SVDV shares over 90% sequence identity at the amino acid level with some coxsackie B viruses (CBVs), and in a recent phylogenetic analysis they have been clustered with the CBVs, several CAVs and several echoviruses. The human enteroviruses included in the cluster vary with the region of the genome that was analysed. However BEV (strain VG-5-27) is more distinct, with 30–50% amino acid sequence identity with human enteroviruses in the structural proteins and 30–70% in the nonstructural proteins. Thus these viruses appear to have diverged much earlier in evolutionary history. They have been placed in a separate cluster from the human enteroviruses when both the 5′ NCR and 3′ NCR sequences were considered. However, CAV16 was included in the cluster containing them following analysis of the coding region. The capsid regions of two serotype 1 and two serotype 2 BEVs have been sequenced. As expected, sequence identity is greatest within serotypes and suggests that two branches of these viruses have evolved. The serotypes are more closely related to each other than to any other sequenced picornavirus, implying that the two BEV serotypes have emerged from each other relatively lately in evolution or, alternatively, that there is some constraint on the evolution of these viruses.

Serologic Relationships and Variability

Enteroviruses from various different animal species have been comparatively characterized using a variety of immunological techniques and placed into serotypes. There are 18 different prototypes of simian enteroviruses (1–18) which do not appear to be related to any of the human enteroviruses. However, many simian species exist and it is likely that further isolation of enteroviruses from these will give rise to other distinct viruses. Numerous attempts have been made at serologically classifying the PEVs. Currently 13 serotypes are recognized (not including SVDV) with designated prototype viruses. Other work indicates that there may be as many as 15 serotypes. The BEVs were initially classified into seven serotypes but later reclassified into only two, based on data obtained from virus neutralization and complement fixation studies. Those in serotype 1 are more closely related serologically than those in serotype 2. There is only one serotype of SVDV. However, strains are divided into distinct phylogenetic groups. All strains of AEV are antigenically similar but they can vary in neurovirulence. ANV is antigenically unrelated to AEV. DHV types I and III are also antigenically distinct. DHV type II, which was once thought to be a picornavirus, is now classified as an astrovirus.

Epidemiology

Many animal enterovirus infections are subclinical and transient and therefore their true incidence are not known. Serological methods have indicated that many enteroviruses are widespread; for example, in one study, antibodies against porcine enteroviruses were found in serum samples from all herds tested from throughout the world. Feral pigs living in Georgian swamps have also been demonstrated to have antibodies to several porcine enteroviruses. Pigs are most susceptible to infection at 4–5 weeks when maternal antibody has dropped to below protective levels, although infection may occur *in utero* and at any age after birth. The spread of swine vesicular disease in pigs to various European countries and Japan may have been linked to the importation of pork products from infected countries. Some salami sausages, for example, use nonheat-treated pork and may harbor virus for considerable lengths of time. In England, pigs may have become infected because they were transported in vehicles previously used for infected animals, even though the trucks were cleaned between cargoes. The stable nature of this virus makes decontamination of infected premises very difficult and virus has been isolated from earthworms collected from soil above burial places for carcasses of slaughtered diseased animals.

Serological studies have indicated that BEVs are also widespread, with as much as 80% of tested cattle sera in certain herds having been reported to have antibodies against such viruses. Cattle may be

infected *in utero* and at any time thereafter. The simian enteroviruses, also on the basis of serological evidence, appear to be widespread.

Avian encephalomyelitis has been reported from most countries of the world where there is a commercial poultry industry. Embryos may be infected and young chicks are also susceptible. When the virus is first introduced into flocks, the morbidity and mortality rates are high, but once established both drop considerably due to protection of young chicks by maternal antibody. ANV occurs worldwide in domestic fowl. It is probably spread via ingestion of fecally contaminated food or water. DHV occurs in most countries where ducks are reared commercially. The virus is very stable and may remain viable in feces for considerable lengths of time, allowing ducklings to become infected following ingestion of contaminated food. The disease spreads rapidly through the flock.

Transmission and Tissue Tropism

The major mode of transmission of the animal enteroviruses is by the faecal–oral route, and in most instances infection is confined to the gastrointestinal tract. SVDV infection is thought to occur mainly though damaged skin, particularly around the feet, or in some instances through pigs eating contaminated garbage. During the viremic stage all tissues contain virus. Other porcine enteroviruses infect through the mouth and nose. In addition to showing a tropism for intestinal tissues, one such virus has been isolated from the spiral colon, ileum and tonsils following experimental infection of pigs. Various serotypes have been isolated from fetuses and serological evidence has implicated most of the others in such infections. BEVs have been isolated from blood, semen, vaginal washings, placenta, liver, kidney, pancreas, spleen, hard palate, epithelium and lymph node of infected animals and from fetal fluids and fetuses. AEV is spread by the faecal–oral route. It can also be transmitted through the egg. In young infected chicks, virus can be found in a variety of organs, including the central nervous system. Following infection, ANV can be recovered from a variety of organs including the kidney. DHV and THV are both spread by the faecal–oral route. The principal organ affected with both is the liver.

Pathogenicity

Most enterovirus infections are subclinical and inapparent and only the porcine and avian enteroviruses cause diseases of economic importance. Certain porcine enterovirus strains are neurotropic, giving rise to pig polioencephalomyelitis. The most severe form of the disease was first reported from a town called Teschen in Czechoslovakia and proved highly fatal. This was caused by a virulent strain of serotype 1. Although such cases are still reported, less severe forms of the disease, such as Talfan disease, which was originally reported in the UK, are now more common. These are caused by less virulent strains of serotype 1. In addition, serotypes 2, 3 and 5 strains have been implicated in some less severe cases of polioencephalomyelitis. Variations in pathogenicity of strains within serotypes have been observed. The frequent isolation of these viruses from stillborn and aborted fetuses has implicated them in the SMEDI *s*tillbirth, *m*ummification, *e*mbryonic *d*eath, *i*nfertility) syndrome which results in reproductive failure. SVDV causes a vesicular disease of pigs; however, subclinical infections have also been reported. In general, the disease in itself is not severe and most animals recover. Induced serum antibody prevents reinfection of these animals.

Strains of various avian enterovirus-related viruses have been reported to vary in pathogenicity. Field isolates, which normally give signs of infection only after hatching, have been adapted for growth in embryos. The adapted strains induce gross symptoms following infection.

Clinical Features of Infection

The clinical features of disease caused by animal enteroviruses are wide and varied. The initial symptoms of classical Teschen disease, a neurological disease of pigs caused by virulent strains of PEV-1, are high temperature, some lack of coordination in the back limbs, listlessness and loss of appetite. This is usually associated with mild diarrhea. Extreme stiffness generally follows, resulting in pigs walking with a limping gait and falling frequently. Mortality may be high, with death occurring at about 3–4 days after the onset of neurological symptoms. Surviving pigs show residual paralysis and muscular wasting. Teschen disease is also referred to as pig polioencephalomyelitis. The Teschen viruses cause disease in animals over a wider age range than the less virulent viruses such as Talfan virus. The latter mainly affect young pigs, resulting in similar but less severe symptoms than in Teschen disease. Morbidity and mortality rates are much lower in these cases. Porcine enteroviruses associated with the SMEDI syndrome produce different pathogenic effects depending on the stage of gestation. At early stages, infection may cause embryonic death and return to estrus. Fetuses infected between 40 and 70 days die, whereas those infected at a later stage may survive, although some are stillborn.

Viruses from other families such as the parvovirus family can also give rise to the SMEDI syndrome.

The clinical features of swine vesicular disease are virtually indistinguishable from foot-and-mouth disease. The disease is often first detected when several animals in the same herd go lame and is characterized by the appearance of vesicles of various sizes on one or more feet, usually about the coronary band, and later spreading to the metacarpals, metatarsals and soles of the feet. In the most severe cases there may be so many lesions that claws may slough off. In up to 10% of the cases vesicles also occur on the snout, tongue and lips. The vesicles develop into raw ulcers, which heal quickly, with most animals returning to normal within 3 weeks; however, if secondary infection of lesions occurs, the pig may become chronically lame. Animals on soft bedding tend to show less serious disease symptoms than animals kept on concrete floors. In general, the morbidity rates are moderate and the mortality rates are low.

AEV produces disease only in young birds. Clinical signs include weight loss, ataxia, head and neck tremors, blindness, paralysis and, in severe cases, coma and death. ANV causes growth depression but little or no signs of illness. DHV causes a severe disease in ducks of less than 21 days. Affected ducks stop moving, partially close their eyes and eventually fall on their sides and kick their legs. Death may follow rapidly. Morbidity is 100% and, depending on the age of the flock, mortality rates vary. It has approached 95% in birds of less than a week old, whereas in birds older than 5 weeks it is negligible.

Pathology and Histopathology

The intestinal phase of porcine enterovirus infections is generally not accompanied by histological changes, although atrophy of villi has been reported for recently weaned scouring pigs. Changes have been reported in the lung, liver, kidney, spleen, heart and in adrenal and thyroid glands. Teschen/Talfan viruses have the ability to invade the central nervous system. The histological changes in Teschen disease are more severe than those of Talfan disease. These include varying degrees of neuronal degradation, neuronophagia, lymphocytic perivascular cuffing and the development of focal areas of gliosis. The endoplasmic reticulum appears to be the target organelle in the infected degenerating neuron. Central nervous system changes are most prevalent in the gray matter of the spinal cord, with the cerebellum being the next most affected region. At the height of the disease the meninges above the cerebellum are severely infiltrated with lymphocytes. The pons and medulla oblongata are also often affected, followed by other areas of the brain to lesser extents. The gross lesions of swine vesicular disease are very similar to those caused by the foot-and-mouth disease viruses and it is the differentiation between these two diseases that is important. SVDV infection often causes microscopic neurological lesions and produces a mild or moderate, diffuse encephalitis. Neuroglia cell foci and lymphocytic perivascular cuffing occur to varying extents.

Macroscopic lesions are seen only rarely as a result of infection by AEV. Histological changes in the central nervous system include lymphocytic perivascular cuffing, evidence of gliosis and axonal-type neuronal degradation. In addition, hyperplasia of the lymphoid follicles in visceral tissue occurs. The livers of ducks suffering from duck virus hepatitis are enlarged and contain hemorrhages. The spleen is often also enlarged and the kidneys may be swollen. Histological signs include hepatic necrosis, varying degrees of inflammatory cell infiltration and proliferation of bile duct epithelium. Gross lesions are observed in the liver and pancreas of turkeys suffering from turkey virus hepatitis. The histological changes include necrotic foci, hemorrhage and mononuclear foci. Focal parenchymal foci of necrosis may also be observed in the pancreas.

Immune Response

In general, enterovirus infection results in a strong immune response. PEV infection results in the appearance of serum virus neutralizing antibody at about 6 days postinfection and intestinal antibody at about 14–15 days postinfection. The former is predominantly IgG and persists for a long period, whereas the latter is IgA and transient. Neutralizing antibody has also been demonstrated in sow milk and may provide protection to piglets until they are weaned. The cell-mediated response appears to be weak and to provide little antiviral protection. Fetuses infected with SMEDI enteroviruses at 65–70 days gestation produce IgM antibody initially and start producing IgG antibodies at 1 month from term. Pigs infected with SVDV produce neutralizing antibody at 4 days. This is initially IgM but later IgG predominates. Birds recovering from avian encephalomyelitis develop neutralizing antibody and this is transferred vertically into yolk sacs.

Prevention and Control of Disease

Economic loss is not considerable with most of the milder forms of pig encephalomyelitis, and therefore vaccination is not considered justifiable. In addition, subclinical infections prevent the success of a slaughter policy. Both oral and parenteral vaccines have been used successfully against Teschen disease.

Eradication has been achieved in one area by a combination of improved sanitary methods, slaughtering of diseased animals and ring vaccination. Virulent serotype 1 viruses have been prevented from spreading to disease-free countries by restrictions on the importation of pork products and swine. Vaccines have been prepared against SVDV, which in most countries is a notifiable disease. However, the preferred method of control is by containment and stamping out using a slaughter policy. The stability of the virus makes the eradication of the disease difficult. Following slaughter of an infected herd, premises have to be cleansed and disinfected thoroughly and possible infected pigs that have left the premises have to be tracked, with particular attention paid to vehicles used in their transport. In Great Britain, a small number of pigs are placed in previously infected farms and are observed for 3 weeks for evidence of disease development before full restocking is allowed. In the past, garbage containing pork products harboring virus has been a major source of infection. Careful monitoring of food products has helped to limit spread of infection in some instances. The banning of pork and swine imports has prevented the spread of the virus to disease-free countries.

Live vaccines are available against AEV and control has been achieved by administering these in drinking water to chicks that are more than 10 weeks old. Younger chicks are not vaccinated directly because the vaccine is not sufficiently attenuated. Immunization of laying hens is usually sufficient to pass on specific immunity to their progeny chicks in the critical 3 weeks after hatching. A killed vaccine is also available. Chicken egg-adapted DHV vaccines are also available and are used in a similar manner to that described above.

Future

Apart from the BEVs, SVDV and a few PEV serotypes, few biochemical studies or modern molecular biology techniques have been applied to the viruses discussed. Indeed it has not been confirmed that the enterovirus-related viruses are typical members of any of the recognized genera of the picornavirus family. Only the application of cloning and sequencing techniques and the analyses of generated data will help clarify the taxonomic relationships of this large group of agents that have previously been considered to be the animal enteroviruses.

Human Enteroviruses (Serotypes 68–71)

Jeffrey W Almond, School of Animal and Microbial Sciences, University of Reading, Reading, UK

Margeruite Yin-Murphy, Raffles Park, Singapore

Introduction

Because the subdivision of human enteroviruses into the polioviruses, coxsackieviruses group A, coxsackieviruses group B and echoviruses was not always unambiguous, it was decided in 1969 that enterovirus serotypes not previously assigned to the above groups be designated enterovirus (EV) followed by a number starting from 68. Since that time four enteroviruses, EV68–71, have been described and are in the *Enterovirus* genus of the *Picornaviridae* family. In addition, hepatitis A virus was provisionally identified as EV72, but this virus is now classified in a distinct genus (*Hepatovirus*). EV68 and EV69 seem to be of relatively minor importance in terms of human disease. Reports of their isolation and associated illnesses are infrequent and the viruses have not been studied extensively. By contrast, EV70, a cause of

Eradication has been achieved in one area by a combination of improved sanitary methods, slaughtering of diseased animals and ring vaccination. Human Enteroviruses (Serotypes 68–71)

Jeffrey W Almond, School of Animal and Microbial Sciences, University of Reading, Reading, UK

Margeruite Yin-Murphy, Raffles Park, Singapore

Introduction

Because the subdivision of human enteroviruses into the polioviruses, coxsackieviruses group A, coxsackieviruses group B and echoviruses was not always unambiguous, it was decided in 1969 that enterovirus serotypes not previously assigned to the above groups be designated enterovirus (EV) followed by a number starting from 68. Since that time four enteroviruses, EV68–71, have been described and are in the *Enterovirus* genus of the *Picornaviridae* family. In addition, hepatitis A virus was provisionally identified as EV72, but this virus is now classified in a distinct genus (*Hepatovirus*). EV68 and EV69 seem to be of relatively minor importance in terms of human disease. Reports of their isolation and associated illnesses are infrequent and the viruses have not been studied extensively. By contrast, EV70, a cause of

epidemic and occasionally pandemic acute conjunctivitis, and EV71, a major cause of aseptic meningitis, have attracted considerable attention. In terms of their acid stability, size, morphology, protein structure, RNA genome organization and structure, EV68–71 have characteristics typical of the enteroviruses, as described elsewhere in this volume.

Enterovirus Serotype 68 (EV68)

The first and prototype isolate of EV68 is known as 'Fermon virus'. This virus was one of four similar agents isolated in California in 1962 from oropharyngeal swabs of infants with lower respiratory tract illnesses. The isolation of these viruses is relatively rare: apart from the California isolates, countries that reported to the World Health Organization (WHO) in Geneva on a surveillance of virus diseases for the years 1975–1983 showed that, of 864 infections caused by the new human enteroviruses, only three were EV68. The California strains were isolated from infants aged between 10 months and 3 years with pneumonia and bronchiolitis. In addition, one isolate was obtained from a young adult with upper respiratory tract infection in Australia. It appears therefore that virus transmission is via the respiratory–oral route with virus affinity for epithelial cells of the oropharynx and respiratory tract producing pneumonia and bronchiolitis. EV68 in clinical specimens produces enteroviral cytopathic effects (CPEs) in primary monkey kidney but not human fetal kidney cell cultures incubated at 33°C. Only the Rhyne strain of E68 is pathogenic for mice; the Fermon, Franklin and Robinson strains are not. The histopathological picture of tissue from infected mice is similar to that of group A coxsackievirus. Zenker's necrosis occurs as swellings in short segments of muscle fibers accompanied by increased basophilia, loss of striations and pyknosis of nuclei. Some muscle lesions are characterized by infiltration of neutrophils into the endomysium and perimysium. Lesions are generalized throughout the skeletal muscles but the intrascapular fat pads and cardiac muscles are not affected. Recent partial sequencing of EV68 in the capsid encoding region of its genome suggests that it is most closely related genetically to EV70. These two serotypes appear to form a distinct genetic cluster among the enteroviruses.

Enterovirus Serotype 69 (EV69)

The prototype, Toluca-1 virus (obtained from a rectal swab of a healthy 4-year-old child), together with two other isolates were recovered from Toluca, Mexico in 1959. EV69 is also a relatively uncommon virus: only seven isolations of this virus were made from countries reporting to WHO on a surveillance of virus diseases in the years 1975–1983. The Fairfield Hospital, Victoria, Australia recorded one isolation in 1979 and the WHO Collaborating Centre for Virus Reference and Research, Singapore, has identified only two strains, both in 1984. EV69 can be isolated from feces and from nasopharyngeal aspirates, and virus from both sources produces enteroviral CPEs in primary rhesus kidney, Hep-2 and Hela cell cultures. Genetically, on the basis of partial nucleotide sequence data, EV69 clusters with the coxsackie B viruses, coxsackie A9 and the major group of echoviruses. Some crossreaction antigenically with one of this group, echovirus 6, had previously been reported, viz: Toluca-1 antiserum, with homologous hemagglutination inhibition (HI) and neutralization (N) titers of 1:320 and 1:500 respectively, had an HI titer of 1:40 and an N titer of 1:50 against echo 6 D1 (Cox) strain. Conversely, D1 (Cox) antiserum, with homologous N and HI titers of 1:5000 and 1:50 respectively, had HI titer of $<$1:10 and N titer of $<$1:50 against Toluca-1. Whereas E6 agglutinates human erythrocytes to much higher titers at 37°C than 4°C, the reverse was observed for Toluca-1. Although the Toluca EV69 strains were obtained from feces of apparently healthy children, the Australian (1979) and Singapore (1984) strains were isolated from nasopharyngeal aspirates of infants with respiratory illnesses. EV69 was implicated in cases of two infants hospitalized with symptoms of pharyngitis and bronchiolitis in Singapore and a child treated for pertussis in Australia. The respiratory illnesses had no distinctive feature. Transmission of virus via oral–fecal and respiratory routes would be expected, with virus tropism for cells of alimentary and respiratory tracts.

Enterovirus Type 70 (EV70)

History

EV70 is the second human enterovirus isolated from extensive epidemics where the dominant clinical manifestations are in the eye, the first being coxsackievirus A24 variant (CA24v). Together these viruses are universally recognized as causative agents of acute hemorrhagic conjunctivitis (AHC). EV70 was first isolated in 1971 during the 1969–1971 wave of AHC in Morocco, Singapore, Hong Kong (concurrently with CA24v) and Japan. Explosive outbreaks of acute conjunctivitis, thought intitially to be due to a virulent strain of adenovirus, were reported from Ghana in June 1969 and the disease extended rapidly along the coastal areas of west, east and north Africa. Clinically

similar epidemics of conjunctivitis involved major cities in the Indian subcontinent, southeast Asian countries and Japan, and small localized outbreaks occurred in London, Holland and Moscow in 1970–1971. The extent of the involvement of EV70 as compared with CA24v during the 1969–1972 AHC pandemic cannot be ascertained because most reports were based on clinical findings. Furthermore, the agent responsible for the African 1969–1970 epidemics has not been available for comparative investigations. It is clear that EV70 played a prominent role in the 1980–1982 AHC pandemic, during which not only Africa, southeast Asian countries, India and the Middle East were affected but the western hemisphere also became involved for the first time. A small localized outbreak in Oakland, California occurred in July 1980 and extensive epidemics which originated in Brazil spread rapidly through South and Central America, Oceania and Islands of the Western Pacific Ocean from mid-1981 to the beginning of 1982.

J670/71, the most extensively studied strain and the one that grows best in cell lines, has been classified as the prototype EV70.

Geographic and seasonal distribution

Australia is the only continent that has not reported an outbreak of AHC caused by EV70 or by CA24v. Extensive epidemics have occurred mainly in countries which are hot and humid. Unhygienic conditions, poor personal hygiene and overcrowding are conducive to the spread of conjunctivitis. There is no apparent seasonal influence on outbreaks but increased incidences are observed during the warmer humid months. In temperate countries, localized outbreaks occur in all seasons.

Properties of the virion

EV70 has the general physicochemical properties of enteroviruses. Electron micrographs reveal a typical nonenveloped virion of 22–27 nm in diameter with icosahedral symmetry. The virions have a buoyant density of $1.34\,g\,ml^{-1}$ in cesium chloride and a sedimentation coefficient of 160 S in sucrose. EV70 is inactivated by phenol, cresol, formaldehyde, chlorine at a concentration of 1 p.p.m. in distilled water, 50% methanol, 70% phenol, 0.0125% free iodine in disinfectant PA10DO and 0.004% free iodine in DIASAN. Replication of EV70 is inhibited in *in vitro* experiments by interferon β, arildone {4-[6-2-chloro-4-methoxyphenoxy)hexyl]-3,5-heptanedione}, Ro 09-0179 (4′,5-dihydroxy-3,3′,7-trimethoxyflavone), the benzimidazoles – enviroxime (LY-122772) and enviradone (LY-127123) – and guanidine hydrochloride but not actinomycin D. Benzalkonium chloride, benzethonium chloride, chlorhexidine gluconate and hexachlorophene at concentrations applied as germicides have no effect. EV70 retains infectivity at 40°C for at least 30 min but is largely inactivated at 50°C within 30 min. EV70 hemagglutinates human erythrocytes by virtue of its receptor (CD55) being expressed on these cells.

Properties of the viral genome

The complete nucleotide sequence of EV70 (J670/71) has been determined. The positive-sense single-stranded RNA has a typical enterovirus organization. It contains a 5′ noncoding region (NCR) of 726 nucleotides, a long open frame of 6582 nucleotides and a 3′ noncoding region of 82 nucleotides prior to the poly(A) tract. The genome encodes a VPg protein which by implication, in common with other picornaviruses, is covalently attached to virion RNA. The 5′ NCR is predicted to contain a high degree of secondary structure, consistent with it containing an internal ribosome entry site (IRES) to allow initiation of protein synthesis. The 3′ NCR also contains sequences likely to form secondary structures, although the function(s) of this region remains obscure. EV70 has been included in a genetic and phylogenetic analysis of a substantial number of partial and complete enterovirus sequences. This indicates that EV70 is most closely related to EV68 and that these two viruses form a distinct genetic cluster fairly well separated from other enteroviruses. Paradoxically, over most of its genome, EV70 does not appear to be closely related to coxsackie A24 variant, even though these viruses cause indistinguishable disease. It is interesting however, that, in its 5′NCR, EV70 does appear to be CA24v-like, clustering also with poliovirus type 1 and coxsackie A21. This raises the possibility that a recombination event may have occurred at some point in its evolution.

Viral proteins

In common with other enteroviruses, the icosahedral virion of EV70 is made up of 60 copies each of four virus-encoded proteins 1A (Vp4, 9kD), 1B (Vp2, 28kD), 1C (Vp3, 27kD) and 1D (Vp1). Comparison of the predicted amino acid sequence of the EV70 polyprotein with published findings for other enteroviruses permits prediction of some antigenic regions and most of the polyprotein cleavage sites. The organization and cleavage pathway of virus-encoded proteins appear to be in accordance with the L434 system, with glutamine–glycine as the most common cleavage site. Occasionally, for example at the 2B/2C junction and possibly also at the 1C/1D junction,

glutamine–serine appears to be used. Alignment of the structural proteins with those from related viruses whose crystal structures are known suggests that the VP1 protein contains an antigenic loop corresponding to the 'site 1' observed in poliovirus type 3. Other surface loops or 'puffs' can be predicted, although their significance remains to be determined.

Replication

The receptor on Hela cells for EV70 has been recently identified as CD55, otherwise known as decay-accelerating factor (DAF). This GPI-anchored cell surface protein is a natural regulator of complement action which functions through accelerating the decay of C3 and C5 convertases in both the classical and alternative pathways of complement fixation. In using this protein as its cellular receptor, EV70 is similar to a range of echoviruses, including types E6, 7, 13, 21, 29 and 33. This interaction with DAF explains the ability of some isolates of the virus to agglutinate human red blood cells. After attaching to DAF on permissive cells, EV70 enters the cell and replicates in the cytoplasm of infected cells. The optimum growth temperature is 33°C. Above 39°C (the nonpermissive temperature), viral RNA synthesis is blocked and replication stops. *In vitro* experiments suggest that the temperature-sensitive step is the uridylation of VPg. Little specific information is available about the steps in virus replication such as translation, RNA synthesis and assembly, but EV70 is believed to conform to the general strategy best understood for poliovirus.

Host range and virus propagation

EV70 from conjunctival swabs and scrapings, throat swabs and feces produces CPEs in tissue cell cultures of human and simian origin, with Hela cells being the preferred cell line. Other cell lines and organ cultures vary in sensitivity. Generally, 3–5 cell culture passes are required to attain characteristic CPEs. Optimum incubation temperature is 33°C but EV70 grows well between 33 and 37°C.

Genetics and evolution

EV70 strains isolated from Asia and the Americas during the 1980–1981 AHC pandemic are closely related to each other but differ from the 1981 Japanese endemic and the 1971 strains by many nucleotides. This finding suggests that only one basic EV70 genotype circulates worldwide at any one time but that clusters of EV70 strains emerge and evolve independently from each other. Partial nucleotide sequence information is available for a large number of isolates taken from various geographical regions in the period 1971–1981. These sequences infer a phylogenetic tree with an origin for all branches occurring in approximately 1967, suggesting that the virus first arose in the human population, giving a recognizable AHC, at that time. The rate of nucleotide substitution was estimated to be 3.8×10^{-3} per year, higher than that seen in influenza virus and human immunodeficiency virus.

Serologic properties

EV70 is antigenically distinct from existing members of the human enteroviruses by crossneutralization tests. Neutralization kinetics revealed only slight antigenic variations between strains isolated in 1971 and strains isolated from subsequent epidemics. The major antigenic sites remained unchanged. Epitopes reacting in microneutralization test with monoclonal antibodies are also relatively stable and conserved.

Epidemiology

Alternating and together with CA24V, EV70 has been responsible for sporadic and epidemic outbreaks of AHC globally. AHC affects all age, social-income and ethnic groups. However, incidences in children under 10 years of age, in particular infants, and the over-60 age group have been markedly low. AHC is most prevalent in young adults and teenagers, and more males than females are affected. The overall attack rates vary from 20% to 100% within members of families.

Transmission and pathogenicity

EV70 is transmitted by the fecal–oral route, ocular and respiratory secretions and contact with contaminated objects such as facecloths, bath towels, handkerchiefs and bedding. In ophthalmic clinics, crossinfections occur when the eye is infected with contaminated fingers of attending physicians and nurses, ophthalmic instruments and solutions. Although water stored in containers and basins and spring water have been identified as sources of virus transmission, contaminated utensils used to bale water and contaminated water taps and door knobs are also possible vehicles of virus spread.

EV70 has affinity for epithelial cells of the conjunctiva, which is the primary site of replication. Only a few strains have been isolated from the throat and feces. Virus neurotropism is suggested in patients with central nervous system (CNS) involvement and polio-like radiculomyelitis accompanying or following AHC, and in patients who have been in contact with cases of AHC. However, to date, EV70 has not been isolated from the CNS.

EV70 produces an enteroviral CPE in cell cultures of primate origin and some strains can be adapted to grow in nonprimate cells. The virus is not pathogenic for mice. Monkeys inoculated with EV70 via the intraspinal and intrathalamic routes develop paraplegia or monoplegia of lower limbs. However, feeding and instillation of virus into the eyes does not cause pathological changes. Rabbits with experimentally induced conjunctivitis develop clinical disease and virologic and immunologic responses similar to AHC in humans. Conflicting reports on animal studies may be attributed to differences in the preparation of virus inoculum, choice and origin of EV70 strains, and the method of inoculation.

Clinical features of infection

Acute conjunctivitis caused by EV70 is clinically indistinguishable from conjunctivitis caused by CA24v, poliovirus and adenovirus type 2. The eye affliction is characterized by a short incubation of 1–2 days and high secondary attack rate. Common features are sore red eyes with a 'foreign body' sensation, swelling of the eyelid, lacrimation, chemosis, edema and hyperemia of the conjunctiva, photophobia, blurring of vision and preauricular gland enlargement. Seromucous and purulent discharge due to secondary bacterial infection are common. Follicular hypertrophy of the conjunctiva is most prominent in the upper and lower fornix. Small petechiae to large blotches of subconjunctival hemorrhage have been reported in 10–100% of patients in various countries. Subconjunctival hemorrhage usually initiates in the bulbar conjunctiva near the upper fornix and spreads to the upper half of the bulbar conjunctiva and to the lower fornix. It is this striking appearance of subconjunctival hemorrhage which prompted the coining of the name acute hemorrhagic conjunctivitis. Corneal lesions cause blurring of vision and pain. Iritis is rare. Uni- or bilateral, the conjunctivitis varies in severity and usually resolves within 1–2 weeks without sequelae. With few exceptions, cases of radiculomyelitis involve adults. Three clinical forms of CNS manifestations have been identified. The most common is the spinal form, which is characterized by acute asymmetrical flaccid motor paralysis or paresis in one or more limbs, followed by atrophy in severely affected muscles. Pain in the limbs, back and neck are present during the early phase of disease. The next most common form is the cranial form, which is characterized by acute motor cranial nerve palsy and involves a single nerve or groups of nerves. The third form features a combination of spinal and cranial involvements. The preparalytic manifestations, prognosis of flaccid motor paralysis, changes in cell count and total protein level in cerebrospinal fluid (CSF), resemble poliomyelitis. The distribution of flaccid paralysis and development of muscular wasting indicate involvement of anterior horn cells of the spinal cord. Rare incidences of facial palsy, palatal paresis, Bell's palsy, bladder paralysis, vertigo, parotitis resembling mumps and sensory loss have also been reported. Respiratory and gastrointestinal symptoms accompany AHC in some patients.

Pathology and histology

Histological examinations of the conjunctiva reveal a predominance of mononuclear cells with diffuse lymphocytic infiltration into the adenoid layer and accumulation of lymphocytes in areas corresponding to lymph follicles. The tarsal conjunctiva is hyperemic, with small petechiae. Small follicles in the temporal portion of the lower tarsal conjunctiva are seen in 10–100% of patients. Subconjunctival hemorrhages vary in severity. Large areas of blotchy bleeding may extend over the whole bulbar conjunctiva. Hemorrhages usually disappear within 1 week but in severe cases a crescent-shaped hemorrhage remains longer. Fine pinpoint epithelial opacities in the cornea are common but punctate subepithelial keratitis is rarely seen. Sections of the spinal cord of three patients with polio-like paralysis revealed degeneration of cells of the anterior horns, hemorrhages and neuroglial cell proliferation. EV70-specific antigen was demonstrated in the microglial and/or neuronal cells by immunofluorescent testing.

Immune response

EV70-specific IgM and IgG antibodies and interferon are found in response to infection. When sera are taken at the acute stage of infection and again 3–4 weeks later, a $\geq$ fourfold increase in antibody is frequently discernible. However, the absence of antibody from patients from whom virus has been isolated has also been encountered. Neutralizing antibody has been detected in the CSF of patients with radiculomyelitis. In a few patients, blood serum to CSF neutralizing antibody ratios of <20 have been observed and are indicative of direct invasion of the CNS by EV70. Despite two major EV70 AHC epidemics in 1971 and 1980 and sporadic interepidemic incidences of EV70 conjunctivitis in Singapore, sera sampled at the acute stage of conjunctivitis do not appear to have neutralizing antibody ($<1/10$) to EV70. A similar seronegativeness was observed in Hong Kong. This transient immunity may be attributed to the predominantly localized nature of the infection.

Prevention and control

Intrafamilial and epidemic spread of AHC is controlled by public education through mass media on the mode of virus transmission, practice of good personal hygiene, exclusion of persons with conjunctivitis from schools, institutions, offices, factories, recreation centers and crowded locations. Nosocomial transmission of the disease can be prevented by segregation of patients with conjunctivitis, thorough hand washing before and after contact with infected eyes, use of separate eye-droppers for treatment and proper sterilization of instruments used for the eye. The future prospects for treatment of AHC include application of interferon β, arildone and chemically related compounds that have been shown to inhibit replication of EV70 and CA24v *in vitro*.

Enterovirus Serotype 71 (EV71)

History and classification

CNS disease caused by EV71 was first recognized in California (1969–1972) when patients presented with aseptic meningitis (AM) and encephalitis. BrCr/1970, the prototype EV71 strain, was isolated from the brain of a fatal case of encephalitis. Since then, EV71 has been isolated from patients with neurological involvement and various clinical conditions in many parts of the world. Indeed, EV71 seems to be increasing in importance as a cause of, sometimes severe, neurological disease.

Geographic and seasonal distribution

EV71 seems to be widespread in the world. It was implicated in cases of AM and encephalitis in New York State in 1972 and in Australia in 1972–1973, 1978, 1979, 1982–1983 and 1986 in similar cases of CNS involvement and additionally hand–foot–mouth disease (HFMD), respiratory illness and polyneuritis. Similar EV71 outbreaks occurred in Sweden (1972), Japan (1973, 1978) and Bulgaria (1975) where poliomyelitis-like paralysis occurred with a high rate of fatality in children. EV71 has been associated with a concurrent epidemic of tick-borne encephalitis in Hungary (1978), an outbreak of acute respiratory illness with CNS involvement in Lyon, France (1979), a case of HFMD in Singapore (1984), an outbreak of monoplegia in Hong Kong (1987), a case of HFMD in China (1989) and two cases of acute viral encephalitis in Japan (1996). More recently (April–August 1997), EV71 was implicated, possibly with concurrent coxsackie B virus, in an extensive epidemic of HFMD in Malaysia in which 30 children died of cardiac failure, with or without CNS involvement.

There is no apparent seasonal influence on outbreaks.

The virus

EV71 shares the physicochemical characteristics of the enterovirus group. Like the other viruses in this group, EV71 is a typical enterovirus. The complete nucleotide sequence of strain MS7423/87 has been determined. This reveals that it is very closely related to coxsackieviruses A16 and A2 and clusters genetically in a group that contains many other coxsackie A viruses, including 3, 5, 7, 8, 10, 12 and 14. Little specific information on replication, receptor recognition and three-dimensional structure is available, but the virus probably does not differ significantly in these properties from the better-studied enteroviruses such as polio.

Host range and viral propagation

EV71 in feces, throat swabs, tissue from brain, spinal cord, mesenteric lymph nodes, CSF and skin vesicles produce CPEs in monkey kidney cell cultures, human fetal kidney, Hela and HEL cell lines. Some strains require several tissue culture passes to produce CPEs. Strains from patients with encephalitis produce CPEs at incubation temperatures of 35°C and 39°C, while strains from patients with HFMD grow at 35°C but not 39°C. EV71 strains vary in pathogenicity for suckling mice.

Serologic relationships and variability

BrCr/71 and related strains are antigenically distinct from previously classified enteroviruses as determined by neutralization and immunodiffusion tests.

Clinical features

EV71 is a prime example of an enterovirus capable of causing a variety of illnesses in sporadic or epidemic proportion. It is a major cause of aseptic meningitis often accompanied by encephalitis and bulbar–spinal dysfunction and polyneuritis. It can cause outbreaks of HFMD with or without neurological complications and has also been associated with cases of encephalomyocarditis and respiratory illnesses.

Epidemiology, transmission and tissue tropism

Generally, infants and young children are most frequently and severely affected. In the Bulgarian 1975 encephalitis epidemic, the highest incidence and mortality rates were in the 5 years and below age group.

EV71 can be transmitted by oral–fecal and respiratory routes and also in vesicular fluids from skin lesions. It has tropism for epithelial cells of the

alimentary and respiratory tracts, the skin and cells of the CNS.

Pathogenicity

Primate cell cultures inoculated with EV71 produce characteristic enteroviral CPEs, and EV71 strains vary in pathogenicity for suckling mice, cotton rats and hamsters, where they induce group A coxsackievirus-type myositis and paralysis. Strains isolated from patients with encephalitis are neurovirulent for monkeys, while strains from HMFD cases are less so.

Pathology and histology

In monkeys, neurotropic strains produce marked chromatolysis, degeneration and necrosis of the neurons and neuronophagia by polymorphonuclear or mononuclear leukocytes. Perivascular cuffings and petechiae are found in the lumbar and cervical cord, medulla oblongata, midbrain, pons and cerebral stem.

Immune response

Neutralizing antibody is produced in response to infection. Because of the relatively long incubation period in CNS disease, high antibody titers may be observed at the time of neurologic manifestations, and the diagnostic fourfold antibody rise between paired sera may be absent. However, persistence of EV71-specific immunoglobulin (Ig)M is transient and is indicative of current infection.

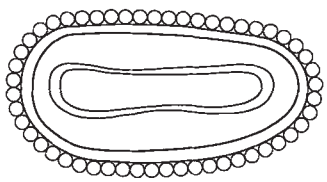
ENTOMOPOXVIRUSES (*POXVIRIDAE*)



Richard W Moyer, Department of Immunology and Medical Microbiology, University of Florida, Gainesville, Florida, USA

Introduction

The entomopoxviruses (EPVs) and vertebrate poxviruses comprise the two subfamilies of the poxvirus family. The EPV subfamily includes a varied collection of insect viruses which share features associated with the more commonly known and more intensively studied vertebrate poxviruses such as vaccinia, fowlpox, variola (smallpox) and myxoma viruses. While EPVs and the vertebrate poxviruses have some properties in common, there are also some striking distinctions. Similarities include: general virion morphology, a large linear double-stranded DNA genome comprising by weight about 5% of the particle; common sequence motifs that are associated (at least in the vertebrate viruses) with regulation of transcription; nonspliced transcripts; a cytoplasmic site of replication and the encoding of a wide variety of cytoplasmic enzymes necessary to support transcription and replication of the virus within the cytoplasm. Differences include: the G + C content of the viral DNA (EPV G + C content is quite low; 17–27% as compared to the 32–39% observed for vertebrate poxviruses); length of the replication cycle and optimal growth temperature (26–28°C as compared to ~37°C for vertebrate poxviruses) and host range.

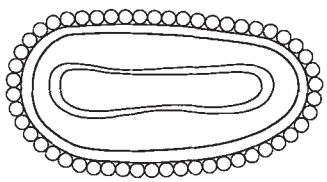
ENTOMOPOXVIRUSES (*POXVIRIDAE*)



Richard W Moyer, Department of Immunology and Medical Microbiology, University of Florida, Gainesville, Florida, USA

Introduction

The entomopoxviruses (EPVs) and vertebrate poxviruses comprise the two subfamilies of the poxvirus family. The EPV subfamily includes a varied collection of insect viruses which share features associated with the more commonly known and more intensively studied vertebrate poxviruses such as vaccinia, fowlpox, variola (smallpox) and myxoma viruses. While EPVs and the vertebrate poxviruses have some properties in common, there are also some striking distinctions. Similarities include: general virion morphology, a large linear double-stranded DNA genome comprising by weight about 5% of the particle; common sequence motifs that are associated (at least in the vertebrate viruses) with regulation of transcription; nonspliced transcripts; a cytoplasmic site of replication and the encoding of a wide variety of cytoplasmic enzymes necessary to support transcription and replication of the virus within the cytoplasm. Differences include: the G + C content of the viral DNA (EPV G + C content is quite low; 17–27% as compared to the 32–39% observed for vertebrate poxviruses); length of the replication cycle and optimal growth temperature (26–28°C as compared to ~37°C for vertebrate poxviruses) and host range.

The limited serology available suggests that there is little immunological relationship either among the insect poxviruses or with the vertebrate poxviruses. Using an ELISA, antibodies made against purified *Amsacta moorei* entomopoxvirus (AmEPV) detected little antigenic relatedness between the structural proteins of the *Amsacta, Euoxa* or *Melanoplus* EPVs or vaccinia virus. However, antibodies against the *A. moorei* (red hairy caterpillar) EPV occlusion body protein crossreacted extensively with the occlusion body protein of the *E. auxiliaris* (army cutworm) EPV. The EPVs are relatively recent discoveries, the first being observed in 1963 as a disease of *Melolontha* (the common European cockchaffer). Since that time, these viruses have been discovered in well over 60 species of insects, which to date are the only known hosts to give a totally permissive infection. Distribution of these viruses is throughout the world – the Americas, Europe, Asia, Australia and Africa – and they are found in both agricultural and aquatic insect populations. These viruses have been found to infect primarily, if not exclusively, four orders of insects, Orthoptera, Diptera, Coleoptera and Lepidoptera, with most members being associated with coleopteran and lepidopteran hosts. More recently, poxvirus-like particles have been discovered in Hymenoptera (bumblebees and parasitic wasps) but with seemingly little pathological effects. A distinctive property of these viruses is the presence of occluded virions within a protein matrix consisting primarily of a single protein, spheroidin. Presumably spheroidin provides environmental protection and virion stability until exposure, after ingestion, to the alkaline midgut of the insect. While a wealth of biological studies on the behavior of these viruses in their natural hosts is available, molecular studies have been extremely limited due to the paucity of *in vitro* cell culture systems, and the failure to perceive that these viruses have the potential to be generally useful as biopesticides and for expression systems. There are currently only two EPVs which can be readily grown in cell culture. The first, AmEPV, a virus originally isolated from the red hairy caterpillar of India and adapted to the saltmarsh caterpillar (in the US); and more recently HaEPV isolated from *Heliothis armigera.*

Taxonomy

The family *Poxviridae* is divided into two subfamilies: (1) the *Chordopoxvirinae,* comprising the vertebrate poxviruses; and (2) the *Entomopoxvirinae,* which comprises the viruses of insects. The most recent proposals of the International Committee on Taxonomy of Viruses define the genera *Orthopoxvirus* (vaccinia subgroup), *Parapoxvirus* (orf subgroup), *Avipoxvirus* (fowlpox subgroup), *Capripoxvirus* (sheeppox subgroup), *Leporipoxvirus* (myxoma subgroup), *Suipoxvirus* (swinepox subgroup), *Molluscipoxvirus* (molluscum subgroup) and *Yatapoxvirus* (Yaba/tanapox subgroup) within the *Chordopoxvirinae* subfamily. The *Entomopoxvirinae* contains three proposed genera, designated as *Entomopoxvirus A, B* and *C,* devised primarily on observed structural differences between virions. *Entomopoxvirus A* viruses infect the order Coleoptera (beetles). *Entomopoxvirus B* viruses infect insects of the orders Lepidoptera (moths) and Orthoptera (grasshoppers and locusts), whereas *Entomopoxvirus C* infects insects of the order Diptera (flies). The prototype viruses from each genera are those from *Melolontha* (genus A), *A. moorei* (genus B) and *Chironomus luridus* (midge) (genus C). Whether these genera, which were devised primarily on morphological considerations, are substantiated by similarities at the molecular level must await further detailed characterization of individual viruses. However, Southern hybridizations between viruses (see below, Viral DNA) suggest revision at some later date may be necessary.

Virion Structure

The virions are quite large, brick- or oval-shaped, exhibiting a rich, complex and somewhat varied structural morphology reminiscent of the vertebrate poxviruses (**Fig. 1**). Lengths observed vary from 150 to 470 nm and widths from 165 to 300 nm. General structural characteristics shared with the vertebrate poxviruses include a surface envelope, lateral bodies and an internal core located at the center of the virion. The surface characteristics of the envelope of the virions are beaded and 'raspberry-like', resulting from the folding pattern of an external membrane. Similar convolutions at the external surface of vaccinia virus are not evident. Within the virion is located the well-defined electron-dense core which contains the DNA. As in the orthopoxviruses, the lateral bodies are located within the virion, external to the core but inside the envelope. The lateral bodies are distinct from the core and no function has yet been assigned to them. One property distinguishing different genera is the presence of either one or two lateral bodies.

The largest (250 × 450 nm) are the coleopteran EPVs, which contain a single lateral body and a core of concave appearance. The lepidopteran and orthopteran EPVs are intermediate in size (250 × 350 nm) and are characterized by a symmetrical cylindrical core and a cylindrical lateral body. The dipteran viruses are the smallest (230 × 320 nm) and are characterized by a vaccinia-like biconcave core and

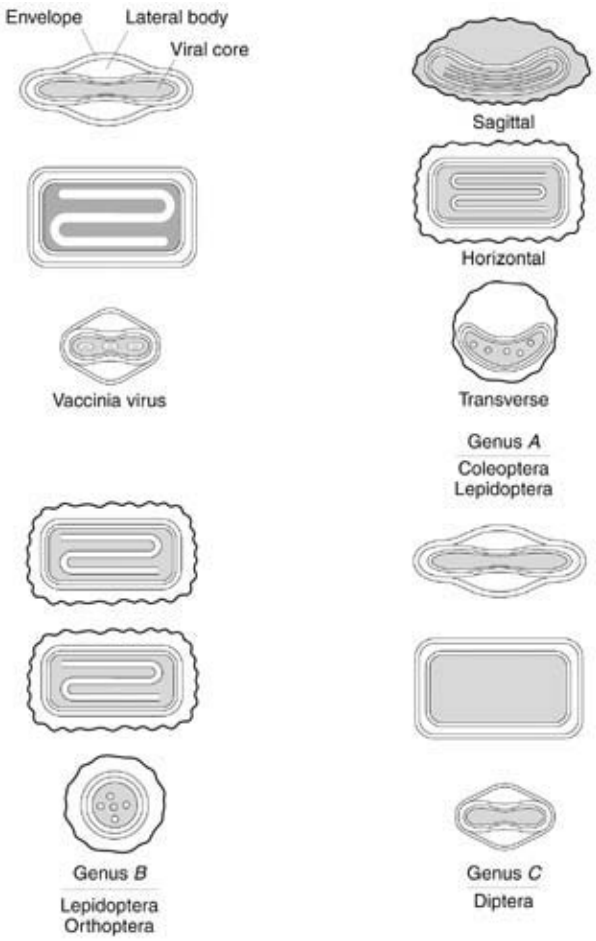


Figure 1 EPV structures from the three genera as compared to vaccinia virus showing the relevant morphological features of each (taken from Arif B (1995) *J. Gen. Virol.* 76: 1.

two lateral bodies. Indeed, the dipteran viruses most closely resemble vaccinia virus in appearance.

Virion and Genome Composition

Virion

Analysis of polypeptide composition by PAGE reveals an extraordinarily complex pattern of polypeptides with molecular weights from approximately 12 kDa to 250 kDa. Many viral particles are occluded within a proteinaceous mass, not an integral component of the virion *per se*, which consists predominately of a single protein, spheroidin. These so-called occlusion bodies are reminiscent of A-type inclusions (ATIs), formed by the vertebrate cowpox virus and the occlusion bodies formed by the nucleopolyhedrosis viruses, structures which again in each case are predominately derived from a single protein (the ATI and polyhedrin proteins respectively). Spheroidins are approximately 115 kDa in size and typically very high in both cysteine and methionine residues, which could explain why carbonate and a reducing agent are required to effect dissolution of occlusion bodies and release of the free virions. The spheroidin genes of the EPVs of *A. moorei* (AmEPV), *Choristoneura fumiferana* (CfEPV), *Melolontha melolontha* (MmEPV) and *Heliothis armigera* (HaEPV) are highly conserved. Identity to the AmEPV spheroidin gene ranges from 81% and 78% for the CfEPV and HaEPV genes, respectively (genus *B* viruses), to 43% for the MeEPV gene (genus *A* virus). There is little significant homology between the spheroidin genes and the ATI gene of cowpox virus. The amounts of spheroidin synthesized within infected cells are large and spheroidin constitutes a significant percentage of total cell mass.

Frequently, but not in every case, EPVs that infect Lepidoptera and Coleoptera (genus *B* and *A* viruses) produce a second very abundant 350–380 amino acid protein (fusolin or spindle body protein) which forms paracrystalline, spindle-shaped structures. Although

the fusolin-containing spindle structures themselves do not contain virions, fusolin can in many cases become occluded together with virions into occlusion bodies (spheroids). AmEPV lacks this gene (hence it is nonessential), but it is present within the genomes of MmEPV, HaEPV, CfEPV, as well as in the EPVs from *C. biennis* (CbEPV) and the armyworm *Pseudaletia separata* (PsEPV). The degree of identity of this protein ranges from about 70–90% among the genus *B* viruses (HaEPV, CfEPV, CbEPV and PsEPV) to 60% between HaEPV and MmEPV (a genus *A* virus). There are two other noteworthy features of this protein. First, it exhibits significant homology (37–42% identity) with a 37 kDa glycoprotein from *Orgyia pseudotsugata* and *Autographa californica* nucleopolyhedrosis viruses. This relationship extends to five conserved regions within the baculovirus glycoprotein which are conserved within the EPV fusolin or spindle protein. The second feature is that the PsEPV fusolin (spindle) protein is reported to serve as a 'virulence enhancing factor' which increases the susceptibility of the armyworm larvae host to a nucleopolyhedrosis virus several thousand-fold.

A third abundantly expressed ~25 kDa protein (filament-associated late protein of EPV, FALPE) has been described in AmEPV infected cells. Fibrils containing this protein are closely associated with occlusion bodies and may play a role in the morphogenesis and/or occlusion process.

As a consequence of a cytoplasmic site of development within the infected cell, EPVs, like their vertebrate counterparts, both encode and contain a number of enzymes within the virion. Enzymes identified to date include a DNA-dependent RNA polymerase, poly(A) polymerase, alkaline protease, topoisomerase, nucleotide phosphohydrolase and acid and neutral DNases. The alkaline protease has been associated with occlusion bodies and may be responsible, in part, for degradation and dissolution of occlusion bodies within the insect gut. The properties of the AmEPV encoded topoisomerase have been compared with those of the vaccinia-encoded enzyme and found to be quite similar, despite significant sequence divergence (only 36% identity).

AmEPV contains a homologue of an unusual vertebrate poxvirus gene first reported in vaccinia virus. The vaccinia virus gene, when mutated, can confer resistance of the virus infection to the inhibitory action of rifampicin.

Viral DNA

The DNA of the vertebrate poxviruses is a linear, large duplex (130–300 kb) and is characterized by a high degree of colinearity amongst all genes located within the conserved central core comprising 60% of the viral genome, as well as terminal inverted repetitions, and crosslinked telomeric termini. The DNAs of EPVs range in size from 200 to 300 kb and are uniformly characterized by an unusually low G+C content ranging from 17 to 27% (compared to 32–39% for the vertebrate poxviruses). The DNA of AmEPV is 225 kb in size and has a G+C content of 18.5%. There is some evidence both for the presence of terminal inverted repetitions in AmEPV DNA, and for the existence of crosslinked telomeric termini, typical of the vertebrate poxviruses. As might be expected, DNA restriction enzyme digests of EPV DNAs from various sources differ significantly and studies of the relative homologies of entomopoxvirus genomes to each other, and to vaccinia have yielded only limited information. Hybridization studies with various entomopoxviruses show no obvious homology to vaccinia virus based on Southern hybridizations. Likewise, no hybridization was observed between EPVs which infect different insect orders. Within the same insect order, extensive hybridization was observed between the lepidopteran *A. moorei* and *E. auxiliaris* viruses. However, the lepidopteran viruses CbEPV and the virus from *Oncopera albogutatta* failed to show hybridization with either the *A. moorei* or *E. auxiliaris* viruses. Hybridization was also observed among some orthopteran viruses: *Melanoplus sanguinipes, Arphia conspersa, Phoetaliotes nebrascensis* and *Oedaleus senegalensis*. However, the two grasshopper viruses from *Aeropedellus clavatus* and *Cataloipus cymbiferus* failed to hybridize to any of the other four orthopteran viruses. These results must be interpreted with caution because significant homologies can still exist in the final protein products and at the DNA level, yet not be detected through Southern hybridizations. Indeed there are now many examples amongst EPVs and vertebrate poxviruses where direct sequencing has shown this to be the case.

Based on available sequence information, it has also been shown that the order of core genes of the AmEPV genome is not colinear with the conserved arrangement of core genes characteristic of the vertebrate viruses (**Fig. 2**). The significance of this observation is not clear but argues that the conserved arrangement of genes observed in the vertebrate poxviruses is not essential for viability nor a feature to be expected of all poxviruses.

Characteristics and Pathology of Viral Infections

These viruses collectively show a wide variety of cell, tissue and host specificity. No productive crossinfec-

tions have yet been produced between the two insect subfamilies. Most viruses replicate within the cytoplasm of cells of the fat body, with the infections being characterized by the appearance of large elliptical occlusions and occasionally microspindles. Some viruses are restricted to the fat body, while others infect, in addition, hemocytes and the epidermis. Some viruses can produce systemic infections. The pathology therefore varies somewhat depending on the order of insect. It has been well described for specific viruses by Granados and Arif (see Further Reading) and is reproduced and summarized here.

Lepidopteran infections are relatively short, generally less than 3 weeks in duration. Infection of larvae is common, of pupae is rare and of adults unknown. Some species become 'white' after infection. Infected larvae may become discoordinated, lethargic and show significant loss of mobility during later phases of the infection. The larvae of *E. acrea* show paralysis in the posterior two-thirds of the body. Death of some species is preceded by regurgitation or defecation of material containing occlusion bodies. Infection of *C. fumiferana* larvae with *C. biennis* virus was characterized by hormonal imbalance. Wing buds were present in insects that died in the sixth instar. Infected pupae retained prolegs. Diseased larvae were approximately twice the size of controls and the last larval stadium was around 15 days instead of the usual 7. Infection by the prototypic *A. moorei* virus is promiscuous, in the sense that many cells and tissues are involved. The fat body, hemocytes, nerve cells, midgut cells, hypodermis, tracheoblasts and muscle cells are all involved. Other lepidopteran virus infections are much more limited and involve primarily the fat body. Midgut infection has been reported infrequently for both the *C. biennis* and *A. moorei* viruses, but may probably be relatively common because the natural port of entry into the insect is through the midgut. The presence of occlusion bodies is typical, whereas the presence of spindles is sporadic, depending on the virus. Indeed, spindles are much more typical of EPV infections of lepidopteran and coleopteran than orthopteran or dipteran species. However, the *C. biennis* virus, a second intensively studied lepidopteran virus, forms extremely large spindles (100 × 500 nm). Antigenically, spindles and the spheroidin derived from occlusion bodies are unrelated, consistent with sequence information which shows them to be distinct.

In the case of the orthopteran EPV from *Melanoplus sanguinipes* (MsEPV), an interesting relationship between the pattern of mortality and infectious dose has been noted. Infections with high or low dosages of virus resulted in early or late death of the insect respectively. Insects that died early (<12 days postinoculation) were devoid of spheroids (occlusions), and homogenates of cadavers were not infectious. However, cadavers of insects that died late (>16 days postinfection) contained many spheroids and were infectious to other grasshoppers. Hence, either nonoccluded virus or a viral toxin or toxic factor are critical elements of early insect mortality.

Coleopteran infections are unusually prolonged and may persist for as long as 30–40 weeks. Early signs of disease in *M. melolontha* larvae include

distension or proliferation of diseased fat body tissue with the lobes of fat body tissue exhibiting a foamy white appearance, a chalky white appearance of the larvae and softening of the integument. Infected larvae lose turgidity and become lethargic. The only cells infected are hemocytes and fat body cells. Late in disease, the hemolymph becomes chalky. All stages of larval development are susceptible to infection, with the first two instars being most susceptible. While fat body and the hemocytes are the most common cell types involved, the intestinal tract and hypodermis can all be infected. Viral infections are characterized by the presence of fusiform spindles and oval occlusion bodies in the cytoplasm of the infected cells. Spindles are smaller, in cross-section, and commonly 15–23 μm in length. Occlusion bodies are 5–20 μm in diameter but larger overall. Virions are only found within occlusion bodies and the function and/or significance of the spindles is unclear.

Dipteran infections are again characterized by a whitening of the larvae as masses of opaque white hemocytes and fat body accumulate. In the case of chironomid larvae, the presence of irregular white areas is observed beneath the integument. The course of the infection is generally from 3 to 8 weeks. Infected hemocytes accumulate early in infection in the dorsal region of the ninth abdominal segment just posterior to the heart. Infected first instar larvae may die as soon as 24–78 h postinfection. The pathology again varies depending on the virus. The EPV of *C. luridus* appears to infect many cells and tissues, including fat bodies, hemocytes, epidermis, oenocytes, imaginal disks of the leg and genital organs, muscles, nervous system and the intestinal tract. Others infect only the hemocytes. Signs of infection include the presence of elliptical cytoplasmic occlusion bodies ranging in diameter from 3 to 6 μm.

Orthopteran infections are characterized (in the grasshopper) by lethargy, slow development and a high mortality. Abdomens of infected nymphs become distended, and show protruding cervical membranes as occlusion bodies accumulate in the fat bodies. Diseased fat bodies become hypertrophied, grayish and take on an irregular shape. Severely infected nymphs rarely develop past the first instar, and become essentially moribund. In grasshoppers, the fat body is certainly the main target of the infection and appears to be the only tissue infected. Again, the presence of occlusion bodies is characteristic of infected insects.

Virus Replication

Infection of the organisms ensues following dissolution of occlusion bodies in the midgut after ingestion. The infectious process initiates with attachment of the released virions to epithelial cells of the midgut. The observed pattern and strategy of infection at the cellular level is quite similar to that noted for the vertebrate poxviruses. Electron micrographs indicate that fusion of the virion envelope to the membrane of the microvilli allows entry of the partially uncoated virion (core and lateral bodies) into the cell cytoplasm. In intrahemocoelic infections, penetration of the free virus occurs via viropexis. In this case, partial uncoating of the internalized virion takes place within the phagosome derived from the process of viropexis, followed by release of the core into the cytoplasm where additional steps of the infectious cycle ensue. Viropexis does not appear to play a significant role during *per os* infections of larvae. Similar to the vertebrate poxviruses, the further, more complete uncoating likely requires early viral gene expression. One of the first signs of replication is the appearance of viroplasm (factories) consisting of irregularly shaped masses of DNA, some of which is coated by or within semicircular bilayer membranes. Later in infection, one observes a series of completely enveloped assembly intermediates (immature particles or virions) consisting of amorphous spheres and spheres with electron-dense cores, as well as other less common forms that accumulate in the cytoplasm. For some viruses, a second type of viroplasm (type II) has been noted that is characterized by aggregated granular material interspersed with spherical vesicles. Once immature particles form, the virus undergoes further maturation, assumed to occur from within, leading to formation of the mature cores and lateral bodies. Only fully mature virions are occluded. Nonoccluded virions bud through the cytoplasm into the hemocele, a process accompanied by the acquisition of a second membrane. It is likely that it is the nonoccluded form of the virus that accounts for generalized dissemination throughout the insect. Occluded virus tends to concentrate in the fat bodies.

While replication of these viruses has been studied intensively in the host organisms, fewer data are available on replication in cell culture, particularly at the molecular level, as there is a paucity of insect cell lines permissive for infection with these viruses. Until recently, only the *A. moorei* virus could be readily propagated in culture using a cell line derived from *E. acrea* (salt marsh caterpillar) hemocytes (BTI-EAA cells) or from the gypsy moth, *Lymantria dispar* (IPLB-LD-652 cells). In cell culture, AmEPV DNA replication can be detected as soon as 6 h postinfection, with a rapid increase in synthesis being observed between 12 and 24 h. Extracellular virus and virus-containing occlusion bodies appear 18 h after infection. Thirty-seven virus proteins ranging from 13 to

200 kDa were found in occluded and nonoccluded forms of the virus. Structural proteins are synthesized from 18 to 34 h postinfection and the occlusion body protein can be detected as early as 24 h after inoculation (see Marlow *et al*, Further Reading). Similar results have been found more recently with HaEPV (see Fernon *et al*, Further Reading). Another lepidopteran virus isolated from *Adoxophyes* (smaller tea tortrix) reportedly can be propagated in about 50% of cells in a cell line derived from *Homona magnanima*. Recently, a virus isolated from *Pseudaletia separata* larvae has been reported to propagate on a cell line derived from *P. separata* or *Bombyx mori* larvae. The replicative potential of the *A. moorei* virus has been examined in mammalian (L) cells. No newly synthesized AmEPV proteins were observed at 37°C. However, AmEPV virions could apparently induce cell fusion and the formation of polykaryocytes in either L or HeLa cells and reduce the numbers of superinfecting vaccinia plaques. More recent studies have shown that AmEPV enters vertebrate cells, expresses early genes, but that viral DNA synthesis fails to occur and late viral protein expression is absent. Most surprising is that the vertebrate cells survive the infection and continue to divide.

Information relevant to the regulation of gene expression in EPVs is now becoming available. This information suggests that while many regulatory signals are likely to be universal amongst all poxviruses, detailed study of the AmEPV spheroidin gene promoter has revealed features unique to the insect virus. Many of the sequences associated with regulatory signals, typical of the vertebrate (vaccinia) poxviruses, appear to be conserved and present in the EPVs. DNA sequence derived from both the *C. biennis* and *A. moorei* viruses suggests that the TAAATG motif, typical of late vertebrate poxvirus promotors is also present at the beginning of at least some EPV late genes, including both the spheroidin and nucleoside triphosphate phosphohydrolase I genes. Promotor elements isolated from the *C. biennis* virus have been shown to generate appropriately regulated gene expression (early or late) when cloned into appropriate vertebrate (vaccinia) constructs. Most late vertebrate poxvirus transcripts are polydisperse with heterogenous 3′ ends, an exception being the transcript for the cowpox ATI inclusion protein gene. The spheroidin transcript derived from the *A. moorei* virus appears, like that for the ATI gene of cowpox virus, also to be of discrete size and not polydisperse. The spheroidin transcript also contains a 5′ noncoded poly(A) tract typical of late transcripts from vertebrate poxviruses which is a feature of transcripts unique to poxviruses. Transcription of the AmEPV spheroidin gene has been shown to initiate within the TAAATG motif. However, despite these apparently conserved motifs, the AmEPV spheroidin gene promoter functions very poorly, if at all, in vertebrate cells. Analysis of recombinant vaccinia virus containing AmEPV-spheroidin promoter *lacZ* fusions also revealed that the expected transcription initiation site observed from similar AmEPV recombinants in insect cells was ignored (Hall *et al*, Further Reading). Thus, the AmEPV spheroidin promoter is the first known example of a promoter active uniquely within the insect environment. On the other hand, it has been reported that the 5′ upstream (promoter) region of the CbEPV spheroidin gene can function as a late promoter in vaccinia when cloned upstream of an appropriate reporter gene. However, expression was not as high as reported for other strong promoters of the vertebrate poxviruses such as the ATI promoter, nor as high as would have been expected based on comparative activity observed in infected insect cells.

At least one early gene product (thymidine kinase) is derived from a transcript of discrete size and the enzyme is functional when cloned into vaccinia virus. The heptanucleotide TTTTTNT, a sequence associated with the termination of early vertebrate poxvirus transcripts, has also been noted downstream of EPV early open reading frames, consistent with the hypothesis that this motif performs a similar function in the insect poxviruses.

Economic Importance

The ready genetic manipulation of EPVs is now possible. This advance required the detection, mapping and sequencing of the thymidine kinase and other non-essential genes from AmEPV for use as sites for insertion of foreign genes. The many similarities between the entomo- and vertebrate poxviruses have facilitated the adaptation of molecular techniques, originally designed for vaccinia virus, to the EPVs. Molecular biopesticides based on AmEPV can now be generated, as well as other potentially useful recombinants. Although traditionally insect control has been through the use of chemical pesticides, increasing environmental concerns are calling many of these chemicals and procedures into question. While the cost of biopesticides today may be higher, the environmental benefits are theoretically large. The potential market for such biopesticides is substantial, as EPVs have been described as causing disease in many insects of economic importance, including the spruce budworm (*C. biennis*), the lesser cornstalk borer (*Elasmopalpus lignosellus*), grasshoppers and locusts. The desert locust, *Schistocerca gregaria*, is

believed to be the most devastating crop pest in the world. Killing of insects following EPV infection in nature has been observed, but usually a second infectious agent was also present, which complicated evaluation of the specific effects of the EPV. At present, evidence suggesting that either laboratory or wild insect populations can be reduced by infection with wild-type EPVs is inconclusive. However, recombinant EPVs containing insect-specific toxins should make these viruses much more effective.

Another potential possibility is that 'shuttle' vectors for insertion of genes into either vertebrate or EPVs can now be developed. Although similarities between EPVs and vertebrate poxviruses permit common technology to facilitate genetic manipulation of both classes of viruses, one concern should be kept in mind – namely, the unintended exchanges of genetic material between the vertebrate and invertebrate families of viruses. Whether this issue is real or imagined, the concern may limit ultimate deployment of such recombinant viruses. Unintended recombination is less of an issue in the case of baculoviruses, as they do not resemble viruses of any other plant or vertebrate group.

An unanticipated application of the EPVs to the area of gene therapy was first suggested by the lack of any observable cytopathology during EPV infections of vertebrate cells. It was subsequently found that such cells survive and continue to grow despite entry of the virus and the expression of early viral genes. These results clearly suggest that rapid, intracellular transient expression of foreign genes, e.g. those encoding anti-inflammatory proteins or proteins which inhibit or induce apoptosis, may be possible in vertebrate cells and tissues through the use of recombinant EPVs as gene delivery systems. If so, such recombinant EPVs could be quite efficacious in treating certain acute clinical disorders.

If EPVs are to be seriously considered as tools for the control of insect populations or as gene therapy vectors, many more in-depth studies related to safety towards unintentional hosts, increasing growth and ease of manipulation *in vitro,* host specificity and basic biology are needed to separate real from perceived problems. Indeed, much useful information can be gained from these studies. In the past, the current limits in technology and lack of interest were the primary reasons the EPVs were not accorded the scientific attention they deserve. Based on more recent studies, the potential uses of EPVs now appear much greater, based on their biological, molecular and morphological similarities to the vertebrate poxviruses, together with the disappearance of many of the technical barriers to their genetic manipulation.

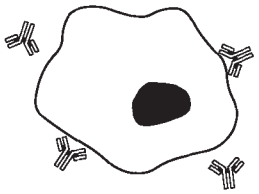
EPIDEMIOLOGY OF VIRAL DISEASES



Frederick A Murphy, School of Veterinary Medicine, University of California, Davis, California, USA

Introduction

Viral disease epidemiology is the study of the determinants, dynamics and distribution of viral diseases in populations. The risk of infection or disease in a population is determined by characteristics of the virus, the host and the host population, as well as behavioral, environmental and ecological factors that affect virus transmission from one host to another. Epidemiology attempts to meld these factors into a unified whole.

The foundations of epidemiology predate the microbiological and virological sciences, starting with Hippocrates, the Greek physician and father of medicine, who in the fourth century BC made important epidemiologic observations on infectious diseases. John Snow is called the father of modern epidemiology because he developed excellent quantitative methods while studying the source of a cholera outbreak at the Broad Street pump in London in 1849. Snow was followed by William Farr, who in the 1870s advanced the use of vital statistics and clarified many of the principles of risk assessment and retrospective and prospective studies. Their vision is reflected in the fast-changing science of epidemiology which is now supported by advanced computer technology, sophisticated statistical methods and very sensitive and specific diagnostic systems.

Assessment of Disease Occurrence and Outcome

By introducing quantitative measurements of disease trends, epidemiology has come to have a major role in improving our understanding of the overall nature of disease and in alerting and directing disease control activities. Epidemiology is also effective in: (1) clarifying the role of particular viruses and viral variants as the cause of disease; (2) clarifying the interaction of viruses with environmental determinants of disease; (3) determining factors affecting host susceptibility; (4) unraveling modes of transmission; and (5) field testing of vaccines and antiviral drugs.

The comparison of disease experience between populations is expressed in the form of *rates*. The terms *incidence rate* and *prevalence rate* are used to describe quantitatively the frequency of occurrence of infection or disease in populations. Incidence rate is defined as the ratio of new cases occurring in a population to the size of the population during a specified period of time. Prevalence rate is the ratio of the total number of cases occurring in a population to the size of the population during a specified period of time. *Seroprevalence rate* relates to the occurrence of antibody to a particular virus in a population. Because viral antibodies, especially neutralizing antibodies, often last a lifetime, seroprevalence rates usually represent cumulative experience with the virus. The term *case-fatality rate* is used to indicate the percentage of subjects with a particular disease that die from the disease. All these rates may be affected by various attributes that distinguish one individual from another: age, sex, genetic constitution, immune status, nutritional status and various behavioral and medical care and patient management parameters. The most widely applicable attribute is age, which may encompass immune status as well as various physiological variables.

An infectious disease is characterized as *endemic* when there are multiple or continuous chains of transmission resulting in continuous occurrence of disease in a population over a period of time. *Epidemics* are peaks in disease incidence that exceed the endemic baseline or expected rate of disease. The size of the peak required to constitute an epidemic is arbitrary and is related to the background endemic rate and the anxiety that the disease arouses (e.g. a few cases of rabies is regarded as an epidemic, whereas a few cases of influenza is not). A *pandemic* is a worldwide epidemic.

Epidemiologic Studies

Case control studies and cohort studies

There are two basic analytic techniques used to investigate relationships between cause and effect and to evaluate risk factors of disease. These are the *case-control study* and the *cohort study*. In the case-control study, investigation starts after the disease has occurred – it is a retrospective study, going back in time to determine causative events. Although this kind of study does not require the creation of new data or records, it does require careful selection of the control group, matched to the test group so as to avoid bias. The retrospective case-control study lends

itself to quick analysis and is relatively inexpensive to carry out. In the cohort study, the prospective study, investigation entails the gathering of new data to identify cause–effect relationships. This kind of study is expensive and does not lend itself to quick analysis as groups must be followed until disease is observed. However, when cohort studies are successful, proof of cause–effect relationship is often incontrovertible.

Molecular epidemiologic studies

The term *molecular epidemiology* is used to denote the use of any of a large number of molecular biological methods in support of epidemiologic investigations. For example, with herpesviruses, restriction endonuclease mapping provides a means of identification of unique viral genotypes – in an epidemiologic study recognized as the first based upon viral molecular characterization, the source of herpes simplex virus 1 causing disease in a hospital newborn nursery was traced to one persistently infected nurse rather than any of several other possible shedders. With rotaviruses and bluetongue viruses, polyacrylamide gel electrophoresis of the segmented viral RNA is used epidemiologically, for example to unravel outbreaks involving multiple viral variants.Partial sequencing is rapidly becoming the most commonly used molecular epidemiologic method: partial sequencing of poliovirus isolates recovered from patients indicates whether they are wild-type (even local or introduced wild-type), attenuated vaccine type, or a vaccine type that has reacquired neurovirulence during human passage. Panels of monoclonal antibodies are used similarly to distinguish virus variants for epidemiologic purposes; they have been particularly useful in elucidating host-range and geographic variants of rabies virus.

Seroepidemiologic studies

Seroepidemiology is useful in public health investigations and in research to determine the prevalence or incidence of particular infections, to evaluate control and immunization programs, and to assess past history when a 'new' virus is discovered. When paired serum specimens are obtained from individuals several weeks apart, the initial appearance of antibody in the second specimen or a rise in antibody titer indicates recent infection. Likewise, the presence of specific immunoglobulin M (IgM) antibody in single serum samples, indicating recent infection, may be used in seroepidemiologic studies. Correlation of serologic tests with clinical observations makes it possible to determine the ratio of clinical to subclinical infections.

Sentinel studies

Because of advanced diagnostic/serologic methods, sentinel studies can yield many valuable data in timely fashion about impending disease risks. For example, sentinel chicken flocks are set out for the early detection of the presence of arboviruses such as St Louis encephalitis virus in the southern and western United States. These flocks are bled and tested weekly for the presence of virus or antiviral antibody; they provide an early warning of the levels of virus amplification that occur before epidemics.

Vaccine trials

The immunogenicity, potency, safety and efficacy of vaccines are first studied in laboratory animals, followed by small-scale closed trials, and finally in large-scale open trials. Such studies employ epidemiologic methods, rather like those of the cohort (prospective) study. In most cases, there is no alternative way to evaluate new vaccines, and the design of trials has now been developed so that they yield maximum information with minimum risk and cost.

Virus Transmission among Individuals

Viruses survive in nature only if they are able to be transmitted from one host to another, whether of the same or another species. Transmission cycles require virus entry into the body, replication and shedding with subsequent spread to another host.

Virus entry

Portals of virus entry into the body include the skin, respiratory tract, intestinal tract, oropharynx, urogenital tract and conjunctiva. In some cases, viruses use a particular portal of entry because of particular environmental or host behavior factors and in other cases because of specific viral ligands and host cell receptors. In many cases, disruption of normal host defense mechanisms leads to entry that might otherwise be thwarted; for example, papillomaviruses may enter the deep layers of the skin via abrasions, acid-labile coronaviruses may enter the intestine protected by the buffering capacity of milk, and influenza viruses may enter the lower respiratory tract because a drug has dampened cilial action of the respiratory epithelium.

Virus shedding

The exit of virus from an infected host is just as important as entry in maintaining its transmission cycle. All portals used by viruses to gain entry are used for exit. The important elements in virus

shedding are virus yield (from the standpoint of the virus, the more shedding the better) and timeliness of yield (again, the earlier the shedding the better). Viruses that cause persistent infections often employ remarkable means to avoid host inflammatory and immune responses so as to continue shedding. For example, the epidemiologically important shedding of herpes simplex viruses 1 and 2 that perpetuates the viruses in populations requires recrudescence of persistent ganglionic infection, centrifugal viral genomic transit to peripheral nerve endings and productive infection of mucosal epithelium, all in the face of established host immunity.

Modes of Virus Transmission

Virus transmission may be *horizontal* or *vertical*. The vast majority of transmission is horizontal, that is between individuals within the population at risk. Modes of horizontal transmission of viruses can be characterized as *direct contact, indirect contact, common vehicle, airborne, vector-borne, iatrogenic* and *nosocomial*. *Vertical* or *transplacental* transmission occurs between the mother and her fetus or newborn. Some viruses are transmitted in nature via several modes, others exclusively via one mode (**Table 1**).

Direct contact transmission involves actual physical contact between an infected subject and a susceptible subject [e.g. kissing (Epstein–Barr virus, the cause of mononucleosis), biting (rabies), coitus (sexually transmitted viral diseases)]. Indirect contact transmission occurs via *fomites*, such as shared eating utensils, improperly sterilized surgical equipment or improperly sterilized nondisposable syringes and needles. Common vehicle transmission pertains to fecal contamination of food and water supplies (e.g. Norwalk virus diarrhea). Common vehicle transmission commonly results in epidemic disease. Airborne transmission typically results in respiratory infections (and less typically in intestinal infections), but these infections may also be transmitted by direct and indirect contact. Airborne transmission occurs via droplet nuclei (aerosols) emitted from infected persons during coughing or sneezing (e.g. influenza) or from environmental sources. Large droplets settle quickly, but microdroplets evaporate forming dry droplet nuclei (less than 5 nm in diameter) which remain suspended in the air for extended periods. Droplets may travel only a meter or so whereas droplet nuclei may travel much longer distances. Vector-borne transmission involves the bites of arthropod vectors (e.g. mosquitoes, ticks, sandflies). Iatrogenic transmission involves health care procedures, materials and workers (e.g. physicians, nurses, dentists). Nosocomial transmission pertains to infections acquired while a patient is in hospital.

Vertical or transplacental transmission occurs from mother to fetus prior to or during parturition. Certain retroviruses are vertically transmitted in animals via the integration of viral DNA directly into the DNA of the germ-line of the fertilized egg. Other viruses are transmitted to the fetus across the placenta, yet others are transmitted when the fetus passes through the birth canal. Another vertical transmission route is via colostrum and milk. Vertical transmission of a virus may or may not be associated with *congenital disease* (i.e. disease that is present at birth) which may be lethal (and the cause of abortion or stillbirth) or the cause of congenital abnormalities. The herpesviruses, especially cytomegaloviruses, and rubella virus cause important congenital diseases.

Common patterns of virus transmission

Enteric infections are most often transmitted by direct contact and by fomites in a *fecal–oral cycle* that may include fecal contamination of food and water supplies; diarrheic feces may also splash to give rise to aerosols. Respiratory infections are most often transmitted by the airborne route or by indirect contact via fomites in a *respiratory cycle*, i.e. virus is shed in respiratory secretions and enters its next host through the nares during inhalation. The respiratory cycle is responsible for the most explosive patterns of epidemic disease.

Perpetuation of Viruses in Nature

Perpetuation of a virus in nature depends on the maintenance of serial infections, i.e. a chain of transmission; the occurrence of disease is neither required nor necessarily advantageous.

Influence of the clinical status of the host

Infection without recognizable disease is called *subclinical* or *clinically inapparent*. Overall, subclinical infections are much more common than those that result in disease. Their relative frequency accounts for the difficulty of tracing chains of transmission, even with the help of laboratory diagnostics. Although clinical cases may be somewhat more productive sources of virus than subclinical infections, because the latter do not restrict the movement of the infected host, they can be most important as sources of viral dissemination. In most acute infections, whether clinically apparent or not, virus is shed in highest titers during the late stages of the incubation period, before the influence of the host immune response

Table 1 Examples of virus transmission patterns

Infectious agent/disease	*Mode of transmission*	*Portal of entry*
Influenza virus/influenza	Contact/direct/indirect via droplets and aerosol	Respiratory tract
Rhinoviruses/common cold	Contact/direct/indirect via droplets, aerosols and fomites	Respiratory tract
Rubella virus/congenital rubella	Contact/direct/indirect via droplets, aerosol	Respiratory tract
	Vertical/congenital	Transplacental
Rotaviruses/diarrhea	Contact/direct/indirect via fomites	Intestinal tract (oral)
Poliovirus/poliomyelitis	Contact/direct	Intestinal tract (oral)
Norwalk virus/diarrhea	Common vehicle/fecal contamination of water	Intestinal tract (oral)
Hepatitis A virus/hepatitis	Common vehicle/fecal contamination of food	Intestinal tract (oral)
New-variant Creutzfeldt–Jakob disease prion/prion disease (spongiform encephalopathy)	Common vehicle/bovine spongiform encephalopathy prion contamination of beef or beef products	Intestinal tract (oral)
Herpes simplex virus/genital herpes	Contact/direct (sexual)	Genital tract
Human immunodeficiency virus 1/ acquired immunodeficiency syndrome (AIDS)	Contact/direct (sexual), contact/direct (blood), vertical/congenital	Genital tract, bloodstream, transplacental, at birth and via breast feeding
Rabies virus/rabies	Zoonotic/contact/direct (saliva)	Skin (bite wound)
Russian spring summer encephalitis virus/encephalitis	Zoonotic/arthropod-borne	Skin (tick bite)
Dengue viruses/dengue	Zoonotic/arthropod-borne	Skin (mosquito bite)

Lassa virus	Zoonotic/contact/direct (rodent urine, saliva and feces)	Respiratory tract and intestinal tract (oral)
Ebola and Marburg viruses	Zoonotic/index cases unknown; secondary cases contact/direct/ nosocomial and iatrogenic	Index cases unknown, likely respiratory tract or skin and mucous membranes; secondary cases, contact and iatrogenic (injection)
Leukemia viruses/leukemias (proven only in animals)	Vertical/germ-line	Transmitted as genetic trait

takes effect. Persistent infections, whether or not they are associated with episodes of clinical disease, also play an important role in the perpetuation of many viruses in nature. For example, prolonged virus shedding can reintroduce virus into a population of susceptibles all of which have been born since the last clinically apparent episode of infection. This is important in the survival of rubella virus in some isolated populations. Sometimes the persistence of infection, the production of disease and the transmission of virus are dissociated; for example, togavirus and arenavirus infections have little adverse effect on their reservoir hosts (arthropods, birds and rodents) but transmission is very efficient. On the other hand, the persistence of infection in the central nervous system, as with measles virus in subacute sclerosing panencephalitis (SSPE), is of no epidemiological significance, since no infectious virus is shed from this site.

Influence of virulence of the virus

The virulence of the infecting virus may directly affect the probability of its transmission. The classic example of this is rabbit myxomatosis. In Australia, mosquito-borne transmission of myxoma virus was found to be most effective when infected rabbits maintained highly infectious skin lesions for several days before death. Highly virulent strains of the virus were found to kill rabbits so quickly that transmission did not occur, and naturally attenuated strains were found to produce minimal lesions that healed quickly and did not permit transmission. Virus strains at either extreme of this virulence spectrum were found

not to survive in nature, but virus strains of intermediate virulence have circulated for many years.

Influence of host population immunity

With most viruses, endemic or epidemic transmission leads to a level of immunity in the host population that affects or even interrupts further transmission. The 'herd immunity' effect is countered in some cases by viral antigenic variation. For example, influenza viruses undergo genetic variations ('shift' and 'drift') such that persons immune to previously circulating virus strains are susceptible to new strains. Assessing these genetic changes is the main objective of laboratory-based surveillance programs, which in turn are used to decide the formulation of new influenza vaccines.

Influence of population size

It is self-evident that the long-term survival of a virus requires that it be continuously transmitted from one host to another. In general, for rapidly and efficiently transmitted viruses such as many respiratory viruses, local survival of the virus requires that the susceptible host population be very large. A virus may disappear from a population because it exhausts its potential supply of susceptible hosts as they acquire immunity to reinfection with the same virus. Depending on duration of immunity and the pattern of virus shedding, the *critical population size* varies considerably with different viruses and with different host species. The most precise data on the importance of population size in acute nonpersistent infections come from studies of measles. Persistence of measles virus in a population depends on a continuous supply of susceptible children. Analyses of the incidence of measles in large cities and in island communities have shown that a population of about half a million persons is needed to ensure a large enough annual input of new susceptible hosts, by birth or immigration, to maintain measles virus in the population. Because infection depends on respiratory transmission, the duration of epidemics of measles is correlated inversely with population density. If a population is dispersed over a large area, the rate of spread is reduced and the epidemic will last longer, so that the number of susceptible persons needed to maintain transmission chains is reduced. On the other hand, in such a situation a break in the transmission chain is much more likely. When a large proportion of the population is initially susceptible, the intensity of the epidemic builds up very quickly and attack rates are almost 100% (*virgin-soil epidemic*).

Influence of zoonotic transmission cycles

Because most viruses are host-restricted, most viral infections are maintained in nature within populations of the same or related species. However, there are a number of viruses that may have multiple hosts and spread naturally between several different species of vertebrate host, e.g. rabies and eastern equine encephalitis viruses. The term *zoonosis* is used to describe multiple-host infections that are transmissible from animals to man. The zoonoses, whether involving domestic or wild animals or arthropods, usually represent important problems only under conditions where humans are engaged in activities involving close contact with animals or exposure to arthropod habitats.

Influence of arthropod transmission cycles

Many viral zoonoses are caused by arboviruses. Arboviruses have two classes of host, vertebrate and invertebrate. Over 500 arboviruses are known, of which about 100 cause disease in humans and 40 in domestic animals; some of these are transmitted by ticks, some by mosquitoes and yet others by phlebotomine flies (sandflies) or *Culicoides* spp. (midges). Arthropod transmission may be mechanical, where the arthropod acts as a 'flying pin', or more commonly, biological, involving replication of the virus in the arthropod vector. The arthropod vector acquires virus by feeding on the blood of a viremic person or animal. Replication of the ingested virus, initially in the arthropod's gut, and its spread to the salivary glands takes several days; the interval varies with different viruses and is influenced by ambient temperature. Virions in the salivary secretions of the vector are injected into animal hosts during subsequent blood meals. Most arboviruses have localized natural habitats in which specific receptive arthropod and vertebrate hosts are involved in the viral life cycle. Vertebrate reservoir hosts are usually wild mammals or birds; humans are rarely involved in primary transmission cycles, although the exceptions to this generalization are important (e.g. Venezuelan equine encephalitis, yellow fever and dengue viruses). Humans are in most cases infected incidentally, for example by the geographic extension of a reservoir vertebrate host and/or a vector arthropod. Ecological changes produced by human activities disturb natural arbovirus life cycles and have been incriminated in the geographic spread or increased prevalence of arbovirus diseases.

Mathematical Modeling

From the time of William Farr, who studied epidemic disease problems in the 1870s, mathematicians have

been interested in 'epidemic curves' and secular trends in the incidence of infectious diseases. With the development of computer-based mathematical modeling techniques, there has been a resurgence of interest in the population dynamics of infectious diseases. There has also been a resurgence in controversies surrounding the use of models: critics say 'for every model there is an equal and opposite model'. Models are used to determine: (1) patterns of disease transmission; (2) critical population sizes to support the continuous transmission of viruses with short and long incubation periods; (3) the dynamics of endemicity of viruses that become persistent in their hosts; and (4) the variables in age-dependent viral pathogenicity. Computer modeling also provides useful insights into the effectiveness of disease control programs. Much attention has been given to modeling the future of the acquired immunodeficiency disease (AIDS) epidemic in the United States and the rest of the world. Such models usually start with historical data on the introduction of the etiologic virus, HIV1, proceed to the present stage of the epidemic where the disease has become well established in many countries and in fewer subject to prevention and treatment strategies, and then proceed to project its course into the future. During the first 10 years of the AIDS epidemic in the United States, African countries and then in Asian countries most models underestimated developing trends; more recently models have become more accurately predictive.

Implications for Disease Prevention

Knowledge of the epidemiology and modes of transmission of infectious diseases is critical to the development and implementation of prevention and control strategies. Data on incidence, prevalence and mortality contribute directly to the establishment of priorities for prevention and control programs whereas knowledge of viral characteristics and modes of transmission are used in deciding prevention strategies focusing on vaccine development and delivery, environmental improvements, enhancement of nutritional status, improvement in personal hygiene and behavioral changes.

Table 1 EBV-associated tumors

Tumor	*Subtype*	*EBV genome +VE (%)*
Burkitt's lymphoma	Endemic	100
	Sporadic	10–20
	AIDS	30–40
Nasopharyngeal carcinoma	Undifferentiated	100
	SCC	40
Hodgkin's disease	Mixed cellularity	>80
	Nodular sclerosing	30–40
	Lymphocyte predominant	<10
T cell lymphoma	Nasal	100
	Others	10–40
Immunoblastic lymphoma	Transplant	100
	AIDS	>90

SCC, squamous cell carcinoma.

due to an infectious agent. In 1964 the successful establishment of cell lines from explants of BL enabled Epstein and Barr to identify herpesvirus-type particles by electron microscopy within a subpopulation of tumor cells *in vitro*. W. and G. Henle subsequently demonstrated that BL-derived cell lines expressed antigens that were recognized not only by sera from patients with BL but also by sera from patients with infectious mononucleosis (IM). Similar seroepidemiological studies also suggested a link between the so-called Epstein–Barr virus (EBV) and undifferentiated nasopharyngeal carcinoma (NPC) leading to the subsequent direct demonstration of EBV DNA in the tumor cells of NPC. The ability of this virus to efficiently immortalize B lymphocytes *in vitro* and to induce lymphomas in nonhuman primates established EBV as a putative oncogenic agent in humans. More recent studies have implicated EBV in a variety of other lymphoid and epithelial malignancies (**Table 1**).

Taxonomy and Classification

EBV is a member of the genus *Lymphocryptovirus* which belongs to the lymphotropic *Gammaherpesvirinae* subfamily of the family *Herpesviridae*. The lymphocryptoviruses exhibit a similar genomic structure and can infect the B lymphocytes of Old World primate species, resulting in latent infection often associated with lymphoproliferation. The 172 kbp EBV genome resembles other lymphocryptovirus genomes in that it contains (1) tandemly reiterated 0.5 kbp terminal direct repeats, and (2) tandemly reiterated 3 kbp internal direct repeats which divide the genome into unique short and long regions.

Geographic and Seasonal Distribution

EBV is ubiquitous being found as a widespread and largely asymptomatic infection in all human communities. Primary infection often occurs early in life particularly in tropical areas and in persons of lower socioeconomic class. Thus, in tropical Africa and New Guinea primary EBV infection is common in the first year of life whereas in Western communities infection is continually acquired throughout childhood and early adulthood. Although the EBV-associated malignancies BL and NPC exhibit an unusual geographic distribution this appears not to be due to differences in EBV infection but to additional cofactors.

Host Range and Virus Propagation

Humans are the natural host for EBV infection. Certain nonhuman primates, particularly the cotton-top tamarin, have been used as experimental hosts for EBV but in these animals virus infection is associated with the induction of lymphomas. Lymphoblastoid cell lines (LCLs) generated by EBV immortalization of cotton-top tamarin B lymphocytes *in vitro* produce large amounts of virus compared with their human counterparts and as such have been used as a source of EBV, e.g. the prototype strain of EBV is B95.8 which is produced from a tamarin LCL originally immortalized with EBV from a patient with IM. However, the lack of a fully permissive system for propagating EBV *in vitro* has hampered our understanding of virus replication and prevented the generation of EBV mutants. New culture systems for efficient replication of EBV include anti-immunoglobulin-treated BL cell

lines and epithelial cell lines transfected with the EBV receptor.

Genetics

EBV isolates from different regions of the world or from patients with different virus-associated diseases are remarkably similar when their genomes are compared by restriction fragment length polymorphism (RFLP) analysis. However, variations in repeat regions of the EBV genome are observed among different EBV isolates. Analysis of the EBV genome in a number of BL cell lines has revealed gross deletions in the viral genome some of which account for biological differences, i.e. P3HR-1 virus which is non-transforming contains a deletion of the EBNA 2-encoding gene.

Strain variation over the EBNA 2-encoding (*Bam*HI WYH) region of the viral genome has permitted all EBV isolates to be classified as either 'type 1' (EBV-1, B95.8-like) or 'type 2'(EBV-2 Jijoye-like). This genomic variation results in the production of two antigenically distinct forms of the EBNA 2 protein which share only 50% amino acid homology. Similar strain-specific variation occurs in the EBNA 3-encoding region of the viral genome. These differences have functional consequences as EBV-2 isolates are less efficient in *in vitro* B lymphocyte transformation assays compared with EBV-1 isolates. Recent work demonstrates that sequence variation over the *LMP*1 gene, particularly a 30 bp deletion in the C-terminus of the protein, is a common feature of EBV isolates in certain regions (i.e. China) and may predispose to the development of virus-associated tumors.

Evolution

EBV, like other herpesviruses, has probably evolved with humans. The relatedness of the lymphocryptoviruses at both the genomic and protein levels does not correlate with the evolutionary relatedness of their Old World primate hosts. This implies that the selective pressures governing the evolution of these viruses are different from those responsible for the evolution of primate species. It has been suggested that the specific tissue tropism of lymphocryptoviruses may have constrained their evolutionary divergence.

The evolutionary relationship between the type 1 and type 2 strains of EBV remains obscure. They may have evolved from a common progenitor virus or through recombination of either EBV strain with one of the lymphocryptoviruses infecting Old World primates. The pronounced (but not exclusive) segregation of EBV-2 isolates within equatorial regions suggests that environmental factors may have influenced EBV evolution and may still be responsible for the effective competition between EBV-2 isolates and the ubiquitous EBV-1 family.

Serologic Relationships and Variability

EBV isolates can be classified as type 1 or type 2 on the basis of allelic polymorphism of virus-encoded nuclear antigens EBNAs 2, 3A, 3B and 3C. Both seroprevalence studies and typing of EBV in BL cell lines and LCLs have demonstrated that the majority of wild-type isolates in Western communities are of the EBV-1 strain whereas EBV-2 strains appear to be largely restricted to areas of equatorial Africa and New Guinea. However, in immunosuppressed HIV-positive individuals infection with both EBV-1 and EBV-2 can be found and EBV-2 is frequently detected in the lymphomas arising in these patients.

Further microheterogeneity exists among EBV isolates, particularly over the repeat regions of the viral genome. These give rise to variations in the size of the individual EBNA proteins which are apparent after their electrophoretic separation on polyacrylamide gels. Thus, the EBNA 1, 2, 3a, 3b and 3c proteins encoded by any one virus isolate display a unique size combination in gels which has been termed the 'EBNA type' of that particular isolate. This characteristic of EBV isolates can be used to trace the origin and transmission of EBV within families.

Epidemiology of EBV-associated Diseases

Infectious mononucleosis

Infection with EBV is widespread and, once infected, individuals become life-long virus carriers. Primary infection with EBV in childhood is usually asymptomatic but when delayed until adolescence or early adulthood can manifest clinically as IM, a self-limiting lymphoproliferative disease. The incidence of IM is low in Third World countries where primary infection predominantly occurs in childhood. In certain poorly defined situations IM-like symptoms can persist, resulting in chronic active EBV infection associated with elevated antibody titers to virus lytic antigens but low titers to the EBNAs.

Burkitt's lymphoma (BL)

The endemic form of BL which is found in areas of equatorial Africa and New Guinea represents the most common childhood cancer (peak age 7–9 years) in these regions with an incidence of up to 10 cases per 100 000 people per year. This high incidence of BL is

associated with holoendemic malaria accounting for the climatic variation in tumor incidence first recognized by Dennis Burkitt. More than 95% of these endemic BL tumors are EBV-positive compared with 20% of the low-incidence, sporadic form of BL which occurs worldwide (**Table 1**). In areas of intermediate BL incidence, such as Algeria and Malaysia, the increased number of cases correlates with an increased proportion of EBV-positive tumors. A consistent feature of all BL tumors, irrespective of geographical location, is chromosomal translocations involving the long arm of chromosome 8 (8q24) in the region of c-*myc* proto-oncogene and either chromosome 14 in the region of the immunoglobulin heavy-chain gene or, less frequently, chromosomes 2 or 22 in the region of the immunoglobulin light-chain genes. Seroepidemiological studies have demonstrated elevated antibody titers to EBV capsid antigen (VCA) and early antigens (EA) in BL patients compared to children without the tumor. These elevated antibody titers have been found to precede the development of BL and can therefore be used to screen 'at risk' individuals.

Nasopharyngeal carcinoma (NPC)

The association of EBV with undifferentiated NPC was first shown by serological evidence and later confirmed by the demonstration of EBV DNA in NPC biopsy material. NPC is particularly common in areas of China and Southeast Asia reaching a peak incidence of around 20–30 per 100 000. Incidence rates are high in individuals of Chinese descent, irrespective of where they live, and particularly in Cantonese males. In addition to this genetic predisposition, environmental cofactors such as dietary components (e.g. salted fish) are thought to be important in the etiology of NPC. Extensive serological screening the EBV-specific antibody titers in high incidence areas, in particular IgA antibodies to EBV capsid antigen (VCA) and early antigens (EA), have proved useful in diagnosis and in monitoring the effectiveness of therapy. The association between EBV and undifferentiated NPC has been confirmed for many different racial groups, whether these exhibit a high, intermediate or low incidence of the tumor. Undifferentiated NPC is associated with a prominent lymphoid stroma and tumors arising at other anatomical sites (e.g. lung, stomach, salivary gland) with this morphology (lymphoepitheliomas) tend to be EBV-positive (**Table 1**). EBV infection is also associated with the more differentiated squamous cell NPCs particularly those occurring in the Far East. EBV infection has been detected in a proportion of common gastric adenocarcinomas.

Lymphomas in patients with immunodeficiency

Patients with primary immunodeficiency diseases such as X-linked lymphoproliferative syndrome (XLP) and Wiscott–Aldrich syndrome are at increased risk of developing EBV-associated B cell lymphomas. Because these tumors are extremely rare little is known of their association with EBV infection. Mortality from XLP is high with around 50% of patients developing fatal IM after primary infection with EBV and an additional 30% of patients developing malignant lymphoma.

Allograft recipients receiving immunosuppressive therapy and patients receiving immunosuppressive therapy patients with AIDS are also at increased risk for development of EBV-associated lymphoproliferative disease and lymphomas. The incidence of B cell lymphomas in allograft recipients varies with the type of organ transplanted and with the type of immunosuppressive regimen used. Allogeneic bone marrow transplantation into EBV seronegative children is a particular risk factor for the development of virus-associated B cell lymphomas.

The incidence of non-Hodgkin lymphoma in AIDS patients is increased approximately 60-fold compared to the normal population. Around 60% of these tumors are large-cell lymphomas like those found in allograft recipients, 20% are primary brain lymphomas and 20% are of the BL type. Recent studies have demonstrated that 50% of AIDS lymphomas are EBV-positive and that this association varies with the histological tumor type. Thus, only 38% of the BL tumors are EBV-positive compared with 65% of the large-cell lymphomas.

T cell lymphomas

Recent studies have demonstrated EBV infection in a considerable proportion of T cell non-Hodgkin's lymphomas (**Table 1**). Nasal T cell lymphomas, a tumor which is more common in the Far East, is invariably EBV-positive whereas around 20% of T cell lymphomas arising at other sites (gastrointestinal, lung, lymph nodes) are associated with EBV.

Hodgkin's disease

Epidemiological studies originally suggested a possible role for EBV in the etiology of Hodgkin's disease (HD). Thus, elevated antibody titers to EBV antigens have been detected in patients with HD and these increased antibody levels are present before the diagnosis of disease. Furthermore, there is an increased risk of HD following IM. EBV has been demonstrated in around 50% of HD cases with both viral nucleic acid (DNA/RNA) and virus latent antigens localized to the malignant component of

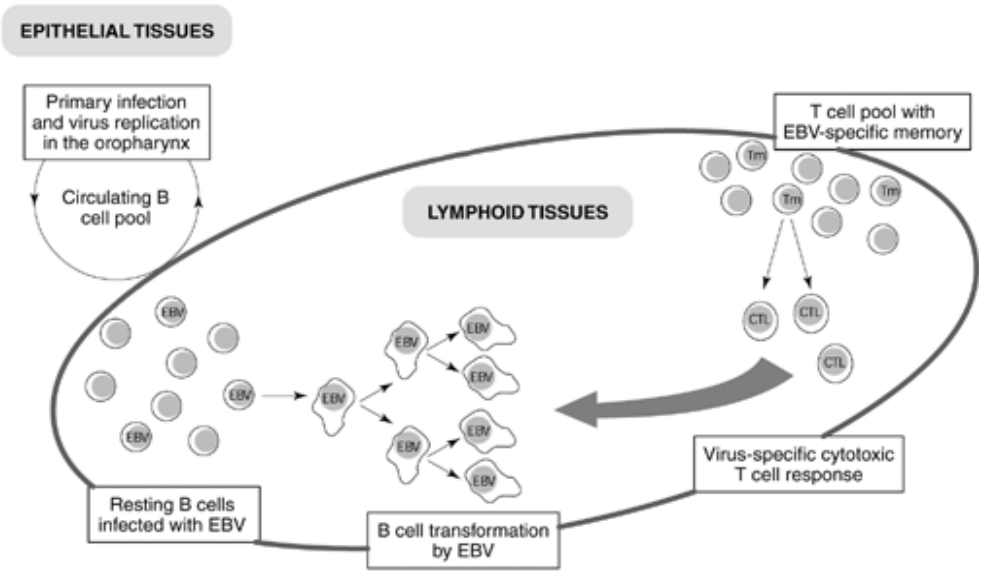

Figure 1 A model for EBV infection in normal healthy virus carriers. Primary EBV infection occurs in the oropharynx and is probably mediated via B cells. Following primary infection, a chronic virus carrier state is established in which EBV infection persists in resting B cells which may only express the EBNA1 protein. Occasional reactivation of EBV in this compartment results in the outgrowth of EBV-infected B cells which resemble EBV-transformed lymphoblastoid cell lines *in vitro*. The growth of these transformed cells is controlled by an EBV-specific cytotoxic T lymphocyte (CTL) response. At certain sites such as the oropharynx, latently infected B cells may become permissive for lytic EBV infection shedding infectious virus (i.e. into the saliva) thereby resulting in infection of other cells in the vicinity such as B cells and epithelial cells.

HD, the so-called Reed–Sternberg cells and their variants. The association of HD with EBV is age-related; pediatric and older adult cases are usually EBV-associated whereas HD in young adults is less frequently virus-positive. The proportion of EBV-positive HD in developing countries is high consistent with a greater incidence of HD in children and more frequent prevalence of the mixed cellularity histiotype (**Table 1**). Although the incidence of HD is relatively low (1–3/100 000 per year) this tumor is not geographically restricted, making its association with EBV significant in world health terms.

Transmission and Tissue Tropism

The usual route of EBV transmission is via saliva, although rare cases of infections transmitted by blood transfusion have been reported. EBV, measured by its ability to transform B lymphocytes *in vitro*, can be detected in oropharyngeal secretions from IM patients, from patients receiving immunosuppressive drugs and, at a lower level, from normal asymptomatic EBV-positive individuals. These observations, together with the fact that EBV-transformed LCLs *in vitro* tend to be poor producers of the virus and B lymphocytes permissive of viral replication have not been demonstrated *in vivo*, suggest that EBV replicates and is shed at epithelial sites in the oropharynx and/or from salivary glands. This is supported by the demonstration of replicating EBV in the more differentiated epithelial cell layers of oral 'hairy' leukoplakia, a benign lesion of the tongue found in patients with AIDS. However, the inability to detect EBV in normal epithelial cells and the demonstration that EBV can be completely eradicated by irradiation in bone marrow transplant recipients indicates that B cells are likely to be the main site of EBV persistence and may also represent the target of the virus in primary infection (**Fig. 1**).

The B lymphotropism of EBV is due to the expression of a specific cell surface receptor on B cells, the CD21 antigen or CR2, which can bind EBV and the C3d component of complement. The EBV-encoded membrane antigen (MA) is a 340 kDa glycoprotein which is expressed on the outer membrane of the virion and has been identified as the viral protein that binds to CR2. The expression of CR2 has also been demonstrated on immature thymocytes and follicular dendritic cells suggesting that these cell types may also be susceptible to EBV infection. The lack of CR2 expression on epithelial cells implies that an alternative receptor or mechanism is responsible for their infection. Under certain circumstances EBV can infect other tissues (i.e. smooth muscle, endothelial cells) but the relevance of this effect to primary and persistent virus infection is unknown.

Pathogenicity

As EBV strain variation does not appear to have a significant effect on the pathogenicity of the virus, attention has concentrated on the patterns of viral gene expression in the different virus-associated diseases. The *in vitro* ability of EBV to transform resting B cells into permanent LCLs is associated with the constitutive expression of a limited number of EBV-encoded latent proteins; the nuclear antigens EBNA 1, EBNA 2, EBNAs 3A/3B/3C and EBNA-LP and the latent membrane proteins, LMP1 and LMP2. Analysis of the expression and function of these viral gene products suggests that the EBNA 2 protein and LMP1 play central roles in EBV-induced cell transformation. EBNA 2 is a transcriptional regulator whereas LMP1 functions as a constitutively activated receptor.

The pattern of EBV latent gene expression varies among the different virus-related diseases. Thus, the proliferation of B cells characteristic of IM and XLP is associated with the expression of all the EBV latent proteins as seen in LCLs. However, in BL and NPC there is a downregulation of the EBV latent protein expression: only EBNA 1 is found in BL whereas in NPC both EBNA 1 and the LMPs are expressed. Recent studies suggest that the pattern of EBV latent gene expression in HD is similar to that in NPC. The large-cell lymphomas of post-transplant patients resemble LCLs in expressing the full range of EBV latent genes whereas the phenotypic heterogeneity of EBV-positive AIDS-related lymphomas is reflected at the EBV latent protein level providing a spectrum of tumors from LCL-like to BL-like. These different patterns of EBV latent gene expression are the result of different virus transcriptional programs influenced by factors such as methylation and the host cell environment. The downregulation of certain EBV latent proteins in BL, NPC and HD does not preclude a role for these gene products at an earlier stage in the oncogenic process. Thus, differences in viral protein expression appear to influence the pathogenicity of EBV as it relates to the development of the various virus-associated malignancies.

Clinical Features of Infection

Although the majority of primary EBV infections are asymptomatic, those resulting in IM can initiate a range of clinical symptoms which may last for weeks or even months. IM occurs predominantly in the adolescent and young adult with rare cases in infants and individuals of greater than 30 years of age. The acute illness is associated with a sore throat characterized by hyperplasia of lymphoid tissue in the oropharynx, fever and generalized lymphoadenopathy. There is lymphocytosis accompanied by the presence of atypical lymphocytes. Enlargement of the spleen is found in around 50% of IM patients at 2–3 weeks after the onset of symptoms. Hepatosplenomegaly is occasionally found and is associated with elevated levels of serum liver enzymes. Resolution of these symptoms results in the establishment of the life-long EBV carrier state as seen after normal, asymptomatic primary infection. Failure of this to occur can precipitate a chronic active EBV infection where the symptoms of IM persist. The fatal IM associated with XLP takes a rapid course usually associated with progressive failure of the lungs, kidneys, liver and bone marrow due to an overwhelming infiltration of these organs with EBV-infected B cells.

In the endemic areas of Africa 60% of children with BL present with jaw tumors. These jaw tumors are common in younger BL patients whereas older children are more likely to present with abdominal tumors similar to those found in the sporadic form of the disease. Whereas bone marrow involvement is frequently found in patients with sporadic BL, it is rarely a feature of endemic BL. Over half of NPC cases present with a cervical mass resulting from lymphoid spread of the primary tumor from its common site of origin in the lateral nasopharynx (fossa of Rosenmuller). Common symptoms resulting from the location of the primary NPC tumor include nasal obstruction and bleeding as well as those due to malfunction of the eustachian tube such as ear blockage, otitis media and conductive hearing loss. Lymphomas in patients with immunodeficiency can present at a number of different anatomic sites including the mediastinum, lungs, central nervous system and abdomen. The site of presentation and rate of development of these tumors appears to be influenced by the type of immunodeficiency. The lymphomas associated with patients on immunosuppressive therapy often develop within the grafted organ. Lymphadenopathy is the most common presentation of HD and in around 30% of patients is accompanied by fever, night sweats and weight loss.

Pathology and Histopathology

The polyclonal activation of B cells and resultant T cell response account for the pathology associated with IM which is evident in the lymph nodes, peripheral blood, liver and spleen. In IM and the lymphoproliferative disorders associated with immunosuppression EBV-infected B cells (immunoblasts) are found as infiltrates in solid organs as well as bone marrow. This is more pronounced in immunodefi-

cient patients where the polymorphic B cell hyperplasia can evolve into a high-grade B cell lymphoma of immunoblastic or undifferentiated large cell type. The jaw tumors characteristic of endemic BL are usually associated with multifocal disease involving liver, kidney and gut. BL is classified as a high-grade malignant lymphoma of small noncleaved follicle center B cell type with a 'starry sky' morphology resulting from infiltrating histiocytes and macrophages. The EBV-associated anaplastic or undifferentiated type of NPC is an aggressive tumor which tends to metastasize to cervical lymph nodes. NPC has been classed as a 'lymphoepithelioma' on account of the associated heavy T lymphoid infiltrate. The histopathology of HD is complicated by the paucity of the malignant Reed–Sternberg cells in tumor biopsies. Histological subtypes of HD reflect the cellular composition of the affected lymph nodes and may correlate with clinical features as well as with EBV association.

Immune Response

EBV illicits both humoral and cell-mediated immune responses in infected hosts. Primary infection with EBV is associated with the rapid appearance of antibodies to replicative viral antigens such as VCA, EA and MA with a later serological response to the EBNA proteins. In IM these responses are accentuated and are accompanied by autoantibodies such as rheumatoid factor as well as a heterophile antibody response directed against antigens on the surface of sheep erythrocytes. These autoantibodies are the result of EBV-induced polyclonal B cell activation. In the chronic, asymptomatic virus carrier, antibodies to VCA, MA and the EBNAs are found, the titers of which remain remarkably stable. Of these antibodies those against MA are particularly important as they have virus neutralizing ability and can also mediate antibody-dependent cellular cytotoxicity. As discussed previously the levels of these EBV-specific antibodies are elevated in the different virally associated diseases.

As with other persistent viruses, cell-mediated immunity plays an important part in controlling EBV infection (**Fig. 1**). This is evidenced by the effect of immunosuppression on EBV-infected individuals which results in increased excretion of the virus and is associated with an increased risk of developing EBV-positive lymphomas. The development and maintenance of class I MHC restricted EBV-specific cytotoxic T lymphocytes (CTLs) is of particular importance in the control of virus infection (**Fig. 1**). Virus-specific CTLs are able to efficiently recognize the EBV latent antigens and thus prevent the unlimited proliferation of EBV-infected B cells. More recent work demonstrates that CTL responses to virus lytic antigens are a common feature of both primary and persistent EBV infection. Although impairment of CTL function is responsible for lymphomagenesis in immunosuppressed patients, the development of BL, NPC and HD is more complex. The growth and survival of these tumors in immunocompetent individuals implies that the tumor cells can evade EBV-specific CTL surveillance. This may be achieved by restricting EBV latent gene expression to those viral proteins not recognized by EBV-specific CTLs and/or by the downregulation of target cell antigens required for immune recognition such as class I MHC and lymphocyte adhesion molecules. Interestingly, EBNA1 which is consistently expressed in all EBV-associated tumors is not a target for CD8-positive CTLs.

Prevention and Control of EBV Infection

The importance of the EBV-associated malignancies in world health terms has prompted the development of a vaccine against viral infection. As the MA glycoprotein on the EBV virion is a target for neutralizing antibodies during normal infection, this molecule has been proposed as a suitable immogen for eliciting protective immunity. In the experimental cotton-top tamarin model, immunization with various preparations of MA is able to protect the animals against lymphomagenic doses of EBV. Recombinant soluble MA has now been produced and clinical trials should take place in the next few years. An important patient group to target will be those children awaiting transplantation where virus-neutralizing antibodies raised in response to MA vaccination may provide protection from the development of EBV-associated lymphomas.

As the nature of primary EBV infection may make prophylactic vaccination extremely difficult, the use of therapeutic vaccines, perhaps directed to other EBV-encoded proteins, should be considered. The possibility of peptide vaccination with well-defined CTL epitopes is attractive particularly in NPC and HD where EBV latent gene expression is restricted. Adoptive CTL therapy using *ex vivo* expanded EBV-specific CTL preparations has proven successful in treating virus-associated lymphoproliferative disease and lymphomas in bone marrow transplant patients. A similar approach to the treatment of NPC and HD is currently being explored.

The antiviral agent acyclovir is a potent inhibitor of EBV DNA polymerase thus preventing virus replication. Acyclovir does not significantly alter the clinical course of IM or XLP. A few reports suggest that this

drug used in conjunction with interferon α may resolve the polyclonal B cell lymphomas found in transplant recipients but in this group withdrawal or reduction in immunosuppression is more effective. Although chemotherapy is extremely effective against BL, recent epidemiological evidence shows that the incidence of disease can be significantly reduced by malaria eradication. NPC can be successfully treated by surgery and local radiotherapy only at early stages of the disease. Early diagnosis using serologic screening for EBV-specific IgA antibodies and CAT scans has helped in identifying those patients with treatable disease. Combined chemotherapy is successful in 70% of HD patients. The EBV-positive form of HD may be more difficult to treat and thus the early identification of these cases using EBV-specific monoclonal antibodies could be useful.

Future Perspectives

The use of a variety of molecular virological techniques has unequivocally identified EBV as oncogenic in humans. However, the precise nature of primary infection and the subsequent establishment of lifelong viral persistence is poorly understood and will require the further refinement of techniques for identifying individual EBV-infected cells *in vivo*. Any prophylactic vaccine must be effective at preventing primary infection and requires a better knowledge of the immune control of EBV infection and replication at the site of primary infection. More efficient *in vitro* systems for studying EBV infection and replication will help in this regard. The use of EBV recombinants has already yielded valuable information on the function of certain viral genes and will continue to help identify the cellular and viral factors responsible for tumor development. Understanding the host cell:virus interaction will be dependent on the generation of appropriate *in vitro* models which are currently lacking for NPC and HD. The application of adoptive CTL therapy for EBV-associated tumors will depend on a better understanding of the tumor microenvironment and may require approaches aimed at manipulating the local cytokine milieu. A more detailed knowledge of the functions of individual EBV latent proteins will allow the development of sophisticated pharmacological approaches to the treatment of virus-associated malignancies.

Properties of the Virion

The Epstein–Barr virus (EBV) virion has a morphology typical of all herpesviruses and comprises four major substructures. The core of the virion contains the DNA genome and associated proteins in a tightly packed torus, which is encased within an icosadeltahedral nucleocapsid that contains 162 capsomeres and is approximately 100 nm in diameter. Between the nucleocapsid and membrane envelope of the virus is a poorly defined amorphous region known as the tegument. The envelope, which is largely derived from cellular membrane, contains several virus-encoded glycoproteins. The most abundant of these glycoproteins are gp350 and gp220, related proteins encoded by alternatively spliced mRNAs expressed from the same gene, that bind to the major cellular receptor for EBV attachment, CD21, and help mediate entry of the virus into the host cell.

Properties of the Genome

The genome of EBV is a double-stranded DNA molecule of approximately 185 kb. The complete genomic nucleotide sequence of the prototype isolate B95-8 has been determined, as have substantial segments of the genomes of other commonly studied isolates. The EBV genome contains approximately 90 genes, of which 12 are variably expressed during latent (nonproductive) infection. The remaining genes encode proteins that are expressed exclusively during the viral replication cycle. As indicated in the previous entry, two distinct strains of EBV (EBV-1 and EBV-2)

Properties of the Genome

The genome of EBV is a double-stranded DNA molecule of approximately 185 kb. The complete genomic nucleotide sequence of the prototype isolate B95-8 has been determined, as have substantial segments of the genomes of other commonly studied isolates. The EBV genome contains approximately 90 genes, of which 12 are variably expressed during latent (nonproductive) infection. The remaining genes encode proteins that are expressed exclusively during the viral replication cycle. As indicated in the previous entry, two distinct strains of EBV (EBV-1 and EBV-2)

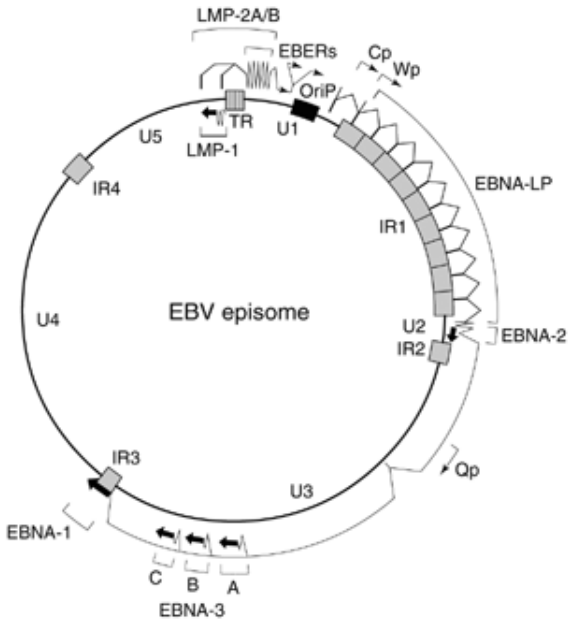

Figure 1 Structure and latency-associated transcription of the EBV genome. The repeat elements (TR, IR1–IR4) and unique sequence domains (U1–U5) of the genome are indicated as are the latency-associated mRNAs and EBERs. Exons that contain open reading frames are bracketed. Note that the EBNA mRNAs are expressed from a common transcription unit under the control of the promoter Cp or Wp during the growth program of latency, and that individual EBNA mRNAs are generated through alternative RNA processing. Exclusive expression of EBNA-1 during restricted latency is mediated by the promoter Qp. LMP-2A and LMP-2B differ in that their expression is controlled by separate promoters; LMP-2A is 119 amino acids longer than LMP-2B due to additional coding sequence in its unique 5′ exon. *OriP* is the latent infection origin of DNA replication. Not shown are the *Bam*HI-A rightward transcripts (BARTs), a complex family of alternatively spliced polyadenylated RNAs that initiate in U4 and terminate in U5.

exist that are defined by specific sequence differences within several of the viral genes expressed during latent infection, most notably those encoding the EBV nuclear antigen (EBNA) -2 and -3 proteins. In its linear configuration within the virion, the genome is bounded by terminal repeats of 538 bp that contain the DNA packaging signals. Internally, the genome is separated into short (12 kb) and long (134 kb) predominantly unique sequence domains by 8–10 copies of a 3 kb direct repeat, IR1. Historically, the long unique domain has been divided into smaller domains by short repeat elements, as illustrated in **Fig. 1**.

Shortly after infection of a B lymphocyte, the terminal repeats of the EBV genome fuse to generate an episome. A variable but relatively stable number of episomes (10–100) are maintained within the nuclei of infected B cells, which do not actively support virus replication. In response to the establishment of a latent EBV infection *in vitro*, B cells undergo immortalization and thus acquire the potential to proliferate indefinitely in cell culture. Replication of the EBV episome in latently infected B cells is mediated by the cellular replication machinery, occurs once per cell division cycle, and is initiated within an origin of DNA replication, *oriP*, located in the short unique domain of the viral genome. Although maintenance of EBV DNA during latency requires only one viral protein, the origin-binding protein EBNA-1, the processes of genome replication is poorly understood. Two separate but highly homologous origins of DNA replication, *oriLyt*, are active during the virus replicative cycle. These lie 100 kb apart within the left and right one-third of the long unique sequence domain, and enable production of the linear genomes that ultimately are packaged into the virion. In contrast to latent infection, replication of EBV DNA during the lytic cycle is predominantly, if not solely, regulated by viral proteins.

Virus Replication

Although the latent state of EBV infection is most often associated with human disease, the replicative component of the virus life cycle is essential for the maintenance of EBV in the general population and therefore ultimately for the pathogenic potential of EBV. Unfortunately, delineation of the specific mechanisms through which mature EBV virions are produced has been hampered by the lack of cell lines that support EBV replication. Although some latently infected B cell lines can be induced to replicate EBV in response to chemical agents such as phorbol esters or by the crosslinking of cell-surface immunoglobulin molecules, the efficiency of induction is generally poor, in that only 20–30% of the treated cells, at best, will actually produce virus. Although epithelial cells are believed to be primary sites of EBV replication *in vivo*, attempts to establish epithelial cell lines readily infectable by EBV and which actively support virus replication have not been successful. Nonetheless, the general process of EBV replication is reasonably well understood, in large part due to parallels that can be drawn to the replication of herpes simplex virus, for which an extensive body of knowledge exists. Furthermore, comparative sequence analyses of the genomes of several mammalian herpesviruses have been identified in each a set of conserved replicative genes which encode viral structural as well as regulatory proteins. Thus, the replication of EBV is

believed to occur through a basic process common to all herpesviruses.

Herpesvirus replication progresses through a highly ordered cascade of viral gene expression that is initiated by the immediate early class of genes (those that do not require *de novo* protein synthesis to activate their expression), followed by expression of the early and then late genes. In general, immediate early and early proteins regulate viral gene expression and DNA replication, whereas late gene products are either structural components of the virion or are required for functions such as virus assembly and egress. Although a thorough description of EBV replication is beyond the scope of this text, there are several unique aspects of the EBV lytic cycle that warrant additional discussion.

Activation of the lytic cycle

Much of the focus on EBV replication has been directed towards the mechanisms that disrupt latency, ultimately enabling the transmission of virus to naive hosts. Although the physiologic signals that trigger activation of EBV replication *in vivo* are poorly understood, the critical event downstream of such signals is the activation of expression of the EBV protein Zta, which alone is capable of initiating the lytic cycle cascade of gene expression. Zta is a transcriptional activator related to members of the cellular AP-1 family of transcription factors, and is able to activate gene expression through binding to AP-1 and closely related Zta response elements. Zta activates the lytic cycle in cooperation with a second EBV transactivator, Rta, itself activated by Zta, through transactivation of EBV early genes which contain Zta and Rta response elements within their promoters. Zta and Rta also function in the replication of EBV DNA, presumably through mediating the assembly of EBV replication proteins into the replication complex at *oriLyt*, which contains Zta and Rta response elements. Additionally, Zta and Rta interact with or induce the expression of a number of cellular proteins that regulate cellular proliferation and differentiation, such as p53, NFκB, retinoic acid receptor, pRB, p21, TGF-β and c-*MYC*. These properties of Zta and Rta likely provide an optimal cellular environment for virus replication. Interestingly, although expression of Rta alone is not sufficient to activate the lytic cycle within latently infected B cells, it may do so within epithelial cells, although this most likely requires Rta-mediated activation of Zta expression. This suggests that different signals may exist for the activation of EBV replication in B lymphocytes and epithelial cells.

Auxiliary functions of lytic cycle genes

The EBV genome encodes several lytic cycle proteins that are not directly involved in the production of infectious virus, but instead influence the intra- or extracellular milieu to enhance the efficiency of replication or promote the infection process by subverting host immune mechanisms that have evolved to control virus infections. The principal example of an EBV gene that may promote efficiency of replication is BHRF1, which encodes a homologue of the cellular protein BCL-2 capable of inhibiting programed cell death or apoptosis. By inhibiting induction of apoptosis in response to stresses associated with lytic EBV infection, the BHRF1 protein presumably prolongs the life of the cell, enhancing virus production.

EBV expresses at least three genes during the lytic cycle that are capable of modulating the host immune response. Two of these encode homologues of human interleukin 10 (hIL-10) and the receptor for colony-stimulating factor 1 (CSF-1). EBV IL-10 (vIL-10), encoded by the BCRF1 gene, displays a colinear homology of 78% with hIL-10, and is functionally equivalent in many (but not all) respects to its cellular counterpart. Because hIL-10 has numerous immunosuppressive effects, expression of vIL-10 is viewed as a mechanism to potentiate EBV infection and establishment of the carrier state. The EBV CSF-1 receptor homologue, encoded by the BARF1 gene, is a secreted protein able to bind and neutralize soluble CSF-1, though a role for CSF-1 in the host defense against EBV infection has not been defined. The third EBV gene, BZLF2, encodes gp42, a glycoprotein that plays an important role in the infection of B lymphocytes through interaction with the cell-surface class II antigen HLA-DR. Additionally, gp42 bound to HLA-DR on the surface of cells supporting virus replication is able to inhibit class II mediated antigen presentation, and is thus another potential mechanism adopted by EBV to interfere with the host immune response.

Latency

During initial exposure to EBV a latent infection is established within B lymphocytes. Whether latency is initiated through direct infection of resident or circulating B cells within tissue of the oropharyngeal cavity, or secondary infection following initial replication of virus in epithelial cells, is currently a matter of contention. Regardless, once latency has been established the virus is maintained within the B cell pool for the life of the host, presumably without further requirement for virus replication. The *in vitro*

Table 1 Functions of the EBV latency-associated genes

Gene/protein	*Properties*	*Required for B cell immortalization*
EBNA-1	Required for genome replication/maintenance; activates EBNA transcription via *oriP* (Cp/Wp); autorepression of Qp; oncogenic potential (?)	+[a]
EBNA-2	Transcriptional activation of EBNA (Cp), LMP-1, LMP-2B and cellular genes	+
EBNA-3A	Transcriptional repression of LMP-1 and LMP-2B; possible regulation of cellular genes	+
EBNA-3B	Transcriptional repression of LMP-1 and LMP-2B; possible regulation of cellular genes	−
BNA-3C	Transcriptional repression of LMP-1 and LMP-2B; activator of LMP-1 and cellular genes	+
EBNA-LP	Potentiator of transactivation by EBNA-2	+/−[b]
LMP-1	Oncogenic; constitutive activation of TNF signaling pathway	+
LMP-2A LMP-2B	LMP-2A affects BCR signaling to inhibit reactivation of virus; provides survival signal; isoform LMP-2B has no known function	−
BARTs	Complex spliced transcripts, may encode at least two polypeptides (RK-BARF0 and RPMS1); function unknown	−
EBER-1 EBER-2	Small nuclear RNAs; bind autoantigen La, dsRNA-dependent protein kinase (EBER-1), ribosomal protein L22 (EBER-1); regulation of translation (?)	−

[a] Assumed to be essential due to requirement for viral DNA maintenance.

[b] Enhances immortalization but not essential (see text).

models of EBV latency have been long-term cultures of Burkitt's lymphoma (BL) cells and EBV-immortalized B lymphoblastoid cell lines (LCLs) which express a subset of 12 EBV genes, collectively known as the latency-associated genes. These genes encode six EBV nuclear antigens (EBNA-1, -2, -3A, -3B, -3C and -LP), three membrane proteins (LMP-1, -2A and -2B), a complex family of alternatively spliced transcripts (BARTs) from the *Bam*HI-A region of the genome, and two small noncoding nuclear RNAs (EBER-1 and EBER-2). The known functions and properties of these genes are summarized in **Table 1**.

For two decades following the discovery of EBV in BL biopsies, EBV latency *in vitro* within LCLs and BL cell lines was widely accepted as the model of EBV persistence *in vivo*. Increasing evidence indicated, however, that EBV-infected B cell lines, and subsequently the latency-associated proteins themselves, were targets of immune cytotoxic T lymphocytes (CTLs). It seemed unlikely, therefore, that EBV could persist solely within an LCL-like cell in a healthy EBV-infected individual, but instead might adopt an alternative, less immunogenic state of latency. Evidence of this was first provided by observations that early-passage BL cells, but not HLA-matched LCLs or late-passage BL cells, were resistant to killing by HLA class I antigen-restricted EBV-specific CTLs. This was determined to be predominantly the result of a downregulation of EBV latent-gene expression in BL tumors, particularly those viral proteins, such as the EBNA-3 molecules, that contain dominant CTL epitopes. In contrast to LCLs, BL tumor cells limit expression of EBV genes to EBNA-1, the BARTs and EBERs (type I latency). Shortly after the discovery of a restricted program of EBV latent-gene expression in BL tumors, similar patterns of EBV gene expression were detected in other EBV-associated tumors, most notably nasopharyngeal carcinoma and EBV-positive Hodgkin's lymphoma, which also express LMP-1 and LMP-2A (type II latency). Recent analyses of EBV gene expression in B cells of otherwise healthy donors have revealed that EBV gene expression progresses from an LCL-like or growth program of latency-associated gene expression during acute (primary) infection, to a restricted program of latency similar to BL upon establishment of the carrier state.

Growth program of latency

During the growth program of EBV latency (alternatively referred to as type III latency), the full complement of latency-associated genes is expressed (**Fig. 1** and **Table 1**). However, the highly proliferative nature of B cells that maintain the growth program is due to the influence of only a subset of these proteins, namely EBNA-2, EBNA-LP, the EBNA-3 proteins and LMP-1, which target, either directly or indirectly, cellular signaling pathways

involved in the regulation of cell growth and differentiation. Discussion of the growth program of latency, therefore, will focus on the functions of these proteins. The remaining EBV latency-associated genes will be discussed in the context of restricted latency.

EBNA-2 EBNA-2 is one of six proteins essential for EBV-mediated B cell immortalization and sustained cell proliferation (**Table 1**). Studies evaluating the effect of EBNA-2 expression in EBV-negative B cell lines provided the first indication that EBNA-2 functions as a transcriptional regulator. EBNA-2 is known to activate expression of several cellular genes: the B cell growth factor CD23, the c-fgr proto-oncogene, and CD21, the EBV receptor and a component of the CD19 signaling pathway. EBNA-2 also activates expression from the EBV promoters for LMP-1 and -2B, as well as the EBNA gene promoter Cp (**Fig. 1**). EBNA-2 does not bind directly to DNA, but is targeted to the promoters of EBNA-2-responsive genes through interactions with cellular DNA-binding proteins. Because EBNA-2 contains a strong acidic transcriptional activation domain within its C-terminus that interacts with a number of basal transcription factors, targeting of EBNA-2 to a promoter leads to increased transcription.

One protein through which EBNA-2 is targeted to a promoter is the ubiquitous cellular transcription factor Jκ. Jκ has been highly conserved throughout evolution, and its importance is underscored by the finding that deletion of the Jκ gene results in embryonic lethality in such diverse species as the mouse and fruit fly. Jκ itself is a component of the Notch signaling pathway, and binds to the intracellular domain of the receptor Notch. Ligand-mediated activation of Notch results in cleavage and release of its intracellular domain, which then translocates to the nucleus and indirectly binds to DNA through its interaction with Jκ. Thus, EBNA-2 mimics activated Notch. Interestingly, Notch is activated or overexpressed in several malignancies, including leukemias, though the role of Notch signaling in EBV-induced cell proliferation is unclear. Since Jκ binding sites are present in numerous cellular promoters, in addition to the EBV Cp and LMP-1 and -2B promoters, a large number of cellular genes are likely to be heretofore unidentified targets for transactivation by EBNA-2.

A second mechanism for targeting EBNA-2 to DNA, particularly the LMP-1 promoter, is interaction with the cellular factor Spi-1 or the highly related Spi-B. Both proteins are members of the Ets family of transcription factors, which recognize the same DNA sequence element within responsive promoters. Whereas expression of Spi-1 is restricted to and plays an important role in the development of B lymphocytes and myeloid cells, less is known of Spi-B, the expression of which is limited to B and T lymphocytes. Of particular interest with respect to the role of EBNA-2 in the regulation of B cell proliferation is the fact that the murine homologue of Spi-1, PU.1, was first identified as an oncoprotein. The importance of these proteins is further highlighted by the embryonic lethality of mice nullizygous for Spi-1, and defective B cell receptor-mediated responses in Spi-B knockout mice. The Ets family of transcription factors, which are clearly important for B cell development and differentiation, regulate a wide variety of cellular genes. The expression of at least some of these genes, therefore, is likely to be regulated by EBNA-2 and important in the EBV-mediated control of B cell growth and differentiation.

EBNA-3 family The EBNA-3 family comprises three genes, EBNA-3A, -3B and -3C, whose tandem arrangement within the EBV genome and similar gene structure (**Fig. 1**) suggests that they may have arisen by gene duplication. There is, however, little notable sequence homology between these proteins. EBNA-3A and -3C are essential for B cell immortalization by EBV, whereas EBNA-3B is dispensable. One common function of the EBNA-3 proteins is their ability to bind to Jκ, which also interacts with EBNA-2. The interaction of the EBNA-3 proteins with Jκ is mediated through a homologous motif in the N-terminus of each EBNA-3 protein, lending further support to the hypothesis that these proteins are distantly related. By contrast to the interaction of Jκ with EBNA-2, interaction with the EBNA-3 proteins inhibits transcriptional activation mediated through Jκ response elements by preventing the binding of Jκ to DNA. Interestingly, the function of the *Drosophila* homologue of Jκ, Suppressor of Hairless, is regulated in an analogous fashion by Hairless, in an analogous fashion to the EBNA-3s, suggesting that the activity of Jκ must be tightly regulated. Conservation of the mechanisms that regulate Jκ-mediated transcription, in a manner requiring four viral proteins, further suggests that modulation of this pathway is critical to the control of cell proliferation by EBV.

The fact that both EBNA-3A and EBNA-3C are required for B cell immortalization by EBV suggests that they possess unique functions in addition to their ability to regulate Jκ. Like EBNA-2, EBNA-3C increases the expression of CD21 in EBV-negative B cell lines. EBNA-3C, in the presence of EBNA-2, can also activate expression of LMP-1. This activation occurs at the level of transcription through a Jκ-independent mechanism. While EBNA-3C does

possess a transcriptional activation domain in its C-terminus, it has not yet been demonstrated to bind to a specific DNA sequence. Furthermore, cotransformation assays using rat embryo fibroblasts have demonstrated that EBNA-3C can immortalize these cells in collaboration with an activated *ras* gene, suggesting that EBNA-3C contributes to the growth program in a manner independent of its ability to regulate LMP-1 expression.

Expression of EBNA-3B in EBV-negative B cell lines results in increased expression of CD40 and vimentin, an intermediate filament of the cytoskeletal network. The combined expression of all three family members induces the expression of pleckstrin, a hematopoietic-cell protein containing two pleckstrin homology domains proposed to mediate protein–protein or protein–lipid interactions. The fact that these domains are found in many proteins that participate in cell signaling or cytoskeletal regulation suggests that the pleckstrin gene may be a significant target of the EBNA-3 proteins. Like EBNA-3C, EBNA-3A and -3B possess a C-terminal transcriptional activation domain, and EBNA-3A also contains a transcriptional repression domain. Thus, all members of the EBNA-3 family clearly function as transcriptional regulators, and have the potential to influence gene expression through Jκ-dependent as well as Jκ-independent mechanisms.

EBNA-LP Relatively little is known of the function(s) of EBNA-LP (leader protein), named for the fact that it is encoded by the common leader sequence of the EBNA mRNAs expressed during the growth program (**Fig. 1**). Although EBNA-LP is critical for the efficient immortalization of B lymphocytes by EBV, it is not absolutely essential. EBNA-LP has been demonstrated to interact with a member of the heat shock family of proteins, p73, and can activate gene expression through the transcriptional activation domain of EBNA-2. This latter property of EBNA-LP suggests that it may act as an adaptor molecule to promote interaction between the activation domain of EBNA-2 and the basal transcriptional machinery. Coexpression of EBNA-2 and EBNA-LP in primary B lymphocytes results in increased expression of the G_1 cyclin D2, and progression from the G_0 to G_1 stage of the cell cycle, clearly a property consistent with a role in promoting cell growth.

LMP-1 LMP-1 is unique among the EBV proteins expressed during the growth program in that it alone induces the classic phenotypic changes associated with transformation when expressed in rodent fibroblasts. In B cells, LMP-1 expression results in the increased levels of cellular adhesion molecules associated with either EBV infection or antigen activation of primary B lymphocytes. Expression of the anti-apoptotic cellular proteins bcl-2 and A20 is also activated by LMP-1, promoting the survival of infected cells. Interestingly, although LMP-1 transgenic mice develop B cell lymphomas, LMP-1 alone is not sufficient to sustain B cell proliferation, underscoring the importance of the contributions of the other EBV proteins expressed during the growth program.

LMP-1 is composed of a small cytoplasmic domain at its N-terminus, and a larger cytoplasmic domain at the C-terminus separated by six transmembrane domains. Genetic studies have demonstrated that two regions of the LMP-1 C-terminal domain, termed transformation effector sites (TES)-1 and -2, are essential for efficient B cell immortalization. Through these domains, LMP-1 directly associates with the intracellular signaling proteins of the tumor necrosis factor receptor (TNFR). Since LMP-1 is a highly hydrophobic membrane protein localized to patches in the plasma membrane, this association results in aggregation of these signaling proteins and constitutive activation of the TNF signal transduction pathway, a critical outcome of which is activation of the transcription factor NFκB. TES-1, located proximal to the membrane, interacts with the TNFR-associated factors (TRAFs) to mediate low-level activation of NFκB that drives the initial proliferation of B lymphocytes following EBV infection. TES-2, located at the very C-terminus of LMP-1, mediates the majority of NFκB activation through binding to the TNFR-associated death domain protein TRADD, and is required for the continued growth of EBV-infected B lymphocytes in culture. TNFR is one of a family of receptors whose members are associated with the promotion of cell growth (CD40) or cell death (FAS receptor), and thus LMP-1 appears to play a direct role in the immortalization or growth-transformation process associated with EBV infection of B lymphocytes.

Within epithelial cells, LMP-1 is able to activate expression of the epidermal growth factor receptor through TRAF signaling, resulting in the inhibition of terminal differentiation. This pathway is likely to mediate the development of epithelial hyperplasia observed in LMP-1 transgenic mice, and suggests a significant role for LMP-1 in the more restricted (type II) latency found in undifferentiated nasopharyngeal carcinoma.

Restricted program of latency

Whereas the growth program of EBV latency drives a rapid expansion of EBV-infected B cells, restricted

latency, commonly referred to as the latency program, is believed to promote the long-term maintenance of infection once a critical pool of infected cells has been established. Within an uncertain time frame following primary infection, but presumably before the maturation of the CTL response to EBV proteins exclusively associated with the growth program, there is a downregulation of the expression of LMP-1, LMP-2B and each of the EBNA proteins except EBNA-1. In the absence of EBV proteins that act in concert to stimulate cell proliferation, infected B cells are thought to re-enter the pool of resting B lymphocytes to become the primary reservoir of EBV-infected cells. Even though several EBV proteins continue to be expressed, namely EBNA-1, LMP-2A and possibly at least two proteins encoded by the BARTs, it is apparent that the host does not effectively perceive these cells as infected, thus permitting them to persist in the face of an otherwise potent anti-EBV immune surveillance. Although LMP-2A and proteins encoded by the BARTs may simply be poor stimulators of a CTL response, EBNA-1 contributes directly to immune escape by blocking its own degradation and subsequent presentation on the cell surface in association with HLA class I antigens. Once restricted latency has been established, it is unclear whether the EBV growth program is subsequently reactivated. Periodic reactivation of the growth program, presumably in response to physiologic signals, may serve to expand and thus sustain the pool of infected B cells. Alternatively, physiologically-induced B cell proliferation might occur in the context of a restricted latency, without induction of the growth program, which presumably would enable limited expansion without risking significant loss of infected cells due to reactivation of the anti-EBV CTL response.

Regulation and function of the latency program

Approximately one B lymphocyte in 10^5 is latently infected with EBV within the peripheral blood of EBV-positive individuals. Although this is a sufficient number of cells to both detect the presence of viral DNA and assess the pattern of EBV gene expression *in vivo* using polymerase chain reaction (PCR)-based technology, these cells cannot be propagated *in vitro* for more detailed analysis unless the growth program of latency is reactivated. Thus, much of what is known about the restricted latency program is based on the analysis of a subset of BL cell lines that, for unknown reasons, continue to maintain restricted latency *in vitro*. In contrast to EBV-infected LCLs, which have not undergone malignant transformation and require EBV for continued growth, deregulation of the c-*MYC* proto-oncogene in BL is able to sustain cell growth in culture independent of EBV. Although these so-called group I BL cell lines do not consistently express LMP-2A, they have nonetheless proven to be a reasonably accurate model of the latency program in normal B lymphocytes.

The apparent mechanism through which a subset of the EBV latency-associated genes are repressed during restricted latency is the selective methylation of EBV promoters by cellular DNA methyltransferases. Methylation of the cytosine moiety of CpG dinucleotide pairs within the targeted EBV promoters results in transcriptional inactivation of the gene. How the selective methylation of EBV promoters is regulated, and whether this is in fact the primary mechanism responsible for restricting EBV gene expression, is unknown. Despite inactivation of the EBNA promoters Cp and Wp during restricted latency, BL and other EBV-infected tumor cells continue to express EBNA-1, which is required for maintenance of the EBV episome in proliferating cells. Exclusive expression of EBNA-1 in these cells, as well as in latently infected B cells *in vivo*, is mediated through the activation of an EBNA-1-specific promoter, Qp, that is not active during the growth program of EBV latency (**Fig. 1**).

With the exception of EBNA-1, which performs an essential but as yet undefined role in the replication and maintenance of the EBV genome, the EBV gene products expressed during the latency program are not required for the immortalization and sustained growth of B lymphocytes *in vitro*. This suggests that the functions of LMP-2A, the BARTs and EBERs may be critical in the context of the latency program *in vivo*. In fact, a number of observations indicate that these EBV genes do indeed target cellular pathways in a manner that would contribute positively to the maintenance of long-term latency. Recent examination of LMP-2A function in transgenic mice indicates that LMP-2A provides a survival signal in B lymphocytes that mimics such a signal provided by the B cell receptor (BCR) that is essential for B cell maintenance. Earlier studies, furthermore, demonstrated that LMP-2A is capable of inhibiting activation of the EBV lytic cycle through inhibition of BCR-mediated signal transduction. Thus, one would predict that LMP-2A contributes to long-term latency by promoting B cell survival through at least two mechanisms: first, by providing a constitutive survival signal to help ensure an extended lifespan of the infected B cell; and second, by preventing the activation of EBV replication and the cellular destruction that would occur as a result.

Further evidence that the genes expressed during restricted latency are important *in vivo* comes from recent studies with the group I BL cell line Akata. A small percentage of Akata cells in culture undergo a

spontaneous loss of the EBV genome that is concomitant with a loss of tumorigenic potential. Reinfection and establishment of restricted latency in these cells restores tumorigenicity, confirming that tumorigenic potential in this BL cell line is dependent on EBV. Whether EBV is universally essential for the tumorigenicity of BL, however, remains to be demonstrated. EBV promotes tumorigenicity in Akata BL cells by inhibiting apoptosis driven by the dominant oncoprotein in this tumor, c-MYC, which is overexpressed in BL due to a chromosomal translocation leading to transcriptional deregulation of the c-MYC gene. Thus, although none of the EBV genes normally expressed in Akata cells (EBNA-1, the BARTs and EBERs) are known to directly promote cell growth, it is clear that one or more of these genes does impart a strong survival signal that is most likely also operational within the context of the latency program in normal B cells. Interestingly, EBNA-1, which has been linked to B cell lymphoma in some lines of mice carrying an active EBNA-1 transgene, does not restore tumorigenicity or inhibit apoptosis in Akata cells when expressed in an EBV-negative background. This suggests that the EBERs or a protein(s) encoded by the BARTs, or a previously unidentified viral protein, is responsible for promoting B cell survival.

In summary, analyses of EBV gene expression and function have defined two predominant programs of EBV latency in B lymphocytes. These are the growth program characterized by rapid virus-induced proliferation of cells that is associated with expression of the full complement of EBV latency-associated genes, including the oncogenic LMP-1 protein, and the more restricted latency program in which the primary function of the limited set of EBV genes expressed is not to direct cell growth, but to maintain the viral episome, promote B cell survival and prevent activation of the virus replication cycle. Retrospective studies of EBV infection *in vivo* have indicated that the growth program is associated with and possibly limited to the acute phase of EBV infection, and thus likely serves to establish a critical mass of infected B cells during primary infection. By contrast, the latency program, though less-well understood, contributes primarily to the long-term maintenance of latency following the resolution of primary infection and in the face of a potent anti-EBV immune surveillance capable of eliminating infected cells should they sustain or reactivate the growth program.

EQUINE ENCEPHALITIS VIRUSES (*TOGAVIRIDAE*)

Diane E Griffin, Molecular Microbiology and Immunology, Johns Hopkins School of Public Health, Baltimore, Maryland, USA

History

Nomenclature for the encephalitic alphaviruses recognizes the characteristic geographic distribution of each and the initial identification of the viruses as causes of encephalitis in horses. The first clear record of epidemic equine encephalitis comes from 1831 when an outbreak in Massachussetts, USA, resulted in the deaths of 75 horses. Over the next 100 years several local epidemics of encephalitis in horses

occurred along the Atlantic seaboard. The virus of this eastern form of encephalitis (EEE) was first isolated from the brain of an affected horse in 1933 by Tenbroek and Merrill. However, 2 years earlier Meyer, Haring and Howitt had isolated a virus from the central nervous system (CNS) tissues of two horses involved in an epidemic of equine encephalitis in the San Joaquin Valley of California. The eastern isolate and the western equine encephalitis (WEE) virus were serologically distinct. Both diseases occurred in summertime epidemics; in 1933 Kelsor showed that WEE could be transmitted by mosquitoes and shortly thereafter mosquito transmission of EEE was shown. In 1938 both the EEE and WEE viruses were isolated from human cases of encephalitis occurring in the same regions as the equine cases. In 1936 an epidemic of equine encephalitis occurred in the Goajira region of Venezuela and the virus, isolated independently by Beck and Wyckoff and Kubes and Rios, was not neutralized by sera from animals immunized with EEE or WEE viruses and was designated Venezuelan equine encephalitis (VEE) virus.

Taxonomy and Classification

In 1954 arthropod-borne viruses were divided by Casals and Brown into three serologic groups, A, B and C, based on crossreactivity in hemagglutination inhibition (HI) tests. EEE, WEE and VEE viruses constituted the original group A arboviruses. A second crossreacting set, including dengue, St Louis encephalitis and yellow fever viruses, constituted the group B arboviruses; the nonreactive viruses were designated group C. As viruses became classified on the fundamental properties of the virion, the group A viruses became the genus *Alphavirus* within the *Togaviridae* family of enveloped RNA viruses. HI has been used to classify alphaviruses into six broad antigenic complexes. EEE, WEE, and VEE form three of these complexes. The EEE and VEE complexes contain only EEE and VEE viruses, while the WEE complex includes several viruses in addition to WEE (Y62-33, Highlands J, Fort Morgan, Aura and Sindbis) that are distinguished from each other by complement fixation and neutralization.

Viruses within each complex can be subtyped using reactivity with monoclonal antibodies, kinetic HI (EEE, VEE) or neutralization (WEE, VEE) assays. EEE and WEE viruses both have North American and South American subtypes. WEE and VEE viruses can also be subdivided into epizootic and enzootic strains. The VEE viruses are differentiated by HI and neutralization tests into subtypes I–VI. Epizootic strains are equine-virulent and fall within subtype I, which has been further subdivided serologically into IAB, IC (epizootic strains) and ID, IE and IF (enzootic strains). Sequence information, where available, has confirmed the validity of these distinctions.

Properties of the Virion

The virions are 60–65 nm in diameter. The RNA is enclosed in a capsid formed by a single protein arranged as an icosahedron with a $T = 4$ symmetry. The nucleocapsid is enclosed in a lipid envelope derived from the host cell plasma membrane that contains the viral-encoded glycoproteins, E1 and E2. These proteins form heterodimers that are grouped as trimers to form knobs on the virion surface that are arranged with a $T = 4$ symmetry. Glycoproteins are arranged with 240 copies of each protein interacting with 240 copies of capsid protein.

Properties of the Genome

The 49S genome is a single-stranded, nonsegmented, capped and polyadenylated message-sense RNA that is infectious. Complete sequence information is available for representative members of all three virus complexes. The genomes contain approximately 11 700 nucleotides and are organized with the nonstructural proteins at the 5′ end and the structural proteins at the 3′ end. Highly conserved regions of the genome are the 19 nucleotides at the 3′ terminus, important for negative-strand synthesis, and 21 nucleotides at the junction between the nonstructural and structural genes, important for synthesis of the subgenomic RNA. Analysis of codon usage shows an underutilization of the dinucleotide CpG.

Properties of the Viral Proteins

Five potential structural proteins (C, E3, E2, 6K and E1) are encoded in the 3′ end of the genome. The capsid protein is 259 (EEE, WEE) to 275 (VEE) amino acids long. The N-terminal portion is conserved, basic and is presumed to bind the RNA, while the C-terminal portion is presumed to interact with the cytoplasmic tail of E2 and with capsid proteins. The E3 protein is 59 (VEE), 60 (WEE) or 63 (EEE) amino acids long, probably serves as a signal sequence for E2 and is shed into the supernatant fluid after cleavage. The E2 glycoprotein is a transmembrane protein that is 420 (EEE) or 423 (WEE, VEE) amino acids long and has two (EEE) or three (WEE, VEE) N-linked glycosylation sites. The intracytoplasmic portion has a second stretch of hydrophobic amino acids. The 6K protein is 55 (WEE, VEE) or 56 (EEE) amino acids long and probably serves as a signal peptide for E1. By analogy to Sindbis virus, small amounts are

probably incorporated into the virion. The E1 protein is 439 (WEE), 441 (EEE) or 442 (VEE) amino acids long and has one or two *N*-linked glycosylation sites. E1 has a short (one or two residue) intracytoplasmic tail and a positionally conserved hydrophobic stretch of amino acids in the N-terminal portion that is postulated to serve as the fusion peptide for virion entry into the cell. By analogy with other alphaviruses it is presumed that the 5′ portion of the genome encodes four nonstructural proteins that function in replication of the viral RNA and production of the subgenomic RNA.

Physical Properties

The virion is sensitive to ether and detergent. Infectivity can be inactivated by heat or acid. The viruses are stable at −70°C for long periods.

Replication

For the most part, knowledge of the replication of EEE, WEE and VEE is based on the extensive studies of Sindbis and Semliki Forest viruses. Initial attachment to the cell may involve interaction of the E1 glycoprotein, which has hemagglutination activity, with phospholipids on the cell surface. Efficient subsequent entry involves binding of E2 to cellular proteins followed by receptor-mediated endocytosis. Within the acidified endosomal compartment the glycoprotein spikes undergo a conformational change that results in fusion with the endosomal membrane and release of the nucleocapsid into the cytoplasm. Acidified endosomes may not be essential for infection of mosquito cells. Once released from the capsid matrix, the virion RNA serves as mRNA and translation of the nonstructural proteins is initiated. Cytopathic vacuoles form and negative-strand 49S, positive-strand 49S and positive-strand 26S subgenomic RNAs are transcribed. The 26S RNA represents the 3′ portion of the genome from which the structural proteins are translated and synthesized as a polyprotein. After translation of the capsid protein is complete, it is autocatalytically cleaved from the nascent chain. E2 and E1 are transported into the endoplasmic reticulum, cleaved by cellular proteases and processed through the Golgi. At the plasma membrane nucleocapsids align with regions containing the E1–E2 heterodimers and bud from the cell surface. The process may be different in mosquito cells, where intracytoplasmic compartments containing mature virus particles are seen *in vitro*; however, these structures have not been seen during ultrastructural studies of alphavirus infection in mosquitoes.

Geographic and Seasonal Distribution

The encephalitic alphaviruses are geographically restricted. All of the viruses are transmitted primarily by mosquitoes and, therefore, transmission is restricted to warm months of the year. EEE is endemic from New Hampshire along the Atlantic seaboard and Gulf Coast to Texas in North America, in the Caribbean, Central America, and along the north and east coasts of South America. Inland foci exist in the Great Lakes region and South Dakota. In the northern part of the range cases occur between July and October, while in the southern region cases can occur throughout the year. Viruses of the WEE complex are widely distributed throughout the Americas as three closely related, but serologically distinct, viruses (WEE, Highlands J and Ft Morgan). Sindbis, Y62-33 and Aura viruses are Old World viruses. Highlands J virus is endemic on the East Coast of the United States in the same areas as EEE virus. WEE virus is widely distributed in the western plains and valleys of the USA and Canada. A subtype of WEE, AG87-646, is found in South America. Enzootic VEE viruses are perennially active in subtropical and tropical areas of the Americas (subtype II in Florida; ID and IE in Central America; IF and III–VI in South America). Epizootics have appeared in Venezuela, Colombia, Peru and Ecuador at approximately 10 year intervals.

Host Range and Virus Propagation

The endemic life cycle of the encephalitic alphaviruses involves replication in vectors, primarily mosquitoes, and in reservoir hosts, primarily birds (EEE and WEE) and small mammals (VEE). In epidemic periods additional hosts such as horses and humans are infected. EEE virus causes encephalitis in humans, horses, pigeons and pheasants. Many birds are susceptible to infection, but remain asymptomatic despite prolonged viremia. The amplifying species for EEE virus in North America are wading birds and migratory song birds. In South America, forest-dwelling rodents and marsupials are frequently infected and may provide an additional reservoir. Infection has also been reported in turtles and snakes. In invertebrates, virus is most consistently recovered from *Culiseta melanura* mosquitoes but the first arthropod isolations were from chicken mites and lice.

WEE virus causes encephalitis in horses and humans. The enzootic cycle in North America involves domestic and wild birds and *Culex tarsalis* for WEE virus in the western USA and songbirds and *Culiseta melanura* for Highlands J virus in the eastern USA. Serosurveys and virus isolations demonstrate

evidence of natural infection in chickens and other domestic birds, passerine birds, pheasants, rodents, rabbits, ungulates and snakes.

Epizootic strains of VEE virus cause disease in horses and in humans. The maintenance cycle in nature is unclear. The enzootic strains of VEE can infect horses but these infections are asymptomatic and may protectively immunize horses against epizootic strains. Enzootic strains produce mild disease in humans. Many wild birds are susceptible to infection. Rodents serve as an important reservoir with efficient transmission of infection by *Culex (Melanconion)* mosquitoes.

In addition to the native hosts, a number of laboratory animals are susceptible to infection. All three viruses cause encephalitis in monkeys, mice, rats, guinea pigs and hamsters. Disease is generally age-dependent so that young animals more often develop fatal infections than adult animals. Primary isolates of these viruses are often made in newborn mice.

In vitro, the viruses are routinely propagated in cultures of chick embryo fibroblast, BHK-21 or Vero cells. Most strains will form plaques on these cell lines and plaque assays provide the usual basis for virus quantitation. Mosquito cell lines support replication, often without cytopathic effect. Many other cell lines (e.g. L cells, HeLa cells) support replication as well.

Genetics

Alphaviruses show genetic changes by accumulation of point mutations in the genomic RNA, but this occurs at a rate that is much slower than that predicted for other RNA viruses. Recombination is infrequent, but can be demonstrated *in vitro* and occurs at least occasionally in nature, as sequence analysis has shown that WEE virus is the result of recombination between EEE and Sindbis-like viruses.

Evolution

The alphaviruses, which replicate in mosquitoes, birds and mammals, derive from a single unknown protoalphavirus and are part of the alphavirus superfamily of viruses. Viruses in this superfamily have a similar genetic organization and include many RNA plant viruses. In general, amino acids important in secondary structure (e.g. cysteine) have been conserved for the structural glycoproteins E1 and E2, suggesting that the three-dimensional structure, is similar, for all alphaviruses. Oligonucleotide fingerprinting and sequence analysis suggest that the encephalitic alphaviruses evolve slowly in nature. Comparative sequence information indicates that the capsid protein and E1 glycoprotein are most conserved of the structural proteins, while the E2 glycoprotein is more divergent. Sequence comparisons show that EEE virus has evolved independently in North and South America over the last 1000 years. Currently there is one group in North America and the Caribbean and two groups in South America, one in the Amazon basin and the other on the coast of South and Central America. North American EEE virus isolates spanning 52 years show considerable overall conservation, with an estimated 0.7% divergence per year. Rates of divergence of WEE and Highlands J viruses of 0.1–0.2% per year have been estimated. It is hypothesized that the short transmission season and limited host mobility constrain genetic diversity in a geographic region.

Epidemiology

EEE virus is endemic in the Great Lakes region of North America and along the Altantic and Gulf coasts of North, Central and South America and causes localized outbreaks of equine, pheasant and human encephalitis in the summer. Cases of equine encephalitis are usually the first indicators of an outbreak. In North America the primary enzootic cycle is maintained in shaded freshwater swamps where the vector is the ornithophilic swamp mosquito *Culiseta melanura* and the reservoir hosts are migratory passerine songbirds. Young birds are probably most important for virus amplification, as they are more susceptible to infection, have a prolonged viremia and are less defensive towards mosquitoes. Human and equine cases usually occur within 5 miles of the swamp, with virus being transmitted by epizootic vectors such as *Coquillittidia perturbani, Aedes sollicitans*, and potentially *Aedes albopictus*. The enzootic vector in the Caribbean is probably *Culex taeniopus* and in South America *Culex (Melanoconion)*. Epizootics appear approximately every 5–10 years and are usually associated with heavy rainfall that increases the populations of enzootic and epizootic mosquito vectors. The mechanism of overwintering in northern areas is not known. The virus may be reintroduced annually by migratory viremic birds or wind-borne infected mosquitoes coming from subtropical areas of year-round transmission. There is no evidence for overwintering in mosquitoes. Human infections are unusual, with a median of five cases per year in the USA. Serological surveys in the northeastern USA suggest that there are approximately 23 inapparent infections for every case of encephalitis, but children are more susceptible and this declines to only 8:1 for children under 4 years of age.

In the western USA, WEE virus is maintained in an endemic cycle involving domestic and passerine birds and *Culex tarsalis*, a mosquito particularly adapted to irrigated agricultural areas. Interseasonal persistence occurs in salt water marshes where vertical transmission of WEEV in *Cx. tarsalis* has been demonstrated. Occasional isolations have been made from *Culex stigmatosoma, Aedes melanimon and Ae. dorsalis*, also competent vectors. Transmission from this endemic cycle has resulted in small numbers of cases of encephalitis in humans. However, periodically there are large, often widespread, epidemics of equine encephalitis occurring from mid-June to late-September in North America with significant spillover into the human population. The estimated case to infection ratio is 1:58 in children under five years and 1:1150 in adults. In the eastern USA, Highlands J virus has been isolated from freshwater swamp habitats along the Atlantic coast from birds and the ornithophilic *Culiseta melanura*, the endemic vector for EEE. Ecologic restriction and limited pathogenicity may explain the paucity of human and equine disease due to this virus. The lack of significant human disease during equine outbreaks of WEE in South America may be related to the feeding habits of the vector or to a difference in virulence for humans of the South American strains.

VEE is maintained in enzootic and epizootic cycles by distinct virus strains. Enzootic strains are maintained by *Culex* (*Melanoconion*) mosquitoes that live in tropical and subtropical swamps throughout the Americas and breed near aquatic plants. They feed at dawn and dusk on a wide variety of rodents, birds and other vertebrates. Humans living in these areas have a high prevalence of antibody, but little recognized disease. The epidemiology of the epizootic strains of VEE is less clear because they have been isolated only during outbreaks. Epizootics have occurred primarily in Latin America in cattle ranching areas during the rainy season. Formalinized vaccines containing residual live virus were responsible for initiating the 1969–1972 outbreak in Central America and Texas. During epizootics horses are an important amplifying species. Virus has been isolated from several species of mosquitoes, including *Aedes taeniorhynchus, Ae. aegypti, Mansonia dubitans* and *Psorophora confinnis*. The incidence of encephalitis in clinically ill humans is generally less than 5% and the mortality less than 1%.

Transmission and Tissue Tropism

The primary mode of alphavirus transmission to birds and mammals is through the bite of an infected mosquito which inoculates virus extravascularly. Mosquitoes become infected by feeding on a viremic host, are able to transmit the virus 4–10 days later (external incubation) and remain persistently infected. Maintenance of this cycle requires an amplifying host that develops a viremia of sufficient magnitude to infect feeding mosquitoes. Other modes of transmission are occasionally important. EEE virus persists in the feather follicles of infected pheasants and secondary transmission among penned pheasants can occur through feather picking and cannibalism. VEE can be transmitted by the respiratory route between infected horses, to humans and in the laboratory. WEE and VEE viruses can be transmitted transplacentally.

In mammals, EEE virus replicates primarily in muscle and neurons and glia of the CNS, with occasional involvement of liver and lymphatic tissue. Skeletal and myocardial muscle and the CNS are infected in susceptible birds. In mosquitoes there is infection of the midgut, muscle and salivary glands without involvement of the nervous system. WEE virus replicates primarily in skeletal and cardiac muscle, brown fat and the choroid plexus, ependyma and neurons in the CNS in mammals. Little is known of its tissue tropism in birds and mosquitoes. Epizootic strains of VEE virus infect the upper respiratory tract, lymphatic and myeloid tissue, pancreas, liver and CNS to varying degrees in different mammals. Mosquito infection is initiated by penetration of the mesenteron, with dissemination to the nervous system, salivary glands and flight muscles.

Pathogenicity

EEE strains vary in their pathogenicity for horses (and presumably humans), with the South American strains being less virulent than the North American strains. The molecular basis of these differences has not yet been defined. The North American strains of EEE are amongst the most virulent of the alphaviruses, causing severe encephalitis in humans, horses, dogs, pigs, pigeons, emus, quail and pheasants. The case fatality rate in humans in 30–50%, up to 90% in horses and 50–70% in pheasants. Laboratory studies indicate a similar neurovirulence of EEE for monkeys, mice and hamsters. Hamsters also develop hepatitis and lymphatic organ infection. At 3–4 weeks of age mice become relatively resistant to peripheral, but not intracerebral, inoculation. Birds vary in their susceptibility, with some birds developing disease, while many others show no morbidity or mortality despite a prolonged viremia. Pheasant deaths are caused by encephalitis, whereas young chickens develop myocarditis. Mosquitoes develop persistent infection of

the fat body and salivary glands without obvious shortening of lifespan.

WEEV in the western USA causes epidemics of encephalitis in humans, horses and emus, but the case fatality rate of 10% for humans, 20–40% for horses and 10% for emus is lower than for EEE. Highlands J virus can cause fatal disease in horses and turkeys, but this is unusual. South American strains of WEE cause fatal encephalitis in horses, but little disease in humans. Epizootic strains are neurovirulent and neuroinvasive in adult mice, whereas enzootic strains are not. Highlands J is intermediate in virulence. With increasing age mice become relatively resistant to fatal infections, whereas hamsters remain susceptible.

Infection of horses with epizootic strains of VEE virus is frequently fatal. Disease is associated with leukopenia and a high-titered, prolonged viremia. In contrast to EEE and WEE, the disease is not consistently indicative of encephalitis and virus is shed in nasal, eye and mouth secretions as well as in urine and milk. Experimental infection of laboratory animals produces a variety of disease patterns. For guinea pigs and rabbits, VEE virus produces necrosis in lymph nodes, spleen, thymus, intestinal and conjunctival lymphoid tissue, liver and bone marrow. Hamsters develop encephalitis and pancreatitis in addition to widespread involvement of myeloid and lymphold tissue. Rats and mice have more limited destruction of lymphoid and myeloid tissue and death is usually due to encephalitis. Virus enters the CNS through the olfactory tract and causes neuronal infection and apoptosis. Neonatal mice show extensive replication in many tissues, including brain, myocardium and pancreas. Comparative studies of the virulent TRD and avirulent TC-83 strains of IA serotype VEE virus and construction of recombinant viruses have led to identification of the 5′ noncoding region and the E2 envelope glycoprotein as important determinants of virulence for mice and presumably for horses.

Clinical Features of Infection

EEE virus is the most virulent of the encephalitic alphaviruses, causing a high mortality due to encephalitis. Prodromal symptoms of fever, headache and myalgias are common. The onset of encephalitis tends to be fulminant and is associated with continued fever, increased headache, meningismus, obtundation and seizures. Mortality overall is 30% in recent studies, with higher rates in children and the elderly. Recovery is more likely in those individuals with a long (5–7 day) prodrome and without coma. Sequelae are common, with more that 80% of survivors having significant neurological residua including paralysis, seizures and mental retardation. The diagnosis is usually made by detection of antibody in serum or cerebrospinal fluid.

WEE virus causes encephalitis with signs and symptoms similar to those of EEE. There is a 3–5 day prodrome of fever and headache that may progress to irritability, nuchal rigidity, photophobia and altered mental status. Severe disease, seizures, fatal encephalitis and significant sequelae are more likely to occur in infants and in young children.

Infection with epizootic strains of VEE virus usually causes relatively mild disease in humans. Illness in adults usually manifests with fever, headache, myalgias and pharyngitis 2–5 days after exposure. Severe disease, including fulminant reticuloendothelial infection and encephalitis, may occur in young children. Children recovering from encephalitis may be left with neurological deficits. Fetal abnormalities and spontaneous abortions may occur with infection during pregnancy.

The cerebrospinal fluid during alphavirus encephalitis usually shows a moderate (up to 4000 cells/mm^3) pleocytosis with predominance of either polymorphonuclear or mononuclear cells. Protein is usually elevated and the glucose is normal. The electroencephalogram and magnetic resonance imaging scans are usually abnormal, but computed tomographic scans may be normal or indicative only of edema.

Pathology and Histopathology

Initial CNS infection with EEE virus in experimental animals is of the capillary endothelial or choroid plexus epithelial cells and spread within the CNS can be cell-to-cell or through cerebrospinal fluid. The targeted cell within the CNS is the neuron and damage to this cell may be severe and irreversible. Histopathology demonstrates a diffuse meningoencephalitis with widespread neuronal destruction, neuronophagia, gliosis and perivascular inflammation, with polymorphonuclear and mononuclear leukocytes early, and vasculitis and vessel occlusion late. Hamsters also exhibit necrosis of hepatocytes and lymphatic tissue accompanied by local infiltration of mononuclear leukocytes. Initial infection of mosquitoes is of midgut epithelial cells. Infection is facilitated when virus in the serum is concentrated next to these cells as the infected bloodmeal clots. Infected midgut epithelial cells subsequently degenerate and slough and this process may facilitate penetration of the virus into the hemocele and rapid dissemination of the infection.

Pathological examination of brains from fatal human cases of WEE demonstrates early perivascular extravasation of blood followed by endothelial hyperplasia, perivascular mononuclear and polymor-

phonuclear inflammation and parenchymal necrosis. Areas of neuronal degeneration, glial nodules and demyelination are found. Neonatal mice develop acute inflammation and necrosis in skeletal and smooth muscle, cartilage and bone marrow. In animals with encephalitis, the brain shows multifocal areas of necrosis and widespread lymphocytic infiltration of the leptomeninges and perivascular regions of the brain parenchyma. The heart shows a necrotizing, inflammatory myocarditis. Infiltration of mononuclear leukocytes into areas of lung, liver and brown fat also occurs.

The pathology of VEE in horses includes cellular depletion of bone marrow, spleen and lymph nodes, pancreatic necrosis and, in cases with encephalitis, swelling of vascular endothelial cells, edema and mononuclear infiltration in the brain. Encephalitis in rodents is characterized by neuronal cell death, severe mononuclear cell cuffing of cerebral vessels and meningitis, followed by the later appearance of demyelinating lesions. Small mammals with widespread involvement of the reticuloendothelial system may develop ileal necrosis.

Immune Response

Both cellular and humoral immune responses are induced by infection. Virus-specific IgM antibody is often detectable very early in the disease by enzyme immunoassay or neutralization in both serum and cerebrospinal fluid and provides a means for rapid diagnosis of infection. IgG antibody appears after 10–14 days and can be measured by enzyme immunoassay, HI or neutralization assays. Many lines of evidence suggest that recovery from infection is primarily dependent on the antibody response. The most extensive experimental studies to define the antibody specificity and the mechanisms of recovery and protection have been done using VEE virus and Sindbis virus, a member of the WEE complex. Neutralizing and nonneutralizing antibodies are protective. Multiple epitopes on the E1 and E2 glycoproteins induce neutralizing, HI and protective antibody. Sequencing of monoclonal antibody escape mutants has localized one neutralization domain to E2 residues 180–210 in VEE. Immunization with peptides has shown that an antibody response to residues 1–25 of the VEE E2 glycoprotein is also protective.

Cellular immunity has received more limited study, but virus-specific lymphoproliferative and cytotoxic responses have been documented. The importance of either for recovery or contribution to fatal disease has not been established. Prior infection with VEEV increases subsequent antibody responses to unrelated antigens. VEEV-specific T cells can inhibit virus replication by an unidentified mechanism. Antithymocyte globulin extends time to death in mice infected with VEE virus, suggesting a T cell-mediated immunopathogenic component to fatal disease.

Prevention and Control

Prevention of infection relies on efforts to control mosquito populations by spraying and reduction of breeding places. Individual use of protective measures such as mosquito repellents and protective clothing are important. Vaccines against EEE, WEE and VEE are available for horses and against EEE for birds. Experimental human vaccines against EEE, WEE and VEE are also available for laboratory workers exposed to these agents. Most of these vaccines consist of formalin-inactivated virus, but TC-83 is a successful live attenuated vaccine against VEE for horses. TC-83 is also an effective vaccine for humans, although minor side effects are common after immunization. No antiviral agents are of proven usefulness in treatment of these infections.

Future Perspectives

The ability to construct full-length cDNA alphavirus clones that can be transcribed into infectious RNA provides tremendous potential for understanding the functions of various genes and their importance for replication and virulence in the multiple hosts necessary for maintenance of these viruses in their natural cycles. An understanding of the folding and three-dimensional structures of each of the structural proteins is needed for interpretation of much of the sequence and virulence data that has been acquired. Further sequence information on virulent and avirulent strains and functional analysis of the nonstructural proteins is likely to provide the next level of understanding of virus–host relationships.

EQUINE HERPESVIRUSES (*HERPESVIRIDAE*)

Dennis J O'Callaghan, Department of Microbiology and Immunology, Louisiana State University School of Medicine, Shreveport, Louisiana, USA

Nikolaus Osterrieder, Federal Research Centre for Virus Diseases of Animals, Friedrich-Loeffler-Institutes, Insel Riems, Germany

History

The first disease attributed to an equine herpesvirus (EHV-1; equine abortion virus; equine rhinopneumonitis virus) was documented at the University of Kentucky Agricultural Experiment Station in Lexington, which is home to the highest concentration of thoroughbreds in the world. HV-1 was first shown to be associated with spontaneous abortions in pregnant mares in 1932. Several years later (1941) equine abortions were found to be associated with mild respiratory disease with symptoms similar to those associated with infections due to equine influenza virus. EHV-1 infection was analyzed in more detail in 1954, and evidence from these studies demonstrated that EHV-1 was the etiological agent of epizootic respiratory disease in young horses. EHV-1 was then regarded mainly as a respiratory pathogen since the lesions in horses and aborted fetuses were concentrated in the respiratory tract. The disease was termed viral rhinopneumonitis, and the agent was called equine rhinopneumonitis virus. In the 1980s, however, the two disease manifestations, viral abortion and viral rhinopneumonitis, were shown to be caused by two closely related but clearly distinct viruses. These findings resulted in a reclassification into EHV-1 (equine abortion virus) and EHV-4 (equine rhinopneumonitis virus) in 1986.

Equine herpesvirus type 2 (EHV-2) was first isolated from horses in 1963. The cytopathology of this virus closely resembled that of cytomegalovirus infections which were first described in 1921 (in humans). Sequence analyses, however, were able to classify EHV-2, together with EHV-5, as slowly replicating viruses which are related to the human pathogen Epstein–Barr virus which causes B-cell lymphomas and nasopharyngeal carcinomas. EHV-2 is a ubiquitous slow-growing virus that infects horses at a very young age (1–2 years) and establishes a lifelong chronic infection such that the horse becomes a continuous shedder of the virus. To date, no major disease has been attributed to EHV-2; however, some workers claim an association of EHV-2 with chronic throat infections (the 'lumpy bumpies'). Also, EHV-2 may be a cofactor in EHV-1 and/or EHV-4 infections in that EHV-2 is obviously able to modulate EHV-1 and EHV-4 replication by an immunosuppression causing general malaise. Also, EHV-2 transactivators are able to modulate gene expression of EHV-1.

Equine herpesvirus type 3 (EHV-3; equine coital exanthema virus, ECE virus) was first isolated independently in 1968 in Canada, Australia and the US. EHV-3 is the etiological agent of equine coital exanthema, which is a generally mild genital infection of both mares and stallions that is transmitted venereally.

Equine herpesvirus type 4 (EHV-4), initially designated subtype 2 of EHV-1, is associated mainly with respiratory disease, but EHV-4 has also been associated occasionally with equine abortions. EHV-1 (equine abortion virus) on the other hand, is associated primarily with equine abortions, but frequently causes respiratory disease in young animals, neurological disease, fulminating neonatal pneumonitis and very rarely, an exanthematous condition involving the external genitalia of the mare.

Equine herpesvirus type 5 (EHV-5) is closely related to EHV-2 and no information on possible disease(s) caused by this virus is available.

Taxonomy and Classification

EHV-1, EHV-2, EHV-3, EHV-4 and EHV-5 are all members of the *Herpesviridae* but belong to several subfamilies in this large virus family. The morphology of all four members is typical of the herpesviruses in that they are enveloped, contain an icosadeltahedral capsid, and have a proteinaceous region called the tegument surrounding the nucleocapsid. The equine herpesviruses are composed of five distinct species: (1) EHV-1 is the major equine pathogen causing fetal abortions, respiratory illness and neurological disease, (2) EHV-2 (and EHV-5?) establish asymptomatic, long-term persistent infections; (3) EHV-3 (ECE virus) is the causative agent of mild genital exanthema; and (4) EHV-4 is a major respiratory pathogen that differs significantly from

Table 1 Characteristics of the genomes of EHVs

	Density (g cm^{-3})	*G+C ratios*	*Sedimentation coefficient*	*Genomic isomers*
EHV-1	1.716	57%	49-55S	2
HV-2	1.7165	58%	61.8S	1
EHV-3	1.725	66%	55.4S	2
EHV-4	ND	51%	ND	2
EHV-5	ND	52%	ND	1

ND = not determined.

EHV-1 at the DNA level, and is associated occasionally with equine abortions.

EHV-1, 3 and 4 are members of the *Alphaherpesvirinae* subfamily. EHV-1 and -4 belong to the genus Varicellovirus. EHV-3 is an unassigned species. EHV-2 and EHV-5 have recently been shown to be members of the *Gammaherpesvirinae* subfamily.

Geographic and Seasonal Distribution

EHV-1 and EHV-4 are distributed worldwide, and infections can occur year-round. Over the past 20 years in the United States, EHV-1 'abortion storms' have occurred in many areas. Major outbreaks have also been reported within the past several years in Australia and England. Due to the nature of the disease manifestation of EHV-1, viral abortion, there is a seasonal dependence of EHV-1 infections whereas EHV-4 infections (rhinopneumonitis) are observed mainly on racing tracks and after crowding of large numbers of animals.

EHV-2 has also been isolated in many countries, including England, Switzerland, Germany, USA and South Africa. The existence of the closely related EHV-5 was described for England and Australia. More thorough studies, however, have led to the assumption that both EHV-2 and also EHV-5 are distributed worldwide.

To date, EHV-3 has been isolated in five countries: Germany, USA, Australia, Canada and England.

Host Range and Virus Propagation

Although the horse is the natural host of the equine herpesviruses, a variety of animals and tissue culture systems can be used to propagate the viruses. Regarding the major equine pathogen, EHV-1, experimental animals include Syrian hamsters and baby hamsters, chick embryos, baby mice and adult mice, and kittens. Primary tissue culture systems used to propagate EHV-1 include cells from a variety of equine tissues such as fetal lung, dermis, spleen and kidney, as well as cells from domestic cats, dogs, hamsters, rabbits, mice, sheep and swine. In the laboratory, permanent tissue culture systems commonly used to cultivate EHV-1 include HeLa, Vero, CV-1 cells, rabbit kidney (RK), mouse L-M and equine Edmin337 cells.

The host range for EHV-2, EHV-3, EHV-4 and EHV-5 is more restrictive than that for EHV-1. Except for rabbit kidney cells and primary cat cells, EHV-2 and EHV-5 growth appears to be restricted to cells of equine origin. The host range for EHV-3 and EHV-4 is limited to cells of equine origin, although Vero cell culture adapted EHV-4 strains have been described.

Genetics

All five equine herpesviruses contain a linear, double-stranded DNA genome ranging between 140 and 184 kbp. The reported molecular masses of the genome of the equine herpesviruses are: EHV-1, 150 kbp, EHV-2, 184 kbp, EHV-3, 144 kbp, EHV-4, 146 kbp and EHV-5, 179 kbp. The genomes of EHV-1, EHV-3 and EHV-4 exist in two isomeric forms, since the short region can invert relative to the fixed orientation of the long region. The short region is composed of a central segment of unique sequences (US) bracketed by a pair of inverted sequences. In the case of the Kentucky A, tissue culture strain of EHV-1, each inverted repeat sequence is 12.8 kbp. In contrast, the genomes of EHV-2 and EHV-5 exist as one isomer and are composed of a large (149 kbp) central segment of unique sequences that is bracketed by a pair of direct repeat sequences. Each of the terminal direct repeat segments is 18 kbp, and the total genome size is 179–184 kbp. Other characteristics of the genomes of EHVs are shown in **Table 1**.

There is some homology at the DNA level among the five equine herpesviruses. The sequences shared by EHV-1, EHV-3 and EHV-4 appear to be arranged colinearly and are dispersed throughout the genome. EHV-1 and EHV-4 exhibit 55 to 84% homology at the DNA level and are antigenically related since antibodies can crossneutralize. EHV-1 and EHV-2 show only 2% homology, as does EHV-2 and EHV-3. EHV-

1 and EHV-3 exhibit approximately 10% homology at the DNA level. Lastly, EHV-2 and EHV-5 show approximately 60% identity both on the DNA and protein level.

Genome Structure

The entire genome of EHV-1, strain Ab4, was sequenced and shown to be 150 223 bp in size and to contain 80 potential open reading frames (ORFs). The 63 ORFs of the unique long region are arranged colinearly with those in the genomes of herpes simplex virus and varicella zoster virus. Several genes mapping within the inverted repeat and unique short segments of the short region differ in arrangement from those of other alphaherpesviruses. In addition, EHV-1 contains a limited number of unique genes, i.e. genes that are present neither in HSV-1 nor in VZV and which might represent the virus' gene repertoire determining host specificity.

Each identical, inverted repeat (IR) sequence of the genomic short region of the Kentucky A, tissue culture strain of EHV-1 is composed of 12 777 nucleotides. Six genes and the origin (ORI) of replication have been localized to the IR sequences of EHV-1:

1 the *IR1* gene is an immediate–early (IE) gene encoding a 6.0 kb mRNA and a major phosphoprotein (1487 amino acids) with an apparent molecular mass of 203 kDa;
2 the *IR2* gene is an early gene that is embedded within the IR1 gene, and its 4.4 kb mRNA appears to encode a 130 kDa polypeptide (1165 amino acids) – the protein product of the *IR2* gene represents a truncated form of the IE polypeptide;
3 the *IR3* gene is a delayed–early gene encoding a 0.9 kb mRNA that overlaps the IE promoter region on the opposite DNA strand;
4 the EHV-1 ORI maps downstream of *IR3* and exhibits 60% homology to the ORI(S) of HSV-1 and HSV-2;
5 the *IR4* gene is a homolog of the *ICP22* gene of HSV-1 and is differentially regulated to encode a 1.4 kb early mRNA and a 1.7 kb late mRNA;
6 the *IR5* gene is a homolog of the *US10* gene of HSV-1;
7 *IR6* is a 'very early' gene encoding a 1.2 kb mRNA and a 31/33 kDa phosphoprotein which has been shown to be a capsid constituent and a major determinant of virulence in some EHV-1 strains.

Additional genes of the Kentucky A, tissue culture strain of EHV-1 have also been identified and mapped to the unique short (US) sequences located between the inverted repeats. These include HSV-1 homologs of the *US2* gene, the protein kinase gene, glycoprotein (g) G, gD and the *US9* gene. In addition, a unique gene (*EUS4*, gene 71) was mapped in the US region. This gene encodes a highly O-glycosylated protein referred to as gp1/2. Some size variations in *EUS4* were documented for EHV-1 strains KyA and Ab4, and a gp1/2 null mutant was apathogenic in a murine model of EHV-1 infection. In contrast to strain KyA, homologues of HSV-1 glycoproteins I and E were also mapped to the US segment of the genomes of other EHV-1 strains. Thus, gI and gE are not essential for EHV-1 replication in cell culture, but appear to play a role in virulence. Restoration of the gI and gE sequences to a gI/gE deletion mutant virus with an attenuated phenotype restores pathogenicity for horses.

Functional analyses of the genes encoded in the unique long (UL) genome region have also been performed. Among the investigated genes is the viral thymidine kinase (TK), the genes and gene products of glycoprotein (g) B, C, and M which show high homology to the genes of HSV-1 and VZV. Functional homology between HSV-1 and EHV-1 genes could be demonstrated for EHV-1 gM and gB.

Several genes mapping within the long and short regions of the EHV-4 genome have been identified including: the genes encoding glycoproteins B, C, E and H; thymidine kinase gene; and genes that are homologues of *US1*, *US9* and *US10* of HSV-1. The genomes of EHV-1, EHV-2 and EHV-4 are now entirely characterized at the nucleotide sequence level, but intensive research on gene functions has not been performed. Nothing is known about EHV-3 gene functions.

Replication

The genes of the Kentucky A, a tissue culture strain of EHV-1 are regulated at the transcriptional and translational levels in a temporal fashion, and three kinetic classes of genes designated immediate–early (IE), early (E) and late (L) have been described. EHV-1 possesses a single IE gene which is present in both inverted repeats and gives rise to a spliced 6.0 kbp mRNA. Multiple IE polypeptide species have been observed, and the major IE protein (IE1, 203 kDa) is a nuclear-localized phosphoprotein that is capable of *trans*-activating other viral genes and autoregulating its own expression. The *trans*activation domain (residues 3–89), the DNA-binding domain (residues 422–597), and the nuclear localization domain (PPAPKRRV; residues 963–970) of the IE protein have been mapped. Following IE polypeptide synthesis, approximately 45 early transcripts can be detected. Three of these early proteins serve as regulatory proteins and are designated EICP22, EICP27

and EICP0. The EICP22 protein serves to enhance the DNA-binding of the IE protein to its target sequence (ATCGT) present within the promoters of EHV-1 genes characterized to date. Early gene expression is followed by viral DNA replication and the production of approximately 29 late transcripts. Although these 75 transcripts have been positioned on the viral genome, only a small number of protein products have been identified and characterized (see above).

Viral DNA replication occurs at approximately 4 h postinfection and requires the virus-encoded DNA polymerase which has been purified. DNA replication is thought to occur by the rolling circle mechanism whereby long concatemers of the viral genome are generated, cleaved and then packaged into the maturing virions. The UL15 homologue of HSV-1, one of the two spliced genes of EHV-1 known to date, appears to be essentially involved in the generation of unit-length genomes and their packaging into mature capsids. Sequences at the L-terminus of the EHV-1 genome are composed of direct repeats (DR1 = 18-mer and DR4 = 16-mer) as well as unique sequences (Uc = 60-mer), whereas sequences at the terminus of the short region contain a 54-mer designated Ub. Thus, the sequence arrangement that is formed at the concatemeric junction following the replication of the EHV-1 genome is Ub-DR1-Uc-DR4, which represents a functional cleavage/packaging signal, similar, but not identical to that of HSV-1.

Three different capsid species were identified in hepatocyte nuclei of Syrian hamsters and tissue culture cells infected with EHV-1 and probably correspond to the capsid forms found in HSV-1 which are designated type A, B and C capsids. The EHV-1 capsid species were designated: (1) L capsids, which appear to be empty capsids; (2) I capsids which possess an electron-lucent, immature core structure in the shape of a cross; and (3) H capsids, which contain an electron-dense, mature core. All three capsid species appear at approximately 6 h postinfection and remain at a ratio of 10:87:3 (L:I:H) throughout the infection. The I capsids are believed to be a major precursor in the formation of mature capsids. The main capsid protein has an apparent size of 148 kDa, whereas other major structural proteins of 59, 46, 37, 30 and 18 kDa have also been identified. As reported for other herpesviruses, EHV-1 maturation occurs by interaction of mature nucleocapsids with the inner portion of the nuclear membrane resulting in the formation of enveloped particles. Two theories for the pathway of herpesvirus release from infected cells after budding at the inner nuclear membrane are discussed. One theory claims that capsids are de-enveloped at the ER membrane and re-enveloped at Golgi-derived vesicles by which mature virions are finally transported to the cytoplasmic membrane. The other theory claims an '*in situ*' processing of enveloped particles, i.e. after budding of virions at the inner nuclear membrane, infectious particles are released via the secretory pathway including the ER and Golgi network.

Infectious EHV-1 particles contain an envelope that is mainly composed of glycoproteins. To date, 12 EHV-1 glycoproteins have been identified and an association of gB, gC, gD, gH, gL, gM, gp1/2 (EUS4), and the tegument protein VP13/14 with purified virions has been demonstrated. The glycoproteins were shown in other alphaherpesviral systems to be involved in virus binding, virus penetration, and cell-to-cell spread of infection. In the case of EHV-1, these functions were confirmed for gB, gM, and gp1/2, and the latter two proteins were shown to be non-essential for virus growth. In contrast, gB-negative EHV-1 mutants are unable to grow *in vitro*. The defect in replication of gB-negative viruses is primarily caused by an inability to spread from infected to uninfected cells. Detailed functional analyses for the other glycoproteins have not been performed, but are now facilitated by the use of engineered virus mutants that are produced by targeted gene deletion. Even less is known for proteins that make up the third component of the mature virion, the tegument. To date, none of the proteins that – by analysis of homology – are related to HSV-1 tegument proteins has been analyzed in detail. Recent studies have shown that the product of ORF12 is a homologue of HSV-1 αTIF. This 60 kDa protein (ETIF) is a late gene product, antigenically crossreacts with HSV-1 αTIF, and participates in an infected cell complex with the EHV-1 IE promoter TAATGARAT motif.

DI Particles and Persistent Infection

Altered outcomes of equine herpesvirus infections have been reported and include oncogenic transformation (EHV-1, EHV-2, EHV-3, and EHV-5) and persistent infection (EHV-1, EHV-2, and EHV-5). EHV-1 persistent infection and oncogenic transformation *in vitro* were shown to be mediated by virus preparations enriched for EHV-1 DI particles (DIPs). EHV-1 DI particles have been generated *in vivo* in the Syrian hamster model, and therefore DIPS may be generated in EHV-1 infection of the natural host. The DIPs are replication defective and require the standard virus as a helper. The majority of EHV-1 DNA sequences have been deleted from the genome of EHV-1 DIPs, such that sequences from three regions of the EHV-1 genome are conserved in the DIP genome. These three segments are: (1) the L-terminus, including genes *UL1*, *UL2* and the 3′ portion of *UL3*;

(2) the junction of the UL and internal IR sequence; and (3) the central portion of the IR, including the 5′ portion of gene *IR4*. The DIP genome also contains a perfectly conserved origin of replication and cleavage/packaging signal. The sequences at the L-terminus and IR are joined by a homologous recombination event mediated by a conserved 8-mer sequence present at both the L-terminus and within the IR4 gene. The joining of these sequences results in the generation of a unique ORF present only in the genome of DIPs. This ORF is expressed as a 31 kDa 'hybrid protein' composed of the amino-terminal 196 amino acids of the EICP22 protein (a homologue of ICP22 of HSV-1) linked in-frame to the carboxy-terminal 68 amino acids of the EICP27 protein (homologue of HSV-1 ICP27). Unique to EHV-1 persistently infected cells is a 2.2 kb transcript (not detected in EHV-1 cytolytic infection) that maps to the UL/IR junction and is antisense to the IE mRNA. Interestingly, this transcript exhibits significant homology to the 'latency associated transcripts' (LATs) of HSV-1, which appear to be associated with HSV-1 reactivation rather than establishment of latency.

Lastly, in EHV-1 persistently infected cells, transcription of certain viral genes appears to be delayed as compared with viral transcription in cytolytically infected cells. Recent findings reveal that expression of the 31 kDa EICP22/EICP27 hybrid protein down-regulates expression of specific EHV-1 promoters. Moreover, altered forms of the EHV-1 IE polypeptides have been observed only in the persistently infected cells. Taken together, these studies indicate that altered or aberrant viral regulatory mechanisms may be involved in establishing or maintaining persistent infection.

Evolution

The five members of the equine herpesviruses are related, but are biologically distinct. Initial DNA sequence analyses have revealed that genes identified to date are colinearly arranged in the genomes of EHV-1, EHV-3 and EHV-4, all of which possess a two-isomer genomic structure. The evolutionary relationships have become more apparent now that EHV-2 is sequenced in its entirety and data on EHV-5 sequences and genomic organization are available. It is clear that EHV-1 and EHV-4 are closely related and may have arisen from the same ancestor. The same is true for EHV-2 and EHV-5. However, it is not possible to determine exactly the EHV ancestor since additional sequence data (especially on EHV-3) are not available.

Serological Relationship and Variability

The four EHV serotypes do share certain antigens, but are considered antigenically distinct. EHV-1 and EHV-4 are closely related antigenically, such that crossneutralizing antibodies are generated following multiple exposures to either EHV-1 or EHV-4. Also, EHV-2 and EHV-5 are closely related. Almost no data are available on the relationship of EHV-3 to other members of the equine herpesviruses, however, all of the EHVs are believed to share complement-fixing antigens.

Epidemiology

Rhinopneumonitis caused by EHV-1 and EHV-4 is spread by direct or indirect contact (ingestion and inhalation). The virus is most commonly shed in nasal droplets for at least 14 days and is present in large amounts in aborted fetuses and the secundinae; however, the virus does not appear to be spread through the genital tract.

EHV-1 infection can also result in spontaneous abortions in pregnant mares. Horses are most susceptible to EHV-1 infection between the eighth and eleventh months of pregnancy. The peak incidence is in the ninth and tenth months at which time approximately 70% of abortions occur.

EHV-2 and EHV-5 have been isolated from the respiratory tract, kidneys, spleen, testicles, genital tract and rectum. Once infected, the horse is a lifelong carrier and excreter of the virus. The exact modes of spread of EHV-2 and EHV-5 are unknown.

EHV-3 causes a mild coital exanthema that is spread by genital contact and, rarely, the respiratory route. An EHV-3 infection is usually cleared after 14 days and is not associated with equine abortions.

Transmission and Tissue Tropism

EHV-1 and EHV-4 are spread mainly by nasal discharge. EHV-2 and EHV-5 establish a chronic infection and may be spread by the respiratory route. EHV-3 is spread by genital contact.

EHV-1 has a wide host range as described earlier, whereas EHV-4 is more limited. EHV-2, EHV-3 and EHV-5 are restricted mainly to cells of equine origin.

Pathogenicity

EHV-1 and EHV-4 cause a mild rhinopneumonitis characterized by a profuse nasal discharge. EHV-1 is also associated with spontaneous abortions as well as neurological disease. Although EHV-1 and EHV-4 respiratory infections are clinically indistinguishable, their pathogenicity is quite different. EHV-1 infection

results in a systemic viremia that can lead to neurological disease. Alternatively, EHV-4 infection is restricted to tissues of the respiratory tract. EHV-2 and also EHV-5 infections are acquired horizontally early in life usually by inhalation. EHV-2 and EHV-5 establish a chronic life-long infection. EHV-3 causes an acute coital exanthema in both the mare and the stallion.

Clinical Features of Infection

EHV-1 and EHV-4 cause outbreaks of upper respiratory disease ('common cold') in young horses (EHV-4 also in adult horses) with no previous exposure to the viruses. Infection is characterized by fever (39–41°C) lasting 2–5 days, and the animal suffers from serous nasal discharge and congestion of the nasal mucosa and conjunctiva. Less frequently, one can detect a transitory period of anorexia, enlargement of the submandibular lymph nodes and edematous swelling of the subcutis and tendon sheaths of the legs. An initial leukopenia is followed by leukocytosis before the temperature falls. Recovery is usually uneventful and occurs within one week. Older horses show few or no clinical signs, although increased sensitivity is seen in stressed horses. Death from naturally acquired infection resulting in neurological disease is not uncommon.

Equine abortions induced by EHV-1 usually occur late in gestation (8–11 months). The foals are usually born dead, but if alive, often succumb to pneumonia within the first few days. Clinical signs of neurological disease caused by EHV-1 are highly variable and include paresis, ataxia and paralysis. EHV-1 and EHV-4 have been isolated from the central nervous system of infected horses; however, isolation of the viruses from the CNS is uncommon. The virus strains do not invade the extravascular nervous tissue and do not appear to be neurotropic. The virus spread from the respiratory tract to the CNS probably occurs via infected leukocytes. Some horses have fully recovered from neurological disease with no permanent neurological sequelae.

The role of EHV-2 and EHV-5 in clinical disease is virtually unknown. However, the viruses have been associated occasionally with chronic throat infections and have been isolated from the respiratory tract of horses with respiratory disease.

An incubation period as long as 10 days can be observed after natural infection with EHV-3. The initial lesions are small (1–2 mm), raised and reddened papules. The lesions then progress rapidly to the pustular form, and there is a general reddening of the vaginal mucosa in the mare. The number of lesions increases in the first few days, and by day 6, many of the lesions form ulcers up to 20 mm in diameter and 5 mm deep. Lesions can also be seen on the vulva and perineal skin, as well as the penis and prepuce of the stallion. The disease is usually mild such that the temperature, pulse, appetite and respiration remain close to normal. The severity of the disease can be increased by secondary bacterial infections; however, uneventful cases are usually cleared within 2 weeks. Lastly, EHV-3 is not abortigenic and does not lead to infertility.

Pathology and Histopathology

Respiratory disease caused by EHV-1 and EHV-4 results in inflammation, congestion and sometimes necrosis of the upper respiratory tract. Extensive swelling of the nasal mucosa may occur, and in later stages, the lungs may become involved. One can find typical herpesvirus inclusion bodies in the nuclei of the respiratory epithelium. The respiratory infection can become more serious if followed by a secondary bacterial infection which may lead to bacterial pneumonia.

Pregnant mares that abort due to EHV-1 infection usually abort only once. The aborted fetuses present with widespread hemorrhages and edema, as well as a yellowish discoloration of the fetal conjunctiva and splenomegaly. The classic histopathology includes the presence of eosinophilic intranuclear inclusion bodies in various organs of the aborted fetuses. However, the gross pathological and histopathological alterations are sometimes not as obvious and only sensitive methods (virus isolation, polymerase chain reaction) are able to confirm the EHV-1 abortion. Classically, features associated with EHV-1 induced abortions differ in those fetuses aborted during the first 6 months of gestation as compared to those aborted after 6 months. Those aborted before 6 months present with widespread cell necrosis and inclusion bodies in the liver and lung. Those aborted after 6 months exhibit jaundice, subcutaneous edema, excessive pleural fluid, pulmonary edema, splenomegaly and necrosis of the liver.

In experimental EHV-1 infections, a severe hepatitis is observed following intraperitoneal infection of the Syrian hamster, and a model of respiratory infection is also available in the hamster. Intranasal infection of mice with EHV-1 results in respiratory disease and subsequent cell-associated viremia, thus serving as a model that closely mimics the disease in equines. The murine model of EHV-1 infection is widely used in virulence and immunogenicity studies.

EHV-2 and also EHV-5 infection becomes widespread throughout the body, and the viruses have been isolated from a variety of tissues. The infected animal becomes a life-long carrier, and the viruses remain highly cell-associated.

Tissues affected following an infection with EHV-3 include the vaginal and vestibular mucosa, penis, prepuce and the skin of the perineal region. One of the characteristics of an infection with EHV-3 is the sloughing of the surface epithelial cells. On occasion the skin of the lips and mucus membranes of the respiratory tract may become involved, but the exanthema is usually mild.

Immune Response

Neutralizing antibodies are detected in the serum soon after an EHV-1 or EHV-4 infection. The neutralizing antibodies can first be detected 7–10 days after infection and are most abundant after several weeks. However, the immunity is short-lived, in that horses can be re-infected and exhibit respiratory symptoms in just 3 months after the initial infection. Multiple exposures to either EHV-1 or EHV-4 will result in the development of neutralizing, cross-reactive antibodies. However, cell-mediated immune responses are thought to be primarily responsible for induction of a sustainable immunity.

Immunity to EHV-2, EHV-3 and EHV-5 is poorly understood; however, virtually all horses have antibodies to EHV-2 and EHV-5, confirming that these viruses are widespread.

Prevention and Control

A number of vaccine approaches are followed to combat EHV-1 infections, among them modified live vaccines (Rhinomune™ or Prevaccinol™), inactivated vaccines which mostly contain both EHV-1 and EHV-4 (Pneumabort K™, Resequin™, Prestige™ and Duvaxyn™) and also subunit vaccines, also covering both viruses (Cavalon IR™). Unfortunately, some EHV vaccines cause undesirable side effects, and most do not afford acceptable levels of protection. All vaccines must be given repeatedly to pregnant mares usually in the third, seventh and ninth months of pregnancy, and to ensure protection, a good level of population immunity is imperative. To protect against viral rhinopneumonitis outbreaks, the vaccine is usually given to all horses every 3–6 months.

Clinical management often involves the use of antibiotics to prevent severe bacterial complications following the viral rhinopneumonitis. Control of EHV-1 and EHV-4 infections involves isolation and quarantine of infected horses (at least 3 weeks) and sound hygiene for prevention of viral infection, since the viruses are highly contagious. Quarantine procedures are required more often with EHV-1 infections, since EHV-1 can lead to more serious disease of the CNS. Since most of the EHV vaccines provide unacceptable levels of protection, the first step in the prevention and control of EHV-1 and EHV-4 infections involves specific management practices and adequate day-to-day care of the animals. The viruses can be spread easily in contaminated feed and water. In addition, minimizing stress and close contact of large groups of horses can prevent the spread of disease.

Lastly, several investigators have examined the effects of some antiviral drugs on the replication of equine herpesviruses. EHV-1 was shown to be resistant to hydroxyurea, but was sensitive to arabinosylthymidine (Ara-T) which specifically inhibited the phosphorylation of deoxycytidine and deoxythymidine by the virus-encoded thymidine kinase, but not by host kinases. Other deoxythymidine analogs were also shown to be somewhat effective against viral replication.

Future Perspectives

Considerable progress in unraveling the nucleotide sequences of EHV-1, EHV-2, EHV-4 and EHV-5 has been made during the last years, and the genomes of EHV-1, EHV-2, and EHV-4 have been entirely sequenced. With this information in hand, it will be possible to pursue studies on gene expression and on those proteins that are involved in virulence of individual EHV-1 strains. These studies will in turn open the possibility for a rational design of anti-EHV vaccines, especially against the most important pathogens, EHV-1 and EHV-4. These goals may be achieved by the use of viral deletion mutants that carry targeted gene deletions. In addition, the suggested interaction of EHV-2 with EHV-1 can be addressed using molecular techniques. Several researchers concentrate on the site of EHV-1 latency which is probably – unlike other alphaherpesviruses – not the neuronal tissues. Using these approaches, a better understanding of EHV biology might be possible in the near future and will open new perspectives in the understanding of diseases caused by EHV.

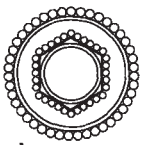
EQUINE INFECTIOUS ANEMIA VIRUS (*RETROVIRIDAE*)



Ronald C Montelaro, Department of Molecular Genetics and Biochemistry, University of Pittsburgh School of Medicine, Pittsburgh, USA

History

Equine infectious anemia (EIA), colloquially known as swamp fever, has been documented in numerous diverse geographical areas and is currently considered a worldwide disease that occurs only in members of the family Equidae. EIA was first identified as an infectious disease of horses by veterinarians in France in 1843. In 1904, the infectious organism that caused EIA was identified as a 'filterable agent', making EIA the first animal disease to be assigned a viral etiology.

Despite this early identification of the equine infectious anemia virus (EIAV), the characterization of this virus was extremely slow because of the difficulties experienced in the isolation and propagation of the virus in cell cultures. Thus, the major focus on the control of EIA has been the development of regulatory policies that involve the identification and elimination of EIAV-infected horses. More recently, advances in animal vaccine strategies and the demand for animal models for acquired immune deficiency syndrome (AIDS) vaccine development have provided renewed impetus to the development of an EIAV vaccine to prevent virus infection. EIAV also offers an important model for the role of antigenic variation in a persistent retrovirus infection.

Classification

EIAV is classified as a member of the lentivirus subfamily of retroviruses based on criteria of virion morphology, serological properties and genomic sequence homologies. There has been no formal further subdivision of EIAV isolates into subtypes.

Properties of the Virion

The EIAV particle has the general morphology of a lentivirus, including an oblong core enclosed in a viral envelope with surface projections (**Fig. 1**). The oblong core observed in EIAV is characteristic of lentiviruses, in contrast to the icosahedral cores found in most oncoviruses. This distinctive structural feature was the initial indication that human immunodeficiency virus 1 (HIV-1) was related to EIAV and was a member of the lentivirus, rather than the oncovirus, subfamily of retroviruses. The virus particles appear roughly spherical in the electron microscope, although there are various degrees of polymorphism, depending on the sample preparation. The overall diameter of the virion is about 100 nm. The surface projections extend about 7 nm and

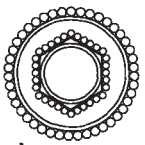
EQUINE INFECTIOUS ANEMIA VIRUS (*RETROVIRIDAE*)



Ronald C Montelaro, Department of Molecular Genetics and Biochemistry, University of Pittsburgh School of Medicine, Pittsburgh, USA

History

Equine infectious anemia (EIA), colloquially known as swamp fever, has been documented in numerous diverse geographical areas and is currently considered a worldwide disease that occurs only in members of the family Equidae. EIA was first identified as an infectious disease of horses by veterinarians in France in 1843. In 1904, the infectious organism that caused EIA was identified as a 'filterable agent', making EIA the first animal disease to be assigned a viral etiology.

Despite this early identification of the equine infectious anemia virus (EIAV), the characterization of this virus was extremely slow because of the difficulties experienced in the isolation and propagation of the virus in cell cultures. Thus, the major focus on the control of EIA has been the development of regulatory policies that involve the identification and elimination of EIAV-infected horses. More recently, advances in animal vaccine strategies and the demand for animal models for acquired immune deficiency syndrome (AIDS) vaccine development have provided renewed impetus to the development of an EIAV vaccine to prevent virus infection. EIAV also offers an important model for the role of antigenic variation in a persistent retrovirus infection.

Classification

EIAV is classified as a member of the lentivirus subfamily of retroviruses based on criteria of virion morphology, serological properties and genomic sequence homologies. There has been no formal further subdivision of EIAV isolates into subtypes.

Properties of the Virion

The EIAV particle has the general morphology of a lentivirus, including an oblong core enclosed in a viral envelope with surface projections (**Fig. 1**). The oblong core observed in EIAV is characteristic of lentiviruses, in contrast to the icosahedral cores found in most oncoviruses. This distinctive structural feature was the initial indication that human immunodeficiency virus 1 (HIV-1) was related to EIAV and was a member of the lentivirus, rather than the oncovirus, subfamily of retroviruses. The virus particles appear roughly spherical in the electron microscope, although there are various degrees of polymorphism, depending on the sample preparation. The overall diameter of the virion is about 100 nm. The surface projections extend about 7 nm and

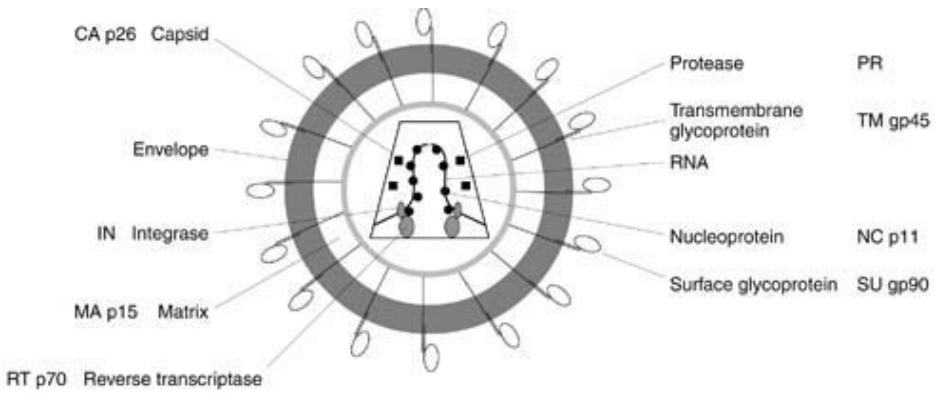


Figure 1 Virion morphology and protein organization of equine infectious anemia virus.

appear to be distributed on the viral surface in a symmetrical pattern.

Properties of the Genome

The EIAV genome consists of a duplex of single-stranded, positive-sense RNA. The genomic organization of EIAV is characteristic of a complex retrovirus, but is the simplest and smallest of characterized human and animal lentiviruses (**Fig. 2**). The viral RNA contains about 8200 bases and contains three major genes (*gag*, *pol* and *env*), encoding viral structural proteins, and three minor genes (*tat*, *S2* and *rev*), encoding nonstructural proteins that regulate various aspects of virus replication. The order of the EIAV genome is 5′-R–U5–*gag*–*pol*–*env*–U3–R-3′. The *tat* and *S2* genes are encoded as distinct alternate reading frames within the *pol-env* intergenic region, while the *rev* gene is encoded by alternate reading frames contained at the beginning of the *env* gene sequences and following the 3′ end of the *env* gene. The relatively small size of the EIAV genome compared to other lentiviruses is primarily due to the much smaller size of the *pol-env* intergenic region.

The EIAV *gag* gene encodes the four viral core proteins in the order of 5′-p15–p26–p11–p9-3′, while the *env* gene encodes the two envelope glycoproteins of the virus in the order of 5′-gp90–gp45-3′. The *pol* gene encodes a complex of enzymes with an organization of 5′-protease–reverse transcriptase–RNAse H–dUTPase–integrase-3′. As with other lentiviruses, the EIAV *tat* and *rev* genes encode important regulatory proteins that either transactivate virus transcription (Tat) or control viral transcription patterns (Rev) after infection of host cells. The function of the 8 kDa protein encoded by the *S2* gene remains to be defined, although mutation studies of this gene indicate that it is not essential for virus replication. The long terminal repeat (LTR) sequences of EIAV contain the usual complex of transcriptional regulatory domains distinctive of lentiviruses.

Properties of the Viral Proteins

The proteins encoded by the *gag* and *env* genes of EIAV constitute the major structural proteins of the virus (cf. **Fig. 1**). The gp90 protein is a highly glycosylated, hydrophilic surface (SU) protein that forms the outermost knobs of the envelope projections, while the gp45 is a sparsely glycosylated, hydrophobic transmembrane (TM) protein that forms the membrane-spanning spike of the envelope projection. There are about 300 copies each of the envelope glycoproteins per virion, and the surface projections appear to be composed of trimers of gp90 and gp45. The final component of the EIAV envelope

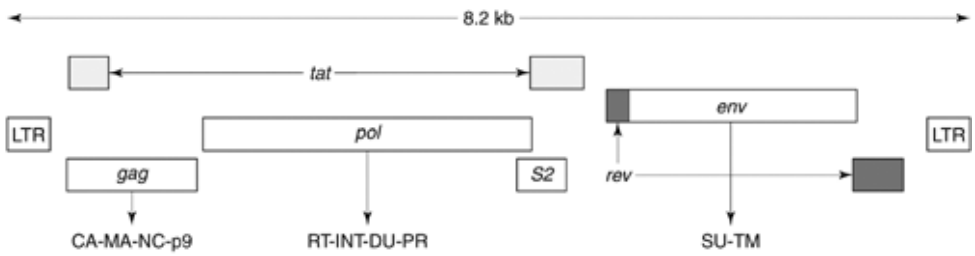

Figure 2 Organization of the EIAV genome indicating viral genes (italic) and the respective proteins encoded by these genes.

structure is the fatty acylated p15 that forms a continuous matrix (MA) immediately beneath the lipid bilayer of the virus particle. The virion core shell or capsid (CA), composed predominantly of p26 molecules, encloses a helical ribonucleoprotein complex containing the basic nucleoprotein (NP), p11, and various polymerases (reverse transcriptase (RT), integrase (IN) and dUTPase (DU)) in close association with the viral RNA genome. The location of the final core protein, p9, is not certain, but it has been proposed as a linker protein between the core shell and envelope matrix. Recent experiments have indicated that the EIAV p9 protein mediates late stages of viral budding.

The *gag*-encoded proteins of the virus are present in molar amounts that are at least 10-fold greater than the envelope glycoproteins, in the range of 3000–5000 copies per virus particle. In contrast, the *pol*-encoded enzymes appear to be present in the virus at levels of about 10 molecules per virion.

Replication Strategy

The EIAV replication cycle is characteristic of retroviruses in general and lentiviruses in particular. Viral recognition, attachment and penetration of target cells is believed to be mediated by specific interaction of the viral envelope glycoproteins and cellular receptor proteins contained in the plasma membrane. These putative receptors for EIAV have not been identified. Once inside the cytoplasm of the target cell the virus reverse transcriptase copies the single-stranded RNA genome into double-stranded DNA provirus that is then transported to the nucleus of the cell. There is no evidence for translation of the incoming EIAV genome at this stage of infection. Once inside the cell nucleus, the EIAV integrase mediates apparently random incorporation of the provirus DNA into cellular chromosomes, although some extrachromosomal viral DNA is always present in productively infected cells. There is typically a total of about 10 copies of proviral DNA per infected cell. Cytopathic infections by EIAV have been correlated with higher ratios of integrated to unintegrated proviral DNA.

Transcription of the proviral DNA by cellular polymerases produces a complex pattern of viral messenger RNA species whose relative proportions may differ, depending on the virus strain and target cell. In all instances, the predominant EIAV transcripts are an 8.2 kb transcript representing the full-length genomic RNA and translated to produce the *gag* and *pol* gene products, and a 3.5 kb mRNA that is a singly-spliced transcript translated to produce the viral envelope proteins. Lentivirus-infected cells usually contain, in addition to these major viral transcripts, a heterogeneous population of small multiply-spliced RNA that are used to produce the various regulatory proteins. In the case of EIAV, however, infected cells reveal only minute quantities of these small, multiply-spliced RNA species. The relatively low abundance of small transcripts may in part reflect the relative genetic simplicity of EIAV and the lack of extensive splicing to insure production of all of the minor viral genes. On the other hand, it is intriguing that the 3.5 kb transcript is in fact a tricistronic messenger that can produce by *in vitro* translation the viral Tat and Rev proteins in addition to the more abundant envelope glycoproteins. The use of a tricistronic messenger may represent a novel mechanism of maximizing genetic efficiency in EIAV replication.

The viral Gag and Env proteins are initially produced as polyproteins that are cleaved into the mature virion components by a combination of viral and cellular proteases. The only modification documented in the core proteins is a fatty acylation at the N-terminus of the matrix protein, p15. The envelope proteins are modified by *N*-linked glycosylation. Although the gp90 and gp45 polypeptides contain about 400 amino acid residues, the gp90 contains an average of 17 potential *N*-linked glycosylation sites, while the gp45 contains only about five potential glycosylation sites. By comparison to HIV-1 gp120, it is assumed that all potential glycosylation sites are occupied by complex oligosaccharides.

Little is known about the precise mechanisms of EIAV assembly, although it is assumed that it follows the general model for retrovirus assembly. Accordingly, the viral envelope glycoproteins are initially inserted into the plasma membrane to create distinct sites of virus assembly at which the Gag polyprotein is accumulated beneath the membrane lipid and cleaved into the mature virion proteins as the particle buds from the cell surface and is released to produce progeny virus.

The mechanisms of EIAV cytopathicity during this replication process are also uncertain. Various studies have suggested that a major mechanism of EIAV cytopathogenesis is structural and functional perturbations of cellular plasma membranes by the viral envelope glycoproteins. In this regard, peptide domains with cytolytic, membrane fusion, calmodulin-binding functions have been identified in the EIAV transmembrane glycoprotein.

Geographic and Seasonal Distribution

EIAV has been diagnosed in many areas of the world and is considered a worldwide disease of horses.

Although localized outbreaks of disease can occur, the incidence of EIAV-infected horses is highest in tropical and subtropical climates, presumably due to the longer seasons and more abundant populations of insect vectors that may transmit EIAV between horses. In the USA, the overall infection rate is reported to be about 0.2% of horses that are tested for EIAV-specific antibodies in diagnostic assays approved by the US Department of Agriculture (USDA). These infection rates, however, are somewhat misleading as only less than 10% of the general horse population in the USA is ever tested for EIAV. In more general surveys of selected herds in the southeastern USA, infection rates of 15% were observed. EIAV infections are especially prevalent in Central and South America, where unregulated herds may have infection rates up to 50%. Although the probability of EIAV infection by insect vectors is greatest during seasons that are warm, infections can occur throughout the year via mechanical transfers of blood by hypodermic needles and other veterinary instruments. Sexual transmission of EIAV has not been demonstrated to date.

Host Range and Virus Propagation

EIAV appears to infect only members of the family Equidae. There is no evidence to support the concept of natural or experimental infections of humans or of other mammalian species. EIAV infection of horses results in high levels of virus replication, persistent infection and clinical disease. EIAV infection of donkeys produces only limited virus replication, presumably a persistent infection, but no signs of clinical disease.

Field strains of EIAV can only be propagated *in vitro* in cultures of equine monocyte or macrophage cells, where virus infection typically produces a cytopathic effect within several days. Large-scale production of EIAV is limited to cell culture-adapted strains of virus that can be grown in primary cultures of equine dermal cells or fetal equine kidney cells and in a limited selection of nonequine continuous cell lines, including canine fetal thymus (Cf2th) cells and the Fea and FEF feline cell lines. The cell-adapted strains of EIAV are noncytopathic to these permissive cell lines. Field strains of EIAV will retain their pathogenic properties when propagated in leukocyte cultures, but usually become avirulent when adapted to other types of cell culture. Cell-adapted strains of EIAV that retain their virulence have been produced by back passage of avirulent cell-adapted strains in ponies or horses. There is no evidence for infection of cultured human cells by EIAV.

EIAV production in cell cultures is most easily detected by the presence of viral antigens or reverse transcriptase activity in culture media.

Genetics

Like other retroviruses, EIAV replication is mediated by a virion reverse transcriptase (RT) that copies the viral RNA genome into proviral DNA that is found in the nucleus of infected cells randomly integrated into the cellular chromosome and as extrachromosomal molecules. There are typically only about 10 copies of EIAV DNA per infected cell. EIAV replication in horses is characterized by relatively rapid and diverse genomic mutations that produce an apparently wide variety of variant virus strains. Analyses of sequential antigenic variants of EIAV from experimentally infected horses suggests that the rate of mutation in the envelope gene of the virus is greater than 10^{-2} base substitutions per site per year. The fidelity of DNA synthesis by purified EIAV RT has been measured *in vitro*, and an average error rate of 1/900 bp has been estimated. This value is similar to the *in vitro* error rate calculated for HIV (1/700 bp), but significantly lower than the rate observed for oncovirus RT, such as avian myeloblastosis virus (1/3000 bp). The error-prone nature of EIAV RT produces significant biological diversity that is important in EIAV persistence and pathogenesis. As demonstrated for HIV and simian immunodeficiency virus (SIV), recombination between variant EIAV genomes in infected cells may also contribute to genetic diversification during persistent infection.

Evolution

Phylogenetic analyses based on the nucleotide sequences of various retroviruses indicate that EIAV is most closely related to the ungulate lentiviruses (visna-maedi virus, caprine arthritis encephalitis virus and bovine immunodeficiency virus) and equally divergent from the human and simian immunodeficiency viruses.

Serologic Relationships and Variability

Field and laboratory isolates of EIAV display a remarkable variability in antigenic properties. The core proteins of the virus contain conserved antigenic determinants that are the basis of current serological diagnostic assays. The viral glycoproteins also contain a limited number of conserved antigenic determinants, but predominantly present an array of variable antigenic sites that can be distinguished by their reactivity with monoclonal antibodies or by neutralization properties with polyclonal immune

serum from infected horses. The range of variation observed among EIAV isolates has precluded any classification of virus strains on the basis of serological properties.

Immune serum from EIAV-infected horses is reactive with the respective major core protein of most animal and human lentiviruses, but not with any of the major core proteins of oncoviruses. Immune serum taken from other species infected with a lentivirus do not generally reveal a crossreactivity with EIAV or with other lentiviruses. This one-way serological reactivity suggests that horses infected with EIAV uniquely recognize a conserved lentivirus-specific antigenic determinant.

Epidemiology

The prevalence of EIAV infections is greatest in warm climate geographical areas with a high insect population. During the 1980s and 1990s, the EIAV infection rate reported by the USDA dropped from about 4% to less than 0.2%. However, these testing results do not reflect the general horse population: less than 10% of the horses in the USA are tested for EIA, usually because of requirements for transportation across state lines or for participation in organized shows or races. General surveys of unregulated herds in the Southeast demonstrate infection rates of up to 15%. In limited surveys of Latin American countries, infection rates in unregulated herds frequently approach 50%, indicating that EIAV infection is epidemic in these areas.

Transmission and Tissue Tropism

Blood from persistently infected horses is the most important source of EIAV for transmission; *in utero* transmissions of EIAV from mare to foal are evidently very rare. This blood transfer can be affected by human or blood-feeding vectors. EIAV has been shown to remain infectious on hypodermic needles for up to 96 h, emphasizing the potential for transmission via routine animal husbandry or veterinary medical practices. However, the mechanical transmission of EIAV by arthropods, especially horse flies, is generally accepted as the major natural means of transmission in the field. Transmission of EIAV by a single horse fly carrying only about 10 nl of virus-infected blood has been documented under experimental conditions.

The target cells during persistent EIAV infections appear to be exclusively cells of the monocyte/macrophage lineage; there is no evidence for infection of lymphocytes, as observed with some other lentiviruses. The virus burden in infected horses is predominantly in tissue macrophages found in liver, kidney and spleen, with much lower levels of virus found in lymph nodes, bone marrow or in circulating monocytes. Thus, the relatively high levels of viremia (10^{4-6} $TCID_{50}$) observed during episodes of chronic EIA evidently result primarily from the production and release of virus from infected tissue macrophages, rather than an extensive infection of blood monocytes.

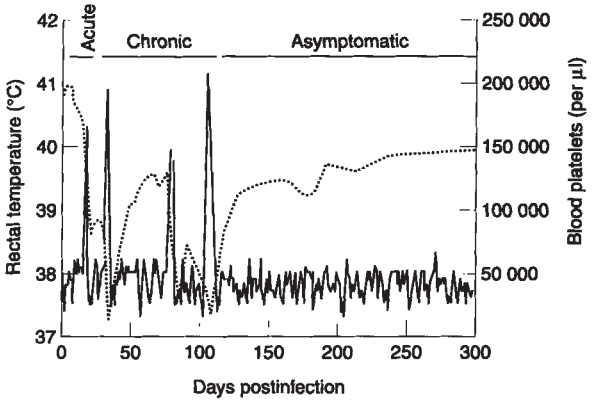

Figure 3 Clinical profile associated with EIAV infection of horses indicating the characteristic stages of EIA. Febrile episodes are defined as rectal temperatures (—) above 39°C (103°F), and thrombocytopenia is defined as platelet levels (----) below 105 000 per microliter of blood.

Pathogenicity

Field isolates and laboratory strains of EIAV differ markedly in their pathogenicity, ranging from avirulent to lethal strains of the virus. Little is known about the viral determinants or host factors that influence the course of virus replication and pathogenesis. In other lentiviruses, differences in viral pathogenesis have been mapped to specific changes in viral envelope genes or to changes in gene regulatory sequences in the viral genome. It is likely that variation in EIAV pathogenicity will follow a similar pattern.

Clinical Features of Infection

The clinical response of horses following artificial inoculation or natural exposure to EIAV is variable and depends in part on host resistance factors, viral virulence factors and environmental factors (e.g. weather, work load, etc.). In general, EIAV infections can be apparent, with distinctive clinical symptoms, or inapparent, without any clinical signs of EIA. The clinical disease is typically described as acute, chronic or asymptomatic (**Fig. 3**).

Acute EIA is most often associated with the first exposure to the virus, with fever and hemorrhages evident from 7–30 days after exposure. Acute disease is thought to be associated with massive virus replication in, and destruction of, infected macrophages. Horses in the initial phase of acute EIA will be seronegative because the immune system has had insufficient time to respond to the viral antigens. During the peak of the febrile response in acute EIA, viremia of greater than 10^6 horse infectious doses per milliliter of whole blood is often observed. The initial acute phase of EIA infection may not be seen by the veterinarian unless there is an epizootic of the infection in a group of horses. Even then, the horses must be under close supervision for the initial fever and anorexia to be detected. Neither anemia nor edema are seen at this stage of disease.

The more classic clinical signs of EIA, such as loss of weight, anemia, diarrhea and edema, are seen later during recurring cycles of the illness, which appear at irregular intervals ranging from a couple of weeks to several months. The frequency and severity of clinical episodes in horses with chronic EIA usually decline with time, about 90% occurring within 1 year of infection. Horses with chronic EIA are seropositive and have variable viremia levels which are highest during the periodic febrile episodes. Although a small percentage of chronic EIA cases may result in death, the predominant clinical course of infection is a cessation of detectable clinical symptoms by the end of the first year postinfection and the establishment of a lifelong inapparent carrier stage.

The highest percentage of EIAV-infected horses in the field are in fact inapparent carriers. These horses have no clinical illness associated with the viral infection and viremia is usually undetectable. However, these inapparent carriers maintain high levels of EIAV-specific antibodies, suggesting a chronic low level of virus replication. Inapparent carriers can be shown to harbor infectious EIAV by transfusions of whole blood (200 ml) to recipient horses, who will become seropositive to EIAV within 3–6 weeks postinoculation. In addition, treatment of certain inapparent carriers with immunosuppressive drugs or exposure to extreme stress can cause the recrudescence of chronic EIA, even in some horses that have been free of clinical symptoms for years.

Pathology and Histopathology

Gross and histopathological lesions in EIAV-infected horses are variable and closely associated with levels of viral replication. In the acute stage of EIA, gross pathological lesions consist of swelling of the parenchymatous organs, and hemorrhages can be observed in most tissues. The most pronounced histopathological lesions are hepatic and lymphoid necrosis in association with large numbers of activated macrophages and Kupffer cells. Hepatic necrosis is most severe near the central vein, evidently resulting from degenerative changes in the parenchymal cells. Lesions in the spleen are characterized by degenerative erythrocytes, and small focal hemorrhages are found in the splenic capsule and adjacent tissue. Lymphocytic infiltrations can be observed in several organs, including liver, spleen, lymph node, kidney, heart and lung. The majority of these lesions are thought to be the combined effect of immune-mediated lysis of virus-infected cells and an immune complex-mediated inflammatory response.

The pathological changes in the chronic form of EIA include a developing immunological control of virus replication. Gross pathological lesions include splenomegaly, lymphadenopathy and hepatomegaly. Microscopic changes are characterized by infiltration of lymphoid cells in almost all organs and tissues. Anemia has long been considered the hallmark of EIA. The two major causes of anemia, hemolysis and bone marrow depression, are closely associated with replicating virus. Hemolysis is immunologically mediated. Erythrocytes are coated with the viral surface glycoprotein which, in the presence of specific antibodies and bound C3, induces erythrophagocytosis and complement-mediated hemolysis. Bone marrow suppression is less well characterized but appears to be associated with iron deficiency. Thrombocytopenia is frequently the earliest pathology observed during chronic EIA and can precede the detection of virus-specific antibodies. The mechanism for the marked reduction in blood platelets is unknown but has recently been associated with cytokine dysregulation.

Immune Responses

Horses infected with EIAV typically become seropositive in standard serological assays within 21 days postinfection. The humoral immune responses are predominantly against the viral envelope glycoproteins, gp90 and gp45, and the major core protein, p26. All currently approved diagnostic assays for EIAV infection are based on the detection of antibody to the major core antigen, although the antibody response to the envelope glycoproteins is at least 10-fold greater than the antibody titer measured against the p26 protein. Significantly lower levels of antibody can be detected against virtually all of the other structural and nonstructural proteins encoded by EIAV. Interestingly, EIAV-specific antibody levels remain rela-

tively constant throughout the course of chronic EIA and even in the asymptomatic stage of infection.

The immune responses generated during chronic EIA initially mediate significant pathogenesis in the presence of sufficient levels of EIAV antigenemia, but progressively evolve to establish a strict immunologic control over virus replication. Thus, the EIAV system is unique among lentiviruses in that the host immune responses routinely accomplish an effective control of aggressive virus replication and recurring clinical disease to maintain an indefinite inapparent stage of infection. The immune correlates of this protection remain to be defined. However, it has been shown that the neutralizing capacity of serum antibodies elicited to EIAV during the chronic stage of disease progressively increases, indicating an evolution of immune responses to the sequential generation of antigenic variants of virus. In addition, recent studies have demonstrated a lengthy and complex evolution of antibody and cellular immune responses to experimental EIAV infections of horses, demonstrating a dynamic maturation process that apparently correlates with the development of protective immunity. The specific humoral or cellular immune correlates of protection have not yet been identified. The ability of the horse immune responses to overcome the array of persistence and escape mechanisms employed by EIAV suggests that a successful vaccine is feasible.

Prevention and Control

The transmission of EIAV infection has been controlled by improving animal husbandry techniques to prevent the spread of infected blood, by reducing the horse fly population in the vicinity of herds, and primarily by identifying and segregating or sacrificing horses that are seropositive for the virus. In the USA the most common diagnostic assays are an agar gel immunodiffusion test, the Coggins assay, which was developed in the early 1970s, and enzyme-linked immunosorbent assay (ELISA), which was approved by the USDA as an EIA diagnostic assay in the 1980s and 1990s. Both diagnostic assay procedures are based on the detection of serum antibodies to the major viral core protein, p26. The diagnostic ELISA has been engineered to produce a sensitivity that is equivalent to the previously established Coggins test. More sensitive diagnostic assays based on the detection of antibodies to the EIAV envelope glycoproteins have been developed, but have not yet been approved for commercial use. The most sensitive and specific assay for detecting EIAV infection is horse inoculation tests with 200 ml of whole blood from the horse being tested. The horse inoculation test is used only in rare cases where the standard serological assays may give ambiguous results.

There is currently no effective vaccine for the prevention of EIAV infection and disease. The primary challenge in developing an effective EIAV vaccine is overcoming the antigenic diversity intrinsic to this virus. An important practical requirement in the development of any EIAV vaccine will be compatibility with established regulatory policies and diagnostic assays. The ability of EIAV-infected horses to routinely establish immunologic control over virus replication and disease suggests that an effective vaccine can indeed be developed, if the critical natural immune correlates of protection can be elicited by a candidate vaccine. An attenuated live EIAV vaccine with a reported protection efficacy of about 70% has been used in China and Cuba since the early 1980s, but the effectiveness of this vaccine remains to be confirmed outside these two countries. Evaluation of other candidate EIAV vaccines (inactivated whole virus, subunit vaccines, synthetic peptides, etc.) under experimental conditions has revealed a spectrum of vaccine efficacy that ranges from 'sterile protection' (prevention of infection upon inoculation with EIAV) to severe elevation of EIAV replication and exacerbation of disease. These results indicate that immune responses to EIAV are a double-edged sword that can either mediate protection or vaccine enhancement. Vaccine enhancement has previously been reported for other viral infections (dengue virus, respiratory syncytial virus, feline infectious peritonitis virus) and is of special concern with macrophage-tropic viruses. Similar examples of vaccine protection and enhancement have been reported in studies of experimental vaccines for other lentiviruses, including feline immunodeficiency virus, caprine arthritis encephalitis virus, and visna-maedi virus. These observations in several diverse animal lentivirus systems suggests that the potential for immune enhancement may be a general property of lentiviruses, including HIV-1. Current efforts in the production of a commercial EIAV vaccine are focused on the development of a vaccine that can achieve sufficient maturation of immune responses to provide protection from virus infection, but allow the serological differentiation between vaccinated and infected horses. In this regard, DNA vaccine strategies appear to be well suited to accomplish these criteria for a commercial EIAV vaccine.

Future Research

EIAV provides a dynamic system for examining the interaction between virus populations and host immune responses that are evolving in response to

each other. In addition, EIAV offers a remarkable model for studying the delicate balance between immune responses to a persistent virus infection that result in disease and those that have beneficial results. A characterization of the nature of protective and enhancing immune responses can provide important information about the mechanisms of lentivirus disease and the type of immune responses to be elicited or avoided by a vaccine. The results of these studies in the EIAV system should be applicable to other lentiviruses, including HIV-1.

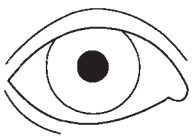
EYE INFECTIONS



James Chodosh, Molecular Pathogenesis of Eye Infection Research Center, Dean A. McGee Eye Institute and Department of Ophthalmology, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma, USA

Introduction

The eye contains diverse tissues intricately linked to subserve visual function (**Fig. 1**). The ocular adnexae – periorbita, eyelids and lashes, lacrimal and meibomian glands – produce, spread and drain the preocular tear film, physically protect the sensitive ocular mucosa, and cushion the globe. The redundant conjunctiva with its low-viscosity tear film allows rapid multidirectional eye movements. Lymphoid tissues within the conjunctiva and lacrimal glands furnish acquired immune defense. The cornea and its tear film fashion the major refractive surface of the eye. The sclera forms the wall of the globe and scaffolds the intraocular tissues. The eye's lens provides additional refractive power and filters ultraviolet light. The iris diaphragm dynamically regulates the amount of light incident on the retina, and together with the choroid and optic nerve head provides immune effector cells to the interior of the eye. The retina transduces light energy into neural signals; retinal function is requisite for vision. The vascular choroid nourishes the outer layers of the retina. The anterior (aqueous) and posterior (vitreous) humors provide internal pressure sufficient for maintenance of normal anatomic relationships, nourish the interior ocular tissues, provide immunosuppressive factors necessary to the maintenance of immune deviation, and during infection act as conduits for the distribution of inflammatory cells derived from the iris, ciliary body and optic nerve head.

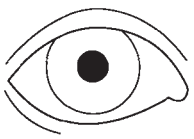
EYE INFECTIONS



James Chodosh, Molecular Pathogenesis of Eye Infection Research Center, Dean A. McGee Eye Institute and Department of Ophthalmology, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma, USA

Introduction

The eye contains diverse tissues intricately linked to subserve visual function (**Fig. 1**). The ocular adnexae – periorbita, eyelids and lashes, lacrimal and meibomian glands – produce, spread and drain the preocular tear film, physically protect the sensitive ocular mucosa, and cushion the globe. The redundant conjunctiva with its low-viscosity tear film allows rapid multidirectional eye movements. Lymphoid tissues within the conjunctiva and lacrimal glands furnish acquired immune defense. The cornea and its tear film fashion the major refractive surface of the eye. The sclera forms the wall of the globe and scaffolds the intraocular tissues. The eye's lens provides additional refractive power and filters ultraviolet light. The iris diaphragm dynamically regulates the amount of light incident on the retina, and together with the choroid and optic nerve head provides immune effector cells to the interior of the eye. The retina transduces light energy into neural signals; retinal function is requisite for vision. The vascular choroid nourishes the outer layers of the retina. The anterior (aqueous) and posterior (vitreous) humors provide internal pressure sufficient for maintenance of normal anatomic relationships, nourish the interior ocular tissues, provide immunosuppressive factors necessary to the maintenance of immune deviation, and during infection act as conduits for the distribution of inflammatory cells derived from the iris, ciliary body and optic nerve head.

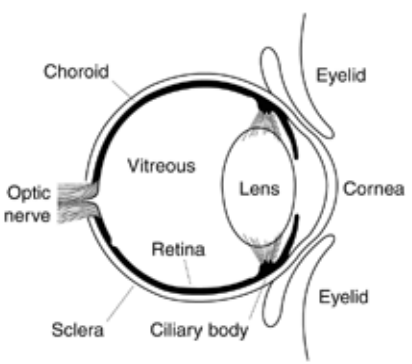


Figure 1 Cross-section of the human eye.

Eye infection by viruses most often follows direct contact with virus externally, either from infected

secretions in the birth canal (herpes simplex virus, human papillomavirus), on fomites (adenovirus), or air-borne particles (rhinovirus), or is acquired during viremia (human cytomegalovirus, measles virus). Other mechanisms of ocular viral infection include extension from contiguous adnexal disease (herpes simplex virus), spread from the upper respiratory tract via the nasolacrimal duct (rhinovirus), and transplacental passage of infectious virus (rubella virus). Rarely, ocular infection may disseminate elsewhere (enterovirus 70).

Acute viral infection produces stereotypic changes in ocular target tissues. Infection of the eyelid skin induces the formation of vesicles and ulcers. Viral infection of the conjunctiva results in vasodilatation, serous discharge, hyperplasia of conjunctival lymphoid follicles, and enlargement of the corresponding draining lymph nodes. Severe conjunctival infection can cause permanent scarring of the globe to the eyelids and turning in of the eyelashes against the eye. Viral infection of the corneal epithelium induces punctate epithelial cytopathic effect evident biomicroscopically as isolated swollen epithelial cells (punctate epithelial keratitis) and loss of individual epithelial cells (punctate epithelial erosions). When extensive, the punctate erosions may coalesce to form confluent epithelial ulcers with dendritic, dendritiform or geographic morphology. With herpetic infection, corneal anesthesia can ensue, and in the absence of epitheliotropic neural growth factors, corneal epithelial integrity is impaired. Reduced corneal clarity and progressive sterile ulceration may result. Corneal stromal infection induces white blood cell recruitment; subsequent corneal scarring, vascularization and lipid deposition may permanently reduce vision. Intraocular infection manifests in inflammatory cell deposits on the posterior surface of the cornea and on the vitreous scaffold, and in free-floating leucocytes and biomicroscopically visible protein spillage into the normally cell-free and protein-poor aqueous humor. Iridocorneal and iridolenticular adhesions may develop and lead to glaucoma and cataract. Retinal infection concludes with necrosis and lost function. Viral encephalitis and meningitis can result in cranial nerve inflammation and secondary dysfunction of vision and extraocular motility.

Classical viral pathogenic mechanisms of latency, reactivation, and carcinogenesis all can be demonstrated in the eye. Herpes simplex virus causes recurrent lytic epithelial keratitis when viral reactivation within sensory ganglia of the first division of the fifth cranial nerve gives rise to virus in the preocular tear film. Necrotizing herpes stromal keratitis follows viral reactivation within the cornea stroma. Intraepithelial neoplasia and invasive squamous cell carcinoma of the conjunctiva and cornea (**Fig. 2**) have been associated with human papilloma virus types 16 and 18. When infected with oncogenic human papillomaviruses, corneal limbal stem cells can

provide a persistent source of dysplastic ocular surface epithelium. Molecular mimicry has also been demonstrated as an immunopathogenic mechanism in ocular disease. Systemic infection with hepatitis C virus is associated with autoimmunity against a corneal stromal antigen and peripheral ulcerative keratitis. In a murine model of herpes simplex infection, nonnecrotizing stromal keratitis accompanies T cell reactivity against a corneal protein antigenically similar to a herpes simplex coat protein.

Ocular Immunology of Relevance to Viral Infection

Tissue diversity within the eye and adnexa compel varied means of innate immune defense. The external surfaces of the eye (conjunctiva and cornea) encounter viruses by both airborne and contact routes. The eyelids, an intermittent barrier, periodically wipe the eye's surface free of debris and spread and drain the preocular tear film. The ability of the tear film to nonspecifically impede primary infection by viruses is unknown, although such mechanisms are well established for bacterial pathogens. An inhibitory effect of goblet cell-derived and intrinsic mucins and meibomian gland-derived lipids on viral adsorption to the ocular surface is speculative. Early in infection, aqueous tears from the main and accessory lacrimal glands furnish proinflammatory cytokines, and the conjunctival blood vessels provide both soluble and cellular components of innate immunity. After viral infection is established, aqueous tears carry lacrimal gland-derived monospecific secretory immunoglobulin A.

The constitutive defense armaments of the cornea and conjunctiva differ. The normal cornea is considered an immune-privileged site due to the high success rate of corneal transplantation; it lacks blood vessels, lymphatics, resident lymphoid cells, and Langerhans cells, expresses Fas ligand on its surface epithelium, and demonstrates reduced delayed hypersensitivity responses. Because corneal inflammation and subsequent scar reduce vision, corneal function is best served by its reduced immunologic responsiveness, also known as immune deviation. Necrotizing inflammation presupposes infection beneath the surface epithelium, and follows chemokine synthesis by infected corneal stromal fibroblasts. In contrast to the cornea, the conjunctiva is well endowed with blood and lymphatic channels, lymphoid cells and Langerhans cells, and demonstrates classical delayed hypersensitivity responses. The immunology of the interior eye is less well established, but immune deviation appears to extend beyond the cornea to the aqueous and vitreous humors and to the central retina.

Ocular Disease Caused by RNA Viruses

Conjunctivitis is probably the most common viral ocular syndrome, and typically accompanies upper respiratory infections due to RNA viruses (**Table 1**). Rhinovirus, influenza virus, respiratory syncitial virus, and parainfluenza virus conjunctivitis typically are mild and self-limited, and most patients do not seek medical attention. More serious are the keratitis, uveitis and retinitis caused by some RNA viruses. For example, influenza virus infection of the respiratory tract, usually associated with a mild and short-lived conjunctivitis, less commonly causes inflammation in the lacrimal gland, cornea, iris, retina, optic and other cranial nerves.

Like influenza virus, other RNA viruses can infect virtually every ocular tissue. For instance, rubella virus when acquired *in utero* may have devastating consequences for the eye. Characteristic features include microphthalmos, corneal haze, cataracts, iris hypoplasia, iridocyclitis, glaucoma and 'salt and pepper' pigmentary retinopathy. Rubella virus can be cultured from the lens of infected neonates at the time of cataract extraction. Congenital ocular abnormalities due to rubella, like those in other organ systems, are much worse when maternal infection ensues earliest in pregnancy.

In contrast to rubella virus, measles (rubeola) virus infection *in utero* rarely causes significant ocular disease. The classic triad of postnatally acquired measles – cough, coryza, and follicular conjunctivitis – can be accompanied by Koplik spots on the conjunctiva and a mild epithelial keratitis. Less common are optic neuritis, retinal vascular occlusion and pigmentary retinopathy. Measles keratopathy, a major source of blindness in the nonindustrialized world, typically presents as corneal ulceration in a malnourished child. A rare and fatal complication of measles virus infection, subacute sclerosing panencephalitis (SSPE), occurs in about 1 per 100 000 cases, and often years after clinically apparent measles. Along with devastating central nervous system damage, ocular abnormalities occur commonly in SSPE, including central retinal (macular) hyperpigmentation and inflammation, optic nerve atrophy, peripheral retinitis, and ocular motility disorders. Cortical blindness can occur in the absence of ocular involvement.

The most common ocular complication of mumps virus infection is dacryoadenitis, and this may occur concurrently with parotid gland involvement. Aseptic meningitis, associated oculomotor palsy, and optic neuritis also occurs. Follicular conjunctivitis, epithelial and stromal keratitis, iritis, trabeculitis, and scleritis have all been reported within the first 2 weeks after onset of parotitis.

Acute hemorrhagic conjunctivitis (AHC), caused predominantly by enterovirus type 70 and coxsackievirus A24 variant, but also adenovirus type 11, is one of the most dramatic ocular viral syndromes. Sudden onset of follicular conjunctivitis associated with multiple petechial conjunctival hemorrhages characterizes AHC. The hemorrhages may become confluent and appear post-traumatic. In approximately 1/10 000 cases due to enterovirus type 70, a polio-like paralysis can ensue. Neurologic deficits are permanent in up to one-third of affected individuals.

Human immunodeficiency virus (HIV) is the etiologic agent of the acquired immunodeficiency syndrome (AIDS). Although HIV can be cultured from the retinas of individuals with AIDS, and has been shown to be present in the donated corneas of deceased AIDS patients, a direct relationship between local viral infection and ocular disease remains to be established. One example is the dry eye so common in AIDS patients. It is not known whether primary HIV infection of the lacrimal gland, immune deficit-induced potentiation of another virus such as Epstein–Barr virus within the lacrimal gland, or a putative HIV-induced neuroimmune–endocrine defect can account for AIDS-related dry eye. However, the severe immunosuppression of AIDS results in a host of other ocular diseases (discussed below).

Ocular Disease Caused by DNA Viruses

DNA viruses (**Table 2**) are responsible for most significant ocular viral infections in the industrialized world. Even the protean ocular manifestations of the HIV, an RNA virus, result largely from reduced immunity to DNA viruses.

Adenovirus is probably the most common DNA virus to cause eye disease. Three common ocular syndromes have been identified. Simple follicular conjunctivitis occurs with infection by many adenovirus types and may be subclinical. Pharyngoconjunctival fever typically follows infection with adenovirus types 3, 4, and 7. As the name implies, patients have pharyngitis, conjunctivitis and fever, and may be misdiagnosed as having influenza. Epidemic keratoconjunctivitis, most often caused by adenovirus types 8, 19 and 37, is a highly contagious syndrome with significant morbidity. The conjunctivitis can be severe (**Fig. 3**); associated inflammatory conjunctival membranes can permanently scar the eyelids to the globe. Corneal involvement begins as a punctate epithelial keratitis and may proceed to a large central epithelial ulcer. Stromal keratitis presents about 2 weeks after the conjunctivitis as multifocal subepithelial corneal infiltrates, and causes both foreign body sensation and reduced vision. The stromal infiltrates may resolve spontaneously, but can become chronic, require long-term treatment with corticosteroids, and cause persistent visual morbidity. A fourth ocular syndrome occasionally associated with adenovirus infection, AHC (discussed above) may be caused by adenovirus type 11. Interestingly, adenovirus type 11 also causes acute hemorrhagic cystitis. Follicular conjunctivitis clinically indistinguishable from adenovirus conjunctivitis can also be caused by Newcastle disease virus, an RNA virus that gives rise to fatal epidemics in poultry and infects the birds' human handlers.

The human herpes viruses are preeminent among DNA viruses in eye disease with at least seven of the eight known human herpes viruses associated with ocular disorders. Herpes simplex virus type 1 (HSV-1) is the most common herpes virus to cause eye disease and herpes simplex keratitis is the most common cause of infectious blindness in the industrialized world. HSV-1 causes self-limited and relatively benign infections of the eyelids, the conjunctiva and the corneal epithelium, but infections of the corneal stroma, uvea and retina may result in chronic or recurrent blinding stromal keratitis, uveitis and retinal necrosis, respectively. Elevation of intraocular pressure due to involvement of the trabecular meshwork is not uncommon and may help to differentiate herpetic uveitis from noninfectious causes. Postnatally acquired HSV-2 ocular infection, less common than HSV-1, causes disease similar in most respects to HSV-1. Neonatal herpes simplex infection, acquired during transit through the birth canal and usually due to HSV-2, commonly causes vesicular blepharitis and conjunctivitis, but can also cause permanent visual loss due to keratitis, chorioretinitis, optic neuritis and encephalitis of the visual cortex.

Varicella zoster virus, the etiologic agent of chickenpox and shingles, rarely causes keratouveitis with primary infection (chickenpox). However, vision-threatening keratitis, uveitis, and less commonly, retinal necrosis, are complications of varicella zoster virus reactivation in the distribution of the fifth cranial nerve (zoster ophthalmicus). Lid ulceration with frank tissue loss or lid malposition leads to corneal exposure and ulceration. Optic neuritis and cranial nerve paresis can accompany onset of the zoster rash. Sectoral iris atrophy is pathognomonic for zoster ophthalmicus. Postinfectious corneal anesthesia and secondary sterile corneal ulceration may follow herpes simplex types 1 and 2, but are most severe in zoster ophthalmicus. Chronic scleritis, keratitis, uveitis and glaucoma may ultimately limit the visual acuity.

Acute systemic infection with Epstein–Barr virus may cause conjunctivitis and epithelial keratitis. Stromal keratitis occurs but is difficult to differentiate

clinically from herpes simplex keratitis, and the true incidence of Epstein–Barr viral keratitis is unknown. Reports of uveitis and retinochoroiditis are unconfirmed. Delayed-onset optic neuritis following infectious mononucleosis is not uncommon.

Human cytomegalovirus (CMV) typically causes infectious retinitis (Fig. 4) in immunocompromised patients with CD4+ T cell counts of less than 50 cells μl^{-}. Although not the most common ocular complication of AIDS, CMV retinitis is the most common cause of blindness in AIDS patients. CMV retinitis in AIDS patients can be controlled but not cured. In contrast, congenital cytomegalovirus infection in an otherwise normal fetus results in various degrees of retinochoroiditis, but is not progressive postnatally.

Human papillomavirus (HPV) causes a range of conjunctival tumors ranging from venereally acquired benign papillomas (HPV types 6 and 11) to invasive squamous cell carcinoma (HPV types 16 and 18). Venereal papillomas are clinically similar to those of the larynx and anogenital tract. Conjunctival intraepithelial neoplasia and invasive squamous cell carcinoma are most similar to dysplastic intraepithelial and invasive squamous lesions of the uterine cervix. Papillomatous eyelid neoplasms due to HPV also occur, and can be benign or malignant.

Molluscum contagiosum virus is a poxvirus that may infect the eyelid skin or less commonly the conjunctiva. Skin lesions typically appear as elevated nodules with umbilicated centers, and may be multiple and quite large in HIV-infected patients. Molluscum lesions of the eyelid are fairly common in children, and can be associated with a follicular conjunctivitis that resolves with incisional or excisional biopsy of the lid lesion.

Prior to eradication, smallpox virus infection was associated with pustular blepharoconjunctivitis, secondary lid scarring and stromal keratitis. In nonindustrialized nations, secondary bacterial infection of smallpox keratitis was a major source of blindness. Vaccination against smallpox virus with vaccinia virus was occasionally complicated by inadvertent autoinoculation of vaccinia into the eye, with potential for a severe blepharoconjunctivitis, keratitis and globe perforation.

Ocular Complications of AIDS

Tay-Kearney and Jabs (1996) classified the ocular complications of HIV infection into five broad categories: (1) HIV retinopathy; (2) opportunistic ocular infections; (3) ocular adnexal neoplasms; (4) neuroophthalmic lesions; and (5) drug-induced manifestations.

HIV retinopathy is seen in over half of AIDS patients; cotton-wool patches, or multifocal infarcts of the retinal nerve fiber layer, are the most common ocular sign of AIDS. Intraretinal hemorrhages occur less often. HIV can be cultured from the retina of

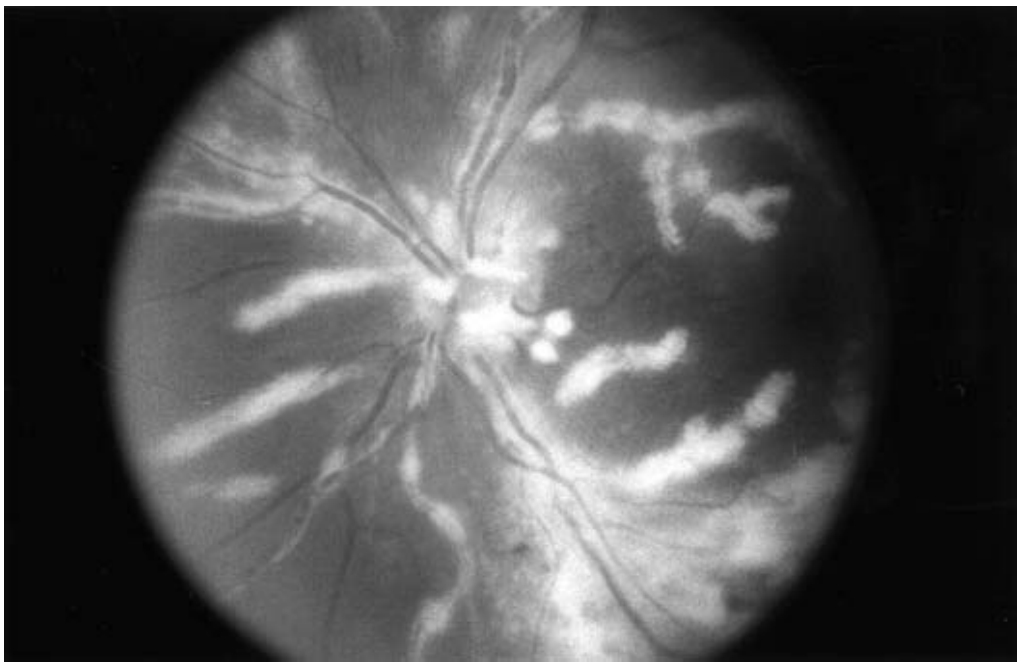

Figure 4 Cytomegalovirus retinitis. Discrete areas of perivascular necrosis and hemorrhage are typical. **(For color references see Color Plate 4.)**

AIDS patients, but a direct relationship between retinal infection and AIDS retinopathy has not been established.

Some ocular infections, including CMV retinitis (**Fig. 4**), *Pneumocystis carinii*, fungal and mycobacterial choroiditis, and microsporidial keratoconjunctivitis are seen almost exclusively in AIDS. Cytomegalovirus retinitis is a major cause of morbidity in AIDS patients. Other infections, such as toxoplasmosis retinochoroiditis, ocular syphilis, herpes zoster ophthalmicus, and molluscum contagiosum of the eyelids are seen in immunocompetent as well as immunosuppressed individuals, but may be more severe and leave more profound deficits in HIV-infected patients. Herpes zoster ophthalmicus in young patients may be the first clinical clue to HIV infection. Acute retinal necrosis due to herpes simplex virus types 1 or 2, or varicella zoster virus, occurs more commonly in HIV-infected than in otherwise normal patients and can result in unilateral or bilateral blindness despite antiviral therapy.

Kaposi sarcoma of the eyelids or conjunctiva, associated with human herpes virus 8 infection, is exceedingly uncommon in immunocompetent individuals, but is probably the most common adnexal tumor in AIDS patients. Non-Hodgkin's lymphomas of the orbit, although rare overall, occur more frequently in AIDS patients than in the general population. Recently, squamous cell carcinoma of the conjunctiva and cornea has been suggested as a marker for AIDS, but whether HIV infection potentiates HPV-induced carcinogenesis in the eye remains speculative.

Neuro-ophthalmic lesions in AIDS may occur directly due to HIV infection of the central nervous system, but most commonly are caused by cryptococcal meningitis or other opportunistic infections. Retinitis and uveitis due to anti-HIV medications can be confused with opportunistic intraocular infections.

Conclusion

Diverse ocular tissues act in concert to create vision. All of the tissues and structures within the eye are susceptible to viral infection, with consequences ranging from mild discomfort to severe pain and blindness, and almost all known human viruses cause ocular disease. Often, the same virus can infect widely disparate tissues within an eye. Classical viral pathogenic mechanisms are readily demonstrated in the eye, but the fine functions of ocular tissues within the visual axis (cornea, anterior chamber, lens, vitreous, and macula) compel altered immune responsiveness. The eye is uniquely affected by viral infection and provides an exceptional model for studies of viral pathogenesis and immunity.

F

FABAVIRUSES (*COMOVIRIDAE*)

JI Cooper, Institute of Virology and Environmental Microbiology, Oxford, UK

History

In 1947, Stubbs attributed vascular wilt symptoms in broad bean (*Vicia faba*) to a virus that he named after the syndrome. The genus *Fabavirus* derives from the Linnean species name of that host.

Broad bean wilt disease had been noticed more than a decade earlier in the state of Victoria, Australia, and the pathogen (broad bean wilt virus, BBWV) has continued to be a cause of significant local plant death and periodic epiphytotics. Soon thereafter, Smith noticed a disease in broad beans growing near Cambridge, UK. An agent transmitted from these plants caused necrotic lesions in inoculated leaves of *Nicotiana glutinosa* and subsequently the 'same' virus was identified in nasturtium (*Tropaeolum majus*). Surprisingly, Smith named his isolates after the common name of this host (nasturtium) but incorporated a symptom descriptor from the tobacco indicator he had used. Hence the name nasturtium ringspot virus (NRSV) entered the literature. From time to time over the intervening years, a range of similar viruses were isolated from carrot (*Daucus carota*), french bean (*Phaseolus vulgaris*), globe artichoke (*Cynara scolymus*), lilac (*Syringa vulgaris*), parsley (*Petroselenium hortense*), spinach (*Spinacea oleracea*), *Catalpa, Digitalis, Galvezia, Helleborus, Petunia, Phytolacca* and plantain (*Plantago lanceolata*) in Europe, and from dogwood (*Cornus florida*), lettuce (*Lactuca sativa*), peas (*Pisum sativum*), spinach, *Amaranthus retroflexus, Pl. lanceolata*, and *Sonchus asper* in the USA. This short list indicates the diversity of potential hosts; BBWV occurs worldwide in many of the crops (notably pulses) which are traded internationally. There is some evidence that BBWV *sensu lato* occurs in South America and spreads in Japan, where narcissus (*Narcissus tazetta*), patchouli (*Pogostemon patchouli*) and eggplant (*Solanum melongena*) are infected, in Africa, where grape (*Vitis vinifera*) and pepper (*Capsicum annuum*) are recorded hosts, in the Peoples Republic of China (infecting many plant species) and in the Republic of Singapore where *Megaskepasma erythrochlamys* is infected. There are no records of BBWV isolation from plants growing in the Indian subcontinent but fabaviruses are most unlikely to be absent from that region.

Thus, as a consequence of work in several crops and continents, a variety of similar virus isolates with an array of common names were described and not all of these have been fully characterized. In and before 1975, Doel concluded that NRSV is a strain of BBWV (which has historical presidence). In 1982, Lisa *et al* characterized an isolate of Lamium mild mosaic virus (LMMV), which was first recorded in 1953 from wild labiates *Lamium album, L. purpureum, Marrubium peregrinum* and *M. vulgare* showing mild mosaic or no symptoms at all when growing near Cambridge, UK, and showed why LMMV should be considered as a fabavirus distinct from BBWV.

Taxonomy and Classification

Fabaviruses are in the genus *Fabavirus* of the family *Comoviridae*. Species in the genus include BBWV-1, BBWV-2 and LMMV. Other genera in the family are *Comovirus* and *Nepovirus*. Fabaviruses are very similer to comoviruses in their capsid composition/morphology, in the sizes of RNA-1/RNA-2 and in the associated cytopathology. Comoviruses, nepoviruses and fabaviruses have been segregated largely on the basis of their vectors and on the fact that they are not known to share any antigenic determinants.

Virus Structure and Composition

Virions of fabaviruses tend to aggregate and no isolate is convenient to purify in large amounts. The particles, which do not have envelopes and are icosahedral (having diameters that have been reported to be in the range 22–32 nm) are very stable and sediment as three components with $s_{20,w}$ of 56–63,

93–100 and 113–126 for T, M and B respectively. M particles contain about 25% RNA and B particles about 35% RNA. The topmost component (T) in rate density gradients is virtually free of RNA. The A_{260}/A_{280} ratio of unfractionated virions was 1.65 and the separate components have values of 1.69 (M), 1.79 (B) for BBWV or 1.00 (T), 1.71 (M) and 1.79 (B) for NRSV. Neither lipid nor carbohydrate has been associated with purified particles. The buoyant densities of M and B components in cesium chloride – Igepon T73 have been estimated as 1.40 and 1.44 g ml^{-1}, respectively. A significant feature of the virions is that each fabavirus which has been analyzed using SDS-PAGE contained two polypeptides in its capsid. The peptides of NRSV and BBWV comigrate and have M_r of 43 000 and 27 000 but neither of these species comigrated with the peptides from capsids of LMMV which, when judged in this way, had M_r of 45 000 and 28 500.

Genome Structure

The genomes of NRSV and BBWV are linear single-stranded RNA (ssRNA) in two parts that are encapsidated separately. When denatured with formaldehyde, RNA-1 has a molecular weight estimated as 2.0×10^6 Da and RNA-2 a value of 1.5×10^6 Da. When not denatured, RNAs from virions of LMMV, BBWV and NRSV have different molecular sizes; the equivalent molecular weights deduced for LMMV are 2.23×10^6 and 1.59×10^6 Da whereas the values for NRSV are 2.02×10^6 and 1.47×10^6 Da, respectively, with data for BBWV being intermediate. There is some scatter in the data concerning the RNA base ratios of fabaviruses but they are characterized by a high A + U content; another of many features which they share with comoviruses and nepoviruses. Proteinase K did not substantially alter the infectivity of three fabaviruses suggesting that a genome-linked virus-coded protein (VPg), if present, is not required for biological function, a feature which fabaviruses share with some comoviruses but not all nepoviruses.

Cytopathology

Virions of all the fabaviruses occur in the cell cytoplasm of foliar mesophyll and epidermis. In some isolates, virions, virus-like shells and probably also capsid protein assemble into a variety of ordered arrays (tubules, rings, square patterns) that can be recognized by electron microscopy (**Figs. 1–3**). Amorphous X bodies (spindle-shaped fibrous or crystalline inclusions visible using light microscopy) may have some diagnostic value. In this respect, the cytopathology of fabaviruses resembles that of some tymoviruses and is unlike that of comoviruses or nepoviruses. Fabaviruses resemble nepoviruses and comoviruses in that single rows of virus-like particles (VLPs) occur in tubules in cells of infected plants. However, the tubules in nepovirus-infected cells tend to be double-walled, whereas those in comovirus-infected tissue tend to be single-walled. Interestingly, cells supporting the NRSV isolate of BBWV contain single-walled tubules. When the same fabavirus isolate was examined in more than one host, the cytopathology has been consistent, implying that the inclusion bodies are features directed by the viruses rather than the hosts. Too few fabavirus isolates have been examined in sufficient detail to form a reliable basis for judging the value of cytopathology for differentiating virus isolates.

Host Range and Symptomatology

Fabaviruses kill lettuce, bean and spinach plants and cause necrotic streaks in foliage of some pea cultivars. Symptoms in other crops are usually transient and have little commercial significance, except in the People's Republic of China where complex intercropping patterns favor damaging epiphytotics also involving celery (*Apium graveolensis*) and pakchoi (*Brassica chinensis*). Along the fertile Yangtse river, soybean (*Glycine max*) and *A. retroflexus* and *Pseudostellaria heterophylla* (an important medicinal plant) are significant summer hosts of BBWV and

vector aphids. In other countries, natural hosts of fabaviruses are numerous and are thought to act as amplifying reservoirs from which the viruses spread to cultivated crop species. No systematic surveys have been done to determine the prevalence of fabaviruses in the uncultivated flora but there are many recorded instances of natural infections in trees or herbaceous nonfood plants. BBWV is recorded as seed-borne in fababeans (0.4–0.6%) but not in nasturtium; there are no comparable data on LMMV.

The experimental host range of fabaviruses is wide. Edwardson and Christie (1986) listed 328 species of 186 genera in 44 families as infectable by BBWV; of these, 40 species in 16 genera were in the family *Leguminosae*. LMMV has been less extensively tested but differs from BBWV/NRSV in not infecting, for example, cowpea (*Vigna unguiculata*) or tomato (*Lycopersicon officinale* cv. Mamande). Furthermore, LMMV produces only local lesions in inoculated leaves of *V. faba* or *P. vulgaris*. Published data suggest that symptoms associated with the fabaviruses have only limited diagnostic value, not only because they are inconsistent but also because they vary seasonally and tend to be transient or partial, if indeed present at all.

As glasshouse indicators, *V. unguiculata, Chenopodium amaranticolor* and *Chenopodium quinoa* are usually reliable bioassay hosts. For maintenance or propagation, *V. faba, C. quinoa* or *Nicotiana clevelandii* are convenient for BBWV, whereas *N. clevelandii* is the most suitable host for LMMV.

Serology

The virions are strongly immunogenic, several polyclonal (rabbit) sera with moderate titers (1/2000) are available. Traditionally, gel-diffusion tests have been used to confirm diagnoses and to assess relationships among putative fabaviruses. When testing for fabaviruses in some hosts (e.g. *V. faba*) satisfactory precipitation requires the presence of a reducing agent in the diluent and in the gel. Immunodiffusion tests with LMMV and, to a lesser extent, the other fabaviruses that have been appropriately tested, are unusual in that their precipitation is facilitated more by citrate than, for example, phosphate-buffered saline.

Fabaviruses, as presently constituted, can be divided into two distantly related serological groups with LLMV representing a third, more distinct, type. NRSV, petunia ringspot and the parsley isolates are serologically indistinguishable from the type (Australian) isolate of BBWV which has been designated serotype I. This serotype seems to predominate in Europe.

A virus obtained from *Helleborus vescarius* growing in a commercial nursery in the UK gave a reaction of identity with a plantain isolate of BBWV from Argentina. These isolates, plus another from *Sisymbrium irio* grown in Argentina, one from dogwood in the USA and one from periwinkle (*Catharanthus roseus*) in Australia failed to react visibly in gels with sera specific for viruses in serotype I and were therefore designated serotype II. All the BBWV

isolates (about 20) so far characterized in the People's Republic of China and the one isolate obtained in Singapore are attributed to serotype II. Isolates differing from BBWV serotype I, BBWV serotype II and LMMV have been recorded in *Pl. lanceolata* growing in Italy, *Ajuga reptans* in Australia, patchouli in Japan and in globe artichoke from several countries but too few tests have been done to decide whether or not these are distinct fabaviruses or additional serotypes of BBWV. However, one virus isolated in Northern Italy from *Phytolacca americana* differs serologically from both BBWV serotypes I and II and all other suspected fabaviruses.

As judged by electron microscopy (antiserum-coated grids/decoration), virions representing the serotypes I or II of BBWV have common antigens. Furthermore, use of cross-absorbed sera indicated that a few antigens present in the type isolate of BBWV are not present in NRSV although both viruses are assigned to serotype I. Viruses attributable to BBWV serotypes I or II cannot be reliably differentiated on the basis of their pathological properties. However, one fabavirus isolate, from *Cynara scolymus* and named artichoke French latent virus, has been assigned by some authors to serotype III of BBWV and was reported as causing distinctive symptoms in *C. amaranticolor, Vigna radiata or Nicotiana tabacum* cv Xanthi-nc thereby differentiating it from LMMV or representative isolates of the other BBWV serotypes.

In electron microscope serology, LMMV was clumped but not decorated by undiluted sera prepared against viruses representing either serotypes I or II of BBWV. In gel-diffusion tests LMMV did not react visibly with antisera against BBWV serotype II. However, in gels, a serum with an homologous titer of 1/2048 (determined in mixed liquids) against a parsley isolate of BBWV (serotype I) reacted at 1/4 with LMMV. These fabaviruses have few if any of their antigens in common with comoviruses, tymoviruses or with nepoviruses including strawberry latent ringspot nepovirus (SLRV).

Virus Transmission

In contrast to nepoviruses such as SLRV which are transmitted by *Xiphinema* nematodes and comoviruses or tymoviruses that have beetle vectors (or no known vector), fabaviruses are transmitted by aphids in the nonpersistent manner (although it is worth noting that the vector potential of nematodes or beetles for fabaviruses does not seem to have been assessed). Whereas nepoviruses and comoviruses are transmitted from seed to seedling progeny, there is only one report showing that BBWV is seed transmitted and there are many other experiences which show that BBWV is not seed transmitted. These properties of fabaviruses can be exploited in that the analysis of virions purified from plants inoculated using aphids rather than by manual means helps to eliminate the risk of nepovirus or comovirus contamination in isolates obtained from 'the field'.

The list of known vector aphids extends to some 20 species including *Acyrthosiphon pisum, Aphis craccivora, A. nasturtii* and *Macrosiphum euphorbiae*. However, there are unpredictable and unexplained differences (some relative and others absolute) between fabavirus isolates in the efficiencies of their transmission by different aphid species. Thus, LMMV is transmitted efficiently by *Cryptomyzus alboapicalis* whereas *Myzus persicae*, which is an inefficient vector of LMMV, is the most efficient vector for the type isolate of BBWV (serotype I). Furthermore, *Aphis fabae* transmitted the NRSV isolate of BBWV but not a parsley isolate (PV3) also attributable to serotype I. Similarly, whereas *Myzus persicae* did not transmit artichoke French latent fabavirus between *Physalis floridana*, isolates from globe artichoke were transmitted from and to physalis by *Capitophorus horni* aphids.

Surprisingly, having regard to the abundance and stability of virions in systemically invaded plants, nasturtium isolates of BBWV were not transmitted by the vascular parasitic plant dodder (*Cuscuta californica, C. campestris* or *C. subinclusa*) except when source plants also contained the unrelated cucumber mosaic cucumovirus. This phenomenon of assisted transmission has not been investigated in detail. The transmission of fabaviruses by aphids is not known to require the presence in source plants of another 'helper' virus.

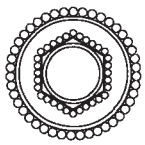
FELINE IMMUNODEFICIENCY VIRUS (*RETROVIRIDAE*)



Janet K Yamamoto, University of Florida, College of Veterinary Medicine, Gainsville, Florida, USA

History

Since the isolation of the human immunodeficiency virus (HIV) in 1983, the search for its counterpart in domestic and laboratory animals has been initiated in a number of laboratories. Prior to the discovery of HIV, retroviruses in the subfamily *Onconovirinae* were better known for their immunosuppressive potential than were the ungulate retroviruses belonging to the same lentivirus subfamily as HIV. Furthermore, none of the animal lentiviruses known till then had antigenic characteristics or clinical manifestations resembling those of acquired immunodeficiency syndrome (AIDS). Animal lentivirus models with clinical disease more closely resembling AIDS were deemed important for research, leading to prophylaxis and therapy of HIV infection and disease. Clinic and laboratory animals ranging from mice to non-human primates with signs of immunodeficiency were evaluated for potential lentiviral infection. Isolation of a lentivirus from a colony of pet cats with clinical symptoms of immunodeficiency-like syndrome in California was reported in 1987. The lentiviral origin of the new feline retrovirus was based initially on the biochemical, antigenic and morphologic characteristics. However, in 1989, sequence analysis of its genome further confirmed its lentiviral lineage and the virus was renamed feline immunodeficiency virus (FIV) in compliance with international nomenclature.

The discovery of FIV in domestic cats has also led to the reassessment of immunodeficiency cases that were previously placed under the category of unknown etiology. FIV causes a naturally occurring infection in domestic cats that is clinically similar to HIV in its immunopathogenesis. FIV infection causes chronic lifelong infections which are followed by a progressively degenerative immune disorder in cats. As with HIV, FIV infection has been found worldwide and has a major impact in veterinary medicine.

Taxonomy and Classification

Based on morphology, genomic organization and nucleotide sequence analysis, FIV belongs to the genus *Lentivirus* in the family *Retroviridae*. Phylogenetic tree analyses of amino acid sequence indicates that FIV is more closely related to the ungulate lentiviruses, equine infectious anemia virus and visna virus, than to the primate lentiviruses, HIV and simian immunodeficiency virus (SIV). FIV has been classified into five clades or subtypes (A–E) based on nucleotide sequence homology at viral *env* and *gag*. Serological survey has demonstrated that wild cats, including lions, pumas, leopards, ocelots and jaguars, have antibodies that react with FIV. Based on phylogenetic analysis, wild cats are infected with lentivirus distantly related to the domestic FIV isolates. Although over 80% of the Serengheti lion population may be infected with lion lentivirus (FIV-Ple), Asian lions appear to be free of such infection. Currently FIV-Ple is classified into three subtypes based on the reverse transcriptase coding sequences of the *pol* gene.

Geographic Distribution

Based on serological surveys, and more recently on sequence analyses, FIV infection of domestic cats occurs worldwide. In general, FIV subtypes distribute according to the geographic cluster. Subtype A is found predominantly in California and Europe, subtype B in central Japan and the USA (excluding California), subtype C in British Columbia, subtype D in southern Japan, and subtype E in Brazil.

Virion and Genome Structure

The FIV virions are 100–125 nm in size and consists of an outer envelope surrounding a nucleocapsid core

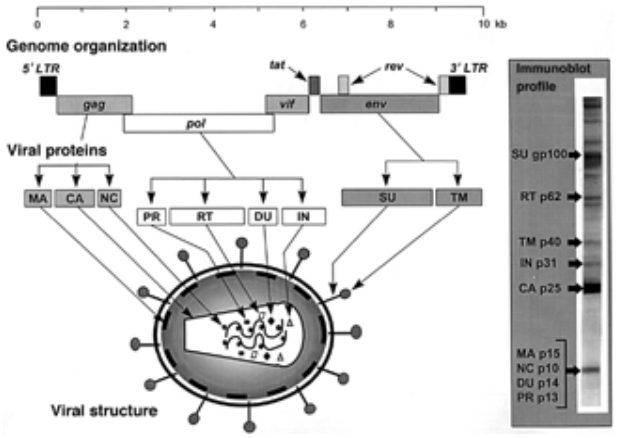


Figure 1 FIV genome organization, viral structural proteins and enzymes, general structure of the virion and the profile of an FIV immunoblot strip reacted with antisera from an FIV-infected cat.

(**Fig. 1**). The nucleocapsid core has the physical appearance of a cone, typical of all nonungulate lentiviruses. The FIV genome consists of two identical single-stranded RNA molecules of approximately 9.5 kb. Associated with the viral genome is nucleoprotein (NC, p10), which may be involved in viral assembly. The viral genome, nucleocapsid protein and viral enzymes are all packaged within the nucleocapsid core. Viral enzymes consist of the reverse transcriptase (RT, p62), integrase (IN, p31), deoxyuridine triphosphatase (dUTPase or DU, p14), and protease (PR, p13). The dUTPase is unique to the nonprimate lentiviruses and its function in FIV replication remains unknown. However, speculation is that dUTPase is important in FIV replication in nondividing macrophages or resting T lymphocytes. The capsid core, composed of capsid protein (CA, p25), is surrounded by a lining of myristoylated matrix protein (MA, p15) associated with the viral envelope. Myristoylation of MA protein is unique to HIV and SIV and only nonmyristoylated MA proteins are found in ungulate lentiviruses. The viral envelope consists of surface (SU, gp100) and transmembrane (TM, gp40) glycoproteins, projecting from the lipid bilayer which is derived from cellular membrane.

The FIV genome, in common with other lentiviral genomes, is more complex in organization than other retroviruses. In addition to the general genomic organization of retroviruses, *5'-LTR-gag-pol-env-LTR-3'*, regulatory genes are found in the open reading frames (ORF 1–4) overlapping or flanking *5'* and *3'* ends of the *env* gene. Based on alignment analysis and physiochemical properties of the predicted polypeptide, *orf 1* is speculated to be analogous to *Q orf* of visna virus and *vif* gene of HIV-1. *Orf 2* is predicted to be the first exon of *tat* gene found in primate lentiviruses. *Orf 3* and *orf 4* are analogous to the exons of *L* gene of visna virus and *rev* gene of HIV-1, HIV-2 and SIV, both of which encode for a splice gene product important in production and transport of viral RNA transcripts.

Host Range and Virus Propagation

FIV has limited host range in that productive infection is found only in felid species. Domestic FIV has been found in the wild cat population, Tsushima cat (*Felis bengalensis euptilura*), and may present problems to the conservation of this endangered species. In domestic cats, FIV infects macrophages, endothelial cells, B cells, and CD4+ T cells as well as CD8+ T cells. In addition, FIV has been shown *in vitro* to infect feline astrocytes and fibroblastic Crandell feline kidney cells (CrFK). Defective infection of a human cell line has been reported; however, there has been no evidence of zoonotic transmission and infection of humans with FIV. As with HIV, propagation of FIV in culture will rapidly adapt the virus and appears to alter the tissue tropism. Thus, the use of laboratory strains for vaccine challenge has been criticized and challenge inocula from *in vivo* sources have been recommended.

Genetics and Evolution

Owing to the large spectrum of genetic variability between worldwide FIV isolates, FIV is currently classified into five subtypes (A–E). Studies on mutation rates in FIV *env* and *gag* have shown positive selective pressure for *env* mutations, consistent with reports that HIV *env* has a high mutation rate compared with *gag* and *pol*. Polymerase chain reaction analyses of FIV variants isolated within individual cats over a 3 year period indicate that sequence variation in *env* increases over time, with later isolates showing divergence of 0.5–1.5%. Hence, the divergence of the variants within individual cats appears to be less than in those variants from an individual infected with HIV.

Phylogenetic analyses of lentiviral *pol* reveal that domestic FIV isolates are more closely related to equine infectious anemia virus and visna virus than to the primate lentiviruses, SIV and HIV. Similar analysis reveals that the domestic FIV (FIV-Fca) is more closely related to lion (FIV-Ple) and puma (FIV-Pco) lentiviruses. FIV-Ple can cause lytic infection in domestic cat T lymphoma cells (3201), suggesting

cross-species transmission. Interestingly, a large number of African lions are infected with FIV-Ple and yet they appear to coexist without apparent pathology. These findings have led to the speculation that the domestic FIV originated from a lineage associated with the African lion lentivirus.

Serologic Relationships and Variability

Antisera from cats infected with different FIV strains react to prototype FIV isolate (FIV_{Pet}). The antibody crossreactivity of the infected sera has been the basis for the diagnostic kit commercially available for FIV. Similarly, antisera from wild cats infected with nondomestic lentivirus reacted with domestic FIV isolates, and vice versa. Rabbit polyclonal antibodies to ungulate lentiviruses, Visna-Maedi virus, and caprine arthritis encephalitis virus, also reacted to domestic FIV at major and minor core proteins (p25 and p15), demonstrating the conserved epitopes of these structural proteins.

The crossreactivity of the FIV antibodies appeared to be limited to the conserved epitopes on the FIV structural proteins and was less frequently detected at the virus-neutralizing domains. In general, FIV-neutralizing antibodies can neutralize highly related strains but not divergent strains. FIV subtyping is based on genotype and little is known about the correlation between the genotype and the cross-neutralizing antibodies elicited by strains from the same and different subtypes. Since neutralizing antibodies generally react to domains in the envelope region, correlation between neutralizing antibodies and *env* sequences may provide insight as to whether antibodies to FIV strains within a subtype can more efficiently crossneutralize than those between subtypes. Preliminary studies suggest that a loose correlation exists between the genotype based on *env* sequence and the virus-neutralizing antibodies elicited by infected cats.

Epidemiology

The worldwide prevalence of FIV infection ranges from 3 to 43.9% in high-risk groups (consisting of symptomatic cats) and 1 to 12.4% in asymptomatic pet cat populations. Serological surveys show that male cats are 2–3 times more likely to be infected than female cats and that FIV infection is found more frequently in cats over 5 years of age than in younger cats, especially those under 1 year old. Furthermore, free-roaming cats have a higher incidence of infection than with indoor cats. Since male cats are territorially aggressive and have higher incidence of wounds and bite abscesses, the high prevalence of FIV infection in male free-roaming cats is consistent with the major mode of FIV transmission via biting.

Transmission and Tissue Tropism

The identity of FIV receptor(s) is still unknown. Although significant loss of CD4+ cells occurs during FIV infection, findings from transinfection studies suggest that the feline CD4 molecule may not be the receptor for FIV. In initial studies, an adhesion molecule, CD9, present on feline B cells, monocytes and T cells was thought to be the FIV receptor. However, recent findings suggest that CD9 play a role at the postentry stage of the viral life cycle and is not the receptor for FIV. It has been reported that chemokine receptor, feline CXCR4, acts as a co-receptor for FIV infection in the way human CXCR4 serves as coreceptor for HIV in human T cells. In recent studies, feline CXCR4 has been shown also to serve as coreceptor for HIV. Although β-chemokine receptor CCR5 has been shown to be a coreceptor for HIV in monocytes, there are no studies demonstrating feline CCR5 as a FIV coreceptor.

Based on experimental transmission studies, the major route of FIV transmission is through bites from infected cats. This route of transmission is consistent with the epidemiological studies as well as with the fact that cats shed significant amount of virus in saliva. FIV transmission by ingestion of virus via grooming, as well as presumably when licking bleeding wounds of an infected cat, cannot be excluded, as oral administration of infected blood can result in experimental FIV infection. Sexual transmission has yet to be reported as a natural route of transmission; however, FIV infection has been demonstrated by experimental vaginal and rectal inoculation and FIV has been isolated from vaginal swabs and semen of experimentally infected cats. Another route of infection is through virus found in the colostrum/milk of infected queens. FIV has been shown to be transmitted to newborn kittens nursed by queens experimentally infected shortly before giving birth. Findings from experimental studies have suggested the possibility of transplacental infection as well as transmission during birth through a contaminated birth canal. In conflict with these experimental observations is the low incidence of FIV infection in kittens born to chronically-infected queens, suggesting that vertical transmission of FIV is rare in nature. This observation is further supported by the epidemiological findings that cats under 1 year of age have the lowest incidence of FIV infection. Thus, it is still uncertain whether transplacental and perinatal routes of transmission play a major role in natural transmission.

Clinical Features and Infection

FIV infection is a natural infection of domestic felid populations and causes a chronic and progressive acquired immunodeficiency syndrome resembling HIV infection of humans. The immunological hallmark of FIV infection is depletion of CD4+ peripheral T cells and reduced CD4:CD8 ratios, leading to B and T cell dysfunctions and hypergammaglobulinemia. T cell dysfunctions include decreased proliferative responses and decreased interleukin 2 (IL-2) production. B cell dysfunctions are less dramatic than T cell dysfunctions, and seem to predominate in primary antibody responses to T cell-dependent antigens, especially during early stages of FIV infection. Interestingly, increased serum IgG levels are also observed in infected cats, indicative of FIV-induced virus-specific B cell hyperactivity akin to that observed in HIV.

Experimental infection studies demonstrate that the clinical stages of FIV infection are similar to human AIDS in several ways. The acute stage of FIV infection is characterized by immunological abnormalities followed by depression, fever, diarrhea, neutropenia and persistent generalized lymphadenopathy. FIV is primarily detected in lymphoid tissues (lymph nodes, spleen, thymus, tonsils and bone marrow), followed by dissemination of the virus into nonlymphoid organs (kidney, lung and liver). In experimental infection studies, both the antibodies against FIV and the virus recovery from peripheral blood lymphocytes persist throughout infection. However, the levels of virus in the blood appear to be lower at the asymptomatic or clinical latency stage than the acute stage. Nevertheless, virus can be readily isolated from lymphoid tissues at the asymptomatic stage. Although there is no major clinical manifestation, the CD4+ T cell counts and CD4:CD8 ratios steadily decline to the extent that, by the late symptomatic stage, the animals are severely immunosuppressed and refractory to supportive treatment. The late stage of FIV infection is similar to that of human AIDS and may be characterized by wasting syndrome, neurologic disorders and a variety of persistent secondary opportunistic infections. The virus load is extremely high at this stage, so that in addition to lymphoid tissues, FIV can be readily isolated from nonlymphoid tissues and organs, such as kidney, saliva and the central nervous system (CNS). In contrast to natural infection, experimentally infected cats housed in a specific pathogen-free environment generally succumb to B cell lymphomas. These lymphomas have FIV proviral integration, suggesting that somewhat innocuous B cell infection can develop into B cell lymphoma of more unusual extranodal forms (found predominantly in the neck and head). The incidence of FIV-induced lymphomas appears to be low in nature. It has been speculated that naturally infected cats succumb to diseases more commonly associated with the immunodeficient state, such as opportunistic infections, before the development of lymphomas.

The major clinical manifestations observed in naturally infected cats are chronic oral diseases, chronic upper respiratory tract disease, chronic enteritis and chronic conjunctivitis. Anorexia, weight loss, lethargy, vomiting, fever of unspecified origin and recurrent cystitis were other signs observed in these cats. Abnormal behavioral problems, lymphosarcoma and myeloproliferative disease were also seen in a small proportion of affected cats. Abnormalities in kidney function and pathology have been reported both in naturally and experimentally infected cats. Glomerulosclerosis, fibrosis, tubular degenerative changes and diffuse interstitial infiltration by phagocytes and plasma cells have been observed in naturally infected cats, while glomerular mesangial cell proliferation has been seen in experimentally infected cats. Overall, natural FIV infection causes progressively degenerative immune disorder, neurologic disorders, wasting syndrome and a variety of persistent secondary opportunistic infections.

Pathology and Histopathology

Major histopathological changes during the acute stage of experimental FIV infection are observed in the lymphoid tissues (thymus, lymph nodes, spleen, tonsils and gut-associated lymphoid tissues). In the first three weeks postinfection, lymphoid hyperplasia is observed in the lymph nodes, tonsils and spleen. The majority of the FIV-infected cells are found in the germinal centers of lymphoid follicles of these tissues. However, some infected cells have been observed in the paracortex and medullary cords of lymph nodes, and in periarterial lymphoid sheaths and the red pulp of the spleen. Shortly after, cats develop myeloid hyperplasia in bone marrow and cortical involution, thymitis and follicular hyperplasia of the medulla in the thymus. Meanwhile, the CD4:CD8 ratio begins to decrease and complete inversion can occur in the acute stage of infection. Both T cells and monocytes/macrophages are infected with FIV at the early phase of the acute stage, followed by infection of B cells. Throughout the asymptomatic stage, a steady loss of the CD4+ T cell population may be the only abnormality detected in infected cats. At the early symptomatic stage, the lymph nodes display a combination of histological lesions, including follicular hyperplasia, involution and lymphoid depletion.

By the late symptomatic stage, destruction of nodal architecture with involution and depletion of lymphoid follicles has been reported.

In comparison to HIV and SIV infection of the CNS, multinucleated cells in the CNS of FIV-infected cats are rare. Furthermore, the number and severity of CNS lesions are much less in experimentally and naturally FIV-infected cats than those observed in HIV-infected individuals or SIV-infected macaques. However, there are many features of the CNS lesions of FIV-infected cats that resemble those induced by HIV and SIV. These include perivascular mononuclear cell infiltrates, glial nodules and diffuse gliosis of gray and white matter, and neuronal loss. Similar to HIV infection, neurotropic FIV strains infect microglia, astrocytes and brain microvascular endothelial cells. Current findings suggest that neuronal cells cannot be infected by FIV. Both anti-FIV antibodies and FIV virions have been isolated from cerebral spinal fluid (CSF) of experimentally and naturally FIV-infected cats, in addition to the elevated IgG index detected in the CSF. Like HIV, the level of FIV infection in the CNS cannot account for the cognitive/motor function abnormalities observed in these cats, suggesting that cytokines induced during CNS infection may play a key role in FIV neuropathogenesis. Neurologic abnormalities included limb paresis, delayed righting and pupillary reflexes, behavioral changes, delayed visual and auditory evoked potentials, decreased spinal and peripheral nerve conduction velocities, and sleep abnormalities similar to sleep disturbances described in AIDS patients. In fact, cats infected with neurotropic FIV-MD strain spent 50% more time awake than the sham-inoculated controls, and approximately 30% of these cats had rapid eye movement (REM) sleep reduction when compared with controls. Neurophysiological abnormalities and sleeping disorders of FIV-infected cats have been more extensively investigated than any other AIDS model.

Immune Response

Both humoral and cellular immune responses to FIV are generated in the infected cats. The nature of immunity elicited appears to be dependent on both the exposure dose and the strain infecting the cats. Some strains do not elicit high or even significant virus-neutralizing antibodies even though high levels of antibodies to their structural proteins, including surface envelope, are produced. Early on during the infection, infected cats produce antibodies to FIV, as well as FIV-specific cellular immunity. The cellular immune responses of these cats include FIV-specific cytotoxic T lymphocyte (CTL) activity and FIV-specific T-helper cytokine production. In spite of the presence of virus-neutralizing antibodies and CTL responses, a steady loss of T cells occurs, resulting in an immunodeficient state. The immunological events that ensue upon FIV infection can be assessed more readily in experimentally infected cats. Upon experimental infection with a moderate dose of FIV, anti-FIV antibodies can be detected as early as 3 weeks postinfection, by FIV ELISA and immunoblot assays, followed by virus-neutralizing antibodies starting about 6 weeks postinfection. A decrease in primary proliferative response to foreign antigen (keyhole-limpet hemocyanin, KLH) has been observed at 5 weeks postinfection, the earliest time point tested. Since the proliferative response to T cell mitogen and the antigen-specific recall response were still unaffected at this time, it has been speculated that selective defects in primary antigen-specific response of naive CD4+ T-helper cells represent the early signs of T cell dysfunction. However, CTL response to FIV Gag peptide can be detected in peripheral blood mononuclear cells at 7–9 weeks postinfection, and to FIV Env peptide by 16 weeks postinfection. Since the earlier time points were not tested for these cellular responses, it is possible that the onset of these cellular changes may be earlier than those described.

A defect in B cell mitogen response has been observed as early as 8 weeks postinfection, before a major decrease in CD4:CD8 ratio occurs. The time of CD4:CD8 inversion depended greatly on the FIV strain used in the study. Overall, the earliest time of CD4:CD8 inversion detected with a highly virulent strain has been 6 weeks postinfection with high dose and 12 weeks with moderate dose. In general, the loss of CD4+ cell numbers accounted for the CD4:CD8 inversion with most FIV strains, but increase in CD8+ cell counts also contributed to this inversion in a number of FIV strains. A defect in proliferative response of memory T cells to recall antigen has been observed at about 19 weeks postinfection. Decreased T cell mitogen responses appear to occur late in the infection when a considerable decrease in CD4:CD8 ratios prevails. In addition to T cell and B cell dysfunctions, functional abnormalities in macrophages, neutrophils and natural killer cells have also been observed in these cats.

Elevated serum levels of proinflammatory cytokines (IL-1, IL-6 and tumor necrosis factor α (TNF-α)) have been reported in naturally infected, symptomatic cats. In contrast, experimentally infected asymptomatic cats maintain normal TNFα levels in the serum, resembling the serum TNFα levels of asymptomatic HIV-positive humans. In spite of the humoral and cellular responses mounted by the infected host, a steady loss in CD4+ T cells continues

throughout the asymptomatic stage, leading to an immunocompromised state which can potentially be fatal to the infected cats. Furthermore, the anti-FIV immunity generated in the infected host is not sufficient to prevent superinfection with other FIV subtype strains. In experimental studies, long-term infected cats (>1 year infection) appear to resist superinfection more than short-term infected cats, suggesting that antiviral immunity broadens with increased duration of infection. However, the presence of FIV recombinant isolates in nature (which are recombinants of two subtypes) also supports the view that immunity generated by primary FIV infection may not be sufficient to prevent superinfection.

Prevention and Control

Currently, no commercial FIV vaccine is available. Experimental FIV vaccine trials ranging from conventional inactivated virus vaccine to proviral FIV DNA vaccines are being tested. Protective efficacy of these vaccines to homologous FIV challenge has been observed. However, protection against highly divergent strains has been more difficult to achieve. Based on studies evaluating the immune correlates of vaccine protection, it has been speculated that an effective FIV vaccine needs to elicit both anti-FIV humoral (virus-neutralizing antibodies) and cellular (CTL) immunity for complete and long-lasting immunity against the virus. Such a vaccine is an achievable goal, as inactivated virus or infected-cell vaccines have been shown to elicit virus-neutralizing antibodies, FIV-specific T-helper proliferative responses and FIV-specific CTL responses. However, these single-subtype vaccines were unable to protect cats against highly divergent strains, especially from different subtypes. As a result, multisubtype FIV immunogens are currently being investigated as a means of broadening protective immunity against worldwide FIV isolates.

A number of antiretroviral drugs have been tested in clinic and experimental cats. These include azidothymidine (AZT), 9-(2-phosphonylmethoxyethyl)adenine (PMEA), dideoxycytidine 5′-triphosphate, dideoxycytidine, lamivudine (3TC), cyclosporine A and interferon α. AZT has been studied most extensively as therapy against FIV. AZT monotreatment suppresses FIV infection in culture; however, its antiviral efficacy in cats has been controversial. In general, high-dose AZT therapies initiated shortly before or after FIV infections caused a significant loss or delay in detection of plasma viral core antigen levels, some delay in development of viral antibodies, and milder FIV-related clinical episodes. However, adverse effects were noted at these high doses, including hemoglobinemia, anemia and depressed packed cell volume. Furthermore, a resurgence of the virus has been observed in cats upon withdrawal of the drug in a majority of these studies. The AZT-resistant FIV mutants have been shown to develop in culture by drug selection. In a more recent study, prophylactic therapy with a high dose of AZT and 3TC combination, started 3 days before experimental FIV inoculation, resulted in complete protection of cats from FIV infection. In contrast to this observation, low-dose therapy with AZT and 3TC combination did not decrease virus load or improve CD4:CD8 ratios and counts of chronically FIV-infected asymptomatic cats. Although the prophylaxis with nucleoside analogues appears to be remarkable, the therapeutic use of these drugs has been somewhat disappointing. However, a promising light has been shed on FIV therapy by a recent finding that some of the drugs initially developed as HIV protease inhibitors have potent anti-FIV activity in culture and enhance inhibition of *in vitro* FIV replication when combined with AZT and/or 3TC. Thus, FIV therapy, like the triple drug combination currently used in HIV-positive individuals, will require multiple drug combination with each drug inhibiting different stages of lentiviral life cycle.

Future

Advances in FIV vaccine development and therapy is important, not only for veterinary medicine but as an animal model for human AIDS. Although our understanding about FIV pathogenesis has greatly increased in recent years, the development of an effective prophylaxis and therapy against FIV has been slow. The lack of immunological reagents for feline species has been one of the initial setbacks in the progress of FIV research. However, within the last decade, more feline reagents are now available as a result of concerted efforts made by laboratories throughout the world. Hence, the FIV–cat system can now serve as a more effective small animal model for AIDS. Innovative therapy, such as immune reconstitution therapy using stem cell growth factor, can be assessed using the FIV model. New generation antiretroviral drugs can be combined with established antiretroviral drugs or with novel immunotherapy and tested in the FIV model. Novel vaccine approaches can be evaluated more rapidly and economically in the FIV model than many of the nonhuman primate lentivirus models. These vaccine studies can increase our understanding of the types of immunity required for vaccine protection. Similarly, better understanding of the mechanisms underlying the FIV-induced immuno-

suppressive diseases may provide new insights into HIV immunopathogenesis, also important in identifying novel prophylactic and therapeutic strategies. Overall, future progress in FIV research should make a major impact in the feline medicine of pet cats and enhance our understanding of the control and prevention of lentiviral infections and diseases.

FELINE LEUKEMIA AND SARCOMA VIRUSES (*RETROVIRIDAE*)

James Neil and **David Onions**, University of Glasgow Veterinary School, Glasgow, Scotland, UK

History

The description of murine leukemia viruses by Moloney and others stimulated an intensive search for similar viruses in other species. William Jarrett made the perceptive observation that lymphomas (lymphosarcomas) in cats often occurred at particularly high incidence in certain households, and in 1964 he showed that typical type C retroviruses could be demonstrated in the tumor cells by electron microscopy. He went on to show that these feline leukemia viruses (FeLVs) could be transmitted to cats where they induced lymphosarcomas and a range of degenerative diseases, including anemias and thymic atrophy.

Following these studies, Snyder and Theilen isolated a retrovirus from a feline fibrosarcoma that rapidly reproduced this tumor on inoculation into experimental cats. It is now recognized that feline sarcoma viruses (FeSVs) arise by recombination between FeLV and cellular proto-oncogenes and that, in contrast to FeLV, these viruses are not transmitted from cat to cat.

In clinical veterinary medicine, FeLV is one of the most important viruses affecting the cat and considerable attention has been paid to controlling this infection. However, FeLV has a wider importance in the study of viral oncogenesis. Research on FeLV has led to the discovery of novel cellular transforming genes and elucidated the complex interactions between this class of retroviruses and their host species.

Taxonomy and Classification

Feline leukemia viruses are RNA viruses and belong to the family *Retroviridae*, genus Epsilonvirus.

Virion and Genome Structure

The virion particles are around 100 nm in diameter and consist of an outer membrane derived from the host cell surrounding an icosahedral core particle. The core encapsidates the viral genome which, as in other members of this viral family, is present as two linear single-stranded (ss) RNA molecules linked as dimers. The virion RNA is positive-stranded and

suppressive diseases may provide new insights into HIV immunopathogenesis, also important in identifying novel prophylactic and therapeutic strategies. Overall, future progress in FIV research should make a major impact in the feline medicine of pet cats and enhance our understanding of the control and prevention of lentiviral infections and diseases.

FELINE LEUKEMIA AND SARCOMA VIRUSES (*RETROVIRIDAE*)

James Neil and **David Onions**, University of Glasgow Veterinary School, Glasgow, Scotland, UK

History

The description of murine leukemia viruses by Moloney and others stimulated an intensive search for similar viruses in other species. William Jarrett made the perceptive observation that lymphomas (lymphosarcomas) in cats often occurred at particularly high incidence in certain households, and in 1964 he showed that typical type C retroviruses could be demonstrated in the tumor cells by electron microscopy. He went on to show that these feline leukemia viruses (FeLVs) could be transmitted to cats where they induced lymphosarcomas and a range of degenerative diseases, including anemias and thymic atrophy.

Following these studies, Snyder and Theilen isolated a retrovirus from a feline fibrosarcoma that rapidly reproduced this tumor on inoculation into experimental cats. It is now recognized that feline sarcoma viruses (FeSVs) arise by recombination between FeLV and cellular proto-oncogenes and that, in contrast to FeLV, these viruses are not transmitted from cat to cat.

In clinical veterinary medicine, FeLV is one of the most important viruses affecting the cat and considerable attention has been paid to controlling this infection. However, FeLV has a wider importance in the study of viral oncogenesis. Research on FeLV has led to the discovery of novel cellular transforming genes and elucidated the complex interactions between this class of retroviruses and their host species.

Taxonomy and Classification

Feline leukemia viruses are RNA viruses and belong to the family *Retroviridae*, genus Epsilonvirus.

Virion and Genome Structure

The virion particles are around 100 nm in diameter and consist of an outer membrane derived from the host cell surrounding an icosahedral core particle. The core encapsidates the viral genome which, as in other members of this viral family, is present as two linear single-stranded (ss) RNA molecules linked as dimers. The virion RNA is positive-stranded and

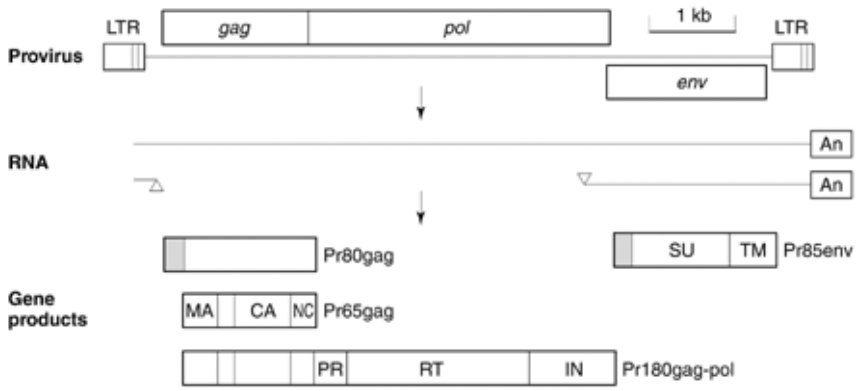

Figure 1 Proviral structure, RNA transcripts and gene products of feline leukemia virus. The provirus is flanked by long terminal repeats (LTR) and includes two long open reading frames (gag-pol and env). Two major polyadenylated (An) transcripts are produced, one encompassing the entire genome and the other spliced to join the 5′ leader sequence to env coding sequences. The longer RNA species is translated to produce the precursor for the internal virion proteins (Pr65gag) which is cleaved by the viral protease to yield mature products including the p15 matrix protein (MA), p27 capsid protein (CA) and the p10 nucleocapsid (CA). The envelope protein precursor (Pr85env) is cleaved by cellular enzymes to yield the mature gp70 virion surface glycoprotein (SU) and the transmembrane anchor protein p15E^{TM}. The virion enzymes (protease, PR; reverse transcriptase, RT; integrase, IN) are produced from the Pr180gag-pol precursor which is expressed by virtue of suppression of the gag termination codon. Also, an upstream in-frame AUG gives rise to an alternative Gag precursor (Pr85gag) which is glycosylated and expressed at the infected cell surface.

resembles cellular RNA having a 5′ cap and a 3′ poly(A) tract. As deduced from sequencing of proviral forms, the FeLV genome is around 8 kb long with a 67 base terminal redundancy and the gene order *gag-pol-env*.

The particles have surface spikes composed of multimers of the two env-coded proteins, the gp70 surface glycoprotein (SU) and the p15E transmembrane anchor protein (TM). Inside the envelope is the structural *gag* gene product which forms an icosahedral core particle composed of p27, the major capsid protein (CA), with an outer layer formed by the p15 matrix protein (MA). Another gag product, the p10 nucleocapsid (NC) is associated with the virion RNA. Other minor virion proteins encoded by the *pol* gene comprise the protease (PR), reverse transcriptase (RT) and integrase (IN) enzymes.

Replication

Virus replication proceeds, after binding to specific host cell surface receptors, internalization and uncoating. The virion RNA is converted into a double-stranded DNA form by the virion reverse transcriptase which used a proline tRNA primer and carries a ribonuclease H function that degrades the virion RNA. After nuclear translocation, viral integration is catalyzed by the integrase protein and involves the creation of a staggered cut in cellular DNA with a consequent 4 bp duplication of host DNA at the insertion site.

As illustrated in **Fig. 1**, the proviral form is flanked by long terminal repeats (LTRs) of 480–560 bp. These are generated during reverse transcription by duplication of unique sequences at the 3′ (U3) and 5′ (U5) ends of the RNA genome. The LTRs contain promoters and enhancers that drive transcription of viral RNA and also processing signals for cleavage and polyadenylation of the RNA transcripts. The 5′ LTR functions to initiate transcription whereas the 3′ LTR acts primarily as an RNA processing signal.

The virion RNA can function as a messenger RNA for Gag and Pol products, whereas a spliced subgenomic mRNA of around 3 kb encodes the Env products. Most full-length RNA translation products terminate at the 3′ end of *gag* to produce the Pr65gag precursor, whereas a small percentage readthrough into *pol* by misreading of UAG termination codon, generating the Pr180Gag-pol precursor. During and after the budding process, the virion aspartyl protease catalyzes the cleavage of both precursor proteins to their mature forms. The envelope gene products are synthesized as a Pr80env precursor and processed by cellular proteases to the mature, disulfide-linked gp70 and p15E envelope proteins. The *gag* gene is also abundantly expressed in an alternative, glycosylated form via an upstream AUG codon. This product is expressed on the cell surface and shed after cleavage by cellular proteases. Its role *in vivo* is unknown. It is dispensable for *in vitro* virus replication but highly conserved among FeLV strains.

Assembly of virus particles occurs at the cell surface by extrusion of cores which form at the budding

site, concomitantly acquiring a host cell-derived outer membrane with virus-coded surface spikes. Virus replication and release is often noncytopathic.

Geographic Distribution

FeLV occurs worldwide in domestic cat populations and it has also been isolated from the European wild cat (*Felis sylvestris*). Endogenous retroviral sequences closely matched to FeLV are found in the same species and in related small felids such as the sand cat (*F. margarita*) and the jungle cat (*F. chaus*). Although not a direct source of disease, these endogenous sequences can participate in recombination with exogenous FeLV to generate variant viruses with altered host range.

Epidemiology

The outcomes of FeLV infection can be divided into three categories. The majority of cats undergo a transient infection lasting up to 3 months, during which they are viremic and shed virus. They then develop neutralizing antibody and concomitantly eliminate the virus and a little later, virus antigen from the bloodstream. It is now recognized that these recovered cats may harbor latent virus in the bone marrow for some years following recovery but reactivation from latency is not a frequent event in the absence of iatrogenic immunosuppression. The vast majority of these cats do not develop an FeLV-related disease.

In a few cases, virus production from the hematopoietic tissue is halted, but productive virus infection is sequestered in an epithelial compartment like the mammary gland. These cats are not usually viremic but they may have circulating viral antigen.

The final group remain actively infected, shedding virus from epithelial surfaces and possessing an associated high titer plasma viremia. Such cats may remain healthy for 2–3 years before succumbing to an FeLV-related disease. A recent survey in the UK showed prevalence of active FeLV infection in sick cats at 18%, but only 6% in healthy individuals.

The proportion of cases falling into these groups differs between multicat households and those households containing one or two free-ranging cats. In the former case, the introduction of an FeLV carrier results in repeated exposure of susceptible cats, often at a young age so that up to 30–40% become persistently viremic and at risk of disease. Approximately 50% of free-ranging urban and suburban cats have serological evidence of exposure to FeLV but only 1–5% of these cats are actively infected and the disease incidence is correspondingly lower.

Dual infection with FeLV and feline immunodeficiency virus (FIV) occurs and is associated with rapid disease onset, particularly if cats with pre-existing FeLV infection encounter FIV. Rapid death of dually infected animals may reduce the apparent overlap of these agents in the field, but the populations at risk of infection also differ. FIV infection rates increase directly with age whereas persistent FeLV infection has a peak incidence in young cats.

FeLV Subgroups

FeLV isolates are classified as subgroup A, B or C according to their viral interference properties in feline fibroblast cells *in vitro*, that is, viruses of a given subgroup prevent superinfection (interfere) with other viruses of the same subgroup (**Table 1**). This property appears to be based on the use of three different host cell surface receptors by FeLV-A, B and C, and the blockade of these receptors in persistently infected cells by viral Env glycoproteins. Natural isolates contain either subgroup A alone, or mixtures of subgroups A + B, A + C or A + B + C.

Host Range and Virus Propagation

FeLV isolates of subgroup A are generally restricted to growth in feline cells, whereas subgroups B and C have a greatly expanded host range, infecting cat, human, mink and canine cells. Their host ranges are further distinguishable since FeLV-C also infects guinea-pig cells, whereas FeLV-B appears to use the same human cell receptor as gibbon ape leukemia

Table 1 Properties of feline leukemia virus subgroups

Subgroup	*Origin*	*Host range*	*Receptor*	*Pathogenesis*
A	Exogenous	Ecotropic	?	Minimally pathogenic to acute immunosuppression
B	Recombination FeLV-A × endogenous FeLV	Amphotropic	Pit-1, Pit-2	More common in leukemic cats Some isolate-specific diseases e.g. FeLV-GM1 myeloid leukemia
C	Mutation of FeLV-A (Env vr1)	Amphotropic	?	Erythroid hypoplasia

virus. FeLV infection is generally noncytopathic and persistent and the virus is commonly propagated in long-term cultures of embryo-derived fibroblasts.

Clinical Features and Pathology

Of those cats which become persistently viremic following FeLV exposure, over 80% will die within 3.5 years. Most young cats infected with FeLV die from degenerative diseases rather than from tumors. Profound immunosuppression associated with thymic atrophy is a common finding in kittens. Immunosuppression is also a feature of infection in older cats but its pathogenesis is complex and not fully understood. Highly immunosuppressive (feline autoimmune deficiency syndrome, FAIDS) variants have been isolated. These are defective for replication and genomes accumulate as unintegrated forms in lymphoid tissue.

Other diseases seen in FeLV-infected cats include enteritis, immune complex glomerulonephritis, pancytopenia and hemolytic anemia. Erythroid hypoplasia, an acute disease involving failure of red cell development past the erythroid burst-forming unit (BFU)-E-stage, is specifically associated with FeLV subgroup C.

The most common neoplasm induced by FeLV is lymphosarcoma of T cell origin, usually restricted to the thymus or sometimes occurring as a multicentric tumor in lymph nodes. The tumors often develop between 1 and 3 years after infection and the first signs may be chronic wasting and anemia. At presentation, the normal architecture of the lymphoid organ has usually been destroyed by a monomorphic infiltrate of lymphoblastic cells. The thymic tumors frequently display a rearrangement of the T cell antigen receptor β-chain gene and are often CD4+ and CD8+. FeLV is also found in association with 35% of alimentary tumors, primarily of B cell origin, but the virus is not always clonally integrated in these tumors and the role of the virus is, therefore, unclear.

FeLV is also associated with a variety of other neoplastic diseases, including primary myeloid and lymphoblastic leukemias and multicentric fibrosarcoma.

Envelope Gene Variation and Pathogenicity

The common infectious form of FeLV is FeLV-A which is a remarkably highly conserved virus as shown by sequence analysis of several strains and serotypic analysis of a large number. FeLV variants frequently arise from FeLV-A by mutation and recombination, and such variants are often implicated in the acute diseases which develop in persistently infected cats. The variant viruses generated from FeLV-A are generally dependent on the continued presence of the prototype for their propagation *in vivo*.

The most commonly isolated FeLV recombinants are subgroup B viruses (**Table 1**). These are derived by recombination between FeLV-A and endogenous FeLV-related proviruses which are found in the genome of the domestic cat and related small feline species. Although the endogenous FeLV-related proviruses all appear to be replication-defective, their envelope genes can be rescued by the recombination process leading to the generation of FeLV-B viruses. FeLV-B can infect cells refractory to, or already containing, FeLV-A by virtue of their distinctive receptor specificity.

The anemia-inducing FeLV-C isolates are rarer and appear to be derived from FeLV-A by mutation of a single variable domain (VRA) of the *env* gene. Minor *env* mutations also appear to give rise to the acutely immunosuppressive FeLV–FAIDS variants. The prevalence of acutely immunosuppressive viruses in nature is unknown, but immunosuppressive disease is a common manifestation of FeLV infection.

The relationship of subgroup variation to oncogenesis is complex. FeLV-B recombinants are more common in tumor-bearing than in infected asymptomatic cats. This higher frequency might reflect merely longer-standing infection, but some FeLV-B-containing isolates have an altered spectrum of neoplastic disease. For example, FeLV-GM1, which contains a replication-defective FeLV-B component, induces mainly myeloid leukaemia.

FeLV Oncogenesis: Virus Evolution and Mutagenesis of Cellular Oncogenes

Two modes of virus-induced host gene mutation have been described in FeLV-associated cancers. The first is *transduction,* where recombination leads to the generation of an acutely oncogenic variant. Such viruses are found in nature in association with a replication-component FeLV helper virus. Although they may explain the genesis of the primary neoplasm in which they occur, the recombinant viruses are not transmissible and will die out with their host.

Multicentric fibrosarcomas of young cats are relatively rare, but are generally FeLV positive and frequently involve a novel sarcoma virus. Similarly, transduction of c-*myc* has been observed in up to 20% of naturally occurring thymic lymphosarcomas in FeLV-positive cats. In all, nine different host cell genes have been shown to be transduced (**Table 2**). The transducing viruses induce tumors with short

Table 2 FeLV gene transduction in neoplasia

Gene	*Normal function of host gene product*	*No. of examples*	*Associated tumor*	*Examples*[a]
abl	Plasmamembrane protein kinase	1	Fibrosarcoma	FeSV-HZ2
fes	Plasmamembrane protein kinase	3	Fibrosarcoma	FeSV-GA, -HZ1, -ST
fgr	Plasmamembrane protein kinase	1	Fibrosarcoma	FeLV-GR, -TP1

[a] Isolated from naturally occurring tumors apart from the indicated exception.

latency in cats and in the case of feline sarcoma viruses may transform cells in tissue culture.

Alternatively, host genes can be affected by proviral *insertional mutagenesis* (*cis*-activation). Three known oncogenes and two novel integration loci have been identified as common tumor-specific insertion sites for FeLV in thymic lymphosarcomas (**Table 3**).

Changes within the LTR are also a feature of tumor-associated FeLV. In thymic lymphosarcomas, sequence duplications of the core enhancer domain are frequently found, even when the infecting virus is a molecularly cloned FeLV isolate lacking such features. By analogy with the murine oncoretroviruses, the duplications are likely to increase the oncogenicity of the virus and reduce the latent period for tumor formation, possibly by increasing the potency of viral enhancer activity on nearby cellular promoters. In proviruses integrated at the *flvi*-1 locus in non-T, non-B splenic lymphomas, triplication of an alternative motif 3′ to the core enhancer has been observed, suggesting that these adaptive changes to the LTR operate tissue-specifically.

Immune Response

Unlike infection with the human leukemia virus, HTLV, FeLV infection of cats may lead to recovery. Recovery is associated with the production of neutralizing antibody and passive transfer of this antibody can also protect kittens from infection. The role of cell-mediated immunity in recovery has not been extensively investigated.

In the early literature on FeLV a distinction was made between antiviral immunity and antitumor immunity. Cats with antitumor (FOCMA) antibody were thought to be protected from tumor development. This antibody response is now believed to be directed to endogenous FeLV *env* proteins and its role in modulating tumor development is uncertain.

Transmission

Cats persistently infected with FeLV shed virus in their saliva, urine and feces but, as the virus is fragile, close contact is required for transmission. The most frequent routes involve saliva and transplacental spread. Kittens infected *in utero* become persistently infected, but the consequences of infection in older cats depend on a number of factors. There is an age-related resistance to infection such that cats up to 12 weeks of age are highly susceptible but above 16 weeks they are difficult to infect either naturally or experimentally.

FeLV subgroup A is always found in field isolates and about half also contain FeLV-B whereas FeLV-C is present in only 2% of isolates. Although FeLV-B

can arise *de novo* by recombination, it may also be transmitted between cats. This occurrence is dependent on pseudotype formation in which the genome of the B virus becomes enclosed in an envelope containing glycoproteins of the A subgroup.

Prevention and Control

Successful control measures can be adopted in multicat households by removing or isolating persistently infected animals. Productively infected cats are detected by virus isolation from plasma or more usually by enzyme-linked immunosorbent assay (ELISA) for virus antigen in the blood. A few cats remain persistently antigenemic but nonviremic. These cats do not usually transmit the virus unless they are shedding virus in the milk or saliva. Assays are conducted twice, 3 months apart, to exclude cats that are transiently viremic.

Numerous vaccine strategies have been shown to offer protection against FeLV in laboratory conditions (**Table 4**) and FeLV is the only retrovirus for which commercial vaccines are in routine use. These vaccines offer a measure of protection against experimental challenge but do not appear to be 100% effective against exposure in the field.

Future Perspectives

There is continuing interest in control of FeLV infection due to its importance in veterinary medicine. In the future we can look forward to improvements in vaccine efficacy and further dissection of the host responses that confer protection. Although the focus of attention of cancer genetics has moved on to more easily manipulated models, FeLV remains as a useful touchstone for our understanding of oncovirus pathogenesis in an outbred, naturally infected host. Also, with the impetus of feline immunodeficiency virus as a model for human AIDS, the generation of reagents to probe the feline immune system offers new opportunities for comparative study of FeLV.

FILAMENTOUS PHAGES (*INOVIRIDAE*)

Robert E. Webster, Department of Biochemistry, Duke University Medical Center, Durham, North Carolina, USA

Introduction

Filamentous bacteriophages are a group of structurally related viruses which contain a circular single-stranded DNA genome. Many use the tip of a conjugative pilus as a cell surface receptor and thus are specific for bacteria containing certain conjugative plasmids. They do not kill their host during productive infection. Filamentous bacteriophages with these characteristics have been classified in the family *Inoviridae*, genus *Inovirus*. Those which infect *Escherichia coli* containing the F plasmid are collectively referred to as Ff bacteriophages. The three most extensively studied Ff phages are f1, fd and M13, which were independently isolated in the early 1960s. They differ in their DNA sequence by only a small number of nucleotides and, consequently, the protein sequences of the gene products are nearly the same.

E. coli containing other conjugative plasmids can also be infected by specific filamentous phages. The most studied is IKe, which requires the presence of N pili and consequently the N plasmid for infection. Its DNA sequence is 55% homologous to the Ff bacteriophage and it appears to have the same genome organization. Filamentous phages that infect other bacterial species, such as *Pseudomonas* (Pf1, Pf3), *Salmonella* (If1, If2), *Vibrio* (CTXphi, fs1) and *Xanthomonas* (Cf, Lf, Xf), have also been isolated. CTXphi encodes the gene for cholera toxin, one of the virulence factors of *Vibrio cholerae*. Some of these phage are able to integrate their DNA into the genome of the host.

Structural analysis has been done primarily on Pf1 and the Ff group of filamentous bacteriophages. X-ray crystallographic and nuclear magnetic resonance techniques show differences in the packing of the protein and DNA between Ff and Pf1 viral particles. On the basis of these studies, the filamentous bacteriophages have been divided into two structural classes: class I containing the Ff bacteriophages and class II bacteriophages Pf1, Pf3 and Xf. The structure of Pf1 has been subjected to the most extensive study. Comparison of the structure of the major capsid protein in the membrane and in the Pf1 phage particle itself has suggested a mechanism by which the phage particle may be assembled. However, it is difficult to know how accurate such a hypothesis is, in view of the lack of knowledge about the biology of this particular filamentous bacteriophage. At the present time, the biology and life cycle of the Ff bacteriophages f1, fd and M13 are the most completely studied and will be the subject of the remaining discussion. However, increasing knowledge of the other filamentous phage suggests there exists great similarity between all filamentous bacteriophage.

Structure of the Bacteriophage

The bacteriophage is a flexible rod, about 900 nm long and 7 nm in diameter (**Fig. 1**). It has a mass of approximately 16.3 MDa, of which 13% is contributed by the DNA. The virus consists of a protein sheath enclosing a circular single-stranded DNA extending the entire length of the particle. The length of the sheath consists of approximately 2700 molecules of the major coat protein, a 50 amino acid protein encoded by the phage gene VIII (pVIII). It is highly α-helical in structure with its N-terminal acidic domain exposed to the outside and its basic C-terminal domain toward the inside of the protein tube. These two domains are connected by a very hydrophobic sequence which appears to interact to form the stable protein tube. The proteins are arranged in an overlapping shingle-like array and have a symmetry defined by a fivefold rotational axis with a twofold screw axis of pitch 3.2 nm.

About five copies each of the 33 amino acid gene VII protein and the 32 amino acid gene IX protein make up one end of the particle. The other end contains approximately five copies each of the gene III (406 residue) and gene VI (112 residue) proteins. This end can be recognized in the electron micrograph as containing small knob-like structures. These knobs consist of the N-terminal portion of the gene III protein and contain the information for F pilus recognition as well as recognition of the bacterial proteins involved in the translocation of the phage DNA into the bacteria. The C-terminal portion of the

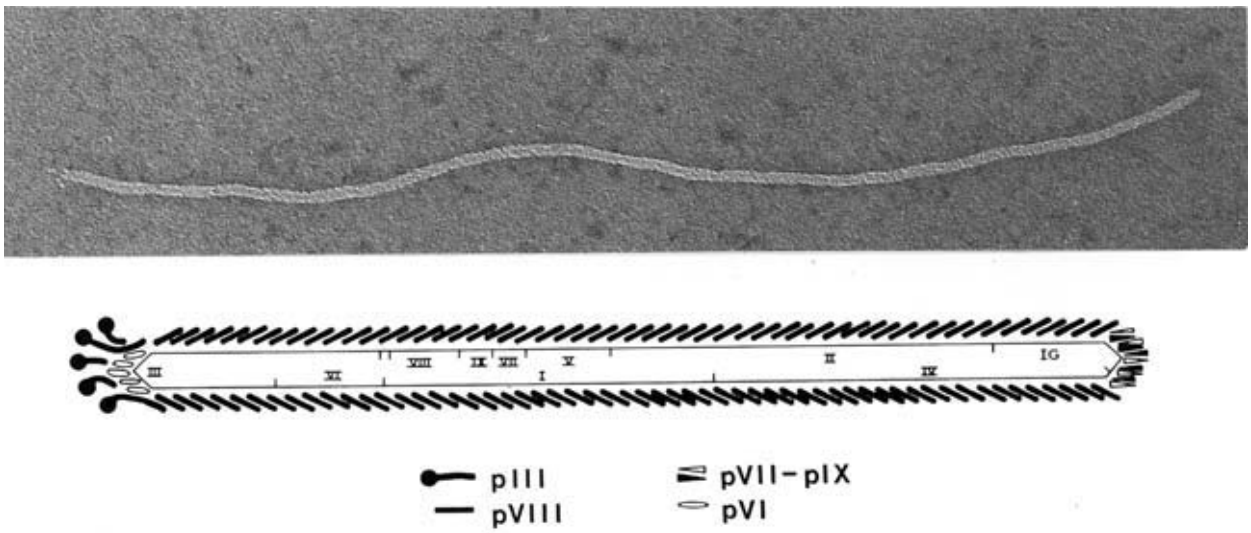

Figure 1 The f1 filamentous bacteriophage. The top is an electron micrograph of a negatively-stained particle with the pIII–pVI end located on the left side. The bottom is a schematic representation of the positions of the structural proteins and DNA in the bacteriophage. This figure is adapted from Webster RE and Lopez J (1985) In: Casjens S (ed.) *Virus Structure and Assembly*, p. 235. Boston: Jones and Bartlett.

gene III protein along with that of the gene VI protein are required to maintain the stability of the particle.

The capsid proteins form a tube with an internal diameter of approximately 3.4 nm, in which the viral DNA resides in essentially a non-base-paired anti-parallel form. The DNA is oriented within the virion such that a 78 nucleotide hairpin loop is always at the gene VII/IX protein end. This hairpin region is called the packaging signal (PS) and is required for efficient assembly of the bacteriophage (**Fig. 2**, hairpin A). The bases of the DNA are arranged in the center of the phage particle so that the negatively charged sugar–phosphate backbone of the DNA can interact with the positively charged C-terminal region of the pVIII protein exposed on the inside of the protein tube of the phage. It is the overall charge density in this region of the coat protein which governs the DNA packing. Removing one of the positive amino acids in the basic region of pVIII results in a longer phage particle containing more altered pVIII to maintain the charge density.

Viral Genome: Proteins and Expression

The genomes of the filamentous bacteriophages f1, fd and M13 have been completely sequenced and shown to code for 11 proteins (**Fig. 2**). There is an intergenic region of approximately 500 nucleotides which contains the origins of replication for the viral and complementary DNA as well as the packaging signal needed for efficient assembly. The genes are tightly packed and are arranged according to the function of their products: capsid proteins (pIII, pVI, pVII, pVIII and pIX), replication proteins (pII, pV and pX) and assembly proteins (pI, pIV and pXI).

All of the capsid proteins appear to reside in the inner membrane until assembled around the viral DNA. The major coat protein, pVIII, is synthesized as a precursor, containing a 23 residue signal sequence which is removed by signal peptidase following insertion into the membrane. Membrane insertion is independent of the *E. coli* encoded Sec proteins normally involved in the translocation of proteins into and across the bacterial membrane. Mature pVIII spans the membrane via its hydrophobic central domain with its N-terminal domain exposed to the periplasm and the C-terminus in the cytoplasm.

The product of gene III is also synthesized as a precursor with an 18 residue signal sequence which is removed following translocation into the membrane. Most of the pIII, including the mature N-terminus, is located in the periplasm, anchored to the bacterial inner membrane via a 23 amino acid hydrophobic sequence near its C-terminus. The other three capsid proteins, pVI, pVII and pIX, are not synthesized as precursor molecules but are inserted into the membrane, where they remain until assembly into a phage particle. Both the small pVII and pIX retain their initiating formylmethionine, suggesting that rapid insertion into the membrane prevents its removal.

Gene II encodes a 409 residue protein, pII, which is a site- and strand-specific endonuclease absolutely required for both the synthesis of the double-stranded replication intermediate and the single-stranded viral

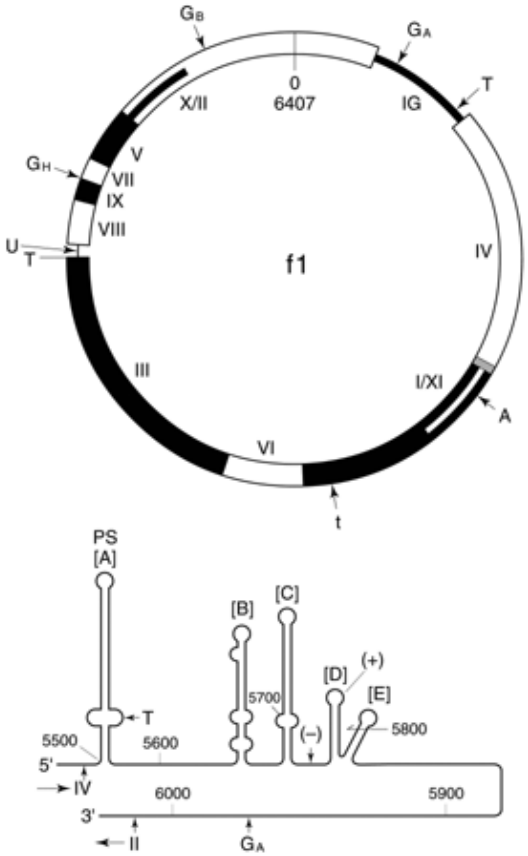

Figure 2 Genome of f1 filamentous bacteriophage. The top represents the whole genome showing the genes, promotors and terminators used *in vivo*. All transcription, along with the number of nucleotides, proceeds in a counterclockwise direction. IG refers to the intergenic region, T the two strong terminators, t the weak terminator in gene I, and G_A, G_B, G_H, U and A marking the beginning of transcripts in the frequently and infrequently transcribed regions. The bottom shows a schematic representation of the intergenic region. The direction of nucleotides has been reversed from the top. A represents the packaging signal hairpin (PS), B and C the proposed hairpins in the complementary strand origin and D and E the proposed hairpins in the viral strand origin. (−) is the beginning of the RNA primer for complementary strand synthesis, (+) the pII nicking site needed for viral strand synthesis. Also shown are the position of the strong rho-dependent terminator (T), the start of the gene II mRNA (G_A) and the beginning of gene II and the end of gene IV. This figure is adapted from Model P and Russel M (1988) In: Calandar R (ed.) *The Bacteriophages*, p. 375. New York: Plenum Press.

DNA. Gene X is encoded within and in phase with gene II and encodes a protein comprised of the C-terminal 111 amino acids of pII. It appears to be required for synthesis of the single-stranded viral DNA. Gene V encodes an 87 amino acid single-stranded binding protein for which the crystal structure has been solved. It exists as a dimer and cooperatively binds the newly synthesized viral DNA to form a linear antiparallel structure which appears to be an intermediate in the assembly of the bacteriophage. This structure contains approximately 1500 molecules of pV per viral single-stranded DNA.

Three phage encoded proteins (pI, pIV, pXI) are required for the membrane-associated assembly of the particle but are not part of the virion itself. The 405 residue gene IV protein is primarily found in the outer membrane of an infected bacteria. It is synthesized as a precursor with a 21 amino acid signal sequence. After translocation to the periplasm and removal of the signal sequence, it integrates into the outer membrane to form a cylinder composed of 14 subunits which spans the outer membrane. The pore of this pIV cylinder has a diameter of approximately 8 nm, large enough to accommodate an emerging filamentous phage. Production of pIV during phage infection induces the expression of the four genes in the *E. coli* stress-induced phage shock (*psp*) operon.

The product of gene I is a 348 residue protein that spans the bacterial inner membrane via an internal hydrophobic region such that its N-terminal 253 amino acids reside in the cytoplasm and its C-terminal 75 amino acids are exposed in the periplasm. Gene XI is encoded within gene I and directs the synthesis of the 108 residue pXI, which is homologous to the C-terminal portion of pI. It is inserted in the inner membrane with the same orientation as pI. It is proposed that the periplasmic regions of both pI and pXI interact with the pIV in the outer membrane to help form an assembly site through which the assembling bacteriophage particle is extruded. Genetic studies have suggested that the N-terminal region of pI, which is missing in pXI, interacts with thioredoxin, ATP and the packaging signal during the assembly process.

Transcription only uses the complementary strand as a template giving mRNAs having the sequence found in the viral strand. The direction of transcription is from gene II through gene IV (**Fig. 2**). There are two strong terminators for transcription, a rho-dependent terminator in the intergenic region and a rho-independent terminator in the region between genes VIII and III. These two terminators divide the genome into two transcription regions: the frequently transcribed region containing genes II through VIII and an infrequently transcribed region extending from gene III through the intergenic region.

The frequently transcribed region contains three strong promoters, G_A, G_B and G_H, leading to three primary transcripts terminated at the end of gene VIII (**Fig. 2**). The 5′ portions of the G_A and G_B transcripts are rapidly removed to leave a set of six smaller, more stable mRNA species. The shortest mRNA of this set is the stable primary transcript starting at G_H. All of

these processed transcripts have a common 3′ end and thus contain the information for pVIII, while four also encode pV. Both of these proteins are needed in large amounts: the pVIII to form the capsid of the 200–2000 virions produced per bacterial generation; and pV to interact with the 200 newly synthesized viral single-stranded DNA molecules in each bacterium. This processing or 'cascade' mechanism provides a sufficient amount of mRNA to code for the large amount of these proteins needed for phage production. However, very little of the products of genes VII and IX, located between genes V and VIII, are synthesized in the bacteria. This is because the expression of these two genes is translationally coupled to that of gene V. The translation initiation site for pVII is inherently inactive and the initiation site for pIX is masked by the secondary structure of the mRNA. Translational activity in the gene V portion of the mRNA is transmitted through the pV–VII junction with a low frequency.

The transcripts from the infrequently transcribed region begin at moderately efficient promoters just before genes III and IV (**Fig. 2**). There is a weak rho-dependent terminator in the region coding for the N-terminal portion of pI. Transcription from the promoter proximal to gene III results in two classes of mRNA: one encoding pIII and pVI, and a smaller amount of the longer transcript encoding pIII, pVI and pI/XI. This mechanism of downregulation for gene I expression appears necessary because large amounts of pI have been shown to be deleterious to the growth of the host bacteria. There is substantial expression of gene IV RNA from the promotor located at the end of gene I.

The synthesis of pII and pX also are regulated at the level of translation. In addition to its role in binding to the newly synthesized viral DNA, pV can specifically bind to the gene II and X mRNA and inhibit translation. In the case of gene II mRNA, the binding site has been localized to a 16 nucleotide region just upstream of the pII coding region. This inhibition occurs at high cellular concentrations of pV, when the amount of pV exceeds that needed to bind the newly synthesized viral DNA.

Life Cycle

Infection is minimally a two-step process requiring interactions with the F conjugative pilus and the bacterial TolQ, R and A proteins. These three Tol proteins are associated with the cytoplasmic membrane and appear to function in maintaining the integrity of the bacterial outer membrane. They also are required for the translocation of the group A colicins to their target following the interaction of these bacteriocins with their specific receptors. TolQ spans the inner membrane three times with the major portion of the protein in the cytoplasm. TolR and A are anchored to the inner membrane by a region near the N-terminus leaving the bulk of the protein, including the C-terminal end, in the periplasm. The C-terminal domain of TolA is connected to the membrane anchor by a long helical region, allowing the C-terminal domain to interact with the outer membrane.

It is the N-terminal portion of the pIII phage capsid protein which appears to interact with these bacterial proteins during infection. pIII is a three domain protein with each domain separated by a glycine-rich region. The C-terminal domain anchors the protein to the end of the phage particle. The N-terminal domain interacts with the Tol proteins, while the middle domain recognizes the tip of the F conjugative pilus. When pIII is present in the phage particle, the N-terminal and middle domains of pIII interact with each other.

Infection is initiated by the binding of the filamentous phage to the tip of the conjugative pilus via the middle domain of pIII, freeing up the N-terminal domain of pIII. The pilus is thought to retract by depolymerization of pilin into the inner membrane, thus bringing the pIII end of the phage particle to the membrane surface. There, the free N-terminal region of pIII interacts with the C-terminal domain of TolA. Then, while the pVIII and probably the pVII and pIX capsid proteins dissociate into the inner membrane, the DNA is translocated into the cytoplasm. The specific mechanism of this process is unknown, but the TolQ, R and A proteins are definitely required. Once in the membrane, the pVIII, pVII and pIX capsid proteins are able to join the pool of newly synthesized capsid proteins and be reutilized in the assembly of new phage particles. The fate of pIII and pVI is unclear.

The entering viral DNA is converted to a double-stranded form by the combined action of the bacterial RNA polymerase, DNA polymerase III and *E. coli* single-stranded binding protein (SSB). The RNA polymerase, in the presence of SSB, specifically recognizes the region containing the possible hairpin structures B and C in the intergenic region (complementary strand origin) (**Fig. 2**). The enzyme initiates the synthesis of a short RNA primer at nucleotide 5753 and DNA polymerase extends this primer the length of the viral strand. The action of DNA polymerase I and ligase generates the closed complementary strand. The resulting double-stranded DNA is supercoiled by gyrase to give the parental replicative form I (RFI). This molecule is a template for

transcription, allowing for the synthesis of the bacteriophage proteins.

Further replication of the DNA requires the presence of the bacteriophage gene II protein. This protein is able to specifically nick the viral strand of supercoiled RFI between nucleotides 5781 and 5782. The 3′ hydroxyl then acts as a primer for the synthesis of a new viral strand in a 'rolling-circle' mode of replication. The bacterial DNA polymerase III, SSB and Rep helicase are required for this reaction. After one round of replication, pII cleaves and circularizes the displaced viral single-strand. The double-stranded molecule, containing the newly synthesized viral strand, is closed, supercoiled and can act as a substrate for pII again. The displaced single-strand becomes a template for complementary strand synthesis, resulting in the formation of progeny RFI molecules.

The specific region recognized by pII (the viral strand origin) is difficult to define. Approximately 40 nucleotides around the nicking site are required for the nicking and termination functions of pII. This would include the region capable of forming the hairpin structures D and E in the intergenic region (**Fig. 2**). Efficient viral strand synthesis also requires up to 150 nucleotides downstream of the nick site (nucleotides 5781–5941 in the intergenic region). The nature of the enhancing effect of this region is not clear.

The RF molecules formed by these reactions can be used for transcription and allow the synthesis of increasing amounts of the bacteriophage proteins. The capsid and assembly proteins are inserted into the membrane, while pV accumulates in the cytoplasm. When the concentration of pV is great enough, it sequesters the newly displaced viral single-strand to form the pV–viral DNA complex. This prevents the viral single-strand from becoming a substrate for complementary strand synthesis and thus contributes to the switch in synthesis from RF to single-stranded DNA.

In addition to pV, pX is needed for the synthesis of viral single-stranded DNA when pII is present. In some sense, it appears that the activity of pII must be kept at a low but persistent level to allow synthesis of viral single-strand while maintaining the necessary amount of RF. This may be accomplished by pX being able to downmodulate the activity of pII. This control would be in addition to the ability of pV to repress the translation of gene II mRNA. Although this translational repression is a real effect, recent results suggest that it may be dispensable for M13 replication.

The assembly of the bacteriophage particle requires the five capsid proteins, the three assembly proteins, ATP and at least one bacterial protein, thioredoxin. This process occurs at membrane sites which resemble bacterial adhesion zones, where the inner and outer membrane appear in close contact. It is proposed that the formation of these assembly sites may require an interaction of the inner membrane-associated pI and pXI with the pIV oligomer in the outer membrane.

The substrate for the assembly reaction is the pV–viral DNA complex. It is proposed that separate segments of the viral DNA bind, in opposite orientations, in the cleft located on the outside of each pV dimer pair. This interaction brings two parts of the circular DNA close together. By binding approximately 750 pV dimers, the DNA becomes part of an elongated structure 1.1 μm long and 8 nm wide. From electron microscopy studies, the overall structure has a left-handed helical appearance with a variable pitch of 6–12 nm. The packaging signal, the 78 bp hairpin structure denoted A in **Fig. 2**, is located at one end of the pV–viral DNA complex, probably not bound by the pV protein.

Assembly appears to be initiated by an interaction of the packaging signal with the cytoplasmic domain of pI and the membrane-associated pVII, pIX and pVIII to form what might be described as an initiation complex. The fact that the packaging signal is located at the pVII/pIX end of the bacteriophage particle, the end of the particle that first emerges from the bacteria, is consistent with the formation of such a complex. The exact order of events involved in the formation of such an initiation complex is not known. However, genetic observations are consistent with the packaging signal interacting with pI, pVII and pIX during the initiating event.

Elongation then proceeds, a process whereby pV is displaced and the positively charged C-terminal domain of the membrane-associated pVIII interacts with the viral DNA. Structural changes probably occur in pVIII during this process, as it may exist as a dimer in the membrane and also appears to contain much less helical structure in the membrane than when it is part of the phage particle. Thioredoxin is proposed to function at this stage, interacting with pI and perhaps aiding it in displacing the pV from the DNA. This does not require the redox activity of the thioredoxin, but only that it be in its reduced conformation. ATP hydrolysis is also required for phage assembly, possibly via its interaction with pI, as the cytoplasmic portion of pI contains a well-conserved Walker nucleotide binding site which is required for phage assembly.

Termination of assembly involves the addition of pVI and pIII to the end of the elongating particle and its release into the media. This occurs when the end of

the DNA is reached and thus the length of the particle is determined by the size of the DNA. Elongation continues in the absence of either pIII or pVI, resulting in the production of extremely long particles which contain many unit length molecules of the viral single-stranded DNA. These polyphage are much less stable than normal virions, suggesting an important role for pVI and pIII in maintaining the structural integrity of the particle. This stabilizing effect contributed by pIII resides in its C-terminal region, as alteration in its N-terminal region still results in stable particles.

Uses of the Filamentous Bacteriophage

The filamentous bacteriophage have been used extensively as cloning vectors. Since there is no constraint on the size of the DNA packaged, theoretically any segment of DNA can be inserted into a noncoding region with no deleterious effect, although the yield of phage particles appears to diminish with inserts greater than 6 kb. Vectors have been constructed with cloning sites between hairpins A and B or distal to hairpin E in the intergenic region (**Fig. 2**). Although those in the latter site disrupt part of the region required for efficient viral strand replication, compensating mutations in the expression or structure of pII allow reasonable production of chimeric bacteriophage with such inserts. An advantage of using these vectors is that both single-stranded and double-stranded forms of the DNA can be obtained from the phage particle or from the intracellular RF DNA, respectively.

Other cloning vehicles, called phagemids, have been constructed; they combine the features of plasmids and the phage. These vectors contain the intergenic regions of the filamentous bacteriophage in addition to a plasmid origin of replication. They are capable of maintaining themselves as a plasmid until infection by a helper filamentous bacteriophage activates the phage origin of replication. The resultant plasmid single-stranded DNAs are encapsulated into phage-like transducing particles using the proteins provided by the helper bacteriophage.

The filamentous phage have been used as vehicles to enrich for peptides or proteins with specific properties, a process termed 'phage display'. Sequences coding small peptides, or epitopes, are commonly inserted into the N-terminal region of pIII. The resulting phage particles display these foreign peptides as part of the chimeric pIII at the tip of the bacteriophage. In this way, large 'epitope libraries' are made which can be screened for a range of binding activities. Peptides have also been displayed as fusion proteins at the N-terminus of pVIII and reportedly with pVI. Only small peptides can be displayed fused to either pIII or pVIII, presumably because larger proteins disrupt the normal function of pIII in infection or make pVIII too large to be assembled into phage particles. Large proteins can be displayed if enough wild-type capsid proteins are available during assembly. To accomplish this, foreign proteins fused to the appropriate portion of pIII or pVIII are expressed from a plasmid in an infected bacterium. The bacteriophage produced have a minor portion of their pIII or pVIII replaced by the chimeric protein.

FISH HERPESVIRUSES (*HERPESVIRIDAE*)

Andrew J Davison, MRC Virology Unit, Institute of Virology, Glasgow, Scotland

Introduction

Vertebrates from fish to humans are hosts to herpesviruses. Although herpesviruses have also been reported in invertebrates (oyster species), those that infect bony fish represent the earliest occurrences of herpesviruses in vertebrate evolution. Most currently recognized herpesviruses of fish infect species that are farmed relatively intensively. Presumably, the conditions used in aquaculture enhance the disease potential of these pathogens and increase the likelihood of their detection. It is likely, therefore, that many more fish herpesviruses await discovery. Herpesviruses of fish, like those of higher vertebrates, are highly species specific. This suggests that they have long been restricted to their hosts and have evolved in close association with them. Those that cause mortality do so only in young fish, and some are also agents of epidermal hyperplasia or neoplasia. Some have been investigated to such a limited extent that causal links with the disease whose occurrence led to their recognition have not yet been fully established.

Channel catfish virus (CCV) was the first fish herpesvirus to be isolated. It has a greater economic impact on farming of its host species and has been studied more extensively than other members of the group. It has also been subject to closest examination at the molecular level. Consequently, most of what follows is devoted to this virus, and the other fish herpesviruses are discussed only briefly.

Two salmonid herpesviruses have been shown to cause virulent disease either naturally or experimentally. Herpesvirus salmonis (ICTV proposed nomenclature salmonid herpesvirus 1; SalHV-1) was isolated on several occasions from a rainbow trout (*Oncorhynchus mykiss*) hatchery in the state of Washington. The virus causes disease when injected into young rainbow trout maintained at 6–9°C, but not in other salmonid species. A similar temperature optimum is characteristic of growth in the rainbow trout cell line RTG-2. *O. masou* virus (ICTV proposed nomenclature salmonid herpesvirus 2; SalHV-2) has a slightly wider host range, causing virulent disease in the young of several members of the genus *Oncorhynchus* (Pacific salmon) and the rainbow trout. It has a higher temperature optimum for growth in RTG-2 cells than salmonid herpesvirus 1 (15°C), and has the interesting property of causing epithelial tumors in survivors of experimental infection.

SalHV-1 and SalHV-2 have been shown to be distinct viruses on the bases of serological comparisons, DNA hybridization studies and limited DNA sequencing. Two additional herpesviruses, the NeVTA and Yamame tumor viruses, have been isolated from *Oncorhynchus* species. They appear to be related to each other, but it is not known whether they represent distinct salmonid herpesviruses or whether they are isolates of SalHV-2 or, as seems less likely, SalHV-1.

Several other fish herpesviruses have been described. Walleye herpesvirus (ICTV proposed nomenclature percid herpesvirus 1) is associated with epidermal hyperplasia in the walleye (*Stizostedion vitreum*), but causality has not been demonstrated. It has been cultured in cells of walleye origin, but not in cell lines from other fish species. Carp pox herpesvirus (ICTV proposed nomenclature cyprinid herpesvirus) is also implicated as the cause of a localized epithelial hyperplasia in the common carp (*Cyprinus carpio*). The condition manifests itself as benign smooth nodules on the skin, and may be transferred by applying material from the lesions to the abraded skin of other fish. The agent has not yet been successfully grown in cell culture, and so its direct involvement in disease has not been proven. Similarly, the role of turbot herpesvirus (ICTV proposed nomenclature pleuronectid herpesvirus) has not been elucidated in episodes of substantial mortality among farmed fry. Recent reports of new fish herpesviruses include those that infect the pilchard (*Sardinops sagax*), the Japanese eel (*Anguilla japonica*), the white sturgeon (*Acipenser transmontanus*) and the goldfish (*Carassius auratus*).

History and Classification

In 1968, Fijan reported the first isolation of CCV from young channel catfish (*Ictalurus punctatus*), in which it causes an acute disease of short duration and high mortality. The first detailed characterization of the virus was published 3 years later by Wolf and Darlington, and showed that the nucleocapsid is a 100 nm icosahedron with 162 capsomeres, and that assembly of capsids takes place in infected cell nuclei. These features are typical of a herpesvirus, and have led the ICTV to propose the nomenclature ictalurid herpesvirus 1, as the type species of the genus

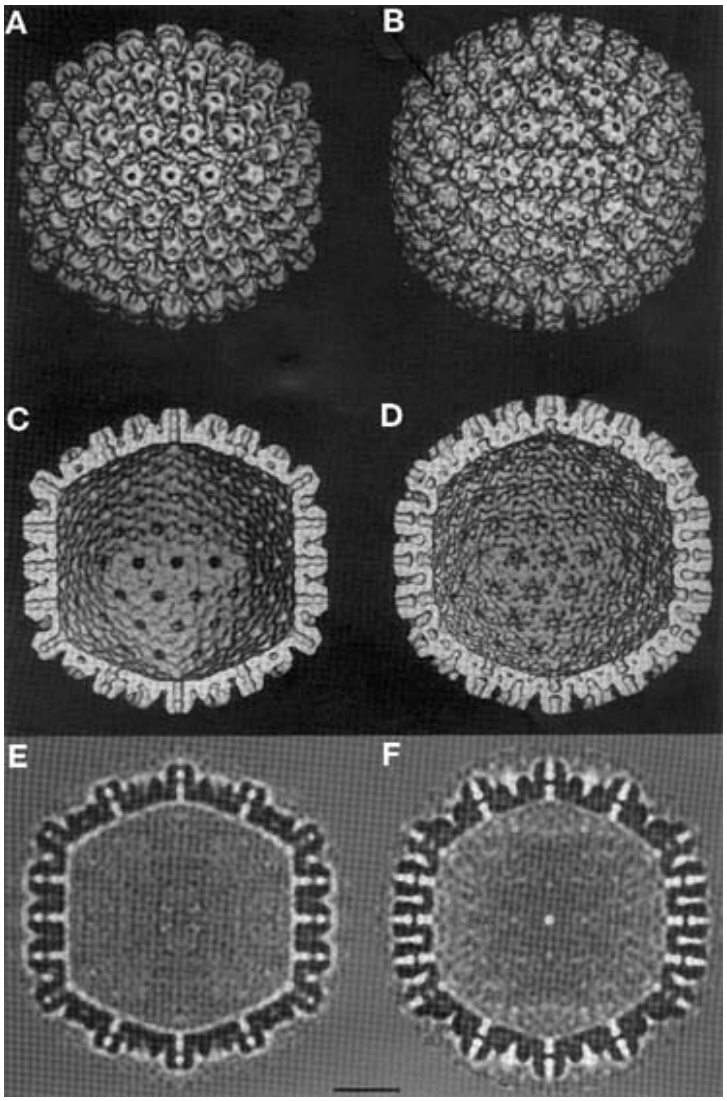

Figure 1 Comparison of the three-dimensional capsid structures of CCV (**A**, **C**, **E**) and HSV-1 (**B**, **D**, **F**). The capsids are viewed along a twofold symmetry axis. Outer surfaces, (**A**) and (**B**); inner surfaces, (**C**) and (**D**); central thin sections, (**E**) and (**F**). The distribution of capsomers (**A** and **B**) is distinctive for the triangulation number, $T = 16$, with lines of three hexons connecting pentons along each edge of the icosahedral surface lattice. Bar = 25 nm. (Reproduced from Booy *et al* (1996) *Virology* 215: 134–141, with permission of Academic Press.)

Ictalurovirus. This genus is as yet unassigned to a subfamily for reasons described below in the section on evolution. Three-dimensional reconstructions derived by cryoelectron microscopy have recently shown that, apart from minor dimensional differences, the CCV capsid is strikingly similar to that of herpes simplex virus type 1 (HSV-1) (**Fig. 1**).

Geographic and Seasonal Distribution

The channel catfish is a North American species. The frequency of occurrence of CCV disease has paralleled the intensification of channel catfish farming in the southern USA and some other warmer temperate regions. The lack of reported isolations of CCV from wild channel catfish strongly indicates that factors such as dense stocking and poor environmental conditions may predispose farmed fish stocks to outbreaks of disease. A key factor is temperature, as epizootics occur in the summer months and the incubation period has been shown to be considerably shorter at higher temperatures up to 30°C.

Host Range and Virus Propagation

CCV causes acute infection only in young channel catfish, usually up to about 6 months old – the degree of mortality depending on the strain of fish. Certain other closely related species, such as the blue catfish (*I. furcatus*), may be infected experimentally by injection, but other species are refractory to infection even by this route. Host cell requirements are a little less stringent in cell culture, but virus growth still only occurs in ictalurid and clariid fish cell lines. BB (*I. nebulosus* or brown bullhead) and CCO (channel catfish ovary) cell lines are commonly used; the latter

is the more susceptible. Optimal virus yield is obtained at 25–30°C, and about 50% of progeny virus is released into the culture medium. Virus infection causes the formation of syncytia, particularly at lower multiplicities of infection, followed eventually by disaggregation and lysis. Under optimal conditions, peak virus yield may be attained only 12 h after infection. In this respect, CCV is one of the fastest growing herpesviruses.

Genetics

Expression of CCV proteins during infection of cells in tissue culture appears to be coordinately regulated. The major immediate early protein, which is likely to regulate the expression of other virus genes, has an apparent molecular mass of 117 000 Da. Experimental determinations of the number of proteins expressed or induced in infected cells are likely to be underestimates, but about 50 have been identified. The capsid contains an abundant constituent with a molecular mass of 128 000 Da and at least two smaller proteins. The major capsid protein of higher vertebrate herpesviruses is invariably larger, having a molecular mass of about 150 000 Da.

Different isolates of CCV may be differentiated by restriction endonuclease digestion of their DNAs, but nevertheless are recognizably similar. The reference strain Auburn is deposited as VR-665 with the American Type Culture Collection. The overall structure of the linear double-stranded DNA genome consists of a unique region flanked at each end by a large direct repeat. CCV DNA replicates in the nuclei of infected cells via head-to-tail concatemers made up of a unit comprising the unique region linked to a single copy of the direct repeat.

The complete CCV DNA sequence has been determined. It contains 134 226 bp and has a nucleotide composition of 56.2% guanosine plus cytosine. The unique region and direct repeat are 97 114 bp and 18 556 bp in size respectively. Analysis of the DNA sequence indicates the presence of 63 genes in the unique region (one comprising three exons) and 14 genes in each direct repeat (**Fig. 2**). The CCV genome shares some general characteristics with other herpesvirus genomes, but these indications of an evolutionary relationship are not reflected at the genetic level. Several gene functions have been proposed from examination of encoded amino acid sequences and computer-aided comparisons of predicted CCV proteins with proteins from other organisms. They include two sets of related protein kinases (genes 14, 15 and 16; genes 73 and 74), a set of three related proteins containing a potential zinc-binding domain (genes 9, 11 and 12); another potential zinc-binding protein (gene 78), a helicase (gene 25), a DNA polymerase (gene 57/58, probably composed of two exons), a deoxyuridine triphosphatase (gene 49), a thymidine kinase (gene 5), a serine protease (gene 47), a DNA-packaging protein (gene 62/69/71, composed of three exons), an envelope glycoprotein (gene 46) and seven other membrane-associated proteins (genes 6, 7, 8, 10, 19, 51 and 59).

The principal constituent proteins of CCV virions have been identified. The capsid includes the major capsid protein (gene 39), a potential scaffold protein (gene 28) and two other proteins (genes 27 and 53). The tegument (the proteinaceous region between the capsid and the envelope) includes proteins encoded by genes 11, 15, 65, 72, 73 and 74, in addition to actin. The major envelope protein is specified by gene 59.

Evolution

Surprisingly, no CCV proteins appear to be related to proteins that are considered to be specific to higher vertebrate herpesviruses, such as those that make up the virion. This is in distinct contrast to herpesviruses of mammals and birds, which are clearly related to each other and probably evolved from an ancestral virus. Thus, the initial biological classification of CCV as a member of the *Alphaherpesvirinae*, a subfamily of the herpesviruses typified by HSV-1, is not supported by genetic data. Indeed, CCV does not fit into any of the three currently recognized subfamilies. It is probable that CCV has diverged from herpesviruses of mammals and birds to such a degree that no convincing genetic evidence remains of a common evolutionary origin.

The SalHV-1 genome is 174 kb in size and has counterparts to at least 18 CCV genes. Limited sequence data indicate that SalHV-1 and SalHV-2 are related to each other and, more distantly, to CCV. These observations indicate that fish herpesviruses form a group that is distinct from herpesviruses of mammals and birds. In that classification should reflect genetic phylogenies, radical modifications in the current taxonomy are necessary in order to accommodate fish herpesviruses in the family.

Pathogenesis

CCV is readily transmitted from fish to fish, probably entering through the gills. In more artificial settings, it can also be transmitted by injection or orally by ingestion of contaminated food. After experimental infection, CCV can be isolated first from the kidneys and then from other organs, in some of which impressively high titers of virus may be attained.

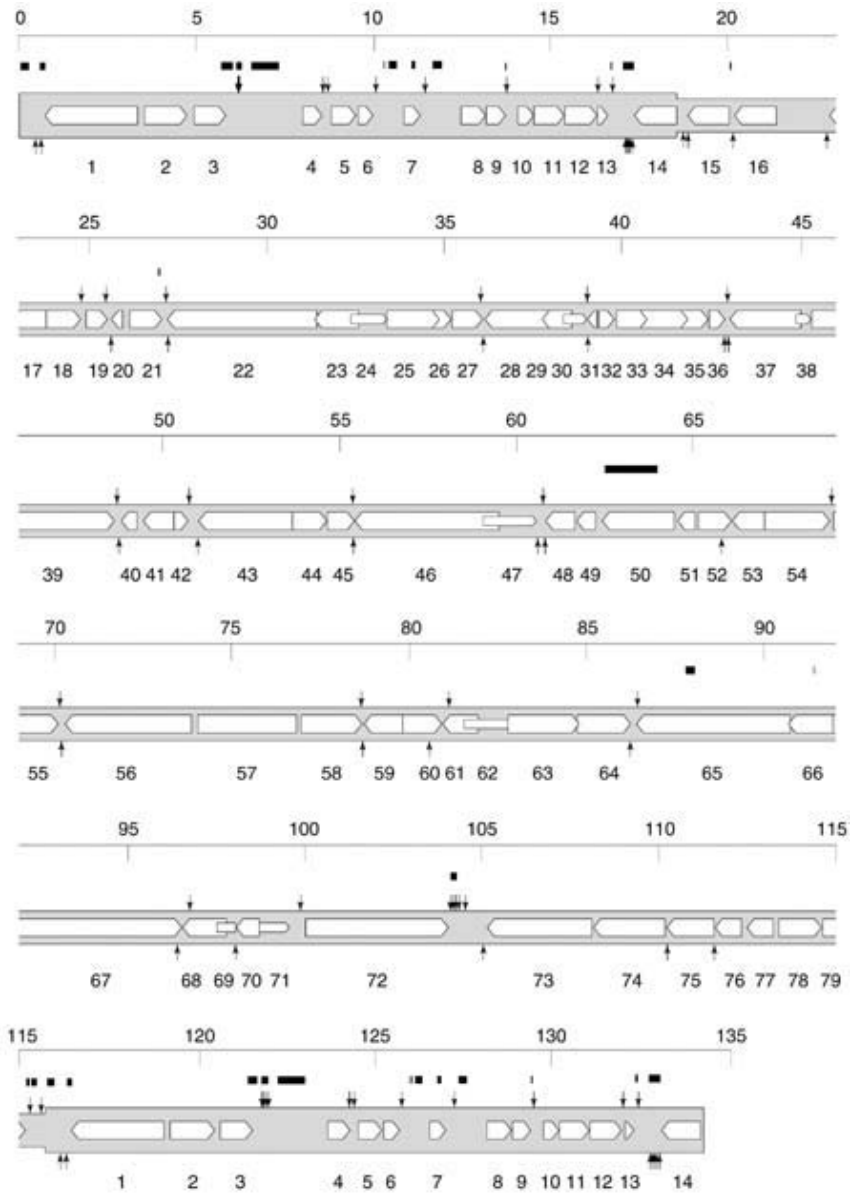

Figure 2 The arrangement of genes in the CCV genome predicted from the complete DNA sequence. The thinner and thicker portions of the genome denote the unique region and direct repeats respectively. The scale is in kilobase pairs. Protein-coding regions are shown as open arrows and numbered below the genome. Thinner arrows are used to reveal regions of overlap. Protein-coding regions 62, 69 and 71 are probably expressed by splicing; regions 57 and 58 may also be spliced. Potential polyadenylation sites are indicated by vertical arrows above and below the genome for rightward and leftward oriented genes respectively. Locations of tandem direct reiterations of short elements are denoted by filled rectangles above the genome. (Modified from Davison AJ (1992) *Virology* 186: 9–14, with permission of Academic Press.)

The primary route for virus shedding is probably via the urine.

Given the virulence of CCV in young catfish, it is quite reasonable to suppose that the virus might persist in an inapparent form in adult fish. This hypothesis is made all the more attractive by the existence of a characteristic latent phase of infection in the natural growth cycles of higher vertebrate herpesviruses. Viral mRNA and antigens have been detected in adult fish and, more recently, virus was recovered by cocultivation of tissues from wintering adult fish, some of which had been immunosuppressed. The site of latency has not, however, been identified. Reactivated CCV from adult fish could, of

course, be transmitted horizontally, but there is good circumstantial evidence that vertical transmission may also occur.

Clinical Features and Pathology

CCV can be remarkably virulent in susceptible populations of channel catfish. Under optimal conditions the incubation period can be as short as 3 days, and mortality can rise rapidly to 100%. Signs of distress may be accompanied by convulsive swimming, including a 'head-up' posture, and lethargy and death follow. Externally, affected fish may display exophthalmia, a distended abdomen and hemorrhages, largely on the ventral surface. Internally, viscera may be enlarged and hemorrhagic, but certain organs, such as kidneys, liver and spleen, may be pale. The digestive tract is empty of food, instead containing a mucoid secretion, and a fluid accumulation is present in the peritoneal cavity. Histopathological examination reveals widespread and profound changes. Initially, the kidneys show edema, hemorrhage and necrosis, and then these features develop in the liver and digestive tract. Electron microscopic studies reveal virus particles in affected organs.

Immune Response, Prevention and Control

Adult channel catfish produce peak neutralization titers on average 8 or 9 weeks after primary immunization with CCV, and a further moderate increase in titer of short duration is apparent after boosting. The importance of virus growth in eliciting the immune response is indicated by the observation that heat-inactivated virus is poorly immunogenic. Serum neutralization indices have been used to document a link between outbreaks of CCV disease and potential carriers of the virus. These studies, though not extensive, have given some indication that seroconverted adult fish are able to transmit CCV. Hopefully, other tools and techniques developed from genome studies will widen the scope and sensitivity of investigations into this aspect of pathogenesis.

Attempts to vaccinate channel catfish against CCV disease have shown promise, and there is increasing interest in this aspect of prophylaxis. CCV that has been attenuated by passage in a clariid fish cell line is able to provide substantial protection against the lethal effect of infection by virulent CCV, particularly when the initial immunization is subsequently boosted. This virus exhibits several genomic differences from wild-type virus, most notably a substantial deletion in gene 50, which potentially encodes a secreted glycoprotein. The use of avirulent strains of virus produced by deleting specific genes may lead in the long term to an efficacious vaccine which, in being unable to revert to virulence, would also be safe. In this context, deletion of gene 5, which encodes thymidine kinase, has been shown to cause attenuation of virulence in channel catfish fingerlings.

CCV is sensitive to nucleoside analogues which inhibit the growth of higher vertebrate herpesviruses. In general, these compounds are phosphorylated by the virus, but not the cellular, thymidine kinase. Further steps in phosphorylation probably involve cellular enzymes. The triphosphate form then inhibits DNA replication by direct interaction with the DNA polymerase or by incorporation into nascent DNA. These compounds include the widely used antiherpetic drug acyclovir. Phosphonoacetate, which inhibits the DNA polymerase by mimicking pyrophosphate, is also inhibitory. It is doubtful, however, whether antiviral therapy will ever be practical for the treatment of CCV disease. Avoidance and containment of outbreaks presently involve the use of ostensibly virus-free breeding stock, as clean environmental conditions as practical, destruction of affected populations and disinfection of ponds.

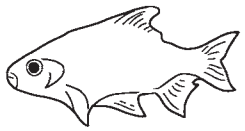
FISH VIRUSES



Carol H Kim and **Jo-Ann Leong**, Department of Microbiology and Center for Salmon Disease Research, Oregon State University, Corvallis, Oregon, USA

Introduction

Fish, like all other living organisms, can be infected by virus representatives from most of the virus families. Predominantly described as fish pathogens, these viruses include rhabdoviruses, birnaviruses, herpesviruses, iridoviruses, reoviruses, orthomyxoviruses and retroviruses. In this brief review, the most well characterized viruses from each family will be discussed and tables listing the general characteristics of these fish viral pathogens as well as other less well characterized viruses within the family are included (**Tables 1** and **2**). In addition, viral agents that have not been confirmed as the etiologic agent and are tentatively classified are listed separately in **Table 3.**

The history of fish virology parallels the development of fish aquaculture, which began more than 3000 years ago. The culture of cyprinid fishes in China was first described at that time and, since then, many more fish species have been cultured for food and the ornamental trade. Along with the development of fish husbandry have come the first descriptions of viral diseases of fish, including spring viremia of carp and carp pox, which was noted as early as 1563.

The basic replication mechanisms and infectious processes of the fish viruses appear to be no different from their counterparts in warm-blooded vertebrates. However, as the viral genomes have been characterized by sequence and expression analysis, several new genera in different virus families have been discovered. For example, the aquabirnaviruses are classified as a separate genus in the family *Birnaviridae* and are distinguished from the other genera by serological and host range parameters. The novirhabdoviruses, containing certain members of the fish rhabdoviruses, are distinguished by a unique viral gene located between the glycoprotein and polymerase gene. No other rhabdovirus contains such a gene encoding a nonvirion protein. Thus, the study of fish viruses has become a fruitful field of investigation that provides unique opportunities to study pathogenesis in significant numbers of animals.

A great deal of effort has been devoted to the development of control strategies to prevent the spread of virus and to control it once it appears at a hatchery. For aquaculture, as with care of other food animals, the disease control measures must be cost-effective, practical and easy to administer in the field. Avoidance continues to be the most effective and economical control measure for the fish pathogens described here. Presently, strict certification of eggs and fry as specific pathogen-free is required for the shipment of eggs and fish between states and countries. Outbreaks are controlled by the destruction of all eggs and fish at the facility that might be contaminated with virus. Stocks of specific pathogen-free eggs or fish are reared in noncontaminated water (well water). Vaccines have been developed for several of the fish pathogens, and include attenuated vaccines, killed vaccines, DNA vaccines and subunit vaccines prepared by recombinant DNA technology. The vaccines have varying degrees of efficacy, but none are presently licensed and commercially available.

The host species and the relative fecundity of these animals make it possible to develop models for transmission and to study environmental effects that may be too subtle to detect in groups of 10–20 animals. With fish studies, it is possible to work with groups of 500–1000 fish. It is also possible to study the effects of developmental stage on virus infection, which is not always possible with warm-blooded mammals, which undergo a large part of early development *in utero*. With egg-laying fish, the effect of different stages of development on viral pathogenesis can be examined very early in the life cycle of the animal.

Significant contributions to the basic understanding of biological processes in eukaryotic cells are being made through the study of viral diseases of fish. This, as well as the need to control diseases in aquaculture, has provided the impetus to discover and characterize more viruses of fish.

1. RNA Viruses

Rhabdoviridae

Infectious hematopoietic necrosis virus

Infectious hematopoietic necrosis virus (IHNV) is a member of the *Rhabdoviridae* family, genus 'IHNV-like viruses', and is the causative agent of an acute, systemic disease in young salmonid fish.

Table 1 Fish RNA viruses

Classification	*Virus*	*Size (nm)*	*Environment*	*Host*	*Disease*
Birnavirus	Infectious pancreatic necrosis virus	55–65	Marine and freshwater	Salmonids	Necrosis of internal organs and tissue
Orthomyxovirus	Infectious salmon anemia virus	80–120	Marine	Atlantic salmon	Anemia
Paramyxovirus	Chinook salmon paramyxovirus	125–250	Marine	Chinook salmon	No associated disease
Retrovirus	Walleye dermal sarcoma virus	100–130	Freshwater	Walleye pike	Tumors
	Golden shiner reovirus	75	Freshwater	Golden shiner, grass carp	Viremia and necrosis
Reovirus	Channel catfish reovirus	75	Freshwater	Channel catfish	Transient viremia
	Chum salmon reovirus	75	Marine and freshwater	Salmonids	Focal necrosis of liver
	Infectious hematopoietic necrosis virus	160–180 × 60	Marine and freshwater	Salmonids	Necrosis of internal organs and tissues
Rhabdovirus	Viral hemorrhagic septicemia virus	185 × 65	Marine and freshwater	Salmonids	Necrosis of liver, kidney, spleen
	Spring viremia of carp virus	180 × 70	Freshwater	Cyprinids	Viremia, swim bladder inflammation

Table 2 Fish DNA viruses

Classification	*Virus*	*Size (nm)*	*Environment*	*Host*	*Disease*
Iridovirus	Lymphocystis virus	150–300	Freshwater and marine	Freshwater and marine fish	Lymphocystis
	Erythrocytic necrosis virus	140–360	Marine	Marine and anadromous fish	Viral erythrocytic necrosis
Adenovirus	Atlantic cod adenovirus	77	Marine	Atlantic cod	Hyperplastic dermal lesions

Table 3 Fish viruses

Tentative classification[a]	*Virus*
Iridovirus	Carp gill necrosis virus, catfish iridovirus, chromide cichlid iridovirus, cod ulcus syndrome iridovirus, epizootic hematopoietic necrosis virus, goldfish iridovirus, icosahedron cytoplasmic deoxyribovirus, lymphocystis virus, sheatfish iridovirus, white sturgeon iridovirus
Adenovirus	Dab adenovirus
Birnavirus	Eel virus European, flounder ascites virus, Menhaden virus, sand goby virus, turbot birnavirus, yellowtail ascites virus
Calicivirus	Opaleye virus
Coronavirus	Carp coronavirus
Picornavirus	Atlantic samon virus, bluegill virus, cutthroat trout virus, rainbow trout smelt picornavirus
Paramyxovirus	Rainbow trout paramyxovirus
Reovirus	13p2 reovirus, Atlantic salmon reovirus, chinook salmon reovirus, eel reovirus, fancy carp reovirus
Rhabdovirus	Eel rhabdovirus, Hirame rhabdovirus, pike fry rhabdovirus, snakehead rhabdovirus
Unclassified viruses	Atlantic salmon papilloma virus, brown bullhead papilloma virus, erythrocytic inclusion body syndrome virus, intraerythrocytic virus, platyfish virus, winter flounder papilloma

[a] Tentative classification is based on virus morphology.

History The virus was first discovered in sockeye salmon (*Oncorhynchus nerka*) dying at hatcheries in Washington in 1953. Similar outbreaks among hatchery-reared chinook salmon in California were reported in 1960. The virus was spread to new sites by the use of unpasteurized sockeye salmon viscera as feed. Although this practice was soon stopped, the disease continued to spread in the 1970s by the shipment of infected eggs to Japan, the eastern USA and Europe. The first laboratory propagation of IHNV was carried out when salmonid fish cell lines became available.

Taxonomy and classification IHNV particles have a bullet-shaped or cone-shaped morphology. The virus belongs to a new genus which has six viral genes in the order 3′-N-P-M-G-NV-L-5′ on the negative-sense single-stranded RNA genome. The N is the nucleoprotein gene; P, the phosphoprotein gene; M, the matrix protein gene; G, the glycoprotein gene; NV, the nonvirion protein gene, and L the polymerase gene. Recently the International Committee on the Taxonomy of Viruses accepted the classification of IHNV with a new genus called *Novirhabdovirus* for the unique *Non-Vir*ion protein gene located between G and L on the viral genome.

Geographic and seasonal distribution Originally, the range of IHNV was thought to be confined to salmonid fish in the Pacific Northwest of North America. However, the shipment of infected eggs or fry has extended the range to include Japan, Korea, Taiwan, China, Spain, Belgium and France. Sporadic outbreaks of the disease have also been reported in Colorado, South Dakota, Virginia and Montana. Most infectious hematopoietic necrosis (IHN) outbreaks occur at temperatures of 12°C or lower among fry and fingerlings. Thus, the disease among steelhead trout fry normally appears in March or April in Washington.

Host range and virus propagation Initially, the host range was confined to the genus *Oncorhynchus* and included the sockeye, kokanee, chinook, cherry, biwa and chum salmon, and yamame, amago, steelhead, cutthroat and rainbow trout where the virus can kill at 3–18°C. The virus can also infect and kill Atlantic salmon (*Salmo salar*), brown trout, brook trout and Japanese char. Coho salmon, arctic grayling, pink salmon, lake trout and Arctic char are relatively resistant to IHNV. The virus can be propagated in a large number of cell lines including RTG-2 (rainbow trout gonad), CHSE-214 (chinook salmon embryo), and EPC (epithelioma papillosum cyprini) at temperatures ranging from 4 to 20°C. Growth is not supported at 23–25°C.

Transmission and tissue tropism Horizontal transmission of the virus from infected feed and in the water from infected fish has been amply demonstrated. However, the vertical transmission of the virus has been the subject of much discussion among scientists studying IHN in the field. Clearly, vertical transmission from infected parents occurs predominantly from surface-contaminated eggs and sperm. The decontamination of eggs by iodophore treatment prevents the vertical transmission of the virus in most cases.

In the infected animal, IHNV is found predominantly in the anterior kidney tissue, where the fish

hematopoietic cells are located, in the spleen, liver and pyloric caeca. There are isolates of the virus that target the brain tissue and selected variants can be found preferentially in liver tissue.

Clinical features and infection In acute disease, moribund fish are lethargic, with periods of sporadic whirling or hyperactivity. Affected fish show signs of the disease, with dark coloration and petechial hemorrhages at the base of fins as well as distended abdomen, exophthalmia, pale gills and mucoid, opaque fecal casts. Histopathologic examination reveals severe degenerative changes throughout the kidney, the hematopoietic organ of fish.

Immune response Fish that have recovered from a virus infection have been shown to have anti-IHNV antibodies by both virus neutralization assays and by ELISA. The presence of a cellular immune response has not been demonstrated satisfactorily because assays for cell-mediated immunity in rainbow trout have not been adequately developed. Nevertheless, laboratory studies with infected versus uninfected CSHE-214 cells indicate that the infected cells are killed at a much increased rate by cytotoxic cells from fish that have recovered from IHN than from control fish.

Viral hemorrhagic septicemia virus

Viral hemorrhagic septicemia virus (VHSV) is the etiologic agent for an acute to chronic disease of rainbow trout and other salmonid species. The disease, viral hemorrhagic septicemia (VHS), is caused by this virulent strain of the virus that is found only in Europe. A VHSV strain that is avirulent in salmonid fish has been found in cod and herring in marine waters of the Pacific Northwest and Alaska.

History The disease was first recognized in the small village of Egtved, Denmark, where trout were dying of an entero-hepatic-renal syndrome. The virus is thought to have existed in Europe for eons as a low level pathogen among the native salmonid fish species, i.e. brown trout and Atlantic salmon. However, when the North American rainbow trout was introduced in 1879 into France and in 1882 into Germany, the new host–pathogen relationship proved deadly. The virus is still a problem at trout farms in France, Belgium, Germany, Norway, Czech Republic, Switzerland and Italy.

Taxonomy and classification VHSV is a member of the *Rhabdoviridae* family with an unassigned genus. The entire sequence of the viral genome has been determined. The genome contains six viral genes arranged in the order, 3′-N-P-M-G-NV-L-5′, where N is the nucleoprotein gene, P is the phosphoprotein gene, M is the matrix protein gene, G is the glycoprotein gene, NV is a nonvirion protein gene, and L is the polymerase gene. The genome order, the presence of the NV gene, and phylogenetic analysis of the glycoprotein gene has placed VHSV in the *Rhabdoviridae* along with infectious hematopoietic necrosis virus, snakehead rhabdovirus and hirame rhabdovirus. The virion has the typical bullet-shaped morphology and measurements indicate that the size of the virion in negatively stained preparations is 70 nm × 180 nm.

Geographic and seasonal distribution To date, VHS is only known to occur in Europe. Outbreaks of the disease have not been found in other parts of the world where trout are raised in large numbers, such as Australia, Japan, North or South America. A North American strain of VHSV has been isolated and appears to be enzootic among certain species of marine fish in the North Pacific Ocean. This strain is not proven to be virulent in salmonid fish species.

Outbreaks of VHS typically involve young fish at the fingerling to yearling stage of development. The disease usually appears when water temperatures drop to 10°C or lower.

Host range and virus propagation The susceptible species include Atlantic salmon, brook trout, brown trout, golden trout, grayling, lake trout, pike, rainbow trout, sea bass, turbot and whitefish. The incubation time after virus infection is usually 2 weeks after inoculation and 3–4 weeks by waterborne exposure. Interestingly, common carp, chinook salmon, chum, coho salmon, goldfish, roach and tench are refractory to the lethal effects of virus infection. In cultured cells, the virus grows well in BF-2 (bluegill fibroblasts), CHSE-214, EPC, FHM (fathead minnow epithelial cells) and RTG-2 cells. The range of replication extends from 4 to 20°C, with optimal yields at 10–15°C. The virus loses infectivity at temperatures above 20°C. At 14°C, new virus first appears at 7–10 h postinfection, with exponential production to 6–10 h until production reaches a plateau at about 24–48 h. Virus production can reach high titers of 7.5×10^7 PFU ml^{-1}.

Transmission and tissue tropism Horizontal transmission is very temperature dependent. It occurs readily at temperatures between 1 and 12°C; temperatures above 15°C are nonpermissive to virus transmission. The source of this virus is believed to be the urine of infected fish. Vertical transmission is

considered extremely rare and probably due to the surface contamination of the eggs with virus in the ovarian fluid. However, unlike IHNV, VHSV has never been isolated from seminal fluid. The virus has been found in the anterior kidneys where the hematopoietic tissues are located and focal necrosis occurs in the liver, another prime target organ.

Clinical features and infection The disease outbreaks begin with individual fish that do not feed and become lethargic or hyperactive. The afflicted fish are noticeably darker, may have exophthalmia in one or both eyes, pale gills which may have petechiae, and hemorrhages at the fin bases. The mortality rates are high. Among the survivors, virus can be isolated for a short period after the peak of mortalities and then infectious virus cannot be isolated, much as has been described for IHNV.

Immune response Production of neutralizing antibody in fish is surprisingly low even after monthly infection of attenuated virus for a year. Specific lymphostimulation to inactivated VHSV was observed in fish that survived a VHS outbreak and in about half of the trout vaccinated by immersion. These studies indicate that fish can mount an immune response to VHSV, and efforts to develop a useful vaccine has been continuing since 1976.

Spring viremia of carp virus

Spring viremia of carp virus is a member of the *Rhabdoviridae* family and the causative agent of an acute infectious dropsy of carp

History In 1971, Fijan and colleagues reported the multiple isolation of a rhabdovirus from carp with signs of the disease, acute infectious dropsy of carp (IDC). They subsequently showed that the rhabdovirus, which they named *Rhabdovirus carpio*, was the causative agent of the viral infection, spring viremia of carp (SVC). The virus is now called spring viremia of carp virus (SVCV). Outbreaks of the disease have been confined to Europe, where reports of its isolation from infected carp have come from The Netherlands, France, Hungary and Germany.

Taxonomy and classification SVCV is a member of the *Rhabdoviridae* family and has been placed within the *Vesiculovirus* genus. The sequence of the viral genome has largely been determined and its gene order is 3′-N-P-M-G-L-5′, where N is the nucleoprotein; P, the phosphoprotein; M, the matrix protein; G, the glycoprotein; and L, the virion polymerase. Unlike the other fish rhabdoviruses described in this review, SVCV does not have an additional gene between the G and L genes. The virus is distinct serologically from IHNV, VHSV, several eel viruses, pike fry rhabdovirus and Rio Grande perch rhabdovirus. Two strains of SVCV have been recognized by serological analysis.

Geographic and seasonal distribution The range of SVCV is still considered to be confined to cyprinid fish species in Europe, Russia and China. The isolation of SVCV has never been reported in the USA despite the repeated introductions of common carp in North America. This may be due to the fact that carp are not highly regarded as game or food fish. Little effort has been expended in determining the virologic status of the carp population in the USA.

As the name implies, disease outbreaks occur in the spring. When temperatures warm in the spring from 11 to 16–20°C, fish become more easily infected; however, the virus kills more fish at the lower temperatures when the fish immune system is less active.

Host range and virus propagation SVCV kills both adult and young common carp. The virus has also been isolated from other cyprinid species, such as silver carp (*Hypophthalmichthys molitrix*), bighead carp (*Aristichthys nobilis*), crucian carp (*Carassius carassius*) and the sheatfish (*Silurus glanis*). It has been grown in guppies (*Lebistes reticulata*) and the fry of the northern pike (*Esox lucius*).

The virus can be propagated in tissue culture cells grown at 20°C. The susceptible lines which exhibit cytopathic effects induced by SVCV infection are FHM, EPC and BF-2 (Bluegill fibroblast) cells. At 20°C, cytopathic effects appear within 2 days.

Transmission and tissue tropism Horizontal transmission is thought to be the primary mode of virus transmission. There is circumstantial evidence that vertical transmission also takes place, as ovarian fluids but not seminal fluids of 5–10-year-old asymptomatic carp contained virus. The carp louse (*Argulus foliaceus*) may be a vector for the virus, as these parasites have been shown experimentally to ingest the virus from SVCV-infected carp and transmit the virus to healthy fish 6–7 days later.

The virus is normally found in the kidneys at 7–14 days after infection. By days 14–21 the liver and spleen have the highest concentration of virus. The virus can also be isolated from the blood, brain, gills, intestine and spleen.

Clinical features and infection The clinical diagnosis of SVC is aimless swimming, abdominal

distension, ascites and hemorrhagic condition of skin, gills and viscera.

Immune response The immune response to SVCV is influenced by temperature, route of immunization, and the age and condition of the host. Adult carp infected at 14°C produced neutralizing antibody slowly; when the fish were held at 25°C, antibody appeared more rapidly. In addition, the fish respond with interferon production within 24 hours of infection.

Birnaviridae

Infectious pancreatic necrosis virus

Infectious pancreatic necrosis virus (IPNV) is the etiologic agent for an acute systemic disease of young trout and Atlantic salmon. The disease is widespread and is a serious pathogen in fish farms in Europe.

History Although the disease had been described in newly feeding hatchery trout fry as early as 1941, the discovery of the viral agent was not made until 1957 by Wolf and Dunbar. They described the isolation of IPNV, the first fish virus to be grown *in vitro*. Since those early investigations, the virus genome has been characterized, cloned and sequenced for a variety of different IPNV strains. The disease process has been characterized and vaccines have been developed for IPNV infection in Atlantic salmon.

Taxonomy and classification IPNV is the prototype virus for the genus *Aquabirnavus*, family *Birnaviridae*. The virions are about 60 nm in diameter, single-shelled, nonenveloped icosahedrons and contain two segments of double-stranded RNA, each with a covalently linked protein at the 5′ end. The buoyant density of the virion in CsCl is 1.33 g ml^{-1}. The viral genome constitutes between 9 and 10% of the virus particle by weight. The size of the larger segment A for IPNV ranges in size from 2962 to 3092 bp and encodes a polyprotein containing NH_2-VP2-NS-VP3-COOH. The smaller segment B, 2731–2784 bp, encodes the viral protein, VP1.

The major virion polypeptides are: VP1 (94 kDa), which is the RNA-dependent RNA polymerase as well as the genome-linked protein; VP2 (54 kDa), the major capsid polypeptide and type-specific antigen; and VP3 (30 kDa), an internal capsid protein and group-specific antigen. A nonstructural protein, NS (29 kDa), is the virus-coded protease that autocatalytically cleaves the polyprotein to produce VP2, NS and VP3. An additional nonstructural polypeptide that is positively charged has been designated as the 17 kDa protein and is encoded in an overlapping open reading frame preceding the segment A encoded polyprotein.

Geographic and seasonal distribution Although the disease was first known in North America, outbreaks of infectious pancreatic necrosis (IPN) among fish have been reported in almost all parts of the world where fish are reared. The virus has been found in countries in Europe, Asia, and North and South America. It has not appeared in Australia and New Zealand, yet. The mortality rate for the virus is markedly influenced by temperature: at 14–15°C, it may be 80%; and at 10°C, it may be only 20%.

Host range and virus propagation The possible hosts for IPNV range from salmonid fish species to at least 20 piscine families, including tropical fish, eels, sea bass and lamprey. The virus is pathogenic for many of these species. IPN-like viruses have also been isolated from mollusks and crustaceans as well as trematode parasites of fishes. Virus propagation *in vitro* can be carried out in a wide variety of cell lines, although the CHSE-214 and RTG-2 cell lines are generally recommended for isolation. The temperature range of incubation is 4–26°C and cytopathic effects become apparent sooner at higher temperatures (9 h at 26°C versus several days at 4°C).

Transmission and tissue tropism Survivors of IPNV epizootics become carriers and shed large quantities of virus (10^3–10^5 $TCID_{50}$ g^{-1}) intermittently for long periods of time in their sex products and feces. Thus, horizontal transmission occurs by contact and ingestion of contaminated water. The virus enters through the digestive tract and gills. Vertical transmission is likely due to the virus presence in the seminal and ovarian fluids. There is also strong evidence that the salmonid egg from carrier fish can carry the virus at a site that is resistant to iodophore treatment. In acutely infected fish, virus can be isolated from the pancreas, intestine and kidneys.

Clinical features and infection In brook and rainbow trout, the disease is first detected by an erratic swimming behavior when the victim trout rotates about its long axis. This is usually a terminal sign but some fish do recover. There is overall darkening, mild exophthalmia and abdominal distension. The affected fish may trail long, thin, whitish cast-like excretions from the vent. In order fingerling trout, IPNV infection sometimes results in petechial hemorrhages through the viscera. Histopathologic examination of the pancreas reveals extensive necrosis.

Immune response Survivors and fish vaccinated with killed IPNV vaccine all produce neutralizing anti-IPNV antibody. Despite high concentrations of IPNV antibody in these fish, virus is also produced in the survivors (carrier) and the presence of antibody is not a good indicator that fish will be protected against the lethal effects of IPNV infection. Thus far, no IPNV vaccine has proven to be effective in field trials.

Reoviridae

Golden shiner reovirus

Golden shiner virus (GSV) disease is a reovirus infection that occurs during high temperatures, frequently in the late summer and fall, among commercially reared bait minnow *Notemigonus crysoleucas*.

History GSV was first discovered in the southern USA in 1977 by Schwedler and Plumb in populations of golden shiner bait fish. The virus only kills fish in large numbers when the fish are stocked at high density.

Taxonomy and classification The virus belongs to the genus *Aquareovirus* in the family *Reoviridae*. Its genome is composed of 11 segments of double-stranded RNA that occur in three size classes. The three large segments range in size from 2.6 to 2.1×10^6 Da; the three medium segments from 1.9 to 1.5×10^6 Da, and the five small segments, from 1.1 to 0.3×10^6 Da. The total genome length is 22 500–23 000 nt. The virus has five structural proteins: two large polypeptides of 135 and 125 kDa, one medium size polypeptide of 70 kDa, and two small polypeptides of 45 and 34 kDa.

The virion is nonenveloped and contains a double-layered icosahedral capsid of 75 nm in diameter. The diameter of the core structure in 50 nm.

Geographic and seasonal distribution The virus was first recovered from golden shiners in several southern states, where they were raised and shipped to other areas of the USA. Since then, the virus has been found in California golden shiners and in grass carp.

Host range and virus propagation Only the golden shiner and grass carp have been identified as susceptible to virus infection. In the case of grass carp, the infected fish appear normal. Virus can be propagated in grass carp cells and EPC.

Transmission and tissue tropism Horizontal transmission has been documented and accounts for natural infections. The incubation time is estimated to be 1–2 weeks. Although specific histologic studies have not been carried out, the visceral organs of suspect fish are sampled for virus infectivity assays.

Clinical features and infection Infection in golden shiner is first noted when the fish swim near the surface and appear listless. Dying fish will swim in a spiral. There is marked hemorrhage on the dorsal surface and petechial hemorrhages on the ventral surfaces, the cornea, the intestinal mucosa and visceral fat.

Orthomyxoviridae

Infectious salmon anemia virus

Infectious salmon anemia (ISA) is a disease of farmed Atlantic salmon (*Salmo salar* L.) in Norway that affects both erythrocytic and leukocytic cells to produce a severe anemia.

History ISA has been the cause of massive economic losses in the Atlantic salmon farming industry in Norway, where it was first recorded at the end of 1984. The disease incidence peaked in 1991 and is now considered the most dangerous fish disease in the European Union. The etiological agent has been identified as an orthomyxovirus.

Taxonomy and classification The genome of infectious salmon anemia virus (ISAV) is composed of eight segments of single-stranded RNA that range in size from 1.0 to 2.3 kb, with a total molecular size of approximately 14.5 kb. Investigators in Norway have cloned and sequenced the smallest genome segment. Although analysis of this segment does not reveal any significant homology with the available sequences for orthomyxoviruses, the morphological and replication properties indicate strongly that ISAV is a member of the *Orthomyxoviridae*.

Geographic and seasonal distribution Outbreaks of ISA were once confined to Norway at Atlantic salmon farms; it has since been reported in New Brunswick, Canada, at Atlantic salmon farms in the area.

Host range and virus propagation The virus has only been reported in farmed Atlantic salmon. It has been propagated in tissue culture cell lines, including CHSE-214, SHK-1 (salmon head kidney) and AS (Atlantic salmon) cells. Cytopathic effects are observed 12–14 days after inoculation with ISA-infected

tissue material. The virus propagation is severely reduced when the growth temperature exceeds 18°C.

Transmission and tissue tropism Transmission trials demonstrated that Atlantic salmon parr developed ISA after intraperitoneal injection. The macrophages in the liver were the first cells to show infection and then hemorrhagic necroses appeared by day 21. The erythrocytic cells are targets for virus infection.

Clinical features and infection The infected fish (postsmolt) have ascites, congestion and enlargement of liver and spleen, congestion of the foregut and petechiae in the peritoneum. The hematocrit values drop from 25 to less than 10 near the end of the disease.

Retroviridae

Walleye epidermal hyperplasia retrovirus, walleye dermal sarcoma retrovirus

Four virus-associated skin lesions have been observed in walleyes, *Stizostedion vitreum vitreum:* lymphocystis, diffuse epidermal hyperplasia, dermal sarcoma and discrete epidermal hyperplasia. Lymphocystis is caused by an iridovirus. Diffuse epidermal hyperplasia appears to be caused by a herpesvirus. The other two diseases are caused by closely related retroviruses. These diseases can be found singly or in combination.

History The presence of translucent and raised nodular lesions on the skin of walleye in New York was first reported in 1969 by Walker. Similar neoplastic lesions were reported in walleyes from two provinces in central Canada and further studies showed that the 'tumors' contained C-type virus particles. More recently, Bowser and Casey at Cornell University have conducted further studies regarding the epizootiology and virus structure of the retroviral agents of walleye discrete epidermal hyperplasia and provided evidence for two different retroviral etiologic agents.

Taxonomy and classification The viruses, walleye dermal sarcoma virus (WDSV) and walleye discrete epidermal hyperplasia virus (WEHV) types 1 and 2 (WEHV1 and WEHV2) are closely related by sequence analysis. The polymerase regions are related by 77% identity for WEHV1 and WEHV2, and 64% identity for WDSV. Although the viruses appear by phylogenetic analysis of the reverse transcriptase domain to cluster with the mammalian type C retroviruses, their classification in the family *Retroviridae* remains unspecified. The WDSV virus has been cloned from tumor tissue and found to be 12.7 kb in length with three open reading frames in addition to gag, pol and env.

Geographic and seasonal distribution The disease, walleye discrete epidermal hyperplasia (WEH), has been observed on approximately 10% of adult breeding walleyes in Oneida Lake, NY, and up to 20% of the walleyes in some lakes in Canada. WEH is present in sexually mature fish during the fall through spring and disappear during the summer months. Apparently, the lesions appear and regress on a seasonal basis. In the case of walleye dermal sarcoma (WDS), the disease can affect up to 27% of walleyes in North American lakes. These lesions, which are distinct from epidermal hyperplasia, also develop in the fall, regress in the spring, and disappear in the summer.

Host range and virus propagation Both viruses, WEHV and WDSV, are found in walleye. Cell free filtrates of tumor tissue when injected into 9-week-old walleye fingerlings produce tumors in 87% of the animals in a 14 week period. The introduction of the virus into other fish species has not been reported. There are no reports of the propagation of WEHV or WDSV in tissue culture cells. All reports on sequence of different viral genes are on clones derived from tumor tissue-prepared virus.

Transmission and tissue tropism Horizontal transmission from infected fish is presumed. Whether or not vertical transmission occurs has not been determined and alternate hosts or reservoirs have not been identified. Both diseases appear to be confined to the surface areas of the fish dermis and epidermis.

Clinical features and infection WEH appears as a hyperproliferative skin disease with plaques of thickened epidermis that can be found on any part of the body. WDS is a disease of benign cutaneous neoplasms that arise multicentrically from the superficial surface of the scales. These lesions often appear to be malignant histologically but they regress in the summer and neither local invasion nor metastasis has been observed in feral fish.

Immune response The immune response to WEHV and WDSV has not been determined. Investigators are determining whether fish whose tumors have regressed during the summer will develop a new crop of tumors in the fall.

2. DNA Viruses

Iridoviridae

Lymphocystis virus

Lymphocystis virus is the etiologic agent for a benign, chronic infection of lymphocytic cells that causes a gross hypertrophy but has little impact on the host. A viral infection is generally superficial and the condition is much like warts.

History Lymphocystis has been documented in the literature for the last century and was first thought to be the result of a parasitic infection of the fish. In 1914 it was first proposed that the disease was caused by a virus, and in 1951 this claim was substantiated by demonstrating transmission of the disease with cell-free filtrates. The virus was transmitted to healthy bluegill fish with bacteria-free homogenates in 1962, and in 1966 the virus was isolated in tissue culture which was subsequently used to infect naive fish.

Taxonomy and classification Lymphocystis virus has an icosahedral symmetry with a large double-stranded genome. It is in the *Lymphocystivirus* genus of the *Iridoviridae* family. The particles contain a dense core within two noncellular membrane-derived envelopes and have filaments extending from the vertices. The size of the virus particles varies with the host that is infected and range from 150 to 300 nm.

Geographic and seasonal distribution This virus has a worldwide distribution and, although it infects fresh as well as marine fishes, it is primarily found in the more evolved fish species, with the exception of salmonid fish. Lymphocystis virus displays a host specificity, and may crossinfect at the genus level, but not family. Temperature plays a role in the development of lesions and there may therefore be seasonal variation in infection rates.

Host range and virus propagation At least 97 species of fish have been infected with the virus, which can also infect invertebrates. There is a host specific for each isolated virus, indicating that there may be many serotypes. The virus replicates in fibroblastic cell lines and is best propagated in cells derived from the host or closely related species. These cultures are maintained in conditions that would provide the best environment for the cells. Cytopathic effects caused by the virus in culture include the formation of giant cells, cytoplasmic inclusion bodies and hyaline capsules.

Transmission and tissue tropism The disease is maintained in host fish and is passed horizontally by fish that have damaged or abraded lesions. Contact is the principal means of transmission, but external parasites have also been implicated in the spread of disease. The virus enters through external surfaces, including the gills. Onset and duration of clinical disease is dependent on the infected host species and the host environment, with fish in colder temperatures experiencing longer incubation periods and lesions persisting for up to a year, while fish in warmer temperatures may resolve the infection and ensuing lesions within a few weeks.

Clinical features and infection The virus causes a lymphocystis in fish that is chronic but benign. Lesions on the skin and fins are composed of grossly hypertrophied cells. The hypertrophy can result in a 50 000–100 000-fold increase in cell volume. Usually there are no mortalities associated with infection and the lesions heal spontaneously. The infection is first apparent with the development of small, pearl-like tumefactions on skin of body, fins, tail and gills. The lesions increase in size and become bibulous, white to opalescent and may become pink in larger lesions. As the lesions mature, they may become hemorrhagic in appearance and look more wart-like. Lesions have also been found in the peritoneum or pericardium, pharynx, intestinal walls, ovaries, spleen and liver. At maturity, the lesions are 100 μm in diameter and can sometimes exceed 1 mm.

Erythrocytic necrosis virus

Formerly called piscine erythrocytic necrosis virus (PENV), viral erythrocytic necrosis virus (VENV) is the etiologic agent that causes serious anemia in at least 20 species of marine and anadromous fish.

History Viral erythrocytic necrosis (VEN) was first reported in 1969 and described as a pathological condition affecting the erythrocytes of three marine species of fish. A hallmark of this condition was the appearance of inclusion bodies in the cytoplasm of infected cells; in 1971, electron microscopy studies showed that virus particles were associated with the inclusion bodies.

Taxonomy and virion structure VEN, in the *Iridoviridae* family, are icosahedral particles with a hexagonal profile. The particles are 140–360 nm in diameter, depending on the species of fish that is infected. Structural details also vary according to species infected. For example, viral particles isolated from herring and salmon have an electron dense coat

8 nm thick, a 22 nm clear zone and a 130 nm nucleoid core with a less electron dense center. Particles from cod have a larger outer hexagonal capsid of 300–360 nm, which appears trilamellar, and an electron dense central core.

Geographic distribution and host range VEN is most probably found worldwide in marine and anadromous fish. The virus has been reported from the Pacific and Atlantic coasts of North America, the UK, Japan, Norway and Chile. Hosts include cyclostomes, elasmobranchs and 14 families of marine or anadromous fish. Chum, pink, coho and chinook salmon and steelhead trout are all susceptible. Older inapparent carrier fish are assumed to be the reservoirs of infection for young fish. Infection of fish has been demonstrated by intraperitoneal and waterborne transmission studies. In addition, transmission of virus infection from herring to salmon under experimental conditions indicates a marine source of virus in aquaculture. To date this virus has never been successfully grown in cell culture.

Clinical features and infection Younger fish are more susceptible to VEN infection and the disease is more devastating to juvenile fish. Infected erythrocytes can be readily identified by appearance and are more easily lysed than normal cells. Infected fish are more susceptible to secondary bacterial infection and environmental stresses. Blood smears show inclusion bodies in the cytoplasm of erythrocytes. Giemsa-stained smears display inclusions that are acidophilic, 1–5 nm in diameter, and intracytoplasmic. Infected erythrocytes show nuclear degeneration, margination of chromatin, pyknosis, karyorhexis and karyolysis. An increased number of immature erythrocytes occurs in peripheral blood, and hematocrit values are depressed. In addition, blood from fish with VEN clots abnormally slowly or not at all. Two types of inclusion bodies have been identified from herring erythrocytes by electron microscopy. One type is associated with virions and is coarsely granular, round and electron dense. The other type of inclusion body is membrane bound with few, if any, virions. The primary diagnostic tool is stained blood smears, with definitive diagnosis by the examination of particles by electron microscopy.

Pathology and histopathology There are no external signs of disease, except for pale gills due to severe anemia, and no mortalities directly associated with VEN infection. Herring may display red external surfaces if heavily infected with virus and organs may be pale as a result of anemia.

Adenoviridae

Atlantic cod adenovirus

Atlantic Cod adenovirus was first described in 1980 and was the first adenovirus-associated disease described in fish. Fish with raised epidermal hyperplastic lesions were examined during a study of ulcus syndrome in cod (*Gadus morhua*) off the coast of Denmark, and virus was seen in the nuclei of cells of these lesions. Epithelial neoplasms have also been found in dab (*Limada limanda*) from the adjacent North Sea, and a common viral etilogy has been proposed.

Taxonomy and classification The virus is in the *Adenoviridae* family and unassigned to a genus. The particles have an icosahedral morphology and are 77 nm in diameter. A 10 nm capsid surrounds an electron dense nucleoid. Although this virus is considered the etiologic agent of the disease, there are few virus particles associated with infected tissue and they are found only in the outermost cells of the epidermis.

Clinical features and infection The skin lesions are flat, raised and transparent plaques that can occur anywhere on the body of the fish, but are most often seen on the caudal regions. The lesions range from 3 to 20 nm in diameter. The infected epidermis is four times thicker than normal tissue and has no or few mucous glands. In addition, there is an increase in the vasculature under the plaques.

Sturgeon adenovirus

Sturgeon adenovirus particles have an icosahedral morphology with a double encapsidation of the nucleoid core. The virus is associated with hypertrophied nuclei of infected epithelial cells of the gastrointestinal tract and causes mortalities of white sturgeons (*Acepenser transmontanus*).

History The sturgeon adenovirus was the first virus to be identified in a sturgeon. In 1984, white sturgeon fry from the Sacramento River in California were experiencing devastating mortalities. It was first thought to be of bacterial etiology but was later found to be caused by an adenovirus.

Virion structure The viral particles have an icosahedral morphology with an inner capsid of 47 nm diameter and outer capsid of 74 nm in diameter.

Virus propagation Propagation of the sturgeon adenovirus has been attempted in several fish cell culture systems, including sturgeon heart (SH-1) and

spleen (SS-2) cells, without success. Primary cultures from infected sturgeon tissues have also been unsuccessful in propagating the virus.

Fish were experimentally infected with the sturgeon adenovirus by intraperitoneal inoculation with tissue homogenates from infected fish. The fish were maintained for 4 weeks and then histologically examined. The gastrointestinal epithelial cells displayed hypertrophy of the nuclei similar to, but in a less intense presentation, the natural infection.

Clinical features and infection White sturgeon infected with the adenovirus were lethargic, anorexic and emaciated, with no food found in the alimentary tract, and the liver tissue was pale. Histological examination showed hypertrophied nuclei of mucosal cells of the gastrointestinal tract.

FOOT-AND-MOUTH DISEASE VIRUSES (*PICORNAVIRIDAE*)

David J Rowlands, Molecular Science Department, The Wellcome Research Laboratories, Beckenham, Kent, UK

History

The earliest recorded account that clearly describes foot-and-mouth disease was made by Fracastorius in 1546. The importance of this highly contagious disease of cloven hoofed animals increased with the accelerating productivity of the livestock industry and the control of more lethal infections of cattle such as rinderpest towards the end of the nineteenth century. It is now amongst the most important and feared diseases of domestic livestock.

It was the first animal disease demonstrated to be caused by a filterable agent in 1897 by Loeffler and Frosch, who also demonstrated the presence of neutralizing antibody in serum. It is also the first virus for which serotype differences were recognized. Research on the virus was greatly facilitated when Waldemann and Pope showed in 1921 that guinea pigs could be infected, and in 1951 when Skinner showed that it caused a lethal infection in suckling mice. Subsequently the demonstration that the virus could be cultured in tissue culture cells and particularly in the BHK-21 cell line has enabled both studies of viral replication and the large-scale production of vaccines.

Taxonomy and Classification

Foot-and-mouth disease viruses (FMDVs) form the *Aphthovirus* genus of the *Picornaviridae* family. The nature and organization of the genome, the mode of replication and the structure of the virion are, in general, similar to other viruses in the family. The original subdivision of the *Picornaviridae* into the four genera, *Enterovirus*, *Rhinovirus*, *Cardiovirus* and *Aphthovirus*, was based on physicochemical properties such as susceptibility to acid inactivation, buoyant density of CsCl solution and the nucleotide composition of the genomic RNA. More recently, analysis of evolutionary relationships by nucleotide sequence comparisons have largely endorsed the original classifications. However, hepatitis A virus is now classified within a separate genus, *Hepatovirus*, and Equine Rhinovirus Type 1 is included within the genus *Aphthovirus*. Properties which distinguish the aphthoviruses are: (1) extreme sensitivity to acid inactivation (<pH 6.8 in low ionic strength buffer); (2) high buoyant density in CsCl (1.43–1.50 g ml^{-1}); (3) possession of a poly(C) tract in the 5′ untranslated region (UTR) of the RNA (a property shared with some cardioviruses); (4) three separately encoded VPg proteins; (5) the use of two alternative in-frame protein translation initiation sites; and (6) a leader protease protein located in the N-terminal region of the polyprotein.

Properties of the Virion

As for other picornaviruses, FMDV particles are naked icosahedrons comprising 60 copies each of four

spleen (SS-2) cells, without success. Primary cultures from infected sturgeon tissues have also been unsuccessful in propagating the virus.

Fish were experimentally infected with the sturgeon adenovirus by intraperitoneal inoculation with tissue homogenates from infected fish. The fish were maintained for 4 weeks and then histologically examined. The gastrointestinal epithelial cells displayed hypertrophy of the nuclei similar to, but in a less intense presentation, the natural infection.

Clinical features and infection White sturgeon infected with the adenovirus were lethargic, anorexic and emaciated, with no food found in the alimentary tract, and the liver tissue was pale. Histological examination showed hypertrophied nuclei of mucosal cells of the gastrointestinal tract.

FOOT-AND-MOUTH DISEASE VIRUSES (*PICORNAVIRIDAE*)

David J Rowlands, Molecular Science Department, The Wellcome Research Laboratories, Beckenham, Kent, UK

History

The earliest recorded account that clearly describes foot-and-mouth disease was made by Fracastorius in 1546. The importance of this highly contagious disease of cloven hoofed animals increased with the accelerating productivity of the livestock industry and the control of more lethal infections of cattle such as rinderpest towards the end of the nineteenth century. It is now amongst the most important and feared diseases of domestic livestock.

It was the first animal disease demonstrated to be caused by a filterable agent in 1897 by Loeffler and Frosch, who also demonstrated the presence of neutralizing antibody in serum. It is also the first virus for which serotype differences were recognized. Research on the virus was greatly facilitated when Waldemann and Pope showed in 1921 that guinea pigs could be infected, and in 1951 when Skinner showed that it caused a lethal infection in suckling mice. Subsequently the demonstration that the virus could be cultured in tissue culture cells and particularly in the BHK-21 cell line has enabled both studies of viral replication and the large-scale production of vaccines.

Taxonomy and Classification

Foot-and-mouth disease viruses (FMDVs) form the *Aphthovirus* genus of the *Picornaviridae* family. The nature and organization of the genome, the mode of replication and the structure of the virion are, in general, similar to other viruses in the family. The original subdivision of the *Picornaviridae* into the four genera, *Enterovirus*, *Rhinovirus*, *Cardiovirus* and *Aphthovirus*, was based on physicochemical properties such as susceptibility to acid inactivation, buoyant density of CsCl solution and the nucleotide composition of the genomic RNA. More recently, analysis of evolutionary relationships by nucleotide sequence comparisons have largely endorsed the original classifications. However, hepatitis A virus is now classified within a separate genus, *Hepatovirus*, and Equine Rhinovirus Type 1 is included within the genus *Aphthovirus*. Properties which distinguish the aphthoviruses are: (1) extreme sensitivity to acid inactivation (<pH 6.8 in low ionic strength buffer); (2) high buoyant density in CsCl (1.43–1.50 g ml^{-1}); (3) possession of a poly(C) tract in the 5′ untranslated region (UTR) of the RNA (a property shared with some cardioviruses); (4) three separately encoded VPg proteins; (5) the use of two alternative in-frame protein translation initiation sites; and (6) a leader protease protein located in the N-terminal region of the polyprotein.

Properties of the Virion

As for other picornaviruses, FMDV particles are naked icosahedrons comprising 60 copies each of four

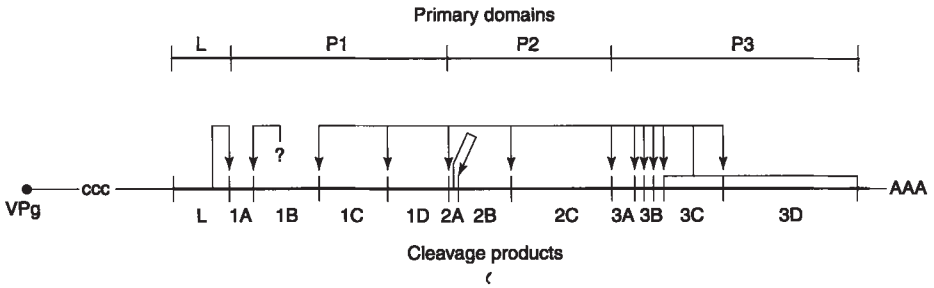

Figure 1 Organization of the FMDV genome. (Modified from the original by LS Titey and AMQ King.)

structural proteins, VP1–4, encapsidating a single copy of the single-stranded positive-sense genomic RNA. The crystallographic structure of the virus has shown that the three larger proteins (VP1–3) have the same eight-stranded antiparallel β-barrel folding motif seen in other picornaviruses and some plant viruses. VP4 is disposed on the inner surface of the particle. In common with other picornaviruses, VP1 molecules are located around the axis of fivefold symmetry, whereas VP2 and VP3 alternate around the two- and threefold symmetry axes. Heat or acid degradation of the particles results in the separation of pentameric subunits, consisting of five copies each of VP1–3, with release of the RNA and an insoluble aggregate of VP4.

Several features of the structure are unique to FMDV. The protein shell is generally thinner and the external surface is smoother than in other picornaviruses. This results from the comparatively smaller sizes of VP1–3 (VP1 213, VP2 218, VP3 220 amino acids for virus O1) compared with other picornaviruses. The reductions in size have generally been in the loop regions, linking the core elements of the β barrels, which in other picornaviruses form prominent features at the outer surface. Another consequence is that the deep grooves or canyons encircling the fivefold axes of enteroviruses and rhinoviruses or the series of pits in the cardioviruses are not present in FMDV. The position of FMDV particles equivalent to these invaginations is occupied by the C-terminal portion of VP1 which arises at the surface at about residue 200 and traverses in a clockwise direction from one protomer to the next. The lack of depressions in the surface at positions equivalent to the canyon or pits of other picornaviruses is of particular significance because these have been implicated as the sites at which those viruses interact with their receptors at cell surfaces.

An important exception to the generally smooth contours of the surface of FMDV is provided by the G–H loop of VP1. This large loop extends from about residue 130 to 160, of which circa 135–158 are too disordered to be visible in electron density maps. In serotype O1 viruses the disorder of the VP1 G–H loop is induced by a disulfide bond between the cystine residues VP2 130 and VP1 134. Under reducing conditions this bond is broken and the G–H loop collapses on to the surface of the virus in an ordered configuration. This feature includes an immunodominant antigenic site to which a high proportion of virus-neutralizing antibodies are directed. Also, synthetic peptides representing sequences from this region are highly effective immunogens and can induce protective immunity. The sequence of this region is hypervariable both in composition and length between different viruses, with the exception of a highly conserved triplet, Arg, Gly, Asp at residues 145–147.

Another structural consequence of the truncation of VP1 is the exposure of a pore at the fivefold axis. This is large enough (*c.* 6 Å) to explain the unique permeability of FMDV to photoinactivating dyes, such as proflavine, and may account for the high buoyant density of the virus in cesium salts.

Properties of the Genome

The genome consists of a single molecule of single-stranded positive-sense RNA, which is infectious. The order of the gene products on the genome is basically similar to other picornaviruses but there are some unique features (**Fig. 1**). The genomic RNA terminates at the 5′ untranslated end in a small protein, VPg, linked by a phosphodiester bond through a Tyr. There is a variable length of poly(A) tract at the 3′ end. Instead of the usual single VPg, the FMDV genome encodes three distinct versions of the molecule, which are used with equal efficiency. The reasons for this gene triplication are unknown. In fact, virus derived from an infectious cDNA clone from which one or two of the Vpg copies had been deleted was still infectious, although RNA synthesis was reduced. The 5′ UTR is exceptionally long (*c.* 1300 nucleotides) even by picornavirus standards. There is an uninterrupted poly(C) tract of 100–200 residues, depending on the virus isolate, located *c.* 400

nucleotides from the 5′ end. The function of the poly(C) tract is unknown, but studies with an infectious clone of the genome have shown that a minimum of 35 C residues is required for virus viability (cf. cardioviruses which are viable in the absence of a poly(C) tract), and circumstantial evidence suggests that the length of the poly(C) tract may be related to virus virulence.

The sequence between the 5′ end and the poly(C) tract has a high degree of secondary structure and is predicted to fold into an almost complete hairpin. Its function is unknown. To the 3′ side of the poly(C) tract there is a variable number (three or four, depending on virus strain) of repeat domains which are predicted to fold as pseudoknot structures. The 3′ 435 nucleotides of the 5′ UTR fold into a series of stem loop structures similar to those present in the equivalent region of cardiovirus UTR.

Protein Products

The protein coding region is a continuous open reading frame of 6999 or 6915 nucleotides for A^{10}, depending on which of two functional in-frame initiation codons is used. The order of the gene products is shown in **Fig. 1.**

1. Leader protein. The leader protein(s), Lab and Lb, which precede the structural proteins, have a proteolytic function which results in cleavage at the L–P1 junction and also affects the cell translation machinery (see Translation). The significance of the presence of two forms of L, dependent on which translation initiation site is used, is unknown. The L proteins are not essential for virus viability, as virus derived from an infectious clone from which their coding region had been deleted was still infectious. However, this virus has an attenuated phenotype and has been proposed as a candidate live vaccine.
2. P1 region. The P1 region consists of the structural proteins. P1A, B, C and D are equivalent to VP4, 2, 3 and 1 respectively.
3. P2 region. The P2A protein is vestigial in size compared to other picornaviruses, being only 18 amino acids long, but it enables the nascent cleavage of the polyprotein at the P2A–2B junction. The function of P2B is unknown. P2C is involved in RNA replication, as mutations affecting sensitivity to guanidine inhibition occur in this protein, but its precise role is unclear.
4. P3 region. P3A does not have the hydrophobic character of the equivalent protein in poliovirus. P3B or VPg occurs as three tandem copies on the genome. The three proteins are 23, 24 and 24 amino acids in length. Although differing from each other in sequence, they share the properties of being rich in Pro, Arg and Lys residues and each has a single Tyr at position three. Despite differing from each other, each of the VPg molecules is highly conserved between the A, O and C serotype viruses. The VPg molecules probably play a role in the initiation of RNA synthesis since they are found at the 5′ end of nascent RNA molecules of both positive and negative polarity. All encapsidated RNA molecules terminate with a VPg molecule and each of the three forms is found in equal abundance. A proportion of intracellular viral RNA, including actively translating polysomal RNA, lacks VPg, and cell extracts contain an enzyme that specifically removes the protein. This enzyme cleaves the phosphodiester bond to produce RNA terminating with a 5′-monophosphate. The observation that no VPg-lacking RNA molecules are found in viral particles suggests that it may have a role in the selection of molecules for encapsidation. Mutagenesis experiments with an infectious cDNA clone have provided some support for this conclusion. P3C is a protease that is responsible for the majority of the processing cleavages. In common with the 3C protease of other picornaviruses, sequence analysis suggests that the catalytic site of the enzyme is related to trypsin, a serine protease, but with the replacement of the nucleophilic serine residue with cysteine. P3D is an RNA-dependent RNA polymerase. Purified preparations of the enzyme are active *in vitro* when provided with natural (viral RNA) or synthetic substrates and a complementary primer.

RNA Replication

RNA of infecting virus acts as a template for the synthesis of a negative-sense complementary strand(s) which is capped at the 5′ end with a VPg molecule. Complementary strand RNA serves in turn as a template for the synthesis of positive-sense strands, identical to the original infecting molecule. Positive-strands are synthesized in a complex structure (replicative intermediate (RI)) consisting of a single negative-strand template and several (*c.* six) nascent positive-strands. RNA synthesis is asymmetrical in favour of positive strands. The details of the features that differentiate positive- and negative-strand synthesis are unclear. A proportion of the negative-strand templates occur as full-length double-stranded hybrids (replicative form (RF)) and appear to take no

further part in RNA synthesis. RF molecules accumulate in the cell during viral replication.

A single molecule of viral RNA is sufficient to initiate infection, which implies that it can function sequentially as a template for translation, to produce the polymerase enzyme(s), and as a template for RNA replication. Single-stranded viral RNA is infectious in the presence of inhibitors of host cell DNA-dependent RNA polymerase. Double-stranded viral RNA is also infectious but not in the presence of inhibitors of the cellular polymerases.

Translation

FMDV RNA is efficiently translated in a cell-free system (rabbit reticulocyte lysates) to produce protein products similar to those found in infected cells. Truncated viral RNA lacking *c.* 600 nucleotides from the 5′ end, including the poly(C) tract, is translated as efficiently as intact RNA. The secondary structural folding of the 435 nucleotides upstream of the first AUG initiation codon for the polyprotein is similar to that of the equivalent region of cardiovirus RNAs. This sequence acts as an internal ribosome-binding site (internal ribosome entry site, IRES), allowing the initiation of translation in the absence of the host cell CAP-binding complex. Because of these properties, the IRES sequence can efficiently direct the translation of the second cistron when inserted between protein-coding sequences in a bicistronic mRNA construct. The rate of total protein synthesis by virus-infected cells does not change until its decline at the later stages of the growth cycle, when cytopathic effects are apparent. There is, however, a marked change in the profile of proteins produced. At times when viral replication is maximal, virtually no host cell proteins are produced. This 'swap over' of translation from host to viral products is similar to the situation in cardiovirus-infected cells and differs from the kinetics of translation following infection of cells with entero- or rhinoviruses. In the latter, infection results in a rapid shutdown of host cell protein translation, which is followed later by a resumption of protein synthesis due to the increasing production of viral proteins. The shutdown induced by entero- and rhinoviruses is largely, if not entirely, due to a virus-induced cleavage of a host protein, p220 or eIF4G, an important component of the CAP-binding complex required for the initiation of translation of host mRNAs, which are generally capped at the 5′ end. In these viruses, eIF4G cleavage is indirectly induced by P2A protease. Cardioviruses do not induce eIF4G cleavage and appear to simply outcompete host mRNAs for utilization of the translation machinery. Although the kinetics of protein translation in FMDV-infected cells resemble those of cardiovirus-infected cells, eIF4G is cleaved. In contrast to entero- and rhinoviruses, FMDV cleavage of eIF4G is not induced by P2A but by the leader protein(s).

Post-translation Processing

The polyprotein translation product of FMDV RNA is proteolytically processed by three of four virus-encoded enzyme activities. Three of the cleavages occur nascently on the growing polypeptide chain. The first separates the leader protein(s) from P1, the structural protein precursor, and is carried out by leader protein. The cleavage occurs between a Lys-Gly dipeptide. Cleavage probably occurs in *cis* but can also occur in *trans*. L-P1 cleavage is the only processing step which is inhibited by the tripeptide D-Val-Phe-Lys-CH_2Cl. Both Lb and Lab are proteolytically active.

The second nascent or primary cleavage occurs at the junction of P2A and P2B and is catalyzed by the 18 amino acid P2A sequence. This short sequence promotes cleavage at its C-terminus when inserted within a variety of protein sequences by DNA recombinant techniques. However, it contains no obvious catalytic motifs and the precise mechanism of cleavage is unclear. Cleavage only appears to occur nascently during the process of translation, as synthetic peptides incorporating the sequence do not self-process. It has been suggested that the mechanism may involve a novel process of interrupted translation rather than proteolytic cleavage. FMDV P2A has sequence homology with a region near the C′-terminus of cardiovirus P2A.

The third nascent cleavage is between P2C and P3A and is catalyzed by P3C protease. This protease is responsible for all other processing cleavages, apart from that which generates VP2 (P1B) and VP4 (P1A) from the precursor, VP0 (P1AB). Many cleavages catalyzed by P3C protease occur at Glu-Gly junctions but many other dipeptides are recognized and 3C of FMDV is the most promiscuous of the picornavirus proteases. The cleavages of P1 to generate P1AB, P1C and P1D can occur with 3C alone but are more efficiently carried out by 3CD.

The cleavage event to produce VP2 and 4 from the precursor, VP0, occurs in the final stages of virus maturation. The mechanism of this cleavage is not known.

Virus Assembly and Release

A variety of assembly intermediates containing equimolar amounts of VP1, 2 and 0 are detected in infected cells. These correspond to monomer and

pentamer subunits of the icosahedral capsid and 75S empty particles, which lack viral RNA but possess antigenic properties similar to mature viral particles. Following pulse-labeling experiments, empty particles can be 'chased' into viral particles, but it has not been shown that they are on the direct morphogenetic pathway. Only about 10% of the viral RNA present in cells is incorporated into virions. All encapsidated RNA terminates with VPg, suggesting that this plays a role in selection. Mutated VPg molecules within an infectious cDNA clone are less efficiently encapsidated.

Paracrystalline arrays of virus are visible in infected cells and are released by lysis of the cell. There is evidence that some viral particles are secreted prior to cell disruption.

Attachment to Cell Receptor(s)

Protease treatment of viral particles can destroy their ability to attach efficiently to cells. Only VP1 is cleaved under these conditions. Cleavage within the G–H loop or in the C-terminal region prevents cell attachment, suggesting that both are important for receptor binding.

Synthetic peptides including Arg, Gly, Asp, the highly conserved triplet found in the G–H loop, can compete with virus for attachment to cells and inhibit infectivity. The conformation of the Arg, Gly, Asp triplet in the VP1 G–H loop of reduced O1 virus, in which the loop is ordered, is similar to that in γ-II crystallin, an integrin-binding protein. These observations have led to the suggestion that the cell receptor(s) for the virus belongs to the integrin family. Competition binding experiments suggest that different viral strains bind to different receptors. Integrins $\alpha v\beta 3$ and $\alpha 5\beta 1$ have both been implicated as receptors for the virus. Viruses in which residues within the Arg, Gly, Asp motif are mutated have been selected *in vitro*. Heparin sulphate has been shown to act as a 'second receptor' for the virus in tissue culture cells. The mechanism of virus uncoating is unknown but the conserved property of acid lability may be related to the process.

Geographic Distribution

Foot-and-mouth disease occurs widely and is endemic in many countries, especially in tropical regions (**Fig. 2**). North America, Australia, New Zealand and Japan are free of the disease and maintain this status by rigorous application of import controls and quarantine. Mass vaccination campaigns have virtually eliminated the virus from some areas, e.g. Europe, but have been less effective in others, owing largely to logistical problems of vaccine distribution and the techniques of animal husbandry employed. Of the seven serotypes of the virus, serotypes A, O and C are the most widely distributed while serotypes SAT1, 2 and 3 are confined to the African continent and Asia; 1 is only found in Asia.

Host Range and Viral Propagation

The virus typically infects cloven hoofed species, with domestic cattle being among the most susceptible. Domestic pigs are also important hosts and are particularly effective in propagating the disease, as they secrete large quantities of virus in the form of aerosols. In sheep and goats, the clinical manifestations of infection are usually less severe than those seen in cattle and pigs. Natural infection of Indian elephants and of camels has been reported. Many wild species of deer and antelope are susceptible to infection; in African buffalo infection is asymptomatic. Persistent infection with prolonged shedding of virus for months or years has been reported in wild and domestic species. A wide range of animals, including Australian marsupials and birds, have been infected under laboratory conditions, and, very rarely, infection of humans has been demonstrated.

The most important small animals for laboratory investigations are the guinea pig and the suckling mouse. In the former, injection of virus intradermally into plantar pads results in the formation of vesicular lesions both at the site of injection and in the mouth and the remaining feet, and so resembles the lesion distribution in naturally infected susceptible species. Intraperitoneal infection of suckling mice results in rapid death and is useful for the titration of virus. The viruses can be propagated in primary cells and cell lines of bovine or porcine origin. Cells derived from the BHK-21 line are most widely used for research or vaccine production purposes. The virus can be titrated by plaque assay in cultured cell monolayers or by cytopathic endpoint dilution assay in microtitre plates.

Genetics and Evolution

In common with other RNA viruses, the mutation rate is extremely high, so that, on average, no two genomes are identical. Antigenic sites on the viral particle are tolerant of sequence variation, and antigenic diversity is a significant property of the virus.

In addition to evolution by the accumulation of point mutation, genomic recombination occurs at a high rate *in vitro*. The frequency and genomic

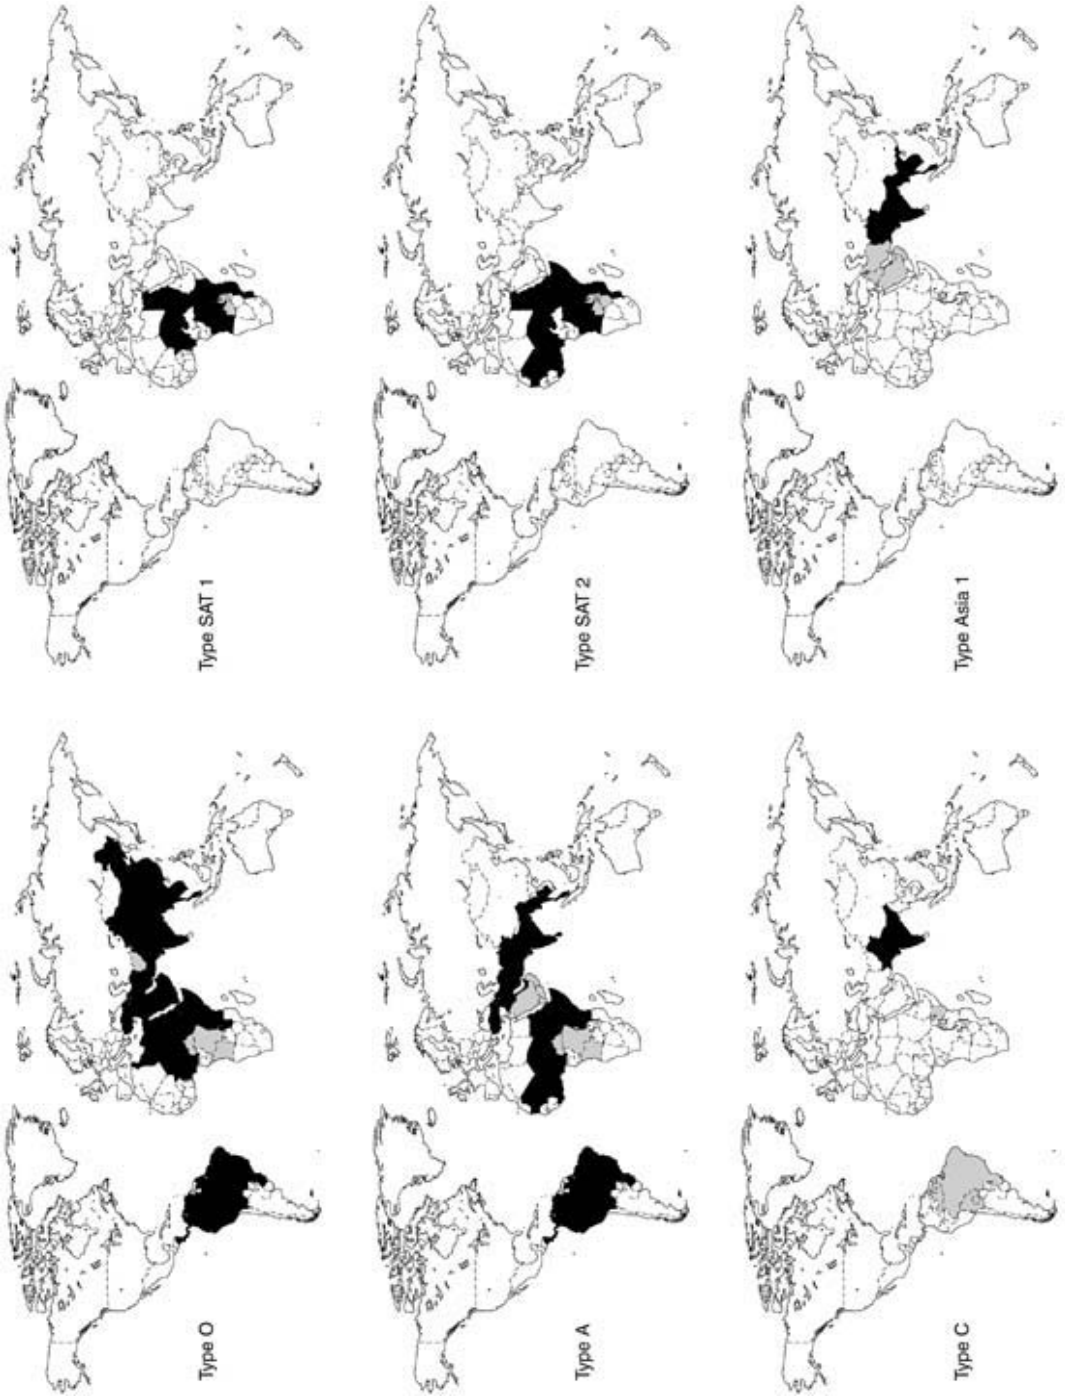

Figure 2 World distribution of FMDV by type. Virus type SAT3 has been recorded only in Botswana, Zimbabwe and the Republic of South Africa.

location of recombinatorial events mirrors the genetic relatedness of the parental viruses.

Serological Relationships and Variability

Seven serotypes of FMDV are recognized, the distinction of serotypes being that an animal convalescent from infection by virus of one serotype is fully susceptible to viruses of any of the remaining six. In addition to the major serotype differences, there is considerable antigenic variation between viruses within serotypes. Serologically distinguishable viruses within serotypes were originally classified as subtypes, but these distinctions became blurred into a continuous antigenic spectrum, and the system has now been abandoned.

For practical purposes in epidemiological studies and vaccine strain selection the serological relationships between field virus isolates or laboratory strains are expressed as *r* values, i.e. the ratio of the neutralizing titers of immune sera against heterologous and homologous viruses. The serological relationships between virus isolates are frequently nonreciprocal, showing that closely related viruses may induce broadly crossreactive or narrowly specific immune responses. Complement fixation assay and enzyme-linked immunosorbent assay (ELISA) using polyclonal sera or monoclonal antibodies are also used for epidemiological studies.

Epidemiology

In regions endemic for foot-and-mouth disease, the virus is most likely maintained in persistently infected animals. It has been shown experimentally that infected bovines can secrete virus for long periods after the initial episode of disease. In some areas the wild animal population may act as a reservoir for infection (e.g. Cape buffalo in Africa). In nonendemic areas infection may be introduced from a variety of sources, such as the importation of infected livestock, contaminated animal products such as carcasses containing bone (in contrast to meat, the postmortem acidification of bone marrow and other nonmuscular tissues is insufficient to inactivate the virus), or contaminated materials. More locally, transmission of infection is by direct transport of contaminated animals or materials or by wind-borne carriage of infectious aerosols. It is also suspected that the virus can be passively transmitted by migrating birds.

Transmission and Tissue Tropism

The principal route of infection appears to be via aerosol impinging on the pharynx and respiratory tract. Aerosols may be produced locally during feeding on contaminated foodstuff or may be transmitted over considerable distances under appropriate meteorological conditions. Pigs secrete particularly high levels of virus-contaminated aerosols. In addition to mucosal secretion, high levels of virus are found in milk. Pasture may be contaminated with virus from urine and feces.

Vesicular lesions appear in the mouth, on the tongue, gums and cheeks, and later on interdigital mucosa and coronary bands of the feet. Virus can be isolated from many tissues in the body. The onset of clinical disease is usually very rapid and lesions can develop as early as 1–2 days after infection, depending on the virus strain and level of exposure.

Pathogenicity

The pathogenicity of FMDV varies according to the virus strain, host species and age. The factors that govern the virulence of FMDVs are poorly understood but there is some evidence from studies of laboratory attenuated strains that the length of the poly(C) tract may influence this property. Domestic cattle are usually the most susceptible species and morbidity is usually approximately 100% in nonvaccinated animals. Wild bovines, such as African buffalo, may produce no clinical manifestations. Although the disease is rarely fatal in adult domestic animals (<5%), significant mortality may occur in young animals (*c.* 50%).

Clinical Features of Infection

Infection typically produces a rapidly progressing febrile illness and the development of often massive vesicular lesions in the mouth and on the feet. The lesions rupture, with considerable loss of epithelial tissue. The resulting discomfort discourages feeding until the lesions heal by the infiltration of fibrous tissue. The severity of the disease results in long-term loss of productivity in terms of meat and milk yield, and lameness may be a serious consequence for draught animals. Abortion and chronic subfertility are also common. Other organs infected include mammary glands, pancreas and heart.

Immune Response

Infection elicits a vigorous humoral antibody response and, after recovery, immunity to reinfection with viruses of the same serotype is prolonged. The role of cytolytic T cells in recovery is unclear.

Five antigenic sites recognized by antibodies capable of neutralizing the virus have been described. One of these is an immunodominant linear sequence located between residues 130 and 160 of VP1, and

synthetic peptides representing this tract are effective in inducing high levels of virus-neutralizing antibody and can protect animals from infection.

Nonprotective antibodies are directed against antigenic sites present on the virus itself, on the 12S pentameric virus subunits and on nonstructural viral proteins, especially the RNA polymerase (virus-infection-associated (VIA) antigen). The presence of antibodies to VIA antigen can serve to distinguish animals that have been infected from those that have been vaccinated.

Prevention and Control

In regions that are free of the disease, natural protection afforded by geographical barriers is rigorously reinforced by strict control measures on the import of susceptible animals and potentially contaminated materials. Where outbreaks occur sporadically, due to occasional introduction from external sources, embargoes on animal movement and slaughter of infected herds have been successful in maintaining a disease-free national herd. In endemic areas, control is by mass vaccination. Ring or barrier vaccination is also used to limit the spread of infection.

The first vaccines against foot-and-mouth disease were produced by formalin inactivation of lymph drawn from lesions on the tongues of infected cattle. This source of immunizing virus was replaced by the Frenkel method of culture in fragments of epithelium stripped from the tongues of slaughtered cattle. Most vaccine in use today is produced by growing the virus in suspensions of BHK-21 cells in fermentation vessels of up to 10 000 litres capacity. Approximately 2×10^9 monovalent doses of vaccine are administered annually. Aziridines have largely replaced formalin as the inactivant, as the inactivation kinetics of the latter are nonlinear and residual live virus in vaccines has occasionally been the source of outbreaks of disease. The serotype and strain composition of vaccines have to be tailored for local requirements. Inactivated virus is usually adjuvanted by adsorption on to aluminum hydroxide gel, and saponin may also be added to enhance potency. In pigs, such vaccines elicit only immunoglobulin M responses and for this species vaccines are formulated with oil adjuvants.

Solid protection requires high levels of neutralizing antibodies, and, to achieve this with inactivated vaccines, immunization is repeated 2–3 times a year. The development of live attenuated vaccines has largely been abandoned, owing mainly to the complexity of antigenic diversity and the fear of reversion to a virulent phenotype.

Future Perspectives

There is scope for developments in foot-and-mouth disease vaccines to improve stability, crossprotective efficacy and duration of immunity. Peptide vaccines or rationally designed nonreverting attenuated viruses are potential routes by which these goals may be achieved. The production of nonbiodegradable peptides and the creation of an attenuated L protein deletion mutant may be important developments.

As to the molecular properties of the virus, both the determination of the crystallographic structure of the particle and the cloning and manipulation of full-length infectious cDNA molecules are important steps towards understanding the unique features of the virus.

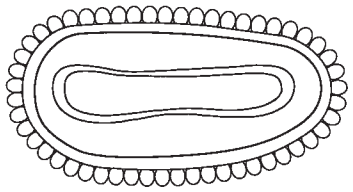
FOWLPOX VIRUS (*POXVIRIDAE*)



Deoki N Tripathy and **William M Schnitzlein**, Department of Veterinary Pathobiology, College of Veterinary Medicine, University of Illinois, Urbana, Illinois, USA

History

Poxvirus infection in avian species resembles its counterparts occurring in mammals and it may have coevolved with its hosts, as it has been observed from time immemorial; indeed, during the seventeenth and eighteenth centuries the infection was described in doves, hawks and turkeys.

The term 'fowlpox' initially included all poxvirus infection of birds, although now this designation usually refers only to disease of chickens. Various synonyms that have been used in the past include chicken pox, avian pox, bird pox, contagious epithelioma, sorehead, avian molluscum, avian diphtheria, *Geflugelpocken* (German), *viruela aviare* (Spanish), *difteria aviar* (Spanish), *Bouba* (Portuguese) and *variole aviaire* (French).

Taxonomy and Classification

Fowlpox virus is the type species of the genus *Avipoxvirus*, in the subfamily *Chordopoxvirinae* of the *Poxviridae* family. Other members of this genus are canarypox, juncopox, mynahpox, pigeonpox, psittacinepox, quailpox, peacockpox, penguinpox, sparrowpox, starlingpox and turkeypox. All of these viruses have a restricted host range, infecting only avian species. Since fowlpox virus is the most studied member of this genus, most of this entry focuses on this prototype virus but information on related viruses is also provided.

Chemical Composition of Fowlpox Virus

During infection of a cell, the majority of the virus is retained in inclusion bodies. The average weight of an inclusion body is 6.1×10^{-7} mg, of which approximately 50% is extractable lipid. The average amount of protein and DNA per inclusion is 7.69×10^{-8} mg and 6.64×10^{-9} mg, respectively. The average weight of a fowlpox virus is 2.04×10^{-11} mg. A virion contains 7.5×10^{-12} mg of protein (36.8% w/w), 4.03×10^{-13} mg DNA (2% w/w) and 5.54×10^{-12} mg of lipid (27.2% w/w). Predominant lipids in fowlpox virus are cholesterol and phospholipids.

Geographic and Seasonal Distribution

Avian poxviruses are distributed worldwide in poultry, pet birds and wild birds. The incidence of fowlpox in domestic poultry is variable in different geographical regions because of differences in management practices, hygienic conditions and the use of prophylactic immunization. Avian poxviruses have been considered to be population limiting factors in some Hawaiian forest birds. In some areas the disease is usually more common during summer months when the mosquito population is high. However, in large poultry operations, especially in multiple age complexes, it may occur at any time of the year.

Host Range and Virus Propagation

Most avian species are susceptible to one or more poxvirus strains. On the basis of host specificity, strains can be mono-, bi- or tripathogenic. Usually, avian poxvirus strains are pathogenic for several species. Naturally occurring poxvirus infections have been reported in some 60 species of wild birds comprising 20 families. In domestic poultry, fowlpox is an economically important disease in chickens and turkeys. In pet birds, canarypox is of grave concern because of the high mortality associated with this disease. Poxviruses of birds are host-restricted and do not productively infect mammals.

Avian poxviruses can be propagated on the chorioallantoic membranes (CAMs) of 9–12-day-old developing chicken embryos. Virus inoculated embryos are incubated at 37°C in a humidified atmosphere for 5–7 days, when the CAMs are examined for lesions. Additionally, fowlpox, canarypox, pigeonpox, Hawaiian crowpox, mynahpox, psittacinepox and quailpox viruses have been grown in either primary cell cultures obtained from chicken embryos or chickens (fibroblasts, liver, kidney and skin) or secondary cell lines derived from chicken liver (LMH), quail fibroblasts (QT-35) and quail liver (IQ1A).

Genetics

The general properties of fowlpox virus include: a large complex virion containing enzymes capable of synthesizing mRNA; a single linear A- and T-rich

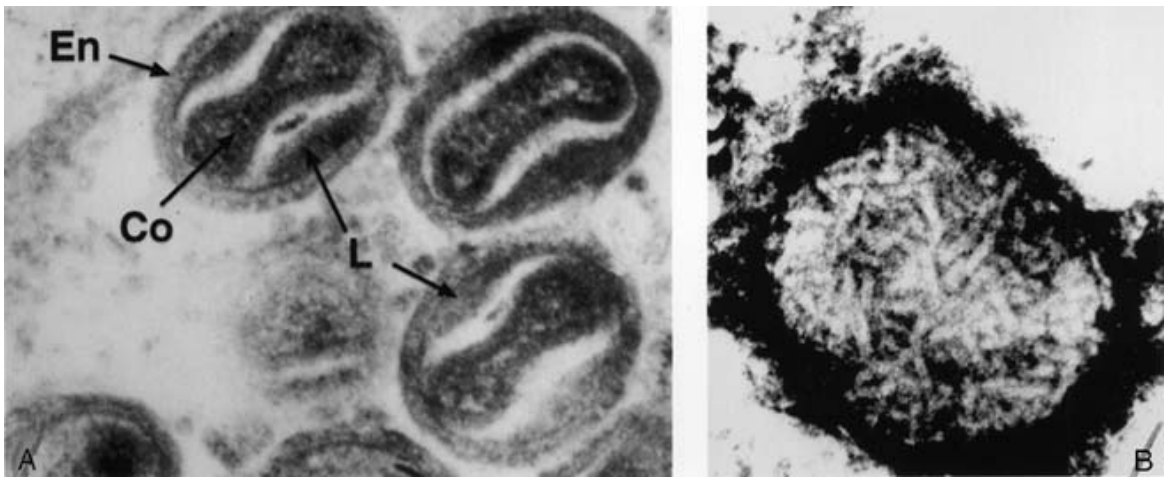


Figure 1 (**A**) Ultrathin section of fowlpox viruses from a diphtheritic lesion. Co, core; L, lateral bodies; En, envelope. (**B**) Negatively stained fowlpox virus particle showing random distribution of surface tubules. For additional illustrations of fowlpox pathology.

double-stranded DNA genome of approximately 300 kb with a hairpin loop at each end; and a replication site primarily in the cytoplasm of infected cells. While poxviruses in general are larger than other animal viruses, fowlpox is the largest of all poxviruses. Indeed, the viral particles, referred to as elementary bodies, can be seen in stained preparations under light microscopy. Individual virions are brick-shaped, with dimensions of about 330 nm × 280 nm × 200 nm. They consist of an electron-dense, centrally located biconcave dumbbell-shaped core or nucleoid, containing the viral genome, and two lateral bodies in each concavity, which are enveloped by one or more membranes (**Fig. 1A**). Infectivity is usually ether-resistant.

Like other poxviruses, the fowlpox virus genome consists of a conserved central region and variable termini. The ends of fowlpox virus DNA contain inverted terminal repeats which are not identical in size at each terminus. Thus, variations in physical maps near the ends of the genome of different strains of fowlpox virus may be observed. Changes have also been found near to or at the ends of fowlpox virus DNA after multiple tissue culture passages of the virus.

Genomic characterization of virus isolates is usually based on restriction fragment length polymorphisms (RFLPs), in which the DNA profiles are compared after restriction enzyme digestion of the virus genome and subsequent agarose gel electrophoresis of the resulting fragments. Based on this type of analysis, the genomes of fowlpox, pigeonpox and juncopox viruses show a marked degree of similarity. On the other hand, the DNAs of quail, canary and mynah poxviruses are distinct from each other and those of fowlpox virus. Likewise, the genomes of two poxvirus isolates from Hawaiian forest birds are not only different from fowlpox virus but also from each other. Like vaccinia virus, fowlpox virus must encode several enzymes involved in the synthesis of deoxyribonucleotides in order to enhance DNA replication in the cells. However, unlike vaccinia virus, only part of the fowlpox virus genome has been sequenced and not all of its genes have been identified. Among those which have been recognized in fowlpox virus are ones encoding for DNA polymerase, NTPaseI, uracil glycosylase, and thymidine kinase (TK). Despite the nonessentiality of TK for virus multiplication in cell cultures, deletion mutants become significantly attenuated *in vivo*. These biological properties have been exploited for genetic modification of the virus.

Replication

DNA replication and packaging within the infectious virus particle occur exclusively in the cytoplasm of infected cells. These cytoplasmic replicative events have been determined through the use of light, fluorescent and electron microscopy. Ultrastructural studies reveal that, after adsorption to and penetration of the cell membrane by fowlpox virus (1 h for dermal epithelium and 2 h for CAMs of developing chicken embryos), there is an uncoating of the virus prior to the synthesis of progeny virus from the precursor material. Areas of viroplasm with incomplete membranes around them can be seen in the cytoplasm by 48 h postinfection. Inclusion bodies are observed after an additional 24 h (dermal epithelium) to 48 h (CAM). The virus emerges from cells by a

budding process, with acquisition of an additional outer membrane obtained from the cell.

The infection of dermal epithelium of the chicken or of the ectodermal CAM is characterized by hyperplasia, ballooning of the cells and presence of cytoplasmic inclusion bodies. The elementary bodies or virus particles are contained within the inclusion bodies.

Evolution

In recent years outbreaks of fowlpox have occurred in previously vaccinated chicken flocks. Most outbreaks are characterized by the diphtheritic form of infection resulting in high mortality. Some of these isolates show minor genetic and antigenic as well as biologic differences from the vaccine strains. Instances of persistent dual infection by fowlpox and herpes viruses, e.g. Marek's disease virus and infectious laryngotracheitis virus, have been reported. During sequencing of a segment of Marek's disease virus, a fowlpox virus open reading frame (ORF) was detected. In spite of differences in the mode of replication of these viruses, these observations suggest a possible exchange of genetic material from one type of DNA virus to another.

Recent evidence of the genomes of fowlpox viruses carrying integrated sequences of reticuloendotheliosis virus indicate the possibility of re-emerging strains of fowlpox virus. Integration of a retrovirus into the DNA of a large DNA virus provides an important mechanism for virus evolution, resulting in genetic, antigenic and biologic alterations. Moreover, reticuloendotheliosis virus is known to induce immunosuppression – a property conducive to extending the viruses' persistence in the host.

Serologic Relationships and Variability

Avian poxviruses are antigenically and immunologically distinguishable from each other to an extent, but various degrees of crossrelationships do exist. In this regard, a nucleoprotein precipitinogen is common to all poxviruses. Limited crossprotection may occur between some viruses. The various strains of avian poxviruses are thought to be variants originating from a common ancestor. Some strains have remained similar or closely related antigenically to each other, while others have become immunologically distinct. For example, the similarity between fowlpox and pigeonpox viruses has enabled the use of the latter as a vaccine against fowlpox infection. Minor antigenic differences in strains of fowlpox virus can be detected by SDS-polyacrylamide gel electrophoresis (PAGE) and immunoblotting, although the majority of their antigens are common. In contrast, the antigenic profiles of quailpox virus are remarkably different from those of fowlpox virus, and thus these viruses do not provide crossprotection against infection by each other.

Epidemiology

In commercial poultry, fowlpox and turkeypox infections are of economic significance. Prophylactic vaccination using live modified virus vaccine of fowlpox or pigeonpox virus origin has been effective for many years. Consequently, vaccination was indicated only in areas where the disease was endemic. Improved management, biosecurity, hygienic conditions and timely vaccinations have been effective in controlling the disease in many poultry operations. Thus in such operations vaccination was unnecessary unless there was a threat of an infection spreading from neighboring flocks or wild birds. However, in recent years the epidemiology of disease in many areas has changed because of an increasing concentration of poultry in large complexes, retention of layer flocks for a second cycle of production, and maintenance of multiple age birds. As a result, frequent outbreaks of fowlpox have been reported from different geographical regions in the USA and elsewhere, especially where multiple age chickens are raised in one complex. In addition, outbreaks of fowlpox have occurred in previously vaccinated birds. Moreover, in some flocks a low level persistent infection can erupt into a highly pathogenic one, especially in birds subjected to the stresses of invasion by other microbes and molting.

Transmission and Tissue Tropism

Overall, poxviruses can withstand extreme environmental conditions and remain viable in dried scabs for extended periods. For example, the viability of fowlpox virus is undiminished by emersion in 1% phenol or 0.1% formalin for 9 days. Trypsin has no effect on the DNA or whole virus. The virus is, however, inactivated by 1% caustic potash when separated from its matrix or by heating at 122°F (50°C) for 30 min or 140°F (60°C) for 8 min. It can be readily preserved by lyophilization. The virus can survive in dried scabs for months or even years. Scabs shed by the recovered birds may contaminate soil, food and water. The virus can be transmitted either directly by contact between infected and susceptible birds or mechanically by arthropod vectors. Small abrasions in the skin or mucous membranes are necessary to allow the entry of the virus, as it is unable to penetrate unbroken tissue. Skin lacerations as a

result of cannibalism, fighting or preening may assist in the entry of the virus. Insects such as mosquitoes act as mechanical vectors to transfer the virus from infected to susceptible birds. In addition, oral and respiratory infections may occur by exposure to aerosols present in contaminated environments, especially in concentrated housing. In this regard, inhalation of virus-laden dust, which may contain particles of feathers, skin or scabs, provides an important route for virus exposure. Transmission is facilitated by the housing of a large number of birds in close quarters. In some flocks of chickens, fowlpox virus may persist for a long time. Since the disease spreads slowly, the virus may circulate in the susceptible population for a considerable time. This is a common occurrence where multiple age chicken flocks are maintained.

Pathogenicity

Generally the disease occurs in two forms, cutaneous and diphtheritic, although a systemic form of infection caused by canarypox virus is observed in canaries. The cutaneous form is characterized by the development of lesions on the comb, wattles, angle of the beak, feet, vent and other areas of the skin (**Fig. 2A**). In the diphtheritic form, lesions may occur on the mucous membrane of mouth, nares, esophagus, larynx, pharynx and trachea (**Fig. 2B**). Both cutaneous and diphtheritic forms of the disease may be present in a single bird. When the diphtheritic form of the disease is manifested by mouth or tracheal lesions, the afflicted birds experience difficulty in breathing or feeding and thus may die by suffocation or starvation. Birds affected with the cutaneous form of the disease are more likely to recover than those that have the diphtheritic form involving the oral or respiratory tract. Flock mortality due to cutaneous infections alone is usually low and affected flocks generally return to normal productivity upon recovery. Depending upon the virulence of the virus, mortality is significant, however, in flocks with the diphtheritic or generalized form of the disease. Among pet birds, infections often occur in large aviaries of canaries and the disease is likely to be enzootic. Canarypox virus infection is, therefore, of great concern to aviculturists, as the virus is highly lethal for susceptible canaries. Mortality may be as high as 80–100%. Severe outbreaks of quailpox in pen-raised quails have also been reported.

Clinical Features and Infection

A mild cutaneous form of the disease involving unfeathered areas of skin may often remain unnoticed due to the lack of any significant effect on the host, and may be self-limiting. When only the cutaneous form is present in the flock, the birds recover readily. However, those lesions on the eyelids (**Fig. 2A**) or around the beak may interfere with vision and feeding. In such birds productivity is reduced. There is poor feathering in young birds and a transient drop in egg production may also occur in layers. In the diphtheritic form of the disease clinical signs will vary, depending upon the location and severity of the lesions (**Fig. 2B**). Lesions in the trachea, pharynx and sinuses interfere with breathing. High mortality occurs due to suffocation resulting from blockage by tracheal lesions. Clinically, respiratory tract lesions simulate signs caused by other respiratory pathogens, especially infectious laryngotracheitis virus. Lesions in the mouth interfere with feeding, resulting in lowered productivity and increased mortality.

Pathology, Histopathology and Diagnosis

Localized proliferation of epithelial cells, characterized by hyperplasia and hypertrophy, is an important feature of avain poxvirus infections. The basal germinal layer of cells in the epithelium shows an increased rate of multiplication. Pocks are formed by the piling up of the infected epithelial cells. The time frame for the development and regression of the lesions is variable, depending upon the host and pathogenicity of the virus. Ultimately, desiccation and scab formation is followed by sloughing of the lesion. Diphtheritic lesions on the mucous membranes of respiratory and oral epithelium develop as white, opaque, slightly elevated nodules, which increase in size and coalesce to form yellowish, cheesy, necrotic material, appearing as a pseudomembrane. Solid, tumor-like masses involving the pharynx and anterior part of the esophagus may often be seen.

Microscopically, the affected dermal and mucous membrane epithelium of the chicken and the infected ectodermal CAM show marked hyperplasia with enlargement of the cells and associated inflammatory changes. The infected cells show eosinophilic cytoplasmic inclusion bodies when stained with hematoxylin and eosin (**Fig. 2D**). These inclusion bodies are often referred to as Bollinger bodies and contain the viral particles or elementary bodies also known as Borel bodies. These viruses produce both A- and B-type inclusion bodies, which contain a considerable amount of lipid.

Fowlpox is an economically important disease of commercial poultry and it has been responsible for significant economic losses, especially when a diphtheritic form of the disease with acute respiratory

signs is prevalent. Rapid diagnosis of infection is therefore important for the initiation of appropriate preventive measures. The most commonly used method is the histopathologic examination of the lesion for the presence of cytoplasmic inclusion bodies. Since similar clinical signs involving the respiratory tract in chickens can be caused by infectious laryngotracheitis virus, rapid differential diagnosis of the disease becomes very important. Infection by this herpesvirus is characterized by the histologic demonstration of intranuclear inclusion bodies (**Fig. 2D**). On the other hand, poxvirus infections are diagnosed by histopathologic examination of the lesions for the presence of cytoplasmic inclusion bodies. These inclusions, which contain elementary bodies, can be observed under oil-immersion in stained smears of the lesions. In addition, viral particles exhibiting typical poxvirus morphology can be detected by electron microscopic examination of negatively stained lesion suspensions or in ultrathin sections of the lesions (**Fig. 1A, B**). The virus is isolated by inoculation of the CAM of 9–12-day-old developing chicken embryos. Pocks develop on the CAM in 5–7 days postinfection (**Fig. 2C**). The etiology is confirmed by histopathological examination of the CAM lesions for cytoplasmic inclusions or viral particles of poxvirus morphology in ultrathin sections or in negatively stained preparations (**Fig. 1A, B**). Isolated viruses can be evaluated for pathogenicity in susceptible hosts, e.g. chickens (development of primary and secondary lesions and the duration of their persistence), or for susceptibility of avian cell culture (cytopathic effect and plaque formation). Although cloned genomic fragments as probes and primers based upon published sequences for amplifying a specific portion of the genome can be used for diagnosis, these procedures are not routinely performed.

Immune Response

Crossprotection among avian poxviruses is variable, although these viruses exhibit an extensive degree of serologic crossreactivity. Attenuated fowlpox virus vaccines of chicken embryo or cell culture origin have been used extensively for prevention of fowlpox in chickens and turkeys. The vaccine is administered by wing-web stab or by rubbing the vaccine on the thigh after pulling a few feathers. Similarly, modified live vaccines of pigeonpox and turkeypox origin are also available commercially. Canarypox virus vaccine is used exclusively in canaries, and quailpox virus vaccine is required for quails. Birds recovered from natural pox infection are immune to reinfection with that strain. A natural infection or vaccination is followed by both cell-mediated and humoral antibody responses. Cell-mediated immune responses are detected earlier than humoral responses. Although not commonly practiced, serologic detection of infection may be important in experimental studies and for measuring the immune responses following vaccination. Antibody response can be measured by agar gel precipitation (AGP), passive hemagglutination, immunoperoxidase (IP) and enzyme-linked immunosorbant assays (ELISA). ELISA has become the most common method for evaluation of immune responses. Some tests, e.g. IP, indirect immunofluorescence (IFA) and AGP, can also be used to detect viral antigen in the lesion(s). Antigenic differences among isolates can be determined by immunoblotting, crossprotection tests and virus neutralization assays.

Prevention and Control

Actively acquired immunity against avian poxviruses results after recovery from natural infection or vaccination. Live modified vaccines of fowlpox and pigeonpox virus origin are used for the immunization of commercial poultry. The viruses are propagated either in CAMs or primary chicken embryonic or secondary avian cell cultures. The vaccine should contain the respective poxviruses at a minimum concentration of 10^5 EID_{50} ml^{-1} to establish satisfactory vaccination in parallel with good protective immunity. If the vaccine is properly applied to susceptible birds, immunity will normally develop 10–14 days after vaccination. The absence of elicited protective immunity in a bird could be the result of improper application of the vaccine or the use of a vaccine of inadequate potency. It is important that, in chickens exhibiting passive immunity, vaccination is delayed until the passive antibody titer has declined. Since spread of the disease is slow, all susceptible birds in a commercial poultry flock should be vaccinated as soon as the disease is diagnosed. Vaccination is also indicated for young stock and birds introduced on premises where an infection was diagnosed during the previous year. In areas where pox is prevalent, vaccination may be required to protect birds from virus present in outside sources such as neighboring flocks.

In the past this disease has been prevented by regular use of attenuated strains of fowlpox or pigeonpox virus vaccines. In recent years, however, several outbreaks of fowlpox, especially of the diphtheritic form, have occurred in large commercial poultry operations, despite vaccination. The isolates obtained from these outbreaks are highly pathogenic for susceptible chickens and are somewhat different from the vaccine strains, both biologically and physically.

Future Perspectives

Fowlpox virus as a vector for poultry and other vaccines

In recent years considerable interest has been generated in using fowlpox virus as a vector for the expression of foreign genes from both avian and mammalian pathogens. The main reasons for this are: (1) modified live fowlpox virus vaccines have been used for more than 70 years by the poultry industry for the prevention of fowlpox in commercial poultry; (2) fowlpox virus has a highly restricted host range affecting only avian species; (3) the virus has one of the largest genomes and can accommodate a substantial amount of foreign genetic material without becoming defective in replication; and (4) it has been shown to cause an abortive infection in mammalian hosts. Despite its replicative deficiency in mammals, foreign genes are expressed by recombinant fowlpox virus in these hosts and, more importantly, the resulting proteins can elicit immune responses. Structural and functional studies reveal that regulatory sequences (promoters) are conserved between poxvirus genera, eliminating the need for homologous promoters in the generation of recombinants. Therefore, several promoters from vaccinia virus, a member of the genus *Orthopoxvirus*, have been used rather extensively for transcriptional regulation of foreign genes by avian and other poxviruses. While genetic information on other avian poxviruses is lacking, these can also be utilized as vaccine vectors. In this regard, another member of this genus, canarypox virus, has also been used for expression of mammalian genes.

During the 1990s a number of fowlpox virus-vectored vaccines expressing proteins encoding pro-

tective antigens from several poultry pathogens have been developed. For example, recombinants expressing the hemagglutinin of avian influenza and Newcastle disease virus have been shown to provide protection in vaccinated birds against the respective virulent viruses. In fact, a fowlpox virus-vectored Newcastle disease virus recombinant vaccine is commercially available but its use has been limited because of its high cost compared with that of the conventional vaccine. Thus the future of such recombinants is limited unless a polyvalent vaccine expressing antigens from several pathogens becomes available and is more cost-effective than the current vaccines.

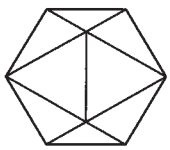
FROG VIRUS 3 (*IRIDOVIRIDAE*)



Rakesh M Goorha and **Allan Granoff**, St Jude Children's Research Hospital, Memphis, Tennessee, USA

History

Frog virus 3 (FV3) was isolated in 1966 by Granoff from a renal adenocarcinoma of the leopard frog *Rana pipiens*. Initially, this virus was suspected of causing the renal adenocarcinomas of *R. pipiens* (Lucké tumor); however, it turned out that FV3 has no relevance to formation of the tumor. Subsequently, additional isolates similar to FV3 were made from cultured normal adult frog kidney cells and liver homogenates of normal or tumor-bearing frogs. Further isolates were recovered from homogenates of normal newt tissue and from viscera homogenates of both normal and edematous tadpoles. Nucleic acid hybridization and restriction endonuclease analyses of DNA from several of these viruses as well as serological comparisons suggest that they probably represent different strains of the same prototype virus.

Taxonomy and Classification

Frog virus 3 is in the genus *Ranavirus* of the family *Iridoviridae* which comprises several viruses from vertebrate and invertebrate hosts. Three other genera *Iridovirus, Chloraridovirus* and *Lymphocystivirus* are included in the family. The characteristic features of an iridovirus are: (1) icosahedral symmetry; (2) a large (≈170 kbp), linear, double-stranded DNA genome; and (3) assembly of virus particles exclusively in the cytoplasm. Members of the *Iridoviridae*, so far examined, have a circularly permuted and terminally redundant genome – a unique characteristic among animal viruses. DNA hybridization studies have shown no sequence homology between FV3 and iridoviruses from other hosts such as fish and insect.

Properties of the Virion

Unenveloped FV3 virions measure 120 nm × 130 nm whereas virions with plasma membrane-derived envelopes measure 160–200 nm in diameter. Enveloped virions have a buoyant density of 1.28 g cm^{-3} and unenveloped particles 1.32 g cm^{-3}. Beneath the icosahedral lattice there is an inner membrane composed of lipids and proteins. The virus core below the membrane is composed of DNA and proteins and appears as a long filament. The unenveloped virion contains 9% lipid, and infectivity of the virus is destroyed by ether or phospholipase A. Even though the FV3 envelope is derived from the host membrane,

tective antigens from several poultry pathogens have been developed. For example, recombinants expressing the hemagglutinin of avian influenza and Newcastle disease virus have been shown to provide protection in vaccinated birds against the respective virulent viruses. In fact, a fowlpox virus-vectored Newcastle disease virus recombinant vaccine is commercially available but its use has been limited because of its high cost compared with that of the conventional vaccine. Thus the future of such recombinants is limited unless a polyvalent vaccine expressing antigens from several pathogens becomes available and is more cost-effective than the current vaccines.

Taxonomy and Classification

Frog virus 3 is in the genus *Ranavirus* of the family *Iridoviridae* which comprises several viruses from vertebrate and invertebrate hosts. Three other genera *Iridovirus, Chloraridovirus* and *Lymphocystivirus* are included in the family. The characteristic features of an iridovirus are: (1) icosahedral symmetry; (2) a large (≈170 kbp), linear, double-stranded DNA genome; and (3) assembly of virus particles exclusively in the cytoplasm. Members of the *Iridoviridae*, so far examined, have a circularly permuted and terminally redundant genome – a unique characteristic among animal viruses. DNA hybridization studies have shown no sequence homology between FV3 and iridoviruses from other hosts such as fish and insect.

Properties of the Virion

Unenveloped FV3 virions measure 120 nm × 130 nm whereas virions with plasma membrane-derived envelopes measure 160–200 nm in diameter. Enveloped virions have a buoyant density of 1.28 g cm^{-3} and unenveloped particles 1.32 g cm^{-3}. Beneath the icosahedral lattice there is an inner membrane composed of lipids and proteins. The virus core below the membrane is composed of DNA and proteins and appears as a long filament. The unenveloped virion contains 9% lipid, and infectivity of the virus is destroyed by ether or phospholipase A. Even though the FV3 envelope is derived from the host membrane,

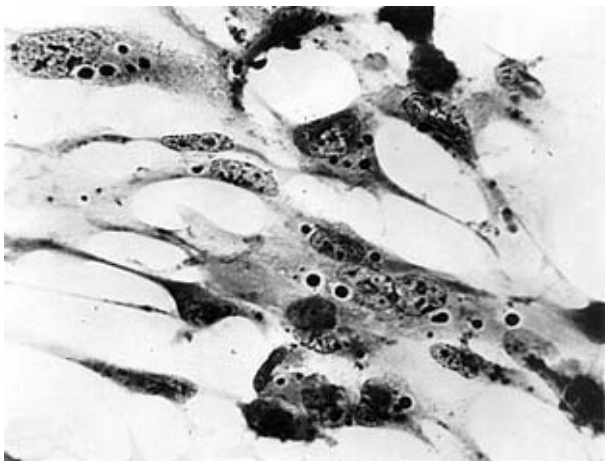

Figure 1 Feulgen-stained FV3-infected baby hamster kidney (BHK 21/13) cells illustrating Feulgen-positive inclusion bodies. Approximately ×210.

its lipid composition differs from that of the host membrane. Apparently, the host membrane is modified after virus infection.

Properties of the Virus Proteins

Two-dimensional gel electrophoresis has revealed approximately 50 viral structural proteins. FV3 proteins do not undergo detectable post-translational processing. No evidence for glycosylation, sulfation, or cleavage from precursor proteins has been obtained. Purified FV3 virions contain at least six enzymatic activities. Two of these, nucleotide phosphohydrolase and pH 5 endodeoxyribonuclease, are found in viral cores, whereas protein kinase, endoribonuclease and pH 7.5 endodeoxyribonuclease are external, i.e. they are solubilized by 0.5% Nonidet P-40 (NP-40). The sixth activity, a protein phosphatase has not been localized.

Properties of the Genome

FV3 virions contain a single, linear, double-stranded genome with a GC content of 53%. The genome is approximately 170 kbp in size and is terminally redundant and circularly permuted. The extent of circular permutation is restricted to 30% of the genome length. An unusual property of FV3 DNA is its high degree of methylation. About 25% of deoxycytosine residues are methylated at C-5. Genetic and biochemical evidence suggests that the FV3 genome is methylated by a virus specified DNA methyltransferase.

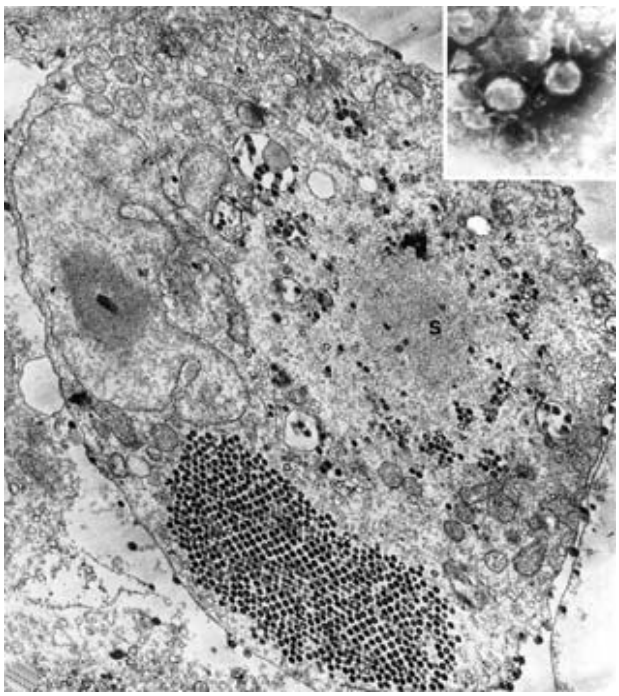

Figure 2 Electron micrograph of a thin section of a FV3-infected fish (FHM) cell at 8 h postinfection. Virions in various stages of assembly are present in assembly site (S). The cytoplasm contains mature virions in a crystalline array and some of the mature virions can be seen budding through the cell membrane. ×8750. The inset shows negatively stained virions. ×52 500.

Replication

General characteristics

FV3 grows in a wide variety of tissue culture cells of piscine, amphibian, avian and mammalian origin at temperatures between 12 and 32°C. At the light microscopy level, virus assembly sites are seen as Feulgen-positive inclusion bodies in the cytoplasm of infected cells (**Fig. 1**) that contain viral DNA and proteins. Electron micrographs of FV3-infected cells show assembly sites as regions free of cellular structures (e.g. organelles, ribosomes, cytoskeletal filaments) that contain virus particles in various stages of assembly (**Fig. 2**). Like all other viruses, the time course of infectious virus production is variable, depending on the type of cells, temperature of incubation, multiplicity of infection, conditions of growth and the strain of the virus. An unusual feature of FV3 replication is that it uses both the nucleus and cytoplasm for its nucleic acid synthesis but virus assembly takes place exclusively in the cytoplasm. At 33°C, a nonpermissive temperature for virus growth, early virus-specific transcription takes place but no

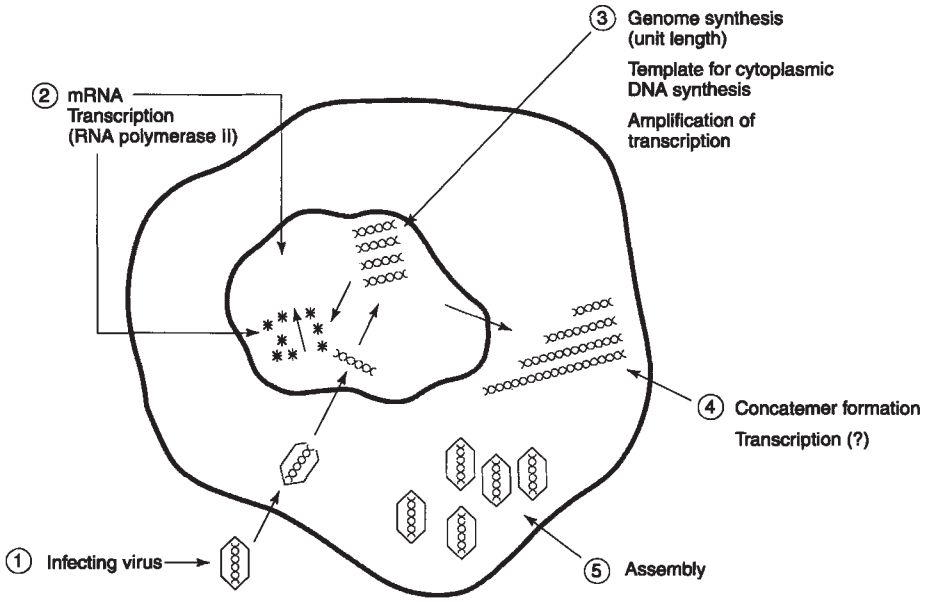

Figure 3 Proposed replication cycle of frog virus-3 (FV3). The genomes of parent FV3 particles reach the nucleus where they are transcribed during the early stages of infection. Cellular RNA polymerase II, modified by the structural protein(s) of the virus particles, is probably used for virus transcription at this stage. The parent genome in the nucleus also serves as the template for stage 1 of DNA replication. Replicative molecules are then transported to the cytoplasm where they participate in stage 2 of DNA replication. The large replicative complex produced in stage 2 is cleaved to produce mature viral DNA. Virus morphogenesis and assembly also occur in the cytoplasm.

viral DNA or infectious virions are produced. Apparently, one or more of the viral proteins are temperature sensitive and nonfunctional at this temperature. FV3 infection results in the 'shut-off' of host cell macromolecular syntheses (DNA, RNA, protein) allowing ready detection of viral DNA, RNA and protein.

DNA replication

An unusual feature of FV3 DNA replication is that it occurs in two stages that are physically compartmentalized in the nucleus and cytoplasm (**Fig. 3**). In the first stage, FV3 DNA replication is initiated at one or more preferred origins, probably on the linear DNA molecule in the nucleus with newly synthesized progeny DNA of genome or less than genome length. Newly synthesized viral DNA in the nucleus is not methylated. Arginine starvation of FV3-infected cells or infection of cells with a temperature sensitive mutant (*ts*12488) at nonpermissive temperature results in the arrest of FV3 DNA replication in the first stage, suggesting that transition from the first to second stage of DNA replication is mediated by a viral protein(s). During infection, progeny DNA synthesized in the nucleus is transported to the cytoplasm where it participates in the second stage of DNA replication. Second-stage DNA replication occurs only in the cytoplasm late in infection (after 3 h) and the replicating DNA is present as a large concatemer (more than 10 times the genome size). Evidently, progeny DNA during the second stage of DNA replication consists of multiple genome length molecules (concatemers). A virus-specified DNA methyltransferase methylates the DNA after its replication in the cytoplasm. During the second stage, FV3 DNA replication is intimately associated with recombination. Progeny molecules at this stage extensively recombine which creates many more replication forks leading to a rapid increase in the rate of DNA synthesis. Since FV3 DNA is circularly permuted and terminally redundant, it greatly facilitates recombination and most likely promotes formation of a complex, branched network of replicating DNA. Inhibition of recombination greatly reduces DNA synthesis, suggesting that recombination and replication at this stage are interdependent. Pulse-chase experiments showed that concatemeric DNA serves as the precursor for production of mature viral DNA molecules.

Functions of FV3 concatemeric DNA

The production of concatemers is required for regeneration of the end of the DNA molecules in viruses that possess linear genomes. The most

thoroughly studied example of such a function is phage T4, in which concatemeric DNA is cleaved and then packaged into virions via a 'headful' mechanism. DNA packaged into phage heads through this mechanism becomes circularly permuted and terminally redundant. As mentioned earlier, FV3 concatemeric DNA is used for production of mature viral DNA. It is, therefore, reasonable to assume that FV3 may also use the 'headful' packaging mechanism to generate circularly permuted and terminally redundant progeny molecules that are found in the infectious virions. However, experimental evidence for the 'headful' or any other mechanism of DNA packaging remains to be established.

Transcription

The genome of an incoming FV3 particle reaches the nucleus where it is transcribed during the early stages of infection. Cellular RNA polymerase II is used for transcription at this stage with a virion-associated protein required for FV3 transcription. It is not known whether this protein modifies RNA polymerase II or the FV3 DNA template for transcription.

FV3 transcripts lack polyadenylation tracts at their 3′-end. At the 5′-end, FV3 mRNAs are capped and methylated. Early viral mRNA molecules are also methylated at the internal position in adenosine residue. In contrast, although late mRNAs are terminally blocked and methylated, internal methylation in this mRNA class is not detectable. Since early FV3 transcripts are synthesized in the nucleus, whereas late transcripts are synthesized in the cytoplasm, these differences in methylation of early versus late transcripts may be due to the different site of their synthesis.

Because of the complete switch-off of host cell mRNA synthesis, and lack of variable-length poly(A) tracts on FV3 mRNA, the FV3 transcript from infected cells can be resolved into 47 bands on denatured gels. Analysis of these bands indicated that FV3 transcription is temporally regulated and can be subdivided into three classes: immediate-early (IE), delayed-early (DE) and late (L). The IE class consists of those RNAs synthesized in the absence of protein synthesis and represents approximately one-third of the single-stranded genome equivalent. Depending on the cell line, IE synthesis takes place 1–2 h postinfection. An additional third of the genome is transcribed in the presence of amino acid analogue fluorophenylalanine or by a temperature sensitive (*ts*) mutant, *ts*9467, that is defective in late transcription at nonpermissive temperature. DE mRNA is normally synthesized 2–3 h postinfection. By 3–4 h postinfection, a complete single-stranded equivalent of the genome is transcribed.

Transcriptional mapping and sequencing of 10 FV3 genes have shown that various classes of FV3 mRNAs, as well as mRNAs within classes, are transcribed from separate promoters. FV3 genes contain no intervening sequences and no polyadenylation sites; apparently there is no post-transcriptional processing of the FV3 transcript.

Site-specific DNA methylation has a strong silencing effect on genes transcribed by eukaryotic RNA polymerase II, yet FV3 uses this enzyme to transcribe FV3 RNA from its highly methylated genome. Experimental evidence indicates that FV3 infection results in the transcription of exogenously supplied, normally silent, methylated genes in infected cells. Thus, FV3 has evolved a mechanism to permit cellular RNA polymerase II to transcribe normally silent methylated genes.

Protein synthesis

In conjunction with FV3 transcription, viral protein synthesis occurs in three phases. First, IE proteins are synthesized at the beginning of infection, then DE proteins after 2 h postinfection, and L proteins by 3–4 h postinfection. Several viral regulatory proteins are required for transition from IE to DE to L protein synthesis. In contrast to other DNA viruses, DNA replication is not necessary for L protein synthesis. However, DNA replication increases the amount of L proteins synthesized in FV3-infected cells. FV3 protein synthesis is also regulated at the translational level. Although transcription of IE and DE genes continues concomitantly with that of L genes, their translation is greatly reduced late in infection. Experimental evidence suggests that at least one viral protein is required to inhibit the translation of IE and DE mRNA late in infection. Late FV3 mRNAs are poorly translated *in vitro*; addition of a factor present in infected cells is required for efficient translation of these messages. Thus, efficient translation of late mRNAs is also mediated by viral regulatory protein(s).

Assembly and release of virions

FV3 virus particles are assembled in specialized structures termed the assembly sites found exclusively in the cytoplasm of infected cells. These sites are less dense than the surrounding cytoplasm, devoid of cellular structures (e.g. organelles, cytoskeletal filaments, ribosomes), and contain assembling virions. Assembly sites are formed in two steps; in the first step, viral DNA accumulates in the cytoplasm as a spheroid mass but devoid of viral proteins (pre-

assembly site). During the second step, reorganized intermediate filaments surround preassembly sites and viral proteins accumulate into it. Cells infected with a temperature sensitive mutant (*ts*9467) at nonpermissive temperature form preassembly sites but not mature assembly sites. The virus assembly sites are the only region of the cytoplasm at which the viral proteins and viral genomes are present in great abundance. Data suggest that viral proteins synthesized elsewhere in the cytoplasm are transported into the assembly sites. In summary, the virus assembly site is a specialized area of the cytoplasm composed of a three-dimensional filamentous matrix in which the viral proteins, viral genomes and assembling virions are suspended. It is possible that the matrix may serve as a substratum on which virus proteins interact in an ordered fashion to form icosahedral particles.

Late in infection, the surfaces of FV3-infected cells exhibit many projections through which the virus buds. These projections have been termed microvillus-like projections because they resemble normal cellular microvilli in general morphology. At a time when the virus is released in abundance, the number of projections greatly increase and each projection possesses a series of bulges, each of which contains a single virus particle. The microvillus-like projections contain microfilaments and virus particles in the process of budding. Microfilaments play an active role in FV3 budding since microfilament-depolymerizing drugs such as cytochalasine B and D prevent virus release. FV3 acquires its envelope during the process of budding. However, acquisition of the envelope is not necessary for virus infectivity. Intracellular virus particles, often seen as crystalline arrays in electron microscopic pictures, are infectious. Similarly, inhibition of virus budding by cytochalasine D has no effect on virus infectivity.

FV3-induced cytoskeletal changes

Soon after infection, FV3 induces dramatic organizational changes in all three classes of cytoskeletal filaments: the microtubules, the intermediate filaments and the microfilaments. In FV3-infected cells, the microtubules appear to decrease progressively with the course of FV3 infection. Concomitant with a decrease in microtubule numbers, there is a reduction (80% reduction by 4 h postinfection) in tubulin synthesis – the constituent protein of microtubules.

In FV3-infected cells, intermediate filaments retract from the cell periphery and reorganize to surround the preassembly sites. There is increased phosphorylation of vimentin (constituent protein of intermediate filaments in fibroblasts) in FV3-infected cells before they reorganize around the preassembly sites. In *ts*9467-infected cells at nonpermissive temperature, there is neither increased phosphorylation of vimentin nor reorganization of intermediate filaments around the preassembly sites. These results suggest that phosphorylation of vimentin is a prerequisite for reorganization of intermediate filaments.

In FV3-infected cells, the bundles of microfilaments (stress fibers) disappear but microfilaments underlying the microvillus-like projections are seen late in infection. The significance of the destruction of stress fibers is not known but it may be related to changes in the cell shape that occur during virus infection. Reorganization of actin into cell surface projections, however, appears to be important in virus release. Biochemical studies have shown that actin, the constituent protein of microfilaments, becomes more acidic than its counterpart in uninfected cells. It is not known whether the observed shift in actin is due to post-translational modification or whether the phenomenon represents the synthesis of a new isoform of actin. In either case, the process must occur during virus replication, since actin synthesized before infection did not show increased acidity. It is noteworthy that the changes in actin precede the formation of microvillus-like structures used in virus release.

Genetics

An ordered genetic map of FV3 is not yet available, but the genetic analysis of 12 FV3 temperature sensitive (*ts*) mutants have revealed 10 complementation groups. Many more complementation groups, i.e. genes, must exist since the FV3 genome is quite large. Recombination frequencies between the temperature-sensitive mutants ranged from 9 to 63%. These high frequencies of recombination are consistent with the mode of FV3 replication, indicating that DNA replication and recombination are interdependent during the second stage of FV3 DNA replication. In spite of high recombination frequencies among *ts* mutants, marker rescue experiments have not yet been successful. Presumably, the exogenously supplied viral DNA does not recombine with the endogenously replicating DNA. Reasons for the failure of marker rescue experiments are not known.

Pathogenicity

FV3 is not known to cause any disease in naturally occurring populations of frogs. However, FV3 causes death of frog embryos and larvae within 15 days of inoculation of the virus. In developing tadpoles, it causes edema of the tail. Intravenous inoculation of purified virion proteins in mice causes acute hepatitis

Table 1 Shared features of frog virus 3 and bacteriophages

Features	*Phage example*
Circularly permuted and terminally redundant genome	T4, P22
High degree of DNA methylation	T4
Two stages in DNA replication	T4
Lack of intervening sequences in viral genes	λ, P22
Lack of polyadenylation in viral RNA	λ, P22
Presence of hyphenated dyad symmetry near transcription termination sites	λ

but the inoculation of the virus in healthy adult frogs causes no apparent effects.

Evolution

Eukaryotic DNA viruses are classified as cytoplasmic or nuclear depending on whether the nucleus or the cytoplasm is the site of nucleic acid synthesis and virus assembly. FV3 replication represents a striking departure from replication strategies of other nuclear or cytoplasmic DNA viruses. Phylogenetically, FV3, because it uses both the nucleus and the cytoplasm for its replication, may be considered as an intermediate form in the evolution of nuclear and cytoplasmic DNA viruses. Another interesting aspect of FV3 replication is its similarity to that of the lambdoid and T bacteriophages. Indeed, FV3 with its highly methylated DNA, circularly permuted and terminally redundant genome, mRNAs lacking poly(A) and two-stage DNA replication most closely resembles a bacteriophage rather than an animal virus. **Table 1** lists the features that are common to FV3 and bacteriophages. Whether the similarity represents an evolutionary relationship between the two organisms or is a coincidence remains unknown.

Future Perspectives

The life style of FV3 is only partly understood. Unknown features include mechanisms of DNA replication (through a circular or linear intermediate), concatemer formation and assembly (headful?). It is known that transcription of early viral mRNAs depends on RNA polymerase II in the host nucleus but the sites and machinery (whether viral or host) of late transcription remain to be identified. Although some clues to the role of highly methylated DNA in FV3 replication (e.g. morphogenesis) and assembly or in restriction modification are available, they require more rigorous experimental support. Investigations into these aspects of FV3 replication, while contributing to our knowledge of DNA structure and replication, may also elucidate the evolutionary relationship of FV3 to other cytoplasmic and nuclear DNA viruses and to bacteriophages.

Taxonomy and Classification

Furovirus was the group name first approved for *fu*ngus-transmitted, *ro*d-shaped plant viruses by the International Committee on the Taxonomy of Viruses in 1987. Criteria for membership of the group were a divided genome composed of two or more components of single-stranded RNA, hollow rigid particles, and transmission through moist soil by motile zoospores of fungi which belong to the poorly characterized taxon, Plasmodiophoromycetes (**Table 1**). Among ten fungus-transmitted, rod-shaped

Table 1 Shared features of frog virus 3 and bacteriophages

Features	*Phage example*
Circularly permuted and terminally redundant genome	T4, P22
High degree of DNA methylation	T4
Two stages in DNA replication	T4
Lack of intervening sequences in viral genes	λ, P22
Lack of polyadenylation in viral RNA	λ, P22
Presence of hyphenated dyad symmetry near transcription termination sites	λ

but the inoculation of the virus in healthy adult frogs causes no apparent effects.

Evolution

Eukaryotic DNA viruses are classified as cytoplasmic or nuclear depending on whether the nucleus or the cytoplasm is the site of nucleic acid synthesis and virus assembly. FV3 replication represents a striking departure from replication strategies of other nuclear or cytoplasmic DNA viruses. Phylogenetically, FV3, because it uses both the nucleus and the cytoplasm for its replication, may be considered as an intermediate form in the evolution of nuclear and cytoplasmic DNA viruses. Another interesting aspect of FV3 replication is its similarity to that of the lambdoid and T bacteriophages. Indeed, FV3 with its highly methylated DNA, circularly permuted and terminally redundant genome, mRNAs lacking poly(A) and two-stage DNA replication most closely resembles a bacteriophage rather than an animal virus. **Table 1** lists the features that are common to FV3 and bacteriophages. Whether the similarity represents an evolutionary relationship between the two organisms or is a coincidence remains unknown.

Future Perspectives

The life style of FV3 is only partly understood. Unknown features include mechanisms of DNA replication (through a circular or linear intermediate), concatemer formation and assembly (headful?). It is known that transcription of early viral mRNAs depends on RNA polymerase II in the host nucleus but the sites and machinery (whether viral or host) of late transcription remain to be identified. Although some clues to the role of highly methylated DNA in FV3 replication (e.g. morphogenesis) and assembly or in restriction modification are available, they require more rigorous experimental support. Investigations into these aspects of FV3 replication, while contributing to our knowledge of DNA structure and replication, may also elucidate the evolutionary relationship of FV3 to other cytoplasmic and nuclear DNA viruses and to bacteriophages.

viruses, four infect cereals (soil-borne wheat mosaic virus, SBWMV; oat golden stripe virus, OGSV; sorghum chlorotic spot virus, SCSV; rice stripe necrosis virus, RSNV), four infect roots and tubers (beet necrotic yellow vein virus, BNYVV; beet soil-borne virus, BSBV; beet soil-borne mosaic virus, BSBMV; potato mop-top virus, PMTV) and two infect legumes (peanut clump virus, PCV; broadbean necrosis virus; BBNV). There are also two weed-infecting viruses, *Hypochoeris* mosaic virus (HMV) and *Nicotiana velutina* mosaic virus (NVMV), which have not been well-characterized but might have been included in this group.

Recently, the complete nucleotide sequences of four fungus-transmitted, rod-shaped viruses (SBWMV, PCV, BSBV and BNYVV) were determined, enabling a more meaningful classification based on genome structure and organization, gene expression strategy and amino acid sequence similarities, rather than a taxonomy based on virion morphology, the number of RNA segments and mode of vector transmission. Taken together with partial nucleotide sequences of several other viruses in the group, the previous grouping was reinvestigated and, except for RSNV, nine viruses have been reclassified into four genera, the genus *Furovirus* (SBWMV, the type species; OGSV and SCSV, the members), the genus *Pomovirus* (PMTV, the type species; BSBV and BBNV, the members), the genus *Pecluvirus* (PCV, the type species) and the genus *Benevirus* (BNYVV, the type species, and BSBMV, a possible member) (**Table 2**). The four genera differ from each other in the numbers of RNA segments, the types of cell-to-cell movement proteins, RNA structures in the 3′-terminal region (tRNA-like structure or poly(A) tail) and phylogeny based on RNA polymerase domains (**Tables 2** and **3** and **Fig. 1**) and have not been assigned a family. Members of the *Furovirus, Pomovirus* and *Pecluvirus* genera are closely related to each other and to tobamoviruses, tobraviruses and hordeiviruses in the amino acid sequence of the polymerase domain and the presence of a tRNA-like structure in the 3′-terminal region of the viral RNA. Only beneviruses have a poly(A) tail at the 3′ terminus and a distant phylogenetic relationship in the polymerase domain to viruses in the other three genera. Nevertheless, they all belong to the Alphavirus-like superfamily based on genome organization, expression strategy and amino acid sequence conservation. Thus, the previous genus *Furovirus* included all ten fungus-transmitted, rod-shaped viruses, whereas the new genus *Furovirus* includes only SBWMV, OGSV and SCSV.

Virus Structure and Composition

Most fungus-transmitted, rod-shaped viruses consist of hollow, rigid nucleoprotein helices around 20 nm in diameter, with two or more dominant particle lengths (270 and 150 nm). In BNYVV and RSNV, the long and intermediate particle lengths are 390 and 270 nm, respectively. NVMV has been claimed to have particles up to 700 nm in length, but the range is

Table 2 Particle sizes and genome compositions of fungus-transmitted, rod-shaped plant viruses

Genus	Virus	Diameter (nm)	Length (nm)	Coat protein (kDa)	RNA (nt)[a] 1	2	3	4

extremely wide with the mode around 125–150 nm. BNYVV, BSBV, PCV and RSNV also possess short particles of 160 nm or less (**Table 2**). Coat protein subunits (approximately 19–24 kDa) form right-handed, single-start helices (pitch 2.6–2.9 nm, with 12.25 subunits per turn for BNYVV) which encapsidate each single-stranded genomic RNA component separately. In all cases, RNA comprises about 5% of the particle weight. Most likely, four ribonucleotides interact with each coat protein subunit. No data are available on the possible presence of divalent cations or polyamine content.

Serology

Studies with conventional rabbit polyclonal antibodies against purified virions indicate that SBWMV, PMTV, OGSV and BBNV are distantly related serologically. BSBV antiserum does not react with BNYVV, while BNYVV and BSBMV are distantly related serologically. Ivory Coast and several Indian isolates of PCV are also serologically distinct from each other. SBWMV and PMTV also have a distant relationship with tobacco mosaic virus (TMV). BBNV is unrelated to TMV, but is related to two other tobamoviruses, cucumber green mottle mosaic virus and odontoglossum ringspot virus. Otherwise, all other viruses in the four genera appear to be serologically distinct. Mouse monoclonal antibodies (MAbs) against SBWMV failed to react with 13 other viruses including TMV, and SCSV. For quantitative enzyme-linked immunosorbent assay (ELISA) and long-term storage, SBWMV-infected leaf samples were best after $CaCl_2$ desiccation. MAbs against

Table 3 Genome structure and expression of four fungus-transmitted, rod-shaped plant viral genera: comparison with *Tobamo-* and *Alphavirus* genera

Genus	No. of RNA segments	Terminal structures 5′/3′	RNA polymerase phylogeny/ expression	Putative fungus transmission factor	MP
Furovirus	2	Cap / tRNA-like	*Tobamo* / 59K RT (UGA)	84K CP-RT (UGA)	37K
Pecluvirus	2	Cap / tRNA-like	*Tobamo* / 60K RT (UGA)	39K Leaky scanning	TGB
Pomovirus	3	Cap / tRNA-like	*Tobamo* / 59K RT (UAA)	104K CP-RT (UAG)	TGB
Benevirus	2	Cap / Poly(A)	*Alpha* / Pro?	75K CP-RT (UAG)	TGB
Tobamovirus	1	Cap / tRNA-like	*Tobamo* / RT (UAG)	n.a.	30K
Alphavirus	1	Cap / Poly(A)	*Alpha* / 69K RT (UGA) and Pro	n.a.	n.a.

MP, cell-to-cell movement protein; RT, readthrough (leaky termination codon); CP-RT, capsid readthrough protein (leaky termination codon); TGB, triple gene block proteins; Pro, proteolytic processing by papain-like proteinase; n.a., not applicable.

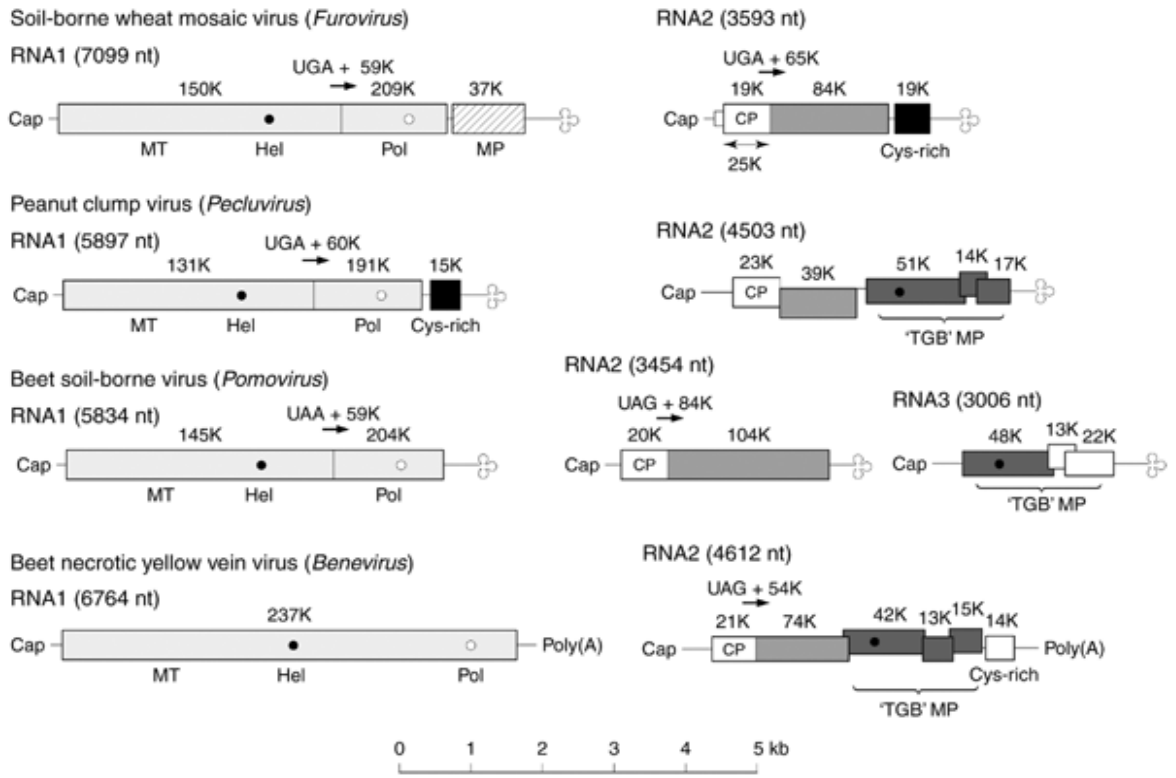

Figure 1 Genome structures of the four genera of fungus-transmitted, rod-shaped plant RNA viruses. Wild-type RNA species encoding all the essential functions required for replication, encapsidation, systemic infection and fungus transmission are drawn. Field isolates of BNYVV contain two or three additional smaller RNAs, which facilitate efficient replication in specific host tissues and transmission by the fungal vector. MT, methyltransferase domain; Hel, helicase domain; Pol, RNA polymerase domain; MP, movement protein; Cys-rich, cysteine-rich protein; 'TGB' MP, triple gene block movement proteins; filled circle, NTP-binding helicase motif (GXXGXGKS/T); open circle, RNA polymerase motif (GDD); cloverleaf, tRNA-like structure; rightward arrow, readthrough at a leaky termination codon.

SBWMV, PMTV or BNYVV have been used for coat protein epitope mapping in virions.

Genome Structure and Expression

Fig. 1 shows the genome organizations of SBWMV, PCV, BSBV and BNYVV, representing the four genera, *Furo-*, *Peclu-*, *Pomo-* and *Benevirus*, respectively. Characteristics of the genomes of the four genera are shown in **Table 3** and described briefly as follows:

- Fundamental viral functions of replication, systemic infection and vector transmission are coded on two RNA segments in furo-, peclu- and beneviruses, whereas those of the pomoviruses are coded on three RNA segments.
- The 5′ end of the RNA is shown to be capped in furo-, peclu- and beneviruses and is probably also m^7GpppX in pomoviruses.
- The 3′ end of the RNA can be folded into a tRNA-like structure in furo-, peclu- and pomoviruses which is shown to be valylated *in vitro*, similar to those of tymoviruses and sunn hemp mosaic tobamovirus, whereas that of the beneviruses is polyadenylated.
- RNA replicase proteins are coded in the 5′-terminal region of RNA1 in all four genera with the capping enzyme, helicase and polymerase domains positioned sequentially from the 5′ end.
- The RNA polymerase domain is located downstream of a leaky termination codon in furo-, peclu- and pomoviruses, whereas in the beneviruses there is no termination codon between the helicase and polymerase domains.
- Capsid protein is encoded in the 5′-terminal region of RNA2 in all four genera.
- The termination codon for the capsid protein can be readthrough to express the downstream region as a capsid fusion protein in furo-, pomo- and beneviruses, whereas in the pecluviruses the down-

stream region is expressed separately by leaky ribosome scanning.

- The cell-to-cell movement proteins of peclu-, pomo- and beneviruses are composed of triple gene block (TGB) proteins, whereas that of furoviruses is a single 37 kDa protein.
- A small cysteine-rich protein of 8–19 kDa is encoded in the 3′-proximal region of one of the RNA segments, except for the BSBV genome.

The molecular details of each genus are as follows.

Furovirus (type virus, SBWMV)

The complete nucleotide sequences of RNA1 and RNA2 of a USA-Nebraska isolate of SBWMV were determined and the details are described below. Partial nucleotide sequences of RNA2 of a French and a Japanese isolate of SBWMV, and a UK isolate of OGSV, have been determined. Amino acid sequences of the capsid proteins of the Nebraskan and French SBWMV, and OGSV, are more than 97% identical to each other, whereas the coat protein of the Japanese SBWMV is about 80% identical to those of the Nebraskan and French SBWMV, and OGSV.

SBWMV RNA1 (7099 nt) codes for a 150 kDa protein at its 5′ terminus (nt 102–4061), the N-terminal and C-terminal regions of which contain the capping enzyme domain and an NTP-binding, helicase domain, respectively. The UGA termination codon of the 150 kDa protein can be readthrough with approximately 10% frequency to produce a 209 kDa protein (nt 102–5585). The readthrough region contains the canonical Gly-Asp-Asp polymerase motif. After a short intergenic region, the 37 kDa, putative cell-to-cell movement protein (nt 5653–6633) is encoded by the 3′-proximal region, which is likely to be expressed via a subgenomic mRNA. The 3′-proximal region, is 466 nt long and consists of four pseudoknot motifs and a tRNA-like structure, which is shown to be valylated *in vitro*.

SBWMV RNA2 (3593 nt) codes for the 19 kDa capsid protein at its 5′ terminus (nt 334–861), the UGA termination codon of which is frequently suppressed to produce an 84 kDa readthrough protein (nt 334–2595). In the 3′-proximal region, a 19 kDa cysteine-rich protein (nt 2665–3186) is encoded, which should be expressed from a subgenomic mRNA. The 3′ terminal untranslated region is 407 nt long and again is composed of four pseudoknot motifs and a tRNA-like structure similar to RNA1. In addition, there is a CUG 'initiation codon' at positions 214–216 for a 25 kDa protein, which represents a 40 amino acid, in-frame extension to the N terminus of the capsid protein. In wheatgerm extracts the CUG initiation site for the 25 kDa protein is as efficient at initiation as the AUG for the capsid protein.

Pecluvirus (type virus, PCV)

The complete nucleotide sequences of RNA1 and RNA2 of an Ivory Coast isolate of PCV were determined and the details are described below. The complete nucleotide sequence of RNA1 and a partial sequence of RNA2 of an Indian H isolate were also determined. Amino acid sequence identities of the capsid proteins and RNA polymerase domains between the two geographical isolates are 59% and 95%, respectively.

PCV RNA1 (5897 nt) codes for a 131 kDa protein (nt 132–3566), containing the capping enzyme domain in the N-terminal region and the NTP-binding helicase domain in the C-terminal region. The UGA termination codon can be readthrough occasionally to express the downstream polymerase domain in a 191 kDa protein (nt 132–5147). The 3′-proximal region encodes a cysteine-rich 15 kDa protein (nt 5225–5596) which should be translated from a subgenomic mRNA. The 3′-terminal untranslated region is 301 nt long, and the last 80 nt can be folded into a tRNA-like structure, which could be valylated *in vitro*.

PCV RNA2 (4503 nt) contains six open reading frames (ORFs). After the 390 nt 5′ untranslated region lies the 23 kDa capsid protein ORF (nt 391–1011). The second ORF, for a 39 kDa protein, starts at the third nucleotide of the C-terminal proline codon of the capsid protein and terminates at nt 2111. ORF 2 was shown to be translated from genomic RNA2 by leaky ribosomal scanning. The third (nt 2250–3590), fourth (nt 3556–3924) and fifth (nt 3767–4225) ORFs code for 51 kDa, 14 kDa and 17 kDa proteins, respectively, which comprise the TGB proteins for cell-to-cell movement. The 51 kDa protein contains the NTP-binding, helicase motif. The TGB proteins should be translated from a tricistronic subgenomic mRNA. The 3′-terminal untranslated region is 279 nt long and shows extensive nucleotide sequence similarity with PCV RNA1.

Pomovirus (type virus, PMTV)

The complete nucleotide sequences of RNAs 1, 2 and 3 of an Ahlum isolate of BSBV were determined and the details are described below. RNA2 and RNA3 of a UK isolate of PMTV were also determined. Amino acid sequence identity between BSBV and PMTV capsid proteins is 52%.

BSBV RNA1 (5834 nt) codes for the 145 kDa (nt 130–3939) and 204 kDa (nt 130–5463) RNA replicase proteins, which are equivalent to the SBWMV

150 kDa and 209 kDa proteins, and the PCV 131 kDa and 191 kDa proteins. The termination codon for the 145 kDa protein is UAA, which is unique as a leaky readthrough codon. The 3′-terminal untranslated region is 371 nt long.

BSBV RNA2 (3454 nt) codes for the 20 kDa capsid protein (nt 383–877) in its 5′-proximal region, the UAG termination codon of which can be readthrough to produce a 104 kDa capsid fusion protein (nt 383–3178). The 3′-terminal untranslated region is 279 nt long.

BSBV RNA3 (3006 nt) has three ORFs which code for the 48 kDa (nt 405–1685), 13 kDa (nt 1675–2022) and 22 kDa (nt 1889–2458) TGB proteins for cell-to-cell movement. The TGB proteins should be translated from a tricistronic subgenomic mRNA. The 3′-terminal untranslated region is 548 nt long.

In all three BSBV RNA segments, the 3′-terminal 80 nt could be folded into a tRNA-like structure.

In the case of PMTV RNA2, which codes for the TGB proteins, there is an additional short ORF for an 8 kDa cysteine-rich protein in the 3′-proximal region.

Benevirus (type virus, BNYVV)

The complete nucleotide sequences of RNAs 1, 2, 3 and 4 of a French isolate and a Japanese isolate (including RNA5) of BNYVV were determined. Details of the French isolate are given below. Amino acid sequence identities of the RNA polymerase protein and the capsid protein between the French and Japanese isolates are 99% and 98%, respectively. RNA 3, 4 and 5 sequences were also determined for a German isolate of BNYVV. Besides BNYVV, the complete nucleotide sequence of BSBMV RNA2 was determined. The capsid proteins of BNYVV (French isolate) and BSBMV are 58% identical at the amino acid level.

BNYVV RNA1 (6746 nt) codes for a single protein of 237 kDa (nt 154–6480) without interruption by a leaky termination codon as in the RNA1 of furo-, peclu- and pomoviruses. There is also a putative papain-like proteinase domain between the helicase and polymerase domains. The 3′-terminal untranslated region is 266 nt long, followed by a poly(A) tail.

BNYVV RNA2 (4612 nt) codes for the 21 kDa capsid protein (nt 145–708), the UAG termination codon of which could be readthrough occasionally to express the downstream region as a 75 kDa, capsid fusion protein (nt 145–2217). In the central region of RNA2, there are three ORFs for the TGB, 42 kDa (nt 2133–3284), 13 kDa (nt 3287–3640) and 15 kDa (nt 3627–4022) proteins. The TGB proteins should be translated from a tricistronic subgenomic mRNA. In the 3′-proximal region, there is an ORF for a 14 kDa protein (nt 4043–4423) which is rich in cysteine residues and probably translated from a subgenomic mRNA. The 3′-terminal untranslated region is 189 nt long, followed by a poly(A) tail.

The two RNAs mentioned above are sufficient for BNYVV replication, systemic infection and vector transmission. However, all field isolates contain two or three additional smaller RNA species, which are designated RNAs 3, 4 (and 5).

BNYVV RNA3 (1775 nt) codes for a single protein of 25 kDa (nt 447–1103). The 5′- and 3′-terminal untranslated regions are quite long, 446 nt and 672 nt, respectively. The 3′ end is polyadenylated.

BNYVV RNA4 (1431 nt) also codes for a single protein of 31 kDa (nt 344–1189). The 5′- and 3′-terminal untranslated regions are 343 nt and 242 nt, respectively. The 3′ end is polyadenylated.

Some Japanese and German BNYVV isolates contain an RNA5 (1347 nt), which codes for a 26 kDa protein (nt 449–1132). The 5′- and 3′-terminal untranslated regions are 448 nt and 215 nt, respectively. The 3′ end is polyadenylated.

Genetics and Replication

Furovirus (type virus, SBWMV)

Both RNA1 and RNA2 are required for systemic infection. RNA1 codes for the 150 kDa and 209 kDa RNA replicase proteins and the 37 kDa, putative cell-to-cell movement protein. RNA2 codes for the capsid protein, the putative fungus-transmission factor in the capsid readthrough region, and a putative replicational/transcriptional regulator protein. The function of the 25 kDa protein derived from a 40 amino acid N-terminal extension to the capsid protein is not known. Neither the 25 kDa nor the 84 kDa proteins are required for virus particle formation, or systemic spread in wheat plants.

Replication requires temperatures lower than 20°C. Above this temperature infection either does not occur, or systemically infected plants recover from the virus.

When systemically infected wheat plants are grown for prolonged periods, or the virus is repeatedly passaged by mechanical inoculation at about 17°C, deletion mutants of RNA2 occur spontaneously. Deletions occur exclusively within the capsid readthrough region, are of various lengths and are mostly single (or occasionally double) deletion events. There is a tendency for larger deletions to make the mutants more virulent on wheat plants. Since deletions occur when virus is maintained or passaged without its fungal vector, the capsid readthrough region has been implicated in fungal transmission.

OGSV requires low temperatures for replication, whereas the optimum temperature for replication of SCSV is around 25°C.

Pecluvirus (type virus, PCV)

Both RNA1 and RNA2 are required for infection. RNA1 codes for two N-coterminal replicase proteins and a small cysteine-rich protein which may function in the regulation of RNA replication and transcription. RNA2 codes for the capsid protein, followed by a 39 kDa protein translated separately from the capsid protein, from genomic RNA, by leaky ribosome scanning; and finally, the TGB, cell-to-cell movement proteins. Spontaneous deletion mutations in RNA2 have been found in virus isolates propagated in *Nicotiana benthamiana*. The deletions occurred within the 39 kDa protein, but the mutants could form virions and infect host plants systemically, suggesting that the 39 kDa protein is involved in virus–fungus interactions.

Pomovirus (type virus, PMTV)

All three RNA segments are required for replication, systemic spread and fungus transmission, as shown for the genome structure and organization of BSBV. RNA1 codes for two N-coterminal, replicase proteins. RNA2 codes for the capsid protein and the capsid readthrough protein, which is believed to be required for fungal transmission. RNA3 codes for the TGB proteins for cell-to-cell movement.

Contrary to BSBV, PMTV RNA2 codes for the TGB proteins and RNA3 codes for the capsid and readthrough proteins. The sizes of RNAs 2 and 3 are reversed in BSBV and PMTV due to the shorter readthrough region (47 kDa) in PMTV compared with 84 kDa in BSBV, and the 3′-terminal untranslated regions (218 nt in PMTV; 548 nt in BSBV). The former may have resulted from spontaneous deletion in wild-type RNA2, while the latter could be due to a cDNA cloning artifact.

Using an antiserum prepared against the PMTV capsid readthrough domain, the readthrough region was found to be present at one end of rod-shaped virus particles.

Benevirus (type virus, BNYVV)

Among the four genera, the molecular genetics of BNYVV have been studied most extensively, using infectious *in vitro* transcripts produced from full-length cDNA clones.

BNYVV RNA1 and RNA2 code for all essential virus functions required for replication, systemic infection and vector transmission. The 237 kDa protein coded by RNA1 is the viral RNA replicase. The TGB 42 kDa, 13 kDa and 15 kDa proteins, and the capsid protein coded on RNA2, are required for cell-to-cell movement and long distance movement of the virus, respectively. The cysteine-rich 14 kDa protein may be required for regulation of RNA transcription and replication.

The RNA1-coded 237 kDa replicase protein contains a putative papain-like proteinase domain between the helicase and polymerase domains. The 237 kDa protein is processed into 150 kDa and 66 kDa polypeptides, and the latter has been detected in infected leaf tissues, indicating that processing occurs *in vivo*. A requirement for this proteolytic processing in viral RNA replication is uncertain.

The capsid readthrough region is required for fungus transmission. Deletion mutants in the capsid protein readthrough region, isolated in the greenhouse or generated artificially by site-directed mutagenesis, were not fungus-transmissible. By alanine scanning mutagenesis, a KTER motif at positions 553–556 in the 75 kDa capsid readthrough protein was shown to be important for efficient transmission by *Polymyxa betae*. The N-terminal domain of the readthrough region also appears to be important for virus particle assembly.

Using an antiserum prepared against the BNYVV capsid readthrough domain, the readthrough region was found to be present at the ends of rod-shaped virus particles.

The RNA3-encoded 25 kDa protein is soluble and responsible for the yellow lesion phenotype on *Tetragonia expansa* leaves. It also facilitates the proliferation of fine rootlets in sugarbeet, thus increasing BNYVV virulence in infected plants. A short ORF overlaps the C-terminus of the 25 kDa protein and induces a severe necrotic response when activated by deleting upstream sequence.

The RNA4-encoded 31 kDa protein increases the efficiency of transmission of the virus by the vector fungus.

An RNA5 is also detected in field isolates from Japan and Germany. The 26 kDa protein contains an FRGPGN stretch in the C-terminal region, as found in the RNA3-coded 25 kDa protein. RNA5 may be related to the virulence of BNYVV, as is RNA3.

Virus–Host Interactions

In ultrathin tissue sections of infected plants, virus particles are observed both scattered and in aggregates, usually as parallel arrays. Virions appear in both the cytoplasm and vacuole. SBWMV, BBNV, PMTV and OGSV also create inclusion bodies consisting of masses of tangled tubules which can be seen easily in the light microscope. For SBWMV, the

shape and size of the inclusion body depends on the nature of RNA2, implying that the extended coat protein readthrough portion forms or determines inclusion body morphology.

In general, the concentration of many of these viruses in infected plants is fairly low, which presents problems for virus purification. Several (e.g. BNYVV and PMTV) are poorly systemic. Yields are typically 20–30 mg kg^{-1} fresh leaf (or taproot) weight, at best. In part, this reflects particle fragility, as well as problems of releasing virions from aggregates sedimented with the cell debris during low-speed centrifugation. In the case of PMTV and NVMV, the first low-speed pellet is taken as the best source for subsequent virus extraction.

In addition to their effects on the grana of chloroplasts, resulting in leaf mosaics and yellowing, PMTV and BNYVV primarily infect root and tuber tissues. Movement of BNYVV from roots to leaves is rare, but causes vein yellowing and necrosis, hence the name of the virus. It has been speculated that the viruses may also affect phytohormone levels and thereby cause growth abnormalities such as severe stunting, 'mop-tops' or 'rhizomanias'. BNYVV infects the vascular tissues of young taproots, causing browning, taproot stunting and loss of sugar content. If serious, the young taproot dies and, through loss of apical dominance or hormone effects, other fine rootlets or lateral roots then develop into new taproots. They too become infected in turn, resulting in the 'hairy root' phenotype. PMTV causes 'spraing' disease (brown necrotic rings) in a few potato cultivars, e.g. Arran Pilot, Saturna.

Best studied is BNYVV, where the RNA3 25 kDa product has been shown to perturb chloroplast structure and cause yellow lesions, despite the fact that the 25 kDa protein is found predominantly in the 30 000 *g* supernatant fraction of infected cells. The availability of full-length cDNA clones and infectious transcripts of BNYVV and SBWMV will add considerably to our understanding of the molecular pathology of these viruses through reverse genetics, production of transgenic plants and complementation studies.

Transmission and Vectors

The natural vector for SBWMV, PCV, OGSV and RSNV is *Polymyxa graminis*. BNYVV, BSBV and BSBMV are transmitted by zoospores of the closely-related species, *P. betae*, whereas PMTV is spread by *Spongospora subterranea*.

All three vectors for fungus-transmitted, rod-shaped viruses belong to the Class Plasmodiophoromycetes and are obligate parasites inhabiting roots and tubers. *P. graminis* and *P. betae* have little effect on their host plants and are morphologically indistinguishable, but have different host ranges. *S. subterranea* is the causal agent of powdery scab on potato tubers. The life cycle of each consists of biflagellate zoospores, multinucleate plasmodia, zoosporangia and thick-walled resting spores in clusters or cystosori, but all lack a mycelial stage. The optimum temperature for growth of *P. graminis* is 18°C and zoospores become immobile at 28°C. Thus most fungus-transmitted, rod-shaped viruses become a problem when soil temperatures are around 15–18°C. In contrast, PCV spreads efficiently in soil at 28°C (or above) in West Africa and India. At higher temperatures, resting spores of the fungal vector produce zoospores more rapidly. The major source of field infections is viruliferous resting spores in cystosori in virus-infected root debris. Cystosori can even survive passage through the alimentary tract of herbivores.

Since zoospores require moisture for release and motility, virus infections are most evident after extended damp weather or irrigation, and then mostly in low-lying areas of fields. The viruses can persist in the vector for many months and, for PMTV for over 12 years, in resting spores in moist field soil growing crops other than potatoes. Only a small fraction (1–10%) of the zoospore population appears to contain virions, although it is not formally proved that virus particles are the form of infection transmitted by the fungal vector. It is still unclear whether or not these viruses replicate inside their fungal vectors. Electron microscopy has shown increasing numbers of virus particles in successively older spore preparations; however, continuous propagation of initially viruliferous fungi on plants which do not support virus replication eventually leads to virus-free fungus. Viruses are acquired by fungi only *in vivo*, from virus-infected root cells by an unknown mechanism (possibly phagocytosis or pinocytosis). Mixing suspensions of fungal spores and virions does not create viruliferous vectors. Virus particles are internal, hence transmission cannot be reduced by treating motile viruliferous zoospores with virus-specific antisera or by washing resting spores with acid or alkali.

Once contact is made with a healthy plant root, the zoospore becomes encysted and the contents, including virions, enter the epidermal cell, which is penetrated by a rigid, subcellular dart-like structure (the 'stachel'). During growth of the plasmodium, virus is probably released into the host cell cytoplasm. The plasmodium becomes either a zoosporangium or a cystosorus with clusters of resting spores, from which viruliferous zoospores are eventually released for infection of further host plants. Clearly a

component of virus–host plant specificity refects some specific fungus–plant interactions.

At the molecular level, it has been shown that RNA4 of BNYVV confers efficient transmission by *P. betae*, and that RNA3 is necessary for efficient virus spread in root tissue. Repeated mechanical transmission through single lesions in leaves of *Tetragonia expansa* or *Chenopodium quinoa* results in greatly decreased levels (or loss) of RNA3 and RNA4. In addition, a natural deletion mutant of BNYVV RNA2 showed that the 75 kDa readthrough protein (the C-terminally extended 21 kDa coat protein) was essential for virus transmission by *P. betae*. By *in vitro*, site-directed mutagenesis using full-length cDNA clones, a KTER motif at positions 553–556 in the 75 kDa coat readthrough protein was shown to be important for efficient transmission of BNYVV by *P. betae*.

No vectors are known for BBNV and SCSV, but *Polymyxa* spp. are most likely. NVMV also has no known vector, but a high rate of seed transmission to several *Nicotiana* spp. may aid its survival in the semiarid region of South Australia where it was isolated. In addition to their fungal vectors, peclu-viruses are also seed-transmitted in groundnuts (peanuts), and PMTV is spread vegetatively through infected 'seed' potatoes.

Zoospores of the unrelated chytrid fungus *Olpidium brassicae* transmit tobacco stunt virus and lettuce big vein virus nonpersistently; however, these labile rod-shaped particles have capsid proteins of 48–52 kDa and genomes consisting of two double-stranded RNAs and, as such, are now considered members of the genus *Varicosavirus*. *P. graminis* and *P. betae* also transmit bipartite, flexuous filamentous viruses belonging to the genus *Bymovirus*, e.g. oat mosaic virus, wheat spindle streak virus, barley mild mosaic virus and barley yellow mosaic virus.

Epidemiology and Control

Because fungus-transmitted, rod-shaped viruses are retained in resting spores in soil for years it is difficult to control the disease once a field becomes infested with viruliferous fungi. Winter wheat is second only to rice as a major crop in global agriculture (584 million metric tonnes in 1996; Food and Agriculture Organization) and, for example, in the USA 34.5×10^6 hectares of wheat have an annual value of $\$7.7 \times 10^9$. SBWMV can cause up to 80% crop loss, although values of 10–50% are more typical and the US national average (1976–1983) was about 3% loss. Losses due to BNYVV in European sugarbeet can amount to 30%.

Conventional control measures, including rotation of nonsusceptible with susceptible crops, reduce, but do not eliminate, the effective 'titer' of field inoculum (e.g. for SBWMV this means growing maize, oats and soybeans for 3 years between wheat sowings). Delayed crop sowing in the autumn reduces the number of SBWMV-infected winter wheat plants, presumably because a less prolonged damp period, and colder conditions, prevent zoospore invasion. Using only PCV-free groundnut seed, or PMTV-free seed potatoes, and 'roguing' (manually uprooting) obviously infected plants can reduce the incidence of disease. Removing potential weed hosts in which the fungal vectors might overwinter is also beneficial. Virus-resistant cultivars are used extensively to reduce the effects of infection. For SBWMV, a single dominant gene in hard red winter wheat has been used successfully to slow virus production and accumulation until later in the season, when symptoms are less pronounced anyway. Thus the wheat plants are not completely resistant to either the fungus or the virus, nor are they tolerant to infection. In fact, roots are more damaged by SBWMV in resistant than in susceptible cultivars. It is the movement of virus from the roots to the foliage that is alleged to be inhibited by the resistance gene. Chemical sterilants and fungicides (methyl bromide, formaldehyde, captan and benomyl) can reduce the incidence of PMTV and SBWMV in small test plots, but are financially and environmentally impractical for large-scale field control. Similarly, reducing the soil pH to 5.0 with sulfur, or adding mercuric or zinc compounds, can kill zoospores, but not resting spores, of the fungal vector (*S. subterranea*) of PMTV. In Japan, sugarbeet seedlings are germinated in sterile soil and later transplanted in paper pots in infested fields. Although BNYVV infection of fine rootlets is severe, the taproots often escape infection. Nevertheless they are still frequently stunted and have a lower sugar content.

Genetic engineering of crop plants to express portions of the virus genome constitutively has provided effective dominant monogenic protection by interfering with the natural life cycle of the pathogen. Some candidate sequences for such experiments include: the viral coat protein gene, the 3′ untranslated viral RNA sequence – to compete with the viral replicase, the viral nonstructural (replicase) polypeptides, catalytic RNA-cleaving ribozyme sequences targeted to essential viral genes, defective RNA or protein species to block cell-to-cell spread, fungus acquisition or transmission. In addition to pathogen-derived resistance, transgenic expression of a single-chain antibody fragment specific to the BNYVV capsid protein in *Nicotiana benthamiana*

has provided some degree of resistance to BNYVV infection.

Geographic Distribution

Table 1 shows that, in common with their widespread fungal vectors, fungus-transmitted, rod-shaped viruses are found throughout the world in temperate as well as tropical regions. Records of their geographic location probably only reflect sites where particular agronomic problems have arisen and where research as been focused. Airborne viruliferous resting spores offer a global opportunity to spread these viruses.

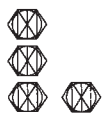
GEMINIVIRUSES (*GEMINIVIRIDAE*)



K. W. Buck, Department of Biology, Imperial College of Science, Technology and Medicine, London, UK

History

The description in an eighth century Japanese anthology of yellow vein of *Eupatorium chinense*, now known to be caused by a geminivirus, may be the earliest record of a plant virus disease. Some of the world's most serious diseases of crop plants, such as beet curley top, African cassava mosaic and maize streak, have been known for over 100 years, but it was not until the 1970s that the causative agents of these and some other diseases were characterized as viruses with an unusual twinned-isometric or geminate morphology and a genome of circular single-stranded (ss) DNA. The *Geminivirus* group was established by the International Committee on the Taxonomy of Viruses in 1978 and upgraded to a family, the *Geminiviridae*, in 1995. Currently there are over 90 recognized virus species, and several tentative species, in the family.

Taxonomy and Classification

Viruses in the *Geminiviridae* family are characterized by geminate particles (about 20 nm × 30 nm) containing circular ssDNA molecules (2.5–3.0 kb). They have been classified into three genera, *Mastrevirus* (type member, maize streak virus, MSV), *Curtovirus* (type member, beet curly top virus, BCTV) and *Begamovirus* (type member, bean golden mosaic virus, BGMV), which are distinguished largely on the basis of differences in genome organization, modes of gene expression, functions of virus-encoded proteins and sequence similarity.

Virion Structure

Chloris striate mosaic virus (CSMV) capsids, and probably those of other geminiviruses, are composed of 110 polypeptide subunits. The geminate structure arises by fusion of two incomplete $T = 1$ icosahedra with 22 pentameric capsomers in total. Each geminate particle contains only one ssDNA molecule, whether the genome consists of one DNA component (e.g. CSMV) or two components (e.g. BGMV).

Genome Organization and Expression

Mastrevirus Genus

The genome of mastreviruses is composed of one circular ssDNA molecule of 2.6–2.8 kb. The complete nucleotide sequences of infectious clones of the DNA of bean yellow dwarf virus (BeYDV), CSMV, digitaria streak virus (DSV), MSV, miscanthus streak virus (MiSV), panicum streak virus (PanSV), sugarcane streak virus (SSV), tobacco yellow dwarf virus (TYDV), and wheat dwarf virus (WDV) have been determined. The DNA has four open reading frames (ORFs), two on the virion DNA strand (V1 and V2) and two on the complementary DNA strand (C1 and C2) (**Fig. 1**; **Table 1**).

Transcription is bidirectional from within a large intergenic region (LIR) that separates the V and C ORFs and contains sequences essential for promoter activity and DNA replication. The other ends of the V and C ORFs are separated by a second smaller intergenic region (SIR) which contains transcriptional polyadenylation signals.

ORF V1 encodes the virus movement protein (MP). MP is not required for DNA replication or accumula-

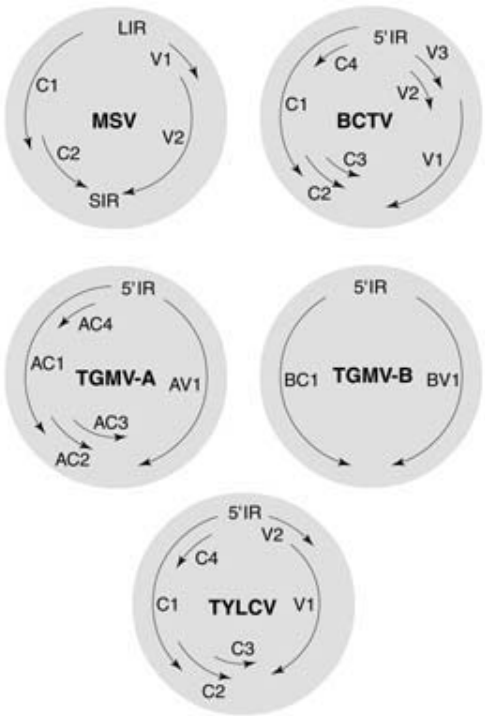


Figure 1 Genome organization and ORFs in the DNA of MSV (*Mastrevirus* genus), BCTV (*Curtovirus* genus), TGMV (*Begamovirus* genus; New World; Bipartite), TYLCV-Sar (*Begamovirus*; Old World; Monopartite). New World begamoviruses lack ORF AV2. Monopartite begamoviruses lack DNA B.

tion of ssDNA in protoplasts. The protein is essential for virus cell-to-cell movement. It is associated with secondary plasmodesmata and a transmembrane domain has been predicted in its amino acid sequence.

ORF V2 encodes the virus capsid protein (CP). In single cells, CP is not required for virus DNA replication, but is needed for accumulation of ssDNA. CP is needed for systemic infection of plants. It binds to double-stranded (ds) DNA as well as ssDNA in a sequence nonspecific manner with a DNA binding domain and/or nuclear localization sequence near the N-terminus. It may be involved in viral DNA nuclear transport as well as in encapsidation. CP is also needed for insect transmission and may be the sole determinant of insect vector specificity.

For MSV, there are two classes of V-sense transcripts, starting 1 and 142 nucleotides upstream of the MP translational initiation codon, respectively. CP appears to be expressed from highly abundant short spliced transcripts of the first class, from which a 76 nucleotide intron in ORF V1 has been removed. MP appears to be expressed from low abundance unspliced long transcripts with a 142 nucleotide leader sequence. Spliced V-sense transcripts have also been identified in DSV-infected plants. Only one (unspliced) transcript spanning ORFs V1 and V2 has been detected in WDV-infected plants and it has been suggested that the CP may be expressed from this dicistronic mRNA by ribosomal frameshifting or by a 'relay-race' mechanism. Spliced V-sense transcripts have also not been detected from TYDV-infected plants.

The product of ORF C1 (Rep A protein) activates V-sense gene expression, possibly in conjunction with the Rep protein. It is probably expressed from an unspliced transcript which spans ORFs C1 and C2. The RepA protein is not required for virus DNA replication in protoplasts, but is required for systemic infection of plants probably due to its activation of V-sense and host gene transcription (see section on DNA replication). For all sequenced mastreviruses except MSV, ORF C2 lacks an ATG translational initiation codon. ORF C2 is expressed as a C1:C2 fusion protein (Rep protein) from a spliced transcript from which an intron, spanning sequences near the 3′-end of the C1 ORF and at the 5′-end of the C2 ORF, has been removed. The Rep protein is essential for virus DNA replication.

Single-stranded DNA from virions of CSMV, MSV, TYDV and WDV has been shown to contain a tightly bound oligodeoxyribonucleotide (about 80 nucleotides) with a few ribonucleotides covalently linked at the 5′-terminus. The sequence of this oligonucleotide is complementary to that of the virion DNA and maps to the SIR. The function of the bound oligonucleotide is probably to act as a primer for complementary-strand DNA synthesis.

DNA from WDV-infected plants contains, in addition to the genomic DNA, a number of deletion mutants (subgenomic DNAs). The deletions in most of these map to the V1/V2 region, but mutants with deletions in the C1/C2 region have also been described. All these subgenomic DNAs retain the LIR and most of the primer binding site. These sequences are required in *cis* for DNA replication. Other replication functions are supplied in *trans* by the wild-type virus genomic DNA which acts as a helper.

Curtovirus Genus

The genome of curtoviruses consists of one circular ssDNA molecule of 2.9–3.0 kb. The complete nucleotide sequences of infectious clones of the DNA of BCTV (three strains), horseradish curly top virus (HrCTV), and tomato pseudo-curly top virus (TPCTV) have been determined. The DNA of BCTV and TPCTV has four ORFs, three on the virion DNA strand (V1, V2 and V3, also called R1, R2 and R3,

Table 1 Geminivirus genes and functions

Genus	*ORF*[a,b]	*Protein encoded*	*Function*
Mastrevirus	C1	RepA	Transactivation of V-sense transcription; binds Rb protein
	C1:C2	Rep	Initiation of DNA replication; sequence-specific endonuclease/ligase
	V1	MP	Cell-to-cell movement
	V2	CP	Encapsidation of virus ssDNA; systemic movement; vector transmission
Curtovirus	C1	Rep	Initiation of DNA replication; sequence-specific endonuclease/ligase
	C2	C2	Suppression of host defense response?
	C3	REn	Enhancement of DNA replication
	C4	C4	Initiation of cell division
	V1	CP	Encapsidation of virus ssDNA; systemic movement; vector transmission
	V2	V2	Regulation of viral ssDNA synthesis
	V3	V3	Movement
Begamovirus			
Monopartite	C1	Rep	Initiation of DNA replication; sequence-specific endonuclease/ligase
	C2	TrAP	Transactivation of V-sense transcription
	C3	REn	Enhancement of DNA replication
	C4	C4	Initiation of cell division? Movement?
	V1	CP	Encapsidation of virus ssDNA; systemic movement; vector transmission
	V2	V2	Virus movement in some Old World begamoviruses
Bipartite	AC1	Rep	Initiation of DNA replication; sequence-specific endonuclease/ligase; transcriptional repression of Rep gene; binds Rb protein; activates transcription of PCNA gene
	AC2	TrAP	Transactivation of AV1 and BV1 transcription; suppression of host defense response?
	AC3	REn	Enhancement of DNA replication
	AC4	AC4	Contributes to transcriptional repression of Rep gene
	AV1	CP	Encapsidation of virus ssDNA; vector transmission; systemic movement in some hosts
	AV2	AV2	Virus movement in some Old World begamoviruses
	BC1	MP	Cell-to-cell movement
	BV1	NSP	Shuttles viral DNA in and out of the nucleus

[a] In an alternative ORF nomenclature, C is replaced by L and V is replaced by R.
[b] ORF V2 (AV2) is found in Old World, but not New World, begamoviruses.

respectively) and four on the complementary DNA strand (C1, C2, C3 and C4, also called L1, L2, L3 and L4, respectively) (**Fig. 1**; **Table 1**). The HrCTV genome lacks ORF C3. As with the mastreviruses, there is an intergenic region (5′-IR) separating the start of the V and C ORFs, which contains sequences essential for promoter activity and DNA replication.

ORF V1 encodes the CP, which is not needed for virus DNA replication in protoplasts, but which is required for systemic infection of plants. It is also required for insect transmission specificity. ORF V2 appears to be involved in the regulation of virus DNA synthesis. In transient replication assays, V2 mutants overaccumulate dsDNA, but produce about 10-fold less ssDNA than the wild-type virus. The V2 gene product is needed for systemic infection of the natural host *Beta vulgaris*, but is not needed for systemic infection of *Nicotiana benthamiana*. ORF V3 is not needed for virus DNA replication. It encodes a protein involved in systemic movement.

ORF C1 encodes the Rep protein, essential for DNA replication, and is the counterpart of the mastrevirus Rep protein. ORF C2 encodes a protein of unknown function. It may possibly suppress a host defense response. BCTV C2 mutants show only a small reduction in virus DNA replication in protoplasts and do not abolish CP synthesis. The C2 protein does not transactivate transcription of the V1 (CP) gene, but may suppress a host defense response. ORF C3 encodes a replication enhancer (REn). REn is

not an absolute requirement for virus DNA replication, but BCTV C3 mutants accumulated three- to five-fold less DNA than the wild-type virus in protoplasts. ORF C4 encodes a protein which can initiate cell division.

BCTV subgenomic DNAs have been described which retain *cis*-essential sequences for DNA replication, but which require a helper virus to provide replication proteins in *trans*.

Begamovirus Genus

The genome of most begamoviruses consists of two ssDNA components, DNA A and DNA B, each 2.5–2.8 kb in size, although some begamoviruses, such as Acalypha yellow mosaic virus (AYVV), tomato yellow leaf curl virus-Israel (TYLCV-Is), TYLCV-Sardinia (TYLCV-Sar), tomato leaf curl virus-Australia (ToLCV-Au), and probably cotton leaf curl virus-Pakistan (CLCuV-Pk), lack a DNA B component. The complete nucleotide sequences of infectious clones of the DNA of abutilon mosaic virus (AbMV), African cassava mosaic virus (ACMV), bean dwarf mosaic virus (BDMV), bean golden mosaic virus-Puerto Rico (BGMV-PR), pepper huasteco virus (PHV), potato yellow mosaic virus (PYMV), squash leaf curl virus (SLCV), tomato golden mosaic virus (TGMV), tomato mottle virus (ToMoV), TYLCV-India (TYLCV-In), TYLCV-Is, TYLCV-Thailand (TYLCV-Th) and ToLCV-Au have been determined, and sequence information for over 40 begamoviruses is available.

Both the DNA A and DNA B components of the bipartite begamoviruses, AbMV, ACMV, PYMV, TGMV and TYLCV-In, are required for efficient infection of plants. However, DNA A can replicate alone and produce virions in single cells. DNA B cannot replicate in the absence of DNA A and is required for systemic virus movement in plants. TYLCV-Th has DNA A and DNA B components, but DNA B is not required to infect plants.

DNA A of all begamoviruses has five ORFs, of which one (AV1, also called AR1) is on the virion DNA strand and the other four (AC1, AC2, AC3 and AC4, also called AL1, AL2, AL3 and AL4, respectively) are on the complementary strand (**Fig. 1**). Begamoviruses from the Old World (Europe, Asia, Africa, Australia) possess an additional ORF (AV2, **Fig. 1**), not found in New World (North America, South America) begamoviruses.

ORF AV1 (V1 for monopartite begamoviruses) encodes the CP. CP is not an absolute requirement for DNA replication, but protoplasts infected with AV1 mutants accumulate decreased amounts of ssDNA and increased amounts of dsDNA, suggesting a regulatory role for CP in ssDNA synthesis. CP is not absolutely required for systemic infection of some plants by bipartite begamoviruses, such as ACMV, TGMV and TYLCV-Th, although mutations in CP can delay symptom development and evidence suggests that CP contributes to systemic movement in a virus- and host-dependent fashion. CP is required for systemic movement of the monopartite begamovirus ToLCV-Aus. As for the mastreviruses and curtoviruses, CP is important for vector transmission of begamoviruses.

Mutational analysis suggests that ORF AV2 (V2 for monopartite begamoviruses) may not be functionally equivalent in different Old World begamoviruses. The AV2 protein is not required for replication of TYLCV-In DNA, although AV2 mutants can reduce the amount of ssDNA produced. TYLCV-In AV2 is required for efficient virus movement in plants. Disruption of ORF V2 in ToLCV-Aus also greatly impaired systemic infection of plants. In contrast, disruption of ORF AV2 in ACMV had no effect on infection of plants.

ORF AC1 (C1 for monopartite begamoviruses) encodes the Rep protein, which is essential for DNA replication, is the counterpart of the mastrevirus and curtovirus Rep proteins. The begamovirus Rep protein negatively regulates its own transcription by binding to a sequence between the TATA box of the Rep promoter and the Rep transcriptional initiation site. The N-terminal region of the TGMV Rep protein mediates this binding. Transgenic plants expressing antisense RNA to the Rep gene of TGMV or TYLCV, or truncated forms of the Rep gene of ACMV or TYLCV in the sense orientation, show resistance to virus infection and reduced viral DNA replication in protoplasts or leaf discs.

ORF AC2 (C2 for monopartite begamoviruses) encodes a transcriptional activator protein (TrAP) which transactivates transcription of the CP gene on DNA A and the BV1 gene on DNA B. Evidence suggests that transcription of the CP gene is activated in mesophyll cells and derepressed in phloem cells. The TrAPs of PYMV and TYLCV-Is have been shown to bind ssDNA with high affinity and dsDNA with low affinity in a sequence-nonspecific manner. The TrAP DNA-binding domain maps to a region rich in cysteine and histidine residues which might form a zinc finger to mediate DNA binding. The TrAP protein may also suppress a host defense response.

ORF AC3 (C3 for monopartite begamoviruses) encodes a replication enhancer (REn), which is the counterpart of the REn proteins of the curtoviruses. It is not an absolute requirement for begamovirus DNA replication, but AC3 mutations reduce DNA replica-

tion by 10- to 50-fold. REn has been shown to interact with Rep via an N-terminal region of the latter.

ORF AC4 (C4) is conserved in most begamoviruses and is contained completely within the AC1 coding sequence, but in a different reading frame. It is apparently not functionally equivalent in different viruses. The TGMV AC4 protein is much more highly expressed than the AC1 (Rep) protein *in vitro* and evidence suggests that it may contribute to transcriptional repression of the AC1 gene. However, TGMV AC4 mutants show no phenotype in a variety of hosts. In contrast ToLCV-Aus C4 mutants show reduced symptoms, while retaining wild-type levels of all viral DNA species. It is possible that the C4 proteins of the monopartite begamoviruses, and possibly those of some Old World bipartite begamoviruses, are functionally equivalent to the C4 proteins of the curtoviruses, and may induce cell division. It has also been suggested that the TYLCV-Is C4 protein might play a role in virus movement.

Like the mastreviruses and curtoviruses, an intergenic region (5′-IR) separates the start of the begamovirus AV1 (or AV2 for Old World begamoviruses) and AC1 genes. This contains transcriptional promoters for these genes, as well as sequences essential for DNA replication. It is likely that the Rep and AC4 proteins are translated from one mRNA, possibly by a leaky scanning or internal initiation mechanism. The promoter for the Rep/AC4 mRNA is located in a region 60 bp immediately upstream of the mRNA start site and contains TATA and G boxes, both of which are important for promoter activity. The TrAP and REn proteins may also be translated from one mRNA; the mRNA for these two proteins is probably synthesized from a promoter which lies within the AC1 ORF.

Begamovirus DNA B has two ORFs, one on the virion DNA strand (BV1, also called BR1) and one on the complementary DNA strand (BC1, also called BL1). The start of these ORFs is separated by an intergenic region, much of which is almost identical to the 5′-IR of the DNA A component of the same virus and this near identical region in both DNAs has been called the 'common region'. The DNA B intergenic region contains promoters for the BV1 and BC1 genes and *cis*-essential sequences for DNA replication. The 3′ ends of the V and C transcripts from both DNA A and DNA B are close together and are adjacent to inverted repeat sequences in the DNA, which act as bidirectional polyadenylation signals.

The BV1 and BV2 proteins are both required for virus movement through the plant. The SLCV BV1 protein binds strongly to ssDNA and less strongly to dsDNA *in vitro*. It localizes to the cell nucleus and has a bipartite nuclear localization signal within the N-terminal 113 amino acid residues. The SLCV BC1 protein binds only weakly to ssDNA and not at all to dsDNA *in vitro*. It is associated with endoplasmic reticulum-derived microtubules in developing phloem cells and with the plasma membrane later in infection. The BC1 protein interacts with a C-terminal domain of the BV1 protein and can relocalize BV1 to the cell surface. A model has been proposed in which the BV1 protein acts as a nuclear shuttle for transport of the virus DNA in and out of the nucleus as a complex that is recognized by the BC1 protein for transport to adjacent cells, possibly through the plasmodesmata via the endoplasmic reticulum-derived tubules. The BV1 protein has been named the nuclear shuttle protein (NSP) and the BC1 protein, the movement protein (MP).

Some isolates of ACMV, PYMV and TGMV contain, in addition to the genomic DNAs, subgenomic DNA B species of about half the size of DNA B. The deletions in these subgenomic DNAs have been mapped to BR1, and in some cases, additionally to the C-terminal part of BC1. All the subgenomic species retain the 5′-IR. Subgenomic DNAs of ACMV act as defective-interfering DNAs and transgenic plants containing an integrated dimer of a subgenomic DNA B, from which a monomer can be released by replication, show partial resistance to infection by ACMV. Defective forms of monopartite begamoviruses (AYVV, CLCuV-Pk and TYLCV-Is) have also been described. The CLCuV-Pk defective DNAs have various combinations of sequence deletion, duplication, inversion, rearrangement, and in some cases, insertion of sequences of unknown origin.

A 682 nucleotide satellite DNA has been found associated with ToLCV-Aus. The satellite DNA (ToLCV-Aus satDNA) is encapsidated by the CP of ToLCV, has no significant ORFs and is completely dependent on the Rep protein of its helper virus for its replication. ToLCV-Aus satDNA has no sequence similarity to ToLCV-Aus DNA, except for *cis*-acting sequences required for virus DNA replication.

Geminivirus DNA Replication

Geminiviruses replicate in the nucleus of infected cells. Curtoviruses and begamoviruses induce morphological changes in the nucleus which include the formation of characteristic fibrillar rings, composed of deoxyribonucleoprotein. Viral and host DNA appear to become compartmentalized with viral DNA forming inclusions in the interior of the nucleus and host DNA localized mainly at the periphery. Viral proteins involved in replication (Rep, REn) and transcriptional regulation (RepA, TrAP) are localized to the nucleus.

Replication of all geminiviruses probably takes place by basically the same mechanism, although there are some differences between the replication of geminiviruses in different genera, partly determined by the virus and partly by the host. Replication is envisaged to occur in two stages in a similar way to that of the ssDNA bacteriophage φX174: (1) synthesis of a minus-strand on the virion plus-strand template to produce dsDNA; and (2) synthesis of plus-strands from the minus-strand template of the dsDNA. Early in the replication cycle, plus-strands synthesized in stage (2) are probably converted into dsDNA to amplify the templates required for virus transcription. Open circular and covalently closed circular (supercoiled) dsDNA, as well as chromatin-like structures, have been isolated from infected plant tissue. Later in the cycle, plus-strand synthesis may be coupled to encapsidation.

As ssDNA extracted from virions is infectious for plants, at least the initial synthesis of minus strands must be carried out by plant proteins and enzymes, before any geminivirus replication proteins have been synthesized. Differentiated plant cells lack detectable levels of DNA replication enzymes and in mature plants, DNA replication and cell division are limited to apical meristems, developing leaves and the cambium. The initial minus-strand synthesis may therefore be confined to existing meristematic cells or cells in which DNA replication and cell division have been induced by wounding during the inoculation process. Subsequent synthesis of plus strands and minus strands will also require host proteins and enzymes. It has been suggested that replication of geminiviruses which are phloem-limited, such as AbMV, BCTV and SLCV, may occur in procambial cells. Other geminiviruses are able to replicate in a variety of differentiated cells, For example, TGMV has been found in nuclei of differentiated cells of leaves, stem and roots of infected *N. benthamiana* plants and MSV DNA is located in mesophyll cells, as well as vascular cells, of mature maize plants; neither virus was found in meristematic cells. Several geminiviruses have been shown to be able to induce the synthesis of proteins and enzymes needed for DNA replication and switch differentiated cells into S phase. For example, the TGMV Rep protein can induce the transcription of the gene for proliferating cell nuclear antigen (PCNA) the processivity factor for host DNA polymerases δ and ε in differentiated cells. Geminivirus Rep proteins may induce synthesis of host replication proteins by binding to plant retinoblastoma (Rb) homologues. In mammalian cells, the Rb protein controls entry into the cell cycle by binding to and inactivating members of the E2F family of transcription factors. When Rb becomes phosphorylated by cyclin-dependent kinases, it can no longer bind E2F transcription factors, which are then able to induce the transcription of DNA replication genes. The genes of several animal viruses which require cellular replication enzymes for virus DNA replication, such as the SV40 large T antigen and adenovirus E1A protein, bind Rb and prevent it from interacting with E2F transcription factors, which are free to induce progression into the S phase. These proteins bind Rb via a conserved motif LXCXE which is also found in the Rep proteins of mastreviruses. The RepA proteins of WDV and other mastreviruses contain the LXCXE motif and can bind to mammalian Rb proteins and plant homologues. The TGMV Rep protein has also been found to bind to maize Rb-related proteins, although it lacks the LXCXE motif. The C4 protein of BCTV is able to induce cell division, possibly by binding to cellular protein kinases.

Little is known about the synthesis of the minus strand, but based on current knowledge of plant DNA replication, it is likely that the origin of minus-strand synthesis is recognized by a DNA polymerase α-primase complex which catalyzes the synthesis of an oligoribonucleotide which acts as a primer for subsequent DNA synthesis. The presence of oligodeoxyribonucleotides with ribonucleotides at their 5′ends bound to virion DNA of several mastreviruses is consistent with this hypothesis. The position of these oligonucleotides suggests a mastrevirus origin of minus-strand replication within or close to the SIR, or somewhere upstream of this region. Such oligonucleotides have not been found bound to virion DNA of curtoviruses or begamoviruses, but analysis of intermediates of replication of ACMV DNA indicates that the minus-strand origin lies within the common region.

Synthesis of geminivirus plus-strand DNA occurs by a rolling circle mechanism, probably similar to that of ssDNA bacteriophages and some bacterial plasmids. All geminiviruses that have been sequenced contain a sequence in the LIR or 5′-IR that can potentially be folded into a stable stem–loop structure, the loop of which contains the invariant sequence TAATATTAC. This sequence is also found in ToLCV-Aus satDNA. The initiation site for plus-strand synthesis *in vivo* lies between the seventh and eigth nucleotide of this sequence. Rep proteins of several geminiviruses have been shown to be site-specific endonucleases which cleave plus-strand viral DNA at the same position *in vitro*. After cleavage, the Rep protein remains covalently bound to the 5′end of the cleaved strand via a tyrosine residue. Rep proteins also have ligase activity. The endonuclease/ligase activity could catalyze the release and circularization

of genome-sized ssDNA after each round of rolling circle replication. The Rep protein probably acts as a dimer with each subunit cleaving the DNA at alternate rounds of replication. The endonuclease/ligase activities map to an N-terminal region of the Rep protein.

Rep proteins can cleave ssDNA, but not dsDNA *in vitro*. Mutational analysis has also indicated the importance of maintaining the stem–loop structure for geminivirus DNA replication, indicating that the dsDNA must be unwound *in vivo* before cleavage can occur. Rep proteins contain ATP-binding motifs in their C-terminal regions, shown to be essential for virus DNA replication, and ATPase activity has been demonstrated for TGMV and TYLCV-Sar Rep proteins. However the ATPase activity is not DNA-dependent, only weak sequence similarity to consensus helicase motifs has been found and helicase activity has not been demonstrated for any geminivirus Rep protein. It is possible therefore that the dsDNA is unwound by one or more cellular helicases, as found for phage φX174.

A conserved stem–loop containing the invariant TAATATTAC sequence is the only structural element in common between plus-strand origins of geminiviruses in different genera. Indeed, replication origins of viruses within the curtovirus and begamovirus genera tend to be virus specific. For example, the BGMV and TGMV origins are not interchangeable between the two viruses. An exception is ToLCV-Aus satDNA which can replicate with either curtovirus or begamovirus helpers. The TGMV origin of replication overlaps the promoter for transcription of the Rep mRNA and includes the stem–loop structure and upstream sequence elements, a G box, AG-motif, TATA box, Rep-binding site and CA-motif. The G box and TATA box, which are transcription factor binding sites, and the CA-motif, are not absolute requirements for TGMV DNA replication, but mutations reduce the efficiency of replication. The Rep-binding site and AG-motif are essential for replication. The TGMV Rep-protein-binding site **GGTAG**TAA**GGTAG** contains two pentanucleotide repeats (shown in bold) and similar repeats were found in Rep-protein-binding sites of other begamoviruses and curtoviruses. The Rep-protein-binding sites are necessary, but not sufficient, to confer virus-specific origin recognition on begamoviruses and curtoviruses. Mastrevirus LIRs contain repeated sequences (iterons) located in the stem of the conserved stem–loop structure and between the TATA box and the transcriptional start site of the Rep mRNA. Iterons may be recognition sites for proteins involved in DNA replication. The WDV origin region consists of a minimal *ca.* 200 bp *cis*-acting element within the LIR, which contains 28 bp and *ca.* 70 bp, downstream and upstream, respectively, from the replication initation site. This is flanked by auxillary elements of *ca.* 70 bp (5′-aux) and 30 bp (3′-aux) which are needed for efficient DNA replication. There is a Rep-protein-binding site upstream of the TATA box.

Transmission, Host Range and Geographical Distribution

In the field, most geminiviruses are transmitted by either whiteflies (begamoviruses) or leafhoppers (mastreviruses and curtoviruses). TPCTV, a curtovirus, is transmitted by a leafhopper. There is no evidence for transmission through seed or by contact between infected and uninfected plants. Once acquired by the vector, the viruses are circulative and persist in it for days or for life, but apparently do not replicate. Transovarial transmission of TYLCV-Is has been reported for at least two generations of whiteflies, suggesting that the vector could act as a virus reservoir between growing seasons of crop plants.

The whitefly-transmitted geminiviruses are transmitted exclusively by *Bemisia tabaci*, although the 'B' biotype is sometimes referred to as *B. argentifolii*. In contrast, each leafhopper-transmitted geminivirus has a different principal vector, e.g. the principal vectors for MSV, WDV and BCTV are *Cicadulina mbila*, *Psammotettix alienus* and *Circulifer tenellus*, respectively. The CP is a major determinant of vector specificity. The CP sequences of the whitefly-transmitted geminiviruses are more closely related to each other than are those of the leafhopper-transmitted geminiviruses. Transmission of ACMV by *B. tabaci* requires sequences from DNA A and DNA B. Some begamoviruses found in ornamental plants, e.g. AbMV and honeysuckle yellow vein mosaic virus, appear to be nontransmissible by *B. tabaci*.

The field host range and geographical distribution of a geminivirus will depend partly on the host range and distribution of the insect vector, and partly on the ability of a virus to infect a particular plant. The host range of *B. tabaci* is very wide, although there may be biotypes with different feeding preferences. Both whitefly-transmitted and leafhopper-transmitted geminiviruses are found predominantly in tropical and subtropical regions, although some geminiviruses, such as WDV, have been found in countries with cooler climates, such as Sweden. Mastreviruses have narrow host ranges and with the exception of BeYDV and TYDV, which infect dicotyledonous plants (dicots), are limited to monocotyledonous plants (monocots) (*Gramineae*). Curtoviruses have

only been found in dicots. BCTV has a very wide host range, infecting over 300 plant species in 44 families. Begamoviruses generally have narrow host ranges and have only been found in dicots. Geminiviruses have been found in a number of weed plants, e.g. AYVV in *Ageratum conyzoides*, which may act as reservoirs for infections of crop plants. TYLCV has been isolated from *Solanum nigrum* in Spain and an Almerian isolate of TYLCV has been found to be transmissible by *B. tabaci* from tomato to *S. solanum* and *vice versa*.

The host range of geminiviruses can be investigated, and potentially extended, by use of inoculation methods that do not involve the vector. Many bipartite begamoviruses can be transmitted mechanically. In contrast, geminiviruses with one DNA component (monopartite begamoviruses, mastreviruses, curtoviruses) either have not been transmitted mechanically or have been transmitted with difficulty. It is possible that mechanical inoculation is aided by DNA B which enables the virus to be transported from cells initially infected to the phloem parenchyma. Agroinoculation and biolistic delivery have been developed as general procedures for infecting plants with geminiviruses. An *Agrobacterium*/Ti plasmid vector system or a high-velocity microprojectile bombardment system is used to introduce a dimer or partial dimer of the cloned viral dsDNA into plant cells. Monomeric viral DNA molecules are then produced either by replication between origins (functionally equivalent to rolling circle replication) or, less efficiently, by intramolecular recombination between homologous sequences.

The ability of a geminivirus to infect a plant will depend on the ability of the virus to replicate in single cells and its ability to move from cell to cell and systemically through the plant via the phloem. Both of these processes will involve interactions between host and viral proteins and nucleic acids and such interactions must be compatible, i.e. able to carry out a particular function, if a productive infection is to occur. For example, DSV and WDV can replicate in monocots, but not in dicots. Synthesis of the DSV or WDV Rep protein in monocots requires the production of a spliced mRNA. In transgenic tobacco plants containing an integrated dimer of DSV DNA, transcription of the C1 region occurs, but no splicing of the pre-mRNA and therefore no production of the Rep protein takes place. Hence failure of DSV and WDV to replicate in dicots is probably due, at least partly, to differences in splicing mechanisms between monocots and dicots. Analysis of host range variants of SLCV suggest that sequences of the common region could be important determinants of host range, perhaps as a result of productive or nonproductive interactions of host DNA primase with the minus-strand origin. Compatibility of virus cell-to-cell movement proteins with plant plasmodesmatal proteins could also be important in determining host range.

Gene Amplification Vectors based on Geminivirus Replicons

The finding that the CP of begamoviruses is not required for DNA replication or systemic infection of some plants led to the development of CP replacement vectors for ACMV and TGMV. Agroinoculation of plants with DNA A vectors containing a reporter gene of similar size to the CP gene, such as *neo*, together with DNA B, leads to systemic infection of plants, stable replication of the vector to average copy numbers up to 500 and concomitant increases in enzyme activity, e.g. neomycin phosphotransferase. Vectors containing reporter genes larger than the CP gene, such as the *gus* gene, show instability in infected plants, undergoing deletions and rearrangements.

Apparently cell-to-cell and systemic movement by begamoviruses in plants requires that the recombinant DNA A construct is of a similar size to the wild-type. However, in transgenic plants containing a master copy (partial dimer) of the vector integrated into the plant chromosomal DNA, vectors up to at least 1.1 kb larger than DNA A replicated stably; in such plants replication occurs in single cells in the absence of DNA B and cell-to-cell movement of the vector is not required. Furthermore, since the plant chromosomal DNA contains a master copy of the vector, gene amplification is heritable. Begamovirus vectors have also been used to study plant splicing signals, to amplify ribozymes in plant cells and to silence endogenous host genes.

Coat protein replacement vectors have also been constructed from mastreviruses. Replication of WDV vectors up to 4 kb larger than the wild-type virus DNA and increased expression of reporter genes occurs in plant protoplasts or cultured plant cells. Replication of WDV replicons smaller than the wild-type virus DNA also occurs. The efficiency of replication of vectors is inversely proportional to their size. WDV vectors have been used to introduce transposable elements into plant cells, to show that transposition requires DNA replication and to determine *cis* requirements for transformation. Since mastreviruses require the CP for systemic infection of plants, infection of plants by mastrevirus CP replacement vectors is precluded. However, a chromosomally integrated TYDV binary vector replicated and maintained a *gus* reporter gene in tobacco plants. MSV mutants with small insertions in the SIR are

viable, but recombinants containing a herbicide resistance gene (*bar* gene), flanked by cauliflower mosaic virus 35S promoter and terminator sequences, inserted into the SIR did not move systemically through plants, probably because even the smallest recombinant with the CP gene deleted was larger than the wild-type virus DNA.

Pathogenesis

The symptoms induced by geminiviruses include striate mosaics and streaks, stunting, enations, leaf curling, vein clearing and vein chlorosis, and yellow and green leaf mosaics. The severity and type of symptoms will depend on the number and type of cells infected, the amount of virus replication per cell and any interactions between virus-encoded proteins and cellular constituents which affect cell function. Since geminiviruses replicate and induce morphological changes in the nucleus, interference with normal nuclear function probably contributes to pathogenic effects at the cellular level. Inappropriate induction of cellular DNA replication and cell division could also result in pathogenic effects Alterations to the plasmodesmata, needed for cell-to-cell virus movement, may contribute to symptoms. For some viruses, such as AbMV, direct effects on the chloroplasts are suggested by the detection of virus ssDNA and dsDNA in these organelles.

Symptoms such as stunting, leaf curling, streaking, vein clearing and veinal chlorosis can be explained by replication of the viruses in phloem cells with consequent disruption of the plant's vascular system. More extensive chlorosis on leaves of dicots indicates wider tissue invasion. Similarly the width of streaks in monocots may be determined by the ability of the virus to spread out of the phloem into other cell types.

Mutational analysis and expression of virus proteins in transgenic plants indicate that several different virus genes contribute to pathogenicity. TGMV AC3 deletion mutants that have reduced DNA replication in single cells produce attenuated symptoms in plants. A mutation in the LIR of MSV which disrupted a TATA box in the promoter for the Rep gene caused a change in symptoms from severe to mild, probably as a result of synthesis of limited amounts of Rep and RepA proteins. Transgenic tobacco plants expressing the TGMV MP (BC1 protein) exhibit symptoms of viral disease, possibly due to an effect of this protein on plasmodesmata. Similarly a mutation within the V1 (MP) gene of MSV, which reduced streak width, reduces the cell-to-cell and/or systemic movement of the virus. This mutation does not result in an amino acid change, but increases the proportion of spliced V-sense transcripts with a concomitant reduction in the amount of MP and an increase in the amount of CP. The C4 proteins of BCTV and ToLCV-Aus are major symptom determinants. Transgenic *Arabidopsis* and *N. benthamiana* plants expressing the BCTV C4 protein show a variety of abnormalities, including the production of tumorigenic growths, probably related to the capacity of this protein to induce cell division.

Evolution

The overall similarity of the genome organization of viruses in the three geminivirus genera suggests their evolution from a common ancestor. All geminiviruses have genes on both the virion DNA strand and its complement with bidirectional transcription and a 5′ intergenic region containing sequences important for transcription and replication, including a potential stem–loop containing the conserved TAATATTAC sequence. The CP genes are located in similar positions on the virion DNA strand and the replication genes are all on the complementary DNA strand.

Despite these similarities, significant differences have emerged, probably as a result of selective pressures dictated by the host and the insect vector. An attractive hypothesis is that the ancestral geminivirus had a single DNA component, resembling that of mastreviruses. Old World monopartite begamoviruses may have evolved from the ancestral mastrevirus. It is noteworthy that the Old World monopartite begamoviruses and the mastreviruses both have V-sense ORFs (V2 and V1, respectively) which encode proteins needed for virus movement and which may be functionally equivalent. Evolution of Old World monopartite begamoviruses from ancestral mastreviruses would have involved several changes. (1) The CP sequence would be altered to allow transmission by whiteflies instead of leafhoppers. (2) An intron would be lost from the Rep gene. A consequence of this would be that the RepA protein, postulated to be a transactivator of the CP gene, would no longer be produced. The TrAP gene, which serves the same purpose in the begamoviruses, may have coevolved with the loss of the Rep gene intron. (3) The REn gene would be acquired. Although the mechanism of replication enhancement by the REn protein, other than its interaction with the Rep protein, is not known, differences in the structure of the LIR and 5′ IR between mastreviruses and begamoviruses, including the presence of iterons in the former, could have led to the evolution of this gene. Old World begamoviruses could then have acquired a DNA-B component to enhance movement of the virus to different tissues and cell types, producing more striking symptoms and increasing

whitefly transmissibility. The formation of bipartite begamoviruses in which the DNA B component is not essential for systemic infection, e.g. TYLCV-Th, could represent the first stage in this evolutionary pathway. The DNA B component probably evolved from the DNA A component, as suggested by their almost identical common regions, the low, but significant sequence similarities between the AV1 (CP) and BV1 (NSP) proteins, the fact that both these proteins bind strongly to ssDNA, and the transactivation of transcription of both genes by TrAP. Acquisition of cell-to-cell movement genes on DNA B could have led to the loss of cell-to-cell movement function of the AV2 protein in some Old World bipartite begamoviruses, e.g. ACMV, and loss of this gene completely in the New World bipartite begamoviruses. The greater sequence diversity within the *Mastrevirus* genus than within the *Begamovirus* genus is consistent with the evolution of begamoviruses from ancestral mastreviruses. Sequence comparisons suggest that curtoviruses, such as BCTV and HrCTV, may have arisen by recombination acquiring the CP gene, and hence leafhopper transmissibility, from a mastrevirus and the Rep gene from a begamovirus.

Geminiviruses have some similarities to another group of multipartite ssDNA viruses (proposed *Nanovirus* genus), comprising banana bunchy top virus, subterranean clover stunt virus, faba bean necrotic yellows virus and milk vetch virus, which all have Rep proteins with the Rb-binding LXCXE motif, have intergenic regions containing a putative stem–loop structure with a conserved consensus TAG/TTATTAC (similar to the geminivirus TAATATTAC sequence) sequence and which probably replicate by a rolling circle mechanism. Geminiviruses and nanoviruses also have some affinities to viruses in the *Circoviridae* family of animal ssDNA viruses. Recently it has been found that ToLCV-Aus DNA can replicate in *Agrobacterium tumefaciens* suggesting that plant ssDNA viruses may have arisen from ssDNA bacteriophages or plasmids which employ rolling circle replication. *Agrobacterium* species are widely distributed plant pathogens known to be able, via their Ti plasmids, to insert DNA into plant genomes. Consistent with this theory is the finding that remnants of geminivirus DNA have been found in the genome of some (uninfected) plants which are hosts for geminiviruses.

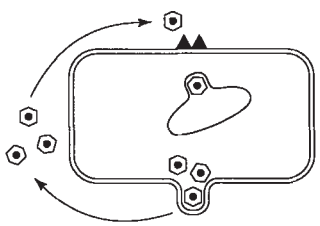
GENETICS OF ANIMAL VIRUSES

Frank Fenner, John Curtin School of Medical Research, Canberra, Australia



History

Although genetic variation was the basis of some of the earliest work with animal viruses, such as Pasteur's attenuation of rabies virus, the first formal demonstration of the occurrence of mutation in an animal virus did not occur until over 60 years later, when Burnet used limiting dilution methods to clone influenza virus. A few years later, in the early 1950s, Burnet demonstrated 'high frequency recombination' (later called genetic reassortment) between different strains of influenza A virus. Intramolecular recombination was demonstrated with herpes simplex virus in 1955 and with vaccinia virus in 1958 and the first

HEPADNAVIRUSES (*HEPADNAVIRIDAE*): HEPATITIS B VIRUSES

Contents

General features

William S Robinson, Stanford University School of Medicine, Stanford, California, USA

History

Infectious icterus or jaundice has been recognized for more than 2000 years and has occurred frequently as epidemic disease in military and civilian populations during wars. Much of this disease was probably hepatitis A now known to occur in epidemics when transmitted by sewage-contaminated water and by fecal-contaminated food. Hepatitis transmitted by serum and blood was only recognized in the mid-nineteenth century when venipuncture, use of the same needle without sterilization for many individuals and vaccines containing human serum came into use. Only in the twentieth century was hepatitis shown to be transmitted by 'filterable' agents (i.e. that could pass through filters that retain bacteria) and those agents fit the emerging concept of viruses as being infectious agents smaller than bacteria and not visible by light microscopy. Epidemiologic and human transmission studies in the 1940s and 1950s led to the clear recognition that 'infectious hepatitis' (hepatitis A) and 'serum hepatitis' (hepatitis B and probably C and D) were caused by distinct viral agents. Hepatitis B virus (HBV) was discovered as a physical entity only in the 1960s.

Hepatitis B surface antigen (HBsAg) was discovered serendipitously in human serum in the mid-1960s and initially was named Australia antigen because it was first found in serum of an Australian aborigine. It was later associated with acute serum hepatitis and eventually identified as a viral antigen (specifically the envelope antigen of hepatitis B virus). The most common form of this antigen in the blood was found to be small lipid-containing envelope particles (i.e. incomplete virus particles without viral nucleocapsids). This led to rapid advances in understanding the epidemiology of the virus, the course of infection and recognition of associated diseases, and the physical nature of the virus. Early during this period, serum HBsAg was found in populations all over the world, and HBV infection was recognized as commonly becoming chronic and as being associated with chronic hepatitis, cirrhosis and hepatocellular carcinoma (HCC).

The complete virus or 'Dane particle' was found to be a 42 mm diameter spherical particle with a lipid-containing envelope with HBsAg on its surface and surrounding a 20 nm core particle or nucleocapsid containing a small circular partly single-stranded viral DNA and a DNA polymerase activity that repaired the single-stranded region of the virion DNA. Within a decade, new viruses which were very similar to HBV were discovered in several species and it was clear that these viruses represented a previously unrecognized virus family.

Taxonomy and Classification

HBV and related viruses make up the virus family designated *Hepadnaviridae* for hepatotropic DNA viruses. This virus family includes hepatitis B virus of man, woodchuck hepatitis virus (WHV) of *Marmata monax*, ground squirrel hepatitis virus (GSHV) of *Spermophilus beecheyi*, duck hepatitis B virus (DHBV) found in several varieties of domestic ducks, and similar viruses in tree squirrels, Richardson ground squirrels, snow leopards and German herons. Less well documented findings in other rodents, marsupials and cats suggest that other hepadnaviruses may have been detected. There may be many undiscovered members of this virus family since naturally occurring infections can be relatively silent for many years.

Hepadnaviruses share many epidemiologic and biological features. All hepadnaviruses exhibit moderately narrow host ranges, strong relative tropism for hepatocytes, *in vivo* production by infected hepatocytes of large amounts of noninfectious viral envelope particles (as well as infectious virus) that can be detected in high concentration (up to 500 $\mu g\ ml^{-1}$) in the blood, and the common occurrence of persistent infections with viral forms in the liver

and blood continuously for years and often for the lifetime of the host. Infections with hepadnaviruses may be associated with acute and chronic hepatitis, immune complex (viral surface antigen-antibody)-mediated disease and HCC.

Hepadnaviruses share unique features of virion size and ultrastructure with an envelope surrounding an electron dense spherical nucleocapsid or core; characteristic polypeptide and antigenic composition; common virion DNA size and structure (3200 bp circular DNA being among the smallest of all known animal viruses) and genetic organization; the presence of DNA polymerase activity in the virion; and an unusual mechanism of viral DNA replication which includes reverse transcription of a viral RNA that is greater than the genome length. These biological and molecular features define this virus family.

Mammalian viruses have four recognized genes and avian viruses only three (the mammalian virus X gene is not present). Viral core and envelope polypeptide sizes are quite similar among mammalian hepadnaviruses and different in DHBV. Different mammalian hepadnaviruses contain cross-reacting antigens which do not cross-react with the respective antigens of avian hepadnaviruses. These and other differences suggest that mammalian and avian hepadnavirus should be considered to represent different genera within the family *Hepadnaviridae*.

Geographic and Seasonal Distribution

Studies of geographic distribution have revealed HBV in all regions of the world, but unevenly distributed. The highest prevalences of serum HBsAg are in eastern Asia and sub-Saharan Africa (for example approximately 10% in China compared with 0.1% in the United States). There are no known seasonal preferences for primary HBV infections. WHV has been found in wild woodchuck populations over a broad region of the eastern United States. GSHV has been found only in wild Beechey ground squirrels in a small area near Palo Alto, California, but not in other areas of California or elsewhere. DHBV has been found in domestic ducks of several varieties and in many eastern, mid-western and western areas of the United States as well as in domestic ducks in parts of China. There is no documented seasonal preference for primary infections. However, wild rodents such as woodchucks and ground squirrels breed and deliver offspring during a narrow time period in the spring in North America and thus perinatal transmission of hepadnaviruses would be expected to occur only during that time period.

Host Range and Virus Propagation

Hepadnaviruses have narrow host ranges. HBV infect humans, chimpanzees, some other great apes but not monkeys or lower species. WHV can infect woodchucks but not ground squirrels, rodents or other species tested. GSHV infects both Beechey ground squirrels and woodchucks but not other rodents or species tested. DHBV infects several varieties of domestic ducks and geese but not chickens, other birds or mammals. Only DHBV readily infects cells in culture (only primary duck hepatocyte cultures). Mammalian hepadnaviruses have not been shown readily or reproducibly to infect any cell type in culture.

Genetics

Genetic studies have been limited by the failure of mammalian hepadnaviruses to propagate in cell culture.

Evolution

Nucleotide sequence homology and genome organization show that mammalian hepadnaviruses are more closely related to each other than to avian hepadnaviruses.

Hepadnaviridae appear to be phylogenetically related to members of two other virus families: cauliflower mosaic virus and *Retroviridae* and related transposable elements. Similarity in gene number, function and order; shared genome nucleotide sequence homology in genomic regions of similar function; and utilization by all of a reverse transcriptase step in genome replication, indicate these virus families are related. Reverse transcription is an unusual mechanism of genome replication for DNA viruses (known at this time only for hepadnaviruses and cauliflower mosaic virus). Undoubtedly it is a mechanism used by these viruses because their evolution from a common ancestor is shared with retroviruses, and differs from the evolutionary pathway of other DNA viruses. Notable differences in the viruses of these families include: (1) the form of the genome packaged in virions is different (linear RNA in the case of retroviruses and nicked or gapped double-stranded circular DNA in hepadnaviruses and cauliflower mosaic virus); (2) retroviruses package two copies of the viral genome in each virion resulting in high rates of homologous recombination and hepadnaviruses one genome copy; and (3) details of the replication mechanisms are different.

Another important difference is in the mechanism of viral integration and the requirement for DNA genome integration in cellular DNA for virus replica-

tion. The orderly integration of retroviral DNA 'provirus' is mediated by a virus-encoded integrase with preservation of the genome sequence and including a terminally repeated sequence (the long terminal repeat or LTR) containing *cis*-acting transcriptional and other regulatory elements. Expression of viral genes and synthesis of new RNA genomes from the integrated provirus is an integral feature of retrovirus replication occurring in all infected cells. This feature is not shared by hepadnaviruses whose replication appears to involve only episomal (unintegrated) viral nucleic acid forms. Hepadnaviral integration appears to be a less well controlled event by a mechanism such as illegitimate recombination without involvement of viral integrase and without preservation of the genome sequence, making it impossible for the viral integrant to function as a template for virus replication.

Serologic Relationships and Variability

There are three major antigens of hepadnaviruses and these are: (1) the surface or envelope antigen (e.g. HBsAg in the case of HBV) contained in the small (s), medium (preS2+S) and large (preS1+preS2+S) surface antigen polypeptides of the viral envelope and this antigen is found in blood exclusively on the surface of small spherical and long filamentous envelope particles and on enveloped virions; (2) the core or nucleocapsid antigen (e.g. HBcAg) contained in the structural polypeptide of assembled core particles; and (3) the e antigen (e.g. HBeAg) contained in a truncated, soluble form of the core gene-encoded polypeptide. The small (s) HBsAg polypeptide contains a constant or group-specific epitope *a* and at least two varying or subtype-specific epitopes, each one always found in one of two distinct antigenic specificities designated *d* or *y* and *w* or *r*. Thus HBsAg subtypes adw, adr, ayw and ayr (less common) have been found. Other minor subtype antigenic differences have also been described. Antigenic subtypes have been used as markers in epidemiologic studies. Different HBsAg subtypes have unique world-wide geographic distributions indicating that each arose in a different geographic region, and the current distribution must reflect that region of origin and the migrations of human populations since that time. No such antigenic variation is known for HBcAg or HBeAg. Recently, S gene and C gene mutants have been found which abolish or alter antigenicity and may be associated with altered virulence.

The respective c and e antigens of mammalian hepadnaviruses cross-react (s more weakly than c) but no cross-reactions between mammalian and avian hepadnavirus antigens have been detected. S antigen subtypes have not been reported for animal hepadnaviruses.

Epidemiology

Most primary infections in highly endemic populations occur at very early ages (between 10 and 50% of HBV infections that become persistent in different high-prevalence geographic regions are acquired perinatally from infected mothers), are silent or subclinical, and many become persistent. In Western countries most primary HBV infections are in adults (acquired by sexual contacts or percutaneous exposure). They are more often associated with clinically apparent acute hepatitis B and only 5–10% become persistent. The prevalence of HBsAg carriers is greater among males than among females in most populations. There are estimated to be more than 200 million HBsAg carriers in the world; these are the only reservoir of HBV for new human infections. The associated chronic liver disease and HCC are among the most important human health problems in high-prevalence regions. On a world-wide basis, HBV is probably the most common single cause of chronic liver disease and HCC in man. The incubation period of hepatitis B (time from infection to onset of hepatitis) is typically 6–24 weeks and accounts for an early name for this disease being 'long incubation hepatitis'.

Transmission and Tissue Tropism

As with other viruses that persist in the blood of infected individuals, HBV is transmitted by heterosexual and homosexual contacts; percutaneously (for example by skin puncture with contaminated shared needles for illicit drug use) and by inoculation with contaminated blood and blood products; and perinatally from infected mothers to their newborn infants. Very few infants of HBV-infected mothers are infected *in utero*. Different HBV carriers may have greatly different degrees of contagiousness for contacts. This is due to different levels of virus replication in the liver and quantity of infectious virus in the blood and body fluids of different carriers. Serum HBeAg and levels of viral DNA-containing virions in the blood are reliable markers indicating the presence of infectious virus. Some HBsAg carriers with no detectable serum HBeAg or viral DNA and reactive for anti-HBe may have no infectious virus in the blood and do not transmit infection.

Hepadnaviruses are hepatotropic (i.e. infect primarily liver cells) although less frequent and less permissive infection sometimes occurs in bone marrow, circulating leukocytes, B cells, T cells and

pancreas. Virtually all active infections are accompanied by high concentrations of HBsAg and often infectious virus in the blood.

Pathogenicity

Hepadnaviruses infect hepatocytes and the most common disease manifestations are in the liver. Acute infection may result in little disease or in clinically apparent acute hepatitis B of varying severity from mild to fulminant hepatitis with extensive liver necrosis. Persistent infection can be associated with very mild changes in liver, chronic persistent hepatitis, or chronic active hepatitis with chronic liver cell necrosis, an inflammatory response, lymphocytic infiltration and liver regeneration. Chronic hepatitis B can progress to macronodular cirrhosis characterized by liver cell necrosis, fibrosis and regenerative nodules.

The mechanism of liver injury in acute and chronic hepatitis B is not completely defined but a cellular immune mechanism is considered to be likely. Some evidence indicates that cytotoxic T cells directed at the viral core antigen (HBcAg) displayed on the surface of hepatocytes can lead to hepatocyte killing. Other studies have suggested that HBcAg expression in infected cells may have a direct cytopathic effect. Another nonimmune mechanism involves accumulation of viral envelope polypeptides in liver cells and resulting liver cell necrosis, a mechanism demonstrated in transgenic mice. Hepatocytes that accumulate HBsAg *in vivo* during natural HBV infection can be recognized by light microscopy, have been termed 'ground glass cells' and are characteristic of HBV infection.

Hepatocellular carcinoma (HCC) may develop after many years of HBV infection and most HBV-infected patients that develop HCC have cirrhosis. A carcinogenic mechanism for HCC has not been established, although genetic changes that could contribute to carcinogenesis have been found in HCC. In WHV-infected woodchucks more than 50% of HCC contain activated c-*myc* or N-*myc* genes related to viral promoter/enhancer insertion near the respective cellular gene. In GSHV-infected ground squirrels, the c-*myc* gene is amplified and overexpressed in more than 50% of HCC but a role for the virus in causing this change has not been shown. Neither of these changes has been found in HCC of HBV-infected humans. Mutations in the p53 gene, however, have been found in more than 50% of human HCC but no role for HBV in causing these mutations has been shown.

It is possible that in man HBV is not carcinogenic by a direct viral mechanism like those shown for numerous other tumor viruses in animals. Instead, HBV may play a role by causing chronic liver cell necrosis with associated host responses of inflammation and liver regeneration that continues for many years. This pathologic process, particularly when it leads to cirrhosis, may be carcinogenic without involving a direct oncogenic action of the virus (e.g. no viral oncogene, insertional mutagenesis, or *cis*- or *trans*-activation of oncogenic cellular genes has been consistently found). Chronic liver injury caused by numerous other agents, such as hepatitis C virus, alcohol and iron overload, can result in a similar chronic pathologic process leading to cirrhosis and ultimately HCC.

The final pathogenetic mechanism known for HBV is in initiating immune complex disease apparently related to HBsAg–anti-HBs complexes. A serum sickness-like illness with fever, rash and arthritis precedes the onset of acute hepatitis B in 10–15% of cases, and syndromes of glomerulonephritis and necrotizing vasculitis (polyarteritis) with respectively glomerular membrane and vascular endothelial deposits of HBsAg-anti-HBs and complement are unusual but not rare.

Clinical Features of Infection

Most HBV infections are asymptomatic with mild serum alanine aminotransferase (ALT) changes that resolve, although clinically apparent acute hepatitis and occasionally fulminant hepatitis with hepatic failure and death can occur. The severity of acute viral hepatitis B appears to be related to age of infection (young children generally have milder disease than adults), the infecting virus dose (higher doses appear to result in shorter incubation period and generally more severe hepatitis), and immunosuppression which may be associated with mild disease and frequent persistent infection.

Chronic HBV infection is most often asymptomatic ('healthy carriers') and symptomatic chronic active hepatitis with periods of fever, malaise and hepatic pain is much less common. In highly endemic regions of the world such as eastern Asia, most HBV infections occur in newborns or young children and are relatively asymptomatic; many of these infections become persistent and remain silent for many years until cirrhosis or HCC develop in middle or old age and become symptomatic with pain, ascites, abdominal mass, etc. In the United States, more primary HBV infections occur in adults and more often result in symptomatic acute hepatitis B, and fewer become persistent.

Pathology and Histology

Acute hepatitis B is not clearly distinguishable from hepatitis A or hepatitis from many other causes in most individual cases. It is characterized by liver cell necrosis, an inflammatory response, lymphocytic infiltration and liver cell regeneration.

Immune Response

Primary infection leads to an antibody (IgM and IgG) response to HBcAg within a few days of the appearance of HBsAg in serum and near the time of onset of hepatitis. Antibody to HBsAg can usually be detected in serum only several weeks later when serum HBsAg can no longer be detected. Similarly serum anti-HBe can usually be detected when HBeAg is no longer detected in serum.

During chronic HBV infection almost all patients have HBsAg in the blood and some have HBeAg. All have a high titer of anti-HBc. A high titer of anti-HBc suggests ongoing or recent HBV infection. Anti-HBs is usually not detected in serum of HBsAg-positive patients, probably because of excess HBsAg. In many HBsAg-positive patients, HBsAg–anti-HBs complexes can be found in serum, indicating an anti-HBs responsive in many HBsAg carriers. Anti-HBe usually appears when HBeAg can no longer be detected in serum of HBsAg carriers.

T cells which proliferate in response to HBcAg can be detected in the blood of many patients with hepatitis B. T cell proliferative responses to HBsAg appear to be less common.

The presence of anti-HBs and/or anti-HBC from previous HBV infection indicates immunity to HBV and a high level of resistance to re-infection.

Prevention and Control

HBV infections are prevented by measures that interrupt routes of transmission. Recognizing and identifying HBV-infected individuals permits avoidance of contacts which may lead to transmission. Changes in behavior with respect to sexual contacts and illicit intravenous drug use can reduce spread of HBV. Elimination of infected blood and plasma donors by HBsAg screening has largely eliminated HBV infections by blood transfusion and by other blood products. Screening all pregnant women for HBsAg permits protection of newborns of infected mothers by use of hepatitis B immune globulin and HBV vaccination (such passive-active immunization protects up to 95% of newborns of HBV-infected mothers).

Clearly the most important advance in controlling HBV in populations is vaccination. Studies with synthetic peptides indicate the group-specific *a* epitope of the small HBsAg polypeptide can elicit protective immunity and there also appear to be protective epitopes in the preS1 and preS2 sequences. However, HBV vaccines containing only the small HBsAg polypeptide in a particulate form are highly immunogenic and protective without preS1 or preS2 sequences. HBsAg particles containing the small HBsAg polypeptide produced in yeast by recombinant DNA methods is currently used in the United States and provides a highly effective vaccine. HBV vaccine use in high-risk populations in the United States over the past decade (e.g. medical and dental personnel, newborns of HBV-infected mothers, homosexual men, etc.) has protected many individuals but has had little impact on overall numbers of HBV infections. This has led to a recent change in the recommendation for HBV vaccine use in the United States to make it a universal childhood vaccine to be given with DPT (diphtheria, pertussis, tetanus). In addition, vaccination of newborns of HBV-infected mothers and nonimmune uninfected adults in high-risk groups is still indicated. Vaccination of all newborn babies is a goal in almost all countries of the world with high HBsAg carrier rates.

Future Perspectives

Among the important and interesting unanswered questions about hepadnavirus are their mechanistic role in HCC and the immunologic and other factors that lead to persistent infection. At the clinical level, achieving full immunization in countries with high HBsAg carrier rates is a goal unmet due to high cost of the vaccine and logistical problems in delivery in some populations. A big challenge is to develop effective strategies for antiviral therapy of chronic HBV infections. Investigations of therapeutic agents directed at blocking virus replication as well as strategies that may act on host antiviral mechanisms such as the immune response are important to pursue.

whitefly transmissibility. The formation of bipartite begamoviruses in which the DNA B component is not essential for systemic infection, e.g. TYLCV-Th, could represent the first stage in this evolutionary pathway. The DNA B component probably evolved from the DNA A component, as suggested by their almost identical common regions, the low, but significant sequence similarities between the AV1 (CP) and BV1 (NSP) proteins, the fact that both these proteins bind strongly to ssDNA, and the transactivation of transcription of both genes by TrAP. Acquisition of cell-to-cell movement genes on DNA B could have led to the loss of cell-to-cell movement function of the AV2 protein in some Old World bipartite begamoviruses, e.g. ACMV, and loss of this gene completely in the New World bipartite begamoviruses. The greater sequence diversity within the *Mastrevirus* genus than within the *Begamovirus* genus is consistent with the evolution of begamoviruses from ancestral mastreviruses. Sequence comparisons suggest that curtoviruses, such as BCTV and HrCTV, may have arisen by recombination acquiring the CP gene, and hence leafhopper transmissibility, from a mastrevirus and the Rep gene from a begamovirus.

Geminiviruses have some similarities to another group of multipartite ssDNA viruses (proposed *Nanovirus* genus), comprising banana bunchy top virus, subterranean clover stunt virus, faba bean necrotic yellows virus and milk vetch virus, which all have Rep proteins with the Rb-binding LXCXE motif, have intergenic regions containing a putative stem–loop structure with a conserved consensus TAG/TTATTAC (similar to the geminivirus TAATATTAC sequence) sequence and which probably replicate by a rolling circle mechanism. Geminiviruses and nanoviruses also have some affinities to viruses in the *Circoviridae* family of animal ssDNA viruses. Recently it has been found that ToLCV-Aus DNA can replicate in *Agrobacterium tumefaciens* suggesting that plant ssDNA viruses may have arisen from ssDNA bacteriophages or plasmids which employ rolling circle replication. *Agrobacterium* species are widely distributed plant pathogens known to be able, via their Ti plasmids, to insert DNA into plant genomes. Consistent with this theory is the finding that remnants of geminivirus DNA have been found in the genome of some (uninfected) plants which are hosts for geminiviruses.

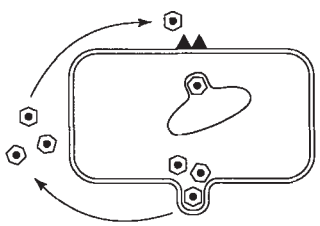
GENETICS OF ANIMAL VIRUSES

Frank Fenner, John Curtin School of Medical Research, Canberra, Australia



History

Although genetic variation was the basis of some of the earliest work with animal viruses, such as Pasteur's attenuation of rabies virus, the first formal demonstration of the occurrence of mutation in an animal virus did not occur until over 60 years later, when Burnet used limiting dilution methods to clone influenza virus. A few years later, in the early 1950s, Burnet demonstrated 'high frequency recombination' (later called genetic reassortment) between different strains of influenza A virus. Intramolecular recombination was demonstrated with herpes simplex virus in 1955 and with vaccinia virus in 1958 and the first

crude maps (of vaccinia virus) were described soon after. Hirst demonstrated that intramolecular recombination could occur among RNA viruses in experiments with poliovirus in 1962 and Cooper published a genetic map of poliovirus in 1968.

Apart from the demonstration of the remarkable variety to be found in the genomes of animal viruses of different groups, animal virus genetics advanced slowly until the discovery of recombinant DNA by Berg, Boyer and Cohen in 1972. This led to the explosive development of molecular genetics. Since animal viruses multiply only in eucaryotic animal cells, viruses were soon found to be a powerful way of investigating the molecular biology of animal cells, especially after the discovery that the DNA of tumor viruses was integrated into the genome of the host cell.

The Genomes of Animal Viruses

Historically, animal viruses were first classified on the basis of the morphology of the virion, but this criterion failed to distinguish between many small isometric viruses or between several different families of enveloped viruses. Morphology was powerfully supplemented as the basis for classification as the genomes of viruses were analyzed and their extraordinary variety demonstrated. Finally, as work proceeded on the replication mechanisms, a third criterion for classification was developed, the strategy of viral replication. Currently eight families of DNA and 16 families of RNA animal viruses are recognized. The genomes of most DNA viruses are double stranded (ds) and range in size from 3.2 to 280 kbp; others have genomes of ssDNA ranging from 1.8 to 5 kb. Some genomes are linear, others circular; among viruses with ssDNA some are of positive sense, some of negative sense.

Viruses are the only living things that use RNA as the repository of their genetic information. The genomes of the RNA viruses are much smaller than those of most DNA viruses, and different families of RNA viruses show a remarkable diversity in genome structure. All except one family of viruses have haploid genomes; the retroviruses, however, have diploid RNA genomes and they also have an obligatory DNA stage in their replication cycle. Among other families the RNA genome may be a single linear strand varying in size from 3.5 to 24 kb, a circular molecule of 1.7 kb, or it may consist, in different genera, of 2, 3, 7 or 8 pieces of ssRNA, or it may consist of segmented dsRNA in 2, 10, 11 or 12 pieces.

Mutations

The most common and important changes in the nucleic acid sequences of viral genomes are due to mutations. In every viral infection of an animal or a cell culture, one or a small number of virus particles replicate to produce millions of progeny. In such large populations, errors in copying the nucleic acid, i.e. mutations, inevitably occur. Many such mutations are lethal. Whether a particular nonlethal mutation survives in the genotype depends upon whether the resultant change in the gene product affords the mutant virus some selective advantage, or whether it is neutral or disadvantageous.

In the laboratory, reasonable genetic constancy of viral stocks (e.g. those used for making viral vaccines or retained as reference strains) is achieved by: (1) isolating a clone, i.e. a population of viral particles originating from a single particle, usually by growth from a single plaque in cell culture, followed by replaquing; then, (2) growing 'seed' stock from this clone; and (3) as far as practicable avoiding or strictly limiting further passage of the virus.

Mutation Rates

Rates of mutation involving single base substitutions (point mutations) are probably the same in DNA viruses as they are in the DNAs of procaryotic and eucaryotic, since viral replication is subject to the same 'proof-reading' exonuclease error correction as operates in cells. Such errors are estimated to occur at a rate of 10^{-8} to 10^{-11} per incorporated nucleotide (i.e. per base pair per replication). Point mutations in the third nucleotide of a triplet often do not result in an altered amino acid, because of coding redundancy, and some point mutations are lethal, because they produce a stop codon or other aberrant regulatory sequences. Viable mutations that are neutral or deleterious in one host may provide a positive selective advantage in a different host.

The error rate in the replication of viral RNA is much higher than that of viral or cellular DNA, because there is no cellular 'proof-reading' mechanism for RNA. For example, the base substitution rate per incorporated nucleotide in the 11 kb genome of vesicular stomatitis virus is $10^{-3} - 10^{-4}$, which is about a million times higher than the average rate in eucaryotic DNA. Of course, most of these base substitutions would be deleterious and the genomes containing them would be lost. Even so, there is growing evidence that nonlethal mutational changes in the genome of RNA viruses occur very rapidly.

Types of Mutations

Mutations can be classified according to the kind of change in the nucleic acid. The most common are nucleotide substitutions (point mutations), deletions

and insertions. Each point mutation has a characteristic frequency of reversion which can be accurately measured. The physiological effects of mutations depend not only on the kind and location of the mutation but also on the activity of other genes. The phenotypic expression of a mutation in one gene may be reversed not only by a back mutation in the substituted nucleotide but, alternatively, by a suppressor mutation occurring elsewhere in the same, or even in a different gene.

Mutations are usually classified by their phenotype – hence temperature-sensitive, cold adapted, host range, plaque size, etc. mutants have been described. Each of these kinds of mutant has been used for the analysis of viral functions, temperature-sensitive mutants being particularly useful (see later). Cold-adapted and temperature-sensitive mutants have been used extensively in attempts to produce attenuated live virus vaccines. Mutations affecting antigenic determinants of virion surface proteins may be strongly favored when viruses replicate in the presence of antibody, and are of importance both in persistently infected animals (e.g. in equine infectious anemia virus) and epidemiologically, as with influenza virus.

Conditional lethal mutants

These are produced by mutations that so affect a virus that it cannot grow under certain conditions, determined by the experimenter, but can replicate under 'normal' or permissive conditions. Their importance is that a single selective test can be used to obtain and analyze mutants in which mutations may be present in any one of several different genes. The conditional lethal mutants most commonly studied are those whose replication is blocked in certain host cells, or at certain defined temperatures. With temperature-sensitive mutants; the selective condition used is a high temperature of incubation of infected cells. A point mutation in the genome, leading to an amino acid substitution in the translated polypeptide product, results in a structurally abnormal protein which, although functional at the permissive temperature, cannot maintain its structural integrity and functional conformation when the temperature is raised by a few degrees.

Defective-interfering (DI) mutants

Mutants of this class have been demonstrated in all families of RNA viruses and in some DNA viruses. They occur when viruses are passed at high multiplicity of infection, because more cells then receive helper virus to support their replication, and the ratio of defective-interfering to infectious particles increases dramatically on serial passage at high multiplicity. The properties that all DI virus particles have in common are: (1) they are defective, i.e. they cannot replicate alone, but can in the presence of a parental wild-type virus; and (2) they decrease the yield of wild-type virus (interference).

All RNA DI particles studied are deletion mutants. In the case of influenza viruses and reoviruses, which have segmented genomes, the defective virions lack one or more of the larger segments and contain instead smaller segments consisting of an incomplete portion of the encoded gene(s). In the case of viruses with a nonsegmented genome, DI particles contain RNA which is shortened – as little as one-third of the original genome may remain in the DI particles of vesicular stomatitis virus. Morphologically, DI particles resemble the parental virions, having a comparable envelope or capsid, but they are sometimes smaller. Sequencing studies of the RNA of DI particles reveal simple deletions and a great diversity of structural rearrangements.

Mutagenesis

Spontaneous mutations arise because of chance errors during replication, the occurrence of which is probably influenced by natural background ionizing radiation. Mutation frequency can be enhanced by treatment of virions or isolated viral nucleic acid with physical agents such as UV or X irradiation or with chemicals such as nitrous acid, hydroxylamine, ethylmethyl sulfonate or nitrosoguanidine. Base analogues, such as 5-fluorouracil or 5-bromodeoxyuridine, are mutagens only when virus is grown in their presence because they are incorporated into the viral nucleic acid.

Site-directed mutagenesis

This process enables the experimenter to introduce mutations at a selected site in a DNA molecule (a DNA genome or cDNA transcribed from an RNA genome). This technique has opened up new research areas; for example: (1) the function of individual genes and the proteins for which they code, or of particular regions of these genes and proteins, can be dissected; (2) mutations can be introduced into particular genes, e.g. those concerned with viral virulence, to produce mutants suitable for use as attenuated live virus vaccines.

Recombination

When two different viruses simultaneously infect the same cell, several kinds of genetic recombination may occur between the newly synthesized nucleic acid

molecules: intramolecular recombination, reassortment, reactivation (when one of the virions has been inactivated) and marker rescue.

Intramolecular recombination

Intramolecular recombination (**Fig. 1A**) involves the exchange of nucleic acid sequences between different but usually closely related viruses. It occurs with all dsDNA viruses, presumably because of strand switching by the viral DNA polymerase. Intramolecular recombination has been demonstrated among RNA viruses only with foot-and-mouth disease virus, poliovirus and coronavirus.

In rare cases, intramolecular recombination occurs between unrelated viruses; the best example is between SV40 (a papovavirus) and adenoviruses. Both SV40 and adenovirus DNAs become integrated into cellular DNA, so that it is perhaps not surprising to find that when rhesus monkey cells which harbor a persistent SV40 infection are super-infected with an adenovirus, not only does complementation occur (see later), the SV40 acting as a helper in an otherwise abortive adenovirus infection, but recombination occurs between SV40 and adenovirus DNAs to yield hybrid (recombinant) DNA which is packaged into adenovirus capsids.

In addition to recombining with each other, or sometimes, as with SV40, with an unrelated virus (adenovirus), many DNA tumor viruses recombine with the genome of cells and in the process the viral oncogenes that they carry may transform the infected cell to a neoplastic state. Integration of proviral DNA into the cellular DNA by a process of intramolecular recombination is an essential part of the replication cycle of retroviruses. Although the genome of these viruses is positive-sense ssRNA, replication does not occur until this is transcribed into DNA by the virion-associated reverse transcriptase and the resultant copy DNA is integrated into the cell's DNA.

Reassortment

A type of recombination called reassortment (**Fig. 1B**) occurs with viruses that have segmented genomes, whether these are ssRNA or dsRNA and consist of two (*Arenaviridae, Birnaviridae*), three (*Bunyaviridae*), seven or eight (*Orthomyxoviridae*), or 10, 11 or 12 segments (*Reoviridae*). In cells infected with two related viruses, there is an exchange of segments with the production of various stable reassortants. Reassortment occurs in nature, and is epidemiologically important in generating new subtypes of influenza virus for example.

Reactivation

The term multiplicity reactivation is applied to the production of infectious virus by a cell infected with two or more viruses of the same strain, each of which has suffered a lethal mutation in a different gene, e.g. after exposure to UV irradiation. Multiplicity reactivation could theoretically lead to the production of infectious virus if animals were to be inoculated with UV irradiated vaccines; accordingly this method of inactivation is not used for vaccine production. Cross-reactivation or marker rescue are terms used to describe genetic recombination between an infectious virus and an inactivated virus of a related but distinguishable genotype or a fragment of DNA from such a virus.

Interactions between Viral Gene Products

As well as interactions between viral genomes, interactions between viral gene products may occur in mixedly infected cells.

Complementation

The term complementation is used to describe situations where in mixedly infected cells one virus provides a gene product that the other cannot make, thus enabling the latter to replicate. Complementation can occur between different strains of the same species of virus and between unrelated viruses; indeed adeno-associated viruses can replicate only if complemented by genes of an adenovirus.

Phenotypic mixing

This term refers to a situation where, after mixed infections, the envelope or capsid of some of the progeny contains gene products of both parents, such as the spikes of enveloped viruses (**Fig. 1E**), the genomes being those of one or other parent, so that on passage the phenotypically mixed particles produce only virions resembling that parent. Phenotypic mixing is an essential part of the life cycle of defective retroviruses, progeny virions being called pseudotypes, with the genome of the defective parental virus but the envelope glycoproteins of the helper retrovirus.

With nonenveloped viruses, phenotypic mixing can take the form of transcapsidation, in which there is partial or usually complete exchange of capsids (**Fig. 1F, G**). For example, poliovirus nucleic acid may be enclosed within a coxsackievirus capsid, or adenovirus 7 genome may be enclosed within an adenovirus 2 capsid.

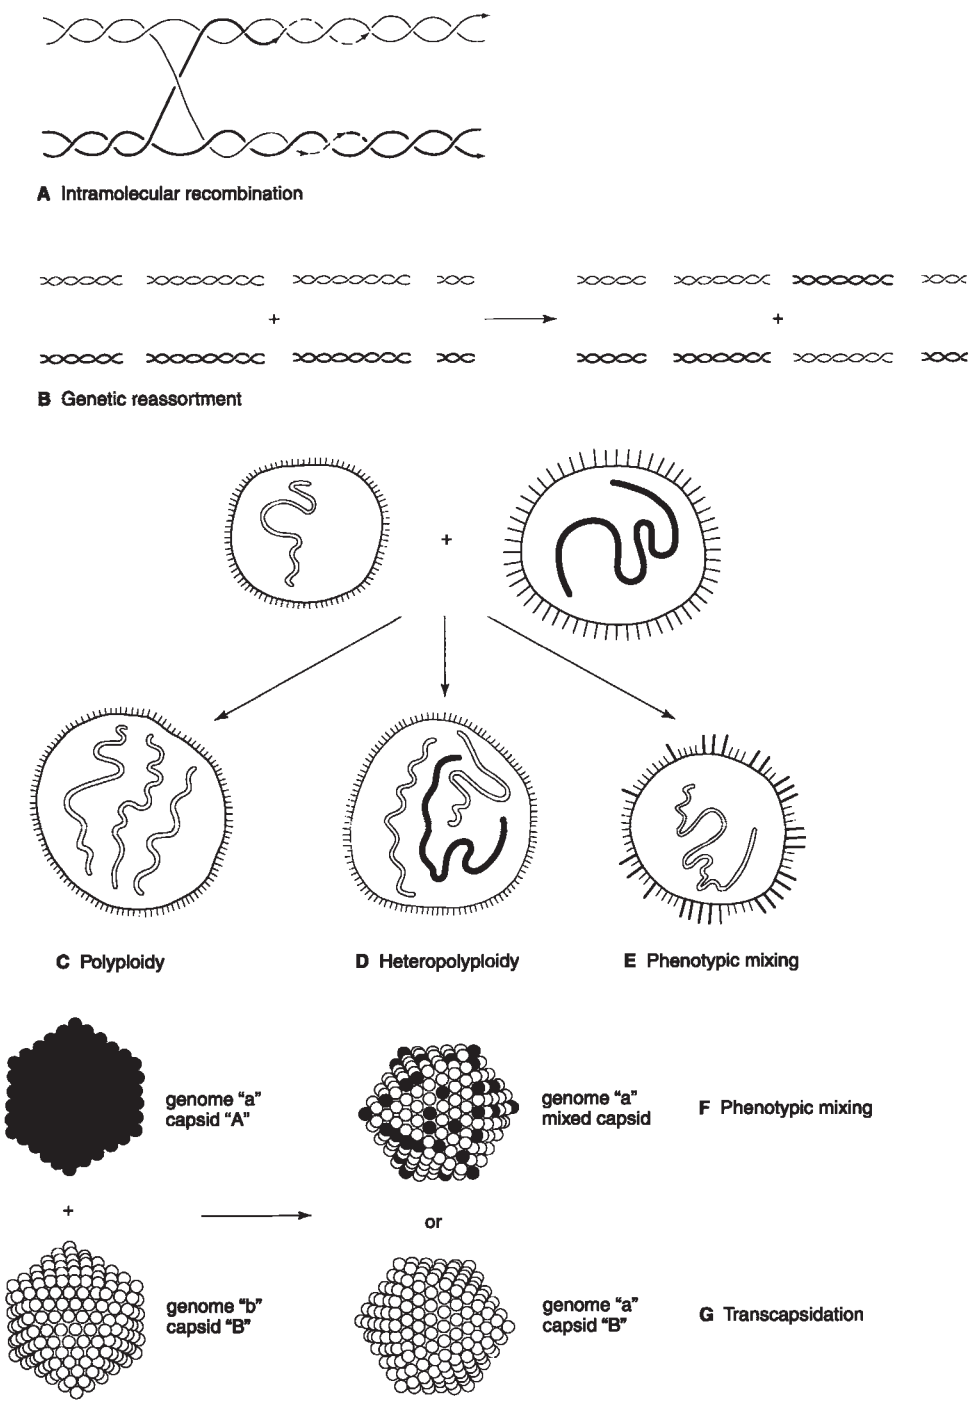


Figure 1 Genetic recombination, polyploidy, phenotypic mixing and transcapsidation. (**A**) Intramolecular recombination. (**B**) Reassortment of genome fragments, as in reoviruses and orthomyxoviruses. (**C**) Polyploidy, as seen in unmixed infections with paramyxoviruses. (**D**) Heteropolyploidy, as may occur in mixed infections with paramyxo-viruses and other enveloped RNA viruses. (**E–G**) Phenotypic mixing: (**E**) with enveloped viruses; (**F**) viruses with icosahedral capsids; (**G**) extreme case of transcapsidation or genomic masking.

Polyploidy

With the exception of the retroviruses, which are diploid, all viruses of vertebrates are haploid, i.e. they contain only a single copy of each gene. However, among viruses that mature by budding from the plasma membrane, e.g. paramyxoviruses, it is commonly found that several nucleocapsids (and thus genomes) are enclosed within a single envelope, i.e.

the virion is polyploid (**Fig. 1C**). If cells are doubly infected with recognizably different strains of such viruses, many of the multiple genome progeny particles are heteropolyploid (**Fig. 1D**) and they may also have phenotypically mixed envelope antigens.

Mapping Viral Genomes

Viral genomes can be mapped several ways. Genetic maps can be constructed on the basis of recombination or complementation tests, and physical maps may show the cut sites of various restriction enzymes or may be obtained by determining the sequence of nucleotides that constitute the viral genome.

Recombination maps

Among viruses that undergo intramolecular recombination, the probability of recombination occurring between two markers reflects the distance between them and recombination frequencies in adjacent intervals are approximately additive. Two-factor crosses are used to determine recombination frequencies between pairs of mutants; for very close or distant markers three-factor crosses are used to resolve ambiguities. Recombination maps have been made for several large DNA viruses, notably herpes simplex virus, and for poliovirus. With the determination of nucleotide sequences the genetic markers of a number of viruses have been located on the relevant physical maps.

For viruses that have segmented genomes, reassortant maps can be constructed by crossing mutants of different serotypes that have electrophoretic polymorphisms for each of the genome segments. They have confirmed that mutations able to recombine reside on different genome segments.

Restriction maps

During the 1960s it was shown that a phenomenon that had been called 'restriction' in bacteriophages, whereby certain bacteriophages failed to replicate in particular species of bacteria, was due to the rapid degradation of the bacteriophage DNA by specific bacterial endonucleases, which were therefore called restriction endonucleases. Subsequently several hundred of these enzymes have been identified and purified from various bacteria. Each recognizes a unique short, palindromic sequence of nucleotides (a sequence that reads the same backwards as forwards), generally four to eight nucleotide pairs long. Depending upon the location and frequency of the specific unique sequence in a particular DNA molecule, a particular restriction endonuclease cleaves the DNA into a precise number of fragments of precise sizes. Other endonucleases, recognizing different sequences, cleave the same DNA into different numbers and sizes of fragments. These DNA fragments, produced by a panel of endonucleases, may be separated by gel electrophoresis. Different viruses, often even very closely related strains of the same virus, yield characteristically different restriction endonuclease fragment patterns, sometimes called fingerprints or restriction fragment length polymorphisms (RFPL). These have been invaluable for distinguishing between different species of viruses with large genomes, such as the various poxviruses. Restriction enzymes can also be used to analyze the molecularly cloned cDNA copies of genes or genomes from RNA viruses. Once the restriction maps of a virus have been determined, the location of many genetic markers, such as temperature-sensitive mutations, at specific locations on the viral genome can be determined by rescue of the deleterious mutation by the corresponding wildtype restriction fragment.

Complementation groups

Complementation tests are used to divide collections of mutants into functional groups, and are particularly useful with virus groups in which recombination mapping is not possible because of the absence of recombination, such as togaviruses and paramyxoviruses.

Molecular Genetics

Since about 1970 there has been an explosive development of techniques that have revolutionized viral genetics, namely methods for molecular cloning, DNA and RNA sequencing, fine mapping of transcripts and expressing genes in procaryotic and eucaryotic cells. In conjunction with site-directed mutagenesis, these techniques have made it possible to introduce into viral genomes virtually any selected mutation and to remove genes and *cis*-acting elements from viral genomes and study their activities in isolation from the rest of the genome. The basic strategy is molecular cloning by the use of recombinant DNA techniques.

Recombinant DNA

The identification of the cleavage sites of the restriction endonucleases and the development of knowledge of the enzymes involved in DNA synthesis opened up the possibility of deliberately introducing specific foreign DNA sequences into DNA molecules. When these recombinant molecules replicate, there is a corresponding amplification of the foreign DNA.

The process is called molecular cloning. When the replicating recombinant molecules are placed in a situation where their genetic information can be expressed, the polypeptide specified by the foreign DNA is produced. These results are usually achieved by incorporating the foreign DNA into a bacteriophage or a plasmid, which serves as a cloning vector for introducing the foreign DNA into bacterial or other cells. Vectors are available that replicate in bacteria, yeasts, animal cells and intact animals. For animal cells, a variety of animal viruses can be used as vectors, SV40, retroviruses and vaccinia virus being popular choices. The development of recombinant DNA methodology has been facilitated by great improvements in the techniques of sequencing DNA and the perfection of methods for making complementary DNA (cDNA) from either viral RNA or mRNA. The cluster of techniques used is often called 'genetic engineering'.

Sequence analysis

A great deal of information can be gleaned from knowledge of the sequence of part or all of a viral genome. Open reading frames (ORF), which are long translational sequences uninterrupted by stop codons (UAA, UAG, UGA), suggest the presence of protein coding sequences, especially if the codons for given amino acids occur with the frequency found in known protein coding sequences of the virus. The function of the predicted protein can sometimes be surmised by the similarity of its imputed sequence to that of a protein of known function. Such comparisons are carried out by searching international computer-based databases of nucleotide and amino acid sequences. Thus the existence of vaccinia growth factor was predicted when sequence analysis of the vaccinia virus genome revealed an ORF similar to that of known mammalian growth factors. It is also possible from an examination of the sequence to predict that specific portions of a predicted protein will have particular functions, such as signal sequences for targeting proteins to the endoplasmic reticulum or the plasma membrane, transmembrane sequences, glycosylation sites and nucleotide binding sites. Short sequence motifs can be identified which serve as signals in gene expression. Methionine codons (AUG) used to initiate translation are found at the beginning of ORFs, embedded in a consensus sequence GCCGCC/GCCAUGG. Sites of mRNA cleavage and polyadenylation are usually signaled by AAUAAA followed by certain other signals. The start sites for transcription by RNA polymerase II are usually about 30 bp downstream from TATA boxes.

Uses of Genetic Engineering of Animal Viruses

Practical applications of genetic engineering of viruses include the development of nucleic acid probes for diagnosis and novel methods for the production of vaccines, such as the use of vaccinia virus as a vector. Combined with the availability of simple and fast methods of sequencing nucleic acids, genetic engineering has also led to studies of animal virus genomes that could not be contemplated before it became possible to produce large quantities of selected fragments of viral nucleic acid by the use of the polymerase chain reaction. Among the achievements so far are:

1. Complete sequencing of the genome of DNA viruses of several families, including the 230 kbp genome of cytomegalovirus (a herpesvirus) and the 192 kbp genome of vaccinia virus.
2. Complete sequencing of cDNA corresponding to the entire genome of several RNA viruses.
3. Recognition of the number and sequence of viral or proviral DNAs that are integrated into the DNA of transformed cells.
4. Development of diagnostic probes for use in *in vitro* assays, including *in situ* hybridization.
5. The polymerase chain reaction can be used to detect low copy number of a viral genome.
6. Marker rescue by transfection with gene fragments, as a method of genetic mapping.
7. Production of proteins coded by specific viral genes, using bacterial, yeast, baculovirus and animal cell expression systems or by cell-free translation.
8. Synthesis of peptides based on DNA sequence data.

Transgenic Mice

Transgenic mice provide a new tool for investigating many problems in virology, immunology and developmental biology. They are produced by injecting selected fragments of DNA into the nuclei of fertilized eggs washed out of the mouse oviduct. After replacement, some ova develop normally to form the base of a colony of transgenic mice. The technique provides insights into the potential role in viral pathogenesis of individual viral gene products in the context of the intact animal. For example, transgenic mice have been produced in which every cell contained greater than genome length hepatitis B DNA sequences. All mice had HBs antigen in plasma, but the viral sequences were selectively expressed only in cells of the liver, kidney and pancreas. Likewise, transgenic mice

containing the DNA for the early region of bovine papilloma virus developed skin tumors at 8–9 months of age. Extrachromosomal viral DNA was detected in tumor cells and integrated viral DNA in normal tissues.

GIARDIAVIRUSES (*TOTIVIRIDAE*)

Alice L Wang and **Ching C Wang**, University of California, San Francisco, California, USA

History

In 1986, a 6.3 kb linear double-stranded (ds) RNA molecule was observed in nucleic acid extracts of *Giardia lamblia* Portland I trophozoites. *G. lamblia* is an anaerobic parasitic flagellate that inhabits the upper gastrointestinal tracts of humans as well as many other mammals. When infecting humans, the parasitic protozoan causes giardiasis, an acute diarrhea that often progresses to chronic, carrier-stage for adults and severe malnutrition for children. Further examination of this 6.3 kb dsRNA isolated from the extract of *G. lamblia* revealed it to be the genome of a small isometric virus, hence named giardiavirus (GLV), that specifically infects this protozoan.

It is interesting to note that although GLV was first detected in an isolate of *G. lamblia* Portland I (P1) obtained from Dr D. G. Lindmark of Cleveland State University, the same P1 isolate from the American Type Culture Center is virus-free. It therefore remains a mystery as to how the Cleveland P1 became exposed to the virus. All the information included here has been derived from studies of the virus originally isolated from this Cleveland P1 strain.

Taxonomy and Classification

GLV belongs to the family *Totiviridae*, genus *Giardiavirus*, of RNA viruses. This family is characterized by the nonsegmented dsRNA genome and simple virion structure. Members of *Totiviridae* include the yeast dsRNA virus (ScV-L). Many of the viruses recently discovered from protozoa, such as the *Trichomonas vaginalis* virus (TVV), *Leishmania braziliensis* virus (LBV), and *Eimeria stiedae* virus (ESV), also belong to this family.

Host Range and Geographic Distribution

Purified GLV readily infects many virus-free isolates of *G. lamblia* trophozoites, but not any other parasitic protozoa tested, including *Tritrichomonas foetus, Trichomonas vaginalis, Trypanosoma brucei brucei, Entamoeba histolytica* and *Eimeria stiedae.* The virus has also been shown not to infect two transformed human intestinal cell lines. It is therefore believed that giardiavirus has a rather narrow host range. It probably infects only *G. lamblia* in nature.

GIARDIAVIRUSES (*TOTIVIRIDAE*)

Alice L Wang and **Ching C Wang**, University of California, San Francisco, California, USA

History

In 1986, a 6.3 kb linear double-stranded (ds) RNA molecule was observed in nucleic acid extracts of *Giardia lamblia* Portland I trophozoites. *G. lamblia* is an anaerobic parasitic flagellate that inhabits the upper gastrointestinal tracts of humans as well as many other mammals. When infecting humans, the parasitic protozoan causes giardiasis, an acute diarrhea that often progresses to chronic, carrier-stage for adults and severe malnutrition for children. Further examination of this 6.3 kb dsRNA isolated from the extract of *G. lamblia* revealed it to be the genome of a small isometric virus, hence named giardiavirus (GLV), that specifically infects this protozoan.

It is interesting to note that although GLV was first detected in an isolate of *G. lamblia* Portland I (P1) obtained from Dr D. G. Lindmark of Cleveland State University, the same P1 isolate from the American Type Culture Center is virus-free. It therefore remains a mystery as to how the Cleveland P1 became exposed to the virus. All the information included here has been derived from studies of the virus originally isolated from this Cleveland P1 strain.

Taxonomy and Classification

GLV belongs to the family *Totiviridae*, genus *Giardiavirus*, of RNA viruses. This family is characterized by the nonsegmented dsRNA genome and simple virion structure. Members of *Totiviridae* include the yeast dsRNA virus (ScV-L). Many of the viruses recently discovered from protozoa, such as the *Trichomonas vaginalis* virus (TVV), *Leishmania braziliensis* virus (LBV), and *Eimeria stiedae* virus (ESV), also belong to this family.

Host Range and Geographic Distribution

Purified GLV readily infects many virus-free isolates of *G. lamblia* trophozoites, but not any other parasitic protozoa tested, including *Tritrichomonas foetus, Trichomonas vaginalis, Trypanosoma brucei brucei, Entamoeba histolytica* and *Eimeria stiedae.* The virus has also been shown not to infect two transformed human intestinal cell lines. It is therefore believed that giardiavirus has a rather narrow host range. It probably infects only *G. lamblia* in nature.

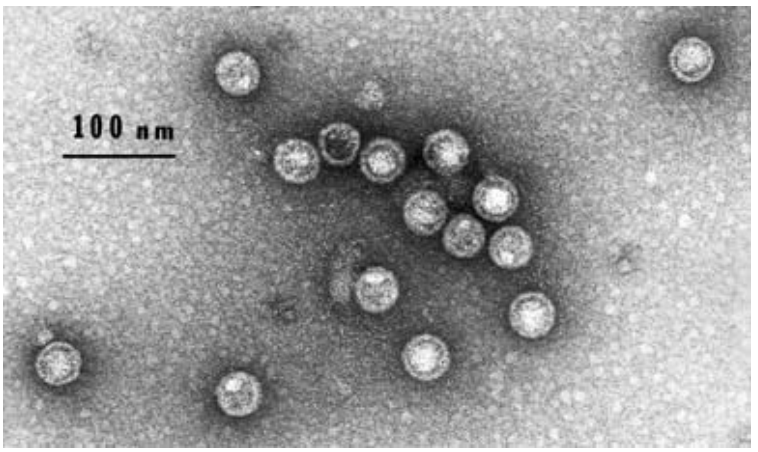

Figure 1 Giardiavirus.

On the other hand, the cellular host for this virus, *G. lamblia*, parasitizes many mammals other than humans. Viruses that are identical in size, shape and size of genomic dsRNA and share dsRNA sequence homology with one another have been detected from many *G. lamblia* strains and isolates obtained from humans, guinea pigs, cats, beavers, llamas and sheep. The human isolates were collected from Belgium, Poland, England, Israel, Ecuador, Puerto Rico and various states in the USA. Since *G. lamblia* is found in almost all parts of the world, affecting developing as well as developed countries, it is expected that GLV follows its host and is distributed worldwide.

Physical and Biochemical Characteristics

Under the electron microscope, GLV appears as an icosahedron of 36 nm diameter, consisting of an electron-dense core encapsidated in a shell 5–6 nm thick (**Fig. 1**). In addition to the 6.3 kb linear dsRNA genome, the virion contains a major polypeptide of 100 kDa (p100) which is most likely the viral capsid. Purified virions are good antigens in mice. Polyclonal antibodies raised against whole virions react with p100 in Western blots and can effectively block viral infection in the *in vitro* culture of *G. lamblia* trophozoites. The same antiserum also reacts positively with a minor component of the virion, a polypeptide of 190 kDa, which is believed to be the viral RNA-dependent RNA polymerase (RDRP). Indeed, GLV-encoded RDRP activity has been detected in the infected cell extract as well as the purified GLV fractions.

Antisera raised against synthetic dsRNA crossreact only with the viral dsRNA and are not protective against viral infection of *G. lamblia* trophozoites *in vitro*. Giardiavirus does not contain any lipids nor is the p100 polypeptide glycosylated.

The entire nucleotide sequence of the linear GLV dsRNA genome has been determined. It consists of 6277 bp and is flush at either end. As the dsRNA can be readily radiolabeled by [^{32}P]pCp and RNA ligase, this molecule must have a free 3′-OH group at one or both of its 3′ termini. The exact structure at the 5′ termini of the dsRNA has not yet been elucidated. It is known that the dsRNA molecule cannot be phosphorylated by T4 polynucleotide kinase, and that the denatured dsRNA molecule can be circularized with T4 RNA ligase. Therefore, the 5′ termini of the GLV genomic dsRNA are probably phosphorylated. Additionally, no covalently linked protein is found at these termini such as in the case of poliovirus.

Organization and Molecular Biology of the GLV dsRNA Genome

The 6277 nucleotide (nt) GLV dsRNA genome contains only two large open reading frames (ORFs), both on the same strand of RNA (**Fig. 2**). The first ORF (nts 368–3015) encodes the precursor polypeptide for the GLV capsid protein. Thirty-two amino acid residues from the N-terminus of this precursor protein are apparently removed by a cellular cysteine protease before the processed capsid protein is assembled into the virion.

The second ORF (nts 2806–5976) is −1 relative to ORF 1, and the two ORFs overlap by 220 nucleotides. Amino acid sequence motifs conserved for all RDRPs have all been found in ORF 2. It is now known that the 190 kDa GLV RNA polymerase is synthesized as a fusion protein of ORFs 1 and 2 at a level that is 2–5% of p100. Apparently, ribosomes carrying the growing nascent polypeptide chain are stalled when they encounter the pseudoknot structure residing within the 220 nt overlap of these two ORFs. At a 2–5% frequency, the ribosomes slip back one reading frame and proceed to translate ORF 2 as the C-terminus of a

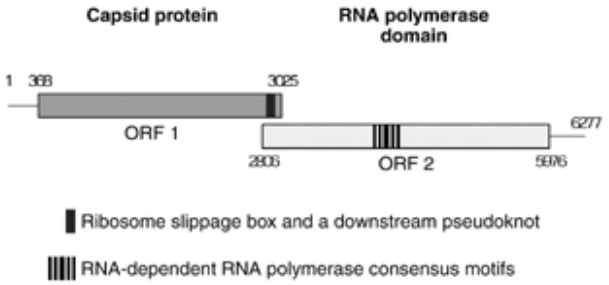

Figure 2 Organization of the giardiavirus dsRNA genome.

fusion protein. The ability of this GLV overlap fragment to induce −1 ribosomal frameshifting has been demonstrated in a reporter system in yeast.

Flanking the two ORFs, there are 367 and 301 nt untranslated regions respectively on the 5′ and 3′ sides. These two regions contain sequence elements that are critical for initiation of transcription and replication of GLV RNA. For example, deletion of a single nucleotide from the 5′ terminus of the (+) strand GLV RNA totally abolishes transcription of GLV mRNA. Similarly, deletion or alteration of sequences in these two regions drastically reduces the level of progeny viral RNA.

In recent years, GLV has been successfully used as a vector for the introduction of foreign genes into *G. lamblia*. When a portion of the GLV genome is replaced with the firefly luciferase gene in a cDNA construct downstream from a T7 promoter, chimeric RNA can be synthesized *in vitro* using T7 polymerase. *Giardia* cells that are infected with wild-type GLV and electroporated with the chimeric RNA show luciferase activity of a millionfold above background. The chimeric RNA is replicated as dsRNA and packaged into recombinant virions that are shed into the culture supernatant. These recombinant viruses, together with wild-type GLV, can in turn infect naive *Giardia* trophozoites to produce luciferase activity. The list of foreign genes tested in this system include genes encoding neomycin phosphotransferase, hygromycin phosphotransferase and green fluorescence protein. All can be delivered and expressed at high levels. Inclusion of a fragment, nts 368–631 in the coding region of p100, as the N-terminus of a fusion protein with the foreign gene product has been shown to enhance translation level by 5000-fold. This region therefore may contain elements that can promote interaction between GLV mRNA and ribosomes of *G. lamblia*.

Infection and Replication

GLV infects susceptible isolates of *G. lamblia* very efficiently. It has been estimated that demonstrable infection can be achieved at a multiplicity of infection as low as ten GLV particles per cell. The exact mode of viral entry into the cell has not been elucidated. However, a number of virus-free *G. lamblia* strains have been found resistant to GLV infection. When trophozoites of these strains are electoporated with the single-stranded (ss) GLV RNA (see below), they become infected by GLV and can support and complete the cycle of replication, producing progeny virions that are fully infective to sensitive strains. It is therefore probable that certain cellular component(s) such as viral receptors are involved in the initial interaction between GLV and susceptible strains.

Using purified GLV to infect virus-free *G. lamblia* WB strain, it was shown by *in situ* hybridization that dsRNA replication was first detected in the cytoplasm. Towards the late stage of infection, viral dsRNA was found to spread into the twin nuclei of the infected flagellate. Transmission electron microscopic examination of thin sections of infected cells at stationary phase also reveals paracrystals of virus-like particles in the nuclei (**Fig. 3**). It has been estimated that an infected cell may harbor as many as 10^5 GLV particles without lysis. Meanwhile, mature and infectious GLV particles begin to appear in the supernatant of *Giardia* culture medium 42 h after infection. It is not known whether a specific cellular process is involved in the release of giardiavirus into the culture supernatant, although cell lysis has not been observed as a consequence of viral infection.

The growth rate of newly infected cells decreases with increasing multiplicity of infection. As the ratio

Table 1 Physical properties of some small dsRNA viruses

Virus	Shape	Diameter (nm)	Density (g ml^{-1})	dsRNA (μm)	dsRNA (kb)	Capsid protein (kDa)
GLV	Isometric	33	1.368	1.50	6.277	100
TVV	Isometric	33	1.468	1.50	4.3–4.8	85

of the infecting virus to cell increases, the percentage of the nonadhering (nondividing) trophozoites also increases. However, in established infected cell lines or at moderate multiplicity of infection (<1000), the infected cell assumes normal appearance and maintains the same growth rate as its uninfected counterpart. Furthermore, GLV infection persists indefinitely throughout repeated subculturings.

In addition to the 6.3 kb genomic dsRNA, an ssRNA (SS) of identical length that is homologous to only one of the two strands of GLV dsRNA is also found in the GLV-infected cellular extract. Studies of the infection time course showed that, in contrast to GLV dsRNA which increases steadily from 23 h to 141 h after infection, SS becomes detectable at about the same time, peaks at 42–50 h after infection, then gradually declines. Electroporation of gel-purified SS into the uninfected WB cells resulted in the recovery of dsRNA from the cell extract and infectious GLV particles in culture supernatant, demonstrating that SS is the viral messenger RNA as well as the full-length replicative form of the viral genome. Recent nucleotide sequence analysis of GLV cDNA clones also verifies that it is the SS strand that encodes the large open reading frames. There is no subgenomic viral RNA detected inside the infected cell.

The RNA products synthesized *in vitro* by the virion-associated RDRP are homologous to SS and complementary to the negative strand. Transcription of viral message therefore must proceed conservatively by utilizing the dsRNA as its template.

Evolution

The extent to which a person is affected by giardiasis varies widely. The outcome of the severity of parasitic infection depends on many variables derived not only from the parasite but also from the human host. Attempts at correlating the presence or absence of GLV with the severity of giardiasis have been inconclusive, and we still do not know the role GLV might play in the delicate balance of the host–parasite interaction, if any.

Some of the characteristics of GLV are listed with those of other dsRNA viruses of *Totiviridae* in **Table 1**. When compared with ScV-L, the best known virus of this group, GLV and ScV are similar in many ways: (1) single molecules of genomic dsRNAs of similar sizes; (2) single major capsid polypeptides of similar sizes; (3) virion-associated RDRP with similar amino acid sequence motifs deduced from the genomic sequence, (4) ability to synthesize viral messages from intact virions *in vitro;* and (5) use of ribosomal frameshifting for the synthesis of viral polymerase. However, the two viruses do not crossinfect and the two dsRNAs do not crosshybridize in Northern blots. GLV dsRNA has also been shown not to cross-hybridize with dsRNAs of TVV or LRV. Comparison of the nucleotide sequence from GLV cDNAs with that of ScV-L, LRV or TVV indicates that, despite the similar organization of the viral genomes, GLV share very little overall sequence identity with any of these viruses whose genomic sequences have been completely determined. GLV is therefore not closely related to any of these viruses evolutionarily.

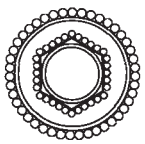
GIBBON APE LEUKEMIA VIRUS (*RETROVIRIDAE*)



Marvin S Reitz Jr, Institute of Human Virology, University of Maryland, Baltimore, USA

Introduction

Gibbon ape leukemia virus is the designation for a related group of retroviruses which have been seroepidemiologically linked to leukemias in captive gibbon apes (species *Hylobates lar*). The occurrence of leukemias and lymphomas in gibbons was first described in the late 1960s. Outbreaks of multiple cases were reported within a gibbon ape colony used for malaria research in Thailand by the Southeast Asia Treaty Organization (SEATO), in a colony at the animal care facility of the San Francisco Medical College, University of California, and a colony maintained for psychological testing on Hall's Island in the Caribbean.

Taxonomy and Classification

The gibbon ape leukemia viruses are typical mammalian type C retroviruses (genus) and are transmitted horizontally (either congenitally or from one individual to another) rather than vertically (via germ lines). Horizontal transmission is a property shared by all other leukemia viruses, such as those of cats, mice, chickens, cattle, and, more recently, humans.

The gibbon ape leukemia viruses (GaLV) and the related simian sarcoma virus and its helper virus, simian sarcoma-associated virus, form a closely related group and as a group are most like the murine leukemia viruses. The gibbon ape viral receptor on target cells is the same receptor used by feline leukemia virus subgroup B.

Clinical Features of Infection

The disease at the San Francisco facility was characterized as lymphoblastic lymphosarcoma, with lymph node, liver, spleen and bone marrow involvement. A more current description would probably be T-cell leukemia/lymphoma. A lymphoid cell line called UCD-144 (alternatively MLA-144) was established from one of the leukemic animals, and the first GaLV isolate was obtained from this cell line. UCD-144 cells have the phenotype of relatively mature T cells, including the production of IL-2. Indeed, IL-2 was first cloned from this cell line. The strain of GaLV isolated from this cell line is designated as the San Francisco strain of GaLV (GaLV-SF).

A second GaLV isolate was obtained from tissues of gibbons from the SEATO Medical Project colony in Bangkok, Thailand, with a disease resembling human chronic myelogenous leukemia. Other gibbons in the colony were found to be seropositive for the virus. Inoculation of this virus, which has been designated GaLV-SEATO, into young gibbons induces a myeloproliferative disease within a year.

The third isolate of GaLV was from the frozen brain tissues of three nonleukemic gibbons. Two of these had been inoculated with brain extracts of human patients with the progressive neurodegenerative disease kuru. These isolates, designated GaLV-Br, have not been associated with hematopoietic neoplasms.

A fourth strain of GaLV was isolated from a gibbon ape with T-cell leukemia who was a member of a gibbon colony kept in isolation on Hall's Island, near Bermuda, for psychological studies. A lymphoid cell line was established from this animal, and retrovirus was readily detected. The cell line had properties characteristic of immature T cells, including the expression of terminal transferase. The distribution of virus corresponded closely to the degree of infiltration of leukemic cells, which was extensive and evident in blood, heart, liver, spleen, lymph nodes and salivary glands. The tongue was coated with viral particles, as determined by electron microscopy. This virus was designated GaLV-H.

Serologic Relationships and Variability

All four subtypes of GaLV are closely related to each other by protein serology and by nucleic acid sequence homology, but are readily distinguishable by both criteria. Differences among the envelope genes are probably greater than in other regions of the viral genome.

As mentioned earlier, the GaLVs as a group appear to be most closely related to the murine leukemia viruses, but the relationship appears to be closest to an endogenous virus of the Asian mouse *Mus caroli*. This suggests that GaLV could have originated by a trans-species transmission, but it is not clear when this might have happened or what mouse might be the source. It is not yet known if GaLV is found in feral gibbons.

Table 1 Pathogenicity

Virus	*Isolated from*	*Pathogenic activity*
Herpesviruses		
H. saimirii	Normal squirrel monkey	Rapidly lymphomagenic in heterologous hosts
H. ateles	Normal spider monkey	Rapidly lymphomagenic in heterologous hosts
Retroviruses		
GaLV-SF	Lymphoid leukemia of gibbon ape	Highly associated with and probably causes lymphoid leukemia in host of origin
GaLV-H	Lymphoid leukemia of gibbon ape	Highly associated with and probably causes lymphoid leukemia in host of origin
GaLV-SEATO	Myeloid leukemia of gibbon ape	Causes myeloid leukemia in host of origin
SSV	Fibrosarcoma of woolly monkey	Causes fibrosarcoma in host of origin and other species
MPMV	Breast adenocarcinoma of rhesus monkey	Causes immunosuppression and thymic atrophy in host of origin
HTLV-I	Adult T-cell leukemias and lymphomas of man	Highly associated with and probably causes adult T-cell leukemia and lymphoma in man
HIV-1	T-cells from human AIDS patients	Causes AIDS in man

The simian sarcoma virus (SSV) and its associated helper virus, simian sarcoma associated virus (SSAV) were isolated from a spontaneous fibrosarcoma in a pet woolly monkey. These viruses were, in retrospect, actually the first isolate of the GaLV group. SSAV is genetically as similar to the other members of the GaLV group as the latter are to each other. The woolly monkey from which SSV was isolated lived in the same household as a pet gibbon ape, and it has become clear, from the otherwise restricted distribution of GaLV to gibbons and their absence in New World monkeys, that the woolly monkey was infected by a strain of GaLV from the gibbon.

Pathogenicity (Table 1)

SSV is able to transform fibroblasts *in vitro*, and it causes fibrosarcomas when inoculated into marmosets. SSV is a defective virus whose genome was formed by a deletion of all of the reverse transcriptase gene and parts of the genes for the envelope and core structural proteins and a recombinational insertion of a cell-derived gene, called *sis*. It is the last gene which gives SSV the ability to transform fibroblasts *in vitro*. SSAV and the GaLVs are not transformation competent for cultured fibroblasts, and SSV, due to its lack of any functional viral genes, is not replication competent. Consequently its replication requires the presence of its helper virus, namely SSAV. The *sis* gene was subsequently shown to be identical to β-platelet-derived growth factor, a cellular gene involved in the process of wound healing and which promotes the growth of fibroblasts *in vitro*. The normal human analogue of *sis* has been shown to directly transform fibroblasts when transfected *in vitro* and can confer tumorigenic potential *in vivo* when its expression is constitutively high. The *sis* gene appears to have been derived from the woolly monkey, indicating that the SSV genome was formed by recombination subsequent to transmission from the gibbon.

The reason for the disease specificity of these viruses is unclear. Presumably differences in the ability to replicate or be expressed in different cell types helps to determine the type of leukemia they cause, but the situation is not simple. All strains of GaLV apparently use the same cell surface receptor, a transmembrane sodium-dependent phosphate transporter, yet have somewhat different host cell specificities *in vitro*, suggesting that envelope–receptor binding is not the basis for disease specificity. The ability to grow in different cell types, however, is also influenced by events following binding of the viral envelope proteins to their cell surface receptor, including entry, uncoating of the viral core, reverse transcription of viral DNA, transport to the nucleus, integration into the host cell genome, and transcription of the viral genome. Presumably the ability of the different strains of GaLV to induce different kinds of leukemia is determined at one or more of these levels.

The basic mechanisms by which these viruses cause leukemia in their hosts is not known, although it presumably shares features with the other leukemia viruses. The infected host shows a persistent immune response to the virus, but the response is not always protective. Very little work on infected gibbons has been performed beyond the mid 1970s. This is primarily due to the appearance of gibbons on the endangered species list and to the unfortunate dissolu-

tion of the gibbon colonies in which these viruses were described, through lack of financial support.

Recent work involving GaLV has primarily involved the adaptation of viral genes, especially the envelope gene, for the construction of improved retroviral vectors for gene delivery and gene therapy. The PG13 gene delivery vector system uses a standard murine retroviral core and packagable genome, along with the GaLV-SEATO envelope, and has been reported to give significantly improved efficiencies with some human hematopoietic cells. Further developments of GaLV-related retroviral vectors include substitution of a GaLV core and/or packagable genome for the murine analogues and use of the envelope proteins from strains of GaLV other than SEATO. These may well provide superior retroviral gene delivery vehicles to those currently available.

H

HANTAVIRUSES (*BUNYAVIRIDAE*)

Connie S Schmaljohn, Virology Division, United States Army Medical Research Institute of Infectious Diseases, Ft Detrick, Frederick, Maryland, USA

History and Classification

Hantaviruses are rodent-borne viruses which may be transmitted to humans in aerosolized urine, feces or saliva, and occasionally by bite. Certain hantaviruses cause hemorrhagic fever with renal syndrome (HFRS) or hantavirus pulmonary syndrome (HPS). Other hantaviruses are not known to be human pathogens.

The term HFRS was adopted in 1983 by the World Health Organization to collectively describe clinically similar diseases such as Korean hemorrhagic fever, epidemic hemorrhagic fever, and nephropathia epidemica. Although HFRS was undoubtedly a disease problem historically, it first became a widely recognized health threat in 1951 when an intense epidemic occurred in military personnel stationed in Korea. A mortality rate of 10–15% was reported among the more than 3000 United Nations soldiers hospitalized with HFRS during the Korean war. Hantaan virus (HTNV) was first associated with HFRS in 1978 when Korean HFRS patient sera were found to react with antigens in the lungs of striped field mice (*Apodemus agrarius*). After the isolation of HTNV in cell culture in 1981 it was possible to characterize the virus for the first time and to determine that molecular properties were consistent with those of other viruses in the family *Bunyaviridae*. Based on those findings, the *Hantavirus* genus was added to the family in 1987. In addition to HTNV, at least three other hantaviruses, Seoul virus (SEOV), Puumala virus (PUUV) and Dobrava-Belgrade virus (DOBV), cause HFRS.

HPS was first described in 1993 when a cluster of cases of acute adult respiratory distress, with mortality rates of approximately 50%, were reported in the southwestern part of the United States. A previously unknown hantavirus, Sin Nombre virus (SNV), was detected in deer mice (*Peromyscus maniculatus*), and was subsequently shown to be responsible for most of the approximately 200 confirmed cases of HPS in North America. At least three other hantaviruses, New York virus (NYV), Bayou virus (BAYV), and Black Creek Canal virus (BCCV), also cause HPS in North America.

The discovery of HPS in North America prompted prospective and retrospective studies in South America to determine if hantaviruses were responsible for unexplained cases of respiratory distress. In Argentina, more than 140 cases of HPS were confirmed. Investigations involving a cluster of cases in a family from southern Argentina identified Andes virus (ANDV) in long-tailed pygmy rice rats (*Oligoryzomys longicaudatus*). ANDV is the only known hantavirus to be transmitted person-to-person. In 1995–1996, an outbreak of 17 cases of HPS in Paraguay led to the discovery of another HPS-associated virus, Laguna negra virus (LNV), carried by the vesper mouse (*Calomys laucha*).

Viruses in the Genus *Hantavirus*

Since the discovery of HPS, a number of novel hantaviruses have been detected in rodents throughout the western hemisphere. Many of these were not isolated in cell culture, but instead were identified by reverse transcription and polymerase chain reaction (RT-PCR) with hantavirus crossreactive primers. Therefore, although distinct species of hantaviruses are defined historically by fourfold or greater differences in serological assays, particularly in neutralization assays, genetic relationships are used to define some of the newly discovered viruses. In general, viruses that are antigenically distinct also display at least an 8% difference in predicted amino acid sequence of one or more of their proteins. Additionally, distinct viruses are usually associated with different rodent hosts. A single hantavirus species has been identified in an insectivore; however, it is possible that this virus, Thottapalayam virus, may

also have a rodent reservoir. A current list of hantavirus species is shown in **Table 1.**

Virion Properties

Morphological features of hantaviruses provided the first clues relating them to viruses in the *Bunyaviridae* family. When examined by electron microscopy, hantaviruses are roughly spherical with a diameter of 80–120 nm (**Fig. 1**). Elongated, oval-shaped particles are sometimes evident with reported lengths of up to 210 nm. Negatively stained particles exhibit a grid-like pattern of morphological subunits on their surfaces. Sectioned virions display a distinct, bilayer envelope with a fringe of short projections. Immunoelectron microscopy with monoclonal antibodies identified the projections as the viral G1 and G2 glycoproteins. The envelope surrounds a granulofilamentous interior, which consists of ribonucleoprotein structures. RNA-dependent RNA polymerase activity is associated with virions (**Fig. 1**).

Physical Properties

Like other enveloped viruses, hantaviruses are sensitive to detergents and organic solvents. Other physical properties of virions include sedimentation densities in sucrose of 1.16–1.17 g ml^{-1} and in cesium chloride of 1.20–1.21 g ml^{-1}. Disruption of virion particles with nonionic detergent releases the nucleocapsids, which sediment at densities of approximately 1.18 g ml^{-1} in sucrose and 1.25 g ml^{-1} in cesium chloride. HTNV infectivity is generally stable for up to 12 h at 0–4°C. Nonphysiological pH extremes (<7.0 or

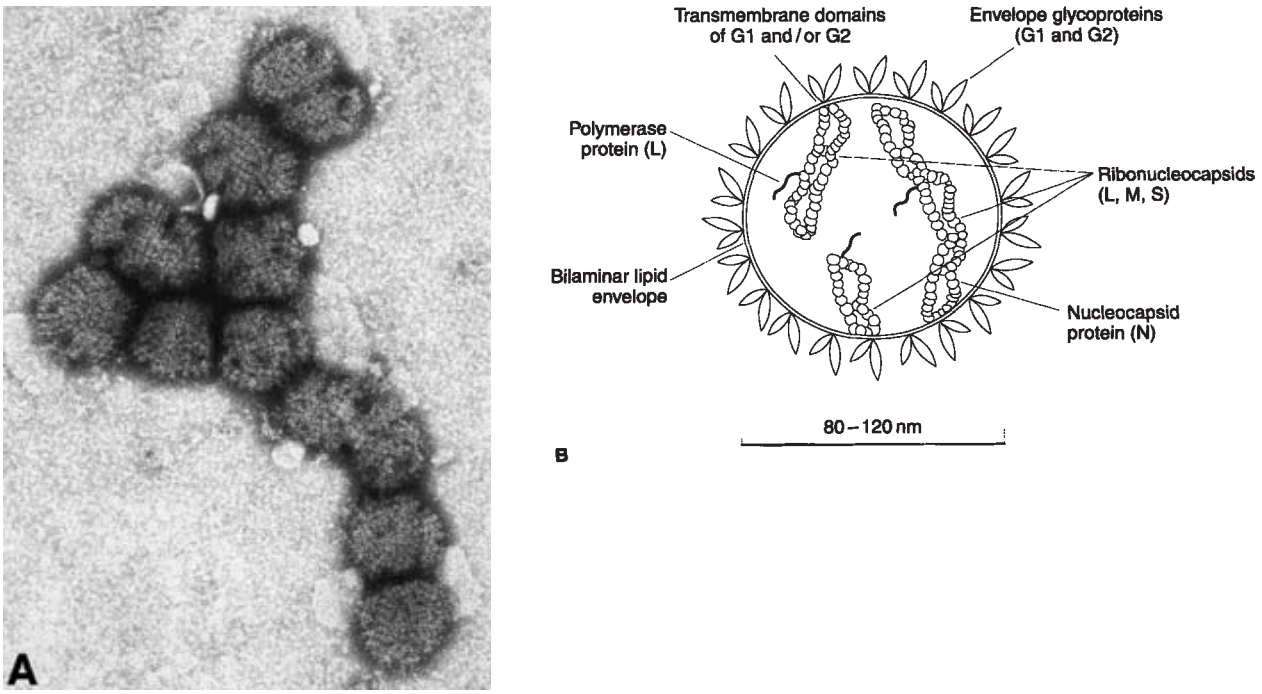

Figure 1 (**A**) Electron micrograph of negatively stained Hantaan virions. Surface morphology shows a grid-like structure. (**B**) Virions contain three noncovalently closed circular ribonucleocapsids designated L, M and S. The ribonucleocapsids are surrounded by a bilaminar lipid envelope of host origin into which are embedded two viral glycoproteins, G1 and G2. Transmembrane regions of G1 and/or G2 are believed to interact with the nucleocapsid protein, N, to trigger budding at Golgi membranes. The viral polymerase protein L is associated with virions and is needed to copy the negative sense vRNA to mRNA.

>8.0) and high salt conditions, such as 32% potassium tartrate, inactivate HTNV infectivity completely after 12 h at 4°C. After drying HTNV may remain viable for 1–3 days. The presence of 10% serum considerably extended the pH and temperature ranges as well as the length of time after drying during which infectious virus could be recovered.

Genome Properties

Hantaviruses have tripartite negative sense genomes with a total size of approximately 13 kb. The large (L), medium (M) and small (S) segments, respectively, encode the viral polymerase, envelope glycoproteins and nucleocapsid protein (**Fig. 2**). Each gene segment has conserved complementary nucleotide sequences which can base pair to form panhandle structures (**Fig. 3**).

Properties of Viral Proteins

A single nucleocapsid protein (N) of approximately 48 kDa is found associated with each of the three gene segments of hantaviruses. The nucleocapsid protein is always associated with virion and complementary sense RNAs but not with messenger RNAs.

The G1 and G2 proteins are integral membrane proteins. Like those of other viruses in the family, hantavirus envelope proteins have asparagine-linked

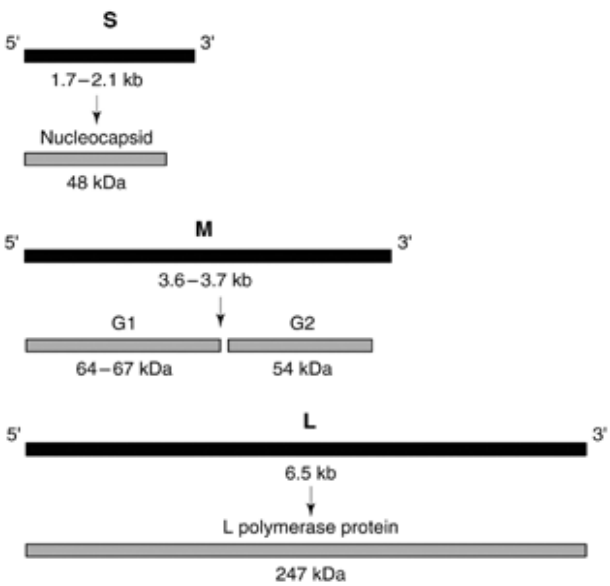

Figure 2 Coding strategy and gene organization of the L, M and S segment sequences of hantaviruses. Approximate nucleotide and predicted amino acid sizes are indicated.

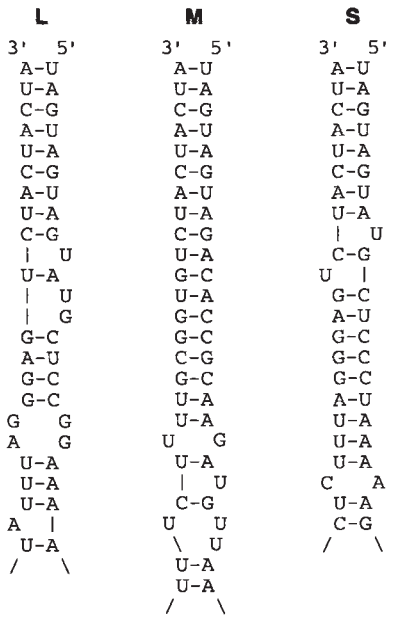

Figure 3 Predicted panhandle structures formed by base-pairing of complementary terminal nucleotides of the L, M and S segments of HTNV.

sugars, are rich in cysteine residues, and induce neutralizing antibody responses in animals. Amino acid sequences typical of signal sequences precede both G1 and G2 and stretches of hydrophobic amino acids are found at their carboxy termini.

The L protein serves several functions necessary for viral replication. It acts as an endonuclease to cleave host mRNAs approximately 10–18 nucleotides beyond the 5′ cap structure. The resultant capped oligonucleotides are used to prime mRNA transcription (**Fig. 4**). The L protein also serves as a transcriptase for generating exact copies of the genome (cRNA), which in turn are used as templates for synthesis of genomic RNA (vRNA). The L protein may also act as a helicase for unwinding the encapsidated RNAs during transcription.

Replication: Strategy of Replication of Nucleic Acid

Transcription

A prime and realign model for hantavirus transcription of vRNA and cRNA was proposed to explain experimental data indicating that the 5′ residue of

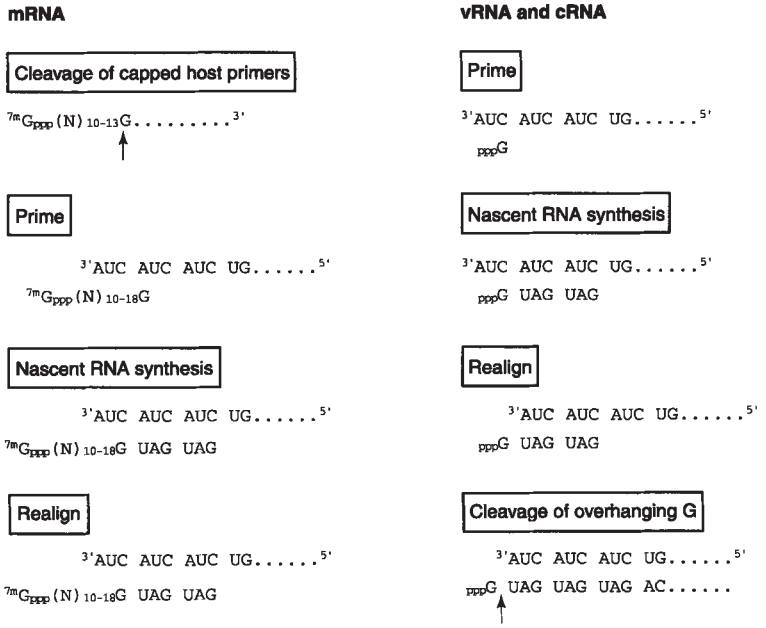

Figure 4 Transcription and replication model for hantaviruses. For synthesis of mRNA, the L protein cleaves capped oligonucleotides approximately 10–18 nucleotides long from host-cell messenger RNAs (preferably after G residues) and uses them to prime transcription. According to the proposed prime and realign model, the terminal G residue aligns at position 3 (C). After several nucleotides are added, the RNA slips backward and realigns with the G residue adjacent to the templated hantavirus nucleotides. Transcription is terminated at undefined signals shortly after the end of the ORF. For cRNA and vRNA synthesis, the L protein uses nonprimed synthesis and must ignore transcription termination signals to produce exact copies of the vRNA (or cRNA) template. According to the prime and realign model, the first nucleotide added is a G which aligns at position 3 (C). After several nucleotides are added, the nascent RNA slips backward and realigns. The overhanging G residue is then cleaved, leaving a terminal U monophosphate residue at the 5′ end of the newly synthesized RNA.

HTNV vRNA is a monophosphorylated U residue. According to the model, transcription is initiated when pppG aligns at the third nucleotide position (C). After synthesis of several nucleotides, the polymerase slips, allowing the nascent RNA to realign such that the initial priming G residue is overhanging (**Fig. 4**). The L protein then serves as an endonuclease to remove the G, leaving a monophosphorylated U residue at the nascent 5′ end.

Transcription of mRNAs may also follow a prime and realign strategy, but instead of a triphosphate residue, capped oligonucleotides cleaved from host mRNAs are used for priming transcription. There appears to be a preferential, but not absolute preference for cleavage of the host oligonucleotides after G residues, as indicated by the preponderance of Gs adjacent to the templated hantavirus residues. As for vRNA and mRNA, this G residue could align at the third C, and after synthesis of a few oligonucleotides, the nascent RNA could realign by slipping backward two nucleotides. The frequent deletion of one or two of the triplet repeats in mRNA also supports this sort of slippage mechanism and suggests that sometimes the initial priming might start at the C residue of the third triplet in the conserved sequence rather than at the C of the second triplet.

Slippage by the viral polymerase is likely to be a general feature of polymerases in the family as well as within the *Hantavirus* genus. Polymerase slippage has been suggested to account for the large amount of noncoding and repeated sequences present at the 3′ ends of the S segments of certain hantaviruses such as SNV.

Distinct transcription termination signals are not clearly defined for hantaviruses, but mRNAs appear to terminate shortly after the open reading frames (ORFs) present in each gene segment as indicated from sequence analysis of mRNAs. The mRNAs are therefore extended at their 5′ ends by 10–18 nucleotides derived from host messages and are truncated at their 3′ ends by approximately the length of the noncoding information. It is not known what factors are involved in the ability of the L protein to recognize or ignore transcription termination signals when switching from mRNA to vRNA and cRNA synthesis, but it is suspected that it involves accumulation of N.

Translation

The L, G1 and G2, and N proteins are the only known translation products of the L, M and S genome segments, respectively. Hantaviral L and N proteins are translated on free ribosomes and G1 and G2 on membrane-bound ribosomes.

Post-translational processing

The G1 and G2 envelope glycoproteins of hantaviruses are expressed from a single mRNA and are probably cotranslationally cleaved, as evidenced by the absence of a precursor polypeptide of a size corresponding to that encoded by the complete M segment ORF. It is believed that cleavage is mediated by host cell protease (i.e. signalase). Typical signal sequences precede both G1 and G2 and probably dictate insertion of the nascent proteins into membranes.

Both G1 and G2 are glycosylated with asparagine-linked carbohydrates, predominantly of the high mannose, endo-H sensitive type. Other post-translational modifications, such as phosphorylation or myristoylation, have not been described.

Assembly and transport

In general, hantaviruses assemble by budding into Golgi cisternae, as do other viruses in the family *Bunyaviridae*. Complete virions are then transported to the cell surface within Golgi vesicles. However, at least two hantaviruses, BCCV and SNV, also bud from cell membranes.

The specific steps in hantaviral assembly are poorly understood. Nascent vRNA and cRNA molecules probably associate with N immediately on transcription. It is presumed that a specific interaction of N and viral nucleic acid is required for their encapsidation. If hantaviruses are analogous to viruses in the *Bunyavirus* genus, this interaction probably involves some sort of signal at the 5′ ends of vRNA and cRNA. The cap structure and/or the deletion of the 3′ terminal complementary sequences of mRNA most likely prevents its association with N.

For all hantaviruses studied to date, the G1 and G2 proteins are synthesized in the endoplasmic reticulum (ER) then transported to the Golgi without the need for other viral proteins or nucleic acid. For HTNV, G1 and G2 must dimerize in the endoplasmic reticulum to achieve correct conformation and efficient transport competency. When individually expressed, both G1 and G2 remain predominantly in the ER, although some G1 migrated to the Golgi. In contrast, the G1 and G2 proteins of SNV are able to exit the ER and transport to the Golgi when expressed independently, although G1 transport depended on the formation of homotrimers. Coexpression of G1 and G2 resulted in quicker transport to the Golgi.

After G1 and G2 are transported to the Golgi, their carbohydrates are modified. It is assumed that either or both proteins have a Golgi retention signal, but if so, it has not been defined. The interactions of G1 and G2 proteins with N during morphogenesis have not

yet been studied in detail. Hantaviruses have no matrix proteins to facilitate interation between the envelope proteins and ribonucleocapsids. It is suspected that there is a direct interaction between transmembrane regions of G1 or G2 and N which triggers budding.

Cytopathology

Hantaviruses persistently infect cultured cells as well as their natural rodent hosts. In both cell cultures and rodents hantaviruses cause no obvious cytopathology.

Geographic and Seasonal Distribution

HTNV causes severe HFRS throughout Korea, The People's Republic of China, and the eastern part of the former Soviet Union. Before the discovery of DOBV in Slovenia in 1992, severe HFRS occurring in Balkan countries was attributed to HTNV infections. Today, however, it is not clear if both HTNV and DOBV circulate in the Balkans or if DOBV is solely responsible for severe HFRS in this region.

SEOV infections occur worldwide. The global distribution of SEOV coincides with the distribution of its rodent host, the urban rat (*Rattus norvegicus*). Although not native to many parts of the world, these rats are now ubiquitous because of their transport on cargo ships over the past several hundred years.

A mild form of HFRS caused by PUUV occurs throughout Sweden, Finland, Norway, the western part of Russia and western Europe.

The seasonal distribution of hantaviruses coincides with rodent population densities and activities. For example, in Korea there are two seasonal peaks of HFRS caused by HTNV in late spring and fall when the populations of infected *Apodemus* field mice are highest. PUUV infections exhibit similar bimodal peaks coinciding with infected *Clethrionomys* densities. Year-to-year variation is also observed, reflecting rodent population periodicity. HFRS caused by SEOV transmission from infected house rats occurs throughout the year but also tends to be more frequent in the fall and winter seasons in temperate climates.

The occurrence of HPS has also been linked to factors that influence rodent density such as rainfall and availability of food. The rodent hosts of HPS-causing viruses are primarily associated with rural environments, but may invade homes in more urban areas either when food supplies are short or in cold weather. The initial recognition of HPS in the spring of 1993 involved a cluster of approximately 27 cases; however, the majority of cases in North America that have occurred since then have appeared sporadically throughout most of the United States and in three Canadian provinces, suggesting an infrequent yet endemic presence. To date, five countries of South America have reported HPS. Although cases have occurred throughout the year in an endemic fashion similar to that seen in North America, clusters of cases in South America generally appear in the spring and summer months (September–January).

Host Range and Virus Propagation

Rodents in the family Muridae are the natural hosts and reservoirs of hantaviruses (**Table 1**). Each hantavirus species is generally (but not always) associated with a single rodent host species. Thus, the natural distribution of a hantavirus is limited to the range of its rodent host. Infection of rodents is generally asymptomatic and persistent despite the presence of neutralizing antibodies. All known HPS-causing hantaviruses are associated with the Sigmodontinae subfamily of rodents. HFRS-causing hantaviruses are associated with the subfamilies Murinae or Arvicolinae.

Although members of the genus replicate in a variety of different vertebrate cell lines and viral antigen can be detected by fluorescent antibody and other techniques, cytopathology is not a consistent characteristic of these infections. Virus isolation in cell culture requires multiple passages, frequently without evidence of viral multiplication; however, once infected, cultures remain persistently infected, with virtually all cells in a culture exhibiting viral antigen. Vero E6 cells are used most frequently for laboratory propagation and assay of hantaviruses.

Genetics

Hantaviruses display classic negative-strand, viral gene-coding properties. That is, all of the recognized viral proteins are encoded in the virus-complementary sense RNA. Comparative sequence analysis suggests that nucleotide sequence conservation parallels antigenic differentiation of viruses defined by plaque-reduction neutralization tests.

Evolution

The high concordance between rodent and hantavirus phylogenies supports a coevolutionary relationship of each hantavirus and its reservoir, probably over thousands of years. Because each hantavirus usually circulates only within a defined rodent population, there are probably restricted possibilities for genome reassortment and genetic mixing. Natural reassortment among strains of SNV has been described, and is probably also common for other hantaviruses. A single example of reassortment between two closely

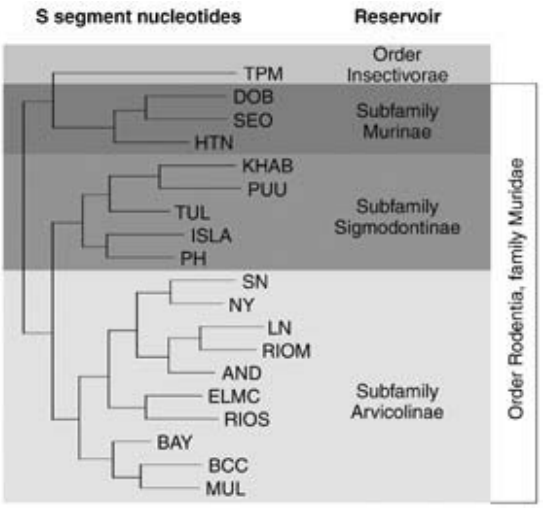

Figure 5 Genetic relationships of hantaviruses and association with natural reservoirs. The phylogenetic tree was constructed by pairwise comparison of S segment nucleotides encoding the nucleocapsid protein. Abbreviations for viruses are as in **Table 1.**

related species (BAYV and BCCV) is known. It is likely that reassortment between more distant species is not possible. Humans are generally dead-end hosts of hantaviruses, and thus probably play no role in their evolution.

Serologic Relationships and Variability

All hantaviruses are serologically related. Techniques such as the indirect fluorescent antibody test (IFAT) and enzyme-linked immunosorbent assays (ELISA) are commonly used to measure the degree of that relationship. Many viruses within the genus have been classified by reciprocal plaque-reduction neutralization assays with convalescent antisera from experimentally infected laboratory animals. However, some hantaviruses have not been isolated in cell culture and are characterized strictly by gene sequence comparisons. A total of 22 distinct hantaviruses have been described to date (**Table 1**), and others will undoubtedly be discovered as additional rodents are screened. Because the phylogenetic relationships among hantaviruses generally reflect their antigenic diversity, such genetic analyses are often used to study the variability among hantaviruses (**Fig. 5**).

Epidemiology

There are three basic epidemiological forms of hantaviral diseases: rural, urban and laboratory-acquired. Rural HFRS is usually associated with transmission of HTNV or DOBV from *Apodemus* or with transmission of PUUV from *Clethrionomys*. Urban HFRS is usually caused by *Rattus*-borne SEOV and is globally distributed with different epidemiological features that vary between countries and geographic regions. Laboratory-acquired HFRS is associated with the infection of both wild-caught and laboratory-bred rodents. Mortality rates are estimated as $< 1\%$ for PUUV infections, 1–5% for SEOV infections, and 5–15% for HTNV and DOBV infections.

HPS in both North and South America is primarily rural. Although case numbers are small, serosurveys suggest that there may be a higher seroprevalence rate among South American populations than those in North America. Whether this implies that there is less asymptomatic infection with HPS-causing hantaviruses in North America is currently unknown. The overall fatality rate for HPS in North America is approximately 45%. Lower case-fatality rates for more recent HPS infections probably reflect both better physician awareness and improved patient care. In South America, case fatality rates have been estimated at from 12% to more than 60% in various outbreaks. Although it is possible that these rates reflect infection by less and more virulent viruses, it is also possible that either or both estimates are incorrect. More consistent diagnosis and reporting of HPS should help to clarify the true fatality rate of HPS in South America.

Transmission and Tissue Tropism

Among rodents, hantaviruses are transmitted by aerosol and bite. HFRS and HPS are almost always traceable to contact with rodents or their excreta. HFRS is associated with activities such as farming, military exercises or other activities which disturb hantavirus-infected rodent nests or burrows. HPS is associated with activities such as inhabiting dwellings invaded by infected rodents, opening or cleaning seasonally vacant cabins or other buildings, or disturbing rodent-infested areas during recreational or occupational pursuits. There is no evidence for person-to-person transmission of HFRS. Similarly, HPS is not yet known to be transmitted among humans in North America. However, in South America there is good evidence for human-to-human transmission of ANDV in one Argentinian outbreak.

Hantaviruses can be isolated early in infection from human plasma, peripheral blood mononuclear cells, and urine sediment obtained from severely infected individuals. Samples taken later in disease are normally associated with high-titer neutralizing antibody which is presumed to reduce isolation efficiency.

Limited unsuccessful attempts to detect virus in clarified urine, saliva, feces, milk, and semen from infected humans have been made. Isolates have been obtained from autopsy material, although most deaths occur beyond the suspected viremic period and after the development of neutralizing antibody. Experimental infection of human endothelial cells and demonstration of endothelial cell infection in laboratory animal infections suggest one possible tropism for these viruses.

Pathogenicity

The pathogenesis of HFRS and HPS are incompletely understood, largely due to the absence of animal models of human disease. Rodent pathogenesis studies for HPS-causing hantaviruses have not been reported, most likely because Biosafety Level 4 containment is suggested for rodent work with these viruses. Pathogenesis studies for HFRS-causing viruses indicate that experimentally infected rodents display viral antigen in virtually all organ systems, but antigen is most apparent in lungs, nerve tissue and vascular endothelium. Infection of newborn rodents is often fatal but infection of adult animals results in a chronic or persistent infection without apparent histopathology, despite the presence of large amounts of viral antigen in numerous tissues including brain.

Clinical Features of Infection

The clinical features of HFRS are well defined, and although they may vary slightly for the different viruses in various geographic settings, most severe human infections can be divided into five characteristic phases. After a variable incubation period of 1 or 2 weeks with extremes from 4 to more than 40 days, a febrile phase is initiated with the sudden onset of high fever, chills, malaise and myalgia, which are often accompanied by significant headache, backache and orbital pain. Flushing is observed on the face, neck and anterior chest as well as conjunctival hemorrhage and petechiae on the soft palate, face, neck and axillary folds. Clinical features of this phase appear to correlate closely with disease prognosis. Albuminuria appears early with microscopic hematuria and tubular cells in the urine, which may progress to massive proteinuria in this phase. Within the first week of illness, the hypotensive phase develops abruptly and can last from hours to days. Massive edema and hemorrhage may lead to hypovolemia, hypotension and clinical shock. About one-third of all deaths are associated with irreversible shock in this phase. Capillary hemorrhages are prominent, electrolyte imbalance is common, hematocrit increases and numbers of platelets drop. Blood urea and creatinine begin to rise in this phase. The oliguric phase can last from 3 to 7 days and blood pressure returns to normal. Some patients become hypertensive because of their hypervolemic condition. Urine output decreases and blood urea and creatinine increase often associated with hyperkalemia, hyponatremia, hypocalcemia and occasional metabolic acidosis. Cardiac failure, pulmonary edema, and cerebral bleeding are complications of severe cases, and half of all fatalities occur during this phase. Clinical recovery is initiated with the onset of the diuretic or polyuric phase in which a daily urine output of 3–6 liters is not uncommon. Lassitude and anorexia are common in this phase, which normally lasts a few days but can continue up to a few weeks due to dehydration, electrolyte imbalance, or infection. The convalescent phase generally lasts for 2–3 months with a progressive improvement in glomerular filtration rate, renal blood flow and urine concentrating ability. Clinical diagnosis is very good in endemic regions with experienced clinicians but HFRS may not be easily recognized if infected individuals suddenly present with symptoms in nonendemic areas.

HPS presents in four phases which parallel the five phases of HFRS: febrile, shock or pulmonary edema, diuretic and convalescent phases. The incubation period for HPS has been estimated to be 4–30 days and the febrile phase 1–12 days. The prodromal symptoms of HPS are similar to those of HFRS and include fever, chills, dizziness, headache, muscle aches, nausea and abdominal pain. A rapid progression to shock and pulmonary edema may ensue (within 4–24 h). At the onset of pulmonary edema, hematological findings include thrombocytopenia, left-shifted myeloid series and immunoblasts. Symptoms of pulmonary edema include tachypnea, exertional dyspnea and non-productive cough. Shock is indicated by hypotension and oliguria. Elevated creatinine and blood urea nitrogen reflect the degree of shock and hypovolemia, rather than renal disease as seen in HFRS. Microscopic hematuria and elevated liver enzymes are found in most cases. Capillary leakage in HPS patients is found exclusively in the lungs and large amounts of serum may accumulate in the airways. Death from HPS is due to shock and cardiac complications. Convalescence may be protracted with lung capacity diminished for many months.

Pathology and Histopathology

The onset of clinical symptoms in both HFRS and HPS patients coincides with specific immune re-

sponses. The most significant pathological event of HPS or HFRS is increased vascular permeability which appears to arise from endothelial damage. An immune component is probable for both HFRS and HPS, although how the shock in these diseases relates to factors such as viral distribution in vascular endothelia and immunological and chemical mediators of capillary permeability remains to be explained.

Autopsy specimens from HFRS patients show tubular damage in the kidneys as well as hemorrhagic necrosis in the renal medullary junctional zone, cardiac right atrium and anterior pituitary. Histopathological changes in the kidney correlate with severity and clinical staging of disease, beginning with congested subcortical medullary vessels in late febrile and hypotensive phases. Tubular damage progresses and late stage autopsies often reveal swollen kidneys with a hemorrhagic, congested medulla under a pale cortex. Tubular lesions, which include patterning and differentiation of epithelium with loss of the brush border and epithelial cell vacuolization, have been reported for both severe and mild HFRS. In the majority of HFRS patients studied between days 5 and 30 of disease, it was possible to identify cytoplasmic foci of viral glycoproteins in tubular epithelial cells and in sloughed cells displaying tubular degenerative changes. It was suggested that direct viral invasion of renal tubules may partly explain the pathogenesis of acute renal failure in HFRS.

Hemorrhagic manifestations are rare in HPS patients and necrotic lesions, other than those due to shock, are not seen. Histology of autopsy specimens shows moderate interstitial pneumonitis characterized by variable degrees of edema and an interstitial mononuclear cell infiltrate composed of a mixture of small and enlarged mononuclear cells with the appearance of immunoblasts. Focal hyaline membranes composed of condensed proteinaceous intra-alveolar edema fluid, fibrin and variable numbers of inflammatory cells are observed. Neutrophils are reported to be typically sparse and the alveolar pneumocytes are unaltered. Other commonly reported characteristics of HPS include immunoblasts within the splenic red pulp and periarteriolar white pulp, lymph nodal paracortical zones, hepatic portal triads, and in the peripheral blood.

In both HPS and HFRS, viral antigens are found extensively in endothelial cells of various tissues. This accumulation, however, does not coincide with obvious cytopathology.

Immune Response

Rodents with their characteristic chronic or persistent infections exhibit high levels of circulating antibody for life. Infectious virus can be readily demonstrated in antibody-rich sera of infected animals, suggesting that immune complexes are either infectious or readily dissociable under the conditions of infectious virus isolation.

In HFRS and HPS patients, immunoglobulin (Ig)M antibody appears rapidly after onset of disease; this is the most commonly used diagnostic indicator of these diseases. In a retrospective analysis of patient sera collected during the Korean conflict of 1951–1954, specific IgM antibodies were present in the first sera available (frequently as early as the first day of disease), and all patients had measurable IgM antibodies by day 7. IgG can also be detected relatively early in disease by ELISA with hantaviral antigen attached directly to the plate and specific anti-IgG reagents. The IFAT has historically been used to diagnose this disease and remains a reliable test for IgG but not IgM antibody. IgM persists for at least 3–6 months after infection, and IgG can be detected for years and possibly the life of the recovered patient. Both IgM and IgG can be virus-specific in their reaction with infected cell antigens. This can cause some concern that low-level reactivities might be missed in geographic areas where multiple hantaviruses overlap if sera are tested only against a single viral antigen. Antibody has been detected in the urine of HFRS patients and immune complexes may be important in disease; however, immune complex excretion appears sporadic and does not appear to correlate with clinical severity or prognosis.

Humoral immunity is probably the most important factor in protection from HFRS and HPS, as indicated by the ability to passively protect animals from hantavirus infection with neutralizing monoclonal antibodies. Thus, for vaccine development purposes, the elicitation of neutralizing antibodies is often regarded as a correlate of protection. Cell-mediated immunity may also play a role in protection or recovery from infection. Consistent with this was the finding that baculovirus-expressed nucleocapsid protein of HTNV protected hamsters from challenge with HTNV. Also, crossreactive cell-mediated immune responses to a number of hantaviruses were observed in mice. The type of cell-mediated response and its overall importance to disease prevention or recovery need to be further examined.

There is mounting evidence for an immune component of both HFRS and HPS. It is likely that much of the pathogenesis of both diseases is related to damage of vascular endothelial cells caused by the release of as yet undefined cytokines that are triggered by immune cells in response to the presence of viral antigens.

Prevention and Control of Infection

The risk factors for HFRS and HPS are clearly associated with exposure to infected rodent excreta. Although avoiding any rodent excrement may be difficult for persons who must work outdoors in endemic regions, knowledge of these significant risk factors can be very helpful in reducing aerosol transmission.

Direct exposure to infected laboratory rodents has been responsible for numerous infections and some deaths. Complete eradication of all infected animals, disinfection of the facilities, and replacement with uninfected animals from a clean source is the only accepted solution to a laboratory hantavirus infection problem. Animals reared under strict sanitary conditions involving delivery by cesarean section and foster nursing on known negative mothers has resulted in a good source of hantavirus-negative animals.

Inactivated cell-culture derived and rodent brain-derived vaccines for HFRS have been developed, tested, and are licensed for use in Asia. Preliminary information suggests that these vaccines are well-tolerated and that they can elicit antibody responses detectable by ELISA. Some of the vaccines also elicit neutralizing antibody responses in humans. Controlled efficacy studies have not been reported.

A recombinant vaccinia virus vaccine for HFRS was developed in the US and tested in phase I and phase II clinical trials. The vaccine elicited neutralizing antibodies in the majority of vaccinia-naive individuals but not in vaccinia preimmunes. Other genetically engineered vaccines are under development but have not yet been tested in humans.

Future Perspectives

The successful application of PCR technology to detect hantaviruses has greatly expanded our knowledge of the ecology and epidemiology of these viruses. Undoubtedly more hantaviruses remain to be discovered in as yet unstudied rodents. Additional oligonucleotide and amino acid sequence homology comparisons may provide insight into the genetic variation within the genus, the basis for variable virulence among the isolates, and evidence for genetic interaction between viruses, if it exists.

Because of the plenitude of different hantaviruses that cause human disease, it is likely that multivalent vaccines will be needed. Genetically engineered vaccines containing multiple hantavirus genes may most readily meet that need.

Finally, a reverse genetics system based on an infectious clone of a hantavirus would be invaluable for helping to describe specific aspects of viral replication. To date, such a system has proven elusive.

Avian Hepatitis B Virus

William Mason, Fox Chase Cancer Center, Philadelphia, Pennsylvania, USA

Patricia Marion, Division of Gastroenterology, Stanford University Medical Center, Stanford, California, USA

History

At present, only two species of avian hepadnaviruses have been identified and well characterized: duck hepatitis B virus and heron hepatitis B virus. Duck hepatitis B virus was first discovered in 1979 in duck (*Anas domesticus platyrhynchos*) serum samples collected in the People's Republic of China. The discovery that ducks might be carriers of a hepadnavirus followed the observation that ducks in certain areas of China had a high incidence of primary hepatocellular carcinoma. This cancer was already known to be of common occurrence in humans infected with hepatitis B virus, which led to the idea that a similar virus might be present in ducks. Subsequent research has neither sustained nor refuted the possibility that infection contributed to the liver cancer that had been observed in the ducks, which may, instead, have been caused by environmental carcinogens.

A second avian hepadnavirus species was discovered in 1988 in the sera of grey herons (*Ardea cinerea*) from Germany. The discovery of this second virus was facilitated by the fact that its DNA genome hybridized with a radioactive probe prepared from the cloned genome of the duck hepatitis B virus, indicating that the two viruses share considerable DNA sequence homology, as was subsequently shown by comparing the complete sequences of the two viruses.

A preliminary report suggests the existence of an avian hepadnavirus, possibly distinct from the duck or heron viruses, in the Australian woodduck (*Chenonetta jubata*). A novel strain of duck hepatitis B virus has also been isolated from the Ross goose (H. Shi, J. Cullen, and J. Newbold, personal communication; GenBank accession no. M95589).

Classification

The *Hepadnaviridae* family has been divided into two genera: *Orthohepadnavirus*, of which human hepatitis B virus is the prototype, and *Avihepadnavirus*, of which duck hepatitis B virus is the prototype.

Properties of the Genome

All members of the *Hepadnaviridae* family have a partially double-stranded DNA genome of about 3 kb that is held in a circular conformation by a short cohesive overlap between the 5′ ends of the two DNA strands (**Fig. 1**). One strand is always complete in virus particles, whereas the second strand is incomplete, with a 3′ end that is heterogeneous in location. The incomplete strand is of plus polarity and the complete strand of negative polarity. When these viruses infect a cell, the plus strand is completed and the fully double-stranded DNA is then converted to a covalently-closed circular (CCC) molecule, which serves as a template for viral RNA synthesis (**Fig. 2**). The two genera of hepadnaviruses are thought to differ in that orthohepadnaviruses encode four open reading frames (ORFs) whereas the prototypic avihepadnavirus, duck hepatitis B virus, encodes only three, lacking the X ORF. This ORF appears to encode a protein that modulates transcription, possibly by acting on signal transduction pathways. There is now evidence for a fourth ORF in heron hepatitis B virus and in Ross goose virus, capable of coding for a 7–8 kDa protein, in the same genomic location as the C-terminal half of the X ORF of the orthohepadnaviruses. Functional studies on this ORF have not been reported. With one exception, the known products of the different ORFs are each translated from distinct mRNAs, transcribed from one of the four (*Orthohepadnavirus*) or three (*Avihepadnavirus*) viral promoters. The major nucleocapsid protein and the product of the polymerase gene appear to be encoded by the same mRNA, the pregenome, which also serves as the template for viral DNA synthesis. It was originally thought that mRNA splicing did not have a role in virus replication; however, it was recently found that the larger (L) of the two envelope proteins of duck hepatitis B virus is translated both from a spliced mRNA as well as from an unspliced mRNA. The spliced mRNA is transcribed from the major nucleocapsid promoter, located about 1200 bp upstream of the start codon for the large envelope protein. The unspliced mRNA is synthesized from a promoter located immediately upstream of the ORF for the large envelope protein (**Fig. 1**).

All hepadnaviruses replicate their DNA by reverse transcription of a viral RNA, a process which takes

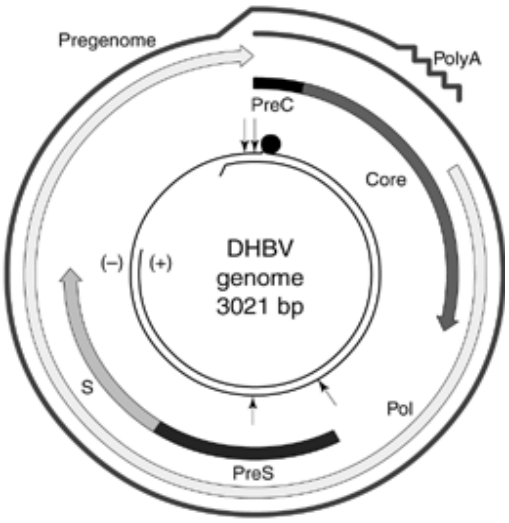

Figure 1 The DHBV genome. Duck hepatitis B virus (DHBV) the prototypic avihepadnavirus, has a 3021 bp genome which is held in a relaxed circular conformation by a short cohesive overlap between the 5′ ends of the two DNA strands. The minus strand is slightly larger than unit length, with a 9 base terminal redundancy. The plus strand is always less than unit length within virions. The viral pol gene product, a reverse transcriptase, is found covalently attached to the 5′ end of the minus-strand DNA, reflecting its dual role as a polymerase and as a protein primer of reverse transcription. A short, 17 base capped RNA, derived from the 5′ end of the pregenome (the template for reverse transcription) is covalently attached to the 5′ end of the plus strand. The three open reading frames are shown. The core reading frame encodes the 262 amino acid viral nucleocapsid subunit, while the PreC/core frame encodes a secretory protein (e-antigen). The pol reading frame encodes the 836 amino acid viral DNA polymerase, a reverse transcriptase. The PreS/S reading frame encodes the 364 amino acid L envelope protein, while the S region encodes the 167 amino acid S envelope protein. The start sites for transcription of the viral mRNAs are shown by arrows. The mRNA for the core protein is the pregenome mRNA, which also acts at a lower frequency as the mRNA for the reverse transcriptase. When reverse transcriptase is made, it binds to the 5′ end of its own message and directs it into the reverse transcription pathway. Reverse transcription takes place following packaging of the pregenome/polymerase complex into viral nucleocapsids. The pregenome is terminally redundant, as shown, by 270 bases. A second mRNA, initiating *c.* 30 bases upstream of the pregenomic mRNA, serves as the message for the PreC/core protein. The mRNA for L initiates just upstream of the open reading frames, while the S protein mRNA initiates within the PreS domain. All viral mRNAs end at the same polyadenylation site as the pregenome.

place within viral nucleocapsids found in the cytoplasm of the infected cell (**Fig. 2**). At the cellular level, infection can be chronic and productive, or it may be latent. Infections seen in the liver are generally productive, and evidence for true latent infection of hepatocytes has not so far been obtained. The reverse transcription process, observed in productively infected cells, differs mechanistically from that employed by members of the *Retroviridae* family. Following synthesis of viral DNA, the nucleocapsids are enveloped with a lipoprotein coat, possibly by budding into the endoplasmic reticulum.

Properties of the Proteins

For DHBV, the coat probably contains only two proteins, L and S, that appear to be both structurally and functionally important. L, the larger of the two, is transcribed from the same ORF as S, spans all of S, but initiates at an AUG further upstream in the ORF, so that it is almost twice as large as S. Some investigators believe that a third envelope protein, M, is also produced by this ORF, initiating at an AUG located between the start sites of L and S and extending to the end of S. The M protein is in fact produced by all orthohepadnaviruses. The protein domain unique to L would be referred to as PreS1, the domain common to L and M as PreS2, and the domain common to all three as S. Here, we keep to the convention that only two proteins, L and S, are produced; the PreS1 and PreS2 domains are combined to PreS. PreS sequences of L are often located on the external surface of the viral envelope, where they are believed to specify a critical step in viral host range by interacting with specific cell surface receptors. For a portion of the large envelope protein molecules the PreS sequences remain on the cytoplasmic side of the viral envelope, where they probably interact with the viral nucleocapsid to facilitate virion formation during budding.

Hepadnaviruses produce a large excess of the envelope proteins, above the amount needed for virion assembly, and the excess is secreted as surface antigen particles. The S protein appears to be sufficient for production of surface antigen by orthohepadnaviruses, though L can also be incorporated into these particles. Both L and S have been detected in surface antigen particles produced by duck hepatitis B virus, the prototype avihepadnavirus. The surface antigen particles produced by avihepadnaviruses are pleomorphic spheres, 40–60 nm in diameter, whereas orthohepadnaviruses produce regular, 22 nm diameter rods and spheres. The particles produced by the orthohepadnaviruses may have a much lower lipid content than those produced by the avihepadnaviruses, and in neither case has the mechanism of assembly been determined, although, as for the virions, the particles first appear in the cisternae of the endoplasmic reticulum.

In addition to the envelope proteins, DHBV produces 3 other proteins (**Fig. 1**). The 262 amino acid core protein forms the nucleocapsid shell. The

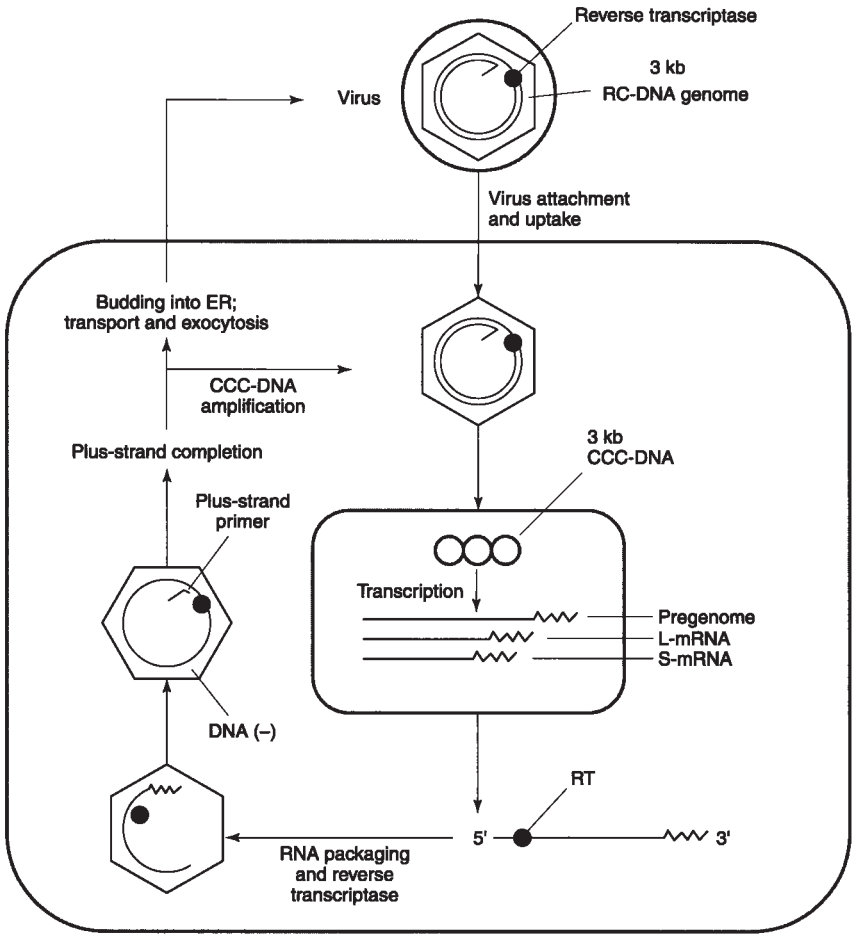

Figure 2 The replication of duck hepatitis B virus within hepatocytes. When virus, shown at the top, infects a cell, the DNA migrates to the nucleus and is processed to a unit length, covalently-closed circular species (CCC-DNA) which serves as the template for all viral mRNAs. If pol is translated from a pregenome mRNA, the translation product binds near to the 5′ end, to a stem loop structure called epsilon, and the protein–RNA complex is then packaged into nucleocapsids, composed of a core protein subunit, where reverse transcription actually takes place. Early in infection, newly made viral DNA is transported to the nucleus, resulting in an increase of the CCC-DNA copy number to *c.* 10–50. Accumulation of CCC-DNA is eventually shut down because the abundant synthesis of viral surface antigens leads to envelopment of mature nucleocapsids and subsequent secretion of the virus from the cell. For all hepadnaviruses, envelope proteins are made in vast excess over the amount used in virion assembly, with the excess being secreted in the form of noninfectious surface antigen particles. Overproduction of envelope proteins may be needed to effectively shut down CCC-DNA formation, as excess CCC-DNA accumulation can lead to cell death. ER, endoplasmic reticulum. RC, relaxed-circular.

polymerase, with protein priming, reverse transcriptase, and RNase H activity, carries out viral DNA synthesis. The 305 amino acid PreCore/core protein is processed and secreted from the infected cell, as the viral c-antigen. The function of the e-antigen is unknown. It has been conjectured that this core related protein protects infected cells from the antiviral immune response.

Geographic and Seasonal Distribution

Except for the Muscovy duck (*Cairina moschata*), most varieties of domestic ducks are thought to derive from the wild mallard (*Anas p. platyrhynchos*) and, despite wide differences in appearance due to domestication, belong to a single species. Duck hepatitis B virus has been found both in the wild mallard and in domestic flocks of this species throughout the world, but not in Muscovy ducks. The incidence of chronic infection in individual flocks can range from zero to 100%. Infections are primarily acquired congenitally, by virus passed into the egg laid by a viremic duck. Transmission by this route leads to a chronic viremia that is probably lifelong. Horizontal spread of infection may also occur. Since the virus is bloodborne, horizontal spread presumably occurs through

open wounds. Sexual modes of transmission have not been studied. Except during the first few days of life, horizontal spread would be expected to lead to a transient infection, with subsequent immunity, rather than to a chronic infection (see Pathogenicity and Clinical Features of Infection, below). In domestic flocks, the only seasonal effects that might be expected to arise would be attributable to breeding and the associated congenital transmission, together with the presence of hatchlings that would be more susceptible than older birds to chronic infection resulting from horizontal transmission.

The geographic and seasonal incidence of the heron hepatitis B virus has not been described.

Host Range and Virus Propagation

Duck hepatitis B virus infects wild mallards and related domestic ducks (*Anas platyrhynchos*). Transmission to the Muscovy duck and the chicken has not been successful, but the virus can be transmitted to domestic Embden and Toulouse geese and has also been detected as an apparently natural infection in domestic geese. The distribution of duck hepatitis B virus in geese and other waterfowl has not been studied in detail. The virus is not known to be infectious to mammals. The virus will infect and replicate in primary duck hepatocyte cultures, and can be transmitted to developing duck embryos. *In vivo*, hepatocytes produce infectious virus, which is released into the bloodstream, producing a persistent viremia in the chronic carrier.

The apparently limited host range of duck hepatitis B virus is probably due to a lack of cell surface receptors for the virus in nonsusceptible species. Indeed, the virus will replicate efficiently in a chicken hepatocellular carcinoma cell line transfected with the cloned viral genome, and even in transfected human hepatocellular carcinoma cell lines. Some of the viral promoters are relatively inactive in cell lines that are not of hepatocellular origin, suggesting that a lack of appropriate transcriptional factors may also limit viral host range or lead, following virus uptake, to a latent infection. Evidence for latent infection of lymphocytes by human and woodchuck hepatitis viruses in their respective hosts has been reported, but latent infections have not, so far, been demonstrated in the duck.

Transmission of heron hepatitis B virus has not yet been achieved in the laboratory. The virus does not infect ducks. As with the duck virus, replication of heron hepatitis B virus can be demonstrated following transfection of the cloned viral genome into hepatoma cells.

Genetics

The mutation rate of the avihepadnaviruses has not been measured, but would be expected to resemble that of the woodchuck hepadnavirus, which has been estimated to be $\leq 2 \times 10^{-4}$ base substitutions per site per year. This relatively low rate of genetic change is one or two orders of magnitude lower than that estimated for other viruses which lack polymerase-associated proofreading functions, including the retroviruses. The apparently low rate of mutation may reflect two factors: (1) constraints on the viabity of genetic changes that are imposed by the compact coding of genetic information by the hepadnaviruses, with multiple overlapping reading frames; (2) a low rate of turnover of infected hepatocytes and, accordingly, of the template for transcription of the RNA that is reverse transcribed into viral DNA.

Evolution

As there is amino acid sequence homology between hepadnaviruses and retroviruses in both the polymerase and core genes, it has been suggested that these viruses have a common origin, with hepadnaviruses arising from deletions of a retrovirus or retrovirus-like ancestor. These virus families also share a common genomic sequence: a conserved hepadnavirus sequence near the initiation site for minus-strand DNA synthesis is homologous over 67 nucleotides to the U5 region in retroviral long terminal repeats. On the basis of nucleotide and amino acid homologies, it has been proposed that the avihepadnaviruses and the orthohepadnaviruses diverged from a common ancestor around 30 000 years ago. The least conserved proteins among the hepadnaviruses are the preS regions of the surface protein, which are thought to be those involved in binding to the cellular receptors. As each of the hepadnaviruses is fairly species specific, variation in the preS region could be necessary to correspond to the host variation of cellular receptors.

Serologic Relationships and Variability

There are currently no defined subtypes or serotypes of duck hepatitis B virus, though there are monoclonal antibodies which distinguish between different amino acid sequences of the surface antigen. The amount of variation in nucleotide sequence in the published sequences of duck hepatitis B virus (1.2–11.6%) appears to resemble that of hepatitis B virus subtypes (8–10%). Sequences from three genomes cloned from ducks from the USA and Germany appear more closely related to each other (1.2–5.9% variation) than to five sequences cloned from ducks

from China (9.1–11.6% variation). The Pekin ducks in the USA and Germany are thought to have come from China about 140 years ago. Within the sequences cloned from ducks from China, there is variation ranging from 3.7 to 9.4%.

Five sequences of heron hepatitis B virus have been published. Up to 7% sequence diversity has been found in the heron hepatitis B virus isolates. The prototype heron hepatitis B virus sequence differs from duck hepatitis B virus sequences by 21.6%, somewhat more than the 16.4% variation between the woodchuck and ground squirrel hepatitis viruses.

Epidemiology

Congenital transmission to virtually all progeny of infected female ducks appears to be the major route for maintenance of duck hepatitis B virus infection in a natural setting. It is not known whether transmission to the embryo will occur when a viremic drake mates with a nonviremic duck. Preliminary observations suggest that transmission from infected males to progeny is, at best, a low frequency event. The virus accumulates in the yolk of eggs laid by viremic birds and infects the yolk sac, liver and pancreas of the developing embryo. This early exposure produces an immunological tolerance to the virus, and, in fact, there is no evidence of an immune-mediated liver disease, including hepatitis, in these ducks. A mild hepatitis has been observed when ducks are experimentally infected with duck hepatitis B virus. This does not seem to lead to the extensive lobular destruction, fibrosis, or cirrhosis associated with severe or long-term infections of humans by hepatitis B virus, and, although hepatocellular carcinomas with integrated viral DNA have been observed in infected ducks, a strong correlation between liver cancer and virus infection has not been found. The finding of integrated DNAs is perhaps not surprising if the cancers arise from infected hepatocytes, as spontaneous integration may be quite common during virus replication. It is presumed that the worldwide distribution of duck hepatitis B virus reflects its presence in the wild flocks from which the domestic were derived, as well as the intermingling and interbreeding that may occur between wild ducks and domestic ducks maintained in fields or pens that are not completely enclosed.

Compared to the situation with duck hepatitis B virus, virtually nothing is known about the epidemiology of heron hepatitis B virus. Approximately 30% of the grey herons examined in Germany were virus infected.

Transmission and Tissue Tropism

Duck hepatitis B virus, as already indicated, is transmitted congenitally and, in crowded conditions, horizontal spread has been observed, and presumably took place via a parenteral route. There is no evidence, however, that is either for or against other routes of transmission. Rather, it is generally assumed that transmission parallels that of the better studied human hepatitis B virus, that blood is the major source of virus and that introduction through the parenteral route is the only source of horizontal infection that is of any importance. In ducks, as in mammals, hepatocytes are the quantitatively most significant target, and in chronic carriers virtually every hepatocyte appears to be productively infected. Virus replication intermediates have also been detected in bile duct epithelium in the liver, in endocrine cells and scattered exocrine cells in the pancreas, and in tubular epithelium in the kidney. Except for the endocrine islets of the pancreas, which can be totally infected, infection appears to be limited in extrahepatic organs to only a few percent of the potential target cells, although the basis for this restriction in the presence of high titers of circulating virus is not known. There is also evidence for virus in germinal centers in the spleen, probably in dendritic cells (A. Jilbert, personal communication), although the results may be consistent with accumulation of viral components from the bloodstream rather than actual infections. In contrast to the mammalian hepadnaviruses, duck hepatitis B virus infection of lymphocytes has not been demonstrated. Cell-free preparations of virus derived from the blood of an infected duck are, indeed, highly infectious. The specific *in vivo* infectivity of fresh virus preparations is probably close to 1.

Heron hepatitis B virus also infects the liver and produces a viremia in its natural host, the grey heron. Modes of transmission remain to be characterized.

Pathogenicity and Clinical Features of Infection

Studies of pathogenicity in the infected duck have generally focused on the liver as the main target of infection. From this limited point of view, congenital infection is apathogenic. Therefore, infection with wild-type virus does not kill host cells in the absence of an immune response. Experimental infections of birds less than 1 week of age usually produces a chronic infection, with a mild to severe, transient, hepatitis. Infection of older ducks, in contrast, almost always produces a transient infection, followed by recovery and the development of a humoral immune

response to the virus envelope, with only a mild hepatitis. Infection has not been associated with a significant rise in liver enzymes in the bloodstream, or with any other clinical features, again suggesting that hepatocellular destruction is mild. It is not known if horizontal infection accelerates the development of secondary amyloidosis of the liver in ducks, a common condition in waterfowl which is seen in infected ducks, as well as in ducks that are not infected with duck hepatitis B virus.

Experiments with variants of duck hepatitis B virus have been performed to address the consequences of direct cytotoxicity of hepadnaviral infections. These variants were mutated so that the transcriptional template (**Fig. 2**) would be overproduced, a situation which leads to cell death. Infection of ducks with the variants led to severe but transient liver disease, followed by repopulation of the liver with spontaneously arising viral mutants that exhibited wild-type behavior. Thus, there is a strong selection against variants that are cytopathic in hepatocytes.

Pathogenicity due to extrahepatic virus infection would not, for the most part, be expected to be clinically important, as so few cells are infected. Only in the endocrine pancreas are the majority of parenchymal cells infected. An effect on β islets has, in fact, been observed in ducks chronically infected by the congenital route. In these ducks there is a marked deficiency in the rise in plasma insulin levels normally seen in response to arginine, a physiological secretagogue.

Pathology and Histobiology

Laboratory infection of ducklings or older birds can produce a variable degree of hepatic injury, usually mild, including portal hepatitis with penetration of the limiting plate by mononuclear lymphoid cells and, occasionally, lobular hepatitis. Portal hepatitis, by itself, is quite common in domestic ducks, irrespective of exposure to duck hepatitis B virus, whereas a periportal or lobular hepatitis can be correlated with experimental viral infection. Piecemeal and focal necrosis have also been observed, as have occasional apoptotic (eosinophilic) bodies. Chronic persistent and chronic active hepatitis have not so far been observed as a response to infection in a controlled setting. Histopathologic features have not been described that distinguish transient from chronic infection resulting from experimental inoculation of duck hepatitis B virus. The deficiency in insulin secretion reported in congenitally infected ducks is not due to an overt pancreatitis and is more probably a direct consequence of virus infection (i.e. cytotoxicity).

Immune Response

A humoral immune response to viral nucleocapsid antigens has not been detected in congenitally infected ducks. In contrast, antibodies to determinants of the viral nucleocapsid have been detected in ducks that have become chronically infected as a result of experimental inoculation, and an immune response to epitopes of viral coat proteins eliciting both neutralizing and nonneutralizing antibody has been detected in ducks recovering from a transient infection. Presently four epitopes on the DHBV preS protein region and one on the S protein are known to be involved in neutralization of virus infection in *in vitro* studies, and antibody to some of the PreS epitopes can significantly reduce the level of viremia and extend its onset in experimental infection of ducklings.

The presence of a mononuclear infiltrate (hepatitis) in the liver during transient infection suggests a T cell recognition of viral antigens, though the actual targets are unknown. Antibodies to viral coat, core and *pol* proteins might also function in antibody-dependent cellular toxicity. The observation that infections can rapidly resolve, even after infection of up to 70–80% of the hepatocytes, but without evidence of major liver damage, raises questions about the quantitative importance of killing of infected cells in the large-scale disappearance of virus from the host. Experiments with hepatitis B virus transgenic mice suggest that cytokines produced by the cellular immune response may induce degradation of viral DNAs and proteins that are present in the cytoplasm of infected cells. It is speculated that the transcriptionally active DNA in the nucleus is lost as infected hepatocytes proliferate to replace those cells killed by the antiviral response. It is not clear if neutralizing antibodies are needed for elimination of an infection.

Prevention and Control

Because duck hepatitis B virus has not been demonstrated to cause morbidity, mortality or even minor adverse effects on the health and viability of domestic ducks, a serious effort at primary prevention (i.e. vaccination) has not seemed warranted. However, because the *in vivo* replication of the duck hepatitis B virus is virtually identical to that of human hepatitis B virus, this animal model has been used to study antiviral agents and strategies that might eventually be tried in humans. Selected nucleoside analogues have been shown to have good specificity against virus DNA synthesis, mediated by a viral encoded reverse transcriptase, and to cause a reduction of viremia and a drop in hepatic levels of replicating viral DNA.

With one exception, prolonged (3–6 months) administration of inhibitors of viral DNA synthesis has not been found to significantly reduce the number of infected hepatocytes from the >95% characteristic of chronic infection. One nucleoside analogue, 2′-carbodeoxyguanosine, caused a 10–100-fold reduction in the number of infected hepatocytes in about a month, an effect that could be attributed to the hepatotoxicity of the analogue rather than to inhibition of virus replication *per se*. The spontaneous and complete recovery usually seen following virus inoculation of adult ducks implies that a more effective treatment than has been found, so far, is theoretically possible. The main issue is whether this can be achieved in the absence of a major contribution from the immune system of the host or if, in a duck or human carrier infected at an early age, and perhaps tolerant to some viral antigens, particularly those that are targets for neutralization, a life-time of multidrug therapy might be required to control the infection (i.e. keep the hepatocyte population substantially, but not 100%, virus free).

Future Perspectives

Though a vaccine effective against human hepatitis B virus has been produced for more than a decade, availability or delivery have not been universal, and perinatal and transfusion-mediated infections still remain common, as do infections among intravenous drug users. For infections acquired in adult life, interferon therapy has demonstrated some promise, and the hope remains that immune modulators and/or combined therapy with direct inhibitors of viral replication can be utilized to produce even greater efficacy. Unfortunately, infections acquired perinatally or during childhood do not respond well to interferon therapy, and new treatment strategies are needed for this population group which, worldwide, may number in excess of 1×10^8. The chronically infected duck remains as a particularly attractive model for chemotherapeutic approaches to antiviral therapy, especially because of the ready availability and simplicity of housing and handling of infected animals. Moreover, for the duck hepatitis B virus there is a simple and dependable cell culture system in which to evaluate antiviral strategies before initiating *in vivo* trials.

Some of the same considerations discussed above have made the duck hepatitis B virus a favorite of molecular biologists interested in modes of hepadnavirus replication. The role of reverse transcription in hepadnavirus DNA synthesis was first deduced with duck hepatitis B virus, and subsequent studies with this virus have revealed not only the fine details of genome DNA synthesis but also the role of cytoplasmic viral DNA synthesis in amplification to 10–50 copies per cell, of CCC-DNA, the nuclear template for viral RNA synthesis (**Fig. 2**). Recent studies have also shown how CCC-DNA copy number is controlled through a feedback mechanism employing the viral L and S proteins (**Fig. 2**). In the near future, we should expect ongoing research to produce a detailed picture of all the major intracellular processes required to maintain an infection that is both chronic and productive.

Molecular Biology

Christoph Seeger, Fox Chase Cancer Center, Philadelphia, Pennsylvania, USA

Properties of the Virion

The virion or 'Dane particle' of human hepatitis B virus (HBV) appears as a spherical structure with a diameter of approximately 42–47 nm. Within the sphere is an electron-dense core with an estimated diameter of 22–25 nm. The viral envelope consists of a lipid bilayer containing three polypeptides, termed large (L), middle (M) and small (S) surface protein (also known as pre-S1, pre-S2 and HBsAg). Incubation of the virion with nonionic detergent releases the nucleocapsid (core particle), which contains the 3.2 kb-long, partially double-stranded viral DNA genome and the viral DNA polymerase, a reverse transcriptase. The nucleocapsid is composed of 240 monomers of core protein (core antigen, HBcAg) arranged to form an icosahedral structure with a triangulation number $T = 4$. Dane particles and subviral core particles present in infected hepatocytes exhibit DNA polymerase (endogenous polymerase) and protein kinase activities. Although the former can add nucleotides to the 3′ ends of the incomplete positive-strand DNA, the latter phosphorylates predominantly serine residues at C-termini of core polypeptides.

In HBV-infected patients the titer of virions can vary from 10^3 to 10^9 per milliliter of blood. In addition to Dane-particles, sera of infected patients also contain nucleic acid-free, lipid-containing sphere- and rod-like (filamentous) subviral structures composed largely of S and some M protein. The spheres have a diameter of about 22 nm and the rod-like structures are approximately 20 nm wide and vary in length from approximately 20 nm to 200 nm. The concentration of these subviral particles can exceed that of virions by a factor of 10^3–10^5.

The rodent hepadnaviruses, woodchuck hepatitis virus (WHV) and ground squirrel hepatitis virus (GSHV) share their principal ultrastructural features with those described for HBV and, with HBV, are within the genus *Orthohepadnavirus*. The DNA-containing virus particles are somewhat larger than the Dane particles, reaching 47–55 nm in diameter. Subviral filamentous forms in sera of GSHV infected Beechey ground squirrels are more abundant and about three times longer than their HBV counterparts.

Properties of the Genome

The mammalian hepadnaviruses have a partially double-stranded, 3.2–3.3 kb-long DNA genome held in a circular conformation by an approximately 220 nucleotide-long cohesive overlap demarcated by the 5′ ends of the two DNA strands (**Fig. 1**). Whereas negative-strand DNA contains a complete copy of the viral genome, and hence, is referred to as 'the complete DNA strand', the positive-strand DNA is incomplete, only extending on average to approximately 60% of the length of negative-strand DNA. The 5′ end of negative-strand DNA is covalently linked to a tyrosine residue located near the N terminus of the viral polymerase polypeptide. The 5′ end of the positive-strand DNA is linked to an approximately 18 nucleotide-long RNA sequence, which is derived from the 5′ end of pregenomic RNA. Negative-strand DNA is the template for the synthesis of the viral mRNA transcripts and bears four known open reading frames (ORFs) encoding the core, polymerase, envelope and X genes.

The genomes of WHV and GSHV have the same general structural properties as those described for HBV. The length of their genomes exceeds that of HBV by approximately 140 nucleotides due to additional nucleotide sequences in the region encoding the N-terminal domain of the L envelope protein. Whereas WHV and GSHV share 82% nucleotide sequence homology, HBV and the rodent viruses exhibit approximately 55% sequence identity. The

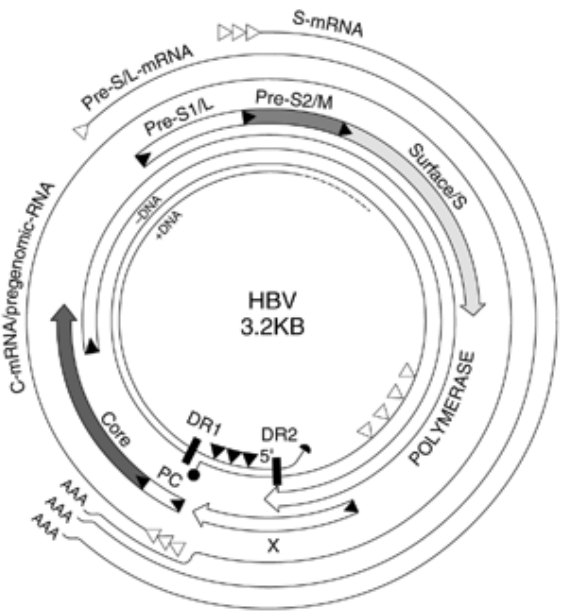

Figure 1 Physical map of the hepatitis B virus (HBV) genome. The inner circle depicts the viral genome with the complete, 3.2 kb-long, negative-strand DNA and the incomplete positive-strand DNA. The viral polymerase covalently linked to the 5′ end of the negative-strand is indicated with a filled circle and the cap-structure at the 5′ end of the RNA oligomer attached to the 5′ end of positive-strand DNA with a solid half circle. Interrupted lines show the heterogeneous 3′ ends of positive-strand DNA. The sites for initiation of viral DNA synthesis (DR1 and DR2) are shown as filled rectangles. Open and solid triangles illustrate the positions of the two transcriptional enhancer elements, enhancer I and II, respectively. The viral genome is surrounded by the viral coding regions, which are depicted by four circular arrows (for details see text). The initiation sites for the translation of the seven known viral gene products are indicated with the filled triangles. (PC, precore). The three major viral RNA species are shown in the outer circle. The 5′ and 3′ termini of individual transcripts are delineated with open rectangles and the letters AAA, respectively. RNAs with multiple initiation sites are marked with three symbols at their 5′ ends.

GC content of the mammalian hepadnavirus genomes is about 48%.

Physical Properties

Infectious virions (Dane particles) have a buoyant density of 1.24–1.26 g cm^{-3} in CsCl and a $s_{20,w}$ of 280S. The density of intracellular core particles is 1.36 g cm^{-3}. Subviral HBsAg particles, in which lipid accounts for approximately 25% of their weight, have a density of 1.18 g cm^{-3} in CsCl. The viral nucleic acid is a circular partially double-stranded DNA molecule with a mol. wt of about 1.6×10^6 kDa and a $s_{20,w}$ of 15S. Virions are inactivated following incubation in formaldehyde (1:2000) at 37°C for 72 h, heat treatment at 98°C for 2 min or incubation in 2% glutaraldehyde at room temperature for 5 min.

Properties of the Viral Proteins

The four protein-coding regions of the mammalian hepadnaviruses are translated into seven known proteins (**Fig. 1**). The core ORF codes for the 21 kDa viral capsid protein, also called hepatitis B core antigen (HBcAg) and the 16–18 kDa precore polypeptide, termed hepatitis B e-antigen (HBeAg). The HBcAg is the most highly conserved polypeptide among the mammalian hepadnaviruses showing 68% amino acid homology between HBV and GSHV (GSHcAg) and 92% between GSHV and WHV (WHcAg). It is a cytoplasmic and nuclear phosphoprotein with a basic C-terminus that is essential for the packaging of viral RNA. Core polypeptide monomers form dimers that assemble into spherical shells with icosahedral symmetry consisting of 120 dimer subunits. The formation of these dimers is mediated by two long alpha helices that form spikes on the surface of nucleocapsids. Dimers are further stabilized through the formation of two homologous intermolecular disulfide bridges.

The HBeAg is a secreted protein of unknown function that is antigenically distinct from HBcAg. This polypeptide is translated from an initiation codon preceding the core AUG in the same phase. The primary translation product is proteolytically processed resulting in the removal of 10 and 34 amino acids from its N- and C-terminus, respectively.

The surface or envelope ORF encodes the co-C-terminal proteins of 39 kDa (L, pre-S1), 31 kDa (M, pre-S2) and 24 kDa (S, HBsAg). S is an integral transmembrane protein that is present in both unglycosylated and glycosylated (gp27) forms and bears the signals necessary for assembly into 42 nm viral and 20 nm subviral particles, a process leading to the formation of disulfide bridges between the S components. The S proteins of the mammalian hepadnaviruses show strong antigenic crossreactivity and reveal amino acid homologies of 61% between HBV and GSHV and 90% between WHV and GSHV. The S polypeptides of WHV and GSHV have a molecular weight of about 22 kDa and are, as in HBV, present in both unglycosylated and glycosylated forms.

The M and L proteins are translated from AUG initiation codons located upstream of the initiation site for the translation of S. Hence, these polypeptides share their C-termini with S. The L and M proteins are expressed at a level of approximately 5–15% and 1–2% compared to S. Whereas M protein is present in both viral and subviral structures the L protein is

primarily found in Dane particles. The ratio of L:M:S in 42 nm Dane particles is about 1:1:4. In contrast, 20 nm subviral structures lack L and consist mainly of S and some M polypeptides. Like S, both L and M proteins contain N-linked oligosaccharides (gp33 and gp42). Glycosylation sites have been localized to the S region and to the N-terminal domain of the M polypeptide. The L polypeptide is further modified with myristic acid at its N terminus. The function of the M protein is obscure, but L protein is believed to carry the binding site for the viral receptor on susceptible cells.

All three envelope components are integral transmembrane proteins with at least two, but possibly four, membrane-spanning domains present in the S domain. Both N- and C-termini of L, M and S are exposed on the outside of virions. In the absence of S, L is retained in membranes of the endoplasmic reticulum with its N-terminus on the cytoplasmic site of the membranes. Since the N-terminal domain of L is on the outside of mature virions, at least a fraction of L proteins must undergo a conformational change during viral morphogenesis. The L and M specific domains of HBV lack 43 amino acids compared to their GSHV and WHV counterparts and represent the least conserved regions between the mammalian hepadnaviruses.

The polymerase ORF encodes the viral reverse transcriptase. Based on the length of its coding region, the primary polymerase translation product has a predicted molecular weight of about 90 kDa. The polypeptide consists of two domains that are separated by a tether region. Whereas the longer C-terminal domain contains sequence motifs characteristic of other known reverse transcriptases, the shorter N-terminal domain is, so far, unique to hepadnaviruses. It plays a critical role in the priming of viral DNA synthesis. The polymerase exhibits at least four enzymatic activities, which are required for the synthesis of the viral DNA genome from an RNA intermediate, called the pregenome. They include RNA- and DNA-directed DNA polymerase and RNAseH activities. Furthermore, the polymerase acts as a primer for reverse transcription of negative (first)-strand DNA. Enzymatic activity of the DNA polymerase has been demonstrated in permeabilized Dane particles (endogenous reaction), core particles isolated from infected liver tissue and with polymerase polypeptides expressed in insect cells and frog oocytes.

The X ORF encodes a 17 kDa protein, termed X, whose function for viral replication is not known. X is expressed in livers of WHV-infected woodchucks and is essential for viral replication *in vivo,* but dispensable for replication in tissue culture cells. Experiments in tissue culture cells revealed a plethora of functions for X. It can activate many viral and cellular promoters as well as several signal transduction pathways. Other activities include interactions with the tumor suppressor p53, the UV-damaged DNA binding protein and a subunit of the proteasome. In addition, overexpression of X in certain lineages of transgenic mice can lead to the formation of liver neoplasms. Next to the L region of the envelope products, the X protein is the least conserved protein among the hepadnaviruses with 33% amino acid homology between GSHV and HBV and 71% between the two rodent isolates.

Replication, Assembly and Release

HBV replication occurs primarily in hepatocytes. Circumstantial evidence suggested that tissue tropism is determined by the viral receptor. However, the nature of the receptor is still not known. Since uptake of virus in cultured cells is restricted to primary hepatocyte cultures it is likely that the expression of the putative receptor, or a component thereof, is suppressed in immortalized cell lines. In addition, tissue tropism is determined by liver specific transcription factors that orchestrate viral gene expression. A few differentiated hepatoma cell lines can support viral gene expression and produce infectious virus following their transfection with plasmids containing intact viral genomes.

Following infection and uncoating of the viral envelope, the relaxed circular (RC) DNA genome is transported by an unknown mechanism into the cell nucleus. During this step, RC DNA is converted into a covalently closed circular (CCC) molecule (**Fig. 2**). The 3.2 kb-long CCC DNA is the template for the transcription of a 3.4 kb-long RNA species, termed pregenomic (pg) RNA. pgRNA has redundant 5′ and 3′ ends and short sequence repetitions (DR1, DR2), one of which maps to the redundant termini (DR1). The RNA is packaged together with polymerase into core particles where it serves as a template for reverse transcription of negative-strand DNA. RNA packaging depends on the binding of the polymerase to a signal, termed epsilon, located near the 5′ end of pgRNA. This interaction also requires cellular proteins that include the molecular chaperone heat shock protein 90. The formation of this RNA–protein complex is believed to trigger assembly of nucleocapsids.

Negative-strand DNA synthesis is primed by a tyrosine residue located near the N-terminus of the reverse transcriptase. The protein-priming reaction leads to the formation of a phosphodiester bond between the tyrosine residue and the first nucleotide

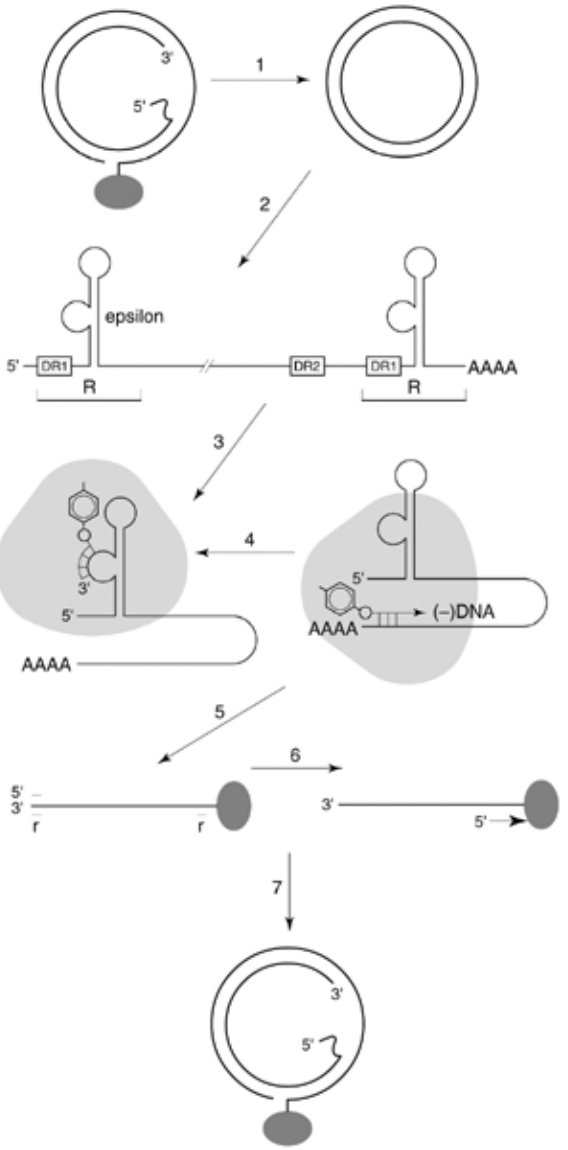

Figure 2 Model for the replication of the hepatitis B virus (HBV) genome. Relaxed circular (RC) virion DNA is converted into covalently closed circular (CCC) DNA (1), the template for transcription of pgRNA (2). The terminal redundancy (R), the packaging signal, termed epsilon, and the position of the direct repeats DR1 and DR2 on pgRNA are indicated. The polymerase (shaded oval) binds to epsilon at the 5′ end of the pregenome to prime negative-strand DNA synthesis from a tyrosine residue on the reverse transcriptase (3). Following a template switch to the 3′ end of the RNA template, DNA synthesis continues toward the 5′ end of pgRNA (4). The result is a negative-strand DNA with a short terminal redundancy (r) that remains covalently attached to the polymerase (5). An RNA oligomer spanning the 5′ end of pgRNA including DR1 is transferred to an internal acceptor site (DR2) on negative-strand DNA to prime positive-strand DNA synthesis (6). Following the synthesis of positive strands to the 5′ end of negative strand DNA a template switch, facilitated by the r region, is required to continue DNA synthesis and leads to the formation of RC DNA (7).

of negative-strand DNA and the synthesis of a 3–4 nucleotide-long DNA strand. The template for this reaction is the RNA packaging signal epsilon (**Fig. 2**). Following a template switch, the reverse transcriptase continues to elongate DNA from DR1 near the 3′ end of pgRNA. After the completion of negative-strand DNA synthesis, a capped RNA oligomer originating from the 5′ end of pgRNA containing a copy of DR1 is transferred to DR2 on negative-strand DNA, where it functions as a primer for positive-strand DNA synthesis. Once the nascent positive-strand reaches the 5′ end of negative-strand DNA, a template switch to the 3′ end of negative-strand DNA is necessary to continue DNA synthesis. Facilitated by a short redundancy at the ends of negative-strand DNA, this strand transfer accounts for the formation of the relaxed circular structure of virion DNA.

During viral DNA synthesis, core particles gain the ability to interact with L envelope polypeptides retained in membranes of the endoplasmic reticulum. This step leads to the translocation of cores into the lumen of the endoplasmic reticulum and to the assembly with the viral envelope components. Viral particles assemble into mature Dane particles as they pass through the secretory pathway. After they have traversed the Golgi, they exit the infected hepatocyte through a budding step. Aggregates of S antigen can enter the same pathway independently of nucleocapsids, which leads to the secretion of 20 nm subviral particles, the major viral components present in sera of HBV-infected patients.

Inferring from studies with an avian hepadnavirus, intracellular core particles can also enter an alternate pathway leading to the amplification of CCC DNA in the nucleus of the infected hepatocyte. Presumably, cores are redirected into the same pathway used for the formation of CCC DNA during infection. This mechanism is believed to play a major role in the maintenance of viral DNA in infected hepatocytes and thus, for the observed persistence of viral infection.

Transcription

CCC DNA is the template for the transcription of the viral RNAs. In HBV-infected liver, three classes of unspliced viral transcripts have been identified with 5′ ends located near the beginning of the precore, L and M ORFs (**Fig. 1**). All three transcripts terminate at a common polyadenylation site present in the HBcAg coding region. Transport of the unspliced mRNAs from the nucleus into the cytoplasm appears to depend on sequences located between the surface and X genes. It has been suggested that this region bears a signal similar to the so-called rev response

element (RRE) on human immunodeficiency virus (HIV). However, a protein factor that binds to this signal on HBV RNA remains to be identified.

The 3.4 kb transcript spans the entire genome and has terminally redundant ends. In addition to its role in DNA replication, it serves as mRNA for the translation of the HBcAg and the reverse transcriptase and is referred to as pgRNA or C-mRNA. A subspecies of C-mRNA with a short extension at its 5′ end is the template for the translation of the precore polypeptide (HBeAg). The 2.4 kb-long transcript, termed L- or preS-mRNA, directs the translation of the L protein. This transcript appears to be unique to HBV since it has, so far, not been detected in WHV- or GSHV-infected liver tissue. The 2.1 kb-long S-mRNA has heterogeneous 5′ ends that bracket the initiation codon for the M-protein. S-mRNA transcripts that initiate upstream of the translational start signal lead to the synthesis of the M polypeptide, whereas the shorter transcripts serve as templates for the synthesis of the S-protein. A fourth mRNA that could serve as the template for the translation of the X protein has been identified in tissue culture cells transfected with subgenomic HBV fragments. So far, an X-mRNA has not been identified in RNA purified from HBV-, WHV- or GSHV-infected livers. Transcription of the three mRNAs is controlled by distinct promoters located adjacent to the 5′ ends of each mRNA species and two enhancers (enhancer I and II) overlapping with the 3′ end of the polymerase gene and the X coding region (**Fig. 1**). Enhancer I bears binding sites for the transcription factors C/EBP, NF-1, HNF-3, RARE and EF-C and enhancer II for HNF-3, Sp1 and C/EBP.

Translation

Translation of the precore, core, preS1 and S transcripts occurs at the 5′ proximal AUG initiation codon of their respective mRNA templates. In contrast, translation of the polymerase polypeptide begins at an internal AUG codon on C-mRNA (**Fig. 1**). Expression of the polymerase is cap-dependent, suggesting that translation occurs by ribosomal scanning and not by internal landing of ribosomes upstream of the polymerase ORF. Translation of the X polypeptide most likely occurs from the first AUG present in this coding region. However, information on the exact mechanism of X translation *in vivo* depends on the identification of the mRNA used for X expression. As mentioned under Transcription, an mRNA for the expression of the L protein has so far not been identified in WHV or GSHV infected livers. Therefore, it is possible that the L protein of the rodent viruses is translated from C-mRNA by a mechanism similar to that postulated for the expression of the polymerase gene. Whereas translation of the three envelope proteins occurs on membranes of the endoplasmic reticulum the synthesis of the core, polymerase and X proteins takes place on free ribosomes in the cytoplasm of infected cells.

Role of Hepatitis B Virus in Liver Cancer

A consequence of chronic HBV infection is the development of hepatocellular carcinoma (HCC). Although viral DNA integration is not required for genome replication in hepadnaviruses, the large majority of tumors contain viral DNA sequences inserted into chromosomal DNA. The mechanism for DNA integration is not known. The pattern of integrated viral DNA generally reflects a clonal origin of the tumor and indicates that DNA integration is an early event in the development of HCC. Therefore, it has been proposed that viral DNA integration could play an active role in the progression of liver cancer, i.e. through the activation of proto-oncogenes as it occurs with certain retroviruses. Contrary to expectations, extensive analyses of DNA samples obtained from human HCCs failed to reveal any common integration sites for HBV sequences. However, analyses of DNA samples obtained from woodchuck HCCs identified a pseudogene of N-*myc* 2 as a major target for viral DNA integrations in this animal model.

In addition to viral DNA integration, expression of viral genes has also been considered to play a role in HCC formation. Spurred by a report demonstrating the occurrence of liver neoplasms in transgenic mice expressing the X polypeptide, much attention has been directed to understanding the function of this protein in tissue culture cells. As described under Properties of Viral Proteins, X can exhibit many different functions under selected assay conditions and, at present, it is not clear which, if any, of these properties contribute to HCC formation during a natural infection.

Avian Hepatitis B Virus

William Mason, Fox Chase Cancer Center, Philadelphia, Pennsylvania, USA

Patricia Marion, Division of Gastroenterology, Stanford University Medical Center, Stanford, California, USA

History

At present, only two species of avian hepadnaviruses have been identified and well characterized: duck hepatitis B virus and heron hepatitis B virus. Duck hepatitis B virus was first discovered in 1979 in duck (*Anas domesticus platyrhynchos*) serum samples collected in the People's Republic of China. The discovery that ducks might be carriers of a hepadnavirus followed the observation that ducks in certain areas of China had a high incidence of primary hepatocellular carcinoma. This cancer was already known to be of common occurrence in humans infected with hepatitis B virus, which led to the idea that a similar virus might be present in ducks. Subsequent research has neither sustained nor refuted the possibility that infection contributed to the liver cancer that had been observed in the ducks, which may, instead, have been caused by environmental carcinogens.

A second avian hepadnavirus species was discovered in 1988 in the sera of grey herons (*Ardea cinerea*) from Germany. The discovery of this second virus was facilitated by the fact that its DNA genome hybridized with a radioactive probe prepared from the cloned genome of the duck hepatitis B virus, indicating that the two viruses share considerable DNA sequence homology, as was subsequently shown by comparing the complete sequences of the two viruses.

A preliminary report suggests the existence of an avian hepadnavirus, possibly distinct from the duck or heron viruses, in the Australian woodduck (*Chenonetta jubata*). A novel strain of duck hepatitis B virus has also been isolated from the Ross goose (H. Shi, J. Cullen, and J. Newbold, personal communication; GenBank accession no. M95589).

Classification

The *Hepadnaviridae* family has been divided into two genera: *Orthohepadnavirus*, of which human hepatitis B virus is the prototype, and *Avihepadnavirus*, of which duck hepatitis B virus is the prototype.

Properties of the Genome

All members of the *Hepadnaviridae* family have a partially double-stranded DNA genome of about 3 kb that is held in a circular conformation by a short cohesive overlap between the 5′ ends of the two DNA strands (**Fig. 1**). One strand is always complete in virus particles, whereas the second strand is incomplete, with a 3′ end that is heterogeneous in location. The incomplete strand is of plus polarity and the complete strand of negative polarity. When these viruses infect a cell, the plus strand is completed and the fully double-stranded DNA is then converted to a covalently-closed circular (CCC) molecule, which serves as a template for viral RNA synthesis (**Fig. 2**). The two genera of hepadnaviruses are thought to differ in that orthohepadnaviruses encode four open reading frames (ORFs) whereas the prototypic avihepadnavirus, duck hepatitis B virus, encodes only three, lacking the X ORF. This ORF appears to encode a protein that modulates transcription, possibly by acting on signal transduction pathways. There is now evidence for a fourth ORF in heron hepatitis B virus and in Ross goose virus, capable of coding for a 7–8 kDa protein, in the same genomic location as the C-terminal half of the X ORF of the orthohepadnaviruses. Functional studies on this ORF have not been reported. With one exception, the known products of the different ORFs are each translated from distinct mRNAs, transcribed from one of the four (*Orthohepadnavirus*) or three (*Avihepadnavirus*) viral promoters. The major nucleocapsid protein and the product of the polymerase gene appear to be encoded by the same mRNA, the pregenome, which also serves as the template for viral DNA synthesis. It was originally thought that mRNA splicing did not have a role in virus replication; however, it was recently found that the larger (L) of the two envelope proteins of duck hepatitis B virus is translated both from a spliced mRNA as well as from an unspliced mRNA. The spliced mRNA is transcribed from the major nucleocapsid promoter, located about 1200 bp upstream of the start codon for the large envelope protein. The unspliced mRNA is synthesized from a promoter located immediately upstream of the ORF for the large envelope protein (**Fig. 1**).

All hepadnaviruses replicate their DNA by reverse transcription of a viral RNA, a process which takes

HEPATITIS A VIRUS (*PICORNAVIRIDAE*)

Michael R Beard and **Stanley M Lemon**, Department of Microbiology and Immunology, The University of Texas Medical Branch at Galveston, Medical Research Building, 301 University Boulevard, Galveston, Texas, USA

History

Descriptions of epidemic human disease resembling acute hepatitis A extend back into antiquity, although the specific etiologies of these outbreaks remain unknown. Acute infectious hepatitis was first recognized as a transmissible entity in the early twentieth century and was clearly separated from homologous serum hepatitis (hepatitis B infection) during World War II. The virus responsible for hepatitis A was identified by immune electron microscopy in 1973 by Feinstone *et al*. Replication of hepatitis A virus (HAV) in monkey kidney cell cultures was reported by Provost *et al* in 1979. Although virus replication was noncytopathic, Lemon *et al* described a radioimmunofocus assay for quantitation of infectious HAV in 1983. The RNA genome of HAV was molecularly cloned by Ticehurst *et al* in 1983, and the first full-length nucleotide sequences of HAVs were reported in 1987 by Najarian *et al* and Cohen *et al*. These studies revealed that the genomic organization of HAV was similar to that of other picornaviruses, with a single large open reading frame (ORF) encoding a polyprotein which is cotranslationally processed during replication of the virus. The first infectious cDNA clone of HAV was reported by Cohen *et al* in 1988.

Taxonomy and Classification

HAV is classified within the genus *Hepatovirus* of the family *Picornaviridae*. This classification is based on several unique features of HAV: liver cell tropism, small and possibly absent VP4 protein, a unique VP1-2A precursor protein (pX), striking thermostability, a relatively slow and usually noncytopathic replication cycle and a strong tendency to initiate persistent infections in cell culture. The nucleotide sequence of HAV, while relatively well conserved among different isolates, is also widely divergent from those of the other picornaviral genera.

Properties of the Virion

The virion is approximately 27 nm in diameter and appears roughly spherical by electron microscopy. Based on the known structure of other picornaviruses, the HAV capsid is thought to have icosahedral symmetry and to contain 60 copies of each of three major polypeptides: 1B (VP2), 1C (VP3) and 1D (VP1). It is not known whether HAV contains a fourth, smaller capsid protein (1A, or VP4) that is present in other picornaviruses, although the genome of HAV potentially encodes a 1A protein of 21–23 residues. This 1A sequence contains an internal consensus myristoylation site, indicating the possibility of a very short L protein. However, mutagenesis of this site revealed no apparent requirement for myristoylation in HAV replication. HAV preparations made from infected cell cultures typically contain large quantities of empty capsids. These capsids are composed of three polypeptides 1AB (VP0, the precursor of VP2 and VP4), 1C and 1D. 1AB of the empty capsid is larger than 1B present in the complete virion, indicating that maturation cleavage of 1AB occurs in HAV as in other picornaviruses. What remains unknown, however, is whether the 1A protein is incorporated into the virion. Another difference from other picornaviruses is that virion precursors appear to contain unprocessed 1D2A. The function of this precusor protein (termed 'pX') is unknown.

Virions display a conformationally defined immunodominant neutralization antigenic site, in which Asp70 of 1C plays a prominent role. Amino acid residues of 1D also contribute to this antigenic site, as well as to at least one other functionally independent, minor antigenic site. This dominant antigenic site of HAV is highly conserved among all human strains. Reversion of neutralization escape mutants isolated in culture to the wild-type antigenic phenotype has been noted in experimentally infected New World owl monkeys, providing additional evidence for the importance of this antigenic site. Extensive digestion with high concentrations of trypsin and chymotrypsin results in cleavage primarily of 1B, but does not alter the antigenic characteristics, infectivity or exceptional thermal stability of the virion.

Properties of the Genome

The HAV genome is a single-stranded, positive-sense RNA, approximately 7500 bases in length (**Fig. 1**). As in other members of the picornavirus family, a short genome-linked protein (3B or VPg) is covalently

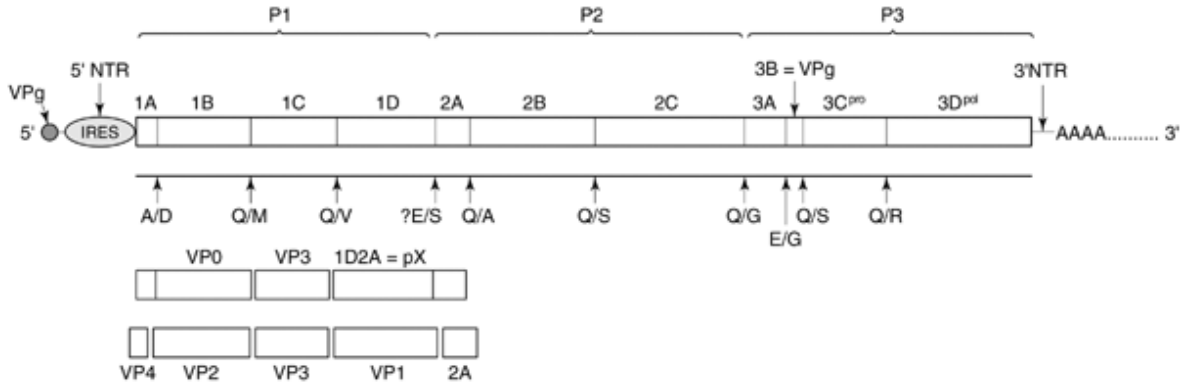

Figure 1 Organization of the positive-stranded RNA genome of hepatitis A virus. There is a small protein (VPg or 3B) attached to the 5′ terminus, followed by a nontranslated region of approximately 735 bases. A large open reading frame encodes the polyprotein that has three major domains: P1 (capsid proteins), P2 and P3 (nonstructural proteins). The primary cleavage event mediated by $3C^{pro}$ occurs at the 2A/2B junction and generates a P12A fusion, after which secondary cleavage by $3C^{pro}$ generates individual proteins and a 1D2A fusion protein termed pX. Arrows indicate authentic and predicted $3C^{pro}$ cleavage sites as determined experimentally. The processing of the P1 structural proteins that comprise the virus capsid is shown in detail. The final maturation cleavage of 1AB (VP0) to 1A (VP4) and 1B (VP2) occurs only after encapsidation of the RNA and is not mediated by $3C^{pro}$. The large open reading frame is followed by a short 3′ nontranslated region, and a 3′ terminal poly(A) tract. IRES, internal ribosome entry site.

linked to the 5′ end of the RNA, while at the 3′ end is a poly(A) tract. Flanking the single large ORF are 5′ and 3′ nontranslated regions (5′ NTR and 3′ NTR) of aproximately 735 and 64 bases, respectively. These regions form an extensive RNA secondary structure containing elements necessary for viral replication. In addition, the 5′ NTR plays an essential role in translation of the HAV polyprotein.

The 5′ NTR is relatively conserved among HAV strains (generally >92% nucleotide identity). There is no sequence similarity with other picornaviruses, but its structure and organization are similar to that of the 5′ NTRs of aphthoviruses and cardioviruses. There are two major functional domains. The larger, located between nucleotides 152 and 735, contains an internal ribosome entry site (IRES) which directs the 40S ribosomal subunit to bind to the RNA and initiate translation internally in a cap-independent manner. Several host cell proteins, including polypyrimidine tract-binding protein (PTB) and glyceraldehyde 3-phosphate dehydrogenase (GAPDH), bind to the *cis*-acting IRES and may influence translation. The smaller 5′ NTR domain, comprising the 5′ ~ 150 nt, contains three stem-loop structures (two of which likely form RNA pseudoknots), a pyrimidine-rich tract, 'pY1', and a short downstream single-stranded RNA segment. Recent evidence indicates that the pY1 segment forms extensive noncanonical base pair interactions involving U-U base pairs (**Fig. 2**). Removal of the pY1 domain does not impair HAV replication; however, extension of the deletion in a 3′ direction into the downstream single-stranded segment results in a temperature-sensitive replication phenotype due to defective RNA synthesis.

The ORF shares a general organization with other picornaviruses, and encodes the following proteins in a 5′ to 3′ order: 1A, 1B, 1C, 1D (the capsid proteins), 2A, 2B, 2C, 3A, 3B (or VPg), $3C^{pro}$ and $3D^{pol}$. These are expressed as a single large polyprotein. Considerably greater sequence variation is evident within the large ORF than in the 5′ and 3′ NTRs, and several distinct genotypes of HAV have been described. These have been defined as groups of strains with >15% nonidentity within the 1D/2A (pX) coding region.

The 3′ NTR is comprised of a short RNA segment which appears to be highly structured, and a 3′ terminal poly(A) segment of uncertain length.

Properties of the Viral Proteins

Compared with other picornaviruses, the proteolytic processing of the HAV polyprotein has been difficult to characterize due to the protracted replication cycle and lack of shut down of host-cell protein synthesis. None the less, most polyprotein cleavage sites have been identified. With the exception of the 1B/1A maturation cleavage, and possibly the 1D/2A cleavage, these cleavages are mediated by the nonstructural $3C^{pro}$ proteinase. The primary cleavage event occurs at the 2A/2B junction, as in the cardioviruses and aphthoviruses.

The structural proteins, 1A–D, are discussed above under Properties of the Virion. Less is known about

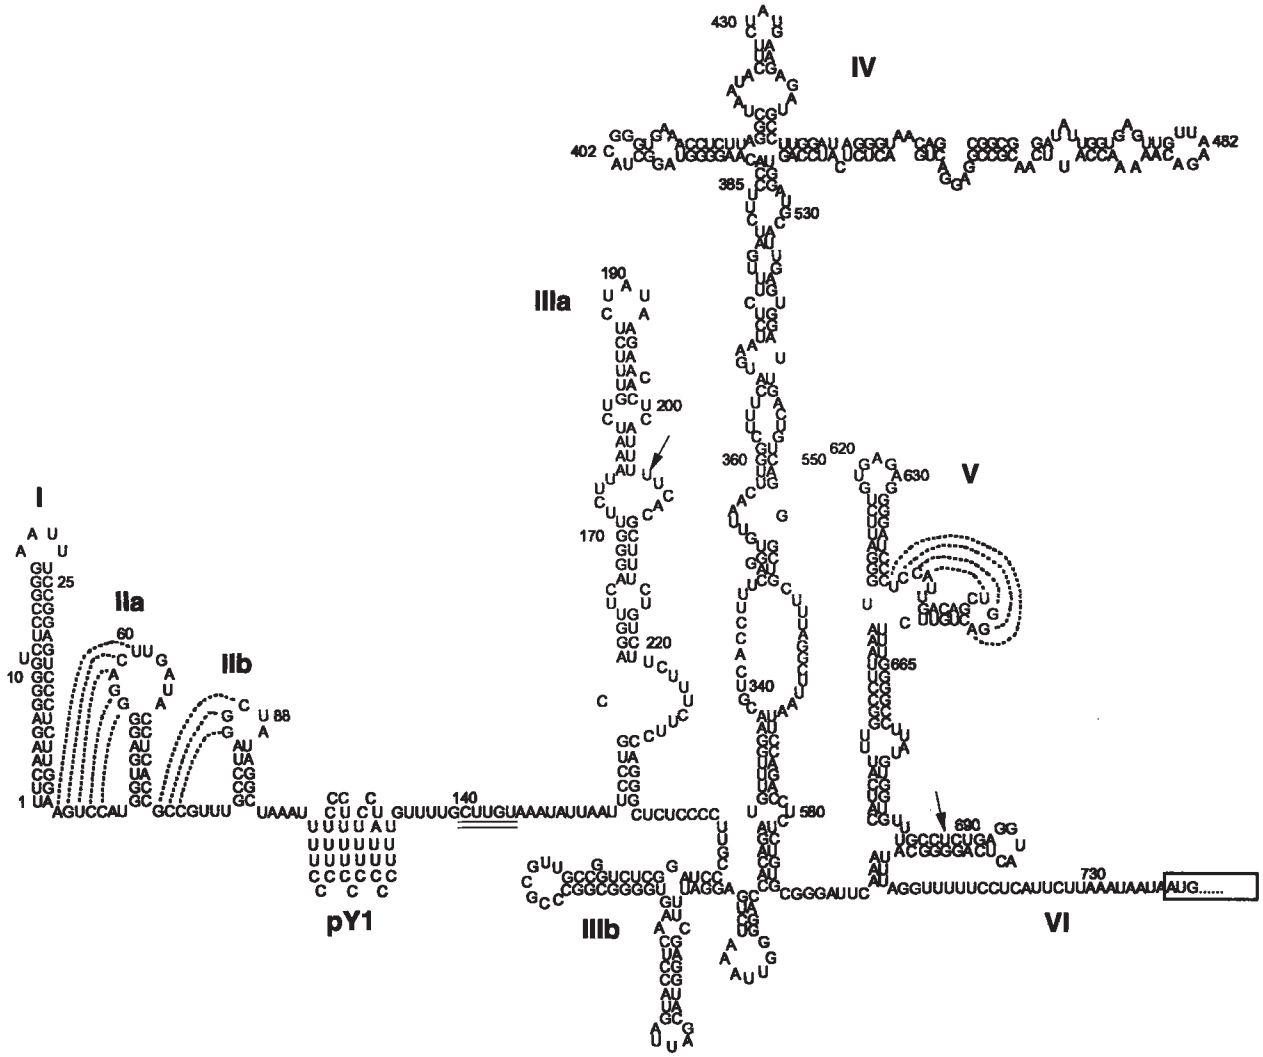

Figure 2 Putative secondary and tertiary structure of the 5′ nontranslated segment of HAV RNA from the wild-type HM175 strain as determined by a combination of comparative sequence analysis, thermodynamic modeling and nuclease probing of synthetic RNA. Major structural domains are labeled I through VI. Dotted lines indicate possible base pair interactions that result in RNA pseudoknots. The segment between nt 1 and nt 152 contains a pyrimidine-rich tract, pY1, within which there is prominent noncanonical U-U base pairing and an immediately downstream single-stranded segment, within which deletions confer a temperature-sensitive replication phenotype (indicated by double underline). The internal ribosome entry site extends from stem-loop IIIA to the first AUG within the large open reading frame (boxed). Arrows indicate sites of mutations that enhance translation and viral replication in cultured cells.

the specific functions of the nonstructural proteins of HAV. For example, the function of 2A remains unknown. It does not contain a proteinase sequence motif, such as found in the 2A protein of poliovirus, and it is unrelated to 2A sequences of other picornaviruses. Viruses with deletions of up to 15 amino acids within 2A have a reduced replication efficiency in cultured cells, but remain infectious when inoculated into chimpanzees. Proteins 2B and 2C play poorly characterized roles in replication. Expression of 2C and 2BC in cultured cells induces rearrangement of intracellular membranes. 2C has NTPase activity, and may be an RNA helicase. Mutations in these proteins are important with respect to a host range change that occurs during adaptation and passage of virus in cell culture (see below). These mutations also contribute to attenuation of the virus.

The function of the 3A protein is unknown, but preliminary data suggest it may associate with cellular membranes, possibly forming a membrane anchor for the replication complex. 3B is the 5′ genome-linked protein (VPg), and it is likely to serve as a primer for RNA synthesis. $3C^{pro}$ is the proteinase that directs the posttranslational processing of the HAV polyprotein.

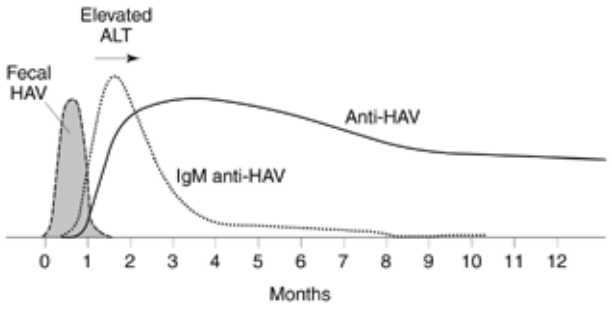

Figure 3 Clinical and virological course of events in acute hepatitis A. The time axis indicates months following exposure to the virus. ALT, serum alanine aminotransferase activity.

Among the nonstructural proteins, it has been characterized in greatest detail, with its structure defined by X-ray crystallography at a resolution of 0.2 nm (2.0 Å). The proteinase has a twofold domain structure characteristic of the chymotrypsin-like serine proteinases. In addition to its role in proteolysis, 3C contains an RNA-binding motif and is capable of binding to multiple sites within the 5′ terminal genomic RNA, suggesting a potential role in replication. Sequence analysis suggests that $3D^{pol}$ is an RNA-dependent RNA polymerase, but this activity has never been expressed *in vitro*.

Physical Properties

The HAV particle has a sedimentation constant of approximately 155 S, and a buoyant density of 1.325 g ml^{-1} in CsCl. 'Heavy particles', which have a buoyant density of about 1.44 g ml^{-1}, appear to have greater permeability to Cs^{2+} and thus resemble heavy poliovirus particles. Lighter particles which are also infectious and resistant to chloroform extraction have also been described, as well as very light particles which can be eliminated by chloroform extraction and most likely have residual associated lipids. A striking property of the HAV particle, which may well contribute to its potential for epidemic spread, is its resistance to thermal inactivation. Significant losses of infectivity (greater than a $\log_{10}$) over a 10 min exposure period are encountered only above 55°C. In the presence of 1 mol $MgCl^2$, this thermal stability is substantially enhanced, with the virus surviving incubation at 70°C for up to 10 min with only a 1–2 $\log_{10}$ loss of infectivity. The HAV particle is also remarkably resistant to low pH conditions, with little loss of infectivity reported at pH 1.0. The virus is relatively resistant to detergent inactivation, easily surviving 37°C for 30 min in 1% sodium dodecyl sulfate. There is no information concerning the radiation sensitivity.

The empty capsid has a sedimentation constant of about 70 S. Possible assembly intermediates (about 135 S) have been described which are enriched in their content of 1D2A (pX).

Replication

Although HAV demonstrates some unique features, such as a very protracted replication cycle, it is generally considered to replicate by a mechanism similar to that of other picornaviruses. Differences in various reports describing replication of HAV in cell culture may reflect significant differences in the extent to which the particular virus strains that have been studied have been adapted to growth in cell culture.

The virus binds to a wide range of cultured cells in a calcium-dependent manner. However, this binding does not necessarily correlate with internalization and establishment of a productive infection. A candidate HAV receptor protein has been recently identified. Expression cloning and nucleotide sequence analysis of a cDNA coding for this candidate receptor revealed it to be a novel, mucin-like class I integral membrane glycoprotein of 451 amino acids. Transfection of cDNA coding for this putative receptor resulted in HAV binding and increased susceptibility to infection in mouse LtK−cells. However, further studies are needed to confirm the functional significance of this putative receptor in HAV infection *in vivo*.

Replication of the genome proceeds via a negative-strand RNA intermediate, present in very small quantities in infected cells. Following infection of permissive cell cultures with cell culture-adapted virus, replication of the viral RNA occurs over several days. New RNA synthesis is then reduced in magnitude as persistent infection becomes established. The factors responsible for this downregulation in viral RNA synthesis remain unknown. Contrary to the situation with other picornaviruses, almost all positive-strand RNA present within infected cells is encapsidated. It has been suggested that a uniquely high affinity of this RNA for the capsid proteins results in its rapid encapsulation, thereby reducing the amount of RNA available to serve as template for further replication. While an interesting hypothesis, it is unlikely that this is the major cause of the relatively slow and restricted growth of HAV in cell culture. Viral antigen continues to accumulate after maximal infectivity has been reached in infections carried out at low multiplicity of infection. The reasons for this are not clear, but in some systems empty capsids represent the dominant form of antigenic material that is harvested from infected

cells. Early studies described defective particles containing RNA with large deletions putatively extending from the PI (capsid-encoding segment) into the nonstructural region of the genome. There have been no recent confirmations of these reports.

As in other picornaviruses, viral translation is initiated under control of an IRES located within the 5′ NTR. If any ribosome scanning is involved, it is confined to a short region just upstream of the two AUGs initiating the large ORF (codons 1 and 3). Compared with other picornaviral IRESs, the HAV IRES is extremely inefficient, a feature that may contribute to the generally slow and noncytolytic replication of the virus. The IRES interacts with *trans*-acting cellular factors that initiate cap-independent translation by positioning the 40S ribosomal subunit in a favorable position for translation. In contrast to other viral IRESs, the HAV IRES activity has a unique requirement for intact eukaryotic initiation factor eIF-4G, the p220 component of eIF-4F that is cleaved by proteinases expressed by several other picornaviruses. There is no cleavage of p220 in HAV-infected cells, explaining in part the absence of host cell shutdown and cytopathic effect. Several putative noncanonical *trans*-acting translational factors have been identified. Characterized in most detail is PTB, a 57 kDa protein that is normally involved in nuclear pre-mRNA splicing. PTB binds to picornavirus 5′NTRs, including that of HAV, and appears to be capable of significantly upregulating HAV translation *in vivo*. More recently a 5′ NTR-binding protein of 37 kDa was identified as GAPDH. GAPHD appears to destabilize important RNA base pair interactions within the IRES. Competition experiments have shown that PTB and GAPDH compete for binding to stem-loop IIIA, suggesting that the relative cytoplasmic levels of the two proteins may influence the translational activity of the HAV 5′ NTR.

There is very little information available concerning the specific mechanisms by which new viral RNA is primed and synthesized within infected cells. However, as in other picornaviruses, this occurs in an asymmetric fashion with much greater increases in positive-strand RNA than in the negative-strand RNA intermediate. It is likely that the 5′ and 3′ terminal structures participate in forming different and specific replicase complexes that are required for the initiation of synthesis of the two forms of viral RNA, and that each of the nonstructural proteins (2B-$3D^{pol}$) play roles in these processes. The site of virus assembly and the means by which HAV exits the cell are also unknown, although HAV has been found within cytoplasmic vesicles in infected cells in the liver. The virus is secreted from the apical surface of polarized, cultured gastrointestinal epithelial cells in the absence of cell death, and this may mimic the secretion of HAV across the apical hepatocyte membrane into biliary canaliculi *in vivo*.

Although HAV infection usually does not lead to demonstrable cytopathic effects, rapidly replicating, cytopathic (RR/CPE+) strains of HAV have been recovered from persistently infected cell cultures. These viruses induce a cytopathic effect characterized by vacuolation and cellular degeneration, but not associated with specific host cell metabolic shutdown.

Geographic and Seasonal Distribution

HAV is found in most human populations. However, the virus enjoys generally wider circulation in developing countries with relatively poor public sanitation standards. This is clearly related to the major mode of virus transmission, which is fecal–oral. Unlike enteroviruses, however, there is no clear-cut seasonal distribution for HAV infections. The incidence of hepatitis A infections may fluctuate widely in cycles extending over several decades.

Host Range and Virus Propagation

Only humans and several higher primate species are susceptible to human HAV. These primates include the chimpanzee (*Pan troglodytes*), New World owl monkey (*Aotus trivirgatus*) and various marmosets (*Saquinus mystax, S. labiatus*). Several macaque species have also been infected with HAV in various studies, but macaques are generally less susceptible than the other primates listed. Recently, several simian HAV strains that are genetically distinct but closely related to human HAV strains have been isolated from the African green monkey and from the cynomolgus monkey. It is not known whether humans are susceptible to infection with these simian 'biotypes', which appear to have a different host range than human HAV in other primates. These simian HAVs crossreact serologically with human HAV (see below) and are being evaluated for their ability to replicate and cause disease in chimpanzees.

The isolation of wild-type HAV in cell culture is a difficult, tedious and often lengthy procedure. Wild-type virus replicates slowly, is nearly always noncytopathic and tends to establish persistent infection. Generally speaking, only primate cells are permissive for HAV, although limited replication has been observed in mouse hepatocyte cultures and cells originating from dolphins. The most commonly used cell types are primary or continuous green monkey kidney cells. The initial isolation of virus in cell culture may be enhanced by prior passage in nonhuman primates. Certainly, with successive passage in

cell culture, the virus may become reasonably well adapted to propagation in a variety of primate cell types, including HeLa cells. Such cell culture-adapted strains often demonstrate a limited ability to replicate and cause disease in either humans or other susceptible primate species. This host-range change is the basis for the candidate attenuated HAV vaccines tested in humans thus far. Certain highly cell culture-adapted variants replicate more rapidly in cell culture and cause cytopathic effects (RR/CPE+ phenotype). However, even with these RR/CPE+ strains, up to 24 h is required to reach maximum virus yields in one-step growth curve experiments. This replication phenotype results from a number of mutations throughout the genome.

Genetics

Most HAV strains recovered from humans are closely related genetically. However, four distinct human HAV genotypes have been identified, each of which differs from the others in sequence at > 15% of base positions within the genome segment encoding the 1D/2A junction. In addition, there are three distinct simian genotypes of HAV.

Mutations responsible for several virus phenotypes have been identified by sequence comparisons and by mutagenesis of infectious cDNA. The altered host range associated with adaptation of HAV to growth in cell cultures and attenuation of the virus in primates has been associated with mutations located within the P2 region of the genome (proteins 2B and 2C) and in the 5′ NTR of the HAV genome. Although mutations in the P2 region are of primary importance in cell culture adaptation, mutations in the 5′ NTR also contribute to a cell culture-adapted phenotype and act cooperatively with P2 mutations in enhancing viral replication. Mutations within the 2B coding region (nt 3889, leading to an Ala to Val substitution) and in the 2C coding region at nt 4087 (Lys to Met) and nt 4222 (Phe to Ser) enhance the growth of wild-type HAV in cultured cells. In addition, selected mutations in the 5′ NTR (UU deletion at nt 203/204 and a U-G substitution at nt 687) both enhance translation and replication in African green monkey (BSC-1) cells but not in fetal rhesus monkey (FRhK-4) cells. The presence of mutations at nt 203/204 and nt 687 in three independently isolated cell culture-adapted HAV isolates and the appearance of the 687 mutation in HAV that has been adapted for growth in human diploid (MRC-5) cells suggests that these mutations play an essential role in overcoming a restriction for growth in cultured cells. The sequencing of multiple virus variants has suggested that RNA recombination occurs between HAV genomes in persistently infected cells.

Evolution

Little is known of the evolution of HAV. At the nucleotide sequence level, HAV shows less relatedness to other picornaviruses than that which exists between each of the other picornaviral genera. Within the region of the genome encoding the capsid proteins, there is only about 25–30% nucleotide identity with other picornaviruses. At the amino acid level, there is greater relatedness with the aphthoviruses and cardioviruses. However, this varies with individual proteins, as VP3 is more related to VP3 of poliovirus type 1, Mahoney strain (about 24%). Overall, however, HAV appears to be closest to the cardioviruses and aphthoviruses in terms of its genome organization, details of the polyprotein processing scheme and IRES structure. Limited studies suggest significantly less genetic drift among HAV strains isolated over several decades than that which has been observed with poliovirus. Strains isolated over a 30 year period have shown a <3% genetic divergence in the 1D/2A region.

Serologic Relationships and Antigenic Variability

Human HAV isolates show no evidence of antigenic variability, and share no antigenic determinants with any of the other picornaviruses or human hepatitis agents. In keeping with the lack of antigenic variability among human HAV strains, the amino acid sequences of the capsid proteins are highly conserved. Indeed, intense conservation of the immunodominant antigenic sites of human HAV appears to be an important biologic characteristic of this virus. One RR/CPE+ variant acquired a spontaneous neutralization escape mutation in residue 70 of 1C during persistent passage in cell culture, but this mutation was rapidly selected against on cell-free passage of the virus. However, simian HAV isolates differ significantly from human HAV at epitopes that are immunodominant in the human strains, even though the simian viruses are recognized by polyclonal human antibody to HAV. These simian viruses appear similar to neutralization escape mutants which have been recovered from human virus passaged in the presence of monoclonal neutralizing antibodies, in that the amino acid sequence of the capsid protein 1C differs at residue 70 (Asp in all human wild-type strains).

Epidemiology

Most commonly, hepatitis A occurs as a sporadic infection and the most commonly identified risk factor for acquisition of hepatitis A is to have lived in the same household with another infected person. Seroprevalence studies demonstrate that HAV infection is widespread in most human populations. The prevalence of HAV antibodies is generally higher in older age groups, with the shape of the age-related seroprevalence curve largely determined by present and past public sanitation standards. In less well developed countries, where hygiene is poor and fecal–oral transmission of infectious agents common, the age-related prevalence of HAV antibodies suggests acquisition of infection by almost all members of society within the first 5 years of life. In contrast, in well-developed countries of Western Europe even older adults have low antibody prevalence. Generally speaking, the incidence of new HAV infections appears to be declining in most populations, usually in keeping with improved public sanitation. This may lead to paradoxic increases in related disease activity in some rapidly developing countries, because a declining overall prevalence of the virus leads to acquisition of infection at older ages, when the risk of associated hepatitis A disease is significantly greater.

Hepatitis A rates increased significantly among illicit users of injected drugs in the United States during the late 1980s, but disease rates have since declined in this group. Several large outbreaks of hepatitis A have also occurred among adult homosexual males in several urban regions. Additional groups at special risk for acquisition of hepatitis A are children attending preschool daycare centers, the staff responsible for the management of such centers, and the older siblings and parents of these children. Increased risks for HAV transmission exist within closed institutions, such as prisons and institutions for the care of developmentally delayed individuals. Occasional hospital-associated outbreaks of hepatitis A have also been described, usually involving infected infants held in neonatal intensive care units.

The exceptional stability of the HAV particle and the fact that considerable amounts of virus are shed in the feces of infected individuals provide an unusual opportunity for common-source outbreaks of hepatitis A. Such epidemics are frequently reported in association with infection of a food handler, and are often linked to contaminated food or drink. Some outbreaks have been associated with ingestion of uncooked filter-feeding shellfish, as these shellfish are capable of concentrating HAV from polluted waters. Blood transmission is a very uncommon cause of infection, although several outbreaks of hepatitis A in hemophilic patients were related to administration of contaminated coagulation factor VIII preparations.

Transmission and Tissue Tropism

HAV is shed in the feces of acutely infected individuals, and transmission of the infection is almost always by the fecal–oral route. Virus shed in the feces is largely replicated within hepatocytes in the liver, and gains access to the intestinal contents by passage through the biliary tract. However, recent studies suggest that there is also a second, probably primary, enteric replication site within epithelial cells of the small intestinal crypts. The presence in infected primates of viral antigen in Kupffer cells, splenic macrophages and along the glomerular basement membrane may reflect antigen trapping rather than local virus replication. A significant viremia (perhaps as high as 10^5 infectious particles per ml serum) is present for several weeks during acute infection, and blood donations collected during the asymptomatic early stages of infection have caused rare, but well-documented, cases of transfusion-associated hepatitis A. It is also likely that needle-borne transmission has contributed to HAV spread among illicit users of injected drugs. Virus has been found in saliva late in the course of infection, but its source (possibly blood) is not known. Sexual activity may influence HAV transmission, especially among homosexual males. This is probably due to enhanced fecal–oral transmission related to oral–anal contact. Heterosexual activity may similarly influence hepatitis A transmission, but the data are less convincing.

Pathogenicity

There are no known differences in the pathogenicity of different HAV strains, although few studies have examined this in detail. The currently available evidence suggests that HAV is not directly cytopathic for the hepatocyte, but rather induces disease through an immunopathologic mechanism. The most important factor influencing disease severity associated with HAV infection is patient age at the time of infection. Very young children, under the age of 2 years, seldom develop symptoms of classic viral hepatitis. Their infections, although possibly not asymptomatic, are seldom icteric. The reverse may be said for adults. In individuals above 18 years of age, most infections are symptomatic and as many as two-thirds may be icteric.

Unlike hepatitis B and hepatitis C viruses, HAV causes only acute hepatitis and has never been unequivocally associated with chronic disease or persistent infection. Although it has been suggested

that premature infants may experience relatively protracted infections, even highly immunocompromised individuals appear capable of clearing HAV infection.

The disease manifestations of HAV infection are limited almost exclusively to the liver. Meningoencephalitis has been reported in association with acute hepatitis A infection in several cases, but this is clearly very exceptional. Acute renal failure has been more frequently reported, but its etiology in this setting is unclear.

Clinical Features of Infection

The incubation period of hepatitis A is approximately 4 weeks, with a range of perhaps 2–6 weeks. During the incubation period, virus replicates in the liver and is shed in the feces at high titers despite the absence of symptoms (**Fig. 3**). This is particularly true near the end of the incubation period. Disease is typically abrupt in onset and may be associated early in the course with high fever. More characteristically, the onset of hepatitis A is marked by malaise, nausea, right upper quadrant tenderness, and eventually scleral icterus and jaundice, dark urine (at times the color of Coca-Cola and quite frothy) and light, clay-colored stool. The latter manifestations represent disruption of the normal clearance of bilirubin by the infected liver. Diarrhea may be common in children (up to 60% of infected children in at least one study) but is usually not reported by infected adults. The disease manifestations taper off over a period of several weeks following their initial onset. However, convalescence may be prolonged and a number of months may elapse before the individual fully regains a sense of well-being. Chronic liver disease is not a recognized complication of HAV infection, but in some genetically predisposed individuals, HAV infection may trigger an autoimmune chronic hepatitis.

Although hepatitis may be recognized on clinical grounds alone, various chemical parameters are helpful in the diagnosis. The serum alanine aminotransferase (ALT) activity is typically elevated many-fold above normal levels. Aspartate aminotransferase (AST) activity is also elevated, but usually to a lesser degree. These enzyme abnormalities are soon followed by an elevated serum bilirubin, up to 20 or 30 times normal levels, and increases in the serum alkaline phosphatase activity. The aminotransferase elevations reflect hepatocellular damage with release of these hepatocellular enzymes into the circulation, while elevations in the serum bilirubin and alkaline phosphatase activity relate to intrahepatic cholestasis. The erythocyte sedimentation rate may be elevated. Serum immunoglobulin levels are generally increased nonspecifically, and rheumatoid factors are found in a large proportion of patients. Clinically and biochemically, acute hepatitis due to HAV cannot be distinguished from that due to the other hepatitis viruses. Thus, serologic tests are necessary for a virus-specific diagnosis.

Pathology and Histopathology

The pathology of the liver in acute hepatitis A has been studied in both infected humans and susceptible primates, including chimpanzees, owl monkeys and several species of marmosets. Characteristic changes include vacuolation and degeneration of hepatocytes, and intense mononuclear cell infiltration, which is usually most prominent in the portal regions. At times, this periportal inflammation may include piecemeal necrosis and thus the histopathologic picture may be confused with more chronic forms of viral hepatitis. These histopathologic changes are relatively short-lived with HAV infection, however, and are largely resolved within several months of the acute infection. During acute hepatitis, viral antigen can be identified (by immunofluorescence) in a large proportion of hepatocytes as punctate, cytoplasmic fluorescence. Electron microscopy may reveal virus particles packed in cytoplasmic vesicles.

Immune Response

The humoral immune response to hepatitis A is well characterized. IgM class antibodies to the virion are present in almost all patients by the onset of symptoms, and persist for up to 6–12 months following infection (**Fig. 3**). IgA and IgG antibodies to HAV also appear within a few days of symptom onset. Both IgG and IgM antibodies have virus-neutralizing activity, and the efficacy of passively administered immunoglobulins in prevention of symptomatic hepatitis A suggests that IgG anti-HAV is protective against subsequent symptomatic reinfection. IgG antibody generally persists for the life of the individual, although that it may fall to less than detectable levels after several decades in individuals who were infected at a very early age. Secretory antibody to HAV has been detected by solid-phase immunoassays, but saliva and feces generally do not contain neutralizing antibodies. Current evidence suggests that mucosal immunity plays little, if any, role in protection against hepatitis A.

Limited studies have examined the cellular immune response to HAV infection. NK cell activity against HAV-infected fibroblasts has been described. In addition, human leukocyte antigen (HLA)-restricted T cell cytotoxicity has also been demonstrated in

individuals with acute hepatitis A. The cytotoxic effector cell is a CD8+ T lymphocyte. Immune T cells release interferon γ, in an HLA-dependent but not restricted fashion, upon exposure to HAV-infected fibroblasts. Interferon γ may promote HLA-restricted cytotoxicity by upregulating the normally low-level display of HLA antigens by hepatocytes. Specific T cell epitopes have not been extensively characterized.

Prevention and Control

As almost all hepatitis A infections are transmitted by the fecal–oral route, good sanitation practices, including high standards of quality for public water supplies, have resulted in a low prevalence of HAV infections in many well-developed societies. Individual protection may be afforded by the passive administration of immune serum globulin, which consists of pooled IgG from a large number of individuals and normally contains a substantial titer of neutralizing antibodies to HAV. Such passive immunoprophylaxis provides transient protection of >80% efficacy. Passively administered IgG both prevents infection and modifies symptoms in those already infected, provided it is given within 2 weeks of exposure.

Active immunization against hepatitis A can be achieved with inactivated HAV vaccines produced by several commercial manufacturers. These vaccines consist of HAV that has been propagated in cell culture, purified and inactivated with formalin. The virus strains used in vaccine production have been adapted to growth in cell culture and are attenuated in their ability to cause disease in susceptible primates. A single dose of purified viral antigen, consisting of both full and empty viral particles, results in seroconversion in most individuals. Antibody levels are greater than those achieved by passive administration of immune serum globulin, but lower than those present following natural infection. The clinical efficacy of these vaccines has been demonstrated in controlled clinical trials to be in excess of 95%. Candidate attenuated HAV vaccines, containing virus adapted to growth in cell culture and extensively passaged in cell culture, have also been tested in humans. These candidate vaccine viruses have a markedly reduced ability to replicate in the liver following parenteral inoculation and have generally demonstrated poor immunogenicity.

HEPATITIS C VIRUS (*FLAVIVIRIDAE*)

Robert H Purcell, Laboratory of Infectious Diseases, National Institute of Allergy & Infectious Disease, Bethesda, Maryland, USA

History

The recognition of the existence of hepatitis C virus (HCV) is a relatively recent event. In 1975, Feinstone and colleagues demonstrated that most cases of transfusion-associated hepatitis were caused by neither hepatitis A virus (HAV) nor hepatitis B virus (HBV), the only two recognized human hepatitis viruses at the time. In retrospect, there were clues to the existence of additional hepatitis viruses. These included the demonstration of multiple cases of hepatitis in drug addicts and hemophiliacs, the high rate of chronicity in non-B transfusion-associated hepatitis (HAV does not progress to chronicity) and the unimodal distribution of incubation periods of transfusion-associated hepatitis centering on 7–8 weeks, intermediate between the modal incubation periods of HAV infection (3–4 weeks) and HBV infection (12–14 weeks).

The disease associated with this newly recognized hepatitis was called 'non-A, non-B' hepatitis and the presumed etiologic agent 'non-A, non-B' hepatitis virus because it was not known whether the disease was caused by one or more viruses. It was not until 1989 that a test specific for the virus responsible for most transfusion-associated hepatitis was developed and the virus was named hepatitis C virus (HCV).

Taxonomy and Classification

Hepatitis C virus is the only member of the genus *Hepacivirus* within the virus family *Flaviviridae*. The genome of HCV is organized in a manner similar to that of the flaviviruses and pestiviruses, which constitute the other two genera, *Flavivirus* and *Pestivirus*, respectively, within the family *Flaviviridae*. Although only distantly related to these two groups of viruses, HCV does share some sequence identity and is slightly more closely related to the pestiviruses than to the flaviviruses. Interestingly, parts of the HCV genome appear to be distantly related to potyviruses and carmoviruses of plants. The former are members of the picornavirus-like superfamily and the latter are members of the alphavirus-like superfamily. These distant relationships suggest a common evolutionary origin of plant and animal viruses.

Properties of the Virion and Genome

Properties of the virion

Virions are approximately 50 nm in diameter, as determined by filtration and electron microscopy (**Fig. 1**). They have a spherical shape and are bounded by a lipid-containing envelope consisting of at least two structural glycoproteins. The nucleocapsid is spherical and approximately 30 nm in diameter.

Properties of the genome

The genome of HCV is single-stranded linear RNA of positive sense. It is unsegmented and consists of a 5′ untranslated region of approximately 340 nucleotides (nt) that contains an internal ribosomal entry site (IRES) and several small, presumably untranslated, open reading frames (ORFs); a protein-encoding region (ORF) of approximately 9400 nucleotides, which encodes a large polyprotein precursor of approximately 3000 amino acids; and a 3′ untranslated region that is surprisingly complex and contains a variable region (approximately 50 nt), a polypyrimidine region of approximately 100 nt but variable in length and a highly conserved terminal region of approximately 100 nt that is predicted to have a complex secondary structure.

The ORF encodes three (or four) structural proteins at its 5′ end and six (or seven) nonstructural proteins at its 3′ end (**Fig. 2**). The gene order is: 5′-core (*C*)–envelope 1(*E1*)–envelope 2(*E2*)–P7–nonstructural protein 2 (*NS2*)–nonstructural protein 3 (*NS3*)–nonstructural protein 4A (*NS4A*)–nonstructural protein 4B (*NS4B*)–nonstructural protein 5A (*NS5A*)–nonstructural protein 5B (*NS5B*)–3′. The small protein (p7) encoded between the three structural proteins and the six nonstructural proteins is of unknown function; it is not clear whether it is a structural or nonstructural protein but an analogous protein encoded by pestiviruses is not a part of the virion.

Properties of the Viral Proteins

The polyprotein of approximately 3000 amino acids that is encoded by the single ORF of HCV is cotranslationally and post-translationally cleaved into approximately 10 proteins. The proteins at the amino-terminus of the polyprotein are: a nonglycosyl-

ated nucleocapsid (core) protein of approximately 19 kDa and two glycosylated envelope proteins of approximately 31 and 70 kDa, respectively. The P7 protein is inefficiently cleaved from the precursor of E2 and exists in two forms, E2-P7 and P7; their ultimate disposition is unknown. The two envelope

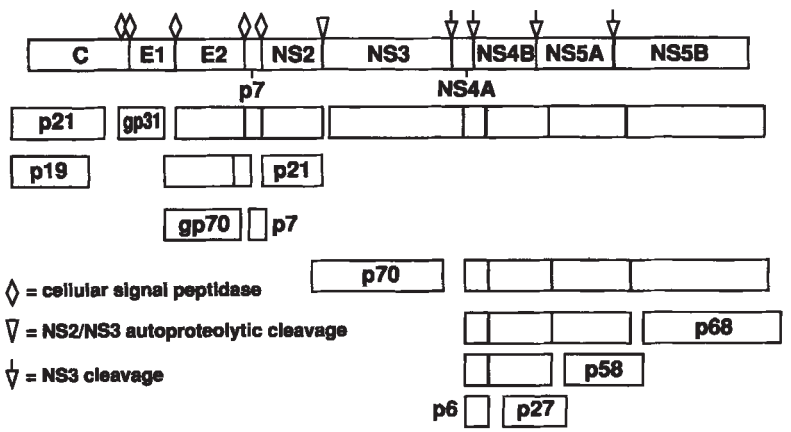

Figure 2 Predicted structure and processing of the HCV polyprotein by host and viral proteases. The viral coding region is displayed at the top. Boxes indicate precursors and mature proteins generated by processing. Approximate sizes of the mature proteins (p) and glycoproteins (gp) are indicated. (Adapted, with permission, from Major ME and Feinstone SM (1997) The molecular virology of hepatitis. *Hepatology* 25: 1527.)

glycoproteins form intermolecular noncovalently linked heterodimers. The nonstructural proteins include NS2 (a 21 kDa protein that, before cleavage, is part of a Zn-dependent protease that bridges NS2 and NS3 and mediates autocatalytic cleavage of the NS2/NS3 junction), NS3 (a 70 kDa protein encompassing three enzyme activities: a serine protease, a helicase and an NTPase; the protease cleaves remaining junctions between nonstructural proteins), NS4A (a 6 kDa protein that is a cofactor for NS3 serine protease function), NS4B (a 27 kDa protein of unknown function), NS5A (a 58 kDa serine phosphoprotein that exists in 56 and 58 kDa forms, depending on the degree of phosphorylation) and NS5B (a 68 kDa protein that is the viral RNA-dependent RNA polymerase). Each of the proteins with enzymatic function has been expressed as a recombinant protein and the enzymatic functions predicted from sequence motifs have been confirmed *in vitro*. Genetic heterogeneity has been identified in all the genes encoding viral proteins, but more variable and hypervariable regions occur in the envelope proteins than in the nonstructural proteins. With the exception of the serine protease, which has been crystallized, the three-dimensional structure of most of the HCV proteins is poorly understood.

Physical Properties

Hepatitis C virus has been recovered from cesium chloride fractions with a mean density of 1.24 g cm^{-3}. The isopycnic density of infectious HCV in sucrose has been measured at 1.06 g cm^{-3} in serum of acutely infected patients and at 1.12 g cm^{-3} for virus recovered from cell culture. The lower density of HCV recovered from serum results from the physical association of very low density lipoprotein with virions. Virus recovered from the serum of chronically infected patients generally has a density in sucrose of 1.15–1.18 g cm^{-3}, probably resulting from the formation of antigen–antibody complexes. The nucleocapsid of HCV was found to have a buoyant density in sucrose of 1.25 g cm^{-3}. The isopycnic density of HCV in potassium bromide is 1.12 g cm^{-3}. The s_{20w} is $\geq$ 150. The virus is stable in buffer at pH 8.0–8.7 but inactivated by exposure to lipid solvents or detergents, evidence that the virus envelope contains essential lipids. It is inactivated in aqueous solution by heat at 60°C for 10 h or 100°C for 2 min and is relatively unstable to storage at room temperature or repeated freezing and thawing. The virus is also inactivated by formaldehyde at a concentration of 1:2000 at 37°C for 72 h. Ultraviolet irradiation and β-propriolactone can also inactivate HCV.

Replication

Little is known about the replication HCV. Transcription and translation are thought to follow the strategies of flaviviruses and pestiviruses. Processing is thought to proceed in a manner similar to that of flaviviruses and pestiviruses. As with these viruses, post-translational cleavage of the structural proteins of HCV by microsomal membrane-bound cellular enzymes can be demonstrated *in vitro*. Translocation of the structural glycoproteins to the endoplasmic reticulum probably occurs via an internal signal sequence. Virus assembly is believed to occur by budding into vesicles.

Viral antigens can be detected in the cytoplasm of infected hepatocytes by immunofluorescent staining and virus-related RNA sequences can be similarly localized to the cytoplasm by *in situ* hybridization. Peculiar cytoplasmic tubular structures observed by electron microscopy in hepatocytes of chimpanzees infected with HCV are thought to result from local expression or action of interferon-related proteins and not directly from replication of the virus. Little is known about the methods of uptake, assembly or release of viral particles in infected cells and it is not known whether the virus is directly cytopathogenic or whether cytopathology is mediated by host immune responses.

Geographic and Seasonal Distribution

Serologic evidence for HCV infection has been found in all regions of the world in which it has been sought. In developed countries, 0.1–2% of the general population have antibody to the virus, as measured by currently available tests. In developing countries, the prevalence is somewhat higher but generally less than 5–10% of the population. An exception is Egypt, where prevalences as great as 20% have been recorded. Interestingly, similar high prevalences of anti-HCV have been found in certain high-risk populations in developed countries. Overall, it has been estimated that 3% of the world's population have been infected with HCV, resulting in more that 170 million chronically infected individuals.

From a clinical standpoint, HCV is thought to cause approximately 10–20% of acute hepatitis in many countries, but this may be as high as 50% in other countries, such as Japan. Infection with HCV has no recognized seasonal distribution.

Host Range and Virus Propagation

The recognized host range of HCV is quite limited. In addition to humans, the virus can be transmitted to chimpanzees and possibly to other greater and lesser

apes. Viral antigens and RNA can be detected in hepatocytes of naturally infected patients and experimentally infected chimpanzees and viral RNA has been detected in peripheral blood mononuclear cells (PBMC) and bone marrow cells of infected patients. Similar results have been obtained with hepatocytes and PBMC of experimentally infected chimpanzees.

Evidence has been obtained for replication of HCV in chimpanzee hepatocytes that were infected *in vivo* and then removed and maintained in culture. In addition, HCV has been reported to replicate in continuous lines of human T cells, B cells and monocytes. Such *in vitro* propagation systems have been used to study the neutralization of HCV by specific antibody and the inhibition of viral replication by antiviral agents such as interferon. However, all *in vitro* replication systems are difficult to reproduce and are limited in their application.

Genetics

The single-stranded RNA genome of HCV is replicated by a viral polymerase lacking proof-reading functions. As with other such viruses, HCV has a relatively high apparent evolutionary rate (approximately 2×10^{-3} base substitutions per genome site per year). This has resulted in genetic diversity among different strains of HCV and within the same strain over time. Strains of HCV can be grouped into six major genotypes, based on their genetic heterogeneity. Genotypes differ from each other by approximately 25–35% at the nucleotide level. The six genotypes have been further subdivided into over 100 subtypes. These differ from each other by about 15–25% at the nucleotide level. Although the genotypes are more or less distinct, discrimination of subtypes is less clear, owing to overlap in the degree of heterogeneity. This is demonstrated by the reported identification in Asia of major genotypes 7–11. More extensive analysis of the sequences of these genetic variants has demonstrated that genotype 10 is actually a subtype of genotype 3 and genotypes 7, 8, 9 and 11 are subtypes of genotype 6. Subtypes can be further subdivided into individual isolates that differ from each other by approximately 10% and, within individual isolates, into individual genomes that differ from each other by approximately 2%. The collection of variants within an individual isolate is called a 'quasispecies'.

Most strains recovered in the United States and Europe belong to genotype 1a or 1b (**Fig. 3**). Approximately 80% of strains recovered from Japanese patients represent genotype 1b. Subtypes a and b of genotype 1, together, are the two most common types of HCV and have a worldwide distribution. Genotypes 2 and 3 and their subtypes also have worldwide distributions. Genotype 4 and its variants are pan-African types; genotype 5 is found principally in South Africa. Genotype 6 and its many variants are mostly Asian strains.

Mutations in the genome of HCV are not uniformly distributed. Variable and hypervariable regions have been identified in portions of the HCV genome encoding the two envelope proteins. In particular, the amino-terminal end of envelope E2 has been designated the 'hypervariable region 1' (HVR1). In strains of genotype 1b, a second hypervariable region (HVR2) is found a short distance 3′ of HVR1. There is evidence that HVR1 is a neutralization epitope for the humoral immune response of infected patients. Thus, the sequence of HVR1 from HCV strains infecting agammaglobulinemic patients changes very little over time but changes rapidly in individuals subjected to immunostimulation. The rate of change of HVR1 in patients with a normal immune system is intermediate. Genetic variation has also been detected throughout the HCV genome. It is least in the 5′ UTR and, as noted, greatest in the genes encoding the envelope proteins.

Evolution

The origins of HCV are unknown. Its history cannot be traced back beyond several decades. Its limited host range and epidemiologic characteristics of transmission, principally by intimate exposure to blood or secretions, suggest that it is predominantly a human or primate virus. Recently, viruses related to HCV were recovered from various species of nonhuman primates. The virus most closely related to HCV, called 'GBV-B', was recovered from New World monkeys (tamarins) that had been inoculated with a virus previously believed to have been recovered from a human case of viral hepatitis. The origin of the virus remains obscure but it is probably a New World monkey virus. Other viruses, designated 'GBV-A' and 'GBV-A-like viruses', and a virus designated 'GBV-C' (also called 'hepatitis G virus'), are all somewhat more distantly related to HCV but are more closely related to this virus than to other members of the *Flaviviridae*. The GBV-A and GBV-A-like viruses have been recovered from a number of New World monkey species; GBV-C has been recovered from humans and has a worldwide distribution. Hepatitis C virus, the GBV agents, the flaviviruses and the pestiviruses form a group of transmissible agents with a probable common ancestry. Only HCV and GBV-B cause hepatitis; the GBV-A and GBV-C viruses appear not to be hepatitis viruses and, in fact, probably do not replicate in the

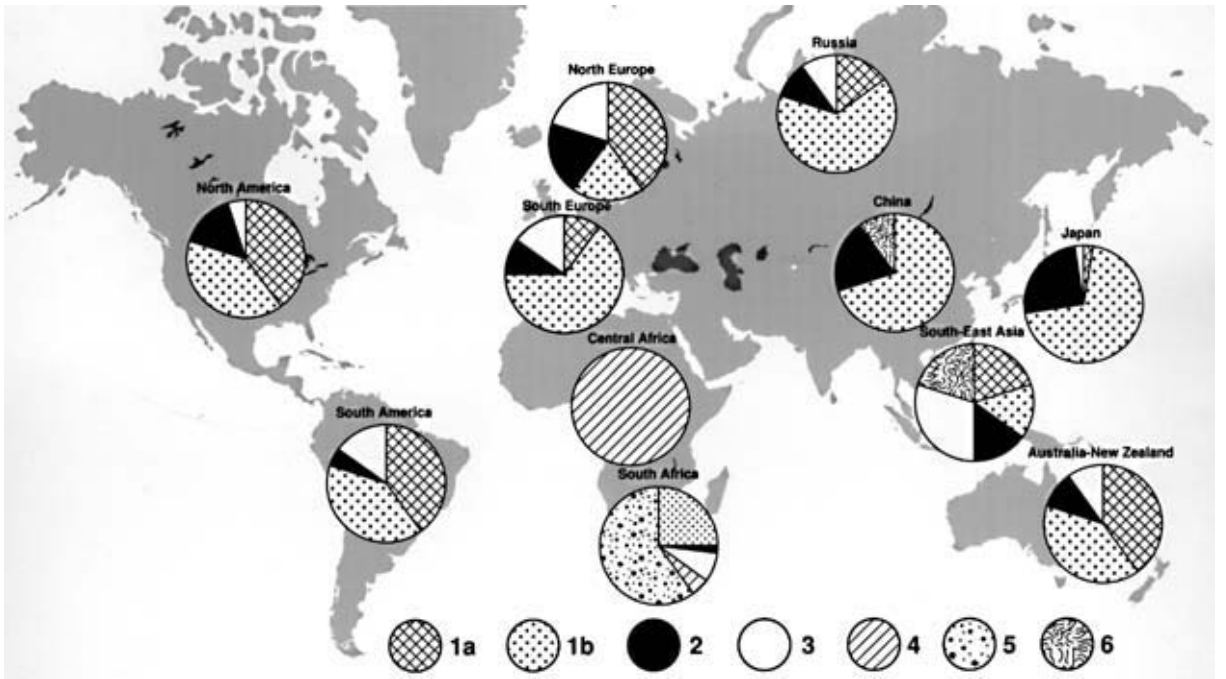

Figure 3 Worldwide distribution of HCV genotypes. (Reprinted with permission from Forns X and Bukh J (1998) *Viral Hepatitis Reviews* 4: 1.)

liver. Hepatitis C virus has no characteristics in common with any other recognized human hepatitis virus, except its ability to replicate in the liver and cause hepatitis.

Serologic Relationships and Variability

The inability to propagate HCV in standard cell cultures has made the serologic analysis of HCV strains very difficult. The search for different serotypes of HCV has been limited to crosschallenge experiments in chimpanzees. These have yielded results that have been difficult to interpret to date. In most studies, exposure to one strain of HCV has rendered chimpanzees resistant to hepatitis following rechallenge with a second strain. However, there have been exceptions. It is difficult to interpret these studies because of the propensity of HCV infection to progress to chronicity and the tendency of these chronic infections to cause recurrent hepatitis at unpredictable intervals. At least some of the strains involved in unsuccessful crosschallenge experiments have been shown to belong to the same subtype of HCV; strains involved in successful crosschallenges have not yet been examined to determine if they represent different subtypes or genotypes. However, even when rechallenge has not resulted in a second case of hepatitis, the chimpanzees have been reinfected with the second strain of HCV, as measured by detection of HCV RNA specific for that strain in the serum of challenged chimpanzees. Rechallenge with the same strain of HCV has also resulted in reappearance of HCV RNA, suggesting that solid immunity even to the homologous strain does not routinely follow infection with HCV. Thus, serologic differences among different HCV strains remain poorly understood.

Antigenic differences in the protein encoded by the *NS4* gene of HCV have been used for measuring antibody to the major genotypes of HCV. However, these have not been useful for typing of antibody to subtypes within a major genotype.

Epidemiology

Hepatitis C virus is predominantly spread by parenteral exposure to blood and blood products. Before the development of screening tests for carriers of hepatitis viruses, up to a third of recipients of large quantities of blood developed transfusion-associated hepatitis. The application of sensitive tests and screening measures to blood and plasma donation has virtually eliminated the transmission of viral hepatitis by transfusion and administration of blood products. This has been one of the great, and incompletely appreciated, achievements of research

on the hepatitis viruses. Another population at risk of acquiring infection with HCV and other blood-borne viruses consists of health care workers, especially those who come in contact with blood or tissues of patients. However, the largest proportion of community-acquired HCV cases among identifiable risk groups are the users of illicit parenteral drugs.

It has been proposed that HCV is a sexually transmitted disease but the evidence for this is controversial. The Centers for Disease Control have reported that up to 11% of community-acquired hepatitis C is caused by sexual transmission, mostly heterosexual, but others put the figure much lower. Perinatal transmission of HCV has been reported, principally to the offspring of mothers who are also infected with human immunodeficiency virus (HIV). The true incidence of such infections is not known, but sexual and perinatal transmissions probably play a real but relatively small role.

However, the largest proportion of individuals with community-acquired hepatitis C (approximately 40%) have no identifiable risk factor other than low socioeconomic status. Similarly, over 30% of patients with community-acquired hepatitis B are not identifiable members of a high-risk group. It is unclear whether these two viruses are spread through the community by still unrecognized means or whether the identification of individuals as members of high-risk groups is still imperfect. Overall, HCV is thought to account for approximately 33 000 cases of acute hepatitis C per year in the United States, approximately 12% of all cases of viral hepatitis. However, since HCV infections are much more likely to progress to chronicity than infections by the other recognized hepatitis viruses, HCV is thought to be responsible for approximately 42% of the estimated 1.5 billion dollar annual economic burden of viral hepatitis in the United States.

Transmission and Tissue Tropism

As noted earlier, transmission of HCV is predominantly through intimate and parenteral exposure to contaminated blood and body fluids. Hepatitis C virus replicates in hepatocytes and, possibly, mononuclear cells (B and T lymphocytes and monocytes).

Pathogenicity

The mechanism by which HCV causes hepatitis is not well understood. It is not known whether the virus is cytopathogenic or whether the clinical manifestations of disease are the result of the host's immune response.

Clinical Features of Infection

Hepatitis C cannot be distinguished clinically from other forms of acute hepatitis. The incubation period ranges from 4 to 13 weeks (mode: 4–8 weeks). The acute disease is often subclinical but approximately 80% of cases become chronic. Chronic HCV infection may be associated with relatively normal liver enzyme values, recurring liver enzyme elevations or, rarely, a rapidly progressive form of chronic hepatitis. Whether or not chronic hepatitis C is clinically apparent, up to 20–30% of cases progress to liver cirrhosis. The clinical progression of hepatitis C is generally more indolent than that of hepatitis B and its clinical manifestations are often not apparent until after the second or third decade of infection. Patients with chronic hepatitis C, especially those with cirrhosis, are at risk of developing hepatocellular carcinoma. Hepatitis C tends to be less clinically apparent in the immunologically immature or compromised, suggesting that, as with hepatitis B, immunity plays an important but poorly defined role in the pathogenesis of disease.

Pathology and Histopathology

The histologic changes in acute and chronic hepatitis C cannot generally be differentiated from those occurring in other types of viral hepatitis. The histologic changes in the liver during acute viral hepatitis are hepatic inflammation and hepatocellular necrosis. Inflammatory cells, principally lymphocytes and macrophages, are present in both the parenchyma and portal areas. Swelling and eosinophilic necrosis of hepatocytes are common. Chronic hepatitis C is characterized by inflammation (lymphocytes, macrophages and histiocytes) that is largely portal in distribution and hepatocellular necrosis that is typically periportal.

Immune Response

The immune response to HCV is complex and not well understood. Virus-specific antibodies against the structural proteins, principally the nucleocapsid and E2, and against nonstructural proteins, principally NS3, NS4 and NS5, have been detected with recombinant expressed antigens in individuals infected with HCV. Both linear and conformational epitopes are believed to be involved in the humoral immune response of the host to infection with HCV. Significant genetic heterogeneity throughout the genome is reflected in serologic heterogeneity of the humoral immune response, principally to the protein encoded by the *NS4* gene. The most extensive heterogeneity of HCV is found in HVR1, a probable

neutralization epitope of HCV. It is likely that neutralization-escape variants of HVR1 are positively selected by the host's humoral immune response. Other neutralization epitopes may exist but they have not been defined.

Cell-mediated immune responses against all of the HCV proteins, but most frequently against the nucleocapsid protein, have been detected but their significance is unknown. Because there is no widely available cell culture system for the propagation of HCV, it has not been possible to carry out extensive *in vitro* neutralization assays. However, data from experimental HCV infections in chimpanzees and from epidemiologic studies of natural infections in humans suggest that standard definitions of serotypes may not be applicable to HCV.

Prevention and Control

At present, control of HCV infection is achieved only by interdicting transmission via transfused blood or blood products by eliminating contaminated blood with tests capable of identifying most chronic carriers of the virus. Despite a number of controlled trials, normal immune globulin has not been shown to have a clear protective efficacy in prevention of HCV transmission associated with transfusion or accidental needle sticks. However, evidence for some degree of protection has been reported, especially when immune globulin has been administered before exposure. Currently, all units of plasma destined for plasma fractionation and production of immune globulin are prescreened to remove anti-HCV positive units. Therefore, current lots of normal immune globulin would not be expected to contain protective antibodies. There are no vaccines for HCV.

Future Perspectives

Knowledge about HCV is in a rapid state of flux. The licensed antibody tests for detecting HCV infection can detect antibody to a broad range of viral antigens. These tests have virtually eliminated transfusion-associated hepatitis and hepatitis among recipients of blood products. Vaccines against HCV are being developed but progress will be slow until more information is available about the serologic heterogeneity of HCV, the identity of viral epitopes involved in neutralization and the nature of the protective immune response.

Hepatitis C virus was the first virus to be characterized almost exclusively by molecular means. Progress was slow because of the low titers ($\leq 10^6$ infectious doses/ml) achieved by the virus during infection and the relatively weak and delayed immune response in many patients. It is unlikely that any progress could have been made without the development of an animal model (chimpanzees) in which the virus could be amplified biologically and specific reagents produced. The future development of vaccines will also depend heavily on the availability of an animal model.

HEPATITIS DELTA VIRUS

Michael MC Lai, Howard Hughes Medical Institute, Department of Molecular Microbiology and Immunology, University of Southern California School of Medicine, Los Angeles, California, USA

History

In 1977, gastroenterologist Mario Rizzetto of Turin, Italy, reported the detection of a new hepatitis B-specific antigen in some patients with chronic B hepatitis. The antigen, termed 'delta antigen', was localized in the nuclei of hepatocytes, closely resembling the hepatitis B core antigen (HBcAg) in its subcellular localization. Its presence was always associated with hepatitis B virus (HBV) infection, and patients with delta antigen also developed antidelta antibodies. Initially, delta antigen was thought to be a previously undescribed form of HBV antigen. In 1980, Rizzetto, in collaboration with Gerin and Purcell, successfully transmitted this new antigen and its associated hepatitis to chimpanzees. A new virus particle distinct from HBV virions or HBV surface antigen (HBsAg) particles was identified in plasma of the infected chimpanzees. Thus, delta antigen was recognized as a component of a novel virus.

This new virus, hepatitis delta virus (HDV), was shown to rely on HBV for transmission because it utilized the HBsAg as its own virion coat. Subsequently, a radioimmunoassay for antidelta antibodies was developed, which revealed that HDV infections were prevalent throughout the world, particularly in Mediterranean countries. In 1986, the RNA genome of HDV was molecularly cloned and sequenced, revealing its unique, circular RNA structure, which closely resembled that of viroids, a class of plant pathogens. Thus, HDV was recognized as a new class of animal pathogen.

Taxonomy and Classification

HDV is a single-stranded RNA satellite virus, which depends on HBV as a helper virus for a complete viral life cycle. To date, HDV is the only member virus of the floating genus *Deltavirus* (no Family designation). No sequence or structural relationship exists between HDV and HBV. Structural and biochemical features of HDV RNA suggest some similarity to plant viroids or virusoids. However, *Deltavirus* is taxonomically distinct from viroids. HDV has been isolated only from humans. HDV isolates can be classified into three genotypes based on the extent of nucleotide sequence divergence, each genotype differing by over 35%; however, all of the isolates are antigenically related.

Geographic Distribution

Hepatitis delta virus infection is found worldwide and is endemic in certain areas, particularly southern Italy and the Mediterranean countries. Its distribution closely parallels that of HBV infections. However, its prevalence rate does not always match that of HBV infection in different geographical areas; for example, in some HBV-prevalent areas such as China, HDV infection is disproportionately low. In developed countries such as the USA, the rate of HDV infections is low in the general population and highest among intravenous drug abusers and hemophiliacs who receive blood products. Genotype I HDV has been isolated in every geographical region in the world. Genotype II so far has been found largely within Asia, primarily Taiwan and Japan. Genotype III, which is associated mostly with fulminant hepatitis, has been detected only in South America.

Host Range and Virus Propagation

In natural infections, HDV has only been isolated from humans. It has been experimentally transmitted to both chimpanzees preinfected with HBV and woodchucks preinfected with woodchuck hepatitis virus (WHV), causing clinical hepatitis similar to that in humans and producing HDV particles with HBV and WHV surface antigens, respectively. The presence of hepadnavirus in these animals is a prerequisite for successful HDV transmission. Viral infection is limited exclusively to hepatocytes. In tissue culture, woodchuck-passaged HDV can infect woodchuck primary hepatocytes, but infection is limited to one cycle in a small number of cells; it does not infect established tissue culture cell lines. An alternative method of virus propagation is the transfection of tissue culture cells with HDV cDNA or RNA. Such studies have shown that both hepatic and nonhepatic human and other mammalian cells lines are capable of supporting HDV replication even in the absence of a helper hepadnavirus. Thus, host range and tissue specificity are restricted primarily by the availability of a viral receptor in hepatocytes. However, these transfected cells do not produce virion particles unless

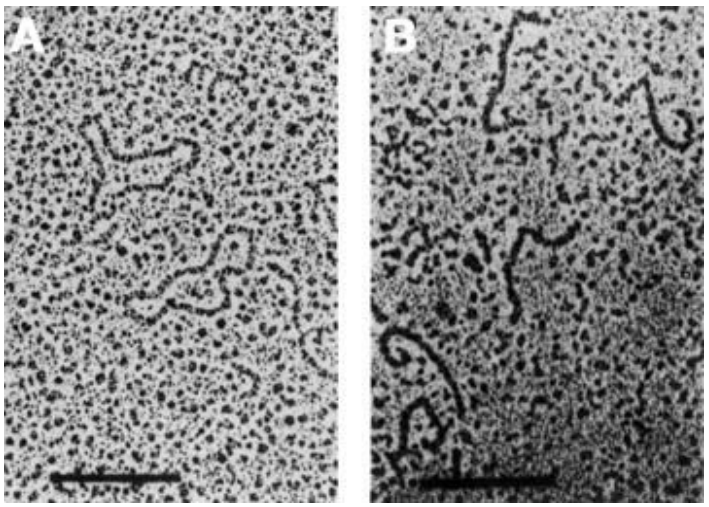

Figure 1 Electron micrograph of HDV RNA. (**A**) Denaturing condition showing the circular shape of HDV RNA. (**B**) Nondenaturing condition, showing the collapse of HDV RNA into a double-stranded RNA form as a result of the presence of intramolecular complementary sequence. Bar = 0.2 mm. a helper hepadnavirus is present. HDV RNA expressed in transgenic mice can replicate in every tissue.

Properties of the Virion

HDV virions are 36 nm, enveloped particles, which do not have surface projections but contain an internal, spherical nucleocapsid of 18 nm. Virus particles have a buoyant density in CsCl of 1.25 g^{-mL}. The envelope consists of HBsAg, while the nucleocapsid consists of hepatitis delta antigen (HDAg) and RNA. The intact virus particle is reactive to the anti-HBs antibody, but not the anti-HDAg antibody. The virus can survive extended periods of dry heat, up to 30 h at 60°C.

Properties of the Genome

The HDV genome is a single-stranded, circular RNA of 1.7 kb. It has a high degree of intramolecular complementarity, with about 70% of its nucleotides being base-paired to each other. Under nondenaturing conditions, HDV RNA forms a double-stranded, unbranched, rod-shaped structure (**Fig. 1**). The complete nucleotide sequence of more than 15 HDV isolates has been determined. The RNAs range from 1670 to 1683 nucleotides and contain about 60% of G + C.

The HDV RNA genome does not have a functional open reading frame (ORF); however, the antigenomic-sense HDV RNA detected in the infected cells has an ORF, which encodes the HDAg. This is the only protein made by the virus.

Both the genomic- and antigenomic-sense HDV RNA possess autocatalytic cleavage and ligation ('ribozyme') activities. Cleavage occurs at a specific site on both the genomic- and antigenomic-sense RNA and can take place in the absence of any protein. The ribozyme activity is contained within the region of HDV RNA that is considered to be a remnant of viroid RNA. However, the sequence and structural requirements of HDV ribozyme differ from those of known viroid or virusoid RNA ribozymes.

Properties of the Viral Proteins

HDV encodes a single protein, HDAg, which was the nuclear antigen originally detected by Mario Rizzetto. HDAg is not exposed on the virion surface; rather, it can be detected only after the virus envelope is disrupted. The protein consists of two species, small HDAg (24 kDa, 195 amino acids) and large HDAg (27 kDa, 214 amino acids). The two protein species are identical, except for the 19 additional amino acids at the C-terminus of the large HDAg. In most patients' sera, these two species are present in roughly equal amounts, but in infected liver the ratio often varies. They are complexed with HDV RNA genome in the virion and in the cells. In infected cells, they are primarily in the nuclei. HDAg is phosphorylated.

The large and small HDAg are translated from two distinct species of HDV RNA, which differ in the presence or absence of a termination codon near the C-terminus of the protein. During HDV RNA replication, small HDAg is synthesized first; large HDAg becomes detectable late in the viral replication cycle. Small HDAg is required for HDV RNA

replication, while large HDAg inhibits HDV RNA replication but is required for virion assembly. Thus, they play distinct roles in the viral life cycle.

HDAg contains several functional domains: The first contains a coiled-coil sequence, which enables the HDAg to form oligomers. The second is the nuclear localization signal, which transports HDAg and HDV RNA into the nucleus. The third contains the RNA-binding motif, which confers an RNA-binding property specific for HDV RNA. The final domain is unique to the large HDAg. It comprises the C-terminal 19 amino acids of the large HDAg and enables it to interact with the HBsAg during the assembly of HDV particles. It also causes the inhibition of HDV RNA replication. This domain is prenylated; prenylation is important for the various functions of the large HDAg.

The second protein present in the HDV particle is HBsAg, which constitutes the viral envelope. The protein is provided by the co-infecting HBV. It is essential for HDV particle assembly and virus transmission, but not necessary for HDV RNA replication. The envelope of HDV contains three HBsAg protein species, i.e. major, middle and large. The major HBsAg is the predominant form in the HDV virion.

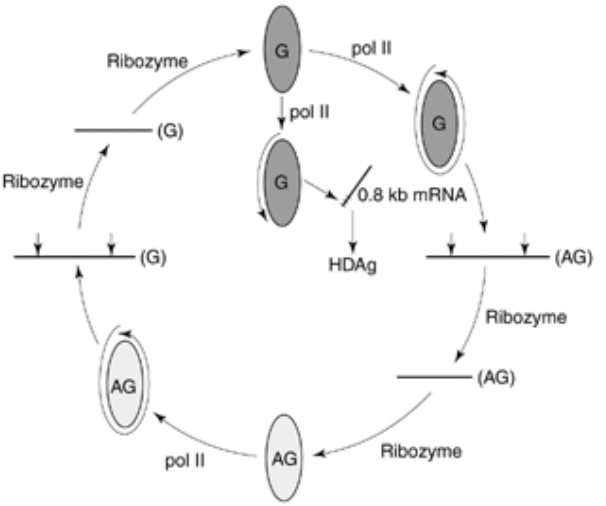

Figure 2 Proposed model of HDV RNA replication. The HDV RNA genome (G) is transcribed into a 0.8 kb mRNA (antigenomic sense) by cellular RNA polymerase II (pol II). The mRNA stops at a polyadenylation signal and is used for HDAg synthesis. The replication of genome length RNA goes through the synthesis of multiple-unit length antigenomic (AG) RNA intermediates, followed by cleavage and ligation by HDV 'ribozyme' to generate a circular antigenomic RNA. The synthesis of genomic RNA from the antigenomic RNA goes through a similar cycle.

Replication

The mode of virus entry into cells is not known, but may involve an interaction between HBsAg and a cellular receptor. Once inside the cell, HDV RNA can replicate in the absence of the helper HBV. The incoming viral RNA is transported into the nucleus by HDAg. RNA replication takes place in the nucleus via RNA-dependent RNA synthesis without a DNA intermediate. This process is most likely carried out by a cellular polymerase, as HDV does not encode its own polymerase. As HDV RNA synthesis can be inhibited by α-amanitin, it most likely utilizes cellular RNA polymerase II. It is not clear how this enzyme is converted from a DNA-dependent enzyme to an RNA-templated enzyme. Replication proceeds according to the double rolling circle model, yielding an antigenomic RNA product of multiple genome-unit length (**Fig. 2**). This RNA intermediate is subsequently cleaved into a single-unit length molecule by an autocatalytic process. The monomeric antigenomic RNAs are ligated into circular RNAs, also by an autocatalytic process. These circular RNAs then serve as templates for another round of rolling circle replication, yielding a genomic-sense RNA that repeats the cleavage and ligation process to form circular genomic-sense RNAs, thereby completing the cycle. The origins of replication for both genomic and antigenomic RNA have not been determined.

A subgenomic-size antigenomic-sense mRNA species of 0.8 kb which encodes the HDAg is also synthesized. The 5′ end of the mRNA begins at a point slightly upstream of the initiation codon and terminates immediately after a poly(A) addition signal in the HDV RNA. How mRNA transcription and genomic RNA replication are differentially regulated is not yet clear. This 0.8 kb RNA is associated with polysomes and used for translation of HDAg. The HDAg then is transported into the nucleus and participates in replication of HDV RNA; the precise mechanism by which the HDAg participates has not been elucidated. Only the small HDAg can promote HDV RNA replication.

During HDV RNA replication, a specific base mutation occurs on the termination codon of the small HDAg, resulting in a longer ORF encoding the large HDAg. This process is called RNA editing, which is probably mediated by cellular double-stranded RNA–adenosine deaminase. Thus, the large HDAg appears only later in the viral replication cycle. The large HDAg inhibits HDV RNA replication and triggers the formation of virus particles by interacting with HBsAg. Thus, the appearance of the large HDAg signals the switch from RNA replication to virion

assembly. How RNA editing is regulated is not yet clear.

The HDV genomic RNA is copackaged with HDAg into the virion. Both the large and small HDAg are packaged, although the small HDAg alone cannot trigger virus assembly. Only the genomic, but not the antigenomic, RNA is packaged into the virion. Virion assembly probably occurs in the cytoplasm, but the precise subcellular site has not been determined.

Genetics

HDV RNA shows very high genetic heterogeneity. Within the same HDV genotypes, different isolates could vary by as much as 21% sequence. Each virus isolate also consists of quasispecies with sequence microheterogeneity of nearly 0.1–0.5% of total nucleotides. Furthermore, mutations accumulate during chronic HDV infections in patients at an estimated frequency of approximately 2×10^{-3} to 1×10^{-2} mutations per nucleotide per year. An unusual characteristic of these mutations is that most are C → U or A → G transitions. In some cases, deletions also can be detected. However, the sequences around the catalytic cleavage sites of both the genomic and antigenomic RNA and the RNA editing site are highly conserved. No recombination has been reported.

Evolution

HDV RNA contains structural features characteristic of plant viroid or virusoid RNAs, but is significantly larger (1.7 kb versus 0.3–0.4 kb for viroids). It has been speculated that HDV RNA evolved from two different origins: a 'ribozyme' domain derived from viroids, which shares some sequence similarity with viroids, and another domain, which contains the ORF encoding HDAg and has been shown to share sequence similarity with a cellular protein termed 'Dip' (Delta antigen-interacting protein). Thus, HDV RNA could have evolved by recombination between a viroid RNA and a cellular mRNA. A portion of the HDV RNA is similar in sequence to the mammalian 7S RNA. HDV is the only animal virus with a circular RNA structure, although such an RNA structure is common among plant pathogens.

Serologic Relationships and Variability

HDV contains only one unique viral protein, HDAg. (The other protein, HBsAg, is shared with HBV.) Serological diagnosis of HDV infection is based on the antigenicity of this protein. Although there are three HDV genotypes, which differ in the amino acid sequence of HDAg, they cannot yet be distinguished serologically.

Epidemiology

HDV infection has been reported in every geographical region of the world. HDV transmission requires co-infection with HBV or occurs in individuals who are HBV carriers. The mode of transmission is parenteral. Approximately 5% of the HBsAg carriers in the world have been infected by HDV. Areas with a high prevalence rate of HDV infections include the Mediterranean Basin, particularly southern Europe, the Middle East, West Africa, the Amazon Basin of South America and certain South Pacific islands. Most of the HDV isolates from these regions (except South America) belong to genotype I. Severe fulminant-type delta hepatitis has been reported among Indians in South America, where genotype III HDV is prevalent. In Asia, the prevalence rate of HDV infections is relatively low, in contrast to the high prevalence rate of HBV infections. Genotype II is prevalent in east Asia (Taiwan and Japan). In nonendemic areas, HDV infection is sporadic and often associated with intravenous drug abusers. Sexual transmission has also been documented. In recent years, the prevalence rate of HDV has seen significant decreases across the world, probably as a result of HBV vaccination and routine blood screening for HBV, hepatitis C virus and human immunodeficiency virus.

Pathogenicity

Two possible mechanisms of HDV pathogenesis have been proposed: the first is the direct cytocidal effects of HDV; the second is an immune-mediated pathology. Consistent with the direct cytopathogenicity of HDV are the histopathology of delta hepatitis, which shows areas of hepatocellular necrosis with foamy degeneration, and the observation that immunosuppressive agents do not have significant effects on delta hepatitis. Furthermore, it has been shown that high levels of HDAg expression in mammalian cells can lead to cell death and that HDV infection of SCID (severe combined immunodeficiency) mice causes hepatic cell death, suggesting the direct cytotoxicity of HDV. However, permanent cell lines harboring integrated HDV cDNA have been isolated, which continuously express HDV RNA and HDAg without apparent cytopathology, and transgenic mice expressing HDV RNA or HDAg did not show any liver pathology; thus, HDV RNA replication alone may not be sufficient to cause cytopathology. Evidence supporting immune-mediated cytopathogenicity is derived from the finding that replication of HDV has often subsided and

immune responses have begun before the appearance of histopathology in delta hepatitis. Furthermore, experimental vaccination of chimpanzees with HDAg exacerbated the severity of subsequent HDV infections. The role of cellular immunity in the pathogenesis of HDV is not clear.

Clinical Features of Infection

The clinical features of HDV infection vary with the mode of transmission. In general, HDV infections have an incubation period of 3–7 weeks. The disease usually begins with a nonspecific prodrome of fatigue, anorexia, nausea and other nonspecific symptoms, followed by the typical signs of hepatitis, e.g. jaundice, increased serum alanine and aspartate aminotransferase activity. In cases resulting from simultaneous infection of HBV and HDV, acute symptoms are often followed by complete recovery within 12–16 weeks. In contrast, disease resulting from the superinfection of HDV in an HBV carrier often leads to chronic hepatitis. Furthermore, about 60–70% of patients with chronic hepatitis D develop cirrhosis. Fulminant hepatitis frequently results from HDV infection and is characterized by a high mortality rate. The probability of developing fulminant hepatitis is much higher for HDV than other types of viral hepatitis. There is no direct association between HDV infection and hepatocellular carcinoma; however, cirrhosis resulting from chronic delta hepatitis increases the risk of hepatocellular carcinoma.

Superinfection of HBV carriers by HDV often results in the inhibition of HBV replication. During the acute phase of HDV infection, synthesis of both HBsAg and HBV DNA are inhibited until the HDV infection is cleared. In chronic delta hepatitis, the HBV markers are suppressed throughout the entire clinical course of disease. The mechanism of suppression has not been elucidated.

During the acute phase of delta hepatitis, both HDV RNA and HDAg can be detected. This is soon followed by the appearance of IgM anti-HD antibody. In chronic delta hepatitis, HDV RNA, HDAg, and IgM and IgG anti-HD antibodies persist.

Pathology and Histopathology

The histopathology of acute delta hepatitis is not different from that of acute hepatitis caused by other viral agents. In delta hepatitis, hepatocytes often appear to be necrotic and surrounded by inflammatory cells, including lymphocytes and macrophages. The hepatocytes have deeply acidophilic cytoplasm and an irregular, rhomboid shape with pyknotic nuclei. In chronic delta hepatitis, there is a prominent necroinflammatory response in the parenchyma, with marked portal and periportal inflammatory changes. The HDAg can be detected in the nuclei of affected hepatocytes in both acute and chronic delta hepatitis. HDV RNA can also be detected in the nuclei by *in situ* hybridization. Furthermore, examination by electron microscopy reveals a 'microtubular structure' in the hepatocytes that is characteristic of, but not unique to, delta hepatitis.

Immunity

HDV infections induce both humoral and cellular immunity in patients. Antibodies are directed against most regions of the HDAg, but different regions are immunodominant in different individuals. Helper, suppressor and cytotoxic T cells are detectable in different areas of the infected liver. Their importance in HDV infection is not clear. Experimental immunization with HDAg in woodchucks did not provide protection for the animal. In fact, this immunization may exacerbate the clinical symptoms of subsequent HDV challenges. Anti-HD antibodies usually do not persist after acute infection is cleared. Thus, the serological evidence of past HDV infection is not easy to demonstrate.

Prevention and Control of Infection

Because HDV infection is dependent on a concomitant HBV infection, control of HDV infection is best achieved by HBV vaccination. However, there is no effective measure to prevent HDV infection of chronic HBV carriers. No routine blood screening for HDV is currently performed; however, HDV infection by contaminated blood sources can be prevented by screening for HBV. Currently, there is no specific treatment for delta hepatitis. Interferon α has been tried therapeutically with only marginal and transient effects. Ribavirin has been shown to inhibit HDV RNA replication in tissue culture.

Future Perspectives

Because of the severe hepatitis associated with HDV infection, its prevention and control is important. Although the molecular cloning of HDV RNA has opened up research on the replication of HDV, many questions remain unanswered, e.g. the enzymology of HDV RNA replication, the mechanisms of action of HDAg, the regulation of RNA editing, the regulation of the synthesis of HDAg, etc. HDV occupies a unique place in the taxonomy of viruses, possibly as a bridge between plant and animal viruses. Understanding these and other issues will be critical for the

future development of prevention measures and therapy for HDV infections.

History

A significant proportion of acute viral hepatitis occurring in young to middle-age adults in Asia, Africa and the Indian subcontinent is caused by an enterically transmitted viral agent that is serologically unrelated to hepatitis A virus (HAV). The disease has been shown to occur in both epidemic and sporadic endemic forms and is primarily associated with the ingestion of fecally contaminated drinking water. The term enterically transmitted non-A, non-B hepatitis (ET-NANBH) was originally used to distinguish this disease from the parenterally transmitted form of NANBH. The latter disease is primarily associated with infection by hepatitis C virus (HCV), a small, enveloped flavi- or pesti-like virus. The viral agent of ET-NANBH was isolated in the mid-1980s, partially characterized, molecularly cloned and has been officially named hepatitis E virus (HEV) by the International Committee on Taxonomy of Viruses (ICTV).

Hepatitis E was first documented in New Delhi, India, in 1955, when 29 000 cases of icteric hepatitis were identified following widespread fecal contamination of the city's drinking water. A similar epidemic of viral hepatitis occurred between December 1975 and January 1976 in Ahmedabad City, India, again due to contaminated water supplies. Both outbreaks were originally thought to be caused by HAV; however, retrospective serologic analysis of paired serum specimens from documented cases revealed that neither HAV nor hepatitis B virus (HBV) was the etiologic agent.

Large epidemics of hepatitis E have also been observed in the Kirgiz Republic of the former USSR. Although these outbreaks were never described in the Western scientific literature, careful review of records and other related documents and manuscripts by D.W. Bradley during a visit to the former USSR in 1986 clearly revealed that HEV was the most likely etiologic agent. Between 1955 and 1956 more than 10 800 cases of acute viral hepatitis were documented in young to middle-age adults; approximately 18% of infected pregnant women died as a direct result of presumed infection with HEV. The epidemiological and clinical features of the Kirgiz outbreaks were remarkably similar to those associated with the 1955–1956 New Delhi outbreak.

Taxonomy and Classification

HEV is a small nonenveloped virus with morphologic features similar to those of Norwalk virus and other caliciviruses (see below). Based on the calici-like physiochemical properties, it was tentatively grouped into the *Caliciviridae* prior to its molecular identification. Subsequent to its cloning, sequence comparison reveals little, if any, homology between HEV and known viruses of *Caliciviridae*. Genomic organization analysis further supports a lack of genetic relationship. As a result, HEV has been declassified from the *Caliciviridae* by the ICTV, and currently remains unclassified in a floating genus, 'Hepatitis E-like viruses'.

Physiochemical Properties of the Virion

Table 1 summarizes what is known to date about the major etiologic agent of hepatitis E. The virus appears to be extremely labile and will not tolerate exposure to high concentrations of salt, including cesium chloride. Pelleting of the virus from stool suspensions or gradient fractions frequently results in loss of virus. Rate-zonal banding of 32–34 nm virus-like particles (VLPs) in linear, preformed sucrose gradients, however, was found to yield partially purified virus suitable for further immune electron microscopy (IEM) studies. The computed sedimentation coefficient for HEV was approximately 183 S, in contrast to 157 S for that of HAV, a member of the *Picornaviridae*. Virus particles were sometimes found to sediment at 165 S; these particles are presumed to be defective and probably lack a complete viral genome. Isopycnic banding of an aliquot of the Telixtac no. 14 stool (HEV isolate from a 1986 outbreak in southern Mexico) suspension in a potassium tartrate/glycerol gradient revealed 32–34 nm VLPs at a buoyant density of 1.29 g ml^{-1}. These biophysical properties were consistent with the earlier notion that the major agent of hepatitis E was a calicivirus-like virus. Like many caliciviruses, the 32–34 nm VLPs described here are also sensitive to freeze-thawing, storage in liquid suspensions at temperatures between −70°C and +8°C, and pelleting from solutions of sucrose or buffer. HAS-15 HAV (partially purified from tissue

Table 1 Properties of hepatitis E virus (HEV)

Size:	32–34 nm mean diameter in 80% of virus particles visualized by immune electron microscopy, with a range of 27–38 nm
Morphology:	Spherical, nonenveloped particle with spikes and indentations visible on surface of virus
Biophysical properties:	Sedimentation coefficient = 183 S (defective particles, 165 S)
	Buoyant density = 1.29 g ml^{-1}
	Sensitive to cesium chloride, freeze-thawing, and pelleting
Genome:	Single-stranded, polyadenylated RNA of approximately 7.5 kb in size with three open reading frames 5′-nonstructural, 3′-structural genomic organization
Host range:	In addition to humans, natural infection reported in nonhuman primates, cattle, pigs, chickens and rodents
	Most reliable experimental infection models in cynomolgus and rhesus monkeys
	No effect on suckling mice inoculated intracerebrally with numerous case study stool suspensions (10% w/v)
In vitro *propagation:*	Reported virus replication mostly in primary cell cultures

culture lysates) and HEV contained in case stools from Burma, Mexico, Somalia and the Soviet Union were independently measured by three individuals at the Centers for Disease Control and Prevention in Atlanta, GA. HAV was found to have a mean diameter of 27–28 nm. HEV was found to have a mean diameter of 32–34 nm, with 78% of the VLPs within a range of 31–35 nm. There were no statistically significant differences in mean particle diameters in any of the four geographically different HEV isolates.

Molecular Biology of Genome Structure

HEV is a positive-sense, single-stranded RNA virus with a polyadenylated genome of 7.5 kb in length. cDNA cloning of HEV was initially attained with a virus isolate recovered from an epidemic outbreak in Burma. Additional strains identified and fully sequenced to date include those from China, India, Mexico, Pakistan and the former Soviet Union. Partial genomic sequences have also been determined from cases in Algeria, Chad, Morocco and the USA. Sequence analysis of all known HEV strains indicates the presence of three open reading frames (ORFs) in the virus genome. Two major ORFs of approximately 5 and 2 kb long are found in the first and second coding frames. A small ORF of 369 bp in length is present in the third forward frame that overlaps both of the two larger ORFs. Relatively short noncoding segments of 27 and 65 nucleotides are found at the 5′ and 3′ ends, respectively, of the viral genomic sequence.

HEV possesses a 5′-nonstructural, 3′-structural genomic organization. Conserved motifs corresponding to such viral proteins as the methyltransferase, papain-like protease, helicase and RNA-dependent RNA polymerase are found in the first open reading frame (ORF 1) that extends from the 5′ end of the virus genome. The nonstructural HEV proteins encoded by ORF 1 have yet to be extensively studied. The identities of these proteins, as depicted in **Fig. 1**, were revealed only by detailed computer alignment analysis of deduced amino acid sequence. Not much has been learned of their biological functionality. Just as the identification of a methyltransferase gene would suggest that HEV genomic RNA is capped, it remains to be empirically demonstrated. Domains X and Y, identified by their conserved motifs with other positive-strand RNA viruses, have no known assigned biological functions. The manner in which proteolytic processing of the ORF 1 polyprotein into individual protein species is also not known at present. The papain-like protease is presumed to play a role, but host cell proteases may also be involved in the process. Epitope mapping using a strategy of overlapping peptides revealed the presence of several potential immunogenic peptides, especially in the polymerase region. However, none has been shown to be of use in diagnostic assays. ORF 2 occupies the 3′-most 2 kb of viral genomic sequence and codes for the single capsid protein of HEV. A hydrophilic electropositive region rich in arginine residues found near the N-terminus of the capsid protein serves to neutralize and encapsulate the electronegatively-charged genomic RNA. A major immunogenic epitope is located at the C-terminus of the capsid protein, and has been found to be most useful in the diagnosis of hepatitis E (see below). The small ORF 3 also codes for an immunogenic protein of 123 amino acids; however, its biological role in the life cycle of the virus remains unclear.

In addition to the full-length genomic RNA, two subgenomic RNA transcripts of 3.7 and 2.0 kb have been detected in Northern blot analysis of infected liver RNA. All three RNA species coterminate at the 3′ poly(A) tail of the virus genome. The two subgenomic transcripts are believed to be involved in expression of the ORF 2- and ORF 3-encoded proteins. Hence, the HEV genome employs all three coding frames for its three ORFs as well as the use of subgenomic transcript in its expression strategy.

Genetics and Evolution

Genetic heterogeneity has been noted among the HEV strains fully sequenced to date. Of these, the Mexican isolate cloned from the Telixtac outbreak is the most divergent genetically. The Asian strains (Burma, China, India and Pakistan) are well-conserved among themselves, with nucleotide sequence identity between 93 and 100% in the coding regions and amino acid sequence identity between 98 and 100%. HEV-Mexico, on the other hand, differs from the Asian strains by about 25% at the nucleotide level and 17% at the amino acid level in ORF 1, 20% and 7% in ORF 2, and 10% and 13% in ORF 3. Unrooted phylogenetic analysis of the ORF 2/3 structural gene coding regions of the Burma, China, India, Mexico and Pakistan strains clearly shows the genetic distance between the Mexico isolate and the Asian strains (**Fig. 2**). These two genetic groups appear to represent the diverse ends of the heterogeneity based on geographical distribution. Limited sequence comparison of the more recently identified African strains (Algeria, Chad and Morocco) indicated that they are more closely related to the Asian strains, but within the phylogenetic continuum between the two ends.

The geographic heterogeneity found among the HEV strains suggests an 'Old World–New World'

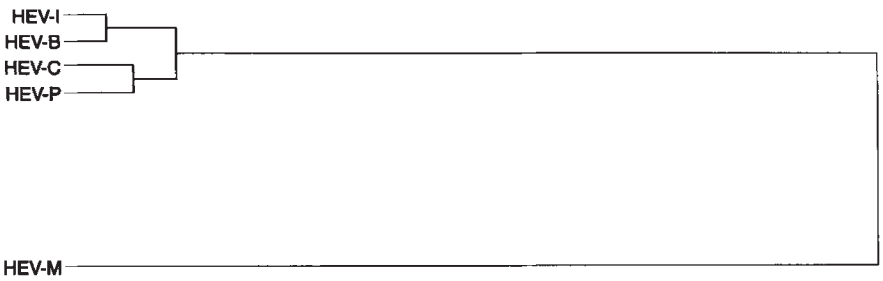

Figure 2 Phylogeny analysis of hepatitis E virus isolates with known structural gene coding sequences. The dendrogram depicts phylogenetic distances between the different strains of HEV and is derived from algorithms for phylogenetic tree generation using the CLUSTAL-V program.

evolution of the virus. Imported cases of hepatitis E in the Middle East region by religious pilgrims and labor workers from Central Asia have been reported. Interestingly, though, partial sequence information from the two most recently cloned HEV strains (USA and Taiwan) has provided conflicting evidence. The US isolate, identified from an acute hepatitis patient with no record of travel, yielded sequences as different from the Burma strain as they were from the Mexico strain. In another study, consensus ORF 1 sequence isolated from four patients in Taiwan was found to be divergent not only from the Mexico strain, but also more removed genetically than expected from strains described for Burma, China, India and Pakistan. Moreover, finding of atypical strains of HEV that did not serologically crossreact with the known strains has recently been reported by several laboratories, suggesting perhaps the existence of different serotypes of HEV. Full phylogenetic analysis of HEV must await the complete cloning and characterization of these recently discovered isolates as well as additional strains from other regions in which occurrence of hepatitis E has been documented.

Host Range and Virus Propagation

Humans are the natural hosts for hepatitis E. HEV is the major cause of acute viral hepatitis in young to middle-age adults living in underdeveloped regions of the world where water sanitation measures are lacking. Anti-HEV has been detected in wild-caught monkeys and rodents, suggestive of prior exposure to HEV or a related agent. Natural infection of various domestic species such as chicken, cattle and pigs has recently been described, especially in hepatitis E endemic regions. The zoonotic nature of HEV is further illustrated by the recent identification of a swine hepatitis E virus in Midwestern USA, where hepatitis E has rarely been reported. HEV researchers have long sought an explanation for the relatively high anti-HEV prevalence surveyed even in non-endemic countries. While the existence of a virus reservoir in animals as exemplified by the swine HEV and its potential transmission to the human population could serve to account for the observed seroprevalence rate, no record of animal strains of HEV infecting humans has been documented.

Nonhuman primates shown to be susceptible to experimental HEV infection include chimpanzees, cynomolgus macaques, rhesus monkeys, African green monkeys, tamarins, owl and squirrel monkeys. The most reliable animal transmission model to date remains the cynomolgus monkey (cyno). Multiple passages of the same virus in cynos has resulted in the shortening of the incubation period from more than 50 days to as little as 5 days, suggesting adaptation of the virus to the host or heightened response to an increased virus load.

As with other known hepatotropic viruses, development of a tissue culture system to replicate HEV has been problematic. Growing of three different strains of HEV in cultivated cells have been reported. Virus recovered in China was reported to be propagated in human embryo lung diploid cells. Cell-derived viruses were found to be reactive with anti-HEV obtained from HEV-infected human patients and nonhuman primates. Virus recovered from the Soviet Central Asia region was cocultivated in fresh fetal rhesus monkey kidney (FRhK-4) cells with primary cynomolgus monkey kidney cells isolated from experimentally infected animals. Nucleic acid hybridization and immunofluorescent detection of HEV antigen provided evidence for tissue culture-derived virus. More recently, the Burma strain HEV was propagated and produced in cell culture from *in vivo*- and *in vitro*-infected primary cynomolgus hepatocytes isolated and maintained in long-term culture using a serum-free medium formulation. The negative strand replicative RNA intermediates were directly detected by a sensitive strand-specific reverse transcription–polymerase chain reaction (RT-PCR)

assay. Presence of intracellular- as well as culture medium-derived viruses was demonstrated throughout the duration of the hepatocyte culture. Continued development of these *in vitro* culture systems may provide high titer virus samples suitable for further studies of HEV biology.

Transmission and Tissue Tropism

HEV can be experimentally transmitted to susceptible primates by either intragastric or intravenous inoculation. For humans, the normal route of infection is through consumption of contaminated drinking water. The incubation period in both nonhuman primates and humans is about 6 weeks, although adaptation or subpassaging of HEV in primates can significantly shorten the incubation period. Studies to date indicate that virus replicates primarily, if not exclusively, in liver cells of experimentally infected primates. There is no evidence for the existence of extrahepatic sites of virus replication, although sensitive *in situ* hybridization procedures may reveal the presence of nascent HEV RNA (negative strand) in cells other than hepatocytes.

The earlier development of an immunofluorescent antibody-staining procedure (FA) for HEVAg in liver tissue of experimentally infected primates permitted the visualization of disease-associated antigen (protein(s)) in liver cells. Fluorescent granules and deposits with a powdery appearance were found by FA in the cytoplasm of hepatocytes. Subsequent 'blocking' studies using a recombinant DNA-expressed, virus-specific protein to absorb the FITC-labeled IgG anti-HEV probe showed that these deposits were virus-specific.

HEV is excreted from the liver via the common bile duct into the duodenum of the small intestine. Although most stools obtained from acutely ill patients contain little or no virus detectable by IEM, numerous investigators have shown that HEV can be readily recovered from gall bladder bile, indicating that the lack of virus in stool samples is probably a function of the labile nature of the virus particle. Host proteases such as trypsin and chymotrypsin may contribute to the degradation in its passage through the gut. It is worth noting that the lower numbers of intact HEV particles present in patient stools may account for the generally lower rate of person-to-person transmission of hepatitis E when compared with that of hepatitis A. Viremia (HEV in blood/serum) is also associated with the course of disease, as shown by RT-PCR studies of HEV RNA in serum. HEV in serum (maximum level) usually precedes the major peak of alanine aminotransferase (ALT) activity.

Epidemiology

In developing countries, infection with HEV is a leading cause of morbidity and mortality. Since its initial documented outbreaks in India, hepatitis E epidemics have been reported in parts of Asia, Africa and North America, namely Nepal, Pakistan, Burma, the former Soviet Union, India, Borneo, Somalia, Sudan, China and Mexico. During epidemics the clinical attack rate has averaged 5% of the population, with the most severe disease observed in young adults. Two of the largest and most recent epidemics occurred in northwestern China between 1986 and 1988 with about 120 000 clinical cases reported and in 1991 in Kanpur, India affecting 79 000 persons. Virus-like particles recovered from stool specimens taken during the epidemics support the theory that one virus type was responsible for all the cases; in all of these outbreaks, hepatitis E was associated with the consumption of fecally contaminated water.

Sporadic outbreaks of hepatitis E have also been documented in Asia and Africa between the epidemic cycles. The virus is implicated in causing more than 50% of the sporadic acute viral hepatitis cases worldwide. The cause of sporadic hepatitis E in endemic regions is currently unknown, although recent demonstration of a swine hepatitis E virus may have implication for zoonosis.

Hepatitis E is not endemic in the USA and parts of Western Europe. With few exceptions, the confirmed cases of hepatitis E have been traced to immigrants and tourists from countries where HEV is endemic. These 'imported cases' establish that hepatitis E is a worldwide public health problem.

Clinical Features of Infection

Hepatitis E infection can be subclinical, acute or fulminant stage hepatitis. Some persons infected with HEV are anicteric without the classical symptoms of hepatitis. Asymptomatic hepatitis E is more likely to occur in infants and young children.

In acute hepatitis E, the diseased state usually becomes apparent within 2–9 weeks of exposure, the average incubation period being 6 weeks. Early symptoms of infection, such as chills, fever, nausea, vomiting, diarrhea, joint pain, headache and abdominal enlargement, can occur a week to 10 days before the onset of jaundice. The icteric phase usually persists for 15–40 days. Jaundice is accompanied by output of dark urine and clay-colored stools. Peak liver enzyme elevations occur usually in early icteric phase. Necroinflammatory changes observed in the liver are consistent with acute virus hepatitis. The period of recovery can take up to 14 weeks, after

which time liver biopsy returns to normal and liver enzyme levels return to baseline. Generally, hepatitis E is self-limiting, with full recovery and no progression to chronic liver disease.

Fulminant hepatitis E occurs in both men and women, but is mostly associated with high mortality rates in the third trimester of pregnancy in woman. Although the overall mortality for hepatitis E in the general population is estimated at 0.5–1.0%, mortality in pregnant women has been reported to be as high as 20%. The mechanism for fulminant hepatic failure during pregnancy is unknown. Endotoxin-mediated cytotoxicity, proposed as a cause for fulminating disease years ago, still cannot be ruled out as a cause. The absence of an animal model to study fulminant hepatitis E has hampered progress in this area.

Limited data from two human self-inoculation studies support the clinical course of disease already well-documented in experimentally infected non-human primates. HEV RNA was detected in serum and feces 22 days and 34 days respectively after self-inoculation. Anicteric symptoms of hepatitis began 30 days after inoculation. Icterus began 8 days later and lasted for more than 80 days. Antibodies to HEV were detectable at 41 days after infection and ALT elevations peaked 5 days later and persisted for 10 weeks. Jaundice was prolonged and hepatitis was severe; however, there was complete resolution of disease without any chronicity.

The clinical course of disease following HEV infection entails virus excretion in the feces, viremia, liver enzyme elevations (ALTs) and seroconversion, followed by the clearing of the virus and resolution of disease. As this clinical profile for HEV infection is similar to that of other forms of acute viral hepatitis, serologic markers for infection have proven most valuable for specific diagnosis.

Pathology and Histopathology

In the majority of hepatitis E outbreaks, liver specimens have rarely been available for histopathologic analysis. The only extensive studies of histopathological changes in the liver were carried out on biopsy specimens obtained from 78 patients during the large outbreak in New Delhi described earlier, and from 128 cases of endemic hepatitis E occurring in Ghana between 1962 and 1963. Two types of histopathologic changes were observed in the Indian outbreak: an obstructive or cholestatic type found in 58% of those examined, and a 'standard' type identified in 42% of cases. The cholestatic type was characterized by bile stasis in canaliculi and parenchymal cells which were arranged in a gland-like fashion. Cholestasis and glandular transformation of liver cell plates were much more significant in the cases from Ghana and West Africa (63% and 93%, respectively). Degenerative changes of liver cells (including acidophilic bodies) and focal necrosis were less frequently seen in the cholestatic types of hepatitis E in the New Delhi patients. Polymorphonuclear leukocytes were observed both in intralobular infiltrations and in portal tracts in larger amounts than seen in the 'classic' (standard) form of acute viral hepatitis, although in portal tracts monocytes (lymphocytes) remained the predominant cell type. In the standard type of viral hepatitis, ballooned hepatocytes, acidophilic degeneration of hepatocytes and acidophilic body formation were the most frequently encountered. Similarly, in experimentally infected primates, the acidophilic type of hepatocyte degeneration was a characteristic morphologic feature, particularly in cynos. Focal necrosis was observed in both patients and infected primates, with prominent accumulations of mononuclear macrophages and activated Kupffer cells and a much less striking presence of lymphocytes. In both human cases and infected primates, lymphocytes prevailed in portal infiltrations. In serial liver biopsy specimens from infected cynos, portal infiltrations seemed to occur later than intralobular changes. In summary, hepatitis E is associated with certain features of necrotic and degenerative changes in both humans and primates and is reminiscent of a toxic type of parenchymal lesion.

Serologic Markers and Immunodiagnosis

The traditional gold-standard diagnosis of HEV infection has been detection by IEM of virus-like particles in fecal specimens. Although highly specific, IEM is difficult to perform and most clinical specimens do not contain sufficient VLPs to be detected. An immunofluorescence-blocking assay using virus-specific antigen measures antibody to HEV in sera, but this assay does not distinguish between recent and past infection. Following the cloning and sequencing of the HEV genome, the identification of type-common viral epitopes within the structural genes led to the development of serologic assays for diagnosis of acute and past infection (**Fig. 3**).

An immunodominant epitope designated 3–2 and a broadly reactive peptide designated SG3 both map to the ORF 2 encoding a protein with properties consistent with being the capsid protein of the virus. A second epitope designated 4–2, that maps to ORF 3, is encoded by a cytoskeleton-associated phosphoprotein of unknown function. The immune response to ORF 3 has been shown to be more transient in experimental infections, waning within a few months

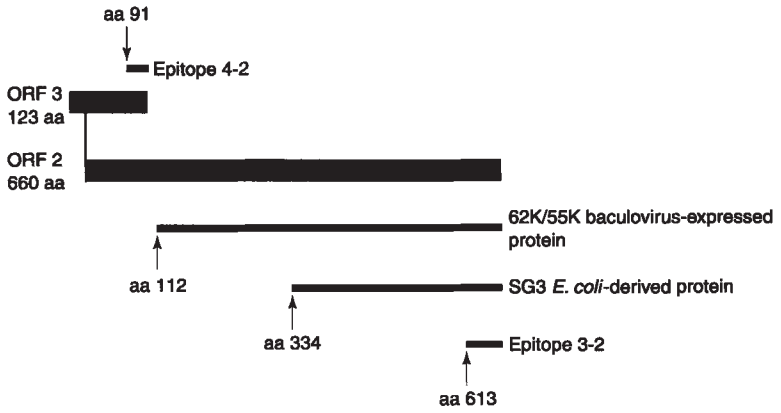

Figure 3 Localization of immunoreactive epitopes and immunogenic proteins encoded in the ORF 2 and ORF 3 structural regions of HEV. Arrows indicate the N-terminal amino acid residue numbers of expressed recombinant proteins. aa, Amino acids.

after ALT levels return to normal. Antibodies to ORF 2 have been shown to persist for years. An ELISA was developed using these virus-specific proteins expressed as recombinant proteins in *Escherichia coli*. The test is convenient, sensitive and specific, allowing the detection of IgG- and IgM-specific anti-HEV and therefore useful in diagnosing acute and past HEV infection. The specificity of the IgG and IgM ELISA is 99% and 97%, respectively. A sensitivity of 93.5% corresponds to IgM antibody measured in sera collected within 2 weeks of illness from acutely infected persons still shedding virus in the feces. The IgM antibodies to HEV decline quickly after acute infection resolves, although IgG antibodies persist at high titer for more than 1 year.

In an effort to preserve the immunologic structures that might be present only in the native structural protein and to improve the detection of acute phase antibodies to HEV, the structural capsid protein was expressed in insect cells by recombinant baculoviruses. The resulting soluble ORF 2 proteins, designated 62K and 55K deriving from the Burma and Pakistan strains, respectively, contain additional epitopes, presumably conformational, not present in the recombinant proteins expressed in bacteria (**Fig. 3**). These proteins are appropriate for large-scale epidemiologic studies and have been shown to be effective in experimental vaccination trials.

Nucleic Acid Diagnosis

HEV can be detected in acute phase stools and acute phase sera by RT-PCR. After recovery of the HEV viral RNA from stool or sera, cDNA is synthesized from RNA, followed by amplification by PCR using sense and antisense primers. PCR primers for the RNA-dependent RNA polymerase (RDRP) region within ORF 1 or the capsid protein within ORF 2 are mostly used to amplify target cDNA from divergent strains. HEV PCR products are analyzed by agarose gel electrophoresis and confirmed by Southern blot analysis with sequence-specific radiolabeled or biotinylated sequence-specific probes. It is important to note that viremia is usually short and often peaks before clinical signs of disease; therefore, depending on the timing of specimen acquisition, some acute phase sera may not contain enough viruses to be amplified. The assay, although useful for supplemental confirmation of infection, is not appropriate for screening.

Prevention and Control

Recent research on the identification of an effective subunit vaccine for hepatitis E has yielded encouraging results. Experimental vaccination of cynomolgus monkeys and rhesus monkeys with two different recombinant HEV capsid proteins, 62K and 55K, provides evidence for the potential to develop an effective vaccine for hepatitis E capable of providing crossprotection for the most divergent HEV strains. Unique antigenic and immunogenic properties of the ORF 2-encoded capsid protein expressed in baculovirus make them leading candidates as vaccine immunogens. Moreover, the amino acid sequence identity of these capsid proteins is 93% between the most divergent strains of HEV and 99% between the closely related Asian isolates of the virus, suggesting the presence of a well-conserved crossreactive immunologic determinant in the particle structure.

In two independent studies, nine cyno monkeys challenged with 1000–10 000 cynomolgus 50% infec-

tious doses (CID_{50}) of HEV following vaccination with 55K or 62K ORF 2 capsid protein were all protected from hepatitis. Postchallenge, there were no indicators of biochemical or histopathologic evidence for hepatocellular damage in any of the immunized animals. Vaccination clearly conferred protection against hepatitis in all animals. In one study there was a delayed and transient presence of viral RNA in the feces of only one of the three vaccinated animals, indicating limited 'breakthrough' viral replication. Although HEV infection was not prevented in this one animal, the presence of HEV-specific immunity at the time of challenge resulted in a limited infection and the absence of the characteristic features of HEV-induced disease.

A titration study with rhesus monkeys demonstrated that a dose of 0.4 μg of protein was effective in protecting the animals against hepatitis E following a challenge dose of virulent HEV. The capsid protein of HEV shows promise as a subunit vaccine candidate to: (1) prevent hepatitis E epidemics; (2) prevent sporadic cases of hepatitis E in developing countries; (3) protect pregnant women at high risk; and (4) provide protection to travelers.

Future Perspectives

Development of serologic tests for both IgM and IgG anti-HEV has allowed a comprehensive epidemiological survey of the distribution of HEV in the last few years. Cumulative data thus far suggest hepatitis E is not limited to endemic areas of the developing world. Clinical cases of HEV infection with no travel history have begun to be reported in Western developed countries. While hepatitis E disease burden in nonendemic areas remains to be fully evaluated, HEV will remain an important cause of morbidity and mortality in regions where fecal contamination of the environment and drinking water are still common. The need to further understand the biology of HEV and its replicative strategy within the host is made evident by recent discovery describing the virus as potentially a zoonotic agent. Development of a tissue culture system capable of supporting propagation of high titer HEV is essential. The mechanism leading to fulminant hepatic failure, especially in pregnant women, is still not understood and will require further studies. With the progressive realization of the medical significance of hepatitis E, recent development of an anti-HEV vaccine will be an important preventive measure for disease abatement in the future.

HERPES SIMPLEX VIRUSES (*HERPESVIRIDAE*)

Contents

General Features

Laure Aurelian, Virology/Immunology Laboratories, Departments of Pharmacology and Microbiology, The University of Maryland School of Medicine, Baltimore, Maryland, USA,

History

The origin of the word 'herpes' as applied to spreading, usually ulcerative skin manifestations can be traced to Hippocrates. In 1736 Jean Astruc classified the condition as a sexually transmitted disease and noted its frequency among homosexuals. Its infectious nature was demonstrated in 1921, when material derived from herpetic lesions was shown to cause a serially transmissible keratoconjunctivitis in rabbits. In 1929 Goodpasture concluded that the virus travels along the axonal route from peripheral sites of infection and resides in a latent state within the nerve cells of the ganglion. In the 1930s it became evident that the manifestation is gingivostomatitis in seronegative subjects and recurrent 'fever blisters' in those who are seropositive. During the last 30 years distinct viruses were shown to cause facial and genital lesions. Molecular biology progress was applied towards herpes simplex virus (HSV) engineering for vaccine development and gene therapy. A critical advance has been the development of successful antiviral chemotherapy.

Classification

The herpes simplex virus serotypes (HSV-1 and HSV-2) are members of the family *Herpesviridae*. Classification is based on the virion architecture. The capsid is a 100–110 nm protein shell with icosadeltahedral symmetry composed of 162 capsomeres with a hole along the long axis. It is surrounded by the tegument, an electron-dense amorphous material which is asymmetrically distributed and may appear to be fibrous on negative staining. Tegument proteins involved in initiating virus replication include the regulatory immediate early (IE) proteins ICP4 and ICP0, the major *trans*-activating protein VP16, the large subunit of the viral ribonucleotide reductase (RR1), and vhs which inhibits host cell translation. The outer covering of the virus is the envelope, acquired from cellular membranes. It is decorated with spikes, approximately 8 nm long, containing HSV-specified glycoproteins (**Fig. 1**). Virions are 150–200 nm and contain 30–35 proteins.

The core is an electron-opaque structure approximately 77.5 nm in diameter, containing the 152 kbp linear, double stranded viral DNA. HSV DNA has two covalently linked components consisting of unique sequences (U_L and U_S) bracketed by inverted repeats. The U_L and U_S components can invert relative to each other, such that DNA extracted from virions or from infected cells consists of four equimolar populations differing in their relative orientation. Genes are contained within both the unique and repeat sequences. HSV genes RR1 and $\gamma_1$34.5 contain regions with cellular homology, presumably acquired from infected cells.

HSV belongs to the subfamily *Alphaherpesvirinae* and the genus *Simplexvirus*. Criteria for *Alphaherpesvirinae* classification are a variable host range, relatively short reproductive cycle, rapid spread in culture, efficient destruction of infected cells and the

Figure 1 Negatively stained virion reveals icosadeltahedron capsid with 9.5 × 12.5 nm capsomeres (longitudinal section) and evidence of a 4 nm in diameter channel that runs from the surface along the long axis. The capsid is surrounded by an asymmetrical fibrous-like tegument and an envelope with spikes projecting from its surface. ×250 000.

capacity to establish latent infections in sensory ganglia. HSV shares four biological properties with all other *Herpesviridae:*

1. DNA codes for enzymes involved in nucleic acid metabolism;
2. DNA synthesis and capsid assembly occur in the nucleus; capsids are enveloped as they transit through the nuclear membrane;
3. Production of infectious progeny is accompanied by cell killing;
4. Viruses remain latent in their natural hosts.

Virus Replication and Host Range

After adsorption to cell surface receptors, the HSV envelope fuses with the plasma membrane. The capsid is transported to the nucleus, where its DNA is released. Three classes of genes are coordinately transcribed and temporally regulated. IE genes are transcribed first, in the absence of viral protein synthesis. ICP4, ICP27, ICP22 and ICP0 regulate the expression of the other viral genes. Early gene products include enzymes, such as thymidine kinase (TK) and DNA polymerase, that are required for virus DNA replication. Their expression requires functional IE genes. RR1 is the only viral gene regulated by cellular AP-1 transcription factors. The late genes require viral DNA synthesis for maximal expression. Onset of early gene expression coincides with irreversible shut-off of host cell macromolecular syntheses. Virus assembly begins in the nucleus. The envelope is acquired by budding through patches of altered nuclear membrane (**Fig. 2**). HSV replication is relatively inefficient with a low ratio of infectious/incomplete virus particles.

The biologic properties of some HSV proteins has been elucidated. Glycoproteins D (gD) and B (gB) are related to infectivity. gD is also a potent inducer of neutralizing antibodies. Glycoprotein G (gG) provides serotype specificity. The 5′-end of RR1 codes for a protein kinase (PK) activity related to the neoplastic potential of HSV-2 (HSV-2 oncogene). IE protein ICP47 downregulates HSV-specific immunity by interfering with antigen presentation to cytotoxic T cells (CTL).

Naturally, HSV causes disease only in humans. However, it infects experimental animals such as hamsters, mice, rats, guinea pigs, rabbits and embryonated chicken eggs. The animal species, virus type, route of inoculation, and state of immune competence affect the outcome of infection. In the mouse, intracerebral, footpad, intranasal and intraperitoneal inoculations are used as models of human fatal neurological or visceral disease. Eye infection is used as a model of encephalitic and latent disease. Certain mouse strains (e.g. C57BL/6) exhibit natural resistance to HSV infection whereas newborn mice are particularly sensitive. HSV-1 infection of the skin was described in mice, rabbits and guinea pigs following skin abrasion or intradermal inoculation. HSV-2 mucosal infections have been studied in the mouse and the guinea pig. The best approximation of human recurrent cutaneous disease was achieved in the guinea pig. A wide variety of cell lines support HSV growth. Primary and secondary cultures of human origin (e.g. MRC-5) are generally more sensitive than established nonhuman lines and they are used for virus isolation. Established lines (e.g. Vero) are used for the production of large quantities of virus for experimental studies and to determine virus titers by plaque assays.

Serologic Relationships

The HSV-1 genome has been entirely sequenced. It expresses at least 84 proteins. Of these, five open reading frames (ORFs) which map in the inverted repeats, are present in two copies/viral genome. A total of 38 HSV-1 ORFs cannot be deleted without ablating the capacity of the virus to replicate in cell culture. The HSV-2 genome has a similar organization, but the overall homology to HSV-1 is only 47–50%. Antigenic differences are evident in regions of low genome homology, such as those coding for gG and the PK domain of RR1. Differentiating biologic markers include virus titers in rabbit kidney cells,

plaque size and morphology in tissue culture, pock size on the chorioallantoic membrane of embryonated eggs, thermal stability, sensitivity to 5-iododeoxyuridine and interferon, properties of RR1 PK activity and neoplastic potential. Relatively few genes (e.g. homologues of HSV-1 gB) are conserved among members of different subfamilies.

Genetics

Epidemiologically unrelated isolates of the same HSV serotype are not identical (intratypical polymorphism). Differences result from base substitutions that add or eliminate a restriction endonuclease cleavage site or substitute an amino acid, occasional deletions, or due to variability in the number of repeated sequences at various genome sites. Intratypic polymorphism was also noted with monoclonal antibodies and isolates may differ with respect to neurovirulence. The restriction endonuclease cleavage patterns of a given strain are relatively stable even after many years of serial *in vitro* passage.

Epidemiology

HSV infections are worldwide. There are no differences in sex or seasonal variation. Animal vectors have not been described. Clustered outbreaks were reported in hospitals and orphanages, but there is no clinical or molecular epidemiologic evidence that HSV causes epidemic disease.

The mouth and lips are the most common sites of HSV-1 infection. Primary infection usually occurs by 5 years of age and is generally asymptomatic. With illness, gingivostomatitis is usually the manifestation. In young adults, primary infection was associated with pharyngitis and a mononucleosis-like syndrome. Geographic location, socioeconomic status and age influence the frequency of HSV infection. In developing countries 95% seroconversion was seen before the age of 15. This likely reflects the increased frequency of direct person to person contact in overcrowded conditions. In presumed middle-class individuals of industrialized societies, seroconversion occurred in 20% before the age of 5 years. Antibody prevalence was 60% in the third decade of life. Only five of 18 countries surveyed had an HSV-1 antibody prevalence of less than 70% at age 20–40 years.

Over a decade ago, conservative estimates were 300 000–500 000 new HSV-2 cases per year, calculated based on a ratio of one case of genital HSV for 5–10 gonorrhea cases. The prevalence of infection determined by cytopathological screening and virus isolation from cervicovaginal swabs was 0.09–0.24% in normal women and 0.002–7.0% in STD clinics. Recent estimates are one case of genital HSV-2 for 2.2 cases of gonorrhea. The current age-adjusted prevalence of HSV-2 in the US is 20.8%, a 30% increase over the last 13 years. Individuals with genital HSV range between 40 and 60 million.

Factors that influence acquisition of HSV-2 include: sex (women greater than men), race (blacks more than whites), marital status (divorced versus single or married), place of residence (city greater than suburb) and number of sexual partners (higher number increased risk). The highest prevalence of HSV-2 antibodies (75–98%) was seen in female prostitutes and homosexual men. Women are about 45% more likely than men to be infected with HSV-2. The risk of susceptible females for contracting HSV from infected males is 80% after a single contact. The probability of infection with HSV-2 is less than 10% for US women having one partner. It increases to 40%, 62% and greater than 80% as the number of partners increases to 2–10, 11–50 and greater than 50, respectively. For heterosexual men, these risks are 0, 20%, 35% and 70% for each of the risk groups respectively. For homosexual men, the risks are greater than 60% and 90% for those with 11–50 and greater than 50 partners, respectively. The frequency of HSV-1 isolation from genital lesions has increased significantly during the last 10 years. It is now estimated that 25 million US adults have genital HSV-1 infections.

HSV-2 infection is associated with acquisition of both human immunodeficiency virus type 1 (HIV-1) and human T cell lymphotropic virus type 1 (HTLV-1) infections. HSV-2 was also shown to activate HIV-1 expression in experimental systems.

The major risk to the fetus is maternal primary or initial genital infection with HSV, the rate of which is 0.5–10% per year. Infection acquired near the time of labor is associated with neonatal herpes and perinatal morbidity. Recurrent infection is the most common form of infection during gestation. The incidence of HSV-2 shedding at delivery is 0.01–0.6%, irrespective of past history and time of gestation. The incidence of cervical shedding in pregnant women with asymptomatic infection averages 3% (range 0.2–7.4%). The frequency of shedding does not vary by trimester during gestation. Most women whose children are infected (60–80%), are asymptomatic at the time of delivery and have neither a past history of genital HSV nor a sexual partner reporting a genital infection.

The estimated incidence of HSV encephalitis is 2.3 cases per million population per year. The age distribution is biphasic with one peak at 5–30 years of age and a second peak above 50 years of age. HSV-1

accounts for 95% of cases. HSV-2 was isolated from the cerebrospinal fluid in 0.5–3% of patients with aseptic meningitis.

Transmission and Tissue Tropism

HSV transmission occurs during close personal contact with active ulcerative skin lesions or virus-positive secretions from asymptomatic subjects. HSV-1 can be isolated from the mouth for 7–10 days after primary HSV-1 infection. Virus shedding in the saliva is uncommon in children less than 6 months of age. It was reported in 20% of children 7 months to 2 years old, 18% of those 3–14 years old, 2.7% in those over 15 years old and 2–9% of asymptomatic adults. This is consistent with a 2–5% shedding frequency reported by contemporary cross-sectional studies. HSV-1 DNA was detected by polymerase chain reaction (PCR) assay in oral secretions from 36–45% of patients at prodrome (24–48 h before clinical recurrence). However, since virus was not isolated, it is unclear whether patients are infectious during prodrome. Genital infection with HSV-1 results from self-inoculation or from oral sexual practices. It may be more prevalent in females than in males and less severe and prone to recur than HSV-2 infections.

Sexual contact is the primary route of HSV-2 transmission. HSV-2 was isolated from the genital tract of 0.3–5.4% of asymptomatic males and 1.6–8% of asymptomatic females attending sexually transmitted disease (STD) clinics. Approximately 18–23% of women evaluated after their first episode of genital HSV, shed virus in the absence of perineovulvar lesions. Protein and PCR assays suggest that asymptomatic vaginal shedding occurs at a rate of 1 day in 5. However, cervical lesions are generally unnoticed and they may be confused with asymptomatic shedding. Also, since virus titers in active lesions are 100–1000-fold higher than in salivary and genital secretions from asymptomatic subjects, the efficiency of transmission during acute episodes is significantly higher. Approximately one-third of the world population represents such a reservoir.

HSV-2 can be transmitted from mother to fetus, primarily during passage through an infected birth canal. Intrapartum transmission accounts for 75–80% of all cases. Approximately 30 babies were identified in the world literature with symptomatic congenital HSV disease. This frequently resulted from ascending infections in women who have had prolonged rupture of membranes before delivery.

The central nervous system (CNS) is a target of HSV infection. The trigeminal, vagal and sacral dorsal root ganglia are the major sites of latent HSV infection. HSV can also infect the liver, the lungs, adrenal glands, pancreas, small and large intestine and bone marrow.

Pathogenicity

For infection to occur virus must come in contact with mucosal surfaces or abraded skin. After replication at the site of infection, virus is transported by neurons to dorsal root ganglia where latency is established. Replication in the ganglia infrequently results in life-threatening CNS infection. However, latency generally predominates. Widespread organ involvement is the consequence of viremia in a host that is not capable of limiting virus replication to mucosal surfaces. The HSV-1 portal of entry is generally the oropharyngeal mucosa and the trigeminal ganglia are invariably colonized. Initial HSV-2 replication is at genital sites with colonization of the sacral ganglia. Wild-type isolates may differ in their ability to grow or invade the CNS. Virulence loci comprising both the ability to grow in CNS (after intracerebral inoculation of mice) and to invade the CNS (after peripheral inoculation) were ascribed to several genes, notably *TK* and $\gamma_1 34.5$.

Clinical Features of Infection

HSV infects neonates, children and adults. It produces a wide spectrum of diseases ranging from mild illness, undiscernible in the majority of patients, to severe and life-threatening disease in relatively few patients. The incubation period is 1–26 days (median 6–8 days). Factors that influence severity are age, gender, host genetic factors, immune competence, associated illnesses, and virulence of the infecting virus strain.

Most (70–90%) childhood HSV-1 infections are asymptomatic, but they may be followed by subsequent recurrent episodes of symptomatic disease. In children 1–3 years of age, the major manifestion of HSV-1 infection is gingivostomatitis, a serious infection of the gums, tongue, mouth, lip, facial area and pharynx, often accompanied by high fever, malaise, myalgias, swollen gums, irritability, inability to eat and cervical lymphadenopathy. Later in life the major clinical manifestation of HSV-1 infection is an upper respiratory tract infection, generally pharyngitis. Reactivated HSV-1 is associated with mucosal ulcerations or lesions at the mucocutaneous junction of the lip, presenting as small vesicles that last 4–7 days and are known as herpes *labialis*, cold sores or fever blisters. Other HSV-1 skin diseases include primary herpes dermatitis (a generalized vesicular eruption), eczema herpeticum (usually a manifestation of a primary infection in which the skin is the portal of entry), and traumatic herpes (resulting from trau-

Figure 3 Genital HSV infection. Lesions are on the vulva (**A**), cervix (**B**), penis (**C**) and perineum (**D**). Hyperproliferative lesion caused by acyclovir-resistant HSV-2 evidences ulceration and yellow exudate and covers the entire perineum (**E**). **E**, reproduced with permission from Beasley KL *et al.* (1997) *J. Am. Acad. Dermatol.* 37: 860.

matic breaks due to burns or abrasions in the normal skin of a susceptible child). Herpetic whitlow is an occupational hazard (dentists, hospital personnel, wrestlers) resulting from infection of broken skin (often on fingers) in contact with virus on another individual. Erythema multiforme is a severe recurrent skin disease that follows HSV episodes. It is initiated by expression of the HSV DNA polymerase gene in the epidermis and has a T cell immunopathology involving, primarily, CD4+ Vβ2 T cells.

Acute HSV-1 rhinitis is a primary infection of the nose recognized by the appearance of tiny vesicles in the nostrils usually associated with fever and enlarged cervical lymph nodes. HSV-1 infections of the eye can lead to stromal keratitis, one of the leading causes of blindness in the Western world. This disease also has a T cell immunopathology involving HSV-specific CD4+ T cells. Chorioretinitis is a manifestation of disseminated HSV infection that may occur in neonates or in patients with acquired immune deficiency syndrome (AIDS). By using PCR HSV-1 DNA was recently found in gastrointestinal sensory neurons and in the geniculate ganglion and adjacent areas, implicating HSV in recurrent gastrointestinal disorders and Bell's palsy, respectively.

In females, HSV-2 infection is manifested by vesicles on the mucous membranes of the labia and the vagina. Severe forms result in ulcers that cover the entire area surrounding the vulva (**Fig. 3A**). Symptoms of primary infection include itching, pain and lymphadenopathy.

Cervical involvement is common, although it generally passes unnoticed (**Fig. 3B**). Common sites of primary HSV-2 infection in males are the shaft of the penis, the prepuce and the glans penis (**Fig. 3C**). Infection at adjacent body sites is also seen (**Fig. 3D**). Urethritis is the main local expression accompanied by a watery discharge often resulting in dysuria. Symptomatic urethritis is rare in recurrent disease, but virus often can be cultured from the urethra.

The infection is more severe in females than in males and systemic symptoms are more common. They often accompany the appearance of primary lesions and include fever, headache, photophobia, malaise and generalized myalgias. Dysuria, urinary retention, urgency and frequency, pain and discharge are also seen. Systemic symptoms are generally not seen in recurrent disease. A prodrome often signals a recurrence. It is characterized by a tingling sensation that may precede the lesions by a few hours to 2 days. This sensation may be accompanied by radiating radicular pain. Anal and rectal infections are seen primarily in homosexuals, as a result of anal intercourse. A newly described HSV-2 presentation takes the form of hyperproliferative lesions often associated with acyclovir resistant HSV-2 strains, co-infection with other agents or mild or severe immunodeficiency (**Fig. 3E**). HSV encephalitis is the most commonly reported viral CNS infection accounting for 10–20% of all cases. In children and young adults encephalitis usually results from a generalized primary infection due to virus that presumably enters the CNS through neurotropic spread by way of the olfactory bulb. In adults, CNS infections are rare and encephalitis is often preceded by recurrent lesions. Meningitis due to HSV-2 infection of the CNS was described in association with genital HSV-2 infections.

Immunocompromised adults can develop a severe generalized disease that is occasionally responsible for herpetic hepatitis. HSV pneumonitis accounts for 6–8% of cases of interstitial pneumonia in recipients of bone marrow transplants. Mortality due to HSV pneumonia in immunosuppressed patients is above 80%. Generalized HSV with involvement of adrenal glands, pancreas, small and large intestine and bone marrow was reported in the immunocompromised patient. HSV has also been isolated from 40% of patients with acute respiratory distress syndrome.

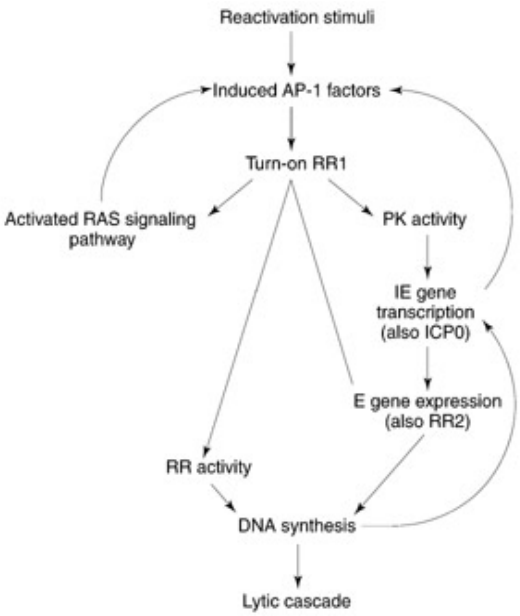

Figure 4 HSV-2 RR1 PK plays a crucial role in latency reactivation. Because RR1 is the only viral gene the basal expression of which is AP-1 dependent, we propose that it is the earliest viral response to latency reactivation stimuli which are known to induce AP-1 factors. The turned-on RR1 supplies the PK activity which is required for IE gene transcription, thereby initiating expression of other viral genes and DNA synthesis. The latter is amplified by the RR enzymatic activity resulting from complexation of RR1 and RR2. IE gene ICP0 interacts with AP-1 to further amplify RR1 expression. RR1 activates the RAS signaling pathway further amplifying AP-1 levels. The outcome is increased DNA synthesis and initiation of the lytic cascade. Reproduced by permission from Aurelian L, Herpes simplex virus type 2: unique biological properties include neoplastic potential mediated by the PK domain of the large subunit of ribonucleotide reductase. MS #97-190 published in *Frontiers in Bioscience* 3, D237–D249, 1998.

Other rather uncommon complications of HSV include monoarticular arthritis, adrenal necrosis, idiopathic thrombocytopenia and glomerulonephritis.

Latency

Latency is the ability of HSV to persist in the infected host in a nonreplicating state compatible with cell survival and followed by subsequent episodes of virus reactivation and clinical symptoms. Following replication in the skin, sensory or autonomic nerve endings are infected. Virions, or more likely capsids, are thought to be transported intra-axonally to the nerve-cell bodies in the ganglia. At this stage, in some animal models there is a short (1–2 days) period of virus replication in the ganglia, which can be detected by virus isolation from cell-free homogenates of the ganglia. It is unknown whether this also occurs in humans and it may be an artifact due to the animal species, route of inoculation or the large virus inoculum used in experimental models. At approximately 2–4 weeks post infection, a latent infection is established in which viral DNA is maintained in the neurons as an episome and there is limited HSV gene expression. Infectious virus is no longer detected in cell-free homogenates, but it can be detected by explantation and organ culture of the ganglia. Human trigeminal ganglia contain approximately 20 copies of the HSV genome per latently infected neuron. Persistence at peripheral sites (e.g. eye) was demonstrated by PCR, but its role in disease pathogenesis is unclear. Virus isolates obtained at various times from the same patients have different restriction endonuclease patterns, indicating that ganglia can be colonized by multiple HSV strains.

Certain stimuli cause reactivation of virus replication in latently infected ganglia (detected within 3–5 days of exposure) with concomitant reverse axonal transport of virus progeny to a peripheral site, at or near the portal of entry. Reactivating stimuli include fever, axonal injury, exposure to ultraviolet irradiation (sunlight), stress and possibly hormonal irregularities. The development of clinically apparent recurrent lesions is probably influenced by the amount of virus, virus–cell interactions, and the rapidity of the host's immune response in clearing virus. In the guinea-pig model latent virus reactivates spontaneously. In other animal models it is reactivated by neurectomy, ganglionic trauma, electrical stimulation, epinephrine iontophoresis or cadmium treatment. Depending on the host immune response, the outcome of virus reactivation may vary from severe debilitating lesions (in immunosuppressed individuals) to no lesions, or barely visible ones.

Viral gene products that govern the establishment and maintenance of latency are unknown. A region of the HSV-1 genome, termed latency associated transcript(LAT) and two ORFs (ORF-O and ORF-P) which are read antisense to LAT on the HSV genome, are the only transcripts in latently infected sensory neurons. LAT may be involved in site-specific (trigeminal and sacral neurons) reactivation of HSV-1 and HSV-2. A hypothetical virus reactivation pathway is shown in **Fig. 4**. It is based on the finding that reactivating stimuli function by inducing AP-1 transcription factors and argues that they induce expression of *RR1*, the only viral gene that can respond to AP-1. In turn, *RR1* amplifies AP-1 levels through activation of the RAS signaling pathway by its PK activity (**Fig. 5**). Our recent studies of a HSV-2 mutant deleted in RR1 PK indicate that the PK activity is required for early onset of *IE* gene

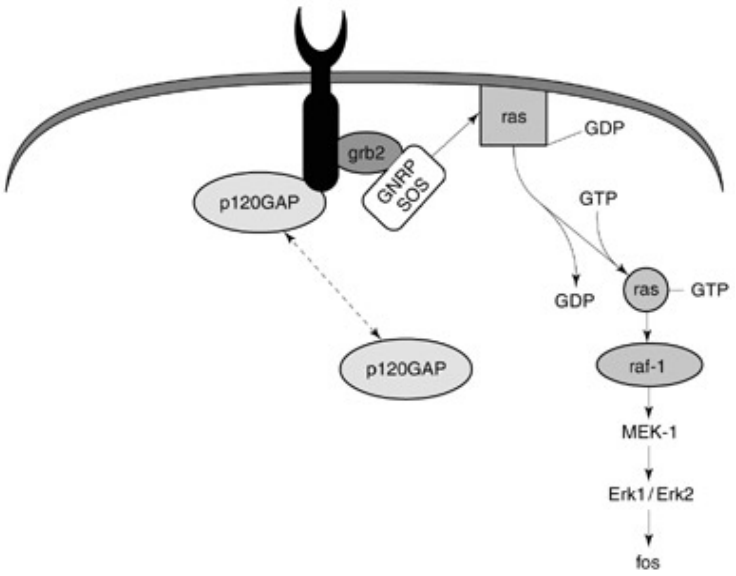

Figure 5 HSV-2 RR1 PK activates the RAS signaling pathway. The constitutively activated oncoprotein binds the Grb_2–hSOS complex thereby bringing hSOS in the vicinity of RAS. This results in the conversion of RAS-GDP into RAS-GTP (RAS activation). HSV-2 RR1 PK also binds the downregulatory factor RAS-GAP (p120GAP) which it inactivates through phosphorylation. The activated RAS initiates the kinase cascade that leads to the nucleus and results in AP-1 (fos) activation. Reproduced by permission from Aurelian L, Herpes simplex virus type 2: unique biological properties include neoplastic potential mediated by the PK domain of the large subunit of ribonucleotide reductase. MS #97-190 published in *Frontiers in Bioscience* 3, D237–D249, 1998.

expression, thereby initiating viral DNA synthesis. The levels of viral DNA synthesis are further amplified by the ribonucleotide reductase activity. The outcome is initiation of the lytic cascade and production of infectious virus.

HSV Infection during Pregnancy and Neonatal Disease

Localized genital infection is the most common form of HSV infection during pregnancy. In a small number of patients multiple visceral sites are also involved. Mortality among these pregnant women was reported to be $\geq$50%, presumably due to altered cell-mediated immune responses. Fetal deaths occurred in 50% of cases, although mortality did not correlate with the death of the mother. Severe intrauterine fetal growth retardation was reported in women with primary HSV infection during pregnancy. Maternal primary infection before 20 weeks of gestation was associated with spontaneous abortion in as much as 25% of infected women. Fetal infection is generally due to virus shed at the time of delivery. Neonates have the highest frequency of visceral and CNS involvement of all HSV-infected patients. Skin lesions are the most commonly recognized features of the disease. However, at least 70% of untreated neonatal HSV cases will lead to disseminated disease. Infection of the neonate can be prevented by delivery by cesarean section.

Pathology

Histopathologic changes characteristic of HSV-1 or HSV-2 induced skin lesions represent a combination of virus-mediated cellular death and associated inflammatory responses. HSV-induced changes include ballooning of the infected cells, the appearance of condensed nuclear chromatin and subsequent degeneration of the nuclei, generally within the parabasal and intermediate cells of the epithelium. Multinucleated giant cells are also formed and a clear (vesicular) fluid containing large quantities of virus, cell debris and inflammatory cells, appears between the epidermis and the dermal layer. An intense inflammatory response is seen in dermal structures particularly in the primary infection. With healing, the vesicular fluid becomes pustular and then scabs. Scarring is uncommon. As host defenses are mounted, an influx of mononuclear cells can be detected in the infected tissue. Similar histopathologic findings are seen in mucous membranes. Vascular changes in the area of infection include perivascular cuffing and areas of hemorrhagic necrosis. These are particularly prominent in organs other than skin. In the brain

oligodendrocytic involvement, gliosis and astrocytosis are common.

Host Immune Responses

Immune responses induced by HSV infection include an early nonspecific containment phase and a later HSV-specific effector phase. The relative contribution of these two phases differs according to the experimental model, the route of virus inoculation and the HSV serotype. Natural killer (NK) cells and/or interferon (IFN) are the major factors involved in the nonspecific containment phase against HSV-1. Natural resistance of certain mouse strains to HSV infection was correlated with these factors. They act early in infection, thereby limiting HSV-1 growth and reducing the virus load. Intrinsic macrophage resistance, the mechanism of which is abortive infection, was implicated as the major determinant of the nonspecific containment phase against HSV-2. Langerhans cells are involved in the control of cutaneous HSV infections. Various reports have incriminated or refuted the association of HLA with HSV infections. A1, A2, A9, BW16 and CW2 were associated with recurrent oral lesions; A1, A2, A9 and DR3 with recurrent ocular infections.

Humoral and cell-mediated responses are involved in the specific effector phase. HSV specific antibodies are first observed on days 5–10 postinfection and they persist indefinitely. Antibody titers are higher in subjects with, than those without, a history of recurrent disease, reflecting the propensity of the latent virus to reactivate. The response is heterogeneous with respect to protein specificity. Soon after onset of infection, antibodies to structural proteins are followed by those directed against gD, gB, ICP4, gE, gG-1/gG-2 and gC. Both IgM and IgG antibodies can be demonstrated depending on the method and time of assesment relative to disease onset. In children, antibodies to ICP4 may be predictive of long-term neurologic outcome. Infected newborns produce IgM antibodies (particularly against gD) within the first 3 weeks of infection. Transplacentally acquired antibodies do not protect the newborn.

Recovery from HSV infection, primarily involves the T-cell system. Newborns have delayed (2–4 weeks) HSV-specific T cell responses and decreased IFN-α and IFN-γ production in response to HSV antigen as compared to older individuals. This may be responsible for a higher frequency of disease progression. Effector mechanisms include: (1) delayed-type hypersensitivity (DTH), an early (days 5–10 postinfection) HSV-type common response that remains inducible for at least 2 years after infection; (2) effector lymphokines such as IFN-γ, interleukin 2 (IL-2) and other soluble factors, and (3) CTL. In contrast to other viruses, CTL to HSV are generally difficult to induce. In mice the activity is present only in draining lymph nodes, it is detected only in mice pretreated with cyclophosphamide or after extended (3 days) *in vitro* culture of the effector cells, and it is no longer seen by day 12 postinfection. HSV-1 specific CTL clones are directed against cell surface glycoproteins, primarily gB, gD or gE, and intracellular IE proteins; HSV-2-specific clones are against gC, gD, gE or gG. Naturally acquired HSV immunity reduces the severity of the disease but it does not prevent the establishment of latency, development of recurrent disease or reinfection, even by autoinoculation with the same HSV strain. This is due to transient downregulation of the HSV-specific T cell responses on re-exposure to the virus, resulting from increased production of downregulatory factors such as prostaglandin E_2 (PGE_2) and transforming growth factor β (TGFβ).

Neoplastic Transformation

Numerous seroepidemiologic studies have associated HSV-2 infection with an increased risk of human squamous cervical cancer. The exact role of HSV-2 in cervical carcinogenesis is unclear. Current opinion is that HSV-2 is a cofactor, or infection reflects the increased sexual activity of cervical cancer patients. However, HSV-2 is a tumor virus. It causes neoplastic transformation, also of human cells, and tumor formation in animals. Both are achieved with inactivated virus, temperature sensitive mutants, sub- or supraoptimal infection temperatures, sheared viral DNA and subgenomic fragments. Depending on conditions, the transformed cells retain and express the viral DNA or not, suggesting that viral genes cause increased cell proliferation or they initiate the transformation process which can subsequently progress independently. HSV-2 DNA sequences have both immortalizing and neoplastic functions, the latter mediated by the unique PK-encoding 5′ terminal of RR1 (HSV-2 oncogene). Transformed human cells cause tumors that express the viral oncoprotein when injected in nude mice. Mutations that inactivate the PK activity of the oncoprotein abrogate neoplastic potential, and both cell proliferation and tumor growth are inhibited by antisense oligonucleotides which inhibit oncoprotein synthesis. The HSV-1 RR1 PK does not have oncogenic potential. However, HSV-1 causes mutagenesis and gene amplification, activates cellular genes and causes morphologic transformation.

Prevention and Therapy

Neonatal infection is decreased by surgical abdominal delivery when membranes are ruptured for less than 4 h. For women with a past history of genital infection, HSV culture at the time of delivery can establish whether virus shedding can lead to fetal infection. Detection of viral DNA by PCR does not establish infectivity. Detection of HSV-2 specific antibodies could be valuable in identifying those women at greatest risk.

Vaccination remains the ideal method for prevention of infection. Recombinant and subunit vaccines have been engineered during the past 15 years in an attempt to remove transforming HSV DNA and enhance antigenicity. At Biocine/Chiron, a gD-2 gene was truncated to yield a mature protein containing 348 residues of gD-2. When administered together with adjuvants, this, as well as a similar gB-2 preparation induced neutralizing antibodies and caused amelioration of morbidity and reduction of mortality in immunized animals. However, disease was not prevented, and the preparations offered very little benefit in humans. Vaccinia/gD recombinants protected from HSV-2 recurrent disease in the guinea-pig model. However, not all constructs were equally protective. Information gained from these studies is that protection is contingent upon: (1) regulation of gD expression as an early gene, (2) optimal gD post-translational modification in epidermal cells and (3) antigen presentation by Langerhans cells to T cell subpopulations involved in protective immunity. Live genetically engineered HSV vaccines are predicated on their ability to fulfill these requirements. Two such vaccines, currently under development, are respectively deleted in $\gamma_1$34.5 or glycoprotein gH but retain oncogenic DNA. The third vaccine currently under development is an oncogene-deleted and growth-attenuated virus.

The ideal HSV therapy would both reduce the severity of the primary disease and prevent the establishment of latency. However, as there is no known agent that can prevent latency, the major goals for the treatment of HSV disease are to reduce: (1) the time to resolution of clinical symptoms; (2) the likelihood of complications and, should they occur, their severity; and (3) the time of virus shedding and therefore the likelihood of transmission. Synthetic nucleoside analogues licensed for the treatment of HSV infections include idoxuridine for HSV keratitis and vidarabine for HSV encephalitis, neonatal herpes and HSV keratitis. Agents currently used for the treatment of HSV infections are acyclovir, available in topical, intravenous and oral formulations, famciclovir, valaciclovir, foscarnet and cidofovir, the latter two available in intravenous formulation for use in infections caused by acyclovir-resistant HSV. Acyclovir is phosphorylated by HSV thymidine kinase at a rate 10^6-fold faster than by the cellular enzyme. Acyclovir triphosphate, the active form of the drug, is recognized by HSV DNA polymerase much more readily than by the host cell DNA polymerase. Acyclovir triphosphate blocks DNA synthesis by acting as an inhibitor of polymerase activity as well as its substrate, becoming incorporated into the growing DNA chain and causing termination of chain growth. As DNA synthesis is required for acyclovir to function, the drug cannot destroy the virus during the latent period.

Oral acyclovir speeds the healing and resolution of symptoms of primary and recurrent HSV infection. However, the subsequent recurrence rates are not affected. Routine use for recurrent disease, especially for mild episodes, is not recommended. Long-term daily suppressive therapy may be useful in reducing the frequency of reactivation in patients with very frequent recurrent episodes. Daily administration of two to five 200 mg capsules of oral acyclovir for 4–6 months appears to be safe. Long-term suppressive therapy with oral acyclovir does not eliminate ganglionic latency, and reactivation of disease occurs after therapy is discontinued. A recently voiced concern about potential consequences of long-term suppressive treatment is that nonreplicating HSV-2 is oncogenic. Acyclovir-resistant HSV strains emerge with moderate frequency. These strains can become sensitive after treatment with cidofovir, suggesting that alternating acyclovir and cidofovir therapies may provide a strategy for managing the emergence of alternating acyclovir-resistant and sensitive infections. A topical cidofovir formulation is currently under review by the FDA.

Future Perspectives

Better understanding of the molecular pathogenesis of HSV infections along with the role of HSV immunity in protection remain the principal goals for future research efforts. Vaccines that prevent infection and recurrent disease and are free of oncogenic DNA are currently under development. Further research must also focus on the mechanism of latency establishment and virus reactivation to develop improved antiviral chemotherapy and overcome problems of drug resistance. Antisense technology permits the design of drugs that can specifically inhibit critical HSV genes and can be modified to overcome resistance causing mutations. Significant progress may be achieved by developing novel delivery vectors that increase the intracellular levels of antisense oligo-

nucleotides and optimize their cellular localization. HSV is an attractive vehicle for delivery of therapeutic genes to the nervous system. The viral genome persists in the trigeminal and sacral ganglia and in brain neurons without apparent pathologic consequences and transgenes can be expressed from the viral genome. Further research is needed to elucidate the potential of HSV as a vector for gene therapy of brain tumors and certain neuropathies.

The Virion

The capsid

Like all herpesviruses, HSV-1 and the closely related HSV-2 are enveloped icosahedral virions. The 152 000 bp (152 kbp) genome is densely packaged in a liquid–crystalline, phage-like manner within a 100 nm capsid. The capsid comprises 162 capsomeres of 150 hexons and 12 pentons. Hexons contain six molecules of the 155 kDa major capsid protein (VP5 or U_L19) with six copies of the vertex protein VP26 (U_L35) at the tips. Pentons contain five copies of VP5. Hexons are coordinated in three-fold symmetry with a triplex structure made up of two other proteins – one copy of VP19c (U_L38) and two copies of VP23 (U_L18) per triplex. Small amounts of other viral proteins are also associated with the capsid; these include VP24 (derived from U_L26), a maturational protease, and the U_L6 gene product.

The tegument

The capsid is surrounded with the 20 or so tegument or matrix proteins. These include the *α-trans*-inducing factor (αTIF, VP16 or U_L48) and a virion-associated host shut-off function (U_L41).

The envelope

The trilaminar viral lipid envelope forms the outer surface of the virion. This envelope has a nominal diameter of 170–200 nm, although exact dimensions will vary depending upon the method of visualization. The envelope is derived from the host cell nuclear membrane and contains at least ten viral encoded glycoproteins. One glycoprotein (gG–U_S4) has sufficient differences in amino acid sequence to serve as a type-specific immune reagent to differentiate HSV-1 and -2. At least four (gL–U_L1, gH–U_L22, gB–U_L26, gD–U_S6) are involved in virus penetration into the host cell; of these, the sequence of gB is conserved among a broad range of different herpesviruses. Another glycoprotein, gC (U_L44) facilitates the initial attachment of the virion to glycosaminoglycans on the cell surface, but is not essential for virus infectivity. Two others, U_S7–gI and U_S8–gE function together as a hetero-oligomer which binds the Fc region of IgG and influences cell-to-cell spread of virus.

The functions of the others are not fully known but presumably are involved in mediating host response to infection and (perhaps) certain levels of cell specificity.

The HSV Genome

General genome arrangement

Genome size and sequence. The complete sequences of prototype strains of both HSV-1 and HSV-2 are available in standard databases. Homology between HSV-1 strains is >99% for most regions of the genome, while overall homology between HSV-1 and HSV-2 approximates 85% within translational reading frames and significantly less outside them. The HSV-1 genome is schematically shown in **Fig. 1**, it is a linear, double-stranded DNA duplex 152 000 bp in length, with a base composition of 67% G+C. The genome circularizes upon infection. Because the

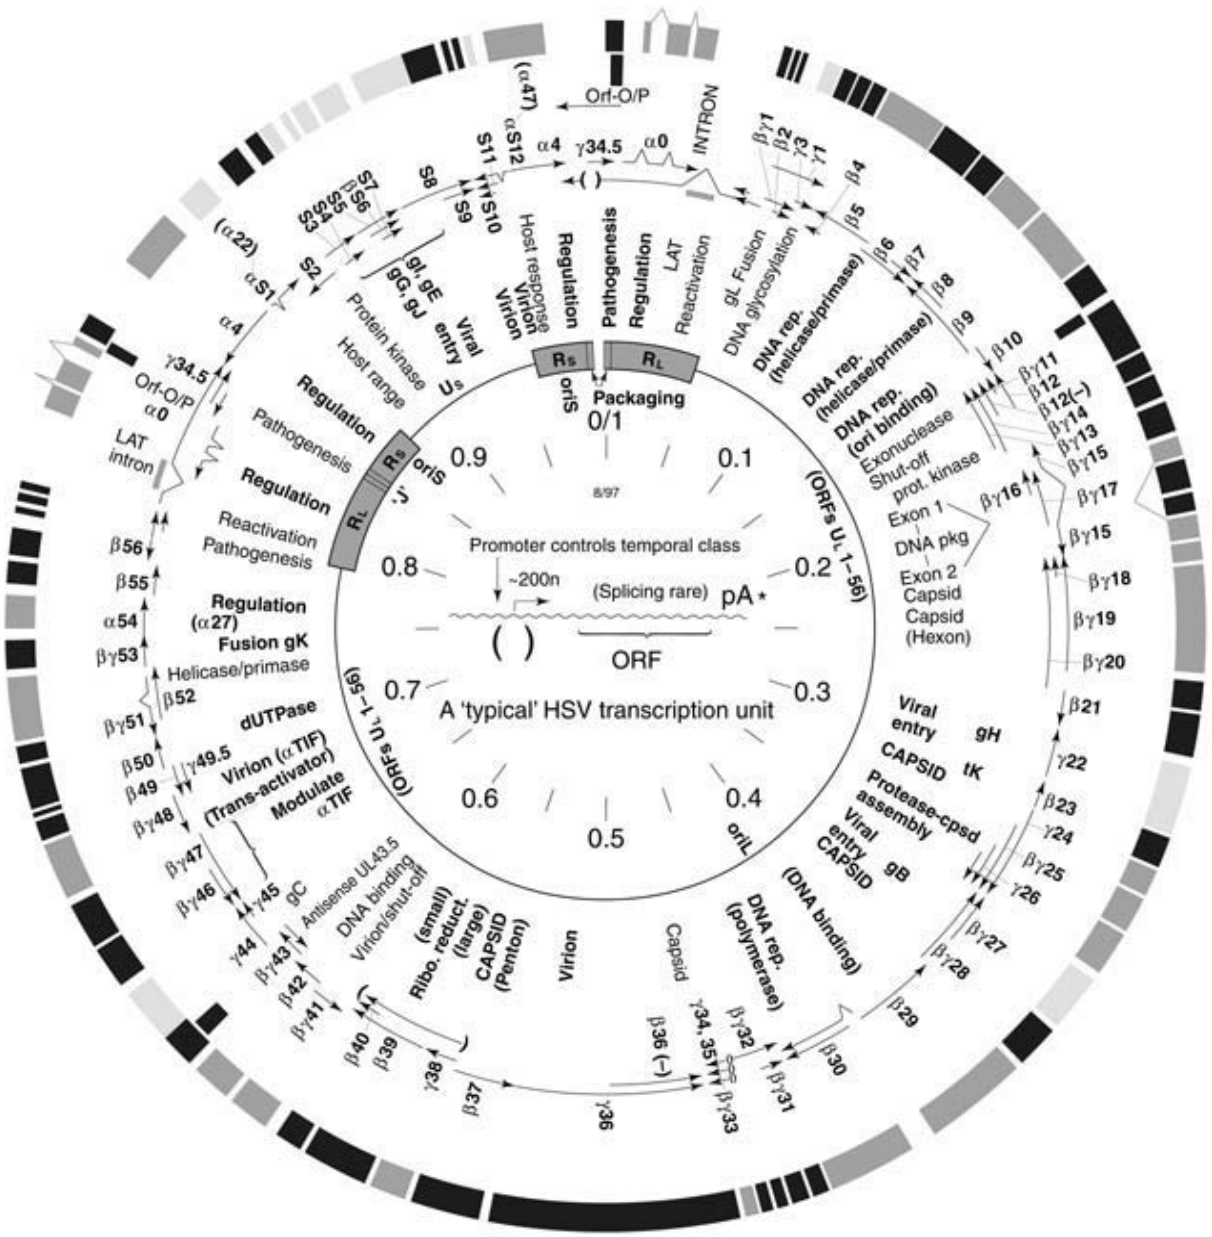

Figure 1 The genetic/transcription map of the HSV-1 (strain 17*syn*$^+$). The map is shown as a modified circle to indicate the fact that the linear genome circularizes upon infection. Open reading frames predicted from sequence data are named as described in the text, and transcripts expressing all or portions of them are indicated with the arrow heads showing the transcription termination/polyadenylation sites. Known kinetic classes of transcripts are indicated; the latency associated transcripts (LATs) in the R_L regions are the only transcripts expressed during latent infection. The functions of the two partially overlapping transcripts occurring in the R_L 5′ of the LAT start site are unknown. Also shown are the location of the origins of replication and the 'a' sequences at the genome ends which are involved in encapsidation. In addition, and where known, the functions of individual genes are shown.

genome circularizes, the genetic/transcription map is conveniently shown as a circle. Since the virus encodes nearly 100 transcripts and more than 80 open translational reading frames (ORFs), the map is complex. Still, general lack of splicing of HSV transcripts means that most ORFs are expressed by a single transcript.

The organization of the genome can be represented as $a_nbU_Lb'a_mcU_Sc'a$. It is made up of five important regions. These are:

1. The ends of the linear molecules made up of multiple repeats of 'a' sequences. These are important in both circularization of the viral

DNA upon infection, and in packaging the DNA in the virion.

2. The 9000 bp long repeat (R_L–'b' region). It encodes an important immediate early regulatory protein ($\alpha 0$), the promoter of and most of the 'gene' for the latency-associated transcript (LAT). It also encodes the translational reading frame for the ICP34.5 gene important in neurovirulence, and two partially overlapping ORFs antisense to that of ICP34.5, ORF-O and ORF-P. Preliminary reports suggest that these two ORFs encode proteins that may downregulate immediate early gene expression. Two other short translational reading frames 5′ of the LAT cap, ORF-X and ORF-Y, are also present but have unknown function.
3. The long unique region (U_L), which is 108 000 bp long, encodes more than 60 distinct proteins. It contains an origin or replication (the ori_L) and genes encoding DNA replication enzymes as well as capsid and many other proteins.
4. The 6600 bp short repeats (R_S–'c' region) encode the very important $\alpha 4$ immediate early transcriptional activator. It also encodes the polyadenylation signal for the 9 kb primary LAT, the major origin of replication (ori_s) and the promoter for two other immediate early proteins.
5. The 13 000 bp unique short region (U_S) encodes 12 ORFs, a number of which are glycoproteins important in viral host range and response to host defense.

Sequence inversions. The arrangement of the inverse repeat elements allows the viral genome to 'isomerize' or invert relative to each other into four sequence arrangements: prototype (P), inversion of the long segment relative to the short (I_L), inversion of the short relative to the long (I_S), and inversion of both relative to the P (I_{LS}). Inversion is facilitated by the 'a' sequence elements noted above.

HSV ORFs and transcripts

Number and genomic location. Superficial nucleotide sequence analysis reveals 70 'reasonable-sized' translational reading frames, but, when shorter, overlapping and complementary reading frames are included, this number increases markedly. Each viral protein is expressed from its own independently regulated transcript. The viral transcription map is included in **Fig. 1**, and correlation between transcripts and expressed proteins is evident from this map as well as the data in **Table 1.** Independent starts of overlapping transcripts, (rare) splicing, and temporally differentiated polyadenylation site utilization result in the number of independent transcripts expressed to over 100.

General properties of HSV transcripts and their promoters Generally, the translational reading frames of HSV-1 are expressed as unique, unspliced mRNA molecules which are controlled by temporal class-specific promoters. The functional architecture of a 'typical' transcript is shown in **Fig. 1**, and HSV-1 promoters representing the four temporal classes of productive infection are shown in **Fig. 2.** The average size of HSV mRNAs ranges between 1500 and 2000 bases, but transcripts as long 9000 bases (U_L36) are expressed. Nested, partially overlapping transcripts, each encoding a unique ORF but utilizing a common polyadenylation site are common (cf. transcripts encoding U_L24, 25 and 26 or those encoding U_S5, 6 and 7). Some complementary reading frames also exist; e.g. the mRNAs encoding ORFs-P and -O with that encoding ICP34.5, and transcripts encoding reading frames complementary to U_L43.

Most HSV promoters are recognizable as eukaryotic polII promoters with obvious 'TATA' box homologies 20–30 bases 5′ of the mRNA cap sites. The promoter for the early (β) HSV thymidine kinase gene (U_L23) has served as a prototype for eukaryotic polII promoters in general. Promoters generally occur outside of ORFs but examples exist of promoters lying within ORFs encoding upstream genes.

The *cis*-acting elements mediating transcription of early (β) promoters include several transcription factor binding sites located within the region from −120 to −50. These and the TATA box at −30 comprise the functional promoter; no elements important in activating transcription have been identified downstream of the TATA box. This pattern appears to be maintained with the promoters for immediate early (α) transcripts which also feature the presence of upstream enhancer elements at sites distal to and extending to several hundred bases upstream of the cap sites. These enhancers contain multiple copies of a nominal 'TATGARAT' sequence which interact with cellular transcription factors of the POU family (notably, Oct-1). Enhancement of transcription occurs through the action of virion-associated (tegument) αTIF (U_L48) protein, which is a powerful transcriptional activator. Some immediate-early promoters contain a strong binding site for the $\alpha 4$ protein near the cap site that represses transcription.

Leaky late ($\beta\gamma$ or γ_1) and strict late transcript (γ or γ_2) promoters characterized to date contain critical sequence elements mediating full levels of transcription at or near the cap site, and at least some contain transcription factor binding sites in the proximal part

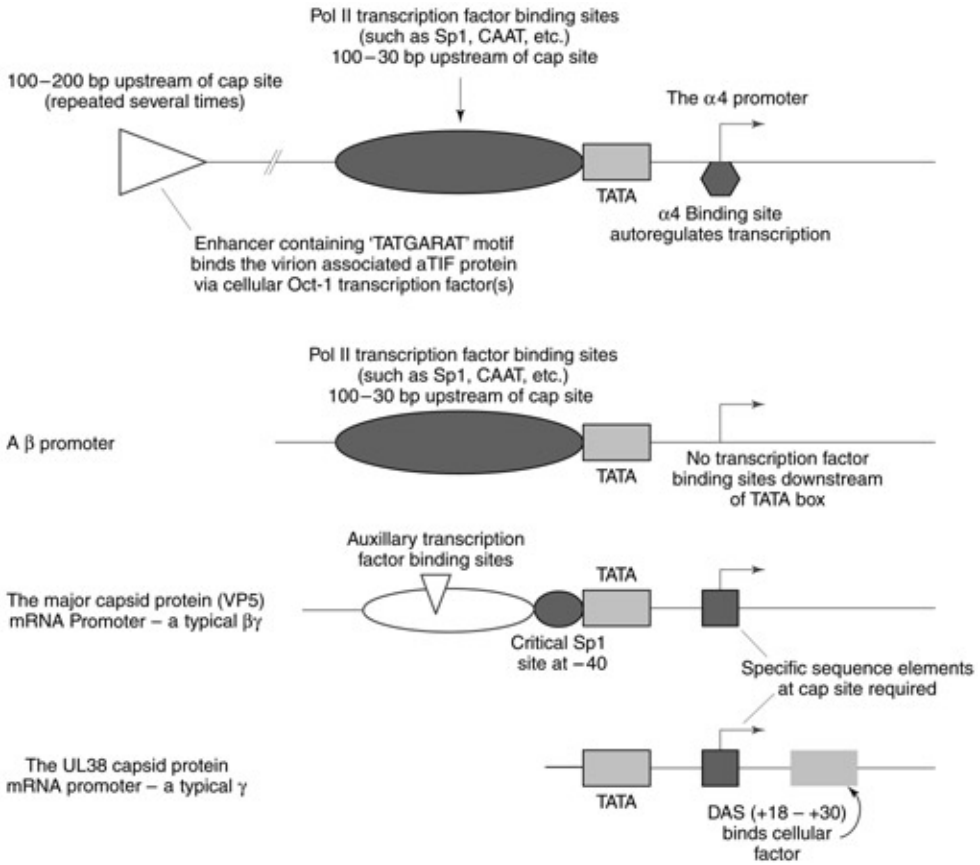

Figure 2 Architecture of productive cycle HSV promoters. Features of the promoters controlling representative members of the four kinetic classes of viral transcripts expressed during productive infection are shown.

of the leader. The promoter for the LAT (**Fig. 3**) has not been characterized in quite as much detail as those promoters controlling productive cycle transcripts. It appears to have a number of regulatory elements, some important in neuronal expression and some downstream of the cap site important for expression over extended periods of time.

Splicing The immediate-early α ICP27 protein actively inhibits splicing of cellular and viral transcripts, especially late in infection. Inhibition of splicing has also been reported to be a function of the ORF-O protein. For this and other reasons, the complex splicing patterns such as seen with adenovirus late transcripts or with the latent phase transcripts expressed by the γ herpesvirus Epstein–Barr virus do not occur. A few relatively abundant spliced transcripts are expressed: the $\alpha 0$, $\alpha 22$ (U_S1) and $\alpha 47$ (U_S12) transcripts; the latency-associated transcript family (LATs) in the long repeat which spans the joint region; and the transcript encoding the U_L15 ORF in the long unique region. This last transcription unit and the protein it encodes is conserved in all herpesviruses sequenced to date, and it may be related to a protein encoded by T_4 bacteriophage important in packaging newly synthesized viral genomes. Other spliced transcripts occur as low abundance spliced mRNAs encoding a portion of the major ORFs of unspliced mRNAs; notable examples are minor spliced variants of the transcript encoding gC (U_L44) – the function of these transcripts is unknown.

HSV replication origins

The HSV genome contains three *cis*-acting origins of replication 800–1000 bp in extent, with a much smaller (100–200 bp) critical 'core' region. They exhibit a high degree of dyad symmetry and palindromic sequences. At least one of the three copies of the ori is required for replication, and the ori in the long region (ori_L) has been suggested as having a role in neuronal replication and/or reactivation from latency, although there are no direct data to support this claim. As with bacteriophage T4, transcription through the origin occurs during virus replication,

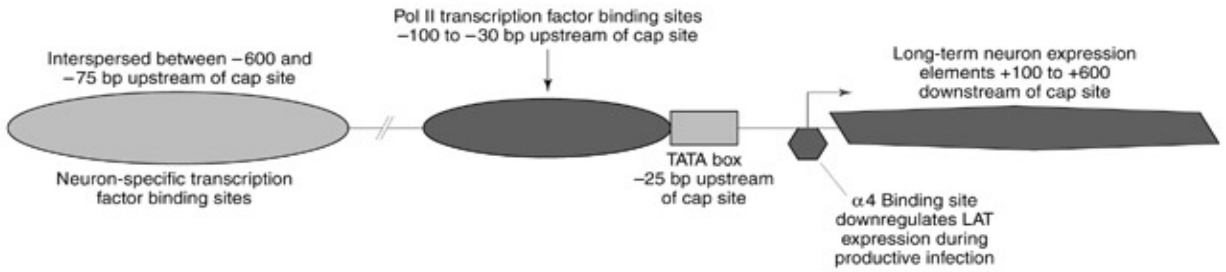

Figure 3 Architecture of the HSV latency associated transcript (LAT) promoter. Salient features of the latent phase promoter important in expression are indicated.

and a portion possesses some properties of a promoter sequence.

HSV Proteins

Nomenclature and general properties

The proteins encoded by HSV-1, their functions (if known), and their location on the genome are given in **Table 1.** Only 25 or so of the more than 80 HSV proteins expressed during productive replication are absolutely essential for virus replication in cultured cells. The remainder function in a number of ways to increase host range and tissue tropism, replication and/or plaquing efficiency, and to control or subvert the host response to infection.

Currently accepted protein nomenclature is a mix of trivial and systematic systems. Proteins encoded in the repeats and a number of other proteins of well-established function are referred to by their trivial or functional names. Proteins encoded by ORFs in the U_L and U_S regions are often referred to by the location of the ORF. Both nomenclatures are used in **Table 1.**

As predicted by the sizes of the ORFs encoding them, HSV proteins expressed during productive infection range in size from less than 10 000 M_r to more than 300 000 M_r for the tegument-associated U_L36 protein. Viral proteins tend to be quite proline rich (typically 10–14%) because of the high G+C content of the HSV genome, and thus they generally migrate anomalously slowly in denaturing SDS-acrylamide gels (i.e. the $\alpha4$ protein has a M_r of 140 000 Da but migrates at a rate expected for a protein of 170 000 Da). In addition, many HSV proteins tend to be rather rich in basic amino acids due to the preponderance of GC-rich codons encoded. It is not known whether either of these general properties has any role in specific aspects of HSV pathogenesis.

Functional classification of HSV proteins

Regulatory proteins The cascade of viral gene expression culminating in productive infection begins with the expression of α or immediate early proteins. This expression involves an interaction between the 50 000 M_r virion-associated αTIF (U_L48) protein and the cellular transcription factors, Oct-1 and CCF, mediated by the consensus 'TATGARAT' sequences upstream of α-gene promoters. The C-terminal 'acid blob' transcription activator of the αTIF protein is responsible for the enhanced expression of the immediate early transcripts.

Three of the five immediate early genes ($\alpha4$, $\alpha0$, $\alpha27$–U_L54) have roles in regulating viral gene expression at the level of transcription. Two of these ($\alpha4$ and $\alpha27$) have extensive areas of sequence similarity among a large number of α herpesviruses, but only $\alpha27$ appears to be recognizably conserved among the more distantly related β and γ herpesviruses.

The protein encoded by the $\alpha4$ transcript is a 140 000 M_r transcriptional activator with auto-regulatory functions. It is strictly required for virus replication and is continuously required for the transcription of all save the α kinetic class of viral mRNAs. It can be located in the nucleus of infected cells by immunofluorescence. Multiple phosphorylated forms of the protein have been identified in the infected cell, and it has been recently reported that the protein can also be post-translationally modified by uridine ribosylation. It has an extremely broad specificity in transient expression assay and apparently stabilizes the formation of the transcription initiation complex at and near the TATA box of viral and other promoters. This stabilization involves weak binding that does not require a highly conserved consensus sequence; however, weak binding sites occur near promoter/regulatory regions as well as many other regions in the genome. Its transcription-repressive function requires the strong association of

Table 1 Genetic functions encoded by herpes simplex virus type 1

R_L	'a'	*cis* genome cleavage, packaging signal
	ICP34.5	RL1, neurovirulence, inhibits cellular apoptosis
	ORF-O	Modulates ICP0, ICP22 – inhibits splicing
	ORF-P	Modulates ICP4
	ICP0	(α0, IE1) immediate early *trans*-activator, disrupts nuclear ND10 structures, modulates early/late switch
	LAT-intron	Stable accumulation in nucleus of latently infected neurons, unknown function
	LAT	ca. 600 bases in 5′ region facilitates reactivation. No protein involved
	ORF-X	Unknown
	ORF-Y	Unknown
U_L	U_L1	gL, essential glycoprotein which functions as a heteromer with gH – involved with viral entry
	U_L2	Uracil DNA glycosylase, DNA repair
	U_L3	Nonvirion membrane-associated protein(?), dispensable in cell culture
	U_L4	Tegument protein, unknown function, dispensable in cell culture
	U_L5	Part of helicase/primase complex, essential for DNA replication
	U_L6	Capsid protein, capsid maturation, DNA packaging in capsid
	U_L7	Unknown, dispensable in cell culture
	U_L8	Part of helicase/primase complex, essential for DNA replication
	U_L9	ori binding protein, essential for DNA replication
	U_L10	gM, glycoprotein of unknown function, dispensable in cell culture
	U_L11	Tegument protein, capsid egress and envelopment
	U_L12	Alkaline exonuclease, DNA packaging (?), capsid egress
	$U_L12.5$	C-terminal 2/3 of U_L12, expressed by separate mRNA – specific function unknown
	U_L13	VP18.8, tegument-associated protein kinase
	U_L14	Unknown
	U_L15	DNA packaging, cleavage of replicating DNA(?), spliced mRNA, exons span U_L16 and U_L17
	U_L16	Unknown, dispensable in cell culture
	U_L17	Cleavage and packaging of DNA
	U_L18	VP23, capsid protein, triplex
	U_L19	VP5, major capsid protein, hexon
	U_L20	Membrane associated, virion egress
	U_L21	Tegument protein, dispensable in cell culture, auxillary virion maturation function (?)
	U_L22	gH, glycoprotein involved in viral entry as heteromer with gL
	U_L23	TK, thymidine kinase
	U_L24	Unknown
	U_L25	Tegument protein, capsid maturation, DNA packaging
	U_L26	VP24, maturational protease
	$U_L26.5$	Scaffolding protein
	U_L27	gB, glycoprotein required for virus entry, mediates binding through interaction with GAGs in plasma membrane
	U_L28	ICP18.5, capsid maturation, DNA packaging
	U_L29	ICP8, single-stranded DNA binding protein, essential for DNA replication
	ori_L	Origin of replication
	U_L30	DNA polymerase
	U_L31	Nuclear phosphoprotein, unknown function
	U_L32	Capsid maturation, DNA packaging
	U_L33	Capsid maturation, DNA packaging
	U_L34	Membrane phosphoprotein, unknown function
	U_L35	VP26, capsid protein, capsomer tips
	U_L36	ICP1/2, tegument protein
	U_L37	Tegument phosphoprotein
	U_L38	VP19c, capsid protein, triplex

Table 1 Continued

Location	*Name*	*Function*
	U_L39	Large subunit ribonucleotide reductase
	U_L40	Small subunit ribonucleotide reductase
	U_L41	*vhs*, virion-associated host shut-off protein, destabilizes mRNA
	U_L42	Polymerase accessory protein, essential for DNA replication
	U_L43	Unkown
	$U_L43.5$	Antisense to U_L43
	U_L44	gC, glycoprotein involved in initial stages of virion-cell association with GAGs, complement binding protein, dispensable in cell culture
	U_L45	Membrane associated, dispensable in cell culture
	U_L46	VP11/12, tegument associated, modulate αTIF
	U_L47	VP13/14, tegument associated, modulate αTIF
	U_L48	α-TIF, VP16, VSP, virion-associated acidic blob transcriptional activator, enhances immediate early transcription through cellular Oct-1 and CTF binding at 'TATGARAT' sites
	U_L49	VP22, tegument protein
	$U_L49.5$	Unknown
	U_L50	dUTPase, nucleotide pool metabolism
	U_L51	Unknown
	U_L52	Part of helicase/primase complex, essential for DNA replication
	U_L53	gK, glycoprotein involved in virion egress
	U_L54	α27, ICP27, IE2, Vmw63, immediate early regulatory protein, RNA transport, inhibits splicing, mediates poly(A) signal utilization
	U_L55	Unknown, dispensable in cell culture
	U_L56	Tegument protein, dispensable in cell culture, affects pathogenesis
R_L	R_L	See R_L above
	R_L/R_S junction	Joint region, site of inversions of long and short segments, contains 'a' sequences
R_S	LAT-poly(A) site	Polyadenylation site for the primary LAT and the transcripts encoding ORF-O and -P (only transcripts through the joint region)
	ICP4	α4, IE3, essential immediate early *trans*-activator, also represses the transcription of itself, α4, and latency associated, and some other transcripts by strong binding to cap site at consensus sequence 'ATCGTN$_5$YSG'
	ori_S	Origin of replication
	Promoter for ICP22	Promoter and splice donor for immediate early transcripts ICP22 and ICP47
U_S	ICP22	α22, U_S1, IE4, splice acceptor and ORF for nonessential spliced immediate early protein, affects ability of virus to replicate in certain cells
	U_S2	Unknown
	U_S3	Tegument-associated protein kinase, phosphorylates U_L34 and U_S9
	U_S4	gG, glycoprotein of unknown function
	U_S5	gJ, glycoprotein of unknown function
	U_S6	gD, glycoprotein involved with virus infectivity and entry, binds HVEM
	U_S7	gI, glycoprotein that, as heterodimer with gE, binds IgG Fc and influences cell-to-cell spread of virus
	U_S8	gE, glycoprotein that, as hetero-oligomer with gI, binds IgG-Fc and influences cell-to-cell spread of infection
	U_S9	Tegument-associated phosphoprotein
	U_S10	Tegument-associated protein
	U_S11	Tegument-associated protein phosphoprotein, RNA binding, post-transcriptional regulation
	U_S12	α47 ORF and splice acceptor for spliced immediate early protein, nonessential in cell culture, inhibits MHC I antigen presentation in human and primate cells
R_S	R_S	See R_s above
	'a'	*cis* genome cleavage, packaging signal

the $\alpha 4$ protein with the consensus sequence 'ATCGTC' at or near the transcript start site. This sequence is found at this location in the $\alpha 4$, $\alpha 0$ and LAT promoters.

The essential $\alpha 27$ protein (M_r 51 000) has sequence elements consistent with its formation of zinc fingers. It also binds DNA and RNA. This multifunctional protein accumulates in the nucleus of infected cells, and is absolutely required for the expression of a number of γ (γ_2) transcripts. Different functional domains of the protein are involved with inhibition of cellular splicing through specific association with splicosomes, inhibition of transport of spliced cellular transcripts mediated by its RNA binding activity, and in utilization of specific cleavage polyadenylation sites for the expression of some late mRNAs. The protein also exhibits transcriptional regulatory functions.

The non-essential $\alpha 0$ protein (M_r 79 000) enhances the transcriptional activation of the $\alpha 4$ protein in transient assays, and has been reported to act as a transcriptional activator on some promoters by itself. Interaction with the $\alpha 4$ protein is mediated by domains in the C-terminal region of the $\alpha 0$ protein. The protein is localized in the nucleus in infected cells, and while its function is dispensable for virus replication in cell culture, $\alpha 0$ null mutants have very poor plaquing efficiency. This implies an important role in virus replication in low-multiplicity infections and explains the observation that $\alpha 0$ negative viruses reactivate poorly from latent infections. Its mode of action remains obscure. While the protein binds to DNA, specific base sequence elements important in this binding have not been identified. The protein causes disruption of PML-containing subnuclear structures, and is thought to be a major factor in the changes in nuclear structure observed as viral infection proceeds. The $\alpha 0$ protein also interacts with the novel cellular herpesvirus-associated ubiquitin specific protease (HAUSP), but the result of this interaction is currently unclear. Finally, the $\alpha 0$ protein has been shown to be involved with the turnover of the catalytic subunit of cellular DNA-dependent protein kinase; again, the functional manifestation of this activity is unclear.

Other HSV regulatory proteins include three $\beta\gamma$ (γ_1) proteins: the U_L46 and 47 proteins, which modulate the activity of αTIF by unknown mechanisms; and the virion-associated host shut-off protein (U_L41), which functions by destabilizing all mRNA molecules in the infected cell. The major β DNA binding protein (U_L29), which has an essential role in viral DNA replication (see below), also appears to function in gene regulation by mediating the shut-off of transcription of at least some β genes. Finally, the ORF-O and ORF-P proteins have regulatory functions that may have a role in the latent phase of infection.

DNA replication Seven β proteins are strictly required for the formation of the viral DNA replication complex. The 123 000 M_r DNA polymerase (U_L30) exhibits regions of significant sequence similarity with other eukaryotic, viral and phage DNA polymerases. It functions in a complex with U_L42, the double-stranded DNA binding protein. The ori binding protein (U_L9) binds to the critical core sequence 'GTTCGCAC' in the ori_S and may function as a dimer. Equimolar amounts of proteins U_L5, 8 and 52 make up the helicase/primase complex; and, finally, the 120 000 M_r major DNA binding protein has been hypothesized to function in a manner analogous to phage T4 gene 32 single-stranded DNA binding protein in keeping the replication fork open.

A number of other β proteins are involved in genome replication by altering the pool of deoxyribonucleotide precursors and for repair and proofreading functions. While none is strictly essential, they increase the range of potential cells available for HSV replication in the host. Viral encoded pool enzymes include: thymidine kinase (U_L23); the large and small subunits of ribonucleotide reductase (U_L39 and 40), the former having significant areas of sequence similarity with the human enzyme; and deoxyuridine triphosphatase (U_L50). Enzymes with potential repair function include uracil-DNA glycosylase (U_L2).

Structural proteins More than 30 HSV proteins, all $\beta\gamma$ (γ_1) or γ (γ_2), are found associated with mature virions. These include the five capsid proteins described above, a large number of tegument proteins, and ten or more glycoproteins. Some of the tegument proteins, such as the host shut-off function (*vhs*–U_L41), are not absolutely required for viral replication in cell culture, although they increase plaquing efficiency and/or host range. While the transcriptional stimulatory function of αTIF (U_L48) is not strictly required for viral viability, this protein also has an important role in morphogenesis. Four glycoproteins have been shown to be strictly required for HSV viability – gB (U_L27), gD (U_S6), gL (U_L1) and gH (U_L22) – all of which are involved in the internalization of the virion in the initial stages of infection.

Proteins involved in capsid formation and maturation Capsid assembly can be readily accomplished both *in vitro* and in Sf9 cells with proteins expressed from a panel of recombinant baculoviruses expressing the four principal capsid proteins (U_L19-VP5, U_L38-

VP19c, U_L18-VP23, and U_L35-VP26), the scaffolding protein (encoded by ORF U_L26.5), and the maturational protease (U_L26). Other proteins have been implicated genetically in the capsid assembly process, but are dispensable in minimal *in vitro* systems.

The packaging of the viral DNA in the mature capsid requires a large number of viral proteins including U_L6, 15, 17, 25, 28, 32 and 33. The protein encoded from the spliced mRNA transcribed from the U_L15 gene in conjunction with U_L26 may function as a terminase, cleaving genome-sized fragments from the growing concatomeric replication complex. The U_L15–U_L26 complex also appears to mediate the initial entry of viral DNA into the capsid, i.e. it serves a 'docking' function. The alkaline exonuclease gene (U_L12) also plays a role in DNA packaging.

This latter enzyme is expressed in two forms via two partially overlapping mRNAs, the larger having a M_r of 63 000 and the smaller about 40 000. Interestingly, comparative sequence analysis suggests that in the γ herpesvirus Epstein–Barr virus homologues of these two proteins are encoded in two distinct genomic locations; therefore, two copies of this enzyme seem to have a significant general role in some aspect of herpesvirus replication or pathogenesis.

Proteins involved in pathogenesis and cytopathology Based upon dispensibility in productive infection in cultured cells, many, if not the majority, of HSV proteins are involved in aspects of pathogenesis and dealing with host defenses. A striking example is the ICP34.5 gene product which mediates many aspects of the ability of HSV-1 to replicate effectively in neural tissue, perhaps by inhibition of apoptosis in productively infected neural cells. The α47 protein appears to have a role in modulating host response to infection by specifically interfering with the presentation of viral antigens on the surface of infected cells by major histocompatibility complex (MHC) class I. While this function may be modulated by the neighboring U_S11 protein, the immediate expression of the α47 gene product appears to preclude immune surveillance by CD8+ T lymphocytes at the very onset of infection. Interestingly, it has recently been established that this activity is confined to cells of human and primate origins.

A number of the envelope glycoproteins found in the intact virion appear to have a significant role in controlling host response. The complex of glycoproteins gE (U_S9) and gI(U_S8) function as immunoglobulin Fc receptor, blocking the presentation of this region of the antibody molecule and precluding activation of the complement cascade. In addition, gC (U_L44) binds several components of the complement complex, and viruses with mutations in gD (U_S6) display altered pathogenesis in mice. Viral glycoproteins and other gene products also have a role in cytopathology. For example, gL (U_L53) is involved in the ability of many strains of HSV-1 to form syncytia among infected cultured cells, and a virion component (U_L41) mediates the disruption of host polysomes and destabilizes host (and viral) mRNA following infection.

Other viral gene products also have a role in cytopathology and pathogenesis. While dispensable for productive infection in some cells, the immediate early protein encoded by the α22 gene is required for HSV replication in others – perhaps by mediating the expression of a set of late transcripts. Such transcripts presumably encode other viral proteins important in full productive cytopathology. Viruses lacking thymidine kinase (U_L23) have significantly altered pathogenic patterns in experimental animals, while certain mutations in the DNA polymerase gene (U_L30) have altered patterns of neurovirulence.

Physical Properties of HSV

Being an enveloped virus, HSV is relatively stable in aqueous solution in the pH range from 6 to 8 and is resistant to gentle protease treatment. Its infectivity is rapidly lost following treatment with lipid solvents and lipases. The capsid is relatively unstable in CsCl; therefore banding is difficult. Specific capsid proteins can be extracted with mild guanidinium treatment without causing the gross morphology of the capsid to collapse; more rigorous treatment results in the release of viral DNA through the penton vertices of the capsid. Viral infectivity is rapidly lost with UV irradiation, but individual viral genes can be expressed from heavily irradiated virions following infection of cultured cells. This is consistent with both the fact that individual viral genes are expressed via individual promoters, and with the fact the target size for viral transcriptional regulatory functions is much smaller than that for the essential genes *in toto*.

Viral Replication: Viral Entry

Initial association of HSV with a host cell is mediated by the association with the envelope gC (U_L44) and glycosaminoglycans such as heparin sulfate on the cell surface. Clearly, this is not an obligatory route of initial interaction, as gC null mutants of the virus replicate efficiently in both cultured cells and in animal model systems. Virus internalization involves the mediation of four essential glycoproteins, gB (U_L27), gH (U_L22), gD (U_S6), and gL (U_L1). In many cells, this is mediated by interaction of gB, gD, and

other glycoproteins with one of at least three cellular surface proteins named the herpes virus entry mediator proteins (HVE – A, B, and C). HVEs are members of the TNF/NGF family of proteins. Other cellular surface proteins may also function in a similar capacity as some cells lacking this receptor still allow efficient viral entry. The viral genome is accompanied into the nucleus by the αTIF protein (U_L48) which functions in enhancing immediate early viral transcription via cellular transcription factors. The virion-associated host shut-off protein (*vhs*–U_L41) appears to remain in the cytoplasm, where it causes the disaggregation of polyribosomes and degradation of cellular and viral RNA. Infecting DNA may remain associated with one or several structural components of the virion since it does not interact with cellular histones in a manner analogous to infecting papovavirus DNA.

Viral Replication: Translation and Post-translational Processing

HSV mRNA is translated on polyribosome structures that are grossly identical to those seen in the uninfected host. The half-life of all mRNA is reduced in infected cells by the action of the virus-encoded *vhs* (U_L41); this, coupled with the high transcriptional activity from the viral genome, rapidly results in virtually all protein synthesis in the infected cell being virus specific. The protein encoded by the γ (γ_2) ICP34.5 mRNA has been shown to have an inhibitory effect upon the ability of ribosomes from infected cells to translate cellular mRNAs; thus, translational control of gene expression appears to have a role in viral pathogenesis if not viral replication.

Extensive proteolytic processing of HSV proteins does not occur, but the maturation of the capsid absolutely requires the activity of the maturational protease encoded by the U_L26 gene product. Many viral proteins are extensively phosphorylated, including the α4 and α27 transcriptional activators and a number of structural proteins. The precise role of such processing upon the function of these proteins is not well characterized. Other modifications such as the uridine-ribosylation of the α4 protein have also been described.

Replication: Virus-induced Modification of Nuclear Compartmentalization and the Role of Viral DNA Replication in the Productive Cycle Transcription Program

The temporally controlled transcriptional regulation program exhibited during productive infection by HSV is accomplished with class-specific viral promoters that are ostensibly cellular. There is no presently convincing evidence that the virus-encoded regulatory proteins alter cellular transcriptional machinery by changing its basic specificity. Rather, the viral transcription program appears to be mediated by virus-induced modifications of the nuclear organization of the infected cell. Although yet to be fully characterized, the virus-induced modifications are well illustrated by the disruption of the nuclear 'pod' structures (ND10) by the action of the immediate early α0 protein followed by a reassembly of viral replication/transcription compartments later in the replication cycle. This change involves interaction with α0 and α27.

These observations strongly suggest that transcription of early and late genes is likely to occur in two distinct environments. The other major factor in the restructuring of the nucleus during infection is the replication of viral DNA. The specific role of viral DNA replication enzymes was described above, and the best model for HSV DNA replication is probably exhibited by T4 bacteriophage. The vegetative replication of viral DNA represents a critical and central event in the viral replication cycle. High levels of DNA replication irreversibly commit a cell to producing virus, which eventually results in cell destruction.

DNA replication has a significant influence on viral gene expression. Early expression is significantly reduced or shut off following the start of DNA replication, while late genes begin to be expressed at high levels. Immunofluorescence studies show that DNA replication occurs at discrete sites, or 'replication compartments' in the nucleus. Prior to DNA replication, the α4 protein and the single-stranded DNA binding protein ICP8 (U_L29) are distributed diffusely throughout the nucleus; concomitant with viral DNA replication, the distribution of these proteins changes to a punctate pattern. The transcriptional environment within replication compartments seems critical in the preferential transcription of late genes, although the precise role of the many viral proteins involved, as well as the role of cellular proteins, is yet to be determined.

Viral Replication: Viral Assembly and Release

Viral capsids form in the nucleus in association with the scaffolding protein (U_L26). A vertex of the empty capsid then interacts with the 'a' sequence at a free end of replicating DNA and a genome equivalent of DNA is packaged and cleaved. As noted, this requires the function of the U_L15 and 28 proteins. The

packaging process also involves the 'a' sequence at the other end of the genome-sized DNA fragment, leading to maturational cleavage of the growing DNA chain, resulting in encapsidation of a full-length genome.

Presumably, full capsids associate with tegument proteins near the nuclear membrane which has become modified by inclusion of viral glycoproteins that have been glycosylated in the cellular Golgi apparatus. Two models have been proposed for what happens then: either the virion retains its nuclear membrane upon egress, or this nuclear membrane is lost by fusion with the cytoplasmic membrane prior to exocytosis. Experimental evidence has been variously interpreted to support either one or the other. Whatever the exact mechanism, full infectious virus can be recovered from cells many hours before cellular disintegration and release of virions into the extracellular medium. Indeed, virus spread by cell-to-cell contact and/or cell fusion is probably an important feature of the pathogenesis of infection in the host and can be readily observed with infections in cultured cells.

Viral Replication: Cytopathology

Classic features of the gross cytopathology of cells infected with HSV have long been used diagnostically. A very noticeable modification of the nucleus of the host cell with the condensation and margination of host chromatin at the nuclear membrane can be observed within a few hours after infection. This is followed by the accumulation of semicrystalline arrays of empty viral capsids in the nucleus leading to the formation of macroscopic inclusion bodies. Such nuclear changes are seen with most human and animal herpesvirus, and served for an early basis of classification of herpesviruses. Other 'classic' features of virus-induced cytopathology include extensive reduplication of the nuclear membrane as viral capsids associate with it, and the formation of extensive syncytia, which occurs with many (but not) all strains of the virus.

Latent Infection by HSV

Latent infection with HSV can be viewed as having three separable phases: establishment, maintenance and reactivation. In the establishment phase, the virus must enter a sensory neuron; and, following entry, there must be a profound restriction of viral gene expression so that the cytopathic results of productive infection do not occur. Thus, productive cycle genes are transcriptionally and functionally quiescent and only the 8.5 kb LAT is expressed. The expression of LAT is controlled by the latency specific promoter, which has a number of regulatory elements important in neuronal expression over extended periods of time (**Fig. 3**). The establishment of latent herpesvirus infections can be essentially viewed as a passive phenomenon, as replication-defective virus can establish latent infections. This has been taken as support for the model that latency is just the result of the failure of the productive cascade, perhaps due to the specific population of transcription factors in the cell in which the latent infection is established. Some recent analysis of the functions of the proteins encoded by ORF-O and ORF-P in the long repeats suggests, however, that these proteins may serve to modulate immediate early gene expression. Viral genes may therefore function in optimizing the establishment of latent infections.

The maintenance of the HSV genome in latently infected neurons appears passive, i.e. it requires no viral gene expression or gene product at all. This is in keeping with the fact that latent HSV genomes are harbored within the nucleus of a nondividing sensory neuron and do not need to replicate; indeed the challenge arises from the need for the virus to reactivate from a transcriptionally quiescent, non-replicating cell. HSV DNA is maintained as a nucleosomal, circular episome in latent infections, and low levels of genome replication might occur or be necessary for the establishment or maintenance of a latent infection from which virus can be *efficiently* reactivated.

Successful reactivation of HSV results in the appearance of infectious virus at the site of entry in an immune host. Expression of only a 350 bp region of LAT near its 5′ end is both necessary and sufficient to facilitate reactivation in several animal models. Whatever the specific mechanism for this facilitation, it does not involve expression of a protein; rather, the active region appears to function by a *cis*-acting mechanism, the details of which are currently obscure.

The process of reactivation from latency is triggered by stress as well as other signals which may transiently lead to increased transcriptional activity in the harboring neuron. A possible scenario is that one or several latently infected neurons replicate only a few viral genomes and generate only a few infectious virions during the initial reactivation event. This might then lead to infection of critical peripheral tissue when the overall immune capacity of the host is temporarily reduced by stress or other factors. The process may be augmented by viral genes shown to interfere with apoptosis, such as ICP34.5, which act to prevent neuronal death during reactivation where limited replication occurs.

Latent-phase transcripts

Latently infected neurons represent 1–10% of the total neurons in the ganglia, and infected cells contain as few as 5–10 copies of viral DNA. In some neurons, an 8.5 kb polyadenylated transcript whose promoter lies in the long repeat sequences about 1800 bases 3′ of the 3′ end of the $\alpha 0$ mRNA is expressed as the LAT (**Fig. 1**). This primary transcript extends through the joint region to a polyadenylation signal next to that of the $\alpha 4$ transcript in the short repeat.

The primary LAT transcript is extensively processed, forming an unknown number of unstable, spliced, polyadenylated mRNAs, and a stable 2 kb poly(A-)intron in lariat form which accumulates in the latently infected neuronal nucleus. A second, spliced variant of this LAT-intron can also be observed. The function of this stable intron is unclear; it is not involved in the facilitation of reactivation mediated by LAT expression.

Future Trends in Research on HSV

HSV possesses a number of features that will make it a continuing research model in the future. Among the most obvious are the following. (1) The neurotropism of the virus, along with the relative convenience of generating recombinants containing foreign genes expressed either under homologous or heterologous promoters, recommends HSV as a vector for introducing specific genes into neural tissue. This facility is increased by the fact that the viral genome can enter and be maintained in neural tissue in the complete absence of lytic phase viral gene expression. (2) The fact that HSV's replication is restricted in terminally differentiated neurons suggests its potential as a therapeutic agent against neural tumors, provided appropriate mutants can be constructed. (3) The benign nature of normal infection with HSV also suggests its potential use as a vaccine vector by incorporation of specific antigens into the viral genome, although the promise of this application may be clouded somewhat by the ability of replication-defective viruses to persist in the host. (4) The abundance of viral genes dedicated to the efficient replication of viral DNA in the productive cycle provides a number of potential targets for antiviral chemotherapy. (5) The interactive cascade of viral proteins involved in regulation at a number of levels in the infected cell makes HSV a useful model for the detailed analysis of specific aspects of control of eukaryotic gene expression.

HERPESVIRUSES 6 AND 7 – HUMAN (*HERPESVIRIDAE*)

Takuya Shimamoto and **Koichi Yamanishi**, Department of Microbiology, Osaka University Medical School, Osaka, Japan

History

Human herpesviruses 6 and 7 (HHV-6 and HHV-7) are ubiquitous agents of humans. HHV-6 was first isolated by Salahuddin *et al* in 1986 as a novel herpesvirus from patients with lymphoproliferative disorders, and initially named human B lymphotropic virus (HBLV). Subsequently, several laboratories

Prevention and Control

There is no prevention or therapy for the diseases caused by HHV-6 and HHV-7; however, ganciclovir and foscarnet are effective in suppressing replication of HHV-6 *in vitro*. Antiviral therapy might be appropriate in individual cases of severe HHV-6 disease.

Future Perspectives

The functions of most viral gene products of HHV-6 and HHV-7 in the lytic and latent infections have not yet been elucidated. Recently, the entire sequences of both viruses have been determined, accelerating the research of their molecular biology. The development of a recombinant virus system is awaited for the detailed examination of the function(s) of the viral genes in the context of the viral genomes. Since the only known host for HHV-6 and HHV-7 is humans, animal models are also a prerequisite for understanding the functions of the viral genes *in vivo*.

HERPESVIRUS SYLVILAGUS (*HERPESVIRIDAE*)

Peter G Medveczky, University of South Florida College of Medicine, Tampa, Florida, USA

History

Herpesvirus sylvilagus is a model for lymphoproliferative disorders and viral oncogenesis because it induces a lymphoma-like illness in rabbits. It was first isolated by Hinze in 1968 from kidney cell cultures of apparently healthy cottontail rabbits (*Sylvilagus floridanus*) in southern Wisconsin, USA. Morphological and molecular biological analysis proved that herpesvirus sylvilagus is a typical herpesvirus. The viral particle is enveloped and its capsid contains 162 capsomers as described for other herpesviruses. Neutralization assays and partial sequencing of the viral genome also demonstrated that herpesvirus sylvilagus is a unique herpesvirus. A virus referred to as cottontail rabbit herpesvirus (CTHV) has been isolated by Cebrian. This cottontail rabbit virus is unrelated to herpesvirus sylvilagus, as determined by Southern blot hybridization.

Classification

Herpesviruses have been classified into three subfamilies of the *Herpesviridae: Alpha-, Beta-* and *Gammaherpesvirinae*. The gamma or lymphotropic viruses infect lymphocytes and are further divided into two genera, *Lymphocryptovirus* and *Rhadinovirus*, on the basis of biological data, pathogenesis, sequence homology and latency genes (**Table 1**). There is little doubt that herpesvirus sylvilagus is a member of the gammaherpesvirus group but it is not clear whether it belongs to either of the two subgroups. While several investigators concluded that herpesvirus sylvilagus-induced pathology resembles

Table 1 Comparison of genera *Lymphocryptovirus* and *Rhadinovirus* herpesviruses

Virus species and common abbreviation	*Genus*	*Latency in lymphocytes*
Epstein-Barr virus (EBV)	*Lymphocryptovirus*	B
Herpesvirus papio (HVP)	*Lymphocryptovirus*	B
Kaposi's sarcoma associated herpesvirus (KSHV or HHV-8)	*Rhadinovirus*	B(?)
Herpesvirus saimiri (H. saimiri or HVS)	*Rhadinovirus*	T
Herpesvirus ateles (HVA)	*Rhadinovirus*	T
Murine herpesvirus 68 (MHV-68)	*Rhadinovirus*	B
Herpesvirus sylvilagus (H. sylvilagus)	*Rhadinovirus*	B and T

Epstein–Barr (EBV) infection of humans, analysis of the genomic structure suggests that herpesvirus sylvilagus belongs to the gamma-2 subgroup of herpesviruses (EBV is a gamma-1 virus). Typical members of the gamma-2 subgroup include the human Kaposi's sarcoma-associated herpesvirus (KSHV, also referred to as human herpesvirus 8 or HHV-8), herpesvirus saimiri, herpesvirus ateles and murine herpesvirus 68.

Genome Structure

The herpesvirus sylvilagus genome is a linear double-stranded DNA with an estimated size of 158 kbp (**Fig. 1**) and consists of a unique, approximately 120 kbp stretch of DNA flanked by a variable number of tandem repeats. Repeat units are 553 bp in length with an extremely high G + C content (83%). This arrangement of the repeats with high G + C content is typically seen in other gamma-2 herpesviruses. Sequence analysis of the unique central region of the genome should greatly help to determine whether herpesvirus sylvilagus is a member of the gamma-1 or gamma-2 subgroup.

Viral Proteins

Several studies have been conducted to identify and catalogue viral proteins. These studies were based on fractionation of purified virion proteins according to size, isoelectric point, glycosylation and phosphorylation. Pulse-labeling with radiolabeled amino acids during the course of infection was also performed. These early studies show that purified herpesvirus sylvilagus virions contain about 45 virion protein bands ranging from 18 to 230 kDa. There are nine glycoproteins, 13 phosphoproteins and four species that are both glycosylated and phosphorylated. Unfortunately, there are no data available as to how many of these protein bands represent distinct gene products, how many are various modified forms of the same polypeptide, and whether any of these bands are encoded by the host cell. DNA sequencing, transcript mapping in combination with genetic approaches and protein chemistry will be required to identify and match specific viral genes and protein products expressed during latency and various stages of lytic infection.

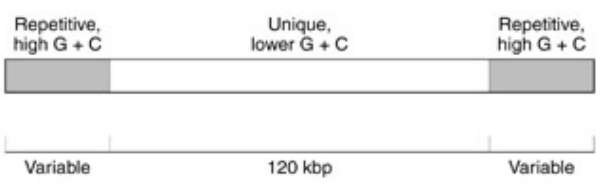

Figure 1 Organization of the herpesvirus sylvilagus genome.

Geographic Distribution

Little information is available on the geographic distribution of herpesvirus sylvilagus. Most surveys examined small numbers of animals from confined small areas of the USA. Prevalence was based on virus isolation assays and on detection of herpesvirus sylvilagus-specific antibodies against late (probably virion) proteins. Some studies found that less than 4% of wild cottontail rabbits are infected, which is an unusually low figure for herpesvirus infections occurring in mammals. It is possible that immune responses against late proteins may represent a recent or persistent infection, and after acute infection the titer of antibodies against virion proteins decreases. Also, viremia may not be detectable after acute infection in wild animals. Therefore, the prevalence of infection of herpesvirus sylvilagus in wild cottontail rabbits may be much higher and needs to be re-examined. Information on putative latent genes (such as the EBNA proteins of EBV) and immunogenicity of recombinant proteins would be required to conduct larger studies. Latent and/or recombinant proteins could be more sensitive and specific markers for estimating prevalence of infection.

Transmission

The mechanism of transmission of the virus is also uncertain. Herpesvirus sylvilagus can be isolated from the nasopharynx, suggesting that natural infection occurs through contact with oral/nasal secretions. According to the available data, herpesvirus sylvilagus infection does not appear to be transmitted through mosquitoes (*Aedes triseriatus*) or rabbit fleas (*Cediopsylla simplex*). Also, transplacental transmission may not occur at high frequency. All of these transmission studies were conducted by evaluating the presence of infectious virus in various tissues and blood of prospective recipient animals. Infectious virus in the blood and tissues is readily detected after experimental inoculation of large doses of the virus. However, it is possible that during natural infection only very low amounts of virus are transmitted. As a result, production of virus in tissues or viremia is much lower during natural infection and may not be detectable by the present assays.

Host Range

The host range of herpesvirus sylvilagus is very narrow and infection appears to be restricted to cottontail rabbits. New Zealand white rabbits (*Oryctologus cuniculus*), mice, hamsters and guinea pigs are resistant to experimental infection.

Virus Propagation

Herpesvirus sylvilagus can be cultured *in vitro* in monolayers derived from kidneys of cottontail rabbits. New Zealand white rabbit kidney cell cultures also support replication of the virus but yield is less than those obtained in cottontail rabbit kidney cultures. No lytic virus replication occurs in primate, mouse, hamster or chicken cells.

Clinical Features

No major studies have been published on the clinical features and pathology of natural infection occurring in wild animals. Most studies have been conducted either by housing infected and uninfected animals in common cages or by injection of herpesvirus sylvilagus grown in tissue culture into naive animals.

Pathogenicity

Experimentally infected cottontail rabbits develop a lymphoproliferative disease which usually spontaneously resolves after a few months. Animals show general lymphadenopathy and enlargement of lymph nodes. Splenomegaly with grayish nodules with petechias is also typically seen after infection. Kidneys are slightly enlarged with lymphoid infiltrates.

A lymphoma-like disease can develop in some experimentally infected animals; it is characterized by a severe and generalized infiltration of lymphoid organs, kidneys, liver and submaxillary glands by atypical lymphocytes. The lymphoproliferative syndrome/lymphoma induced by herpesvirus sylvilagus is more severe in young animals and can lead to death.

Low titers of the virus can be detected in whole blood 1 week after infection of cottontail rabbits inoculated intraperitoneally or subcutaneously with herpesvirus sylvilagus. It is unclear whether this represents viremia or virus production by infected white blood cells. After the second week of infection, total leukocyte count in the blood shows a moderate increase, accompanied by a large rise in the relative percentage of lymphocytes. Lymphocytosis can last for 10–18 weeks.

While the viral genome is a linear molecule in the virion, infected lymphocytes contain predominantly circular episomal forms. Herpesvirus sylvilagus infects both B and T lymhocytes of cottontail rabbits *in vivo* and the viral genome is a circular episome in these cells. Several copies per cell have been detected in the peripheral blood or spleen tissues, which suggests that a fairly large proportion of lymphocytes are infected. These data also show that the overwhelming majority of infected cells harbor only latent virus. These observations are also consistent with very low titers of virus in the plasma produced by a very low percentage of lymphoid or other cells. Whether the latent episomal form of the genome persists in lymphoid cells for the life of infected animals, as described for EBV infection, remains to be determined.

Taken together, clinical and molecular studies show that herpesvirus sylvilagus infection resembles acute lymphoproliferative disease associated with EBV infection. It is a massive and subacute infection that involves the lymphoid system and the virus undergoes latency in lymphocytes. It is also clear that the rabbit model is different because EBV only infects B cells, whereas herpesvirus sylvilagus was found in both B and T cells.

Immortalization of Macrophage-like Cells *In Vitro*

As herpesvirus sylvilagus induces a lymphoma-like disease, it infects both B and T cells *in vivo*, and these cells contain episomal viral genomes typically seen in cells immortalized with herpesviruses. Several laboratories investigated immortalization of lymphoid cells with the virus. All of the *in vitro* and *in vivo* attempts

(published or unpublished) failed, except for a report on a 'macrophage-like' rabbit cell line established by *in vitro* infection of splenocytes with herpesvirus sylvilagus. This cell line contained integrated herpesvirus sylvilagus DNA. Lymphoid cell lines immortalized with other herpesviruses such as EBV or herpesvirus saimiri typically carry multiple copies of episomal viral genomes and integration seldom occurs.

These basically negative results do not rule out the possibility that herpesvirus sylvilagus can immortalize lymphocytes; for example, infected cells may require special growth factors and lymphokines for *in vitro* culturing. To resolve the issue of the transforming ability of this virus, development of reagents and more systematic studies are required. Lymphocytes at various stages of differentiation as well as macrophages could be targets of immortalization by herpesvirus sylvilagus. Most studies have been conducted by using the original virus isolate of Hinze and this strain could have suffered spontaneous mutations; therefore, freshly isolated viruses may prove to be transforming.

Immune Response and Antiviral Drugs

The kinetics of virus-specific antibody development was determined using indirect fluorescent antibody (IFA) technique on herpesvirus sylvilagus-infected newborn cottontail rabbit kidney (NCRK) cells. Antibodies were detected by the IFA test as early as 5 days after experimental infection. All animals seroconverted to herpesvirus sylvilagus by 10 days after infection and antibodies could be observed in serum dilutions of 1:2000 or higher.

Neutralizing antibodies were also detected in experimentally infected cottontail rabbits standard plaque reduction assays. Neutralizing antibodies developed as early as 7 days after infection. The peak of neutralizing antibodies was at 2–4 weeks after infection, decreasing to nonmeasurable levels at 8–10 weeks after infection.

Significant major histocompatibility complex (MHC)-restricted virus-specific cytotoxic T lymphocyte (CTL) responses have been described in spleen cells of infected animals. The peak of CTL activity was observed after 7 days of infection. The level of virus-specific CTLs was much lower in peripheral blood lymphocytes.

No extensive studies on antiviral drugs have been reported. Replication of herpesvirus sylvilagus is significantly inhibited by phosphonoacetate (PAA) and phosphonoformate (PFA). These drugs also inhibit most other herpesviruses.

Future Perspectives

The initial enthusiasm for the study of herpesvirus sylvilagus in the 1970s and 1980s was based on the apparent resemblance of the cottontail rabbit model to EBV pathology in humans. During subsequent decades progress has significantly slowed because of unusual difficulties in handling wild cottontail rabbits. Another factor contributing to loss of interest was that most investigators were unable to establish tumor cell lines from animals infected with herpesvirus sylvilagus or by *in vitro* immortalization; however, renewed interest is anticipated in this rabbit model because of the discovery of the human gamma-2 herpesvirus KSHV. It is possible that herpesvirus sylvilagus is closely related to KSHV but this hypothesis could be only tested by sequencing of the herpesvirus sylvilagus genome. In summary, establishment of latently infected cell cultures and sequencing of the genome appear to be essential for further exploration of this interesting herpesvirus of cottontail rabbits.

HERPESVIRUSES – BABOON AND CHIMPANZEE (*HERPESVIRIDAE*)

SS Kalter and **RL Heberling**, Virus Reference Laboratories, San Antonio, Texas, USA

History

Herpesviruses are ubiquitous, infecting a wide variety of animals, including humans. Because herpesviruses share many biological features in common, availability of nonhuman strains permits experimental studies that would be restricted if only human strains were available. Herpesviruses are capable of manifesting many different clinical syndromes. In their natural host, herpesviruses cause a mild or inapparent form of disease, and rarely give rise to an excessive fatal illness. When crossing species barriers, however, herpesviruses are frequently responsible for a highly virulent form of disease. Following infection, a feature common to all herpesviruses is their ability to persist for the remainder of the host's life as a latent infection.

Despite their sharing of many biologic characteristics, herpesviruses are diverse in their clinical capabilities, widespread in their geographic distribution and generally have their own natural host range. A number of different herpesviruses may be present in nonhuman primates, including baboons and chimpanzees. Depending upon their biologic characteristics each of the herpesviruses have been included among three subfamilies of the family *Herpesviridae*:

- *Alphaherpesvirinae* Herpes simplex virus group
- *Betaherpesvirinae* Cytomegalovirus group
- *Gammaherpesvirinae* Lymphoproliferative virus group

In this entry, consideration will be principally given to two related, but distinct, lymphoproliferative (*Gammaherpesvirinae*) herpesviruses recovered from the baboon and chimpanzee, herpesvirus papio and herpesvirus pan respectively. Other herpesviruses also present in baboons and chimpanzees will be briefly discussed.

The relatedness of lymphoproliferative viruses to Epstein–Barr virus (EBV) is to be noted. Alpha and beta herpesviruses associated with baboons and chimpanzees include: herpesvirus cercopithecus 2 (SA8) and closely related herpesvirus papio 2 (HVP-2) in baboons; cytomegalovirus (CMV) strains, widespread among Old and New World primate species (with their antigenic relative SA6 restricted to African primates) and VZ or varicella-zoster (simian VZ?) found in various species of monkeys and apes. Herpes simplex virus infections may be seen in chimpanzees and other apes.

Both herpesvirus papio and herpesvirus pan, along with the human (gamma) herpesvirus 4 (EBV), have a biologic characteristic that separates them from other herpesviruses and are classified in the lymphoproliferative virus group, subfamily *Gammaherpesvirinae*, genus *Lymphocryptovirus*. This characteristic, consisting principally of invasion and persistence in lymphocytes, results in a proliferative form of disease associated with oncogenicity. EBV, originally isolated from humans, is the prototype species of the *Gammaherpesvirinae*. A major clinical manifestation of EBV is tumor production. EBV-like isolates have been recovered from suspensions of continuous cell lines from both Old and New World simian species. Among Old World simians, isotypes have been obtained from baboons, chimpanzees, orangutans, gorillas and several species of macaques. Similar, but antigenically unrelated, viruses have also been isolated from several New World monkey species. The Old World isolates are B-cell tropic, whereas the New World lymphoproliferative isolates are T-cell tropic. All these isolates are capable of producing lymphoproliferative disease in several animal species.

Other herpesviruses recognized as baboon and chimpanzee associated are not lymphoproliferative and are classified in either *Alphaherpesvirinae* or *Betaherpesvirinae* subfamilies. SA8/HVP-2 is found in African monkeys and has shown pathogenicity in baboons. CMVs, like EBV strains, are worldwide in distribution among animal species. VZ is considered to be a human virus; the origin of the simian strains is not clear. Herpes simplex virus is also regarded as a human virus. **Table 1** lists herpesvirus antibody present in baboons and chimpanzees.

Baboon herpesviruses

In 1975, Agrba *et al* and Lapin *et al* in the former USSR reported the establishment of two continuous lymphoblastoid cell cultures (SPG-1 and KMPG-1) containing herpes-like viral particles from bone marrow and spleen of hamadryas baboons with malignant lymphoma. These investigators had previously reported an outbreak of leukemia among the

Table 1 Herpesvirus antibody detected in baboons and chimpanzees

baboons of the Sukhumi colony in the USSR. The cell lines were shown to contain morphological evidence of herpesviruses and, upon identification, the isolates were found to be distinct from herpes simplex 1 and 2. Confirmation was rapid as a result of a collaborative research effort between Soviet and American investigators. Independently, in 1977 Gerber *et al* also isolated a herpes-like virus from baboon lymphoid cell lines grown in long-term culture. Several investigators had previously demonstrated the presence of antibody to EBV capsid antigen in all Old and several New World monkeys. Moreover, EBV-related viruses have been isolated from a number of primate species.

lpha herpesviruses recovered from baboons have resulted in some confusion in classification and terminology. SA8, closely related to herpes B, was originally isolated from an African green monkey. More recently, related isolates of SA8 have been obtained from baboons. Molecular analyses of these isolates indicate that they are distinct and a separate provisional designation: herpesvirus papio 2 (HVP-2) was suggested. These isolates, capable of causing disease and death among baboons, are not lymphoproliferative, and have the properties of alpha herpesviruses (*Alphaherpesvirinae*). Thus far, there has been no evidence of human involvement.

The presence of antibody to such herpesviruses as human CMV (*Betaherpesvirinae*) and its related monkey virus, SA6, indicates their infectious capability in baboons. Antibody to a simian VZ isolate also suggests baboon infection with this group of agents. Herpes simplex virus antibody is rarely seen in baboons.

Pongine herpesviruses

Herpes-like viruses (herpesvirus pan) were first recovered from leukocytes of chimpanzees previously inoculated with cells or virus derived from human cell lines containing herpesvirus-like particles. Herpesvirus particles were also recovered from leukocytes of normal uninoculated chimpanzees as well as from the oropharynx of immunosuppressed chimpanzees.

Other herpesviruses of chimpanzees, as determined by the presence of antibody, recovery of virus or clinical disease include: EBV, CMV, simian VZ virus and herpes simplex (**Table 1**). Various monkeys and apes (including the chimpanzee) have shown clinical evidence of infection with VZ virus (*Alphaherpesvirinae*) or closely related viruses. Initially considered to be solely a human agent, subsequent outbreaks in nonhuman primates indicate otherwise. The origin and disposition of this 'human' virus is not clear. Another member of the *Alphaherpesvirinae* generally not considered among nonhuman primates is herpes simplex virus, which is frequently transmitted among captive apes.

Taxonomy and Classification

The Herpesvirus Study Group of the International Committee on Taxonomy of Viruses suggested that the family *Herpesviridae*, subfamily *Gammaherpesvirinae* and genus *Lymphocryptovirus* include as species both herpesvirus papio (designated as cercopithecine herpesvirus 2) and herpesvirus pan (as pongine herpesvirus 1) along with EBV (human herpesvirus 4). As a group, these are double-stranded DNA viruses with molecular weights of approximately 110×10^6, virion diameters of 118–220 nm, and capsomeres arranged in an icosahedron.

Herpesvirus papio and herpesvirus pan show a specificity for B lymphocytes and their host range in nature is limited to the same order as the natural host. These viruses all share various degrees of DNA sequence homology (approximately 40%), produce crossreactive viral proteins and immortalize B lymphocytes. EBV, herpesvirus papio and herpesvirus pan DNA all show extensive collinear homology with each other.

Final classification of SA8/HVP-2 must await more definitive analyses. However, because of neurotropic tendencies and antigenic relatedness to herpes B virus (cercopithecid herpesvirus 1), inclusion among the *Alphaherpesvirinae* is suggested. Molecular analysis of SA8 and HVP-2 strains indicate that baboon isolates are similar to, but distinct from, SA8, and should be distinctly designated. Similarly, as the VZ virus is apparently of human origin, it and its closely related simian viruses should continue among the *Alphaherpesvirinae*.

Human CMV is included with the *Betaherpesvirinae*, as SA6, a related CMV, should be. These are all

DNA viruses varying from 120–200 kbp. DNA sequences are present internally in inverted form.

Geographic and Seasonal Distribution

Herpesvirus papio, herpesvirus pan, SA8 (and related strains) are all natural to African species and in nature are restricted to that continent. However, baboons and chimpanzees have been transported throughout the world and as herpesviruses have a propensity for latency, they may be found wherever baboons and chimpanzees are located and without any seasonal distribution. In the Sukhumi colony, however, peak infection with herpesvirus papio occurred in the autumn and spring.

EBV and CMV are worldwide in distribution among primates and not seasonal. Although both EBV and CMV are considered as common human viruses, antibody to these viruses or related viruses are found among Old and New World simians. Little is known about the epizootiology of VZ and related simian viruses. Nonhuman primate infection with VZ probably occurs following contact with an infected human or a simian carrier.

Host Range and Viral Propagation

Gammaherpesvirinae, in general, have a host range limited to the family or order of the natural host. Cultivation of both herpesvirus papio and herpesvirus pan is restricted to B cell lymphocytes. Originally the baboon isolates were obtained by cultivation of bone marrow and splenic cells from a lymphomatous hamadryas baboon. Cells were grown in RPMI 1640 supplemented with 20% heat-inactivated bovine embryo serum and maintained at 37°C in a 5% CO_2 atmosphere. The appearance of cell clumps along with enhanced metabolic activity and cell growth are the criteria of successful cell cultivation. Viral presence is determined by observing typical herpes-like viral particles within the cells and/or the transformation (immortalization) of infected lymphocytes. Serological tests for the presence of viral (V) and soluble (S) antigens, using known positive sera, confirm the presence of virus.

Host range of herpesvirus papio and herpesvirus pan may be determined by the presence of transformed B cells along with development of viral-associated antigens. Transformation by herpesvirus papio is observed in lymphocytes derived from the baboon, gibbon, cynomolgus monkey, rhesus monkey and stump-tailed macaque monkey. Human newborn lymphocytes are inconsistently transformed. Lymphocytes from New World monkeys, such as the cotton top (*Saguinus oedipus*) and other marmosets (*S. fuscicollis, S. nigricollis*), are also transformed by the baboon virus.

In general, the chimpanzee isolates parallel the baboon viruses in their host range and lymphocyte invasiveness. However, herpesvirus pan has not been as extensively studied as the baboon virus so there may be some variation in host cell susceptibility.

Evidently EBV and CMV (or closely related antigenic relatives) are not host restricted, as infection evidenced by antibody is universal. Details of their host range and propagation may be found elsewhere in this encyclopedia. SA8 was originally isolated from the spinal cord of an African green monkey developing paralysis following inoculation with poliovirus vaccine. HVP-2 was isolated from baboons. The full extent of the SA8/HVP-2 host range has not been determined, but SA8/HVP-2 antibodies have been found in various primate species. With the exception of baboon outbreaks, overt disease with SA8/HVP-2 has not been recognized. Apparently invasiveness of HVP-2 may differ from that of SA8. SA8 and related strains may be isolated and propagated in a variety of cells: rabbit kidney, Vero, HEp-2 and a number of other primate cell cultures. Herpes simplex is also readily isolated in a number of cell types.

It is generally considered that VZ infection is restricted to humans. Experimental subclinical infections were produced in a number of laboratory animals with little evidence of clinical disease. In 1966 an outbreak of a fatal exanthematous herpesvirus infection occurred among African green (*Cercopithecus aethiops*) monkeys. Subsequently several other similar episodes occurred in macaques, patas monkeys and apes. Antigenic analyses of these isolates demonstrated a close relationship to VZ virus.

Genetics

The close homology (40%) of herpesvirus papio and herpesvirus pan with EBV suggests that these viruses all evolved from a common ancestor. In addition, extensive crossreactions exist between the viral capsid (VCA) and early antigens (EA) of these three viruses. Lymphotropic herpesvirus-induced EBNA (Epstein–Barr nuclear antigen)-related proteins contain an epitope that has been conserved during the evolution of the EBV family of viruses. Further evidence for a genetic relationship was the identification of a pair of small RNA segments from herpesvirus papio which crosshybridize with two low molecular weight RNAs encoded by EBV. Herpesvirus papio is able to transform B lymphocytes in culture as well as to superinfect EBV-negative or nonproducer B cells inducing viral antigens. Herpesvirus papio also has a nuclear

antigen distinct from that found in EBV. These differences should be valuable for genetic studies on this group of lymphotropic viruses. Although there appear to be some genomic alterations resulting from infection of different simian hosts, the rapid evolutionary changes seen with viruses such as influenza apparently do not occur here.

Although a close antigenic relationship exists between SA8/HPV-2 and herpes B virus, SA8 does not appear to be as pathogenic in laboratory animals as herpes B virus. Clarification is needed on the relationship of SA8 to HVP-2 viruses and their pathogenicity. Eberle and coworkers demonstrated strain variation among the different HVP-2 isolates. As with other *Alphaherpesvirinae*, there is a close genetic and antigenic relationship among members of this virus group. HVP-2 is closely related to SA8, but closer to B virus than is SA8. Questions exist on the genetic relationship of the VZ group of viruses. Many similarities are recognized between the human strains of VZ and the simian isolates. However there are distinct differences not only among the simian and human isolates, but with the simian isolates as well.

Evolution

On the basis of limited information, apparently all Old World B cell tropic primate *Gammaherpesvirinae* evolved from a common ancestor. Some simian EBNA-related proteins contain an epitope that has been conserved during the evolution of the EBV family of viruses.

Common antigens and other biologic characteristics would suggest that diverse baboon and chimpanzee herpesviruses may have evolved from infections following contact with humans or other primates.

Serologic Relationships and Variability

Lymphotropic herpesviruses papio and pan are antigenically closely related to isolates obtained from the gorilla (herpesvirus gorilla) and orangutan (herpesvirus pongo), as well as other EBV-like isolates, although there are antigenic differences. As a group, they all share DNA homology and antigenicity as well as other biologic activities with EBV.

EBV and the EBV-like viruses all have associated antigens: VCA, EA, membrane antigen (MA) and EBNA. Herpesvirus papio and herpesvirus pan will cross react with EBV when sera are tested for anti-VCA, anti-EA and anti-MA. However, the baboon virus does not crossreact with EBV when tested for anti-EBNA. Herpesvirus papio does not induce nuclear antigens in infected cells, as does EBV, but does produce an analogous antigen. All three viruses crossreact when tested by serum neutralization. Depending upon the source of antibody, differences in titer differentiate these viruses. The EA is composed of both R (restricted) and D (diffuse) components recognized by immunofluorescence and, while related, are distinguishable.

It is apparent that the more recently described HVP-2 isolates, while closely related to SA8, are distinct entities. Eberle *et al* even suggest that the recognized baboon infections were due to HVP-2 rather than SA8. A subset of HVP-2 antigens that is consistently present in HVP-2 viruses and able to act as immunogens is: gB and gD glycoprotein homologues, p40 antigen homologues and an unidentified glycoprotein doublet of 80–100 kDa. The first three of these proteins are essential in other *Alphaherpesvirinae* for replication and production of infective viruses.

Analysis of the simian VZ-like herpesviruses indicates properties similar to those of VZ. It is highly probable that all these viruses evolved from the same source. Enveloped virion size, buoyant density, polypeptide composition and immunogenic glycoproteins are consistent with those obtained for VZ.

Epidemiology

Herpesvirus papio was first isolated from a group of hamadryas baboons, previously inoculated with human leukemic blood, in the colony of the Institute of Experimental Pathology and Therapy, Sukhumi. Since 1967, more than 300 cases of lymphoma have been recognized in the main baboon colony. A separate baboon colony in a forest reserve some distance from the main colony has not shown any evidence of lymphoid disease, but the animals do contain herpesvirus papio VCA antibody. A C-type virus (simian T-cell leukemia virus, STLV-1?) along with a high incidence of STLV-1 antibody has also been observed in the Sukhumi baboons with lymphomas. It is not clear what the relationship between the presence of herpesvirus papio and C-type retroviruses (STLV-1) and leukemia is in these animals.

Serological surveys of the main baboon colony have shown an age-related increase in the prevalence of antibodies to herpesvirus papio and STLV-1. Herpesvirus papio is released into the environment by way of nasopharyngeal mucosa and lacrimal gland secretions, which appears to be the main route of horizontal transmission. The exact mechanism of STLV-1 transmission in the baboon is not clear, but evidently parallels that of infection with other retroviruses, i.e. a result of grooming, fighting, biting, sexual activity. The leukemic blood used to inoculate the baboons may also be the source of this virus.

STLV-1, which is closely related antigenically to human HTLV-1, is not to be confused with the vertically transmitted endogenous type C retroviruses present in primates.

The first isolation of herpesvirus pan was a serendipitous finding. Herpesvirus pan was isolated by cultivating chimpanzee leukocytes obtained from uninoculated chimpanzees as well as from chimpanzees previously inoculated with human derived cell lines containing herpes-type particles. Other isolates were obtained from oral secretions of immunosuppressed chimpanzees. Although no definitive data exist relative to the mechanism of viral transfer, it is highly probable that herpesvirus pan is spread via oral secretions or sexual intercourse.

EBV antibody is frequently observed in nonhuman primate sera, reflecting primary infection or cross-reactions of the indigenous EBV-like viruses present in different seropositive species. CMV infection probably parallels that of EBV.

SA8/HVP-2 infection needs additional study, although recent data suggest that the baboon infections were due to HVP-2. Most HVP-2 lesions in the baboons were venereal, implying that the epidemiology is sexual. The few chimpanzee herpes simplex infections are apparently of human origin.

Transmission and Tissue Tropism

Transmitting vehicles of herpesviruses may include such materials as respiratory secretions, blood, saliva, contact with infected lesions and sexual intercourse. Both herpesvirus papio and herpesvirus pan are readily transmitted in nature to their respective natural host animals via respiratory secretions. Experimental production of tumors, however, has been limited to the inoculation of marmosets with large numbers of herpesvirus papio-producing baboon cells. Cotton top marmosets develop an acute, widely disseminated lymphoproliferative disease. In view of the possible need for another virus (STLV-1, other ?) to help in the production of baboon tumors, it would be of interest to determine whether herpesvirus papio alone is responsible for tumor production in marmosets.

Although herpesvirus pan is not known to cause disease, experimental infection occurs in various species of animals, as measured by antibody development.

Lymphocyte infection by herpesvirus papio or herpesvirus pan is prelytic or lytic; at the prelytic stage infection is arrested, with persistence and minimum expression of viral genome. At the lytic stage, cell death results without production of complete virions.

EBV also shows a predilection for B lymphocytes. Antibody surveys demonstrate that it or related viruses are widespread among human and nonhuman primates. EBV-like viruses from both the baboon and chimpanzee are capable of transforming cells from other primates, including humans. Transmission is horizontal by oral secretions with a high frequency of occurrence.

The other herpesviruses, in general, demonstrate a preference for specific cell types, but many exceptions exist. Tissue tropism varies extensively. The *Alphaherpesvirinae* usually relate to mucosal epithelial cells, invade sensory neurons with neurological symptoms in alien hosts and with latent infection centered in ganglia. The major mechanism of SA8/HVP-2 transmission is apparently venereal. *Betaherpesvirinae* favor epithelial and mononucleated blood cells; transmission is principally by direct and indirect contact.

Pathogenicity

Herpesviruses all have their own natural host range which in general is narrow and restrictive. Experimentally there is a greater latitude which may be wide, depending upon the strains of virus. Infection may range from subclinical to that of tumor development or highly fatal neurologic involvement.

Although some variation exists among the herpesvirus papio and herpesvirus pan strains, their infectivity patterns are similar. The latter is apparently nonpathogenic, and infection is limited to antibody production and virus shedding. Infection by either virus is followed by localization of the virus in lymphocytes where a persistent infection results.

The relationship of herpesvirus papio to lymphoproliferative disease in the baboon must await further study. The precise roles of herpesvirus papio and STLV-1 or another virus in the production of tumors remains to be elucidated. However, experimental inoculation of adult marmosets (*S. oedipus, S. nigrifrons*) with herpesvirus papio isolated from diseased baboons results in a mild to severe, and sometimes fatal, lymphoproliferative disease. Such findings do not rule out the presence of endogenous viruses. It does not produce disease when inoculated into the same species newborn marmoset.

In addition to the possible role of herpesvirus papio and STLV-1 in the production of lymphoproliferative disease, a similar role may exist with STLV-1 or other viruses in conjunction with EBV or EBV-like virus infections.

SA8/HPV-2 infection and fatalities in baboons have been alluded to above. VZ infection of apes has also been indicated.

Clinical Features of Infection

In the original studies by Lapin and his collaborators, the observed clinical disease associated with herpesvirus papio infection included a wide variety of lymphomas: non-Hodgkin's lymphoma of the lymphoid type (predominantly); lymphosarcoma; prolymphocytic lymphosarcoma; reticulosarcoma; lymphoplasmacytic, immunoblastic lymphoma; and lymphogranulomatosis.

Advanced disease is associated with immunosuppression. Disease occurs over a long period of time (3–5 years) with cycles of relapse and remission. B, T and null cell type lymphomas have been observed in the 300+ cases reported since 1966. Initial clinical features include conjunctivitis, stomatitis, gingivitis, skin pigmentation and enlarged lymph nodes.

Herpesvirus pan is endemic in its natural host, the chimpanzee, without any evidence of clinical disease. Limited experimental infection with this virus has also shown no capacity to produce disease.

EBV is considered to be widely distributed in humans, but sufficient evidence exists that it, or closely related strains, is present in a variety of primates and other animals. New World primates do not carry EBV homologues. EBV is associated with human diseases (infectious mononucleosis) and oncogenicity (Burkitt's lymphoma, nasopharyngeal carcinoma) and a similar potential is suspected for the simian EBV-like viruses in nonhuman primates. Transforming capabilities of human EBV and simian EBV strains needs clarification. Both transforming and nontransforming strains are recognized.

Similarly, the pathogenic potential of simian CMVs requires further study. Antibody is well distributed among all simian species. Clinical disease has not been reported in nonhuman primates, with the possible exception of a combined infection resulting from a retrovirus and CMV in macaques.

The SA8/HPV-2 epizootic in baboons was manifested by severe ulcerative and/or papillomatous lesions on the penis and scrotum as well as vulvar and perivulvar lesions in the females. Oral lesions were observed primarily in juveniles. Fatal neonatal infections do occur.

Pathology and Histopathology

The pathologic changes induced by herpesvirus papio are those associated with malignant lymphomas. Examination of lymphomatous tissues shows numerous chromosome breaks and structural rearrangements. In advanced disease, the lymphocytes are suppressed. Lymph nodes and spleen are most frequently affected; as the disease progresses, other tissues become involved – lungs, liver, kidneys, bone marrow. Both diffuse and nodular growth are seen.

Pathology due to herpesvirus pan is restricted to the B cell lymphocytes in which the virus induces growth transformation and expression of an intranuclear antigen. Long-term cultivation of lymphoid cell lines will show the morphologic presence of herpes-like virus.

EBV agents from both baboons and chimpanzees transform B lymphocytes of most Old World simians, in which they are modest virus producers. Virus particles are present in about 1% of the producer cells. Overt disease is not seen.

SA8/HVP-2 lesions in the male baboons were observed as erythematous patches which progress to papules or vesicles that coalesce, forming an ulcerative hemorrhagic lesion. Lesions in the females were exclusively ulcerative.

VZ infection of chimpanzees and other apes parallels that of human infection. The zoster-like syndrome has not been reported in any of the simian species. Lesions have not been observed in any of the dorsal root ganglia that have been examined. However, as zoster does not manifest itself for many years post primary infection, necropsies on appropriate animals have not been done. All simian varicella herpesvirus infections have produced cutaneous, oral and visceral lesions similar to human varicella.

Immune Response

Four major classes of antigens are associated with EBV and EBV-like primate viruses: VCA, EA, MA and EBNA (in EBV). Sera from a wide assortment of nonhuman primates show antibody to these viruses and extensive crossreactivities with all of these antigens, although differences have been observed. The serological response of baboons with lymphoid disease due to herpesvirus papio is similar to that of humans with Burkitt's lymphoma and EBV, particularly the response to the VCA. As a group, lymphomatous animals have an increased frequency of, and higher titers to, herpesvirus papio antigens than contact animals or noncontact animals. The elevated antibody responses are specific for the antigens, as shown by lower titers to both CMV and a baboon foamyvirus. These CMV and foamyvirus titers may reflect the immunosuppression occurring as a result of herpesvirus infection. A decrease in the relative percentage of T cells has been noted. Immunosuppression may also be an indication of the accompanying STLV-1 infection. The development of antibodies is not age or sex dependent. Although herpesvirus papio shows considerable relatedness to EBV, the two

viruses may be distinguished on the basis of their EBNA and early antigens.

The immune response of an individual to infection with herpesvirus pan resembles that of infection with EBV. A close antigenic relationship between EBV and herpesvirus papio exists, as demonstrated by the crossreactions seen when testing human or baboon serum for antibody with herpesvirus pan. The EBNA and EA of the chimpanzee virus are distinguishable from those of EBV, but strong crossreactions may be observed with the VCA.

Surveys of baboon and chimpanzee sera for antibodies to other herpesviruses generally indicate widespread infection (**Table 1**). Baboon sera indicate SA8/HVP-2 antibody present in more than 50% of the sera examined. The incidence of SA8/HVP-2 antibody in chimpanzees is very low, suggesting limited infection. Although there is strain variation among the SA8/HVP-2 isolates, this antigenic variation does not appear to induce substantial differences in antibody response. The subset of virus antigens that induce antibodies in all infected baboons was identified as the gB and gD glycoprotein homologues, an unidentified glycoprotein doublet of 80–100 kDa and the p40 antigen homologues. Insufficient chimpanzee sera have been examined for detailed antibody evaluation.

All simian varicella herpesviruses show antigenic relationships to VZ virus; however, the chimpanzee isolate shared an antigen with VZ virus lacking in the other simian isolates. Conversely, these other simian isolates had a common shared antigen with VZ virus that was lacking in the chimpanzee isolate. Antigenic analyses indicate that the chimpanzee virus, the delta herpesvirus and the remaining isolates are three distinct viruses.

Prevention and Control

As with diseases due to EBV, little is available in the way of prevention and control of herpesvirus papio or herpesvirus pan infections. Infection is best prevented by isolation of the animals. The elevated anti-EA titers, as seen in prelymphoma baboons that subsequently die of malignant lymphoma, may be used as a high-risk marker for determining development of malignant lymphoma.

As a generalization, prevention and control of herpesvirus infections are now based on chemotherapy or prevention. Therapy is dependent upon the use of the human antiviral compounds: acyclovir and related agents as well as several newer compounds. Toxicity, resistance and lack of detailed study in the use of these agents in veterinary medicine makes selection and usage questionable.

Future Perspectives

This revised second edition article includes previously omitted herpesviruses of the baboon and chimpanzee. Certain of these viruses are described in detail elsewhere in the encyclopedia, however such viral entities as the SA8/HVP-2 complex, simian EBV and CMV as well as simian VZ, that involve the baboon and chimpanzee should be noted. Herpes simplex infection is seen in chimpanzees, but is rare and probably results from human contact.

Herpesvirus papio and herpesvirus pan have little significance in human disease, other than they may serve as models for those investigators who may wish to research the relationship between host and lymphoproliferative viruses. Herpesvirus papio and herpesvirus pan infections in their natural hosts mimic that seen in the human infected with EBV, however, only restricted use may be made of the chimpanzee as a model. Chimpanzees are both expensive and in limited supply. The baboon, on the other hand, which shows evidence of lymphoproliferative disease, is still readily available, even being bred in captivity, and would be an appropriate model for future studies.

The possible interaction of EBV-like viruses with type C viruses (STLV-1, others ?) found associated with lymphoma in the Sukhumi baboons is a further avenue for investigation. A recent study has raised the question of the association of these two agents in causing lymphomatous disease. Endogenous and exogenous type C viruses are found in a wide variety of animals, particularly in nonhuman primates. It would be of interest to ascertain whether or not herpesvirus papio alone is responsible for tumor production in baboons, as observed in the Sukhumi primate center or experimentally in marmosets. Causation of disease in the baboon by herpesvirus papio may also be questioned in terms of infection of a natural host by herpesviruses. Infection of the natural host by these viruses is usually mild or inapparent, rather than a highly fatal disease. Although a number of studies with a baboon endogenous virus isolate have failed to demonstrate oncogenicity, a pseudotype containing a murine sarcoma virus gene did produce tumors in several species of primates, including chimpanzees, and in other animals. These original findings in the baboon suggest further studies on the association of herpesviruses and various retroviruses as a possible tumor producing mechanism. HTLV-1, a type C virus related to STLV-1, has been implicated in the etiology of a human leukemia.

Other investigative avenues should delineate the pathogenic relationship between SA8 and the HVP-2

isolates. Which of these viruses produces a highly fatal disease in baboons needs clarification.

Recent concerns with regard to xenotransplantation, particularly as it relates to the use of baboon organs, suggests continued investigation into the problem of biohazards and emerging diseases. Of great anxiety is the transfer and activation of a donor's latent infection in association with host immunosuppression. Although the number of human transplant needs far outweigh the baboon capacity (currently the leading contender for the provision of organs), the need for baboon organs will probably continue. Transgenic studies suggest an animal source other than the baboon will undoubtedly be more appropriate in xenotransplantation.

HERPESVIRUSES SAIMIRI AND ATELES (*HERPESVIRIDAE*)

Julia Hilliard, Viral Immunology Center, Department of Biology, Georgia State University, Atlanta, Georgia, USA

History

Herpesvirus saimiri and herpesvirus ateles include four different viruses within the family *Herpesviridae*. This entry focuses upon two of those four: herpesvirus saimiri 2 (HVS-2) and herpesvirus ateles 2 (HVA-2), each classified in the genus *Rhadinovirus* within the subfamily *Gammaherpesvirinae*. Each virus is easily confused with its counterpart herpesvirus saimiri 1 and herpesvirus ateles 1, which are distinct viruses of squirrel and spider monkeys, respectively, and both members in the *Simplexvirus* genus of the subfamily *Alphaherpesvirinae*. All four viruses that are called saimiri and ateles are herpesviruses associated with members of New World monkey species, those originating from Central and South America.

HVS-2 is endemic in the squirrel monkey (*Saimiri sciureus*), while HVA-2 is found most frequently in the spider monkey (*Ateles geoffroyii*), the monkey species from which it was initially isolated. HVS-2 was reported upon following isolation from a owl monkey kidney tumor, and was also found in association with a fatal disease in a marmoset, but additionally from primary kidney cell cultures derived from a squirrel monkey. In time, only the squirrel monkeys were identified to be the natural hosts for the virus. In early reports, it is often difficult to determine whether investigators are referring to HVS-1 versus HVS-2 when reporting or publishing results, or HVA-1 versus HVA-2. Nomenclature for each of these viruses has often been confusing because each virus has had a variety of different common names, some applying to the neurotropic counterparts HVS-1 and HVA-1, and others to HVS-2 and HVA-2, including marmoset herpesvirus (MHV), herpesvirus tamarinus (HVT), herpesvirus platyrrhinae (HVP)

Latent-phase transcripts

Latently infected neurons represent 1–10% of the total neurons in the ganglia, and infected cells contain as few as 5–10 copies of viral DNA. In some neurons, an 8.5 kb polyadenylated transcript whose promoter lies in the long repeat sequences about 1800 bases 3′ of the 3′ end of the $\alpha 0$ mRNA is expressed as the LAT (**Fig. 1**). This primary transcript extends through the joint region to a polyadenylation signal next to that of the $\alpha 4$ transcript in the short repeat.

The primary LAT transcript is extensively processed, forming an unknown number of unstable, spliced, polyadenylated mRNAs, and a stable 2 kb poly(A-)intron in lariat form which accumulates in the latently infected neuronal nucleus. A second, spliced variant of this LAT-intron can also be observed. The function of this stable intron is unclear; it is not involved in the facilitation of reactivation mediated by LAT expression.

Future Trends in Research on HSV

HSV possesses a number of features that will make it a continuing research model in the future. Among the most obvious are the following. (1) The neurotropism of the virus, along with the relative convenience of generating recombinants containing foreign genes expressed either under homologous or heterologous promoters, recommends HSV as a vector for introducing specific genes into neural tissue. This facility is increased by the fact that the viral genome can enter and be maintained in neural tissue in the complete absence of lytic phase viral gene expression. (2) The fact that HSV's replication is restricted in terminally differentiated neurons suggests its potential as a therapeutic agent against neural tumors, provided appropriate mutants can be constructed. (3) The benign nature of normal infection with HSV also suggests its potential use as a vaccine vector by incorporation of specific antigens into the viral genome, although the promise of this application may be clouded somewhat by the ability of replication-defective viruses to persist in the host. (4) The abundance of viral genes dedicated to the efficient replication of viral DNA in the productive cycle provides a number of potential targets for antiviral chemotherapy. (5) The interactive cascade of viral proteins involved in regulation at a number of levels in the infected cell makes HSV a useful model for the detailed analysis of specific aspects of control of eukaryotic gene expression.

HERPESVIRUSES 6 AND 7 – HUMAN (*HERPESVIRIDAE*)

Takuya Shimamoto and **Koichi Yamanishi**, Department of Microbiology, Osaka University Medical School, Osaka, Japan

History

Human herpesviruses 6 and 7 (HHV-6 and HHV-7) are ubiquitous agents of humans. HHV-6 was first isolated by Salahuddin *et al* in 1986 as a novel herpesvirus from patients with lymphoproliferative disorders, and initially named human B lymphotropic virus (HBLV). Subsequently, several laboratories

isolated similar viruses from patients with acquired immune deficiency syndrome (AIDS) and children with exanthem subitum, and revealed that the virus is predominantly T lymphotropic. The name of the virus was changed to human herpesvirus 6 because it was a newly discovered one distinguished from other five known human herpesviruses. HHV-6 isolates are classified into two groups as variants A (HHV-6A) and B (HHV-6B). The two variants are closely related but show consistent differences in biological, immunological, epidemiological and molecular properties. HHV-6B is the major causative agent of exanthem subitum, but no disease has yet been associated with HHV-6A.

HHV-7 was isolated by Frenkel *et al* in 1990, as the seventh human herpesvirus, from CD4+ lymphocytes of a healthy adult. The virus also causes exanthem subitum.

Taxonomy and Classification

HHV-6 and HHV-7 are members of the genus *Roseolovirus*, which belongs to the *Betaherpesvirinae* subfamily, along with human cytomegalovirus (HCMV), of the family *Herpesviridae*. HHV-6 and HHV-7 share many characteristics with other herpesviruses, including typical herpesvirus morphology and large DNA genome, and the ability to establish persistent and latent infections.

Host Range and Viral Propagation

Humans are the natural host for HHV-6 and HHV-7. It was reported that some species of monkeys have antibody to HHV-6. HHV-6 and HHV-7 replicate most efficiently *in vitro* in activated primary T cells and T cell lines. HHV-6 and HHV-7 can be isolated by cocultivation of phytohemaglutinin-stimulated umbilical cord blood lymphocytes with peripheral blood mononuclear cells (PBMCs) from patients and saliva from individuals, respectively. The rate of HHV-6B isolation from PBMCs is nearly 100% on days 0–2 after the onset of exanthem subitum, and gradually decreases to zero during the convalescent phase.

Properties of the Virion

Virions of HHV-6 and HHV-7, like all other herpesviruses, have four main structural elements. The electron-dense core encompasses viral DNA genome and associated proteins. The icosahedral nucleocapsid contains 162 capsomeres and surrounds the core. The tegument occupies the space between the nucleocapsid and the envelope. The envelope is derived from cellular membrane and contains virally encoded glycoproteins and integral membrane proteins. The most characteristic feature of the virions of HHV-6 and HHV-7 is the very distinct tegument layer.

Properties of the Genome

The genomes of HHV-6 and HHV-7 are linear double-stranded DNA molecules of approximately 159 kb and 145 kb, respectively. The gene organization of each is illustrated in **Fig. 1**. The complete genomic sequences were determined for HHV-6A strain U1102 and HHV-7 strain JI, and partial sequences were reported for other strains, including HHV-6B strain HST.HHV-6A and HHV-6B are very similar genetically because their nucleotide sequences differ by 4–10% between the variants, depending on the gene being compared. This similarity, which is higher than that for any other independently recognized herpesvirus species, led to the decision to adopt the variants A and B nomenclature, rather than name the variants as distinct species. Sequence comparison among herpesvirus species revealed the highest conservation of genetic content and encoded protein products between HHV-6 and HHV-7, ranging from 41 to 75% amino acid sequence identity for the core herpesvirus gene products. HHV-6A strain U1102 DNA consists of a single unique component (U) of 143 kb, flanked by two direct terminal repeats DRL and DRR, each of which contains about 8 kb. The overall GC content is 43% but is lower in U (41%) and higher in DR (58%). The genome is considered to contain more than 100 separate genes likely to encode protein. HHV-7 genome has almost the same configuration with that of HHV-6. The relative arrangements of the HHV-6 and HHV-7 herpesvirus-conserved genes are identical to those of homologous genes in HCMV, as expected for betaherpesvirus genomes. At the left and right termini of the DRs are *cis*-acting sequences involved in DNA packaging, pac-1 and pac-2, respectively. The DRs encompass repetitive (TTAGGG)n motifs, identical to human telomeric repeat sequences. The motifs have also been found in Marek's disease virus, which is a lymphotropic alphaherpesvirus of chicken, but not in other human herpesviruses. The function of the telomeric sequences is not known.

HHV-6 encodes adeno-associated virus type 2 (AAV-2) *rep* gene homologue. The rep protein is essential for AAV-2 DNA replication and possesses site-specific ATP-dependent endonuclease and helicase activities. The functions of the *rep* gene and its product in the life cycle of HHV-6 are unknown, although rep from HHV-6 can provide helper function for AAV-2 DNA replication *in vitro*. Additionally, rep from HHV-6A can complement the replica-

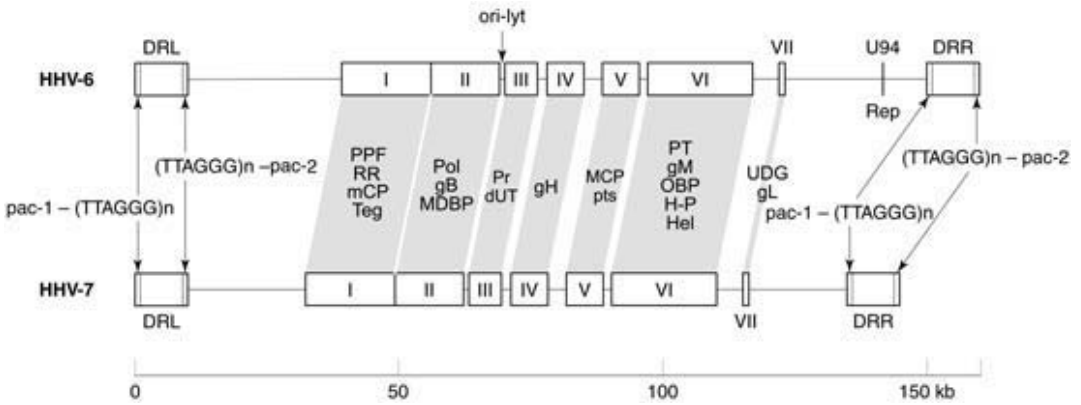

Figure 1 Gene organization of HHV-6 and HHV-7. Gene blocks I–VII containing genes conserved in all herpesviruses are marked in relative positions in HHV-6 and HHV-7. The ORFs encompassed in each block are as follows: I, U27–U37; II, U38–U41; III, U42–U45; IV, U48–U53; V, U56–U58; VI, U60–U77; VII, U81–U82. HHV-6 ori-lyt is indicated by an arrowhead. Representative genes encoded in the conserved and unique regions are listed. Abbreviations are: PPF, DNA polymerase processivity factor; RR, ribonucleotide reductase; mCP, minor capsid protein; Teg, large tegument protein; Pol, DNA polymerase; gB, glycoprotein B; MDBP, major single-stranded DNA-binding protein; Pr, primase; dUT, dUTPase; gH, glycoprotein H; pts, protease/assembly protein; MCP, major capsid protein; PT, phosphotransferase; gM, glycoprotein M; OBP, origin-binding protein; H-P, helicase–primase associated factor; Hel, helicase; UDG, uracil-DNA glycosylase; gL, glycoprotein L; Rep, AAV-2 *rep* gene homologue.

tion of a rep-deficient AAV-2 genome. There is no *rep* homologue in HHV-7, suggesting the acquisition of the gene by HHV-6 after the evolutionary divergence between HHV-6 and HHV-7.

Proteins of HHV-6 and HHV-7

In HHV-6, potentially protein-coding open reading frames (ORFs) are numbered by the order occurring in the U and DR regions of the genome from left to right. Since almost all ORFs of HHV-7 encode homologues of HHV-6 and are present in the corresponding location in the genome, common numbers have been adopted for naming the homologous HHV-7 ORFs. For example, an ORF encoding the DNA polymerase of HHV-6 is the 38th, numbering from the left of the U, and therefore designated ORF U38, which is also used for indicating that of the DNA polymerase of HHV-7.

Proteins involved in DNA replication

The elements essential and sufficient for lytic HSV-1 DNA replication are an origin for lytic phase replication (ori-lyt) and seven viral gene products: the major single-stranded DNA-binding protein (MDBP), the DNA polymerase, a DNA polymerase processivity factor and an origin binding protein (OBP), as well as a helicase–primase complex composed of three proteins (helicase, primase, helicase–primase associated factor). HHV-6 and HHV-7 encode homologues to all of the seven gene products. In HHV-6 and HHV-7, these genes correspond to ORFs U41, U38, U27, U73, U77, U43 and U74, respectively. An interesting feature is that HHV-6 and HHV-7 encode a homologue of herpes simplex virus type 1 (HSV-1) OBP, which has been found only in alphaherpesviruses. HHV-6 has an origin for lytic-phase DNA replication that, as in HSV-1, varicella-zoster virus (VSV) and HCMV, is located upstream of the gene encoding the MDBP homologue (U41). The minimal active region of HHV-6B ori-Lyt is about 400 bp. The HHV-6B ori-lyt includes two binding sites, OBP-1 and OBP-2, for the HHV-6B OBP. The OBP sites are arranged with dyad symmetry, flank an AT-rich spacer, and are within the minimum essential origin region. This region is adjacent to a larger AT-rich imperfect direct repeat of about 195 bp that has been proposed to act as a DNA-unwinding element. Both OBP sites are required for DNA replication. Thus, the HHV-6 ori-lyt has features of both beta- and alphaherpesvirus origins, in having a larger set of repeat motifs (beta, 'complex' ori) and sequences which bind the OBP (alpha ori).

HHV-6 and HHV-7 homologues of herpesvirus gene products that are involved indirectly in DNA replication, by providing nucleotide substrates and DNA repair functions, include ribonucleotide reductase (U28), dUTPase (U45), phosphotransferase (U69), alkaline exonuclease (U70) and uracil-DNA glycosylase (U81). Homologues of the thymidine kinase genes found in the alpha- and gammaherpesviruses are absent in HHV-6 and HHV-7, as well as HCMV. The phosphotransferase encoded by UL97 in HCMV is capable of phosphorylating nucleosides, an

activity that accounts for the efficacy of ganciclovir in suppressing HCMV infections. The *in vitro* susceptibility of HHV-6 to ganciclovir may also be attributed to the function of the phosphotransferase (U69). The dUTPase and uracil-DNA glycosylase homologues of HHV-6 and HHV-7 presumably specify enzymatic activities involved in excision of uridine residues from DNA, by analogy to bacterial and eukaryotic counterparts, although there is notable sequence divergence between the HHV-6 or HHV-7, cellular and other herpesvirus dUTPase homologues.

Glycoproteins

There are several glycoprotein genes conserved in all sequenced herpesviruses. These genes are glycoprotein B (gB), glycoprotein H (gH), glycoprotein M (gM) and glycoprotein L (gL), and also are conserved in HHV-6 and HHV-7. These genes correspond to U39, U48, U72 and U82, respectively. gB and gH are structurally highly conserved between herpesviruses, are membrane-bound glycoproteins, and appear to play roles in virus cell fusion and cellular spread of virus infection. gL forms a physical association with gH precursor protein and may be required for gH transport and/or processing. The gM is an integral membrane protein containing multiple hydrophobic, putative membrane-spanning domains and fairly well conserved between herpesviruses. It has been shown to be a component of the virus particle in HSV-1.

In HHV-6, a highly spliced gene at the right end of the U component of the genome has recently been characterized and shown to encode a glycoprotein species, gp82/105. In strain GS, this gene contains 13 exons. The role of gp82/105 is not known but is likely to be important in the biology of HHV-6, as neutralizing epitopes are present. Three HHV-7 ORFs (U98, U99 and U100) show homology to regions of the gp82/105 amino acid sequence.

Glycoprotein U18 appears to be betaherpesvirus-specific. In HCMV this gene is spliced and encodes an immediate early glycoprotein.

HHV-6 U20 exhibits significant sequence similarity to the immunoglobulin E (IgE) C chain and therefore is a member of the Ig superfamily. The U85 genes of HHV-6 and HHV-7 encode homologues of OX-2 membrane antigen, which is also a member of the Ig family. Members of the Ig family have roles in cell-to-cell contact via protein–protein interactions and it is postulated that expression of these glycoproteins will function in infected cell adhesion to uninfected lymphocytes or monocytes.

Glycoproteins U21, U23, U24 appear to be unique to HHV-6 and HHV-7. There are glycoproteins encoded in a similar location in HCMV, but they share no detectable similarity.

Capsid, tegument and virus assembly proteins

Several of the ORFs identified in HHV-6 and HHV-7 are homologous to herpesvirus genes encoding characterized and candidate structural proteins. These include homologues of the major capsid protein (MCP; U57), minor capsid protein (mCP; U29), large tegument protein (U31) and virion proteins specified by U33, U34, U36, U50, U56 and U76. Betaherpesvirus-specific and conserved structural proteins are homologues of HCMV UL32 (antigenic phosphoprotein, pp150) and UL82/83 (tegument transactivator, pp65/72K), which correspond to U11 and U54, respectively. The HHV-6 U11 gene product is called pp100 and has been characterized as a major antigenic phosphoprotein and a component of the virion. The homologues of herpesvirus gene products involved in DNA packaging and capsid assembly have also been identified in HHV-6 and HHV-7. These correspond to U29 (mCP), U30, U53 and U60/U66. These genes appear to be conserved (at least positionally) in all of the sequenced herpesviruses. The U60/U66 ORFs correspond to the two exons of the late spliced gene characterized initially in HSV-1, which is likely to play a role in DNA packaging and capsid assembly. U53 sequences code for the protease/assembly protein (assemblin) and the scaffolding protein. These proteins are derived through proteolytic cleavage (assemblin) and internal initiation (scaffolding protein). The sequences encoding the scaffolding protein are referred to as U53a and correspond to HSV-1 UL26.5. From studies on HSV-1 UL26/26.5 viral mutants, it appears that proteolytic activity is essential for DNA packaging and virus assembly.

Chemokine receptors

HHV-6 and HHV-7 contains two genes (U12 and U51) that encode putative homologues of cellular G-protein-coupled receptors (GCR). GCR homologues have also been identified in HCMV, as well as in the gammaherpesviruses herpesvirus saimiri (HVS) and Kaposi's sarcoma-associated herpesvirus (KHSV or HHV-8). The U12 gene of HHV-6 is expressed late in infection from a spliced mRNA. U12 functionally encodes a calcium-mobilizing receptor for β-chemokines, such as regulated upon activation, normal T expressed and secreted (RANTES), macrophage inflammatory proteins 1α and 1β (MIP-1α and MIP-1β) and monocyte chemoattractant protein 1, but not for the α-chemokine interleukin 8, suggesting that the chemokine selectivity of the U12 product is distinct from that of the known mammalian chemokine

receptors. These findings suggest that the product of U12 may play an important role in the pathogenesis of HHV-6 through transmembrane signaling by binding with β-chemokines.

Transmission and Tissue Tropism

The *in vivo* host tissue range of HHV-6 includes lymph nodes, lymphocytes, macrophages and monocytes, kidney tubule endothelial cells, salivary glands and central nervous system (CNS) tissues, where viral gene products have been localized to neurons and oligodendrocytes. The human salivary system is the only known source for persistent production of infectious HHV-7. HHV-6 and HHV-7 show predominant CD4 T cell tropism. CD4 is a critical component of the cellular receptor for HHV-7, but not for HHV-6. The membrane receptor for HHV-6 has not yet been elucidated. HHV-6B and HHV-7 are present in saliva, which is considered to be a most common source of transmission from mothers to infants. No HHV-6A isolates from saliva have been described.

Several studies suggest that intrauterine or perinatal transmission of HHV-6B can occur, but the possibility is very low. The detection of HHV-6B DNA by polymerase chain reaction (PCR) in the cervices of approximately 20% of women in late pregnancy, compared with 6% of nonpregnant controls, suggests reactivation of HHV-6 infection during pregnancy, with the possibility of perinatal transmission of the virus. A report of two cases of fulminant hepatitis-associated HHV-6B infection in neonates 3 and 5 days old is also suggestive of pre- or perinatal transmission.

Breast-feeding does not appear to be the route of transmission of HHV-6. HHV-6 DNA has not been detected in breast milk, and no difference was found in the prevalence between breast- and bottle-fed infants.

Epidemiology

HHV-6 and HHV-7 infections are widespread throughout the world.

About 90% of people worldwide over the age of 2 years are HHV-6 seropositive. Antibody against HHV-6 can be detected in more than 90% of infants' serum at birth, most likely due to maternally derived transplacental antibody. The positivity rate decreases during the first 5 months of life to as low as 5% and then rapidly increases between 6 months and 5 years, with 80% of children developing an antibody response by 13 months of age. A number of investigators have reported a decline in seropositivity with age among adults, but others have found no significant differences or even an increase after age 62. Although 95% of children seroconvert to HHV-6 before age 3, approximately 30% in the USA and 60% in Japan experience clinical exanthem subitum.

Like HHV-6, HHV-7 is a prevalent virus to which the great majority of the population become seropositive by adulthood. HHV-7 infection occurs somewhat later than HHV-6B.

Clinical Features of Infection

The primary infection of HHV-6B typically occurs in early infancy and causes exanthem subitum, also known as roseola infantum or sixth disease. The high frequency of the virus isolation from patients with the disease, along with seroconversion during convalescence, were reported by Yamanishi *et al* and established HHV-6B as the etiologic agent responsible for most cases of exanthem subitum. It is a generally benign illness of infants and young children. The incubation period is estimated to be about 10 days. The illness is characterized by 3–5 days of fever, sometimes accompanied by mild upper respiratory infection symptoms and cervical lymphadenopathy. Characteristically, a maculopapular rash on the trunk and neck appears within 48 h following decline of fever. Although roseola is the major manifestation of primary infection in Japan, in the large prospective studies of American children the classical manifestations of roseola are present in about 15–20% of primary cases evaluated in clinics and the emergency room. In most cases, children can recover from this disease after a few days without any complications. As rare events, HHV-6B has also been identified as the causative agent of the other related primary illnesses in young children. These include cases of liver dysfunction, hepatosplenomegaly, fatal and nonfatal fulminant hepatitis, intussusception, thrombocytopenia, thrombocytopenic purpura, fatal and nonfatal hemophagocytic syndrome, and disseminated disease resulting in death.

Neurologic complications are also observed during primary infection. The most frequent complication of acute infection is febrile seizure. Often the seizures appear late and are prolonged or recurrent. HHV-6 infections account for one-third of all febrile seizures in children up to the age of 2 years. In follow-up studies over a period of 1–2 years the HHV-6 genome persisted in blood mononuclear cells after primary infection. Reactivation, sometimes with febrile illnesses, was suggested by subsequent increases in antibody titers and by detection of viral DNA. Other rare complications include encephalitis, meningoencephalitis and aseptic meningitis. Although the

neurologic involvement is usually self-limited, in some cases HHV-6-associated encephalitis resulted in death or was followed by the development of epilepsy.

HHV-6 may be one of the agents of sinus histiocytosis with massive lymphadenopathy (SHML). SHML, also known as Rosai–Dorfman disease, is a rare, usually benign disease of children and young adults, primarily manifested by painless cervical lymphadenopathy.

As described above, most persons are infected with HHV-6B at an early age. Consequently, primary infection of adults is encountered infrequently. Such infections appear to have greater severity than do most primary infections in children. Mononucleosis-like syndrome, prolonged lymphadenopathy and fulminant hepatitis have been described.

There is a possibility that HHV-6 is an important pathogen in organ transplant recipients. Serologic reactivation was reported in recipients of bone marrow, liver and kidney transplants. Specific illnesses associated with HHV-6 seroconversion or reactivation in these patients include fever, rash, hepatitis, pneumonitis, neurologic dysfunction and bone marrow suppression.

HHV-6 has been implicated as the etiologic agent or as a component of pathogenesis for a number of clinical disorders, including chronic fatigue syndrome and multiple sclerosis. It is essential that further studies be performed to determine the association between HHV-6 and these diseases.

HHV-7 primary infection was reported to cause a typical exanthem subitum, confirmed by the isolation of HHV-7 from typical patients with exanthem subitum who had no antibody to HHV-6 and seroconversion to HHV-7 during convalescent phase. Incomplete clinical features of the disease, such as fever without rash and the common cold, were observed in the infection with HHV-7 as in that of HHV-6. Most cases of HHV-7 primary infection seem to show atypical clinical manifestations of exanthem subitum, making it difficult to relate the concerned illnesses to HHV-7.

Latent and/or Persistent Infection

The primary infections of HHV-6 and HHV-7 are followed by latent infection throughout life. HHV-6 can often be reactivated under conditions of immunosuppression, such as AIDS and organ transplantation, at times leading to severe to fatal diseases. Several lines of evidence indicate that PBMCs are one of the sites of latent infection with these viruses. When PBMCs from patients with exanthem subitum during acute and convalescent phases and from healthy adults were separated into two fractions of lymphocytes and monocytes, HHV-6B DNA was detected by PCR in both fractions during the acute phase of the disease, whereas mainly in the monocyte fraction in patients in the convalescent phase and of healthy adults. The virus could not be isolated from cells of convalescent patients or healthy adults, suggesting the latent infection of HHV-6B in these cells. HHV-6B may persist for a long time in monocytes/macrophages in a latent state, although it is not clear whether these cells are the main site of latent infection *in vivo*. HHV-7 can be reactivated from PBMCs of healthy individuals by T cell activation.

HHV-7 has been isolated from saliva and HHV-7 DNA detected in salivary glands by PCR, indicating the possibility that salivary glands are reservoirs of persistently infected HHV-7.

Host Immune Response

Humoral immunity to HHV-6B in exanthem subitum patients is as follows. Virus-neutralizing IgM is not detected in the sera until day 4 after the onset of disease, but is detectable on day 7 and persists for 3 weeks. On the other hand, IgG is first detected on day 7, increasing and persisting for a long time.

Very little is known about immunological defense by cellular immunity against HHV-6. The presence of HHV-6-specific T cell clones in seropositive individuals has been reported. Natural killer (NK) cells, a key component of the innate immune system, are known to play an important role against viral infections. Infections of PBMCs with HHV-6 and HHV-7 lead to upregulation of their NK cell cytotoxicity by inducing IL-15, which is one of the NK activity-enhancing cytokines. The cell type in PBMCs that has been identified as the source of IL-15 is the monocyte/macrophage. In fact, it has been reported that HHV-6 interacts directly with monocytes and induces IL-15 in them. This enhancement of NK cell cytotoxicity following infection is consistent with the previous observation that NK activity increased during the acute phase of exanthem subitum. IL-15 production following viral infections may therefore represent a powerful host defense mechanism involved in restricting viral growth and in limiting the spread of the infectious agents.

HHV-6 is a potent inducer of interleukin 1β (IL-1β) and tumor necrosis factor α (TNF-α) in cultures of PBMCs. In contradistinction, HHV-6 has no effect on IL-6 synthesis. HHV-6 infection also induces the production of interferon α, IL-10 and IL-12 in monocytes. The effects of these cytokines may contribute to our understanding of the pathogenesis of HHV-6 during primary infection and reactivation.

Prevention and Control

There is no prevention or therapy for the diseases caused by HHV-6 and HHV-7; however, ganciclovir and foscarnet are effective in suppressing replication of HHV-6 *in vitro*. Antiviral therapy might be appropriate in individual cases of severe HHV-6 disease.

Future Perspectives

The functions of most viral gene products of HHV-6 and HHV-7 in the lytic and latent infections have not yet been elucidated. Recently, the entire sequences of both viruses have been determined, accelerating the research of their molecular biology. The development of a recombinant virus system is awaited for the detailed examination of the function(s) of the viral genes in the context of the viral genomes. Since the only known host for HHV-6 and HHV-7 is humans, animal models are also a prerequisite for understanding the functions of the viral genes *in vivo*.

HERPESVIRUS SYLVILAGUS (*HERPESVIRIDAE*)

Peter G Medveczky, University of South Florida College of Medicine, Tampa, Florida, USA

History

Herpesvirus sylvilagus is a model for lymphoproliferative disorders and viral oncogenesis because it induces a lymphoma-like illness in rabbits. It was first isolated by Hinze in 1968 from kidney cell cultures of apparently healthy cottontail rabbits (*Sylvilagus floridanus*) in southern Wisconsin, USA. Morphological and molecular biological analysis proved that herpesvirus sylvilagus is a typical herpesvirus. The viral particle is enveloped and its capsid contains 162 capsomers as described for other herpesviruses. Neutralization assays and partial sequencing of the viral genome also demonstrated that herpesvirus sylvilagus is a unique herpesvirus. A virus referred to as cottontail rabbit herpesvirus (CTHV) has been isolated by Cebrian. This cottontail rabbit virus is unrelated to herpesvirus sylvilagus, as determined by Southern blot hybridization.

Classification

Herpesviruses have been classified into three subfamilies of the *Herpesviridae: Alpha-, Beta-* and *Gammaherpesvirinae*. The gamma or lymphotropic viruses infect lymphocytes and are further divided into two genera, *Lymphocryptovirus* and *Rhadinovirus*, on the basis of biological data, pathogenesis, sequence homology and latency genes (**Table 1**). There is little doubt that herpesvirus sylvilagus is a member of the gammaherpesvirus group but it is not clear whether it belongs to either of the two subgroups. While several investigators concluded that herpesvirus sylvilagus-induced pathology resembles

isolates. Which of these viruses produces a highly fatal disease in baboons needs clarification.

Recent concerns with regard to xenotransplantation, particularly as it relates to the use of baboon organs, suggests continued investigation into the problem of biohazards and emerging diseases. Of great anxiety is the transfer and activation of a donor's latent infection in association with host immunosuppression. Although the number of human transplant needs far outweigh the baboon capacity (currently the leading contender for the provision of organs), the need for baboon organs will probably continue. Transgenic studies suggest an animal source other than the baboon will undoubtedly be more appropriate in xenotransplantation.

HERPESVIRUSES SAIMIRI AND ATELES (*HERPESVIRIDAE*)

Julia Hilliard, Viral Immunology Center, Department of Biology, Georgia State University, Atlanta, Georgia, USA

History

Herpesvirus saimiri and herpesvirus ateles include four different viruses within the family *Herpesviridae*. This entry focuses upon two of those four: herpesvirus saimiri 2 (HVS-2) and herpesvirus ateles 2 (HVA-2), each classified in the genus *Rhadinovirus* within the subfamily *Gammaherpesvirinae*. Each virus is easily confused with its counterpart herpesvirus saimiri 1 and herpesvirus ateles 1, which are distinct viruses of squirrel and spider monkeys, respectively, and both members in the *Simplexvirus* genus of the subfamily *Alphaherpesvirinae*. All four viruses that are called saimiri and ateles are herpesviruses associated with members of New World monkey species, those originating from Central and South America.

HVS-2 is endemic in the squirrel monkey (*Saimiri sciureus*), while HVA-2 is found most frequently in the spider monkey (*Ateles geoffroyii*), the monkey species from which it was initially isolated. HVS-2 was reported upon following isolation from a owl monkey kidney tumor, and was also found in association with a fatal disease in a marmoset, but additionally from primary kidney cell cultures derived from a squirrel monkey. In time, only the squirrel monkeys were identified to be the natural hosts for the virus. In early reports, it is often difficult to determine whether investigators are referring to HVS-1 versus HVS-2 when reporting or publishing results, or HVA-1 versus HVA-2. Nomenclature for each of these viruses has often been confusing because each virus has had a variety of different common names, some applying to the neurotropic counterparts HVS-1 and HVA-1, and others to HVS-2 and HVA-2, including marmoset herpesvirus (MHV), herpesvirus tamarinus (HVT), herpesvirus platyrrhinae (HVP)

and others. Additionally confounding the nomenclature is the identification of the natural host of each virus. Crossreactive antibodies found outside the natural hosts in which the viruses are thought to be endemic provide a challenge to investigators identifying the natural versus the foreign host repertoires of each agent. Squirrel monkeys live in the South American rain forests and are the endemic host to HVS-2. The spider monkey is also a South American resident and host to HVA-2. HVA-1 was reported in 1972 in the spider monkey, while HVA-2 was reported also in 1972 and the pathologic features of this lymphoma-causing virus in cotton-top marmosets (*Callithrixjacchus*) were described, but subsequently the spider monkey was identified as the natural host of both HVA-1 and HVA-2.

HVS-2 and HVA-2 are closely related but antigenically differentiable viruses in the laboratory. These agents have been studied primarily with respect to oncogenic potential in hosts, particularly in marmosets. HVS-1 and HVA-1 share little to no crossreactivity with HVS-2 and HVA-2, as is common when comparing alphaherpesviruses with gammaherpesviruses of humans. Recent data have extended knowledge with regard to these agents' (HVS-1 and HVA-1) relatedness to Old World nonhuman primate herpesviruses, particularly with regard to the counterparts, HSV-1 and HSV-2, as each of these four viruses are alphaherpesviruses. To clarify the evolutionary relationship of all of these viruses with each other, both alpha- and gammaherpesviruses, and to specific nonhuman primate hosts, **Fig. 1** illustrates the phylogenetic tree of the New World monkeys and indicates the viruses that have been found in each.

Taxonomy and Classification/Host Range

HVS-2, saimiriine herpesvirus 2, is classified as a gammaherpesvirus, based upon virus molecular organization and growth properties, including cell tropism. This agent is not to be confused with saimiriine herpesvirus 1 (HVS-1) which is an alphaherpesvirus in marmosets. Similar to other herpesviruses, HVS-2 can establish latency within the natural hosts' target cells. HVS-2 DNA sequence analysis has demonstrated that, genetically, this virus is organized most like Epstein–Barr virus (EBV), when compared with viruses within the broad subfamilies of alpha-, beta-, and gammaherpesviruses. However, distinctive features are apparent, including overall arrangement of the genome of the virus. Because of these differences, along with the relatively distant relationships of each of these New World monkey viruses to EBV, HVS-2 is considered a gamma-2 herpesvirus within the subfamily *Gammaherpesvirinae*, genus *Rhadinovirus*, rather than gamma-1 into which EBV (lymphocrytptovirus) is classified.

Interestingly, gamma-2 herpesviruses are T lymphocyte tropic, as opposed to gamma-1 herpesviruses which are B lymphocyte tropic. At least one variant strain of HVS-2 has been found to be especially effective in nonhuman primate T cell transformation, a property that has made this agent an invaluable tool in acquired immune deficiency syndrome (AIDS)-related studies. Differences identified in the genome structure of this variant compared to prototype HVS-2 have provided investigators with information regarding transformation-inducing genes.

HVA-2 is classified in the subfamily *Gammaherpesvirinae*, similar to HVS-2, and also has strong oncogenic capabilities. HVA-1 remains unclassified within the subfamily of *Alphaherpesvirinae*, genus *Simplexvirus*, along with SA8 virus and HVS-1 or MHV.

Properties of the Virion

HVS-2 contains double-stranded DNA that is 67% guanosine plus cytosine (GC), with high intramolecular heterogeneity in G:C content, which results in a unique genomic organization. On analysis by isopyknic density gradient centrifugation, two bands of DNA are found when manipulations of the DNA are performed carefully to avoid shear. These genomes are classified as M and H genomes, the former which are linear double-stranded DNA ranging in size from 145 to 165 kb with a buoyant density of 1.705 g ml^{-1}, or approximately 36% G:C content, characterized by a long unique segment (L-DNA) which is 112 kb with direct repeats of 1.4 kb of H-DNA on either side (DNA with 72% GC content). There is a variable number of these repeats of H-DNA, from 1 to 40 times. The H-DNA, which has a buoyant density of 1.729 g ml^{-1}, can comprise up to 30% of the total M-genome size. Some virions have only tandem repeats of H-DNA linked together to approximate the size of the intact genome, i.e., 145–165 kb; these virions are characterized as particles containing only H genomes. H-DNA, whether in the H genome or M genome, appears to be identical; however, it is H-DNA where evolutionary change occurs more often, as demonstrated by the fact that this DNA shows sequence variation divergence when analysis of DNA by restriction endonucleases, as well as measurement of DNA thermal melting temperature is performed. The M genomes are infectious, whereas the H genomes are highly defective, lacking L-DNA. H genomes are comprised of variable numbers of tandem repeats of H-DNA. The overall genomic organization of HVS-2 resembles that found in EBV,

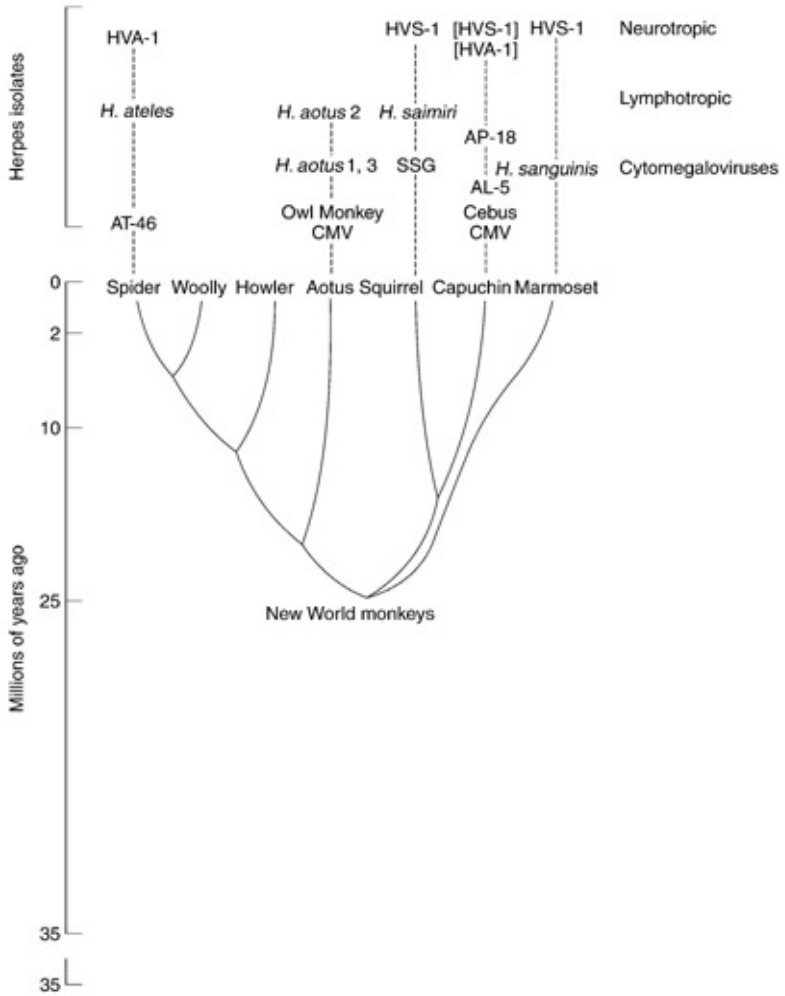

Figure 1 Phylogenetic summary of New World monkey hosts of herpesvirus agents, including the viruses found in each species (shown above each monkey). Those viruses in square brackets indicate that the species of monkey indicated with the virus is not the 'natural' host or endemic carrier of the agent. Viruses that have been identified are categorized into alpha-, beta- and gammaherpesviruses.

although the two are clearly not identical. Variability among HVS-2 isolates often shows heterogeneity in the left region of the unique L-DNA of the M genome, and, as such, isolates are further categorized into A, B and C groups.

HVS-2 DNA is capable of causing transformation of cells in marmosets. The DNA can subsequently be retrieved from the transformed cells, indicating its persistence within the transformed target.

The herpesvirus ateles genome is organized similarly to herpesvirus saimiri; however, the GC content is greater, with a lower number of H-DNA repeats.

Transmission

HVS-2 and HVA-2 can be transmitted horizontally, most often from adult animals to juveniles within the New World monkey populations. Subsequently, juvenile animals can transmit the virus to each other. Transmission of squirrel monkey herpesvirus, HVS-2, is reportedly facilitated by oral contact with virus-contaminated saliva or exposure of respiratory or conjunctival mucous membranes to virus-containing fluids. Virus can be demonstrated in saliva for prolonged periods of time after primary infection. Infection transmission can apparently be facilitated with either cell-associated or cell-free virus. In this regard, HVS-2 is similar to EBV, with the notable exception that the former seems to persist in T lymphocytes, while EBV is primarily B cell tropic. Virus can persist for long periods of time in the host lymphocytes, even for the life of the monitored animal, with as little as 1 copy per 1×10^6 T lymphocytes from normal squirrel monkeys.

Interestingly, longitudinal monitoring of infected animals has shown that different strains of HVS-2 and HVA-2 can be recovered at different time periods from individual monkeys. Intrastrain variation in HVS-2 has been documented by restriction endonuclease cleavage of viral DNA. Whether all strains, or only one, are equally capable of establishing persistence and/or latency is unknown at present. Although vertical transmission of either HVS-1 or HVA-1 is possible based upon knowledge of this family of viruses, it has rarely if ever been observed in hosts for either virus.

Virus cannot be recovered from homogenized lymphocyte populations collected from infected animals, indicating that the virus probably persists in cells as a nonencapsidated form, or even as DNA either in plasmid form or inserted into host DNA. Is virus present in kidney tissue because of contaminating lymphocytes or because the kidney tissue provides a site for virus replication or persistence? The answers to these, as well as many questions regarding these interesting agents, remain unknown at present and await further study.

It is noteworthy that HVS-2 was found initially in marmosets and owl monkeys rather than in squirrel monkeys. It was some time before the natural hosts' identity was recognized as the squirrel monkey. This has resulted in the assignment of a variety of names for HVS-2, names denoting other species of hosts which have now been identified as foreign hosts. Similarly, the existence of HVA-1 has complicated the nomenclature for the ateline herpesviruses, as there are both neurotropic and lymphotropic isolates, which are classified under separate genus names.

Immunological Response in Infected Nonhuman Primates

Comparative analysis of serum antibodies from different nonhuman primate hosts eventually led to the identification of the natural versus foreign hosts for each of these virus members of the genus *Rhadinovirus*. Initially, maternal antibodies induced by HVS-2 can be seen in infants, declining within the first 3–6 months of age. After primary infection, monkeys demonstrate antibody levels to late antigens which rise during the first several months of infection and then subsequently decline, suggesting the persistent state that this virus assumes within the infected host. Early and immediate early polypeptides translated during infection induce antibody which is transient and undetectable within a few months postinfection. Early antibody studies were mostly performed using immunofluorescence assays.

Antibody levels to each virus within their respective hosts were found to be related to age, with older animals showing higher levels of antibodies. Primary infection of squirrel monkeys with HVS-2 follows an age distribution, with onset of infection often seen by the time the monkey is 2 years of age. Antibodies induced by HVS-2 are differentiable from those produced by HVA-2 by application of indirect immunofluorescence as well as by western blot and radioimmunoprecipitation methodologies. The pathogenesis of HSV-2 and HVA-2 are remarkably similar with respect to the specificities and levels of antibodies induced in each host with increasing time postinfection.

Growth and Propagation of Virus in the Laboratory

Each of these New World monkey herpesviruses has a morphology consistent among the agents classified as herpesviruses. Nucleocapsids are formed in the nuclei of infected cells and are approximately 100 nm in diameter, with dense centers. The mature, enveloped particles are slightly larger and located in cytoplasmic vacuoles of infected cells. Glycosylation of envelope proteins occurs within the endoplasmic reticulum and Golgi apparatus to form mature virions. HVS-2 grows well in primary cells derived from New World monkeys but less efficiently in those derived from Old World monkeys, while HVA-2 grows well in a variety of epithelial and fibroblast cells from New World monkeys as well as African green monkeys (Old World monkeys). The spider monkey virus generally replicates to a lower titer in cell culture than the squirrel monkey herpesvirus. *In vitro*, HVA-2 is capable of immortalizing a variety of lymphoid cells from New World primates, whereas there has been more difficulty using prototype HVS-2, which imbues the cells it transforms with natural killer (NK) cell function and phenotypic markers of CD12+ and CD8+. HVA-2 immortalizes cells resulting in CD4+ and CD8+ phenotypes.

The first isolate of HVS-2 is designated SMKI-83, prime strain, or prototype strain, identified as S295C. This virus was isolated from a primary kidney cell culture established from a healthy squirrel monkey. Initial cell culture changes observed were characterized by small clumps of swollen, refractile cells. The monolayer of cells was completely destroyed within 1 month postculture. Intranuclear, acidophilic inclusions of different sizes were seen. Both primary epithelial cells as well as fibroblastic cells from New World monkeys were found to be permissive for virus replication. Owl monkey kidney cells were reported

to be the best choice for a productive system of virus propagation.

HVS-2 transformed can be subpassaged easily and a number of permanent cell lines have been established. The virus causes a lytic infection of the susceptible cells, with complete destruction of the monolayers spanning 2–20 days postinfection and a high titer output of virus. Old World monkey cells in culture are notably less susceptible to HVS-2 infection, although virus will replicate in Vero and CV-1 cell lines. In these cases, yield is significantly reduced compared with that measured from cell cultures derived from New World monkeys. Human cells that are susceptible are fibroblastic in origin, virus yield is low, and persistently infected cells can be maintained.

Summary and Future Perspectives

Each of these *Rhadinovirus* members of the family *Herpesviridae* has immense potential for use as a tool to transform/immortalize target cells of interest, particularly with respect to studies of human immunodeficiency virus (HIV) and AIDS. Gene-specific transformation or immortalization of cells is also possible, reducing the input of the nonessential viral genes against the background of the transfected cells. Transformation-associated genes represent a novel class of viral oncogenes which warrant further investigation. Furthermore, each of these virus–host systems continues to offer investigators a unique and invaluable avenue for epidemiological studies of virus transmission in nature, both within natural and foreign hosts. Last, but not least, due to the capacity of these viruses for carrying large amounts of DNA inserts, the use of HVS-2 and HVA-2 as novel gene vectors will most surely be continuously explored by investigators until ideal vectors are identified.

HISTORY OF VIROLOGY

Contents

General

Frank Fenner, John Curtin School of Medical Research, Australian National University, Canberra, Australia

Introduction

As in other branches of experimental science, the development of our knowledge of viruses has depended on the techniques available. Initially viruses, like other microbes, were studied by pathologists interested in the causes of the infectious

applied to problems of the pathogenesis and epidemiology of animal and plant viral diseases, and the expansion in knowledge of these subjects in the next decade can be expected to exceed that of the previous century.

Bacteriophages

Donna H Duckworth, Department of Molecular Genetics and Microbiology, College of Medicine, University of Florida, Gainesville, Florida, USA

With the recent establishment in the United States of a commercial enterprise whose sole purpose is to isolate bacteriophages for therapeutic purposes, the history of phage research has come full circle. Bacteriophages were first discovered at a time when bacterial disease was rampant and antibiotics were no more than a gleam in the eyes of several visionaries. And although it has never been definitively determined who first discovered phage, at least one of the individuals involved was determined to make that gleam a reality by utilizing the killing power of these viruses in the treatment and prevention of disease. That individual was the French-Canadian, Dr Felix d'Herelle.

In August 1916, Dr d'Herelle was asked to investigate an epidemic of dysentery in a Paris hospital. He had come to Paris after an illustrious career as a bacteriologist which had taken him literally around the world. At various times, he had observed a mysterious killing activity in some of his bacterial cultures, something that made clear spots on his agar plates, and decided to look for this activity in a patient with dysentery to see if it correlated with an amelioration of the symptoms of the disease. So he filtered the feces of a patient with dysentery daily for several days and incubated the filtrate with a culture of the dysentery bacillus. In one of those rare 'Eureka!' moments in the history of science, he found that on the fourth day of the man's disease, a filterable substance from his feces completely killed the dysentery pathogen. He says,

> The next morning, on opening the incubator, I experienced one of those rare moments of intense emotion which reward the research worker for all his pains: at the first glance I saw that the broth culture, which the night before had been very turbid, was perfectly clear: all the bacteria had vanished, they had dissolved away like sugar in water. As for the agar spread, it was devoid of all growth and what caused my emotion was that in a flash I had understood: what causes my clear spots was in fact an invisible microbe, a filterable virus, but a virus parasitic on bacteria. Another thought came to me also: 'If this is true, the same thing has probably occurred during the night in the sick man, who yesterday was in serious condition. In his intestine, as in my test-tube, the dysentery bacilli will have dissolved away under the action of their parasite. He should now be cured.' I dashed to the hospital. In fact, during the night, his general condition had greatly improved and convalescence was beginning.

D'Herelle showed that the agent that appeared in the intestines of individuals recovering from dysentery was not found in normal individuals or in individuals suffering from the acute stage of the disease, that it could be filtered and still retain its ability to kill the dysentery bacillus and that it would not grow on any artificial medium. And, because the killing or lytic activity could be serially transmitted, he concluded that it must be a 'living germ'. These observations were published in 1917 in the *Compte Rendus Academie Science* (Paris).

The paper excited considerable attention. Imagine if, at the height of the acquired immune deficiency syndrome (AIDS) epidemic, someone had announced that they had isolated a natural substance that would destroy the AIDS virus. The situation in 1917 was similar. Infected war wounds and dysenteric diseases were taking an enormous toll, and people everywhere cried out for a cure for these ills – for a magic bullet, as it were. After d'Herelle's report, it seemed to many that this had finally materialized, and people all over the world tried to isolate agents of transmissible lysis

in order to use them in the treatment of infections. Years later d'Herelle described the observation that led to his discovery of phage, the clear spots on a lawn of bacteria on an agar plate, as 'ordinary enough, so banal indeed that many bacteriologists had certainly made it before on a variety of cultures'. Why was it, then, that d'Herelle pursued the observation, whereas others hadn't?

D'Herelle had been working in the Yucatán in 1910 when there was an invasion of locusts. The native Indians reported to d'Herelle that in a particular place the locusts were sick and dying from a severe diarrheal disease. D'Herelle investigated and determined that the locust diarrhea was caused by a bacterium which he described as a coccobacillus, 'le coccobacille de sauterelles'. And in what surely must be one of the earliest attempts at biological control of insects, he found that he could kill the locusts by spreading cultures of the bacteria on plants in front of advancing locust columns, starting epidemics of the diarrheal disease among the insects. He later took this 'technology' to Africa, and when the bacteria were used in Tunisia, a large invasion of locusts that threatened to destroy the harvest was apparently stopped. Even more interesting, Tunisia remained locust-free the following year. So d'Herelle had been primed for the idea of biological control (science *does* favor the prepared mind), and when he found a natural agent that could kill bacteria, as he did in Paris in the dysentery patient, he went after it with a vengeance. His book, *The Bacteriophage and its Behavior*, published in 1925, contains almost two hundred pages detailing the use of bacteriophage in both the prevention and treatment of disease. He describes the behavior of bacteriophage in dysentery, streptococcal and staphylococcal infections, typhoid fever, and other 'colon bacillus infections'. He talks about how he stopped epidemics by using phage – epidemics of avian typhosis, hemorrhagic septicemia of the buffalo, bubonic plague, dysentery, and flacherie of the silk worm. He describes how 'immunization' against a number of diseases was accomplished with phage, and how a formidable list of bacterial diseases – dysentery, typhoid, plague, wound infections and streptococcal and staphylococcal infections – could be cured with phage. Typical of his observations is the following dysentery case:

> Robert D. ... (twelve years). This patient had a very severe dysentery, with vomiting, cold sweats, chilling of the extremities, and involuntary and uncountable stools. September 8. The stools could not be counted. They were fetid, purulent, and streaked with blood. Examination showed: *B. dysenteriae Shiga* present; about 1 out of every 10 colonies on the plates was the dysentery bacillus. The intestinal bacteriophage showed no virulence for *B. coli*, or for the Shiga, Flexner, or Hiss organisms. September 9. Two cubic centimers of a suspension of Shiga-bacteriophage were ingested at 11 o'clock. This suspension was three and one-half months old. During the afternoon and the night, the stools became less numerous but continued bloody. September 10. There were 6 fluid stools, without blood. Examination showed: *B. dysenteriae Shiga*, not present. Intestinal bacteriophage active as follows: *B. coli* ++++, Shiga ++++, Flexner ++++, Hiss +++. September 11. There were 2 normal, formed stools. September 20. The patient was discharged from the hospital.

No controls in which patients were given inactive phage preparations were done, although it could be argued that this would not be ethically appropriate in people. But he also discussed a number of experiments with chickens, and again control experiments were not performed. The following experiments are typical:

> *Experiment III*. This experiment was conducted at Provins, with the aid of M. Sorriau, D.V.M., in an important poultry-yard where typhosis was present in endemic form. For several months the daily mortality had been 2 or 3 fowls. On January 25, the 225 survivors were immunized [author's note: this refers to the use of phage to prevent disease]. The epizootic immediately and permanently disappeared from the date of the immunization.
>
> *Experiment IV*. Performed at Rouillac, Charente, with the assistance of M. Chollet, D.V.M. On December 15, 100 fowls were immunized [author's note: this again refers to use of bacteriophage] in a poultry-yard where typhosis had appeared about ten days previously. The daily mortality had been from 4 to 6 animals. With the immunization there was an immediate and permanent cessation of the epizootic. Typhosis continued to prevail on all the neighboring farms. Among the 100 chickens inoculated, about 12 were already affected. Of these, only 2 died, 2 and 3 hours after the injection.

He does mention that the disease continued on neighboring farms. Presumably, this is evidence that his 'immunization' using phage was working. But injecting only half the chickens on a single farm would have provided more convincing evidence.

But controls or not, d'Herelle's work resulted in trials of phage therapy at a number of places throughout the world. The Department of Bacteriology and Experimental Pathology at Stanford University set up a laboratory to determine whether or

not phage might be used therapeutically. They advertised to physicians that the laboratory would try to adapt a bacteriophage – of which there was a large collection – to any bacterium isolated from a patient. This was done at a cost to the laboratory, then about $2. Eli Lilly, Squibb & Sons, and Abbott Laboratories, all sold bacteriophage to physicians, and spectacular results – especially with staphylococcal infection – were reported up until the mid-1930s. A patient with a ruptured appendix made an uneventful recovery after being instilled with 15 ml of *E.-coli*-specific phage from Eli Lilly. In Brazil, antidysentery phage was widely distributed with apparent success. One clinic reported their results as follows:

> The therapeutic effect – the sudden change in the condition of the patient – consequent to the administration of the bacteriophage has astonished all of the physicians who have worked with it. A few hours after the administration of the first dose improvement has been noted, and the rapidity of the recovery has been a cause of amazement. In examining the collected data pertaining to the patients treated, it appears that the majority of them had first received all known treatments, and had been given the bacteriophage as a last resort. We are, therefore, absolutely convinced that it has saved the lives of a great many patients.

One would think that d'Herelle might have won a Nobel Prize for his seminal discovery and that he would have been a revered scientist. But in fact, he died with questions about his integrity – and about the usefulness of phage therapy – never having been resolved.

In 1921, Jules Bordet and one of his collaborators published a paper entitled, 'Remarks on the History of Research Concerning Transmissible Bacterial Lysis.' They pointed out that someone prior to d'Herelle may have reported on the existence of phage. Said they, 'The burden of an exact history makes it necessary for us to cite a previous work which d'Herelle has not known and that we ourselves have been ignorant of until now that contains the observations that d'Herelle has made. This remarkable work ... appeared in *The Lancet* in 1915, that is to say, two years before the research of d'Herelle'.

The 1915 communication referred to was authored by F. W. Twort, a bacteriologist and the last superintendent of the Brown Institute, a primarily veterinary institution in a rundown section of London, founded by an eccentric Irishman for 'investigations, studying and without charge beyond immediate expenses, endeavoring to cure maladies, distempers and injuries to Quadrupeds or Birds useful to Man'. In his article, Twort describes what he called a 'glassy transformation' of bacteria, discovered while he was performing experiments designed to grow viruses in culture. Twort had performed many such experiments. He would prepare a variety of media: 'generally agar, egg, or serum was used as a basis, and to these varying quantities of certain chemicals or extracts of fungi, seeds, and etc., were added.' He would then inoculate these media with extracts of various soils, dung, or sera, which had been filtered to remove all bacteria. In one of these experiments he inoculated his various media with vaccinia calf lymph – the material used at the time for vaccinating humans against smallpox. Apparently the vaccinia had been contaminated by some harmless bacteria Twort called micrococci, and although the vaccinia virus did not grow in the inoculated agar tubes, the micrococci did. Twort observed what he considered 'interesting results' concerning the growth of these micrococci. After 24 h in the incubator, instead of colonies, 'watery-looking areas' appeared, and some of the micrococci would not grow again if transferred to fresh media. If the cultures were kept on the shelf, some parts of the growth also became 'glassy and transparent'.

> ... This action, unlike an ordinary degenerative process, started from the edge of the colonies, and further experiments showed that when a pure culture of the white or yellow micrococcus isolated from vaccinia is touched with a small portion of one of the glassy colonies, the growth at the point touched soon started to become transparent or glassy, and this gradually spread over the whole growth, sometimes killing all the micrococci and replacing these by fine granules ... This condition or disease of the micrococcus can be conveyed to fresh cultures for an indefinite number of generations; but the transparent material will not grow by itself on any medium. Although the transparent material shows no evidence of growth when placed on a fresh agar tube without micrococci it will retain its powers of activity for over six months.

Twort found it difficult to interpret what he had seen, and thought it might be 'an ultramicroscopic virus, a tiny amoeba which thrives on living microorganisms, living protoplasm that forms no definite individuals, or an enzyme with power of growth'.

In the 1920s, Twort's 'enzyme with the power of growth' idea gained a number of very devoted followers, and it is noteworthy that their description of the way this would work is very similar to the proposed mechanism of prion action. But the idea was not given much credence or even attention in 1915. In fact, no one apparently even noticed Twort's paper

until 1921, when Bordet pointed out that it was Twort who should be called the discoverer of bacteriophage, not d'Herelle, by virtue of his earlier publication, which Bordet thought described bacteriophage. Never mind that Twort's description of the glassy transformation was so unusual that no one even recognized it as the same phenomenon as the bacterial viruses that could cause clear spots on a lawn of bacteria. D'Herelle certainly didn't think it was the same thing and, at a meeting of the Society of Biology in Paris in May 1921, indicated that what Twort had discovered was definitely not bacteriophage! D'Herelle spent much of his energy during the ensuing years proclaining that he, d'Herelle, was the sole discoverer of phage. In fact, he maintained, he really had discovered phage in 1910 while he was doing the research on the disease of locusts. His papers from 1910 do not refer to the phenomenon that he later said were bacterial viruses, however. This led people to become suspicious that perhaps d'Herelle really had known of Twort's 1915 work when he published his 1917 paper. Bordet, in particular, was insistent that Twort had discovered bacteriophage and that d'Herelle had stolen the idea from him. It is an issue that was not, and never will be, resolved.

It is interesting, though, to speculate as to why Bordet was so adamant in his support of Twort. Bordet was an immunologist and a Nobel Prize winning one at that. What could he possibly have cared about bacteriophage? I think it was precisely because Bordet was an immunologist that he got involved in the fight over who discovered phage. It is my feeling that Bordet actually thought d'Herelle's phenomenon really might be an agent of antibacterial immunity in infected hosts. D'Herelle said that the agent appeared in individuals recovering from dysentery and he further claimed that he could actually immunize people by infecting them with phage. By supporting Twort's theories, Bordet could at least feel that he had a hand in the discovery of antibacterial immunity, even though, in fact, he had not had anything to do with it, and phage have yet to be shown to be agents of 'immunity'. Twort, himself, never followed up on his finding or tried to do experiments that would have elucidated the nature of the agent causing the 'glassy transformation'. Had he shown convincingly that it was actually phage that were the agents of the change in his colonies, claims that he was the true discoverer of phage would have been stronger.

Who really first discovered phage and why Bordet became so involved are only two of the unanswered questions about the early history of phage. It would probably raise more than a few eyebrows to ask whether Twort had discovered a bacterial prion. But if not, just what did cause his glassy transformation? A lysogenic phage is the most likely, but who could say for sure? Perhaps of greatest relevance today, as the specter of bacteria resistant to all known antibiotics looms very large, is whether phage really were of any use as antibacterial agents. Reports in the 1930s documented commercial phage preparations with weak or no activity, and the wisdom of uncontrolled use of phage 'at the present state of our knowledge' was questioned. Certainly, as soon as the first antibiotics were discovered, research on the therapeutic use of phage dropped to the level of background noise. It remained a viable topic in Russia (in fact, an institute that d'Herelle founded is still functioning, albeit on a shoestring, in Tbilisi) and Poland and a few other places, but in the mainstream it was not considered worth pursuing until very recently. Still, phage research has contributed to human's ability to cure disease in ways that d'Herelle never could have imagined, in that basic research with bacteriophages has been responsible for almost every discovery underlying modern biological science. This mass of research stemmed from the idea that how an organism decodes its genetic program could be learned by studying phage.

Max Delbruck and Salvador Luria were largely responsible for the idea that phage could be used to understand the basic properties of genes and to determine how they functioned. They formed the nucleus of the 'phage group', scientists from all over the world, most of whom came together each summer at the Cold Spring Harbor Laboratories on Long Island during the 1940s, 1950s, and 1960s, and all of whom were dedicated to using phage to discover how life 'worked'. The group included, in addition to Luria and Delbruck, Thomas Anderson, Seymour Benzer, A. H. Doerman, Emory Ellis, Roger Herriott, Alfred Hershey, Edward Kellenberger, Lloyd Kozloff, Andre Lwoff, Gunther Stent, and many other dedicated scientists. Members of the group unraveled the process of phage replication, showing that it was characterized by a latent period, a rise period and a sudden burst. This pattern of growth was later confirmed for all lytic viruses. In addition, Hershey and his assistant, Martha Chase, showed that it was only the phage nucleic acid that was needed for the virus to reproduce itself, providing the final proof that nucleic acid and not protein was the genetic substance. Seymour Cohen, who was more interested in the biochemistry of the infected cell than the genetic program of the phage, discovered that the DNA of the T-even phages was glucosylated and that a new enzyme was synthesized in the infected cells that carried out the glucosylation. This led to an explosion of work on the enzymology of infected cells and the

discovery of dozens of phage-coded proteins and the genes that controlled them. The power of using conditional lethal mutants to study gene–protein relationships was shown by many studies of these phage-induced enzymes. Other historic discoveries made with phage include the existence of messenger RNA, shown by Hall and Spiegelman, and the colinearity of DNA and protein confirmed in Sidney Brenner's lab. Francis Crick used the strange rII mutants of T4 to show that the genetic code is a triplet code read from a fixed starting point. Phage also proved to be very useful in elucidating the mechanism of action of many mutagens. DNA synthesis was studied in phage-infected cells and it was found that DNA is synthesized discontinuously in 'Okazaki' fragments and that these are primed by RNA. Studies of phage infection in sporulating cells led to the discovery of sigma factors, subunits of RNA polymerase that act to initiate RNA synthesis at certain sequences, and a strange phage called Mu (because it caused infected cells to mutate) led to the discovery of transposition or the ability of certain DNA elements to insert themselves randomly in any DNA. The fact that the diphtheria toxin gene is a phage gene led, eventually, to the realization that many virulence factors are coded for by extrachromosomal elements. In addition, a mortal blow to vitalism was struck when it was shown that biologically-active Q-beta phage DNA could be synthesized in the test tube. No other discovery, however, has had more effect on the future course of research in the biological sciences than another discovery made with bacteriophage. This is, of course, the discovery of restriction endonucleases. This discovery occurred as a result of the study of a fairly arcane phenomenon concerning the behavior of bacteriophage grown on two different strains of bacteria. It was observed that phage grown on one strain of bacteria grew very poorly (i.e. were restricted) on a second strain and vice versa. The few phage that invariably escaped restriction on the second host could subsequently grow very well on this host but grew poorly on the first host. It was later shown that this occurred because the phage DNA acquired host-specific markings or modifications and these protected the DNA from being degraded by restriction enzymes in that host. If unmarked or inappropriately marked DNA entered a bacterium, it would be broken down. Hence, each bacterium appeared to have a way to protect itself from foreign 'invading' DNA. It was later found that many of the enzymes involved in this attack on foreign DNA (restriction) were site-specific endonucleases that generated overlapping ends. Thus any two pieces of DNA cut by the same restriction enzyme could be hybridized and ligated to make a spliced DNA molecule. This ability to join different DNAs together has led to previously unimaginable technologies of which gene therapy is but one. It should be noted particularly that the initial observation that led to the discovery of restriction enzymes – poor growth of a bacterial virus on certain hosts – was in no way remarkable and would not have generated a great deal of public excitement and support, yet it led to one of the most significant biological discoveries of this century.

Many scientists felt that the depth of Nature's secrets to be uncovered with phage had not been fully plumbed, but with the many advances in knowledge about viruses, genes and the production of proteins that phage had made possible, basic research using phage gave way to other fields of endeavor and by the 1980s was relegated to the back burner by the scientific establishment. But just as basic phage research was going out of style, there was some interest being rekindled in phage therapy. Early in the 1980s, the Wellcome Trust gave a small grant to H. W. Smith and his collaborators to study phage therapy in animals. They found phage to be very effective in controlling systemic *E. coli* infections in mice and experimental diarrhea in calves. This led to the opinion expressed in the *British Medical Journal* that 'phages may be poised to make an important entry into veterinary medicine and ... their exploitation in human clinical practice cannot be far behind.' It was thought that phage would be particularly useful in 'side-stepping the tiresome problem of antibiotic resistance'. This promise for human clinical medicine seemed to have been substantiated by a paper from Poland in 1987 that reported positive results in 508 of 550 cases of suppurative bacterial infections treated with bacteriophage.

In 1996 the credibility of phage therapy was given a little boost by a commentary in *Proceedings of the National Academy of Sciences* by Joshua Lederberg. His interest was spurred by the isolation of phage variants that are not rapidly cleared from the circulation by spleen cells – the removal of phage by the immune system being, of course, one obstacle to their usefulness. Lederberg suggested that a study of phage ecology – 'bacteriophage as smaller fleas on their bacterial hosts' – might lead to the knowledge necessary to use these viruses as therapeutic agents. He thought that highly antibiotic-resistant organisms would be a good target, as would agricultural diseases such as citrus canker. He also suggested that perhaps refugee camps could be made less terrifying if the 'transmission of cholera or dysentery could but be mitigated'. This same hope had been expressed by d'Herelle some seventy-five years before! And so the echoes of the past are being heard. Will the venture,

this time around, be more successful? We can but hope.

Polio, Coxsackie, Echo and Other Enteroviruses

Joseph L Melnick, Baylor College of Medicine, Houston, Texas, USA

Introduction

The enteroviruses constitute one of the genera of the picornavirus family. The genus includes the polioviruses, the coxsackieviruses and the echoviruses of humans, plus a number of enteroviruses of lower animals (e.g. monkeys, cattle, pigs, mice). Over 100 serotypes are recognized, the first to be discovered being the polioviruses.

Early Developments

Reports on clinical and epidemiological aspects of poliomyelitis came in the late 19th and early 20th centuries from von Heine and Medin in Germany, Wickman in Sweden and Caverly in the USA, but the virological study of polioviruses only began in 1908 when Landsteiner, Popper and Levaditi transmitted the disease to monkeys, inducing typical histopathological lesions in the animals' spinal cords. Shortly thereafter, Flexner and Wollstein achieved monkey-to-monkey passage. As it turned out, however, their use of rhesus monkeys contributed to serious problems in the development of polio research. Flexner was director of the Rockefeller Institute for Medical Research in New York, and a highly respected advocate of scientific medicine. Unfortunately, he assumed that the disease in man paralleled precisely what he was observing in the rhesus monkeys infected in his laboratory. He influenced many of his colleagues through his belief that polioviruses were strictly neurotropic, because of the way they behaved in his rhesus monkeys. He believed that poliovirus entered the human body through the nasal route and proceeded directly to the central nervous system (CNS). Besides delaying progress in unraveling the pathogenesis of poliomyelitis, this conviction also led to a misguided and unfortunate attempt at prophylaxis in human beings. When zinc sulfate was administered to Flexner's rhesus monkeys to coat the lining of their noses, the animals were protected against development of paralytic polio when challenged by intranasal inoculation. Flexner entirely overlooked Kling's work in Sweden; as early as 1912, Kling and his associates reported isolation of poliovirus not only from the throat but also from the feces of both paralytic and nonparalytic patients. Meanwhile, on the basis of belief in the nasal portal of entry in the human infection and in the efficacy of zinc sulfate to protect that portal, many persons during a 1927 epidemic underwent what was, at least, considerable discomfort produced by administration of zinc sulfate, but received no protection against poliomyelitis.

In 1936, Sabin and Olitsky reported that rhesus monkeys succumbing to polio had olfactory lesions only when infected by intranasal instillation of virus, and not when virus was administered by other routes. Five years later, Sabin and Ward showed that olfactory bulbs from 65 fatal human cases were all negative for virus. This underscored the previous observations by pathologists of the rarity with which olfactory lesions had been observed in autopsy studies of human polio cases – a surprising observation if the infection route had been nasal.

In the late 1930s, American investigators had begun turning toward the possibility of an oral–alimentary route of infection. Investigators at the Pasteur Institute had successfully infected cynomolgus monkeys by the oral route. Impetus was added when Howe and Bodian came across a report by Muller describing spontaneously acquired polio in chimpanzees in a children's zoo in Cologne. They followed up this clue with a series of experiments establishing that chimpanzees were far more susceptible to infection by the oral route than other experimental primates. This

to be the best choice for a productive system of virus propagation.

HVS-2 transformed can be subpassaged easily and a number of permanent cell lines have been established. The virus causes a lytic infection of the susceptible cells, with complete destruction of the monolayers spanning 2–20 days postinfection and a high titer output of virus. Old World monkey cells in culture are notably less susceptible to HVS-2 infection, although virus will replicate in Vero and CV-1 cell lines. In these cases, yield is significantly reduced compared with that measured from cell cultures derived from New World monkeys. Human cells that are susceptible are fibroblastic in origin, virus yield is low, and persistently infected cells can be maintained.

Summary and Future Perspectives

Each of these *Rhadinovirus* members of the family *Herpesviridae* has immense potential for use as a tool to transform/immortalize target cells of interest, particularly with respect to studies of human immunodeficiency virus (HIV) and AIDS. Gene-specific transformation or immortalization of cells is also possible, reducing the input of the nonessential viral genes against the background of the transfected cells. Transformation-associated genes represent a novel class of viral oncogenes which warrant further investigation. Furthermore, each of these virus–host systems continues to offer investigators a unique and invaluable avenue for epidemiological studies of virus transmission in nature, both within natural and foreign hosts. Last, but not least, due to the capacity of these viruses for carrying large amounts of DNA inserts, the use of HVS-2 and HVA-2 as novel gene vectors will most surely be continuously explored by investigators until ideal vectors are identified.

HISTORY OF VIROLOGY

Contents

General

Frank Fenner, John Curtin School of Medical Research, Australian National University, Canberra, Australia

Introduction

As in other branches of experimental science, the development of our knowledge of viruses has depended on the techniques available. Initially viruses, like other microbes, were studied by pathologists interested in the causes of the infectious

diseases of humans and their domesticated animals and plants. These concerns remain the main force advancing the subject. When bacterial viruses were discovered in 1915–1917, it was the hope that they might control bacterial diseases, such as cholera and dysentery, that stimulated their investigation. The idea that viruses might be used to probe fundamental problems of biology arose in the early 1940s, with the development of the Phage Group. These studies helped establish the new field of molecular biology in the period 1950–1970, and molecular biology has in turn revolutionized the study of viruses and led to an explosion of knowledge of them. To keep the subject in perspective, this brief review of the history of virology will be restricted to the period before 1980.

The Word 'Virus'

Since antiquity the term 'virus' had been synonymous with 'poison', but during the nineteenth century it became a synonym for microbe, Pasteur's word for an infectious agent. It did not acquire its present connotation until the 1890s, when the bacterial or fungal causes of many infectious diseases were discovered, using the agar plate, effective staining methods and efficient microscopes. It then became apparent that there were a number of infectious diseases of animals and plants from which no bacterium or fungus could be isolated or visualized with the microscope. After the introduction in 1884 of the Chamberland filter, which held back bacteria, Ivanowski and Beijerinck independently showed that the cause of tobacco mosaic disease was a filterable, infectious agent, in that its infectivity passed through a bacteria-proof filter. Loeffler and Frosch demonstrated that the cause of foot-and-mouth disease was also a 'filterable (or ultramicroscopic) virus'. The first compendium of all then known of viruses was edited by Rivers of the Rockefeller Institute and published in 1928. Entitled *Filterable Viruses*, this emphasized that viruses required living cells for their multiplication. In the 1930s chemical studies of the particles of tobacco mosaic virus and of bacteriophages showed that they differed from all cells, in that at their simplest they consisted of protein and nucleic acid, which was always of one kind, DNA or RNA. Gradually the adjectives 'filterable' and 'ultramicroscopic' were dropped and the word viruses developed its present connotation.

Early Investigations

Tobacco mosaic virus (TMV)

From 1879 there had been an interest in Europe in a mosaic disease of tobacco plants from which no bacterium could be recovered. In 1892 Ivanowski, in St Petersburg, found that the disease could be transmitted with filtered sap and concluded that the most likely cause was a bacterial toxin. Unaware of Ivanowski's work, in 1897 Beijerinck, in Delft, also found that sap from an infected plant remained virulent after filtration, although bacteriologically sterile. Further, he found that the mosaic disease could be transmitted successively, by filtered sap, through an 'unlimited' number of plants. Beijerinck concluded that the cause of tobacco mosaic disease was a living infectious agent in fluid form for which he coined the term *'contagium vivum fluidum'*.

Foot-and-mouth disease virus

While Beijerinck was defining his concept of a *contagium vivum fluidum*, Loeffler and Frosch were making equally revolutionary discoveries with an important disease of cattle. In 1898 they described the filterability of an animal virus for the first time, noting that 'the filtered material contained a dissolved poison of extraordinary power or that the as yet undiscovered agents of an infectious disease were so small that they were able to pass through the pores of a filter definitely capable of retaining the smallest known bacteria'. On the basis of its virulence after successive dilution in experimental animals, they concluded that the causal agent of foot-and-mouth disease was not soluble but 'corpuscular'. Loeffler and Frosch gave filtration a new emphasis by focusing attention on what passed through the filter rather than what was retained, and established an experimental methodology which was widely adopted in the early twentieth century in research on viral diseases.

Yellow fever virus

Following the acceptance of the notion of filterable infectious agents, pathologists investigated diseases from which no bacteria could be isolated and several were soon shown to be caused by viruses. One of the most fruitful investigations, in terms of new concepts, was the work of the United States Army Yellow Fever Commission headed by Walter Reed in 1900–1901. Using human volunteers, they demonstrated that yellow fever was caused by a filterable virus which was transmitted by mosquitoes and that the principal vector was *Aedes aegypti*. They also showed that infected persons were infectious for mosquitoes only during the first few days of the disease and that mosquitoes were not infectious until 7–10 days after imbibing infectious blood, thus defining the extrinsic incubation period and establishing essentially all of the basic principles of the epidemiology of what came to be called 'arboviruses'.

Discovery of Bacterial Viruses

In 1915 Twort, in London, described a filterable principle that caused lysis of bacterial colonies and could be transmitted to fresh cultures for an indefinite number of generations. His paper was virtually unnoticed, and 2 years later d'Herelle, a Canadian working at the Pasteur Institute in Paris, rediscovered Twort's lytic principle, noted that it was an obligate parasite of various species of bacteria, gave it the name 'bacteriophage' (bacteria-eater), and classified it as a filterable virus.

Physical Studies of Viruses

Further advances in understanding of the nature of viruses depended on physical and chemical studies. As early as 1907 Bechhold in Germany developed filters of graded permeabilities and a method of determining their pore size. Subsequently Elford, in London, used such membranes for determining the size of bacteriophage and animal virus particles with remarkable accuracy.

In Germany, on the eve of World War II, Ruska and his colleagues had produced electron microscopic photographs of the particles of TMV, bacteriophages and poxviruses, noting the extraordinary 'sperm-shaped' particles of bacteriophage. Technical improvements in instrumentation after the war, and the introduction of negative staining for studying the structure of TMV and other viruses by Cambridge scientists Huxley in 1957 and Brenner and Horne in 1959 resulted in photographs of the particles of virtually every known kind of virus. These demonstrated the variety of their size, shape and structure, and the presence of common features such as the helical particles of many plant viruses and the icosahedral symmetry of many other viruses.

Following a perceptive paper on the structure of small virus particles by Crick and Watson in 1956, in 1962 Caspar of Boston and Klug of Cambridge, England, produced a general theory of the structure of regular virus particles of helical and icosahedral symmetry. Structure of the virus particle became one of the three major criteria in the system of classification of viruses that was introduced in 1966.

Chemical Composition of Viruses

If the ultramicroscopic particles found in virus-infected hosts were the pathogens, what did these particles consist of? In 1935, stimulated by work on the crystallization of enzymes, Stanley, at the Rockefeller Institute for Medical Research, announced that he had isolated TMV as a crystalline protein. Contemporaneously, Bawden and Pirie at Cambridge University examined the TMV particles that they had purified and showed that their product was a nucleoprotein, containing RNA. At about the same time Schlesinger, working in exile in London, had shown that a purified suspension of bacteriophage particles consisted of approximately equal amounts of protein and DNA, and in 1940 Hoagland and his colleagues at the Rockefeller Institute found that vaccinia virus particles contained DNA but no RNA. Thus evidence was accumulating that viruses differed from bacteria not only in size and their inability to grow in lifeless media, but in that they contained only one kind of nucleic acid, which could be either DNA or RNA.

The development of restriction endonuclease digestion of DNA, based on studies of phage restriction by Arber of Basel in the 1960s, and then elaborated by biochemist Smith of Baltimore in 1970, has simplified the mapping of the genomes of DNA viruses, a study initiated by Nathans, also of Baltimore, using the papovavirus SV40. Improvements in sequencing methods for both DNA and RNA have now led to the publication of the complete genomic nucleotide sequences for representatives of most families of viruses.

Bacterial Viruses

d'Herelle brought wide attention to bacteriophages because of his belief, in the event never realized, in their potential for the treatment of bacterial diseases. The next major figure to elucidate the nature of bacteriophage was Burnet. Working in Melbourne over the period 1924–1934, Burnet showed that there was not a single virus, 'the bacteriophage', as d'Herelle had thought, but a wide variety of bacterial viruses with very different biologic and physical properties. He devised the single-burst experiment, demonstrated the difference between resistance of bacteria at the level of adsorption and the immunity of lysogenic bacteria to the phage already carried, and started phage genetics with the discovery of a mutant virus that inherited the inability to be carried in the lysogenic state.

The Phage Group

In the late 1930s three men working in the United States, physicist Delbrück, medical bacteriologist Luria and bacteriologist Hershey, took up the study of bacteriophages. Their meeting in 1940 led to the establishment of the Phage Group, which was united by the desire to understand how, in the half-hour latent period revealed by the one-step growth experi-

ment, a phage particle achieves its hundredfold multiplication within the bacterial cell. The Phage Group expanded in 1945, when Delbrück organized an annual summer phage course at Cold Spring Harbor. An early and important recruit was Anderson, who used electron microscopy to explore the attachment of phage particles to bacteria by their tails, but was unable to find any particles in the cell during the eclipse period, indicating that there is more to a virus than its particles.

A major advance came with the demonstration in 1952 by Hershey and Chase that phage infection proceeded by injection of DNA, the protein shell being left outside the bacterium. A year later Watson (who had received his PhD degree for work on phage with Luria) and Crick, working in Cambridge, published their classic papers on the structure of DNA.

Phage genetics and molecular biology

During the 1950s and 1960s work with phages advanced the study of viral genetics far beyond what had been established for animal or plant viruses and provided a model for later studies with these agents. In 1946, Hershey had demonstrated that bacterial viruses can undergo genetic recombination, and, by 1955, Benzer had produced a very detailed fine structure genetic map of the T4 bacteriophage. Although the Phage Group included few biochemists, it was the combination of genetics and biochemistry in their studies that led to the birth of molecular biology.

Lysogeny

In the 1930s Burnet had suggested a solution to one of d'Herelle's greatest problems, lysogeny, by postulating that lysogenic bacteria carried a precursor or 'anlage' that multiplied within the bacterium, but could by unknown stimuli be induced to replicate independently and produce virus particles. Because the T-even phages with which they worked were virulent, this problem was never taken up by the Phage Group, but after attending a meeting at Cold Spring Harbor in 1946, Lwoff and his colleagues at the Pasteur Institute in Paris applied themselves to solving the mechanism of lysogeny. By 1950 they had shown that x-rays induced lysogenic bacteria to release phage and, using an elegant single-cell technique, demonstrated that what is reproduced by a lysogenic bacterium during its replication is the genetic material of the phage, which Lwoff called prophage.

Other Discoveries with Bacterial Viruses

All earlier phage work had been carried out with viruses with DNA genomes, but in 1961 Loeb and Zinder, working at the Rockefeller Institute, discovered the first example of an RNA phage. Other seminal discoveries in molecular biology that arose out of studies with phages were the demonstration of transduction by Zinder and Lederberg in 1952, the discovery of messenger RNA by Brenner, Jacob and Meselson in 1961 and the report in 1965 by Spiegelman and his colleagues of the *in vitro* replication of infectious viral (Qβ) RNA.

Animal Virology

Whereas investigations by the Phage Group were motivated mainly by scientific curiosity, animal virology was developed by pathologists studying the large number of diseases of humans and livestock caused by viruses, and it has retained this practical bias. Over the first two decades of the twentieth century, testing of filtrates of material from a number of diseases of humans and animals confirmed that they were caused by viruses. Among the most important was the demonstration in 1911 by Rous, at the Rockefeller Institute, that a sarcoma of fowls could be transmitted by a bacteria-free filtrate.

Cultivation of animal viruses

The first systematic use of small animals for virus research was Pasteur's use of rabbits, which he inoculated intracerebrally with rabies virus in 1881. It was not until 1930 that mice were used for virus research, with intracerebral inoculations of rabies and yellow fever viruses. By using graded dilutions and large numbers of mice, quantitative animal virology had begun. The next important step was the use of chick embryos for growing poxviruses by Goodpasture in 1931–1932, followed a few years later by the demonstration by Burnet that many viruses could be titrated by counting the pocks that they produced on the chorioallantoic membrane, whereas others grew well in certain embryonic cavities of developing chick embryos.

Tissue cultures had first been used for cultivating vaccinia virus in 1928, but it was the discovery by Enders, Weller and Robbins of Harvard University in 1949 that poliovirus would grow in nonneural cells that gave a tremendous stimulus to the use of cultured cells in virology. Over the next few years their use led to the cultivation of medically important viruses, such as those causing measles, by Enders and Peebles in 1954, and rubella, by Weller and Neva in 1962. Even

more dramatic was the isolation of a wide variety of 'new' viruses, belonging to many different families. Also the different cytopathic effects produced by different viruses in monolayer cell cultures were found to be diagnostic.

The next great advance, which greatly increased the accuracy of quantitative animal virology, occurred in 1952, when the plaque assay method for counting phage was adapted to animal virology by Dulbecco, using a monolayer of chick embryo cells in a Petri dish. In 1958 Temin and Rubin applied Dulbecco's method to Rous sarcoma virus, initiating quantitative studies of tumor viruses. Biochemical studies of animal virus replication were simplified by using continuous cell lines and by growing the cells in suspension.

Biochemistry

During the 1950s virus particles were thought to be 'inert' packages of nucleic acid and proteins, although in 1942 Hirst of the Rockefeller Institute had shown that particles of influenza virus contained an enzyme, later identified by Gottschalk of Melbourne as a neuraminidase.

Further advances in viral biochemistry depended on methods of purification of virus particles, especially the technique of density gradient centrifugation. In 1967 Kates and McAuslan demonstrated the presence of a DNA-dependent RNA polymerase in purified vaccinia virus virions, a discovery that was followed the next year by the demonstration of a double-stranded (ds) RNA-dependent RNA polymerase in reovirus virions and then of single-stranded (ss) RNA-dependent RNA polymerases in those of paramyxoviruses and rhabdoviruses. In 1970 came the revolutionary discovery by Baltimore of Boston and Temin of Wisconsin, independently, of the RNA-dependent DNA polymerase, or reverse transcriptase, of Rous sarcoma virus. Many other kinds of enzymes were later identified in the larger viruses; for example, no fewer than 16 enzymes have now been identified in vaccinia virus virions.

Just as investigations with bacteriophages were of critical importance in the development of molecular biology, studies with animal viruses have led to the discovery of several processes that have proved to be important in the molecular biology of eukaryotic cells, although many of these discoveries are too recent for serious historical appraisal. Thus in 1968 Jacobson and Baltimore of Boston showed that the genomic RNA of poliovirus was translated as a very large protein, which was then cleaved by a protease that was subsequently found in the viral replicase gene. RNA splicing was discovered in 1977, independently by Sharp and Chow and their respective colleagues during studies of adenovirus replication. Work with the same virus by Rekosh and colleagues in London in 1977 resulted in the definition of viral and cell factors for initiation of new DNA strands using a novel protein priming mechanism. Capping of mRNA by m^7G and its role in translation was discovered in 1974, during work with reoviruses by Shatkin. Other processes first observed with animal viruses and now known to be important in eukaryotic cells were the existence of 3′-(poly)A tracts on mRNAs, the pathway for synthesis of cell surface proteins and the role of enhancer elements in transcription.

Analysis of viral nucleic acids progressed in parallel with that of the viral proteins. Animal viruses were found with genomes of ssRNA, either as a single molecule, two identical molecules (diploid retroviruses), or segmented; dsRNA; ssDNA, dsDNA and partially dsDNA. The so-called 'unconventional viruses' or prions of scrapie, kuru and Creutzfeld–Jacob disease, which have been extensively investigated since 1957 by Gajdusek of the US National Institutes of Health and Prusiner of the University of California at San Francisco, appear to be infectious proteins. Soon after the discovery that the isolated nucleic acid of TMV was infectious (see below), it was shown that the genomic RNAs of viruses belonging to several families of animal viruses were infectious, namely those with single, positive-sense RNA molecules. Then in 1972 came the discovery of recombinant DNA by Berg of Stanford University who inserted genes from bacteriophage λ into the genome of SV40.

Structure of the virion

Using more sophisticated methods of electron microscopy, the vast majority of animal virus virions have been shown to be isometric icosahedral structures, or to be nucleoprotein tubes of helical symmetry surrounded by a lipid-containing shell, the envelope, which contains a number of virus-coded glycoprotein spikes. X-ray crystallography of crystals of purified isometric viruses has revealed the molecular structure of their icosahedra; similar revealing detail has been obtained for the neuraminidase and hemagglutinin spikes of influenza virus.

Tumor virology

After the discovery of Rous sarcoma virus in 1911 there was a long interval before the second virus to cause tumors, rabbit papilloma virus, was discovered by Shope in 1933. However, after that viruses were found to cause various neoplasms in mice, and in 1962

Trentin of Yale University showed that a human adenovirus would produce malignant tumors in hamsters. Since then, direct proof has been obtained that several DNA viruses (but not adenoviruses) and certain retroviruses can cause tumors in humans. Molecular biological studies have shown that oncogenicity is largely caused by proteins they produce that are encoded by viral oncogenes, a concept introduced by Huebner and Todaro of the US National Institutes of Health in 1969 and corrected, refined and greatly expanded since the mid-1970s by Bishop, Varmus (both of San Francisco) and Weinberg of Boston.

Only one group of RNA viruses, the retroviruses, which replicate through an integrated DNA provirus, cause neoplasms, whereas viruses of five groups of DNA viruses are tumorigenic. Study of these oncogenic viruses has shed a great deal of light on the mechanisms of carcinogenesis. Oncogenic DNA viruses contain oncogenes as an essential part of their genome, which when integrated into the host cell DNA may promote cell transformation, whereas the oncogenes of retroviruses are derived from proto-oncogenes of the cell.

Impact on immunology

Immunology arose as a branch of microbiology and several discoveries with animal viruses were important in the development of important concepts in immunology. It was the discovery in the 1930s, by Traub in Tübingen, of persistent infection of mice with lymphocytic choriomeningitis virus that led to the development by Burnet of the concept of immunological tolerance in 1949. It was work with the same virus that led to the discovery of major histocompatibility complex (MHC) restriction by Doherty and Zinkernagel in Canberra in 1974.

Vaccines and disease control

From the time of Pasteur's use of rabies vaccine in 1885, a major concern of medical and veterinary virologists has been the development of vaccines. Highlights in this process have been the development of the 17D strain of yellow fever virus by Theiler of the Rockefeller Foundation laboratories in 1937, the introduction of influenza vaccine in 1942, based on Burnet's 1941 discovery that the virus would grow in the allantois, the licensing in 1954 of inactivated poliovaccine developed by Salk and in 1961 of the live poliovaccine introduced by Sabin, both based on the cultivation of the virus in 1949 by Enders, and development of the first genetically engineered human vaccine with the licensing of yeast-grown hepatitis B vaccine in 1986. Finally, 1977 saw the last case of natural smallpox in the world and thus the first example of the global eradication of a major human infectious disease, the result of a 10 year campaign conducted by the World Health Organization with a vaccine directly derived from Jenner's vaccine, first used in 1796.

Viruses of Invertebrates

Study of the viruses of invertebrates has lagged a long way behind that of vertebrate viruses. The first virus of insects to be identified was that of silkworm jaundice. In 1907 von Prowazek of Hamburg showed that filtered material, free of the polyhedra he had found in diseased silkworms, would nevertheless transmit the disease, but it was not until 1947 that the German scientist Bergold showed that the polyhedra consisted of a matrix of noninfective protein in which were embedded rod-shaped particles of a virus with a DNA genome. Over the succeeding years a large number of other viruses of insects, some clearly resembling viruses of vertebrates, have been discovered and more recently viruses have been found that affect many other kinds of invertebrates. The development of methods of growing insect cells in culture by Grace in Canberra in 1962 opened the way for the molecular biological investigation of the replication of insect viruses and arboviruses in invertebrate cells.

Arthropods, mainly insects and ticks, were early shown to be important as vectors of virus diseases of vertebrates (the arboviruses) and of plants. Sometimes carriage was found to be mechanical but in most cases the virus was found to multiply in the vector as well as the vertebrate or plant concerned.

Plant Virology

Like animal virology, plant virology was at first dominated by plant pathologists, but subsequently certain plant viruses have been intensively studied by molecular biologists. Because its stable particles occur in such large amounts in infected plants, TMV has been a most important model virus for plant virologists and its study has contributed greatly to virology in general. In 1929 Beale of the USA showed that plants infected with TMV contained a novel antigen, suggesting that the virus contained protein and that serologic methods could be used to estimate its concentration. In the same year Holmes, also working in the USA, discovered that local lesions on plant leaves could be used to assay infectivity in much the same way that plaques were used in phage assays.

The next major dicovery with TMV came in 1956, when Gierer and Schramm, in Tübingen, and Fraenkel-Conrat at Berkeley, demonstrated that, if

protected from inactivation, the RNA isolated and purified from TMV particles was infectious. Two years later Gierer showed that mutants of the virus could be obtained by reacting inocula of its RNA with nitrous acid, a treatment which changes the bases in the RNA. Although it was not the first virus whose RNA was completely sequenced, TMV RNA was the first mRNA used in the establishment of a reliable RNA-requiring translation system, by Nirenberg in 1961.

TMV was also important in the development of ideas about viral structure. Studies in the 1930s–1940s, including x-ray diffraction of preparations of the virus by Bernal and Fanfuchen of Cambridge, suggested that the viral particles were long, thin rods. This was confirmed by electron micrographs taken in Germany in 1939. Then, during the 1950s, Watson and Crick, working in Cambridge University, recognized that the x-ray pictures made in 1941 suggested that the particles were helical, with a turn every 23 Å along the helical axis, and suggested that the protein shell consisted of a large number of identical subunits of molecular weight about 20 000, a view supported by biochemical studies by Knight in California in 1956. Fraenkel-Conrat and his colleagues then developed ways to reconstitute virions from purified viral RNA and viral protein, and showed that the protein tended to aggregate to double disks, each of 17 molecules, and that these disks had a high affinity for a particular site on the RNA. Sequential addition of disks led to assembly of the complete virion. The fact that TMV RNA was infectious showed that it functioned as an mRNA, but experimenters were unable to make the coat protein with this RNA, a result that led to the discovery of subgenomic mRNA.

Kinds of plant viruses

A large number of plant viruses belonging to many different groups have now been characterized. Most contain ssRNA and have particles that are long, nonenveloped, tubular structures, but some are icosahedral. Plant representatives of the dsRNA reoviruses were discovered by Black in 1963, and in 1968 Shepherd showed that cauliflower mosaic virus contained dsDNA; later this virus, like hepatitis B virus, was found to use a reverse transcriptase in the replication of its genome. In addition, plant viruses have been found with several unusual genome structures. Tobacco rattle virus is multiparticulate, with the RNA for its replicative functions in one rod and that for its coat protein in another; the satellite virus described by Kassanis of Rothamsted in 1962 is dependent on tobacco necrosis virus for essential replicative functions. Then in 1971 potato spindle tuber virus was shown by Diener of the US Department of Agriculture to be a replicating, 359 nucleotide circular ssRNA, devoid of a protein coat; it is one of several plant 'viroids'.

Transmission of plant viruses

Unlike animals, plants are not mobile, so that a great many transmission modes are used by plant viruses. Some are passed vegetatively or through seed, others by contact or in soil water, but most are transmitted by vector organisms that feed on plants. In the 1890s, before viruses had been characterized, Japanese workers showed that leafhoppers transmit rice dwarf disease; the virus has since been shown to multiply in both plant and leafhopper. Aphids carry a great variety of plant viruses; more unusual vectors are soil nematodes, first incriminated by Hewitt of the USA in 1958, and soil fungi, incriminated by Teakle of Brisbane in 1960.

Taxonomy and Nomenclature

After earlier tentative efforts with particular groups of viruses, viral nomenclature took off in 1948, with the production of a system of latinized nomenclature for all viruses by the plant virologist Holmes. This stimulated others, in particular Andrewes of London and Lwoff of Paris, to actions which resulted in the setting up of an International Committee on Nomenclature (later Taxonomy) of Viruses in 1966. Adopting the kind of viral nucleic acid, the strategy of replication and the morphology of the virion as its primary criteria, this Committee has now achieved acceptance of its decisions by the great majority of virologists. One interesting feature of its activities is that its rules avoid the controversies about priorities that plague taxonomists working with other groups of living things.

The Future

This brief historical survey stops in about 1980, just as virology began to experience an explosive expansion with the application of techniques of genetic engineering, nucleic acid sequencing, the polymerase chain reaction and the use of monoclonal antibodies. The last decade has also seen the emergence of the acquired immunodeficiency disease syndrome (AIDS), the most important new human viral disease this century, the isolation of the causative human immunodeficiency viruses and their dramatically rapid molecular characterization. All these discoveries are addressed in the appropriate sections of this encyclopedia. Molecular biology, which was initially conceived during studies of bacterial viruses, is now being

applied to problems of the pathogenesis and epidemiology of animal and plant viral diseases, and the expansion in knowledge of these subjects in the next decade can be expected to exceed that of the previous century.

Bacteriophages

Donna H Duckworth, Department of Molecular Genetics and Microbiology, College of Medicine, University of Florida, Gainesville, Florida, USA

With the recent establishment in the United States of a commercial enterprise whose sole purpose is to isolate bacteriophages for therapeutic purposes, the history of phage research has come full circle. Bacteriophages were first discovered at a time when bacterial disease was rampant and antibiotics were no more than a gleam in the eyes of several visionaries. And although it has never been definitively determined who first discovered phage, at least one of the individuals involved was determined to make that gleam a reality by utilizing the killing power of these viruses in the treatment and prevention of disease. That individual was the French-Canadian, Dr Felix d'Herelle.

In August 1916, Dr d'Herelle was asked to investigate an epidemic of dysentery in a Paris hospital. He had come to Paris after an illustrious career as a bacteriologist which had taken him literally around the world. At various times, he had observed a mysterious killing activity in some of his bacterial cultures, something that made clear spots on his agar plates, and decided to look for this activity in a patient with dysentery to see if it correlated with an amelioration of the symptoms of the disease. So he filtered the feces of a patient with dysentery daily for several days and incubated the filtrate with a culture of the dysentery bacillus. In one of those rare 'Eureka!' moments in the history of science, he found that on the fourth day of the man's disease, a filterable substance from his feces completely killed the dysentery pathogen. He says,

> The next morning, on opening the incubator, I experienced one of those rare moments of intense emotion which reward the research worker for all his pains: at the first glance I saw that the broth culture, which the night before had been very turbid, was perfectly clear: all the bacteria had vanished, they had dissolved away like sugar in water. As for the agar spread, it was devoid of all growth and what caused my emotion was that in a flash I had understood: what causes my clear spots was in fact an invisible microbe, a filterable virus, but a virus parasitic on bacteria. Another thought came to me also: 'If this is true, the same thing has probably occurred during the night in the sick man, who yesterday was in serious condition. In his intestine, as in my test-tube, the dysentery bacilli will have dissolved away under the action of their parasite. He should now be cured.' I dashed to the hospital. In fact, during the night, his general condition had greatly improved and convalescence was beginning.

D'Herelle showed that the agent that appeared in the intestines of individuals recovering from dysentery was not found in normal individuals or in individuals suffering from the acute stage of the disease, that it could be filtered and still retain its ability to kill the dysentery bacillus and that it would not grow on any artificial medium. And, because the killing or lytic activity could be serially transmitted, he concluded that it must be a 'living germ'. These observations were published in 1917 in the *Compte Rendus Academie Science* (Paris).

The paper excited considerable attention. Imagine if, at the height of the acquired immune deficiency syndrome (AIDS) epidemic, someone had announced that they had isolated a natural substance that would destroy the AIDS virus. The situation in 1917 was similar. Infected war wounds and dysenteric diseases were taking an enormous toll, and people everywhere cried out for a cure for these ills – for a magic bullet, as it were. After d'Herelle's report, it seemed to many that this had finally materialized, and people all over the world tried to isolate agents of transmissible lysis

this time around, be more successful? We can but hope.

Polio, Coxsackie, Echo and Other Enteroviruses

Joseph L Melnick, Baylor College of Medicine, Houston, Texas, USA

Introduction

The enteroviruses constitute one of the genera of the picornavirus family. The genus includes the polioviruses, the coxsackieviruses and the echoviruses of humans, plus a number of enteroviruses of lower animals (e.g. monkeys, cattle, pigs, mice). Over 100 serotypes are recognized, the first to be discovered being the polioviruses.

Early Developments

Reports on clinical and epidemiological aspects of poliomyelitis came in the late 19th and early 20th centuries from von Heine and Medin in Germany, Wickman in Sweden and Caverly in the USA, but the virological study of polioviruses only began in 1908 when Landsteiner, Popper and Levaditi transmitted the disease to monkeys, inducing typical histopathological lesions in the animals' spinal cords. Shortly thereafter, Flexner and Wollstein achieved monkey-to-monkey passage. As it turned out, however, their use of rhesus monkeys contributed to serious problems in the development of polio research. Flexner was director of the Rockefeller Institute for Medical Research in New York, and a highly respected advocate of scientific medicine. Unfortunately, he assumed that the disease in man paralleled precisely what he was observing in the rhesus monkeys infected in his laboratory. He influenced many of his colleagues through his belief that polioviruses were strictly neurotropic, because of the way they behaved in his rhesus monkeys. He believed that poliovirus entered the human body through the nasal route and proceeded directly to the central nervous system (CNS). Besides delaying progress in unraveling the pathogenesis of poliomyelitis, this conviction also led to a misguided and unfortunate attempt at prophylaxis in human beings. When zinc sulfate was administered to Flexner's rhesus monkeys to coat the lining of their noses, the animals were protected against development of paralytic polio when challenged by intranasal inoculation. Flexner entirely overlooked Kling's work in Sweden; as early as 1912, Kling and his associates reported isolation of poliovirus not only from the throat but also from the feces of both paralytic and nonparalytic patients. Meanwhile, on the basis of belief in the nasal portal of entry in the human infection and in the efficacy of zinc sulfate to protect that portal, many persons during a 1927 epidemic underwent what was, at least, considerable discomfort produced by administration of zinc sulfate, but received no protection against poliomyelitis.

In 1936, Sabin and Olitsky reported that rhesus monkeys succumbing to polio had olfactory lesions only when infected by intranasal instillation of virus, and not when virus was administered by other routes. Five years later, Sabin and Ward showed that olfactory bulbs from 65 fatal human cases were all negative for virus. This underscored the previous observations by pathologists of the rarity with which olfactory lesions had been observed in autopsy studies of human polio cases – a surprising observation if the infection route had been nasal.

In the late 1930s, American investigators had begun turning toward the possibility of an oral–alimentary route of infection. Investigators at the Pasteur Institute had successfully infected cynomolgus monkeys by the oral route. Impetus was added when Howe and Bodian came across a report by Muller describing spontaneously acquired polio in chimpanzees in a children's zoo in Cologne. They followed up this clue with a series of experiments establishing that chimpanzees were far more susceptible to infection by the oral route than other experimental primates. This

work excluded the olfactory portal and also showed that the disease of chimpanzees after oral administration of virus closely resembled that of human beings, both clinically and pathologically.

Evidence from human cases also began to accumulate; some 25 years after the almost-ignored reports of Kling and his associates, investigators again began looking for poliovirus in the alimentary tract. At this point it was not understood how poliomyelitis was spread. Although Wickman had postulated spread through inapparently infected persons, the circumstances under which the paralytic disease occurred, or whether the virus was in the infected or diseased individual, were unknown. The manner of transmission was puzzling: cases in epidemics seemed to move out from a focus, but in erratic patterns, for those afflicted usually had no direct contact with an earlier case. Even within a family where paralytic polio occurred, the disease was hardly ever seen in more than a single member.

At Yale University, the search for virus included specimens other than the spinal cord, and in 1938 John Paul made a 'heretical' report to the American Epidemiological Society on some of the findings: not only was virus found in large quantities in feces, but it was also recovered repeatedly over a period of weeks, from both patients and 'healthy carriers'. This report was met with skepticism by many in the audience, but it was soon confirmed and extended. The shift to the concept of poliomyelitis as an enteric infection was under way. Wickman's observations on the spread of virus by persons with inapparent infections could now be confirmed by laboratory documentation. The new concept also had direct implications for measures to control fecal contamination in hospitals and in households.

Still another series of questions was brought into focus: If polio was an enteric infection, could it be isolated from urban sewage? One of my first tasks upon joining the Yale Poliomyelitis Study Unit in 1940 was to devise methods for testing effluents from one of the large sewage treatment plants of New York City. During periods when paralytic polio was prevalent, I found poliovirus to be present in New York sewage in huge quantities. Knowing the quantity of virus in sewage, the amount excreted by a carrier each day, and the case rate in the area from which the sewage came, I could establish a ratio of inapparent infection to paralytic cases. This turned out to be more than 100 inapparent or subclinical infections for each paralytic case. I also learned that, although purified poliovirus could be readily inactivated by low doses of chlorine, virus in sewage or feces is resistant to extraordinarily high doses of chlorine.

Despite the increasing knowledge about polio that was gained through investigations that had to depend on large and expensive laboratory animals (monkeys and chimpanzees), it was clear that simpler systems were badly needed. Following original efforts by Levaditi in 1913, there had been two decades of repeated attempts to grow polioviruses in various kinds of culture substrates and conditions, with little success. Sabin and Olitsky in 1936 reported the successful growth of poliovirus in tissue culture. However, their study was done with the MV strain of poliovirus, which had gone through 20 years of intracerebral passage from monkey to monkey at the Rockefeller Institute. When these investigators attempted to grow this highly neurotropic strain in human embryonic nervous tissue or in nonnervous tissue from the viscera of the same embryos, it grew only in the nervous tissue. Thus it became accepted doctrine that poliovirus could be grown only in human nervous-system tissue. Such tissue is difficult to obtain, and furthermore its use as a substrate for growing antigenic material for a possible vaccine was precluded because of the known encephalitogenic potential of administering tissue of nervous system origin (as in the case of the early rabies vaccine). Moreover, proof that the poliovirus had indeed multiplied in these cultures still depended upon inoculating monkeys with the tissue culture fluid and duplicating the disease in them. Another 13 years elapsed before the landmark report by Enders, Weller and Robbins, who used different strains of poliovirus and showed that poliovirus could indeed be grown in a variety of tissue cultures and could be assayed by observing its cytopathic effect *in vitro*.

Meanwhile, the search for a susceptible laboratory animal more convenient than monkeys and chimpanzees continued. Armstrong at the National Institutes of Health in 1937 began inoculating several rat species with the Lansing strain of poliovirus. After some partial but erratic success with the cotton rat, he eventually succeeded in producing experimental poliomyelitis in a series of these rodents, and soon thereafter adapted the virus strain from the cotton rat to mice. Other strains of poliovirus were not as readily adapted to rodents, but the mouse model with Lansing strain (subsequently identified as type 2) contributed immensely to studies of poliovirus. With this test animal, quantitative techniques were established for titrating the virus, and a neutralization test in mice was developed. The distribution and duration of type 2 neutralizing antibody in human populations was determined. Thus, we began to have access more readily to the serological history of poliomyelitis in different communities, to correlate the development of antibody with the ages at which cases occur, and to

find that early, and immunizing, exposure to this virus took place in less developed nations, as we found in Egypt in 1952. Within industralized nations, such early immunizing infections occurred in crowded urban slums, but, in affluent segments of industrialized societies, exposure to poliovirus was postponed.

Many new avenues of investigation were opened by the findings that the chimpanzee could be readily infected by oral administration of poliovirus, could become a transient intestinal carrier of the virus but seldom developed clinical signs, and did indeed show many parallels to human beings similarly infected. Some of the unanswered questions that could now be pursued with new insights included the transmission of poliovirus in nature, the patterns of pathogenesis, and the site and course of the infection that results in the development of antibody in the human being. Thus we could approach questions of how efforts toward the development of vaccines might best proceed.

In the 1930s, Burnet, looking at the studies of neutralization with epidemic strains and at the fact that antibody was already present in patients' blood at the onset of CNS-related symptoms, suggested that if antibodies were already present at the 'beginning' of the illness, then such antibodies were not able to protect against the disease. However, Herdis von Magnus and I, in studies with rhesus, cynomolgus and vervet monkeys, induced paralytic disease by feeding them virus. Paralysis occurred within 1–2 weeks, but the monkeys already had neutralizing antibodies in their blood by the first day of paralysis. These findings reopened the question of whether, in the human disease, antibodies found this early were indeed irrelevant to current disease, as Burnet thought, or were a response to a current pathogenic process that included growth of the virus in nonnervous tissue. A number of the monkeys in our study had remained asymptomatic but they also developed antibody, yet histologic examination showed them to be free of CNS lesions. Thus, not only the early antibody production in the paralyzed monkeys but also the development of antibodies in those without CNS lesions suggested that antibody development was an early response to infection of tissue outside the CNS, and that such antibody might actually protect the CNS from virus invasion.

In 1952, Dorothy Horstmann at Yale and David Bodian at Johns Hopkins reported the isolation of virus from the blood of cynomolgus monkeys a few days after oral administration of virus but several days before the appearance of symptoms. When these findings were followed by observations of a similar pattern in humans, hope for immunization increased: if viremia was the route by which virus entered the CNS, then the virus might be blocked by circulating antibody and thus be prevented from invading the human CNS. One result of these developments was a trial to determine whether γ-globulin could be effective in preventing paralytic polio. A large and well-conducted field trial under Hammon's direction in 1952 showed that passive antibody could indeed protect against paralytic polio, although only for about 2–5 weeks. This trial also showed that the quantity of antibody need not be large, and it favored the hope that an effective method of active immunization could be developed.

Application of Laboratory Findings

We had investigated a polio outbreak in North Carolina in 1944, but returned in 1948 when a much larger one occurred. There were more than 2200 cases in the state, an attack rate of about 65 cases per 100 000 population. At the beginning of the summer 'polio season', when we learned that four cases had been reported, we had thought that an epidemic might be in the making, and in early June we obtained blood samples from children in Winston-Salem, along with placental sera which were used to determine the proportion of adults (or newborns) possessing antibodies at that time. These 'pre-epidemic' specimens were then matched by second bleedings obtained in November for testing as 'post-epidemic' specimens. This was the first time that pre- and post-epidemic sera had been studied for polio antibodies, even though, among the 248 children contributing paired specimens, no polio-like illnesses were reported during 1948.

Nada Ledinko and I found that the antibody patterns in the spring of 1948 were similar for all three types of poliovirus; they indicated a low incidence of infection during the previous 4-year period. During the 1948 epidemic, antibodies against type 1 and type 2 were acquired; the antibody conversions indicated infection rates of 23% with type 1 and 17% with type 2. Six children acquired antibodies against both type 1 and type 2 viruses. The development of antibodies took place to a greater extent in children under the age of 4 years than in those 4 years and older. No child in the study produced type 3 antibodies that summer.

The age-specific rates of inapparent infection by type 1 were compared with age-specific attack rates for polio in the epidemic. The number of subclinical type 1 infections per case was found to be about 100.

Previous infection of individuals with type 2 or type 3 virus did not prevent their infection with type 1 virus in 1948. In the spring of 1948, antibody to more than one type of poliovirus was a rare occurrence in

children of 4 years or under, whereas 41% of those over 4 years of age had antibodies against two or three types of poliovirus. This correlated with the fact that in this area the last outbreak prior to that of 1948 occurred in 1944, when we had isolated type 1 and type 3 viruses.

In the lower socioeconomic group of Winston-Salem, antibodies to all three types of poliovirus were present in a larger sector of the population, both in spring and in fall, than in the upper economic group. In this regard, poliomyelitis antibody patterns differed from those for influenza and mumps, for these two viruses, which are spread by respiratory pathways, the patterns were the same in both socioeconomic groups.

The studies in North Carolina also contributed to another series of investigations we were pursuing at the time on polio-related viruses: previously unknown mouse-pathogenic agents were being found in the human enteric tract. A virus that we named High Point circulated widely in Winston-Salem during the summer of 1948, but we could not associate any disease with infections by this virus. Soon thereafter the agent was identified as one of the new coxsackieviruses and became the A4 prototype. This leads me to a discussion of classification and nomenclature of polio and related viruses.

Classification of Polioviruses

> It might be mentioned that although foreseen and unforeseen problems inherent in the classification of any biologic species have existed since the days of Linnaeus, the main reason for laboring the point ... is that the manner in which a given entity is classified usually reflects the contemporary ideas concerning it ...

So wrote John Paul in 1971, looking back on changes that had taken place over the years in the classification and nomenclature of polioviruses.

Serious questions of picornavirus classification and nomenclature were first made a specific issue at the time of the 4th International Congress for Microbiology held in Copenhagen in 1947. There was debate about distinguishing poliovirus isolates not only from each other but also from human encephalitis viruses and from several mouse agents that had properties similar to those of the human polioviruses. Many virologists felt that the problem had not been adequately met at the Congress, and this led Paul and me to circularize virologists in the USA with alternative suggestions for the definition and classification of poliomyelitis virus. A related concern was that, at that time, no-one knew how many serological types of human poliomyelitis existed, clearly a crucial point for many reasons, including our ability to assess the possibility for future immunization.

In the 1930s many investigators already suspected that more than one antigenic type of poliovirus existed, and in fact a report had been published by Burnet and Macnamara in 1931 describing antigenic differences between two Australian strains of poliovirus. Although a number of respected scientists could not accept the idea of diversity among the poliovirus strains, references to antigenic differences among them continued to be made from time to time. Robert Ward and I, in reporting adaptation of two additional human polio strains to rodents, wrote

> Both strains cross immunologically with each other, and with the Lansing strain, but are immunologically distinct from two other 'non-adaptable' strains, the 1944 North Carolina strain and the 1945 Philippine Islands strain. Although ready means of designating strains immunologically as poliomyelitis A, B, or C are not yet available, nomenclature and classification will be discussed.

One year later, Bodian and his colleagues reported definitive results that three antigenic types existed.

With a considerable amount of effort involving the facilities of several laboratories and the use of many monkeys, it was clearly proven that three, and only three, serologic types of poliovirus exist. Furthermore, it was shown that type 1 was by far the most frequent type being recovered from paralytic polio cases.

An International Committee on Nomenclature in 1948 took on the task of establishing a provisional system for nomenclature and classification of poliomyelitis virus. This Committee reported to the First International Polio Conference held in New York later that year, and there followed the establishment of a study group of three members (H. von Magnus, J. H. S. Gear and J. R. Paul), who were appointed by the Virus Subcommittee (headed by Sir Christopher Andrewes) of the International Nomenclature Committee, International Association of Microbiological Societies. This study group incorporated the suggestion, made originally by Burnet of Australia, that the name poliomyelitis virus should be shortened so as to have some uniformity with the provisional names arrived at by other nomenclature groups. Thus the term poliovirus was coined, in line with already accepted terms such as poxvirus, herpesvirus and myxovirus. Paul later wrote

> In retrospect, the only lasting feature of this committee's suggestions was that the name polio-

virus became universally adopted. For within two years the family of polioviruses was embraced by a far larger group. What was more extraordinary was that the uniqueness of polioviruses in inducing characteristic lesions in the central nervous system was given up. Now it was the intestinal tract with which taxonomists were concerned. Viruses that had similar physical and chemical properties, i.e. small size and resistance to ether, and behaved in a similar fashion biologically with regard to the human intestinal tract as their special, though transient, habitat were all placed together in a new category regardless of whether or not they affected the central nervous system. Thus the large family of enteroviruses was created as a subgroup of the newly designated picornaviruses. Included besides polioviruses in the human enterovirus group were the coxsackie and echoviruses. This complete change in the image of polioviruses coincided with the general decline in the incidence of paralytic poliomyelitis. As vaccination became more and more effective the tragic paralytic results of the disease began to fade, and the virus acquired the more earthy name of its main anatomical site of predilection, which had so long been denied it. Polioviruses thus became members of the enterovirus family, incredible as this would have sounded to past generations of investigators.

Coxsackieviruses

The discovery of the large group of viruses to which the polioviruses belong came about in 1948 as follows. Dalldorf and Sickles of the New York State Health Department Laboratories, in their attempts to find an animal more readily available than monkeys for poliomyelitis studies, tried an animal that had been used successfully some years earlier with yellow fever virus. This new animal was the newborn (suckling) mouse. When these investigators inoculated suckling mice with fecal suspensions from two suspected polio patients from the town of Coxsackie, New York, the mice became paralyzed, but not from a poliovirus infection. A new virus had been discovered. The virus differed from polioviruses and from several other neurotropic viruses. It induced fatal disease with paralysis in baby mice, but not in adult mice, adult hamsters or rhesus monkeys. The lesions were located in the skeletal muscles rather than in the CNS, that is, the disease of the suckling mice was a myositis rather than an encephalomyelitis. The isolates subsequently became the first prototypes of the group A coxsackieviruses.

The use of newborn mice helped solve a problem that had been puzzling in some poliomyelitis outbreaks, in which the paralytic cases and the 'nonparalytic polio' (meningitis) cases peaked at different times. This did not make sense in light of what was known about the relationship of meningitis and paralysis as differing manifestations of infection with the same virus. We had been trying to find explanations by studying viruses from polio epidemics that showed this unusual pattern, and we turned up several new viruses in specimens from patients in the atypical polio epidemics. In 1949, together with Curnen and Shaw, I reported on a number of these mouse-pathogenic viruses. Many of our strains not only differed antigenically from the New York viruses, but also differed markedly in the pathologic picture that they produced in suckling mice. With Dalldorf's isolates, the principal damage to the baby mice was generalized and widespread myositis, affecting chiefly the striated muscles. The viruses that we discovered caused only focal and limited myositis in striated muscles, but produced degeneration of the brain, pancreas, heart muscle and embryonic fat pads under the skin. Clearly different from the New York isolates, they became the prototypes of the group B coxsackieviruses.

As more of these agents were found, it was recognized that, unlike most of the viral agents known up to that time, the new coxsackieviruses were associated not with one but with several different kinds of illnesses: one such was 'nonparalytic poliomyelitis' (aseptic meningitis). Thus we came to realize that not all of the 'nonparalytic polio' cases were due to poliovirus infections; this fact accounted for the differences sometimes observed in the epidemic peaks of the paralytic and nonparalytic illnesses. Further, we discovered that dual infections with poliovirus and coxsackieviruses could occur; hence, a patient's disease might be caused by a poliovirus but he could at the same time be excreting a coxsackievirus as a fellow traveler, or vice versa! Illnesses caused by the new viruses were herpangina, myocarditis, rash and pleurodynia, also known as epidemic myalgia or devil's grip. This illness had also been termed Bornholm disease, which some European workers had considered to be limited to the Danish island of that name.

We used every possible lead to gain insight into these new viruses, including some unhappy personal experiences. An isolate from my 3-year-old daughter, Nancy, became the prototype for coxsackievirus B3. And I, together with other members of our laboratory group, involuntarily demonstrated another way in which virologists sometimes learn about their viruses. From a number of infections that occurred among workers in the laboratory, we developed a clearer picture of the course of coxsackievirus infections and

the development of antibodies. We had convincing personal evidence that symptoms of coxsackievirus infections could rightly be said to include 'devil's grip'.

In working with coxsackieviruses in suckling mice, which already became insusceptible to the virus by 1 week of age, the ordinary method for testing antibody development and immunity could not be used: if the animals were given an immunizing dose at birth, they could not be challenged after developing antibodies, because by the time antibodies and immunities appeared, the animals would have been too old to be susceptible anyway. So we devised a method to fit this need: mother mice were vaccinated, and then both homotypic and heterotypic challenges were administered to the newborns. This was the *in vivo* means by which we unraveled the separate serotypes of the group B coxsackieviruses.

Chimpanzees were readily infected, but asymptomatically, following oral administration of various strains of the newly discovered coxsackieviruses, and we were already beginning to see some important similarities between these viruses and the polioviruses. This gave special impetus to extensive studies on the natural history of the coxsackieviruses.

Neutralizing antibodies and cross-protection were found to be specific for each of the different coxsackievirus types and to be maintained for at least 2 years in these chimpanzees. Complement-fixing (CF) antibodies, however, showed marked cross-reactions among coxsackieviruses. Although the animals usually responded with rises in homologous CF antibodies after feeding or inoculation with one serotype, heterologous CF antibodies to a variable number of other coxsackieviruses also increased significantly at the same time.

Tissue Culture

Just as we began to get a grasp on how to work with the coxsackieviruses that were turning up in such variety and quantity from isolates in laboratory mice, another world was opened up. For much of the work discussed above, the presence of poliovirus in a specimen obtained from patients or from their environment could be demonstrated only by producing the disease in monkeys and examining their spinal cords for the characteristic histological lesions of neuronal damage and perivascular infiltrations. Monkeys had to be trapped in Asia or Africa and transported to the laboratory. The supply was often irregular, and research sometimes was delayed for many weeks awaiting a new shipment. Poliomyelitis laboratories had to be equipped with extensive quarters and a large staff to care for large numbers of monkeys; valuable research time was used in dealing with the monkey's special nutritional needs and their susceptibility to diseases acquired in nature, such as tuberculosis, dysentery and parasitic infections.

Then came cell cultures. Cell cultures of nerve tissue had been successfully prepared in 1907 by Harrison at Yale, and there followed some efforts to cultivate polioviruses in such cultures, but there was no way of knowing whether the viruses multiplied except by inoculating monkeys. In 1942 an important new dimension was added by a young research fellow from China, Chen-hsiang Huang, working at Columbia University. He showed that a neurotropic virus, western equine encephalitis virus, when cultivated in cultures prepared from minced muscle of chick embryos, produced characteristic cell damage that could be seen by microscopic examination. By measuring the effects of the virus on cells, Huang was able to calculate the quantities of virus present in the culture, and also to test serum for the presence of antibodies against the virus. In addition, he developed a virus test based on metabolic (color) changes in the culture fluid that could be observed with the naked eye.

Both of these discoveries foreshadowed by several years the work of others that became much better recognized in the development of virology. At the time, the significance of Huang's discoveries may have been missed, partly because he soon returned to his native China and did not pursue his findings. However, he remained active and productive in China's biomedical community, where he became the Director of the Institute of Virology, Chinese Academy of Medical Sciences, Beijing.

A few years later, Enders, Weller and Robbins demonstrated that poliovirus could be grown in cultures of human cells derived from tissues other than those of the nervous system, and produced visible cell damage. The characteristic cytopathic effect in these cultures could be assigned scores, and thus could serve as a basis for quantification of the virus and of its antibody. The important work of these investigators was recognized by their receipt of the Nobel Prize in 1954. With monkey or human cell cultures, relatively simple and rapid tests were soon devised to detect the polioviruses, to measure them quantitatively and to determine the levels of antibodies that developed after infection.

Now the virus could be readily purified and visualized in the electron microscope. Investigators could analyze the biochemical and biophysical characteristics of the virus, trace the details of its multiplication, and explore the mechanisms by which it damages individual cells and the human host. Of

immediate importance, this new technology led to the production of the huge quantities of uniform poliovirus stocks that were required for preparation of killed vaccines. Furthermore, it opened the way to the development of live poliovirus vaccines, since pathogenic poliovirus, by propagation under specified conditions through many generations in cells widely different from human spinal cord cells, could be deliberately attenuated so as to become no longer neurovirulent for man. Less well recognized, but at least as important, were the contributions of the tissue culture methods to the development of cell and molecular biology and to cancer research.

Echoviruses and the Concept of Enteroviruses

The development in Enders' laboratory also allowed virologists working with polioviruses and coxsackieviruses at that time to detect a whole new assortment of previously unknown viruses. These viruses were abundant in human stools and grew in tissue cultures, but did not cause disease in laboratory animals. Moreover, at the time of their discovery they could not be clearly associated with specific human diseases. During 1950 we recovered hundreds of isolates from stools of patients with 'nonparalytic poliomyelitis'. As we looked further, these viruses were also found in healthy individuals in various areas of the world. By 1953 these agents were beginning to be called 'orphan' viruses, that is, viruses in search of a parent disease. A more explicit name was agreed upon, enteric cytopathogenic human orphan (or ECHO) viruses – a name that shortly became echoviruses. By 1955 it was recognized that some order had to be brought into the field, and, under the sponsorship of the National Foundation for Infantile Paralysis (NFIP) (which since has become the National Foundation), a Committee on the ECHO viruses was established, charged with continuing to explore these viruses, their interrelationships and their possible relation to human disease. The committee consisted of G. Dalldorf, J. F. Enders, W. M. Hammon, A. B. Sabin, J. T. Syverton and myself (chairman). A cooperative study on the antigenic types then available (eight from our laboratory, five from Sabin's laboratory and three from Hammon's laboratory) resulted in the differentiation of 13 distinct viruses.

We had thought at first that as soon as an 'orphan' virus could be attached to a parent disease, it would be removed from the echovirus group, but things did not turn out that way. The echoviruses and the coxsackieviruses were shown to cause various illnesses, but a direct and regular linkage of any one serotype with any one disease was (and is) the exception rather than the rule. Any one type may cause any of several syndromes, and a typical 'enteroviral' syndrome may be caused by any of many serotypes. Besides the well-known associations of enteroviruses with diseases such as poliomyelitis, meningitis, encephalitis, epidemic pleurodynia, rashes, hand-foot-and-mouth disease, myocarditis, herpangina and acute hemorrhagic conjunctivitis, as well as minor malaises and undifferentiated febrile illnesses, these viruses are also associated with diseases of the respiratory tract more frequently than is usually recognized. Enterovirus-associated respiratory diseases include pneumonitis of infants, pneumonia and bronchiolitis, as well as the common cold and other upper respiratory illnesses. It should be mentioned that not only polioviruses, but also a number of other enteroviruses may at times be etiologically associated with paralytic disease. Fortunately such cases are rare.

As studies of polioviruses, coxsackieviruses and echoviruses continued, it became more and more clear that these viruses shared far more than a human enteric habitat, and they were placed in one group called the enteroviruses [Committee on the enteroviruses, G. Dalldorf, J. F. Enders, W. M. Hammon, A. B. Sabin, J. T. Syverton, H. A. Wenner, and myself (chairman)].

New Enterovirus Types

As more enterovirus strains were isolated and studied, difficulties were sometimes encountered in attempting to assign them to the coxsackievirus and echovirus subgroups on the basis of the distinctions initially made between these groups (mouse pathogenicity for coxsackieviruses and exclusive growth in tissue cultures for echoviruses). The mouse-pathogenic prototype for coxsackievirus A23 turned out to be a host-range variant of a virus already established as echovirus type 9. The confusions of classification can be seen in the title of a paper published in 1957, 'Association of mouse pathogenic strains of echovirus type 9 with aseptic meningitis', when the cardinal property of an echovirus was its failure to produce disease in mice! In efforts to deal with these problems, the Committee on Enteroviruses in 1962 had suggested that all previously recognized polio-, coxsackie- and echoviruses be designated simply as enteroviruses and that each be given a serial number. One of the major objections of the International Enterovirus Study Group to such sequential numbering was that the new numbers would 'minimize much of the benefit gained from the rich virological and clinical literature in this field', and suggested instead that the designation of 'unclassified picornavirus' be used

when only a single strain of a virus was known, or when a virus did not fall clearly into one or another subgroup. However, neither recommendation gained wide acceptance.

The problem was highlighted once more by experience with the DN19 virus, an agent isolated by Alan Phillips in my laboratory. The virus was accepted by the Directors of the World Health Organization (WHO) Enterovirus Reference Laboratories as a previously unrecognized enterovirus and was designated as echovirus type 34. Data obtained subsequently, however, showed that DN19 virus should be considered an antigenic variant of a previously recognized enterovirus, coxsackievirus A type 24 (prototype strain, Joseph). In contrast to coxsackievirus A23, which was an example of a mouse-pathogenic echovirus, DN19 became an example of a coxsackievirus which was nonpathogenic for mice. But had DN19 been discovered before the coxsackievirus A24 prototype Joseph, then it would have been accepted as an authentic echovirus. If the Joseph strain had been discovered subsequently, it would have been considered a mouse-pathogenic echovirus. A further problem was presented by the Fermon enterovirus, which in 1969 had not yet been given a subgroup or a numerical designation because one strain of this virus produced lesions in suckling mice characteristic of the group A coxsackieviruses, but three other strains antigenically related to Fermon behaved as true echoviruses.

In view of these and other intratypic divergences, the previous proposal for enterovirus terminology was modified. Instead of sequential numbering of all agents in the group, we proposed that current subgroup names of all serotypes of the polio-, coxsackie- and echoviruses recognized through 1970 be retained, but that enterovirus serotypes recognized after that year not be assigned to subgroups. To avoid confusion with the enterovirus numbers proposed previously, we suggested that the new series begin with enterovirus type 68, and that this designation be given to the Fermon virus. This allowed for the three polioviruses, the 24 group A coxsackieviruses, the six group B coxsackieviruses and the 34 echoviruses reported previously in the literature. We did not imply, however, that each of these 67 viruses is antigenically distinct. Early on, echovirus 10 had been reclassified as the prototype reovirus, and echovirus 28 as the prototype rhinovirus. Echovirus 9 was found to be related to coxsackievirus A23, echovirus 34 to coxsackievirus A24, echovirus 1 to echovirus 8 and coxsackievirus A13 to coxsackievirus A18. Nevertheless, we felt that it would be the better part of wisdom to start the new classification with enterovirus 68.

Among the new enterovirus types, enterovirus 68 has caused lower respiratory tract illnesses, enterovirus 70 is the agent of widespread epidemics of acute hemorrhagic conjunctivitis and enterovirus 71 has caused outbreaks of aseptic meningitis and encephalitis, as well as hand-foot-and-mouth disease, in a number of countries.

An important feature of infections with enterovirus 71 has been meningitis. This virus has exhibited a variety of clinical manifestations in different regions of the world and at different times. In the California outbreak from which the prototype strain was reported, meningitis predominated but there were other CNS manifestations including a fatal encephalitis case. Meningitis also predominated in outbreaks in Europe, but there were also some cases of hand-foot-and-mouth disease in some of these outbreaks, and this latter syndrome predominated in Japan. In some parts of Japan a number of the patients had concomitant hand-foot-and-mouth symptoms and meningitis symptoms. This agent received more attention when it was found to cause a severe outbreak of poliomyelitis-like disease in 1975 in Bulgaria: of 700 patients, about 21% developed poliomyelitis-like paralysis and 44 died. A large outbreak in Hungary included chiefly meningitis cases, but fatal encephalitis was also reported.

Hepatitis A virus was provisionally classified as enterovirus 72. After decades of investigation, this virus, which inhabits the enteric tract, had been shown clearly to have many of the physicochemical properties of an enterovirus. However, it has been found to have a genetic composition sufficiently distinct to warrant its being classified as the prototype of a separate picornavirus genus. The name, heparnavirus, has been suggested, to indicate tropism for hepatocytes and an RNA genome.

Future Perspectives

It is interesting to note that the enteroviruses, originally established on provisional bases, now appear to form a 'real' genus, in which the members are indeed related in fundamental ways. The original grouping was based on small size (about 27 nm), an RNA genome, resistance to ether and mild acid and an enteric habitat. The grouping has been validated by studies utilizing sophisticated techniques of modern molecular virology that allow us to compare the genetic makeup of these viruses and details of their structure and their mode of replication.

Regarding the enteroviruses and their relatives within the picornavirus family, new methods have yielded many details. A high degree of homology exists between the genomes of the various members of

the enterovirus genus. The virion consists of a capsid shell of 60 subunits, each of four proteins (Vp1–Vp4), arranged with icosahedral symmetry around a genome made up of a single strand of positive-sense RNA.

By means of X-ray diffraction studies, the molecular structures of poliovirus and rhinovirus have been determined. The three largest viral proteins, Vp1–Vp3, have a very similar core structure in which the peptide backbone of the protein loops back on itself to form a barrel of eight strands held together by hydrogen bonds (the β-barrel). The amino acid chain between the β-barrel and the N- and C-terminal portions of the protein contains a series of loops. These loops include the main antigenic sites that are found on the surface of the virion and are involved in the neutralization of viral infection. There is a prominent cleft or canyon around each pentameric vertex on the surface of the viral particle. The receptor-binding site used to attach the virion to a host cell is thought to be located near the floor of the canyon. This location would protect the crucial cell attachment site from structural variation influenced by antibody selection in hosts, as the canyon is too narrow to permit deep penetration of antibody molecules.

We anticipate many new developments as investigators delve deeper into the structure of the enteroviruses and their mode of replication and survival in nature.

HOG CHOLERA VIRUS (*FLAVIVIRIDAE*)

Jan T van Oirschot, Institute for Animal Science and Health, Lelystad, The Netherlands

History

Hog cholera (synonym: classical swine fever) is a highly contagious virus disease of swine. The infection can run an acute, subacute, chronic or inapparent course, mainly depending on the virulence of the virus. High-virulent virus causes acute disease and high mortality, whereas infections with low-virulent virus often go unnoticed.

The first description of a cholera-like disease among pigs that was later considered to have been hog cholera was from Tennessee, about 1810. Other outbreaks were reported from Ohio in the early 1830s. Hog cholera may possibly have occurred in France in 1822 and in Germany in 1833, but other reports suggest the disease first appeared in the UK in 1862 and subsequently spread to the European continent. The infection was reported from South America in 1899 and from South Africa in 1900.

In 1903, De Schweinetz and Dorset proved the disease was caused by a virus. During the epizootic in the USA in 1914, approximately 90% of the pigs in infected herds died, which was estimated to be a loss of 100 million dollars. Hog cholera was the most devastating disease of pigs and consequently eradication programs were implemented, which have been successful in many countries.

Taxonomy and Classification

Hog cholera virus (HCV) belongs to the family *Flaviviridae*. Together with bovine virus diarrhea virus (BVDV) and border disease virus (BVD), it constitutes the genus *Pestivirus*.

Properties of the Virion

It is among the smallest enveloped animal RNA viruses known, measuring between 40 and 50 nm in diameter; the envelope surrounding the isometric nucleocapsid core measures 27–29 nm in diameter. Fringe-like projections of 6–8 nm have been demonstrated on the surface of the virion.

The buoyant density has been reported to be between 1.12 and 1.17 g ml^{-1} and sedimentation coefficient values of 140–180 S have been found. The large variations reported in size, shape and density of the virion may be due to: (1) the fact that the virus is

the enterovirus genus. The virion consists of a capsid shell of 60 subunits, each of four proteins (Vp1–Vp4), arranged with icosahedral symmetry around a genome made up of a single strand of positive-sense RNA.

By means of X-ray diffraction studies, the molecular structures of poliovirus and rhinovirus have been determined. HOG CHOLERA VIRUS (*FLAVIVIRIDAE*)

Jan T van Oirschot, Institute for Animal Science and Health, Lelystad, The Netherlands

History

Hog cholera (synonym: classical swine fever) is a highly contagious virus disease of swine. The infection can run an acute, subacute, chronic or inapparent course, mainly depending on the virulence of the virus. High-virulent virus causes acute disease and high mortality, whereas infections with low-virulent virus often go unnoticed.

The first description of a cholera-like disease among pigs that was later considered to have been hog cholera was from Tennessee, about 1810. Other outbreaks were reported from Ohio in the early 1830s. Hog cholera may possibly have occurred in France in 1822 and in Germany in 1833, but other reports suggest the disease first appeared in the UK in 1862 and subsequently spread to the European continent. The infection was reported from South America in 1899 and from South Africa in 1900.

In 1903, De Schweinetz and Dorset proved the disease was caused by a virus. During the epizootic in the USA in 1914, approximately 90% of the pigs in infected herds died, which was estimated to be a loss of 100 million dollars. Hog cholera was the most devastating disease of pigs and consequently eradication programs were implemented, which have been successful in many countries.

Taxonomy and Classification

Hog cholera virus (HCV) belongs to the family *Flaviviridae*. Together with bovine virus diarrhea virus (BVDV) and border disease virus (BVD), it constitutes the genus *Pestivirus*.

Properties of the Virion

It is among the smallest enveloped animal RNA viruses known, measuring between 40 and 50 nm in diameter; the envelope surrounding the isometric nucleocapsid core measures 27–29 nm in diameter. Fringe-like projections of 6–8 nm have been demonstrated on the surface of the virion.

The buoyant density has been reported to be between 1.12 and 1.17 g ml^{-1} and sedimentation coefficient values of 140–180 S have been found. The large variations reported in size, shape and density of the virion may be due to: (1) the fact that the virus is

heavily cell-associated and therefore difficult to purify from host cell membranes; and (2) the host cell system used for viral propagation.

Properties of the Genome

The virus has a single-stranded linear RNA genome of positive polarity of about 12.3 kb. The genome contains one large open reading frame that codes for a hypothetical large polyprotein of 3898 amino acids, that is cleaved, co- and post-translationally, by host cell- and virus-encoded proteases to yield mature viral proteins. The open reading frame is flanked by a 5′ noncoding region of almost 400 nucleotides and a 3′ noncoding region of approximately 200 nucleotides, which lacks significant polyadenylation. The order of the gene products along the open reading frame is as follows:

NH_2-(N^{pro}-C-E^{rns}-E1-E2-p7-NS2.3-NS4A-NS4B-NS5A-NS5B)-COOH

Properties of the Viral Proteins

The nonstructural N^{pro} is a protease with autoproteolytic activity; it has no counterpart in flaviviruses. The nucleocapsid protein (C) precedes the three envelope glycoproteins. The E^{rns} protein (formerly called gp42) forms a disulfide-linked homodimer. The mechanisms by which it is associated with the virion is unknown; it is also secreted from infected cells. A remarkable feature of E^{rns} is its RNase activity, which is unique among viruses. The function of this enzymatic activity is as yet unclear. The E^{rns} protein exhibits a strong immunosuppressive effect *in vitro*, and elimination of the RNase activity results in a cytopathogenic virus (HCV is normally noncytopathogenic). The E1 protein (gp31) is, as a disulfide-linked E1–E2 heterodimer, present in the viral envelope, and the E2 (gp53) as a disulfide-linked homodimer and as a heterodimer with E1. The E2 protein is composed of at least four antigenic domains, three of which give rise to neutralizing antibodies. The E2 protein expressed in a replicating vector (porcine herpesvirus) or produced in baculovirus and used as a subunit vaccine confers strong protection in pigs against a lethal challenge with HCV.

The p7 protein is probably not incorporated in the virion. The remaining part of the open reading frame is coding solely for nonstructural proteins. The C-terminal two-thirds of NS2.3 contains sequence motifs like NS3 in other flaviruses. This protein has protease and nucleoside triphosphatase (NTPase) activity. The role of NS4A and NS4B in virus replication is not known. The NS5B protein exhibits characteristic sequence motifs suggestive of an RNA polymerase.

Physical Properties

The resistance of HCV to physical and chemical treatment is partly dependent on the physical state of the material containing the virus. For instance, in cell culture fluid the virus is inactivated more rapidly than in defribinated blood. The mean inactivation rate at 56°C was found to be between 1.6 and 2.7 log units in 30 min. Below pH 4 and above pH 11, viral infectivity is quickly lost. Because the virion envelope contains lipids, solvents such as chloroform and ether easily inactivate HCV. In pork, the virus remains infectious for months, whereas in the environment outside the host the virus is usually inactivated in a couple of days; however, in liquid pig manure, HCV may survive for 2 weeks at 20°C and more than 6 weeks at 4°C. For disinfection, 1–2% sodium hydroxide is most suitable.

Geographic and Seasonal Distribution

HCV is distributed worldwide; it is regularly diagnosed in Africa, Asia, South and Latin America and in Europe. The virus has been eradicated from Australia, Canada, the USA, the Scandinavian countries, Ireland, the UK and Switzerland, but it still circulates in areas of Europe with a dense pig population. Between 1991 and 1996 the European Union was plagued by 530 outbreaks. In 1997 a devastating epidemic swept pig-dense regions in The Netherlands. The number of outbreaks was between 400 and 500. Consequently, 10 million pigs were destroyed and the total losses of the eradication program amounted to 2 billion US dollars. The virus has infected wild boar populations in various European countries, but not those in the USA. In Western European countries there are seasonal peaks in spring and autumn and a 3–4 year periodicity, associated with the so-called 'pig cycle'.

Host Range and Viral Propagation

The pig is the sole natural host of HCV. Experimental hosts include goats, sheep, calves, deer and rabbits. Although HCV can replicate in nonporcine cells, porcine kidney or testicle cells, be it primary cells or established cell lines, are normally used for propagation. Under single growth-cycle conditions, the first progeny virus is detected at 5–7 h after infection, followed by an exponential growth that peaks about 15 h after infection, with yields not exceeding 50 infectious particles per cell. The major portion of infectious virus remains cell associated. The virus replicates in the cytoplasm and induces no or minimal

cytopathology *in vitro*. Infected cells have a slightly extended period of DNA synthesis and may show some chromosomal alterations. Virus spreads from cell to cell and from mother to daughter cells in the presence of immune serum. The virions appear to assemble and to mature at intracytoplasmic membranes and may be released via exocytosis. Viral antigens are either absent or present in low density on the cell surface.

The growth of Newcastle disease virus is enhanced in porcine testis cells infected with HCV.

Genetics and Evolution

HCV shares a common evolutionary history with BVDV and BDV. Sequence analysis revealed that amino acid similarity between HCV and BVDV is around 70%. The lowest degree of homology exists between E2 sequences, the highest between the NS3 part of the NS2.3 protein. The percentage of homology between two HCV strains was 93%. On the basis of nucleotide sequences of the 5′ noncoding region, the N-terminal part of E2 and a region of NSB5, HCV strains may be divided into two major groups.

Serological Relationships and Variability

Although there is antigenic variation among HCV strains, they belong to one antigenic group, as shown by extensive crossneutralization with polyclonal antisera. The antigenic variation appears to reside on the antigenic unit on the N-terminal half of E2, as well as on E1. Within strains, with the use of monoclonal antibodies directed against E2, antigenic heterogeneity is observed as well.

There is a clear-cut distinction between HCV and BVDV, but these viruses are antigenically closely related, as shown by various serological techniques, including immunodiffusion and neutralizing antibody tests. In addition, there is a certain degree of cross-protection, i.e. pigs given a BVDV strain can be protected against mortality, but not disease, due to HCV. The common antigens among pestiviruses reside largely on the nonstructural protein NS2.3.

Epidemiology

The pig is the sole animal that is naturally infected with HCV, and thus the sole source of virus spread. Pigs are mostly infected via the oronasal route, and virus is shed in highest quantities in saliva, then in lacrimal secretions, urine and feces. Pigs infected with high-virulent strains and developing acute to subacute hog cholera, excrete the virus until death, whereas pigs with chronic disease excrete the virus intermittently. Postnatal infections with low-virulent strains are characterized by short periods of virus excretion, until antibodies appear in the blood. A congenital infection may result in the birth of persistently infected healthy pigs that shed virus in high titers continuously until they eventually die. Such pigs constitute a difficult recognizable source of virus transmission. Thus, low-virulent HCV infection may smolder in a herd for several months before it is diagnosed. Virulent HCV strains will usually spread faster in an infected herd and induce a higher morbidity than low-virulent strains.

Direct contact between infected and susceptible pigs is the most common mode of virus transmission. Herd-to-herd spread is commonly effected by pig movements. The risk of infection increases with the size of the herds. Humans and their contaminated equipment contribute considerably to virus spread between herds. The virus can also be transmitted by artificial insemination with infected semen. Aerogenic transmission may be a mode of spread between herds at close proximity. Wild boar are often, directly or indirectly, the source of new outbreaks in Europe.

Because HCV can survive in pork and pork products beyond processing, and for years when the meat is frozen, it can be transported over long distances. An important source of spread is virus-containing kitchen leftovers or garbage that has not been properly sterilized. Because of its potential danger, several countries prohibit the feeding of garbage to pigs.

Transmission and Tissue Tropism

Pigs are infected via the oronasal route. The tonsil is the primary target tissue for virus replication. The spread of high-virulent HCV through the pig is characterized by lymphatic, viremic and visceral phases. The virus primarily replicates in epithelial cells of tonsillar crypts and then invades the underlying lymphoreticular tissues. Through the lymphatic capillaries the virus is carried to lymph nodes and, after replication in these nodes, it enters the efferent blood capillaries, giving rise to a high-titered viremia. It subsequently replicates to high titers in secondary target organs, e.g. spleen, visceral lymph nodes, lymphoid structures lining the intestine and in bone marrow. It is presumably late in the viremic phase, which persists till death, that HCV invades the parenchymatous organs. Generally, the virus titers are higher in lymphoid tissues than in parenchymatous organs. The virus has an affinity for vascular

endothelium and cells of the immune system. The infection induces a severe leukopenia, which persists until death.

Intermediate-virulent virus strains generally induce subacute to chronic infections, during which virus persists in epithelial and lymphoreticular tissue. Infections with low-virulent virus tend to be confined only to the lymphatic phase.

Sows usually transmit the virus to their fetuses, irrespective of the stage of pregnancy. Infected fetuses harbor virus throughout their epithelial, reticulo-endothelial and lymphoidal tissues and a high-titered viremia persists until death, which may be months after birth. Immune exhaustion may develop in chronic and late-onset hog cholera.

Pathogenicity and Virulence

Although there is a continuous spectrum of virulence of HCV strains, one can distinguish strains of high, intermediate and low virulence, whereas the HCV vaccines are avirulent. It is not known which viral genes are involved in the expression of virulence. The severity and outcome of infection is the result of the composite interaction of viral virulence and host factors, such as breed, age, nutritional condition and immune competence. An association may exist between virulence and antigenicity: strains that are antigenically more related to BVDV seem to be less virulent. Low-virulent strains may grow optimally at 33–34°C, whereas virulent strains do so at about 39–40°C. The growth of virus in porcine alveolar macrophage cultures has been used as a marker for virulence. Virulent virus may grow to higher titers *in vivo* and *in vitro* than low-virulent strains. Whereas virulent virus thoroughly infects epithelial cells, reticular cells and macrophages in the tonsil, growth of virus of lowered virulence is mainly restricted to cells of the epithelial crypts. Virulence of CSFV seems to be an unstable property, because enhancement of virulence after one or multiple passages in pigs has repeatedly been reported.

Clinical Features of Infection

The infection can range from an acute disease with high mortality to a harmless subclinical course. Pigs with acute hog cholera show, after an incubation period of 2–6 days, high fever, with peaks above 42°C, anorexia, depression, conjunctivitis, nasal discharge, constipation preceding diarrhea, vomiting, weak hind legs and purplish discoloration of the skin. Concurrent with fever, a leukopenia and thrombocytopenia develop. Most pigs that suffer from acute classical swine fever die between 8 and 20 days postinfection.

Pigs infected with strains of intermediate virulence show a great variation in clinical responses. They may die from (sub)acute disease, they may recover or may survive the acute phase only to succumb later from chronic HCV, or they may develop only mild signs of disease. Chronic HCV is characterized by intermittent disease periods with anorexia, fever, leukopenia, diarrhea and dermatitis. Runt pigs can develop during chronic classical swine fever. Such pigs are severely retarded in growth, have skin lesions and often stand with arched backs. Secondary bacterial infections are common during chronic disease. Pigs infected with low-virulent strains show mild signs of disease or remain healthy.

Depending on the developmental stage of the fetus, a congenital infection can result in prenatal death, followed by mummification or stillbirth, malformation or neonatal death, congenital tremor, or the birth of healthy offspring that develop late-onset disease weeks or months after birth. Late-onset disease is characterized by runting, often associated with leukopenia, and pigs eventually die weeks or months after birth.

Pathology and Histopathology

The pathological picture of (sub)acute HCV is that of a septicemic disease with widespread multiple hemorrhages of various sizes, mainly in lymph nodes and kidneys. Infarction of the spleen is considered almost pathognomonic. There is disseminated intravascular coagulation with the occurrence of microthrombi in small blood vessels. In addition, various inflammatory reactions develop in respiratory, digestive and urogenital tracts. Encephalitis with perivascular cuffing is often observed. The infection results in degeneration and necrosis of capillary endothelial cells and in proliferation followed by necrosis and depletion of lymphocytes along with hyperplasia of histiocytes and reticular cells.

The most outstanding lesion in pigs that die from persistent HCV is a general exhaustion of the lymphoid system, characterized by a complete atrophy of the thymus and lymphocyte depletion of peripheral lymphoid tissues. A consistent finding is degeneration of endothelial cells. Button-ulcers in cecum and colon and rib lesions are frequently seen in subacute and chronic cases.

In stillborn pigs an excessive accumulation of fluid in body cavities is most prominent. The virus is teratogenic, and most commonly defects of the central nervous system, such as cerebellar hypoplasia, are induced.

Immune Response

Compared to other virus infections of pigs, antibodies to HCV appear late in the blood. In pigs that recover from the disease, antibodies first appear in the blood between 10 and 21 days after infection. Neutralization tests are commonly used to detect these antibodies but these tests can detect antibodies to BVDV as well. Recently, ELISAs utilizing HCV-specific monoclonal antibodies have become available that specifically detect antibodies to HCV. Antibodies probably persist during the pig's entire lifetime. An HCV-specific proliferation of T lymphocytes and a cytotoxic T-lymphocyte response have been described.

In chronically infected pigs, the neutralizing antibody response can remain completely absent, be severely impaired and delayed, or only be transiently detectable. Pigs with congenital persistent hog cholera do not mount an antibody response to the virus, but they respond normally to unrelated antigens. This state of immunotolerance is usually maintained until death.

After vaccination, neutralizing serum antibodies are first detectable around 2–3 weeks and persist lifelong. Vaccinated sows transmit antibodies to their offspring through colostrum. These antibodies enter directly into the blood circulation because the intestine of the neonate is permeable for immunoglobulins during the first 36–48 h of life. Piglets are thus passively protected against mortality due to hog cholera during the first 1–2 months after birth. Passively acquired antibodies strongly suppress the induction of active immunity after vaccination, so that pigs born from vaccinated sows cannot be successfully vaccinated before 6–9 weeks of age.

HCV has a distinct affinity for cells of the immune system and consequently can induce defects in immune functions. During acute hog cholera, the pig's immune reactivity is suppressed, e.g. peripheral blood and spleen lymphocytes hardly respond to mitogens, whereas tonsillar and lymph node lymphocytes have normal to enhanced responses. HCV infections seem to induce alterations in lymphocyte recirculation in pigs.

Prevention and Control

Countries that are free from hog cholera have measures in force, such as a ban on the import of pigs and pork from infected countries, to prevent introduction of virus. If, despite these measures, hog cholera is diagnosed, rigorous measures are taken to eradicate the virus. These eradication programs are based on notifying suspected cases to the veterinary authorities, a rapid laboratory diagnosis and an immediate destruction of infected herds. In order to diagnose hog cholera, recently dead or moribund pigs should undergo postmortem examination, and tonsil, spleen, kidney and ileum should be sent to the laboratory for the detection of antigen in frozen tissue sections by an immunofluorescence test. The results can be available in 2 h. Because pigs can also be naturally infected with BVDV, monoclonal antibodies that are directed against conserved epitopes of HCV and do not recognize BVDV are used for staining tissue sections, to distinguish between an HCV and a BVDV infection. The immunofluorescence test is slightly less sensitive than virus isolation in tissue culture. In the latter case, it takes 24–72 h before HCV is diagnosed. Antibody detection, in neutralization tests and ELISAs, is also used as a diagnostic tool to identify herds with convalescent pigs. Once the diagnosis has been made, standstill orders, closure of markets, intensive monitoring of adjacent farmers and immediate destruction of infected herds are implemented.

Systematic and strictly applied large-scale vaccination programs have been implemented to stop the uncontrollable perpetuation of the virus. Such programs, in conjunction with the usual sanitary measures, have contributed enormously to the eventual eradication of hog cholera from heavily infected areas; however, the European Union adopted a nonvaccination policy at the end of the 1980s. Vaccines of HCV are based on strains attenuated by serial passage in rabbits ('Chinese' strain) or in cell cultures. The vaccines are highly efficacious and safe, although they occasionally spread to contact pigs. Vaccination establishes immunity within 1 week and the immunity persists lifelong. Vaccination not only protects against disease, but also prevents transmission of field virus from vaccinated to contact pigs.

Future Perspectives

A wide spectrum of virulence exists among HCV strains: some strains induce almost 100% mortality, whereas others only give rise to inapparent infections. The virus is virtually noncytopathogenic *in vivo*. The viral genes involved, and the processes underlying the expression of virulence leading to severe disease, tissue damage and immune exhaustion, are virtually unknown. Research on the molecular pathogenesis of hog cholera might reveal hitherto unknown disease-making processes and may shed more light on the pathogenesis of related hemorrhagic fevers in humans.

In countries that are (almost) free of HCV, it is of the utmost importance to make an early and rapid

diagnosis once the virus is introduced. By means of reverse transcription–polymerase chain reaction, infected pigs may be detected earlier than with the commonly used immunofluorescence techniques. For pork-exporting countries, an early diagnosis may occasionally mean the prevention of losses of millions of dollars.

In heavily infected countries or in areas where there is an uncontrollable virus spread, a systematic and strict vaccination scheme should be implemented to curtail virus circulation. Vaccination, however, precludes the use of serology for diagnostic purposes, because the antibody response after vaccination cannot be distinguished from that after infection. Consequently, it is difficult to demonstrate convincingly the absence of HCV which jeopardizes the export of pork. Marker vaccines that allow the differentiation between infected and vaccinated pigs with the use of an epitope-specific serological test will soon become available. These vaccines contain the E2 protein, produced in baculovirus, and are formulated with an adjuvant.

HONEY BEE VIRUSES

Brenda V Ball, IACR-Rothamsted, Harpenden, UK

Leslie Bailey, 20 West Common Grove, Harpenden, UK

History and General Characteristics

Isolation and characterization of bee viruses began in the 1960s, with work on two diseases, sacbrood and paralysis, which have striking symptoms. Sacbrood, although extremely common in Britain, was, until the virus was isolated, dismissed there as a genetic disorder. Similarly, paralysis was ascribed to independent, but accompanying and very common, well-known parasites, especially microsporidia and mites, which do not cause any overt symptoms.

Many, if not all, of the viruses of bees persist in the population as slight or inapparent infections, but under certain circumstances they begin to multiply within individuals and spread between them, leading to outbreaks of disease. These are sometimes spectacular, causing severe losses, but mortality due to virus infection, although significant, is usually less obvious, and is still commonly attributed to other factors. This, and the fact that there are no known direct means of controlling bee viruses may persuade beekeepers and their advisors that they are of little consequence and they continue to disregard them. However, past ignorance of the viruses of bees has frequently led to mistaken or seriously inadequate diagnoses of diseases and so to much wasted effort on inappropriate treatments.

Some bee viruses depend on, but do not invariably accompany, certain common parasites of adult bees. Further, at least two usually inapparent virus infections become activated to multiply to lethal levels by *Varroa jacobsoni*, which can also act as a vector of several other viruses.

Physicochemical properties

The principal physicochemical properties of the known bee viruses are summarized in **Table 1**. All except chronic paralysis virus and filamentous virus have isometric particles. Apart from *Apis* iridescent

virus, which is only very distantly related to some other known insect iridoviruses, no virus from honey bees has been found to be serologically related to any other virus.

Chronic Paralysis Virus and Chronic Paralysis Virus Associate

Special features

Particles of chronic paralysis virus (CPV) are mostly ellipsoidal in outline, often with a small irregular protuberance at one end. A wide range of shapes and sizes of particles occur, but these are resolvable in sucrose gradients or by analytical centrifugation into three or four components with sedimentation coefficients of 82, 97–106, 110–124 and 125–136 S. These components contain particles that differ considerably in size but have modal lengths of about 30, 40, 55 and 65 nm respectively, and all have a modal width of about 20 nm.

CPV has five single-stranded RNA components: two larger RNAs designated 1 (M_r 1.35 × 10^6; 4200 nucleotides) and 2 (M_r 0.9 × 10^6; 2800 nucleotides) and three smaller RNAs each with M_r 0.35 × 10^6 (1100 nucleotides). CPV adopts a flexible packaging arrangement in which individual RNA species may be packaged separately or various combinations incorporated together.

Chronic paralysis virus associate (CPVA) has 17 nm isometric particles which are serologically unrelated to CPV but are frequently found associated with it in natural infections. CPVA does not multiply when injected alone into bees and it interferes with the multiplication of CPV, inhibiting particularly the relative amount of the longest, most infective particles. It is more evident in females of the reproductive caste (queens) than in workers and may be of some significance in, or a reflection of, the defence mechanisms of individuals against paralysis. Gel electrophoretic and T1 fingerprint analyses have shown that the three RNAs of CPVA are probably identical to the three smallest RNA components of CPV.

Pathology and epizootiology

CPV causes one of two distinct sets of symptoms or syndromes. One of these, described as 'paralysis' more than a hundred years ago, includes an abnormal trembling motion of the wings and bodies of the infected bees, which are unable to fly but often crawl on the ground beneath their colonies, sometimes in masses of thousands of individuals. The sick bees have a bloated abdomen, caused by distension of the honey sac with liquid, and they frequently have partially spread, dislocated wings. They die within a few days. Severely affected colonies suddenly collapse, leaving the queen with a few bees on neglected combs. All these signs are those attributed to the so-called 'Isle of Wight disease', which is alleged to have been prevalent in Britain early in the twentieth century, but was of unresolved cause.

Bees with the other syndrome become hairless, appearing dark or almost black and shiny. At first they can fly but they suffer nibbling attacks by healthy bees and are prevented from returning to their colony by guard bees. In a few days they become flightless, trembly and soon die. Both syndromes can occur in the same colony and the difference in expression of symptoms probably reflects genetic differences between the bees.

Many millions of particles of CPV can be extracted from one bee with paralysis and about half of these are in the head. Particles resembling those of CPV have been seen in densely but randomly packed groups, either free or within vesicles, in the cytoplasm of thoracic and abdominal ganglia of the gut and of the mandibular and hypopharyngeal glands of paralytic bees. They do not appear in the cytoplasm of fat or muscle tissue. Sections of the hindgut epithelium of paralytic bees show basophilic cytoplasmic bodies (Morison's cell inclusions) which seem specific to the disease.

The LD_{50} by injection into the hemolymph of adult bees is about 100 particles. Individuals are also readily infected by rubbing virus preparations on their bodies, but many millions of particles are required to cause paralysis when applied as a spray or in food. Bees infected by any method become flightless and paralytic between 5 and 7 days later and die soon after. Infected individuals live longer at 30°C than at 35°C, which is about the maximum temperature in a bee colony, yet more virus multiplies in bees at the lower temperature. The disease spreads rapidly between overcrowded adult bees, probably via the cytoplasm of broken cuticular hairs.

CPV occurs commonly throughout the world. Infectivity tests indicate that the virus is endemic in apparently healthy colonies in Britain but there is no seasonality in incidence or in disease outbreaks. Irregular factors that inhibit the normal activities of bees probably increase transmission of the virus. These factors include unseasonable weather, queenlessness, crop failures and high colony densities, each of which decreases the foraging activity of bees and hence increases their bodily contact within colonies during their usually active season. This may well explain the close correlation between the decline in the number of colonies in Britain and the decline in the incidence of outbreaks of paralysis. It contrasts

with the unchanged or somewhat increasing incidences, during the same period, of noncontagiously transmitted infections of bees.

Sacbrood

Special features

Sacbrood virus (SBV) from the European honey bee, *A. mellifera,* is serologically related to a strain identified in the Eastern hive bee, *A. cerana,* from Thailand (TSBV) but is distinguishable from it physicochemically.

Unlike SBV particles, those of TSBV aggregate in buffers of low (about 0.01) molarity, and in the absence of sodium ethylene diaminetetra-acetate TSBV particles appear empty when viewed by electron microscopy. Particles of both virus strains appear empty when Mg^{2+} is added but SBV is much less sensitive than TSBV.

TSBV sediments at 160 S in 0.1 M KCl but at only 150 S in 0.01 M phosphate. It produces three close but well-defined bands of protein on 5% sodium dodecyl sulfate (SDS) polyacrylamide gels. By contrast, SBV sediments at 160 S in 0.01 M phosphate and on 5% SDS polyacrylamide gels gives one band which separates into three only on gels of higher concentration.

Pathology and epizootiology

The symptoms of sacbrood are clear and specific in both *A. mellifera* and *A. cerana.* Infected larvae fail to pupate and remain stretched on their backs with their head towards the cell capping. Much ecdysial fluid, containing millions of virus particles, collects between the body and the tough unshed skin of the larva. The body colour changes from a pearly white to a pale yellow and after death begins to darken from the anterior end, drying down to a dark brown gondola-shaped scale. The remains are usually removed, mostly before they desiccate, by young adult bees, which ingest large quantities of virus in the process. Many particles, sometimes in crystalline array, have been seen in the cytoplasm of fat, muscle and tracheal end-cells of infected larvae.

Sacbrood can be readily caused experimentally by adding fresh suspensions of the virus to the food of healthy unsealed larvae in the brood cell. Larvae about 2 days old are the most susceptible.

SBV ingested by young adult bees multiplies readily without causing obvious disease. It accumulates in the hypopharyngeal glands, from which it probably joins the food of larvae with the gland secretions. However, bees are usually prevented from transmitting the virus by behavioural changes; infection accelerates the normal sequence of duties and shortens the life of individuals. Infected young bees cease to eat pollen; they cease to feed and tend larvae; and they fly and forage much earlier in life than usual. These effects are the same as the changes induced by aging or by brief anesthesia with carbon dioxide.

Outbreaks of sacbrood most commonly occur in the spring and early summer or when forage is limited, probably because, when young bees are few, the usual division of labor according to age is least well developed.

Sacbrood occurs worldwide and in some areas is considered to be the most common honey bee disease; however, this may reflect the ease and reliability of field diagnosis by symptoms. The mite *V. jacobsoni* is sometimes a vector of the virus.

Acute Paralysis Virus

Special features

Acute paralysis virus (APV) is stable below pH 4.0 but, unlike acid-stable mammalian picornaviruses, its buoyant density increases with increasing pH. APV has also been detected in *Bombus* species and is the only honey bee virus that appears to have an alternative host in nature.

Pathology and epizootiology

Bees injected with approximately 100 particles of APV develop trembling and semiparalytic symptoms after 2–3 days and die 1–2 days later. Inoculated bees are killed quickly at 30°C but they live longer, even though more virus accumulates within them, at 35°C. This is in direct contrast with the effect of temperature on bees infected with CPV. Crystalline arrays of particles have been seen in the cytoplasm of fat-body cells, the brain and hypopharyngeal glands of infected bees.

APV commonly persists as an inapparent infection in adult bees and, until recently, had never been associated with disease or mortality in nature. In continental Europe and North America, strains of APV have now been detected in dead adult bees and pupae from colonies infested with the parasitic mite *V. jacobsoni.* The mite induces the virus to multiply when it feeds on apparently healthy but virus-infected bees and the virus rapidly becomes systemic and lethal. Mites acquire virus by feeding on an overtly infected host and can then act as virus vectors, transmitting APV to other adult bees or to pupae within the brood cell.

APV has been detected in *A. mellifera* from most regions of the world. All strains of APV are

serologically closely related and distantly related to Kashmir bee virus.

Kashmir Bee Virus

Special features

Strains of Kashmir bee virus (KBV) from Canada and Spain differ from other strains of KBV in their tendency to aggregate in buffers of low (about 0.01) molarity and in containing only three capsid proteins when analyzed by SDS-polyacrylamide gel electrophoresis, compared with five proteins resolved in the type strain of KBV from *A. cerana* in India and six proteins in KBV strains from South Australia and New Zealand. Protein instability may account for one or two of the minor bands resolved in the latter three strains.

Pathology and epizootiology

KBV multiplies quickly and profusely when injected into adult bees or when suspensions are rubbed on their bodies, killing them within 3 days, but it causes no apparent harm when given in food to adult bees or larvae. The virus multiplies in most tissues of infected bees, apparently within cytoplasmic membrane-bound vesicles, but not in nerve cells. Infected cells show marked changes, including condensation of chromatin and disruption of cytoplasmic organelles.

KBV commonly persists as an inapparent infection in both adult bees and pupae, but it may spread contagiously, in the same way as CPV, to cause overt disease in nature.

KBV has been detected in *A. cerana* from India and Papua New Guinea and in *A. mellifera* from North America, Europe, Australasia and Oceania. It may be more widely distributed than previously thought but, like APV, has remained undetected until the spread of *V. jacobsoni* caused the activation and establishment of overt infection in infested colonies.

Deformed Wing and Egypt Bee Viruses

Special features

Semipurified preparations of the particles of these viruses are unstable, aggregating and disintegrating in buffers of low (about 0.01) molarity or below pH 5.0. Under these conditions, many capsids, typically with six clearly defined thickenings, are penetrated by neutral phosphotungstate stain. Deformed wing virus (DWV) particles are much more sensitive to these conditions than those of Egypt bee virus (EBV).

DWV strains show some differences in their capsid protein profiles but all are serologically closely related to each other and distantly related to EBV.

Pathology and epizootiology

DWV sometimes kills adult bees but infection is most evident in colonies infested with *V. jacobsoni* because the mite transmits the virus to honey bee pupae, causing wing malformation and early death of newly emerged adults. Injecting the virus into very young pupae causes the disorder after an incubation period of about 14 days.

DWV has been detected in *A. mellifera* from Japan, most European countries, Saudi Arabia, Iran, Vietnam and Argentina and in *A. cerana* from China.

EBV was isolated from samples of dead adult bees from Egypt, but nothing is known of its natural history.

Slow Paralysis Virus

Purified particles of slow paralysis virus (SPV) aggregate spontaneously in the agar of immunodiffusion plates when these contain 0.85% sodium or potassium chloride at pH 5.8–8.8.

Until recently, SPV had never been associated with disease in nature. The virus has now been identified as a cause of the death of both adult bees and pupae in honey bee colonies in Britain infested with the parasitic mite *V. jacobsoni*. SPV may be induced to multiply to lethal levels and be transmitted in a manner similar to that of APV in mite-infested colonies. Adult bees injected with SPV die after about 12 days, typically suffering paralysis of the first pair of legs shortly before death.

Black Queen Cell Virus

Black queen cell virus (BQCV) was first identified as the cause of death of queen larvae or prepupae after they had been sealed in their cells, which developed dark-brown to black cell walls. Diseased larvae are pale yellow and have a tough sac-like skin, resembling those killed by sacbrood virus, but unlike this virus, BQCV does not multiply readily when ingested by young worker larvae or young adult bees. It multiplies abundantly and fatally when injected into pupae, but infects adult bees only when these are also infected with the microsporidian *Nosema apis* and in nature it almost always accompanies this parasite. BQCV in association with *N. apis* shortens the lives of bees more than when these are infected with the microsporidian alone, but it causes no sign of disease.

BQCV has been identified in adult bees from every continent and the virus is sometimes transmitted to pupae by the mite *V. jacobsoni*.

Bee Viruses X and Y

Bee virus X (BVX) is distantly serologically related to bee virus Y (BVY) and is almost indistinguishable from it both physically and chemically. They multiply primarily in the gut epithelium when ingested by young adult bees that are maintained at 30°C but not at 35°C. There are no symptoms of infection but each shortens the life of adult bees, BVX being the more virulent. Neither virus multiplies when injected into adult bees or pupae.

Despite their many similarities, BVX and BVY differ strikingly in their epizootiology. In Britain, BVX is most prevalent during winter, whereas the peak incidence of BVY occurs in spring. In nature, infection with BVY is almost invariably associated with the microsporidian *N. apis,* but BVX shows no similar association with this parasite. BVX is, however, significantly associated with the protozoan *Malpighamoeba mellificae* in dead bees in late winter. This association is not due to a dependence of the virus on the protozoan but to the much greater virulence of the pathogens when they occur together in individuals than when they are alone.

BVX has not been detected in Asia, but with this exception both viruses have a worldwide distribution.

Cloudy Wing Virus

Although the particles of cloudy wing virus (CWV) are similar in size to CPVA they differ in their stability in dilute (0.01M) buffer, are serologically unrelated and, as far as is known, CWV multiplies independently of any other virus. The wings of severely infected individuals often lose transparency but this is not a reliable symptom. The lives of infected bees are shortened and colonies in which most individuals are infected soon become inactive and die.

In nature, infection may be airborne over short distances because it spreads between cages of bees that are incubated close together in the laboratory. Crystalline arrays of particles occur in the region of the tracheoles between the muscle fibrils of the thorax where the main inhalatory spiracles are located. Although the virus is primarily an infection of adult bees, it has recently been detected in dead pupae and newly emerging bees from colonies infested with *V. jacobsoni,* which indicates that it may be infective by injection.

There is no seasonal cycle of incidence, which suggests that irregular events determine the spread of CWV within colonies, similar to those controlling the spread of CPV and other contagiously transmitted pathogens.

About 15% of colonies have been found to be infected by CWV in Britain. The virus is widely distributed throughout mainland Europe and has been detected on every other continent.

Filamentous Virus

Special features

Filamentous virus (FV) particles each comprise a flexuous rod-shaped nucleocapsid, measuring 3000 nm × 40 nm, tightly coiled within an ellipsoidal envelope measuring 450 nm × 150 nm. The particles of virus preparations in solutions of low ionic strength appear intact when negatively stained with ammonium molybdate and viewed in the electron microscope, whereas the nucleocapsid emerges partially or entirely from particles in similar preparations stained with neutral phosphotungstate.

Pathology and epizootiology

FV particles have been seen in ultrathin sections of all tissues examined but virogenesis has been observed only in fat-body and ovarian cells. The hemolymph of severely infected individuals becomes milky white with particles but there are no other known symptoms and no unequivocal evidence that the lives of bees are shortened by infection.

The virus can multiply when injected into bees but it infects them most readily when fed to adults together with spores of the microsporidian *N. apis,* with which it is almost invariably associated in nature.

First reported from the USA, FV is probably the most common but least pathogenic of all honey bee viruses in Britain. It has been detected in adult bees from every continent except South America.

Apis Iridescent Virus

Apis iridescent virus (AIV) is only distantly serologically related to the other iridescent viruses isolated from insects and, curiously, unlike the majority of iridoviruses, it fails to multiply by injection into larvae of the greater wax moth *Galleria mellonella,* which is a specific pest of honey bee combs.

Natural infections of AIV in colonies of the Eastern hive bee, *A. cerana,* cause symptoms of 'clustering disease'; colonies become inactive and clusters of flightless bees form on the front of the hive or crawl on the ground. AIV will multiply in various tissues of the European honey bee, *A. mellifera,* forming crystals which appear a bright blue-violet colour when illuminated with white light.

AIV has been found only in *A. cerana* from Kashmir and northern India and is the only known iridovirus of Hymenoptera.

Other Honey Bee Viruses

These viruses or virus-like particles are not known to be related to any virus described above or to be associated with any particular disease or parasite of bees.

Arkansas bee virus

Arkansas bee virus (ABV) was originally detected in honey bees in Arkansas by injecting apparently healthy adult bees with extracts of locally gathered pollen loads of foraging bees. Individuals injected with the virus die after about 14 days but otherwise show no sign of disease.

ABV has been detected, together with chronic paralysis virus, in dead bees from dwindling colonies in California but has not been detected anywhere other than these two localities in the USA.

Berkeley bee virus

Virus-like particles, unrelated to ABV and named Berkeley bee virus, have been found associated with the Californian and Arkansas isolates of ABV, but nothing is known of their pathogenicity or natural history.

Future Perspectives

The recent recognition of virus infections as a primary cause of mortality in honey bee colonies infested with the parasitic mite *V. jacobsoni* has stimulated increased interest and awareness of honey bee viruses worldwide. A more extensive capability to detect and identify these pathogens by serological or molecular techniques will provide information on the natural history and prevalence of virus infections in honey bee populations in many areas of the world where little is currently known. The improved ability to accurately diagnose these infections will also help to clarify the role of viruses in outbreaks of mortality previously attributed to a few well-known groups of larger parasites or to noninfectious causes.

Although almost all of the viruses of bees have been shown to be widespread and to shorten the lives of individuals, their effects under most circumstances are not striking. Indeed, the persistence of a number of distinct and occasionally virulent viruses in apparently healthy, perennial colonies emphasizes the powerful innate ability of bees to resist their multiplication and spread. This natural propensity is most evident when colonies of bees are allowed to develop and undertake their normal activities unhindered – an ideal which is increasingly difficult to attain with the demands of modern intensive beekeeping, particularly migratory and pollination work. Some honey bee viruses may still be localized but their ability to persist as inapparent infections, together with the continued and increasingly rapid international trade in bees seems to make their ultimate distribution worldwide inevitable.

HORDEIVIRUSES

Diane M Lawrence and **Andrew O Jackson**, University of California-Berkeley, Berkeley, California, USA

Taxonomy and Classification

The *Hordeivirus* genus of plant viruses includes three members: barley stripe mosaic virus (BSMV, type member), poa semilatent virus (PSLV) and lychnis ringspot virus (LRSV). The genus has not been assigned to a family. BSMV, PSLV and LRSV have rod-shaped virions that are shorter and are larger in diameter than those of the tobamoviruses and tobraviruses. The coat proteins of BSMV, PSLV and LRSV are the same size, but have different mobilities on polyacrylamide gels, and are distantly related by serotype. The particle morphology, serological relatedness of the coat proteins, and genome organization place these three viruses in the same group. Analyses of the coat protein sequences and the

AIV has been found only in *A. cerana* from Kashmir and northern India and is the only known iridovirus of Hymenoptera.

HORDEIVIRUSES

Diane M Lawrence and **Andrew O Jackson**, University of California-Berkeley, Berkeley, California, USA

Taxonomy and Classification

The *Hordeivirus* genus of plant viruses includes three members: barley stripe mosaic virus (BSMV, type member), poa semilatent virus (PSLV) and lychnis ringspot virus (LRSV). The genus has not been assigned to a family. BSMV, PSLV and LRSV have rod-shaped virions that are shorter and are larger in diameter than those of the tobamoviruses and tobraviruses. The coat proteins of BSMV, PSLV and LRSV are the same size, but have different mobilities on polyacrylamide gels, and are distantly related by serotype. The particle morphology, serological relatedness of the coat proteins, and genome organization place these three viruses in the same group. Analyses of the coat protein sequences and the

serotype indicate that BSMV and PSLV are more closely related to each other than to LRSV. Anthoxanthum latent bleaching virus (ALBV) which has been detected in Great Britain has recently been assigned to the genus and serological analysis shows that ALBV is closely related to BSMV.

Host Range and Economic Importance

Hordeiviruses have been detected in nature in members of both monocot and dicot families. BSMV has primarily been found in barley and occasionally in wild oats and wheat. PSLV has been isolated from *Poa palustris* from two different locations in Western Canada. LRSV appears to be of European origin, and has been recovered from several members of the Caryophyllaceae and Labiatae families. Hordeiviruses also infect several experimental hosts. BSMV will form local lesions on *Chenopodium* species and causes a systemic infection in *Nicotiana benthamiana*. PSLV infects Graminae and also several dicots experimentally, whereas LRSV has been shown to infect several dicot plants. BSMV, LRSV and PSLV have no known vectors, and are all transmitted by mechanical means. BSMV and LRSV are seed transmitted, but as yet PSLV has not been shown to be seed transmitted.

BSMV appears to be the only hordeivirus of economic importance with serious yield losses due primarily to infection of barley. Losses result from poor seed set, shriveled seeds and decreased vigor of seedlings. However, BSMV has no known biological vector and requires efficient seed and mechanical transmission for maintenance in barley, so virus spread can be prevented by planting virus-free seed. As more sensitive detection methods have been developed, seed can be screened prior to planting and plants grown for certified seed production can be rogued prior to harvesting. In North America these practices have significantly reduced the yield losses due to BSMV infection of barley. In addition, investigation into resistance by genome mapping has revealed that in Morex barley, a single gene confers resistance to the BSMV strain CV42.

Physical Properties

Hordeivirus particles are rod shaped with a diameter of approximately 25 nm and lengths ranging from 100 to 160 nm. The particles are composed of a single coat protein species that encapsidates a positive sense single-stranded (ss) RNA molecule. The particles appear to contain three nucleotides per protein subunit, with approximately 24 protein subunits per turn of the helix. The hordeivirus genome is tripartite in nature with the complete sequences of BSMV, PSLV and LRSV RNAs having been determined.

Genome Structure and Organization

The hordeivirus genomes are composed of three RNAs designated α, β and γ. The sizes of the α, β and γ RNAs are 3.8, 3.2 and 2.8 kb (BSMV-ND18 strain), 3.9, 3.6 and 3.2 kb (PSLV) and 3.7, 3.1 and 2.6 kb (LRSV), respectively. The sizes of RNAs α and β are quite constant among the different strains of BSMV examined to date, however RNA γ varies in size between strains. The BSMV type strain is 3.2 kb compared to 2.8 kb in the ND18 strain, and the Argentina Mild strain contains mixtures of RNA γ species of 3.2, 2.8 and 2.6 kb. The 2.6 kb RNA is defective as the result of a deletion in the 3′ terminus of the γa gene. Each of the RNAs has a 7-methylguanosine cap at the 5′ terminus and a conserved 3′ terminal nontranslated sequence. The conserved 3′ termini are variable in length between the different viruses, ranging from 148 nt (LRSV) to 330 nt (PSLV). The sequences form tRNA-like structures which in BSMV are capable of binding tyrosine *in vitro*. Directly upstream of the conserved termini in the BSMV and LRSV genomes is an internal poly(A) sequence of varying length that is located directly following the stop codon of the 3′ proximal gene of each RNA. This poly(A) sequence is absent in the PSLV genome.

Hordeivirus genomes (**Fig. 1**, BSMV) have a number of structural differences that distinguish them from brome mosaic virus, alfalfa mosaic virus, cucumber mosaic virus, and other tricornaviruses. A major difference is that hordeiviruses encode seven rather than four proteins. The α RNAs of all three hordeiviruses encode a single protein (αa) that contains methyltransferase and helicase domains that are highly conserved between Sindbis-like viruses. The γ RNAs encode two proteins, the polymerase (γa) and a cysteine-rich protein (γb). The γa proteins contain the conserved GDD found in RNA-dependent RNA polymerase proteins of RNA viruses. The γa proteins are members of the tobamo-lineage of supergroup III of RNA-dependent RNA polymerases that also includes tricornaviruses, tobacco mosaic virus (TMV), and the furovirus, soil borne wheat mosaic virus (SBWMV). The γb proteins share some structural similarities, but show no direct amino acid sequence homology with the cysteine-rich proteins of tobra and carlaviruses. The organization of the genes on RNAβ are quite distinct from those of the tricornaviruses. The first open reading frame (ORF) encodes the coat protein, and this ORF is followed by a series of overlapping genes termed the 'triple gene

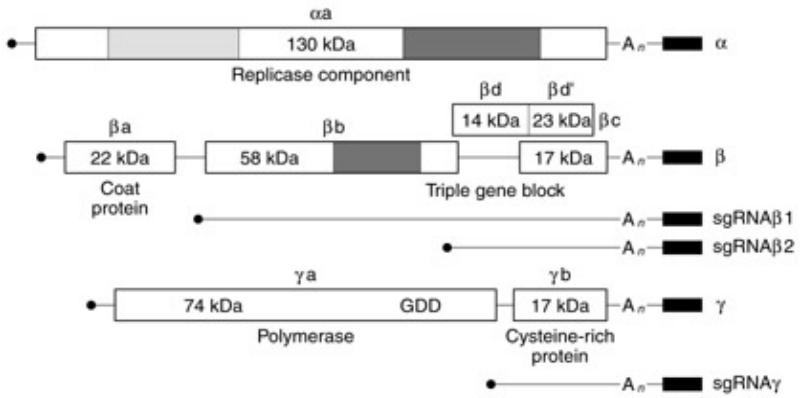

Figure 1 Genome organization of barley stripe mosaic virus. The filled circle, open rectangles and solid rectangles represent the 5′ cap structure, the open reading frames (ORFs) and the 3′ terminal 238 nt tRNA-like structure. The 3′ proximal ORFs of each RNA terminate with a UAA to initiate the short poly(A) sequence separating the 238 nt conserved 3′ termini from the coding region. RNAα encodes a single protein, αa, that is a replicase component and contains methyltransferase ( ) and helicase domains ( ). RNAβ encodes the coat protein (βa) and a series of overlapping genes (the triple gene block), that are separated by a 117 nt intergenic region. The βb and βc ORFs are separated by 173 nt and overlap the βd ORF. The βb protein is translated from a subgenomic (sg) RNA and contains a helicase domain ( ). The βd, βd', and βc proteins are all translated from one sgRNA. Translational readthrough of the βd stop codon occurs to yield the βd' protein. RNAγ encodes two proteins: the γa protein is the polymerase and contains the conserved GDD motif; the γb protein is translated from a sgRNA and is a cysteine-rich protein that has a role in gene expression and pathogenesis.

block' that are also present in carla-, furo-, and potexviruses. In hordeiviruses, the first ORF of the triple gene block encodes the βb protein. This protein contains a conserved helicase domain similar to the helicase domain present in the αa protein. The remaining two ORFs of the triple gene block encode the small hydrophobic proteins, βc and βd.

Molecular Biology

The availability of full-length cDNA clones and the subsequent generation of infectious transcripts has permitted analysis of the proteins encoded by the BSMV genome (**Fig. 1**). Only RNAs α and γ are required for replication in protoplasts, with the αa and γa proteins being essential subunits of the RNA-dependent RNA polymerase. The 17 kDa BSMV γb protein is a cysteine-rich protein that is expressed from a 737 nt subgenomic (sg) RNA. This protein is not strictly required for infectivity in plants, but it has an effect on pathogenicity and expression of the genes encoded by RNAβ. Null mutations in γb alter the symptom phenotype, and affect expression of both the βa and βb proteins.

The γb protein has been expressed and purified from *Escherichia coli* and shown to bind ssRNAs *in vitro*. By subcellular fractionation studies and localization of the γb protein as a fusion protein with the green fluorescence protein (GFP) in infected cells, the γb protein appears to be cytoplasmically localized. Genetic analyses show that changes in localization of the γb protein are correlated with distinct phenotypes in barley.

The 22 kDa BSMV coat protein (βa) is expressed by direct translation of the genomic RNA. BSMV is unusual in that the coat protein is not required for infectivity in barley (a systemic host) or *Chenopodium* species (local lesion hosts) suggesting that the coat protein is not a major determinant in either cell-to-cell or systemic movement. Moreover, the infections elicited by coat protein-deficient BSMV mutants are more aggressive, and the phenotype is more severe and protracted in barley than in the presence of the coat protein. The triple gene block is responsible for cell-to-cell and systemic movement of the virus. The 5′ proximal gene of the BSMV triple gene block encodes the 58 kDa βb protein which is expressed from a 2.45 kb sgRNA. Genetic analyses have shown that βb is strictly required for cell-to-cell movement and it appears to function in part by RNA binding activities. The βb protein has been purified from infected plants and shown to bind ss- and dsRNA, nucleotide triphosphates (NTPs), and to exhibit ATPase activity *in vitro*. Helicase activity has not been detected in association with this protein *in vitro*. However, mutations in any one of the six conserved helicase domains prohibit cell-to-cell movement, demonstrating that this domain has an important function *in planta*. The βb protein appears to associate with membranes in infected cells, as

assessed by examination of the localization of a GFP:βb fusion protein. Viral RNA also associates with βb *in vivo*, because a βb:RNA complex can be recovered from infected tissue. The RNAs in this complex are BSMV specific and of genomic sense. Additional virus- or host-encoded proteins have not been detected in association with the complex.

The remaining genes of the triple gene block are expressed from a 960 nt sgRNA. The βc (17 kDa) and βd (14 kDa) proteins both contain two hydrophobic regions of amino acids separated by a hydrophilic stretch suggesting the presence of transmembrane domains. Each of these proteins is strictly required for cell-to-cell movement of the virus. The βd protein has been shown to be present in membrane fractions using subcellular fractionation. BSMV is unique among the triple gene block-containing viruses in that a fourth protein, βd′ (23 kDa), is encoded by the triple gene block. The βd′ protein is expressed as the result of a translational readthrough of the βd amber stop codon and is present in infected plants, but it is not required for cell-to-cell movement of the virus in barley or *Chenopodium* species.

Replication of each of the BSMV RNAs requires the 5′ and 3′ terminal regions, but different *cis*-elements are required for replication in the internal sequences. RNAα replication is *cis*-preferential, with replication appearing to be coupled with translation of a functional αa protein. Each of the genes on RNAβ is dispensable for replication, however the 117 nt intergenic region separating βa and βb has a *cis*-acting function. In contrast, RNAγ replication is not dependent on the 42 nt intergenic region separating γa and γb, but essential *cis*-acting elements are present in the first 507 nt of the γa gene.

Cytopathology

The cytopathology of the BSMV infection in cells is dependent on many different factors including the virus strain, the host, the timing of the infection and the environmental conditions. During an infection BSMV virions accumulate to high levels in the cytoplasm with a low number being present in the nucleus. The cytoplasmically localized virions do not tend to form crystalline inclusions as observed in TMV infections, but membranes often proliferate and large globular inclusions of unknown function are observed. Most of the visible changes in leaf appearance can be attributed to the disruption of organelles, most notably chloroplasts, in the rapidly expanding cells of the growing leaf. The morphology and shape of chloroplasts are altered during the infection; the grana become disorganized and numerous small vesicles appear between the inner and outer membranes of the chloroplast envelope.

Pathogenicity

Determinants of BSMV pathogenicity have been mapped to different areas of the genome. In *N. benthamiana*, the ND18 strain is able to cause a systemic infection whereas the Type strain is able to replicate and move in the inoculated leaf but is unable to invade systemically. This aberrant phenotype appears to be caused by the presence of a short ORF in the leader sequence preceding γa that reduces translation of γa. Infections with the ND18 or Type strains also result in different local lesion phenotypes on *Chenopodium amaranticolor*. These differences are complex, but are primarily due to expression of γa, the presence of an amino-terminal 372 nt duplication in the Type strain, and differences in amino acids of the γb proteins. The ND18 strain is nonpathogenic on oats whereas the CV42 strain is pathogenic. The ND18 strain phenotype may be the result of relatively simple associations of αa with a host protein, because pathogenicity to oats can be engineered by altering a single nucleotide resulting in an amino acid change in the αa protein.

Future Perspectives

Future emphasis needs to be placed on biochemical and genetic experiments to elucidate the functions and properties of the virus-encoded proteins. The isolation and characterization of the replicase complex will provide us with important information on hordeivirus replication and interaction with the cell. Host components associated with these complexes need to be identified and characterized to define their interactions. Additional cell biological analyses of the triple gene block-encoded proteins and their interactions with the plant cell are required in order to obtain a clearer understanding on how viruses move from cell-to-cell and through vascular tissue to cause systemic infections. These analyses will not only increase our understanding of how viruses move to establish infections in vegetative tissue, seed and pollen, but they may also provide important insights into subcellular transport and plasmodesmatal functions. Dissection of the interactions between virus-encoded proteins and host components will therefore provide a more detailed understanding of disease development and the host cell processes exploited during infection.

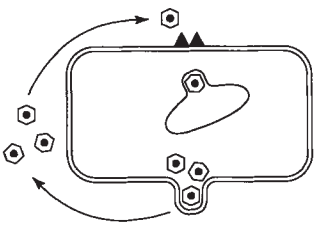
HOST GENETIC RESISTANCE

David G Brownstein, Yale University School of Medicine, New Haven, Connecticut, USA



History

Genetic diversity is maintained among individuals of any noninbred species in order to provide the raw material to adapt to evolutionary forces. Although the species as a whole benefits from this diversity, individuals may not. Individuals may inherit certain genes or gene combinations that make them unusually susceptible to specific infectious or noninfectious diseases. In genetic terms, alleles, or alternative forms of the same gene, are the basis of variations in genetic resistance to diseases whether these variations are controlled by single or multiple loci. Developments in many fields but especially molecular genetics have facilitated the characterization of genes with multiple alleles that regulate disease resistance. Those polymorphous genes that regulate resistance to viral diseases are the subject of this entry.

In 1933, Webster was the first to observe that resistance to a disease caused by a virus could be inherited. The virus was yellow fever and the host was the laboratory mouse. He crossed strains of mice that were resistant and susceptible to the lethal effects of yellow fever virus and showed that segregant progeny expressed resistance according to predictions of Mendelian genetics. Other examples of genetic resistance in mice to what were then termed arboviruses were soon to follow. Today, polymorphous genes that regulate resistance to 11 genera of viruses have been reported.

Experimental results using laboratory mice needed corroboration in a natural population of another species. This came in the 1950s when the highly virulent myxoma virus was introduced into wild European rabbits in Australia to control burgeoning lagomorph populations. Although numerous factors conspired to attenuate initially high mortality rates, selection for resistant host genes was clearly an important factor. In humans, attempts to associate the severity of smallpox, poliomyelitis, congenital rubella and hepatitis B with various blood group and major histocompatibility antigens met with limited success. An impetus for this line of inquiry in humans came with Allison's discovery in 1964 of the relationship between resistance to falciparum malaria and heterozygosity of the sickle cell gene. Although this work did not deal with a viral infection, it established that genetic polymorphisms in humans regulate resistance to at least one microbial disease.

To date, the most systematic approach to the study of relationships between the severity of viral diseases and specific host genes remains comparisons of highly inbred strains of mice that vary in their susceptibility to a particular disease. Derivatives of resistant and susceptible strains such as bilineal congenic and recombinant inbred strains have been especially valuable in these studies. What has emerged from them is confirmation that polymorphous host genes are important regulators of the severity of many if not most viral infections, that single or multiple loci are involved, and that each locus appears to specify resistance to a particular genus of virus, or even a specific strain of virus within a genus. These studies have also shown that polymorphisms within the

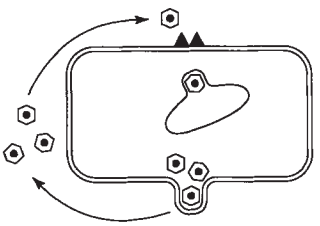
HOST GENETIC RESISTANCE

David G Brownstein, Yale University School of Medicine, New Haven, Connecticut, USA



History

Genetic diversity is maintained among individuals of any noninbred species in order to provide the raw material to adapt to evolutionary forces. Although the species as a whole benefits from this diversity, individuals may not. Individuals may inherit certain genes or gene combinations that make them unusually susceptible to specific infectious or noninfectious diseases. In genetic terms, alleles, or alternative forms of the same gene, are the basis of variations in genetic resistance to diseases whether these variations are controlled by single or multiple loci. Developments in many fields but especially molecular genetics have facilitated the characterization of genes with multiple alleles that regulate disease resistance. Those polymorphous genes that regulate resistance to viral diseases are the subject of this entry.

In 1933, Webster was the first to observe that resistance to a disease caused by a virus could be inherited. The virus was yellow fever and the host was the laboratory mouse. He crossed strains of mice that were resistant and susceptible to the lethal effects of yellow fever virus and showed that segregant progeny expressed resistance according to predictions of Mendelian genetics. Other examples of genetic resistance in mice to what were then termed arboviruses were soon to follow. Today, polymorphous genes that regulate resistance to 11 genera of viruses have been reported.

Experimental results using laboratory mice needed corroboration in a natural population of another species. This came in the 1950s when the highly virulent myxoma virus was introduced into wild European rabbits in Australia to control burgeoning lagomorph populations. Although numerous factors conspired to attenuate initially high mortality rates, selection for resistant host genes was clearly an important factor. In humans, attempts to associate the severity of smallpox, poliomyelitis, congenital rubella and hepatitis B with various blood group and major histocompatibility antigens met with limited success. An impetus for this line of inquiry in humans came with Allison's discovery in 1964 of the relationship between resistance to falciparum malaria and heterozygosity of the sickle cell gene. Although this work did not deal with a viral infection, it established that genetic polymorphisms in humans regulate resistance to at least one microbial disease.

To date, the most systematic approach to the study of relationships between the severity of viral diseases and specific host genes remains comparisons of highly inbred strains of mice that vary in their susceptibility to a particular disease. Derivatives of resistant and susceptible strains such as bilineal congenic and recombinant inbred strains have been especially valuable in these studies. What has emerged from them is confirmation that polymorphous host genes are important regulators of the severity of many if not most viral infections, that single or multiple loci are involved, and that each locus appears to specify resistance to a particular genus of virus, or even a specific strain of virus within a genus. These studies have also shown that polymorphisms within the

major histocompatibility complex (MHC) may influence the course of viral infections, but that loci outside of the MHC are often more important.

During the past several years a number of viral disease resistance genes have been identified. In some cases their protein products or their mechanisms of action are known. In other cases their protein products and their functions are unknown but as they become more precisely mapped and eventually cloned 'reverse genetics' can be used to delineate their functions. Substantial homology between the murine and human genomes makes it possible to identify similar genetic resistance elements in humans. This has already been done for the *Mx1* locus on mouse chromosome 16 and human chromosome 21 which regulates susceptibility to influenza A and B viruses. The resistance loci that have been provisionally or definitively mapped are discussed here since this represents the most substantial progress in recent years (**Table 1**).

General Considerations

Viruses rely heavily upon products of host genes for their replication. Beginning with their interaction with host-encoded cell surface receptors and host factors involved in uncoating, continuing with their use of host transcription and translation factors, and ending with host-encoded post-translational enzymes, viruses require multiple products of host genes. The specific viral requirements differ depending on the replication strategy of the virus. In addition, viruses elicit protective responses in the host that are ultimately orchestrated by the host genome and these responses also vary depending on the virus. Any of these multiple points of interaction between the virus and products of the host genome have the potential to be sources of variation if alleles exist at these points within the host population and if the products of these alleles interact differently with the viral genome or its products.

Polymorphous resistance genes may therefore be expressed at the level of the target cells if they control proteins that are necessary for virus replication or at the organismal level if they regulate antiviral effector mechanisms. The effects of the former can usually be demonstrated in primary cultures of target cells from genetically resistant and susceptible hosts because they are expressed at the cellular level. The effects of the latter cannot usually be demonstrated in pure populations of target cells in culture because they involve cell interactions which are orchestrated at the organismal level. There is at least one exception to this organizational paradigm, however, and that is the antiviral state that is induced in target cells by interferons. In this case, target cells express proteins, now numbering about 24, that inhibit rather than promote virus replication. Polymorphous resistance genes can be classified as follows based on their organizational level of expression and whether they are induced by the infection or are constitutively expressed:

1. Genes expressed at the target cell level:
   a. constitutive expression – these genes regulate proteins that are necessary for virus replication;
   b. inducible expression – these genes regulate interferon-dependent proteins.
2. Genes expressed at the organismal level: these genes regulate antiviral effector mechanisms.

Resistance Genes Constitutively Expressed in Target Cells

Two resistance genes listed in **Table 1** are constitutively expressed in target cells. These are the *H-2D* gene that controls resistance to the lethal effects of mouse cytomegalovirus (MCMV) infection and the *Hv-2* locus that regulates susceptibility to acute mortality caused by mouse hepatitis virus type 4 (MHV4).

Inbred strains of mice that carry the MHC $H\text{-}2^k$ haplotype are among the most resistant to acute mortality caused by MCMV, a herpesvirus. Mice that carry the $H\text{-}2^d$ or $H\text{-}2^b$ haplotypes are 10 times more susceptible to lethal cytomegalovirus infection and permit significantly more virus replication than mice of the same genetic background that carry the $H\text{-}2^k$ haplotype. This difference is determined by the class I gene, *H-2D*. Products of class I MHC genes are important in cellular immune responses. Class I antigens are expressed by a wide variety of cells and serve as recognition molecules for specific classes of T cells. In the case of cytomegalovirus infection, however, the role of *H-2D* in genetic resistance is independent of its role in immune recognition. Cells from $H\text{-}2D^k$ mice are highly insensitive to infection with MCMV. Class I heavy-chain antigens are covalently bound to a second cell surface antigen, β_2-microglobulin, which is believed to serve as a cytomegalovirus receptor. The *H-2D* antigen is therefore directly involved with virus binding or it regulates the affinity of β_2-microglobulin for the virus antireceptor. In the case of $H\text{-}2D^k$ antigen the affinity of mouse cytomegalovirus for β_2-microglobulin is markedly reduced.

The *Hv-2* locus controls susceptibility of mice to the lethal effects of MHV4, a coronavirus. Like *H-2D* in the MCMV system, its effects are readily seen in

infected cells in primary cultures. The mechanism of action of *Hv-2* is currently disputed. Only one strain of mouse, SJL, is known to carry the *Hv-2*^{r} allele. Mendelian genetics of resistance to the lethal effects of MHV4 in crosses between SJL and various susceptible strains indicate that one gene controls resistance. It has been shown that SJL mice fail to express a 110K cell surface glycoprotein that binds MHV4, whereas susceptible strains of mice do. These data suggest that *Hv-2* encodes the viral receptor. *Hv-2* was defined on the basis of differences in the replication of MHV4 in macrophages from resistant and susceptible mice. In macrophages from *Hv-2*^{r} and *Hv-2*^{s} mice, the virus replication diverges at a point after the virus is internalized and after transcription of viral genes. This suggests that *Hv-2* does not encode the virus receptor but a protein that functions subsequent to binding. There is evidence that *Hv-2* encodes the host protease that activates the viral S glycoprotein which serves as the antireceptor. This virus–host interaction is necessary for the infection to spread and could explain why the infection fails to spread in macrophage cultures from *Hv-2*^{r} mice.

Resistance Genes Inducible in Target Cells

The single example of this class of resistance gene is *Mx1* which regulates resistance to diseases caused by influenza A and B viruses. This is the most thoroughly examined resistance gene, having been mapped, cloned and sequenced. Its protein product is known although the exact mechanism whereby it inhibits influenza virus replication has not been determined. Its inhibitory action occurs after virus uncoating and before translation. *Mx1* is an interferon-inducible nuclear protein with an M_r of 72000. Interferons α and β but not γ induce the synthesis of *Mx1*$^+$ mRNA. Most laboratory strains of mice have deletion or point mutations in the *Mx1* gene resulting in a potential coding capacity for the inactive N-terminal half of the *Mx1* protein only.

Resistance Genes Expressed Through Host Antiviral Effectors

Five of the genes listed in **Table 1** are expressed at the organismal level through antiviral effectors. All of these examples are believed to regulate specific immune responses that are involved in virus clearance or in immunopathic injury. Four of these genes regulate susceptibility to Theiler's mouse encephalomyelitis virus (TMEV), a picornavirus. Mice that are inoculated intracerebrally with certain laboratory-adapted strains of TMEV may develop one of several diseases, depending on their genotype. The most intensively studied disease occurs after the acute phase of infection and is characterized by progressive paralysis in association with chronic demyelination of the central nervous system. This disease is immunologically mediated and is associated with viral persistence in the white matter oligodendrocytes and infiltrating macrophages. The genes that mediate susceptibility to viral persistence and myelin breakdown in this system vary with the strain of mouse. In susceptible DBA/2 mice, demyelination is mediated by the *H-2D*^{d} allele of the MHC and a second allele at a locus near the *Car-2* gene on chromosome 3. In susceptible SJL mice, disease is mediated by an allele on a gene located near the structural gene for the T cell receptor β-chain constant region on chromosome 6. The *H-2D*^{s} allele of the MHC of SJL mice also appears to mediate susceptibility in SJL mice but its effects have not been seen in all studies.

All mice that are susceptible to paralytic TMEV infection share augmented delayed-type hypersensitivity responses to the virus when compared to resistant mice. Their susceptibility is therefore believed to result from inappropriate cell-mediated immune responses to the virus which allow it to persist and which mediate tissue injury. Consistent with this interpretation is the fact that most of these loci map to regions that are known to regulate immune responses. The localization of one gene to the vicinity of the T cell receptor β-chain structural gene is of special interest because the T cell receptor repertoire has been implicated as an etiology in certain autoimmune diseases.

Another example of an inappropriate immune response underlying genetic susceptibility to a virus-induced disease is that which occurs after infection with coxsackievirus B3 (CVB3). In this case, however, the immune response that is triggered by the infection is not directed at the virus, but rather at a host protein in the tissue where the virus replicates.

CVB3 is a common cause of infectious myocarditis in humans. CVB3 causes acute and chronic myocarditis in inbred mice depending on the strain of mice. The chronic myocarditis results from an autoimmune response to cardiac myosin that is triggered by viral replication in and injury to the heart of susceptible mice. Both *H-2*-linked and non-*H-2*-linked genes control susceptibility to chronic myocarditis. One form of the disease is mediated by IgG antibodies specific for cardiac myosin. This form is seen in DBA/2 and A mice and is modulated by a gene that is located on chromosome 14 in the vicinity of structural loci for the T cell receptor α-chain and the cardiac myosin α-heavy chain. Associations between the T cell receptor repertoire and autoimmune

diseases has been previously mentioned in the context of TMEV-induced chronic demyelination. The possibility that allelic differences in cardiac myosin may account for the observed chromosomal localization of the susceptibility gene is also being considered. However, the susceptible phenotype has been shown to correlate with susceptibility to autoimmune myocarditis after immunization with cardiac myosin, suggesting that allelic differences in cardiac myosin are not the basis of susceptibility.

Resistance Genes Expressed Through Unknown Mechanisms

Seven of the genes listed in **Table 1** exert their effects through unknown mechanisms. Five of these are linked to the MHC and six regulate susceptibility to acute viral diseases. The associations with the MHC suggest that some of these genes regulate specific immune responses. However, the temporal divergence of phenotypes of mice with resistance and susceptibility alleles for some of these genes occurs before effects of specific immune mechanisms are likely. For this reason the *H-2*-linked genes that regulate susceptibility to acute effects of ectromelia virus (mouse-pox), CVB3 and MHV are more likely to be expressed through early, nonspecific effectors than through specific immune responses. These early effectors include activated natural killer cells, interferon and acute-phase reactants.

There is evidence that *Cmv-1,* which regulates resistance to the lethal effects of MCMV, is expressed through the early inflammatory response. This gene limits virus replication, prevents virus-induced splenic necrosis within 72h of infection, and appears to be expressed at the organismal level. Allelic differences at this locus are correlated with differences in the phenotypic character of the early inflammatory infiltrate. There is preliminary evidence that resistance to the lethal effects of ectromelia virus, an orthopoxvirus is regulated by a gene (not among the two listed in **Table 1**) that maps to the same region of mouse chromosome 6 as *Cmv-1*. Other similarities between these two loci are that they are expressed in the spleen, they regulate virus-induced splenic necrosis, they regulate the influx of cells into the spleen or the proliferation of cells already present, and their resistance alleles are expressed by the same strains of mice. Should these turn out to be the same locus, it would be the first example of a polymorphous gene active against more than one genus of virus.

Future Perspectives

Genetically determined variations in responses to viral infections are important determinants of disease severity in all species, including humans. The difficulty in identifying modifying genes directly in genetically heterogeneous populations has retarded efforts to identify such loci in humans. The continuing success in identifying these genes in mice and the extensive genetic homology between mice and humans provides a means for identifying resistance genes for specific viruses in humans. In some cases, allelic differences at these loci will modulate the severity of human viral illnesses as they do in mice. A thorough understanding of how these polymorphisms modulate viral infections will lead to more enlightened approaches to the therapy of viral diseases and the identification of individuals at risk to develop serious sequelae.

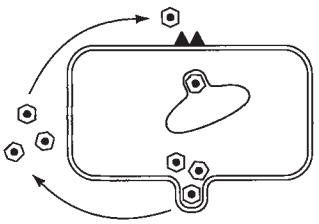
HOST-CONTROLLED MODIFICATION AND RESTRICTION



Detlev H Krüger and **Monika Reuter**, Humboldt University, Charité School of Medicine, Institute of Medical Virology, Berlin, Germany

Introduction

The application of restriction endonucleases has revolutionized molecular biological research. As so often was the case, studies on bacterial viruses led to the discovery of this class of enzymes. At the beginning of the 1950s, the observation was noted that phages 'remember' the last host strain in which they reproduced. Depending on the host cell, the virus carries a specific modification which usually improves its ability to grow on the same host in subsequent rounds of infection, while impairing its growth in others. Host-controlled modification results in a reversible phenotype, clearly distinguishable from irreversible mutational changes in host range (**Fig. 1**).

The molecular explanation of these phenomena (first demonstrated for phage lambda and P2) was elaborated in the 1960s and 1970s by groups of Arber, Smith, Meselson and others. Host-controlled modification consists of a specific DNA methylation at a defined recognition sequence of 4–8 bp. Restriction is caused by DNA cleavage occurring at an unmethylated recognition site. Pairs of corresponding DNA methylases and restriction endonucleases (i.e. recognizing the same DNA sequence) coded by *hsd* genes (*h*ost *s*pecificity of *D*NA) in bacterial cells are responsible for these activities. During DNA replication, recognition sequences in nascent daughter strands are transiently unmethylated. Such hemimethylated sites are preferential substrates for DNA methylases, while sites unmethylated in both strands are primary targets of restriction endonucleases and are very rarely methylated.

DNA modification consists of a C-5 or N-4 methylation of cytosine or in an N-6 methylation of adenine in the recognition sequence. *S*-Adenosylmethionine (AdoMet) functions as methyl donor. DNA restriction results in fragments with cohesive or blunt ends that are further degraded intracellularly by other nucleases, in particular by the *rec*BCD (=*exo*V) enzyme.

Classes of Modification/Restriction (M/R) Systems in Prokaryotes

M/R enzymes are coded by chromosomal, prophage or plasmid genes and are classified into at least three groups (type I, II and III) according to their properties. The types of M/R systems differ in the organization of the genes encoding them, the complexity of their supramolecular structure, their cofactor requirements, the symmetry of the recognized base sequence and in the location of the cleavage site within or outside of the recognition sequence (**Table 1**).

Type I enzymes are hetero-oligomers composed of three subunits (HsdR, endonuclease; HsdM, methylase; HsdS, DNA recognition). Restriction requires

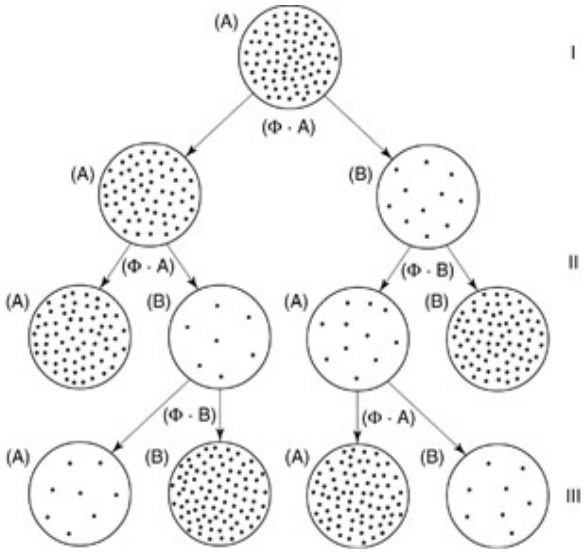


Figure 1 Scheme for the demonstration of host-controlled modification and restriction of a virus Φ. (I) Isolation of a single plaque from cell lawn A (Φ · A) and parallel infection of cell strains A and B with the same virus population. Virus Φ · A is restricted on B (less virus plaques than on strain A). (II) Passage of the virus from the cell strains A or B to both strains. (III) The reversibility of modification proves that Φ · B from the second transfer is not a host range mutant, but a modified virus. When one of the cell strains is restriction and modification negative, the reversibly changeable growth of the virus is only manifest on the other cell strain; plating on the first one is not altered. In the figure the efficiency of restriction is about tenfold; that is, the virus titer on the restriction-proficient host is about 10^{-1} of that on the nonrestricting host. Measured efficiencies vary with the phage and restriction system from barely detectable to about 10^{-5}. (Adapted from Krüger DH and Bickle TA (1983) *Microbiol. Rev.* 47: 345–360.)

Table 1 Distinguishing properties of different types of restriction enzymes

Type	*Structural features of proteins and genes*	*Cofactors*	*DNA cleavage*	*Example*	*DNA recognition sequence*[a]
I	Multifunctional, multisubunit; three structural genes	Mg^{2+}, ATP, AdoMet	Cut randomly, far from asymmetric recognition sites, need two copies of recognition sequence, ATP hydrolysis	*Eco*B	5′-TGA*(N$_8$)TGCT 3′-ACT(N$_8$)$_{\star}$ACGA
II	Separate enzymes for restriction and modification; two structural genes	Mg^{2+}	Cut at fixed positions within symmetric recognition sites	*Eco*RI	5′-GA*ATTC 3′-CTT$_{\star}$AAG
IIE	Like type II	Mg^{2+}	Like type II, but need two copies of recognition sequence for functional interaction, activable by effector oligonucleotides containing the site	*Eco*RII	5′-C*C(A/T)GG 3′-GG(T/A)$_{\star}$CC
IIS	Like type II (sometimes three structural genes)	Mg^{2+}	Cut at fixed distance from asymmetric recognition sites	*Fok*I	5′-GGA*TG (N$_9$) 3′-CCT$_{\star}$AC (N$_{13}$)
*Bcg*I-like	Two structural genes; bifunctional; multisubunit	Mg^{2+}, AdoMet	Cut DNA at defined distances, on both sides of the recognition sequence	*Bcg*I	(N$_{10}$)CGA*(N$_6$)TGC(N$_{12}$) (N$_{12}$)GCT(N$_6$)$_{\star}$ACG(N$_{10}$)
McrBC	Several subunits and genes, no modification enzymes	Mg^{2+}, GTP	Cut DNA with modified C residues at different positions between the two R^{m}C sites	McrBC	5′-R^{m}C(N$_{40-2000}$)R^{m}C
III	Multifunctional, multisubunit; two structural genes	Mg^{2+}, ATP (AdoMet)	As type IIS, need functional interaction of two inversely oriented recognition sites, ATP hydrolysis	*Eco*P15	5′-CAGCA*G(N$_{25}$) 3′-GTCGTC(N$_{27}$)

[a] Nucleotides methylated by the cognate DNA methylase are indicated by asterisks. Strings of unspecified nucleotides are designated (N$_x$), where x specifies the number of nucleotides. R is G or A, ^{m}C is 5-methylcytosine, N^4-methylcytosine or 5-hydroxymethylcytosine.

AdoMet as an allosteric cofactor, as well as ATP. The enzymes recognize asymmetrical sequences interrupted by unspecific spacers of 6–8 bp. DNA cleavage does not occur within the recognition sequence but at a (sometimes very great) distance from it, up to several kilobase-pairs away. After binding to a nonmethylated recognition sequence the enzyme complex starts to translocate DNA on both sides of the recognition site. As soon as it meets a second enzyme complex, the DNA is cut. DNA translocation and scission are accompanied by extensive ATP hydrolysis.

Type II restriction enzymes are extensively exploited in gene technology. Meanwhile more than 2500 enzymes have been isolated, exhibiting more than 200 different DNA sequence specificities. Their usually palindromic recognition sequences encompassing 4–8 bp may also include unspecific spacer sequences. Normally, recognition and cleavage sites are identical. The recognition sequences for subclass IIS enzymes are asymmetric and the cleavage occurs outside the site with a short defined distance of 1–20 nucleotides. The cofactor requirements of type II enzymes are limited to bivalent cations (mostly Mg^{2+}). Restriction endonuclease and modification methylase are distinct molecules.

Similar to type I, type III and McrBC enzymes (**Table 1**), there are a few type II restriction endonucleases (called IIE, where 'E' stands for effector) which need simultaneous recognition of two copies of the specific DNA sequence to form an endonucleolytically active enzyme–substrate complex. For IIE enzymes, however, the second (effector) DNA site can be supplied as an oligonucleotide duplex resulting in a functional interaction of the enzyme with two DNA sites 'in trans'. The requirement of type IIE enzymes for simultaneous interaction with two DNA sites resembles that of proteins mediating site-specific recombination and transposition. Future investigations will show whether these restriction endonucleases provide other biological functions besides restriction of foreign DNA. In addition, the special mode of action of type IIE enzymes may represent a safety mechanism to avoid suicidal restriction of cell-own DNA: necessity of two unmodified sites for DNA scission makes it less likely that the enzyme will attack the rare unmodified sites in the cellular DNA occasionally arising after DNA repair or incomplete methylation.

Only a handful of type III systems have been discovered. Their properties are somewhere in between those of type I and type II enzymes. The molecules are composed of two forms of subunits (endonuclease units and methylase-recognition units). AdoMet stimulates the ATP-dependent nuclease. Recognition sequences of type III enzymes are nonsymmetrical, consisting of 5–6 bp, only one strand of which can be methylated. While each individual unmethylated site represents a substrate for DNA methylation, for DNA restriction the presence of two inversely oriented unmethylated recognition sites is essential.

M/R systems of different DNA specificities have been found to coexist within individual cells of various bacterial species. On the other hand, enzymes acting on identical recognition sequences (iso- and neoschizomers) can be isolated from diverse species.

Biological Functions

The biological significance of M/R systems lies in the destruction of invading foreign DNA while providing protection of self-DNA against suicidal degradation, as has been proven for type I and III systems and for a few representatives of type II. Most type II enzymes have been characterized solely with regard to their use in genetic engineering, and the question of biological relevance has largely been ignored so far.

Obviously, DNA restriction reduces the efficiency with which new genetic material can be introduced into a bacterial cell. This does not only relate to bacteriophage infection but, in certain hosts, also to processes like DNA conjugation and transformation. This is why strains impaired in DNA restriction are the preferred recipients of gene transfer.

Bacteriophage pose the greatest threat to bacteria *in vivo*. Efficient though not absolute protection against viral infection provides the cells with an evolutionary advantage. The perpetual conflict between bacterial and phage populations probably produces the pressure for the development and maintenance of M/R systems. The specificity of individual M/R systems can be altered mutationally or by recombination, and new M/R genes can be acquired by conjugation, transformation or transduction.

Evolutionary and functional links between M/R and cellular recombination systems are suggested by similarities of some of the enzymes involved.

Antirestriction by Bacterial Viruses

Under the pressure of host cell M/R systems, bacterial viruses have evolved a multitude of mechanisms allowing them to escape DNA restriction. Most of these mechanisms act quite specifically against certain M/R systems.

Virus-encoded inhibitory proteins can bind to and inactivate restriction endonucleases. This has been

described for the Ocr protein of bacteriophage T3 and T7 (which can be exploited to prevent the restriction of foreign DNA in experimental gene transfer) and for certain proteins of bacillusphage.

Other bacillusphage and T-even phage encode their own methyltransferases with specificities corresponding to those of restriction enzymes of certain hosts. In addition, the incorporation of unusual bases into viral DNA (this occurs in several bacillusphage as well as in T-even phage containing hydroxymethylcytosine (HMC) instead of cytosine) or specific postsynthetic modifications of DNA bases (formation of N^6-1-acetimidoadenine in phage Mu) can mitigate the effects of certain restriction endonucleases.

Bacterial viruses like P1 protect their genomes by co-injecting internal phage proteins with their DNA. The degradation of cofactors of restriction (and modification) is a further mechanism, exemplified by phage T3 AdoMet hydrolase.

For some phage genomes, counterselection of recognition sequences of potential M/R systems has been demonstrated. The DNA is not merely protected by lack of sites but also by a disposition of sites that thwarts the reaction mechanism of the restriction endonuclease. The type II restriction enzyme *Eco*RII requires two functionally cooperating sites for restriction; T3 DNA is not cleaved because its *Eco*RII sites are too far apart. The type III endonuclease *Eco*P15 can only cleave at a pair of (nonsymmetrical) recognition sites inversely oriented in the DNA double strand; the genome of phage T7 contains all its 36 recognition sites in the same orientation and is therefore resistant to cleavage.

There are additional mechanisms that are not effective in protecting the primary infecting phage DNA but do prevent restriction of progeny and superinfecting phage respectively: the *ral* function of phage λ and the *arn* function of phage T4 (directed against Rgl, see below).

Restriction of Nonglucosylated HMC-containing DNA

It has been known for a long time that the DNA of T-even phage previously grown in host cells with impaired sugar metabolism is attacked by a specific restriction system. These viruses possess HMC instead of cytosine in their DNA. This unusual base protects the genome against virus-encoded nucleases that degrade the host chromosome during virus replication, as well as against some restriction enzymes of the host. However, certain *Escherichia coli* strains have developed nuclease systems specific for HMC-containing DNA (Rgl = *r*estriction of non*gl*ucosylated DNA). The phage, in turn, protects itself against Rgl by glucosylation of HMC, catalyzed by phage-encoded glucosyltransferases. When glucosylation is blocked, e.g. by lack of sugar precursors, the phage DNA in such cells (e.g. in the Gal^- strain *E. coli* $B/4_0$) remains unglucosylated and is degraded during the next round of infection of an Rgl^+ host.

Differences between the Hsd and the Rgl systems are also evident in the phenotypic behavior of phages on passage over different host strains (**Table 2**). The Hsd system relies on the 'classical' principle: one reproductive cycle on a restrictive strain (Res^+Mod^+) leads to adaptation (modification) of the few surviving phages, which are then capable of high replication rates on subsequent infection of this host. This does not in every case apply to the Rgl system; replication of T2 in Gal^- *E. coli* $B/4_0$ cells does not improve the growth of the virus in the next infectious cycle, since the HMC-containing DNA remains unglucosylated.

While the existence of Hsd restriction-proficient but modification-deficient hosts is ruled out due to suicidal degradation of the host chromosome, this constellation does occur in the Rgl system because the host chromosome does not contain HMC and is therefore susceptible to neither modification (glucosylation) nor restriction (**Table 2**).

Methylation-dependent DNA Restriction

Typically, methylation of a given DNA recognition sequence protects it against cleavage by the restriction enzyme of this specificity. But there are also restriction enzymes where cleavage is triggered by methylation. Their best known representative is *Dpn*I from *Streptococcus pneumoniae*, which only cleaves its recognition sequence 5′-GATC when the adenines in both strands are methylated.

Attention has recently been focused on defense systems of *E. coli* which attack incoming methylated DNA. The McrA and McrBC systems (*m*ethylated *c*ytosine *r*estriction) as well as the Mrr system (*m*ethylated adenine *r*ecognition and *r*estriction) interfere with efficient cloning and expression of certain DNA methylase genes. The Mcr systems also destroy cloned C-methylated DNA of eukaryotic origin.

Up to now little is known about the Mrr- and Mcr-dependent enzymes. They are apparently less sequence specific than the other M/R enzymes. However, it became clear that the Mcr systems are equivalent to the earlier described Rgl systems. These restriction systems are targeted to modified DNA cytosine, be it 5-hydroxymethylcytosine, 5-methylcytosine or N^4-methylcytosine (for McrBC, see also **Table 1**).

Table 2 Examples of phenotypical M/R of phage by the Hsd and Rgl restriction systems

Host system	*Phage last grown on*	*Relative efficiency of plating on host strain*[a,b]		
		E. coli B R.*Eco*B$^+$ M.*Eco*B$^+$	*E. coli* K-12 R.*Eco*K$^+$ M.*Eco*K$^+$	*E. coli* C R.*Eco*B$^-$K$^-$ M.*Eco*B$^-$K$^-$
Hsd	$\lambda \cdot$ B	1	5×10^{-4}	1
	$\lambda \cdot$ K	10^{-4}	1	1
	$\lambda \cdot$ C	10^{-4}	5×10^{-4}	1
	$\lambda \cdot$ C · B	1	5×10^{-4}	1
		E. coli B Rgl$^+$ Gal$^+$	*Shigella dysenteriae* SH Rgl$^-$ Gal$^+$	*E. coli* B/4$_0$ Rgl$^+$ Gal$^-$
Rgl	T2 · B	1	1	1
	T2 · SH	1	1	1
	T2 · B/4$_0$	10^{-3}	1	10^{-3}
	T2 · B/4$_0$ · SH	1	1	1

[a] Abbreviations: Hsd, host specificity of DNA; R, restriction endonuclease; M, modification methylase; Rgl, restriction of nonglucosylated DNA; Gal, DNA glucosylation capability.

Further Functions of DNA Methylation in Prokaryotic Cells

Not every methylation of prokaryotic DNA is functionally related to processes of DNA restriction, i.e. by either protecting against, or itself triggering, the cleavage activity of restriction endonucleases. The methylases M.dam (for *D*NA *a*denine *m*ethylation) and M.dcm (for *D*NA *c*ytosine *m*ethylation) occur in *E. coli*. They catalyze the conversion of adenine in the recognition sequence 5′-GATC to 6-methylaminopurine, or of the internal cytosine in the recognition sequence 5′-CC(A/T)GG to 5-methylcytosine, although there are no functionally corresponding restriction enzymes in these cells.

Meanwhile, several functions of M.dam- and M.dcm-specific methylations have been identified. Dam methylation plays a crucial role in DNA repair, specifically in proofreading of nascent DNA. Since methylation of daughter strands lags behind their synthesis, methylase recognition sequences are hemimethylated for a short time, allowing repair enzymes to distinguish between the two strands and correct errors guided by the parental DNA strand.

The methylation of promoter regions can influence gene expression, an effect first described for certain eukaryotic cells and their viruses (see below). The relation between Dam methylation and control of expression of a phage gene is exemplified by the *mom* gene of phage Mu. The gene is only expressed when its promoter is methylated. Since promoters of transposase genes can be methylation-dependent, DNA methylation may also influence DNA transposition.

In several cases where the *ori* region contains M.dam sites (e.g. in *E. coli*, various plasmids and phage P1), primary initiation of DNA replication is regulated via DNA methylation. Packaging of P1 DNA during morphogenesis is also supposed to be dependent on the methylation of certain sequences in the viral *pac* locus. In some cases, phase variation of pilus expression is controlled by Dam methylation in *E. coli* cells.

Just as sequence-specific DNA methylation is not necessarily connected to M/R systems, neither is sequence-specific DNA cleavage (e.g. integration and excision of the λ genome).

Nonclassical Modification and Restriction of Pro- and Eukaryotic Viruses

Phenotypic modification and restriction can also be the consequence of molecular processes not directly involving the DNA but rather certain viral proteins. They were termed 'nonclassical' to distinguish them from the 'classical', purely DNA-based mechanisms.

In nonclassical M/R, which was first described for phage T3, the ability of a phage to adsorb to a given host cell is affected by the prior host strain. Representatives of the genetically unaltered virus varying in their adsorption-protein modification also

differ serologically. The molecular mechanism has not been resolved yet.

In eukaryotic viruses so far all host cell adaptation is explained by the appearance and selection of viral mutants. It has, however, not been investigated whether phenotypic M/R processes of genetically unaltered viruses do also occur in the kingdom of eukaryotes, possibly explaining the occurrence of reversible changes in the host cell tropism of viruses.

DNA Methylation in Eukaryotic Viruses

There is no unequivocal evidence of the existence of DNA M/R systems in eukaryotic cells. Enzymes resembling pairs of DNA methyltransferases and restriction endonucleases are, however, encoded by viruses infecting eukaryotic algae (*Chlorella* spp.); their biological functions remain still unclear. Other viruses, like Frog virus 3 and lymphocystis disease virus (members of the family *Iridoviridae*), encode their own DNA methyltransferases, and their genomes carry high numbers of 5-methylcytosine residues. Functional consequences of the extensive methylation have to be further elucidated.

In the DNA of eukaryotic cells 5-methylcytosine is usually generated by cellular methyltransferase activities and mainly but not exclusively occurs in CpG dinucleotides. DNA methylation is known to be involved in processes like transcription inhibition, genomic imprinting, cell differentiation and dedifferentiation (carcinogenesis), and hypermutability. Furthermore, DNA methylation is assumed to silence transcription from integrated retroviral genomes, whereas demethylation results in the reactivation of the provirus. For some human pathogenic viruses, such as herpes simplex viruses, cytomegalovirus, Epstein–Barr virus or papillomaviruses, a role of DNA methylation in gene regulation has been demonstrated.

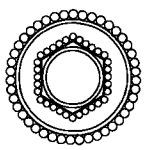
HUMAN IMMUNODEFICIENCY VIRUSES (*RETROVIRIDAE*)



Contents

General Features

Luc Montagnier, Institut Pasteur, Paris, France and Queens College, NY, USA

History

The infectious origin of acquired immunodeficiency syndrome (AIDS) was recognized soon after the identification of the disease itself in 1981. The first AIDS cases diagnosed in 1982 in hemophiliacs

production or perhaps in blocking apoptosis. An amino-terminus domain of Vpr is important for virion targeting and nuclear localization. A carboxyl-terminal domain is important for G2 arrest. Vpx is an additional ORF present in HIV-2 and related simian immunodeficiency virus strains. Vpx is also a virion protein but it does not induce G2 arrest.

vpu

The *v*irus *p*rotein *U* ORF encodes an 81 amino acids protein (Vpu). Vpu is expressed as part of a bicistronic message that also encodes the Env protein and is regulated by Rev. Vpu is a type I membrane protein with two well-described functions: degradation of CD4 in the endoplasmic reticulum and enhancement of virus release from the plasma membrane. The coordinated expression of Vpu and Env is important because CD4 degradation results in the release of Env from a complex with CD4 which otherwise would be retained in the endoplasmic reticulum. Therefore, Vpu expression in CD4+ cells would result in increased levels of Env at the site of particle assembly. A third function has also been described for Vpu, the ability to form a cation-selective ion channel. The role of this ion channel in Vpu activity is presently unknown.

nef

The protein product of the *nef* gene (Nef) was originally described as having a negative effect on virus replication and thus being a *ne*gative *f*actor hence the acronym. Subsequent *in vivo* and *in vitro* studies have shown that Nef has a positive effect on virus replication. The *nef* ORF encodes a 27–29 kDa protein. Nef is expressed from multiply spliced messages that are Rev independent and expressed at high levels early and throughout infection. Nef is myristoylated and phosphorylated in HIV-infected cells. Both post-translational modifications are important for function. Analysis by electron microscopy or immunofluorescence analysis indicates that Nef is found predominantly in the perinuclear region with a small fraction of Nef associated with the inner portion of the cell membrane. Biochemical analysis shows that a large proportion of Nef is associated with membranes through its N-terminus myristyl group. *In vitro* analysis indicates that Nef is a multifunctional protein. There are at least four reproducible functions for Nef: cell surface CD4 and major histocompatability complex (MHC) I downregulation, enhancement of particle infectivity, association with cellular serine/threonine kinases, and cellular activation. These functions of Nef contribute to the high level and efficient replication of HIV *in vivo*, but it is clear that the mechanisms of Nef action remain unknown.

Antiretroviral Agents

Ranga V Srinivas and **Arnold Fridland**, Department of Infectious Diseases, St Jude Children's Research Hospital, Memphis, Tennessee, USA

Introduction

This review attempts to give a brief overview of antiretroviral agents currently used in the control of HIV-1 infections. Compounds in development, as well as other viral targets for the development of potential new drugs are considered briefly. An overview of compounds targeted against various viral gene products is presented and issues that affect the pharmacological response of the various compounds are raised.

Human Immunodeficiency Virus (HIV) Genome and Viral Targets for Drug Development

The HIV genome encodes both structural genes, *gag*, *pol* and *env*, that are common to all retroviruses, as well as additional regulatory/accessory genes unique to lentiviruses. In HIV, these genes include *tat*, *rev*, *nef*, *vif*, *vpu* and *vpr*. *Nef*, *vif*, *vpu* and *vpr* are not essential for virus replication *in vitro* although they play a role in viral pathogenesis. The HIV *gag* gene encodes a precursor polyprotein, which is processed to form the viral capsid which encases the viral

genomic RNA. A properly folded mature viral capsid is obligatory for infectivity, and agents that disrupt any one step in the complex process of capsid assembly can serve as an antiviral agent. The *pol* gene codes for three virus specified enzymes: reverse transcriptase (RT), integrase and protease, all of which play an essential role in virus replication. RT is one of the viral encoded enzymes along with integrase and viral protease that are essential for viral replication. RT converts single-stranded viral RNA into the double-stranded proviral DNA. Proviral DNA is then incorporated into the host cell DNA via the integrase. Transcription and translation of integrated proviral DNA primarily synthesize HIV RNA and polyproteins. Because RT and integrase are not used by host cell metabolism and are specific for viral replication, they are natural targets for inhibitors. HIV protease plays an important role in the processing of viral gag and gag-pol polyprotein, a process essential for the formation of infectious virus. HIV protease inhibitors are by far the most potent HIV inhibitors, and exert their antiviral effects on both acutely and chronically infected cells. Because of their enzymatic nature, *pol* gene products are readily amenable targets for drug development. Furthermore, the three-dimensional x-ray crystal structure has been determined for RT, protease, as well as integrase, which provide an opportunity for rational drug design. These structures can be accessed and viewed on the web using Molecules R US resource from the Center of Molecular Modeling, NIH (*http://molbio.info.nih.gov/cgi-bin/pdb*).

HIV envelope protein is also an attractive target for drug development, since it is responsible for virus attachment and entry to the target cells. The CD4 molecule has been identified as the major receptor for HIV entry. A ganglioside molecule can also serve as a receptor for CD4-independent entry of HIV into certain cell types. More recently, various members of the CXC and CC chemokine receptor superfamily have been shown to function as coreceptors for HIV entry, and determine virus tropism. The molecular biology of various regulatory and accessory genes of HIV, and their role in viral replication and pathogenesis is well studied and identifies several potential targets. HIV *tat* gene transactivates viral RNA transcription, whereas the *ev* gene facilitates nuclear cytoplasmic export of unspliced viral RNAs. Both genes are synthesized early during HIV replication, and are essential for infectivity. The *nef* gene, although dispensable for *in vitro* replication, plays an important role in viral pathogenicity. The other accessory genes, *vif*, *vpu* and *vpr*, although not required for viral infectivity, do have specific effects on cells, that can modulate HIV pathogenicity, and agents that disrupt these functions can prove useful in preventing HIV disease progression.

Reverse Transcriptase Inhibitors

HIV RT is a multifunctional enzyme with RNA-dependent DNA polymerase, ribonuclease (RNase) H, and DNA-dependent DNA polymerase activities. The active protein is a heterodimer comprising p66 and p51 subunits. The N-terminal 440 amino acids of p66 contain polymerase activity and the C-terminal 120 residues show RNase H domain. The p51 of the subunit of HIV-RT corresponds to the polymerase domain of the p66 subunit. The crystal structure of RT has been resolved and identifies four individual subdomains: fingers, palm, thumb and connecting region. The overall folding of p66 and p51 is similar, but the spatial arrangements of the two subdomains are extremely different. Highly conserved regions located in the p66 region, together with two alpha helices of the thumb act as a clamp to position the template-primer relative to the polymerase active site, which is located in the palm region. The 3′ end of the primer terminus is close to residues Asp110, Asp185 and Asp186 in the catalytic site. A spatially distinct hydrophobic pocket comprising residues Tyr181 and Tyr188 in p66 form crucial components for binding non-nucleoside RT inhibitors. Inhibitors of RT can be divided into two categories. The first group include the nucleoside analogues (NRTI) such as zidovudine (ZDV, 3′-azido-2′3′-dideoxythymidine), didanosine (ddI, 2′3′-dideoxyinosine) and zalcitabine (ddC, 2′3′-dideoxycytidine), which compete with normal 2′-deoxynucleoside triphosphates (dNTP) precursors of DNA, whereas the second group comprise structurally diverse compounds referred to as non-nucleoside reverse transcriptase inhibitors (NNRTI). The chemical structures of some of the commonly used reverse transcriptase inhibitors are shown in **Fig. 1**.

Nucleoside inhibitors (NRTI)

Zidovudine (ZDV); didanosine (ddI); lamivudine (3TC, (−)-2′-deoxy-3′-thiacytidine), stavudine (d4T, 2′3′-dideoxythymidine) and zalcitabine (ddC) are currently licensed drugs but their efficacy has been limited owing to both pharmacological factors and emergence of resistant virus strains. Several newer compounds have greatly improved pharmacological properties. Some examples include: N^6-cyclopropylamino 2′3′-dideoxyguanosine (abacavir, BW1592U89), the acyclic phosphonate analogues 9-(2-phosphonylmethoxyethyl)adenine (adefovir, PMEA) and its propyl counterpart, PMPA (9-(2-phosphonylmethoxypropyl)adenine, and F-ddA (2′-β-fluoro-2′3′-dideoxyadenosine). All these com-

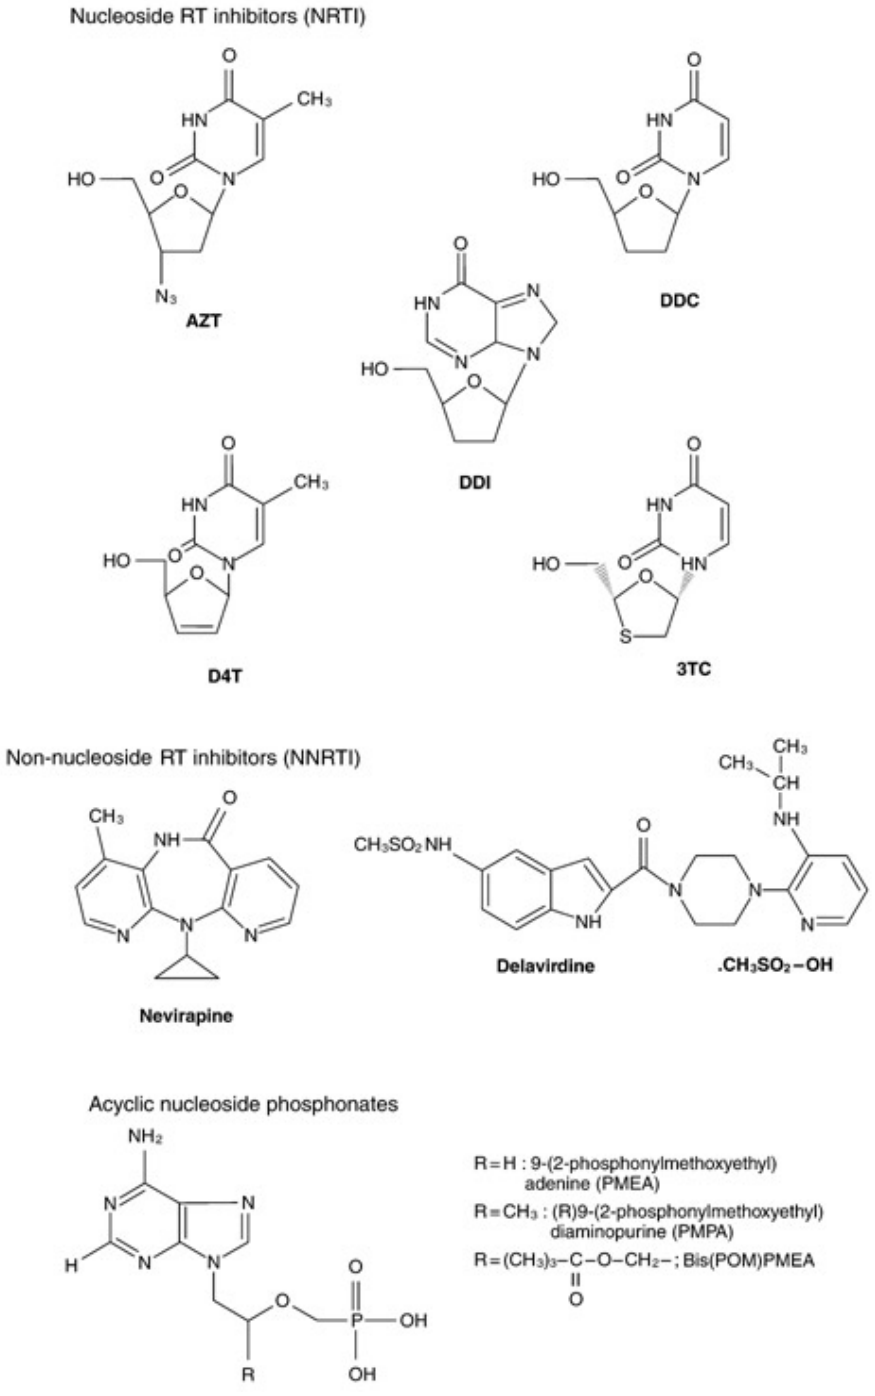

Figure 1 Structures of commonly used reverse transcriptase inhibitors.

pounds are currently undergoing clinical trials for the treatment of HIV infections in human subjects.

All nucleoside RT inhibitors are essentially prodrugs and require intracellular activation to the corresponding triphosphate (ddNTP) forms by cellular pathways. The initial kinase is a crucial step in the intracellular metabolism of the ddNs, and together with the intracellular half-life of the active triphosphate in the target cells can determine the antiviral efficacy of these agents. The dideoxynucleoside analogues such as ZDV and 3TC terminate the DNA chain growth due to lack of a 3′-hydroxyl group. The principal idea is that they replace the natural deoxynucleoside triphosphate as substrates during the viral

DNA synthesis, but terminate chain elongation because there is no 3′-OH group to continue chain growth. In both lymphocytes and monocyte/macrophages, the ddNs are first phosphorylated by either a nucleoside kinase or 5′-nucleotidase (acting as a phosphotransferase). The resulting monophosphate is further phosphorylated by nucleotide kinases to the active triphosphate. The nucleoside kinase activity of resting cells such as the monocytes/macrophages and dendritic cells may be insufficient to phosphorylate adequately certain ddNs, e.g. ZDV or d4T and limit their anti-HIV efficacy. One successful strategy to overcome this problem has utilized the acyclic nucleoside phosphonate analogues. Compounds such as adefovir and PMPA can be considered as monophosphate analogues, in which the first phosphate group has already been added as a phosphonate. These compounds enter cells by endocytosis and after addition of two phosphate groups by ubiquitous cellular nucleotide kinases inhibit the HIV RT. PMEA and PMPA also show a broad antiviral specificity and also inhibit other immunodeficiency viruses, such as simian immunodeficiency virus (SIV) as well as hepadnaviruses (e.g. hepatitis B virus, HBV). These compounds are currently being evaluated in the clinic for the treatment of both HIV and HBV infections in human subjects. A related phosphonate analogue (*S*)-1-[3-hydroxy-2-(phosphonylmethoxy)propyl] cytosine (HPMPC) is licensed for the treatment of cytomegalovirus infections in autoimmune deficiency virus (AIDS) patients.

Non-nucleoside RT inhibitors (NNRTI)

NNRTI are a chemically diverse group of compounds that function as highly selective, allosteric inhibitors of HIV-1 reverse transcriptase. Therefore, they do not compete with dNTP substrates to exert their antiviral effects, nor do they require intracellular activation. The NNRTIs are inactive against HIV-2, SIV and other lentiviruses. This specificity of the NNRTIs for the HIV-1 RT is due to the presence of a unique highly hydrophobic pocket in HIV-1 RT into which the NNRTI fit snugly. The NNRTI binding pocket of HIV-1 RT is functionally and spatially distinct from the substrate (dNTP) binding site on the palm domain of the p66 subunit. Most NNRTIs assume a butterfly-like (or Y-shaped) structure comprising two hydrophobic wings connected to a central polar body. The NNRTIs probably act as π electron donors to aromatic side chains of HIV RT residues around the NNRTI-binding pocket.

The first compounds to be described in that class are the tetrahydroimidazole[4,5,1-jk][1,4]benzodiazapin-2(1H)-one and thione (TIBO) derivatives. Other compounds soon followed such as 1-[(2-hydroxyethoxy)methyl]-6-(phenylthio)thymine (HEPT) derivatives, pyridinone, bis(heteroaryl)piperazine (BHAP), nevirapine, phenylethylthioureathiozole (PETT) derivatives, delaviridine and yet others. Although all these compounds may be assumed to bind to the same pocket site at the HIV RT, different classes of HIV-1 specific RT inhibitors may differ from each other with regard to the exact amino acids of the binding site with which they interact. This conclusion is drawn from the finding that different NNRTI do not exactly show crossresistance to each other, although they seem to overlap. Currently approved NNRTI include nevirapine (Boehringer-Ingelheim) and delaviridine (Rescriptor, Pharmacia-UpJohn). Other compounds, e.g. DMP-266, are in advanced clinical trials.

HIV drug resistance to reverse transcriptase inhibitors

Drug resistance is a major problem leading to treatment failure with antiretroviral agents. The patterns of crossresistance vary with different mutations, and a virus resistant to one agent is not automatically resistant to a related compound. A detailed list of various drug resistance associated mutations in HIV has been reported and a searchable database of drug resistance mutations in HIV is available on the web (*http://www.viral-resistance.com*). **Figure 2** shows an abbreviated list of RT mutations associated with NRTI resistance. Resistance to ZDV is associated with mutations of Met41 → Leu, Asp67 → Asn, Lys70 → Arg, Thr215 → Phe and Lys219 → Gln in the HIV RT gene. Single mutations appear early during treatments with ZDV but are not associated with high level of resistance until several mutations occur. In advanced HIV disease, phenotypic high levels of ZDV resistance and particularly the mutations at codon 41 and 215 are correlated with increased risk of clinical progression and death. Mutations at Leu74 → Val and Val75 → Thr in the RT gene confer resistance to both ddI and ddC. The Val75 → Thr mutation observed with d4T is also crossresistant to ddI, ddC, d4C and 2′-deoxy-5-fluoro-3′-thiacytidine (FTC). Met184 → Val is responsible for resistance to ddC and 3TC. A K65 → R mutation confers resistance to 3TC and PMEA. The genetic background of the virus also contributes to the phenotypic effect of resistance-determining mutations. For example, introduction of T215F/Y mutation in to wild-type RT leads to ZDV resistance, but does not confer ZDV resistance in viruses with mutant RT harboring M184V or L74V mutations.

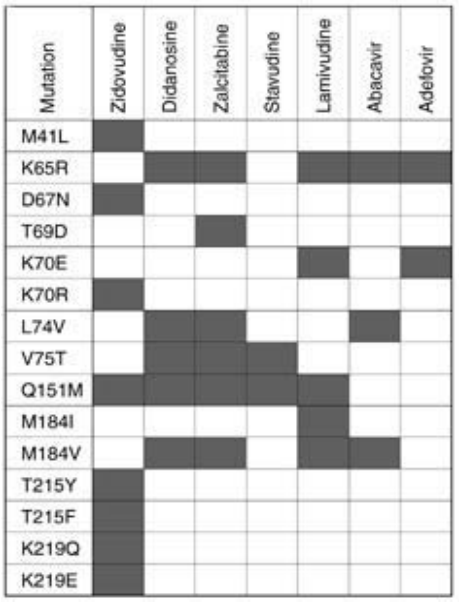

Figure 2 Reverse transcriptase mutations frequently associated with drug resistance to commonly used NRTI. The dark boxes show mutations verified to confer resistance.

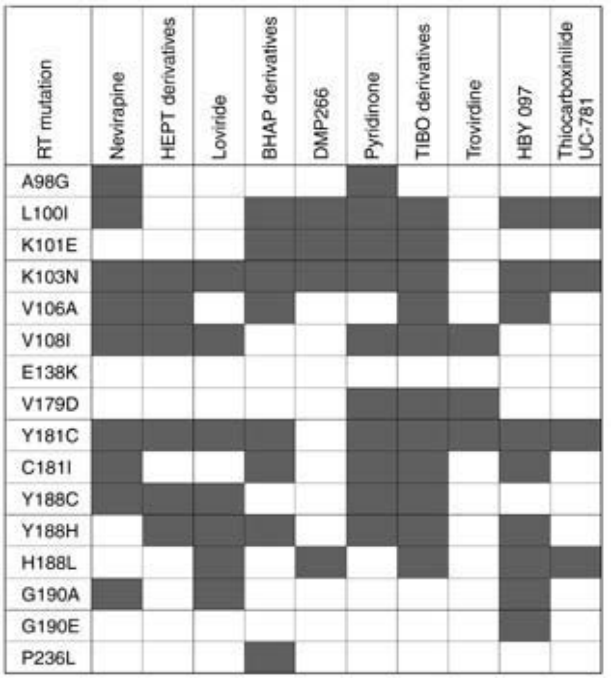

Figure 3 Reverse transcriptase mutations frequently associated with drug resistance to commonly used NNRTI. Dark boxes show mutations associated with resistance.

The observation that the development of resistance to one compound can reverse the effects of resistance mutation, and restore sensitivity to a second inhibitor has been clinically rewarding. The Met 184 → Val and Met 184 → Ile mutations emerge rapidly in patients treated with 3TC, and both mutations can suppress the effects of ZDV-resistant mutations. Other mutations that restore ZDV susceptibility in mutants harboring ZDV resistance mutations at codons 41, 67, 70, 215 and 219 include Leu74 → Val selected by ddI, Gln 161 → Leu and His 208 → Tyr mutations selected with the NNRTI Foscarnet, nevirapine or TIBO. The mechanism for these effects may be due to compensatory effects of certain combinations of mutations on template-primer binding.

The mutations observed with the ddNs do not lead to resistance to the NNRTI and vice versa. Resistance to the ddNs are located in the vicinity of either the substrate (dNTP) binding site or the template binding site. Resistance to the ddNs appear to develop more slowly than for the NNRTI, and as shown for ZDV resistance may develop in a stepwise manner, with each step leading to greater resistance.

Mutations leading to NNRTI resistance tend to cluster around the contact points between NNRTI and HIV-1 RT and often include RT residues L100, K101, K103, E138, V179, Y181, Y188, V189, G190 and P236. NNRTIs have been found to lead rapidly to emergence of drug resistant viruses both *in vitro* and *in vivo*. The mutation Tyr 181 → Cys is associated with resistance (or reduced sensitivity) to most of the NNRTIs (i.e. TIBO, HEPT, nevirapine, pyridinone, BHAP, 2′,5′,bis-O-(tert-butyldimethylsilyl)-3′-spiro-5′(4′-amino-1′,2′-oxathiole-2′,2′-dioxide) pyrimidine, alpha-anilinophenylacetamide (αAPA). The mutation Tyr 188 → His confers resistance to TIBO, pyridinone but not nevirapine, whereas the mutation Tyr 188 → Cys is associated with resistance to TIBO, pyridinone and nevirapine. Likewise, Val 106 → Asn determines resistance to TIBO, nevirapine, pyridinone and BHAP, whereas Val 106 → Ala accounts for resistance mainly to nevirapine and pyridinone. The mutation Leu 100 → Ile is associated mainly with resistance to TIBO and Glu 138 → Lys accounts for resistance to TSAO but none of the other compounds (**Fig. 3**).

Several observations have rekindled interest in the clinical development of NNRTI. Higher doses of NNRTI can be safely used to partially suppress the emergence of resistant variants. Mutations do not result in crossresistance to all NNRTI thus permitting a switch in therapy from one compound to another, or combination therapy with drugs that have different resistance patterns. Multiple sequential mutations are required to confer high level resistance to new NNRTIs, e.g., DMP-266. Some NNRTI mutations, e.g. Y181C selected by nevirapine, or L1001 selected by TIBO R82150 can suppress or reverse the effects

of ZDV resistance mutations. Likewise, mutations selected by delaviridine can sensitize RT over tenfold for nevirapine, TIBO R82913 and L-697,661. Some NNRTI mutations, e.g. G190E, reduce RT enzyme activity and reduce viral replication competence. Some NNRTI inhibit enzymes in the cytochrome P450 pathway which metabolize HIV protease inhibitors, and enhance their bioavailability.

Approaches to minimize emergence of resistant variants include use of combination therapy with multiple agents (NRTIs as well as other compounds, especially protease inhibitors) to ensure maximal virus suppression. A convergent therapy with multiple RT inhibitors was initially proposed with the idea that an enzyme that mutates to acquire resistance to multiple agents may be nonfunctional, but later studies have shown that the RT protein is highly flexible and can simultaneously show resistance to all the currently available compounds.

Integrase Inhibitors

The HIV integrase is an attractive target for selective anti-HIV therapy since there is no known functional counterpart in human cells. The only enzyme required for HIV-1 integration is the integrase (IN), a protein of 32 kDa encoded at the 3′ end of the *pol* gene. This enzyme is produced by protease-mediated cleavage of the gag-pol precursor during virion maturation. The integrase recognizes specific sequences in the long terminal repeat (LTR) of the viral DNA: 5′-ACTG ... CAGT-3′. The TG ... CA repeat has been conserved throughout evolution. In the first step of this reaction, termed 3′ processing, two nucleotides are removed from each 3′ end to produce new 3′ hydroxyl ends (CAOH-3′). This reaction takes place in the cytoplasm. After entering the nucleus, the processed viral DNA is joined to the host target DNA. The joining reaction includes a coupled 4–6 bp staggered cleavage of the target host DNA and the ligation of the processed CAOH-3′ viral DNA. Host enzymes probably accomplish repair of the remaining gaps. Oligonucleotide-based assays have been designed to mimic both the processing and joining reactions *in vitro*. Several DNA binding agents were found to inhibit the integrase. To date, only one integrase inhibitor, zintevir (AR-177), a synthetic 17mer oligonucleotide containing phosphorothioate linkage at the 3′ and 5′ terminal bonds is undergoing clinical trials as an intravenous formulation. AR-177 has an IC_{50} in the 30–50 nM range. AR-177 also inhibits virus binding to *CD4+* cells, and inhibits cell fusion at micromolar concentrations of AR-177.

Other inhibitors HIV IN include DNA-binding agents, topoisomerase inhibitors, aurintricarboxylic acid and cosalene analogues, caffeic acid phenylethyl ester (CAPE), and bis-catechols or other hydroxylated aromatic compounds. A new class, the anthraquinones (e.g. quinalizarin and purpurin) inhibits HIV preintegration complexes *in vitro*. Tyrphostins are protein kinase inhibitors that also exhibit activity against HIV IN. Hydroxycoumarin complexes, such as NSC 158393, have also been reported to have potent anti-HIV IN activity as well as activity against HIV protease. Recently, a novel class of IN inhibitors has been described – the dicaffeoylquinic acids (DCQAs) – which are isolated from medicinal plants used by the Kallawaya herbalists of Bolivia. Several reports have utilized computational analysis to search for potential inhibitors of IN, and identified a number of relatively low-potency inhibitors which could serve as lead compounds.

Protease Inhibitors (PI)

HIV protease is responsible for processing gag and gag-pol precursor polyproteins into essential structural proteins. Inactivation of protease gene by site-directed mutagenesis results in noninfectious virus, thus making HIV protease an attractive target for drug development. Currently four compounds – saquinavir, ritonavir, indinavir and nelfinavir – have been licensed for human use. The chemical structures of the currently licensed protease inhibitors are shown in **Fig. 4**. Amprenavir (Glaxo141) is in advanced multicenter clinical trials. Many other compounds, such as ABT378, PNU140690 and PD178393, are under various stages of development. HIV protease is an aspartic acid protease, and its crystal structure has been resolved. HIV protease is a dimer, and acts like a pair of molecular scissors to cleave target sites. Each 99-residue monomer contributes an aspartic acid residue to the site. The two aspartic acid residues deliver a water molecule to the cleavage site of the substrate to create a tetrahedral transition state intermediate that rapidly breaks apart to give a C-terminal acid and N-terminal amine. HIV protease inhibitors present some classic examples in drug design and development. Numerous inhibitors have been designed by incorporating a nonhydrolysable P1.P1′ cleavage site mimic into a substrate sequence, where P1 and P1′ refer to the first residue to the left and right, respectively, at the cleavage site. Saquinavir (invirase), the first protease inhibitor to be approved for human use, contains a hydroxyethylamine (HEA) at P1/P1′ transition state isostere. Ritonavir was synthesized to exploit the symmetric nature of HIV protease, and imposes an axis of symmetry on the hydroxyethylamine isostere at, or next to, the hydroxyl group of the transition state analogue. In other

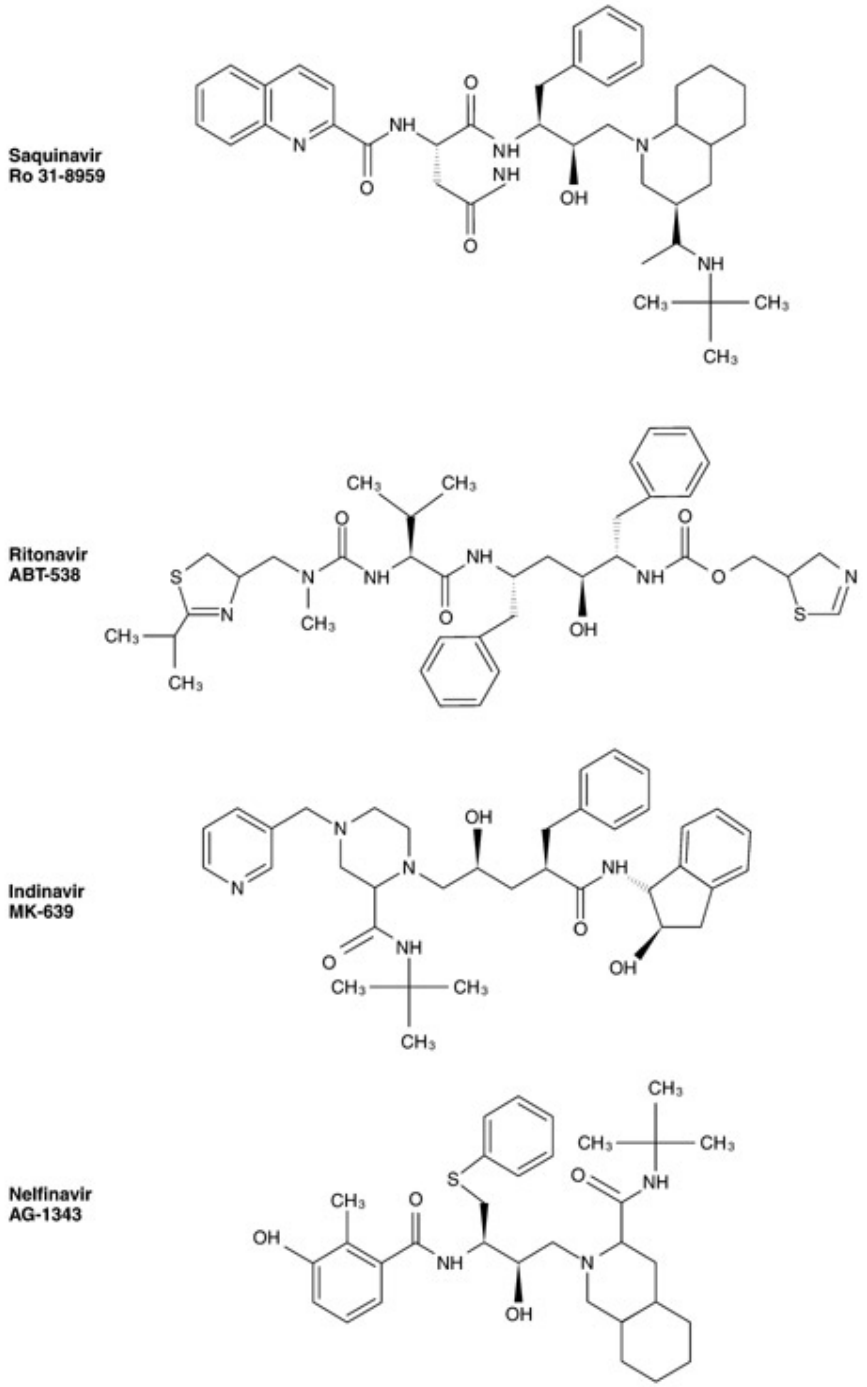

Figure 4 Structures of commonly used protease inhibitors.

studies Merck identified a heptapeptide containing hydroxyethylene isostere as a lead compound by screening compounds that were initially synthesized as an inhibitor of renin, also an aspartic protease. A series of compounds were synthesized to reduce the activity of this compound against renin, and increase activity against HIV protease finally leading to the development of indinavir. Nelfinavir was designed by refining saquinavir structure by replacing the enzymatically labile P3.P2 fragments with a simple hydroxytoluene amide group, and compensate the loss of potency resulting from this change by replacing the P1 phenyl group with a phenylthio group which can more efficiently fill the hydrophobic

pocket of HIV protease. Amprenavir (VX478 or BW141W94) was also designed by refining the saquinavir structure. Here the decahydroisoquinoline group was replaced with an isobutyl sulfonamide group, the P3-P2 groups were replaced with a tetrahydrofuran carbamate, and an amino group was introduced to the phenylsulfonamide group to increase water solubility and oral absorption.

All protease inhibitors show potent antiviral activity. Saquinavir has K_i of 1–8 nM against HIV-1 protease and its EC_{95} values <100 nM against various laboratory and clinical HIV isolates. The corresponding K_i and EC_{95} values are 0.015 nM and <150 nM for ritonavir, 0.4 nM and <100 nM for indinavir and 2 nM and <200 nM for nelfinavir. The HIV protease inhibitors are also highly effective *in vivo*, and accomplish >2-log (>99%) reduction in plasma viral RNA levels, compared ~0.5–1 log reduction by RT inhibitors. However, the major limitations of currently available HIV PIs is that they are all poorly soluble, high-molecular-weight compounds that show very high protein binding. These factors are associated with a poor oral bioavailability and increased hepatic clearance. Consequently, optimal dosing requires frequent administration of several large capsules or tablets, which promotes noncompliance, and also limits their use in younger children. Many PIs are metabolized by the cytochrome P_{450} pathway. The isozyme CYP3A4 is the major enzyme that metabolizes these compounds, and compounds that affect CYP3A metabolism can markedly influence the pharmacokinetics of HIV PI. For example, nevirapine stimulates CYP3A metabolism, and coadministration of nevirapine requires PI dose adjustments. Interestingly, ritonavir is also an inhibitor of CYP3A and can enhance serum concentrations of HIV PIs and other compounds metabolized by this pathway. This property is being exploited to enhance the bioavailability of saquinavir in combination therapies including ritonavir and saquinavir.

HIV resistance to protease inhibitors

Development of resistance is observed primarily when the plasma drug levels are low and insufficient to effectively block viral replication. This may occur either due to differences in individual variations in pharmacokinetics (e.g. poor absorption, increased clearance, food or drug-interactions etc.) or due to poor compliance in taking prescribed doses of medication. The different drugs select for different, although overlapping mutations (**Fig. 5**). All drug resistance mutations affect the substrate binding site. Commonly encountered mutations include substitutions at V82, I84 or L90 for indinavir and ritonavir, G48, I84 or L90 for saquinavir, and D30, I84 or L90 for nelfinavir. In additions to the mutations around the substrate-binding site, all PIs also select for overlapping sets of mutations elsewhere in the enzyme including L10, M46, L63, A71 and N88. Cyclic urea amide inhibitors currently under development (e.g. SD 146) show antiviral activity against HIV harboring protease gene mutations at 10I, 48V, 54T, 63Q, 71V, 77I and 82A and show resistance to currently available protease inhibitors.

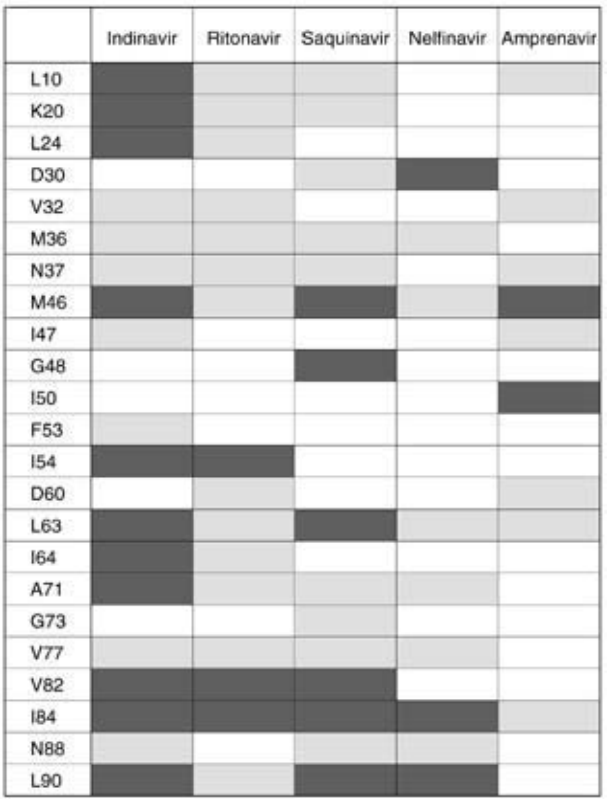

Figure 5 Protease mutations frequently associated with drug resistance. The dark boxes show phenotypically verified mutations. Lighter boxes identify mutations selected by the compound, but their role in determining resistance has not yet been confirmed.

Other Targets

Although potential antiviral targets are identified in other viral genes, no compound has progressed far enough to approach clinical development. Some of the potentially interesting targets and leads are indicated here.

The nucleocapsid protein NCP7 contains two C-X2-C-X4-H-X4-C motifs that are required for viral RNA encapsidation. The mature form NCP7 forms zinc-fingers in the presence of stoichiometric zinc. Certain oxidizing agents, including 3-nitroso-benz-

amides and cupric ions remove zinc complexed to NCp7 *in vitro*. Certain aromatic disulfide compounds also extract zinc from the NCP7. Compounds that extract zinc also inactivate HIV. Although currently tested zinc chelators are far too cytotoxic for therapeutic use, they provide a lead for development of a new class of antiviral agents.

Envelope gene of HIV plays a crucial role in virus entry into target cells. The CD4 molecule is the major cellular receptor for HIV. Although initial studies showed that soluble CD4 (sCD4) can inhibit laboratory-adapted HIV in cell lines, it was not very effective against primary isolates in PBMC. Small-molecular-weight compounds with therapeutic potential to inhibit CD4–gp120 interactions are still being sought.

Recently, various CC and CXC chemokine receptors have been shown to serve as co-receptors for HIV. The T-tropic, syncytium-inducing viruses, now called X-tropic viruses utilize fusin (a CXC chemokine receptor) molecule as coreceptor. AMD3100, a bicyclam, which was previously described as an inhibitor of HIV uncoating, has now been identified as an inhibitor of HIV gp120–fusin interactions. This compound has no antiviral effect against the macrophage-tropic, nonsyncytium inducing R5-tropic viruses that utilize CCR5 chemokine receptor. Peptide mimics of SDF ligands (amino acids 643–678) has also shown antiviral activity against X-tropic HIV *in vitro*. Likewise compounds like amino-oxypyranose and CC chemokine analogues can inhibit R5-tropic HIV *in vitro*.

More recently, a 36-amino acid synthetic peptide (T-20) derived from highly conserved sequences within the HIV-1 gp41 glycoprotein involved in membrane fusion has been evaluated as an antiviral agent. T-20 shows potent and selective antiviral activity *in vitro* against HIV-1 with $IC_{50} \sim 80$ ng ml^{-1} for the inhibition of infectivity and 1 ng ml^{-1} for the inhibition of syncytia formation. Biophysical evidence suggests that T-20 blocks membrane fusion by binding to a coiled-coil motif within the viral transmembrane protein and inhibiting critical virus-cell surface interactions that are necessary for virus entry. Studies performed *ex vivo* indicate that T-20 undergoes no detectable degradation when incubated at 37°C in human plasma preparations for up to 26 h. Pharmacokinetic analyses indicate that the plasma $t_{1/2}$ of T-20 is 2.3 and 3.1 h in rodents and primates, respectively. In primate models, T-20 exhibits relative bioavailabilities of approximately 75%, when given by either intramuscular or subcutaneous injection.

HIV Tat protein is an activator of viral transcription and it is essential for viral infectivity. The Tat inhibitor Ro 24-7429, a benzodiazepine compound is active *in vitro* and interacts with a host nuclear element to inhibit Tat function. However, clinical trials of this agent have failed to demonstrate antiviral activity, although plasma levels of the drug exceeded levels that inhibited HIV propagation *in vitro*. Ro24-7429 was highly protein-bound, which may account for its therapeutic failure. Recently, ALX40-4C a Tat protein mimic that interferes with the tat–TAR interactions has been shown to suppress HIV replication in both acutely and chronically infected cells. It is currently being evaluated.

Other potential antiviral targets include HIV Rev and Nef proteins. HIV Rev protein mediates nuclear export of unspliced or singly spliced viral RNAs and is essential for viral infectivity. The Nef protein of HIV, although indispensable for virus replication *in vitro*, is a major determinant of viral pathogenicity. Compounds that inhibit Rev-mediated RNA transport *in vitro* are either ineffective to prevent HIV replication in culture, or are cytotoxic and lack therapeutic potential. Likewise, macrolide antibiotics (e.g. concanamycin B and bafilomycin A1) that inhibit certain nef functions *in vitro* have been described, but they all lack therapeutic potential.

With increasing information available on the fine structure of various viral proteins, detailed molecular biology of their function, as well as recent advances in combinatorial chemistry and structure-aided drug design, we can be optimistic that new therapeutically effective inhibitors will be developed in the near future.

Chemotherapy of HIV Infections: Guidelines for the Use and Evaluation of Antiretroviral Agents

Currently five NRTI (ZDV, ddC, ddI, d4T, 3TC), two NNRTI (Nevirapine, Delaviridine) and four protease inhibitors (saquinavir, ritonavir, indinavir and nelfinavir) have been approved for human use, and this list is expanding rapidly. A large proportion of patients had earlier been treated by nucleoside monotherapy, primarily with ZDV and to a lesser extent with ddI. Subsequent studies soon showed that combination therapy with multiple agents is vastly superior to monotherapy. A guideline for the use of antiretroviral agents in HIV-infected adults and adolescents has recently been proposed and salient points are summarized below.

When to begin treatment

Treatment is recommended for all patients that exhibit symptomatic disease. Treatment should be initiated in asymptomatic individuals if there are plasma HIV RNA levels above 30 000–50 000 copies

ml^{-1} regardless of laboratory and/or clinical status; or there are plasma HIV RNA levels above 5000–10 000 copies ml^{-1} and a CD4+ cell count and/or clinical status suggestive of progression.

Recommended regimen

The treatment should include a protease inhibitor (either indinavir, nelfinavir, ritonavir or ritonavir plus saquinavir) and two nucleoside RT inhibitors. The suggested combinations of NRTI include ZDV + ddI, d4T + ddI, ZDV + ddC, ZDV + 3TC, and d4T + 3TC. Alternative regimens, in patients who cannot receive protease inhibitors, include one NNRTI (nevirapine or delaviridine) plus two NRTI, but are less likely to provide sustained virus suppression. Any monotherapy and some combinations (d4T + ZDV; ddC + ddI; ddC + d4T; ddC + 3TC) are not recommended since they are less effective, or show overlapping toxicities.

Changing antiretroviral regimen for suspected failure

Treatment changes may be warranted either due to drug intolerance or treatment failure. Single agents can be changed or the dose reduced in the event of drug intolerance. A suboptimal reduction in plasma viremia after initiation of therapy, reappearance of viremia after suppression to undetectable, significant increases in plasma viremia from the nadir of suppression, and declining CD4 T cell numbers all suggest a virological treatment failure and warrant treatment changes. It is important to use at least two new drugs and preferably to use an entirely new regimen with at least three new drugs when changing from a failing regimen. In some cases where patients have limited options for new regimens, it is rational to continue the prior regimen if partial viral suppression was achieved. For patients with no rational alternative options who have virologic failure with return of viral load to pretreatment levels and a declining CD4 T cell count, modification of therapy should be considered. The value of restarting a drug that the patient has previously received is not well understood. With ZDV, resistant strains are often replaced with 'wild-type' HIV when treatment is stopped, but resistance recurs rapidly if ZDV is restarted. Preliminary evidence suggests that this occurs with indinavir as well, but it is not known if similar problems apply to other nucleoside analogues, protease inhibitors, or NNRTIs.

Treatment effects on viral load correlate with clinical outcome including disease progression and survival. Initiation of highly active antiretroviral therapy (HAART) reduces plasma HIV-1 RNA levels below the limits of detection of currently available assays (<400–500 copies ml^{-1}), although this may not always be achievable, especially in HIV-infected children. A 3-fold (0.5-log) sustained reduction in viral load is a minimum indicator of effective therapy. Nucleoside monotherapy results in an average reduction in viral load of 0.5 log compared with 1- to 1.5-log reduction with nucleoside combination therapy and 2.0 to 2.5 log with combination including protease inhibitors. By using more drugs concomitantly, greater reduction in plasma viremia can be achieved, with a shorter time taken to reach the nadir. Changing therapy from a highly aggressive 'inductive' phase comprising three or more drugs, to a maintenance phase with less aggressive dual combination has been unsuccessful.

Can HIV infection be cured?

A small cohort of patients treated early, and aggressively with HAART have remained free of detectable plasma virus even with the most sensitive assay currently available (<40 copies ml^{-1}). It was hoped that these patients may actually have cleared HIV from the body. However, after treatment was stopped, HIV could be detected in the plasma of these patients. A very small fraction of latently infected CD4+ memory T cells was found to harbor the virus, which re-emerged after treatment was stopped. Current efforts are targeted at designing strategies to eradicate this subset of latently infected cells.

Use of Antiretroviral Agents for Chemoprophylaxis

Although postexposure prophylaxis is a highly attractive option, several factors restrict the use of current antiviral agents to certain circumstances. A combination of two NRTI and a protease inhibitor for a period of one month postexposure has been recommended for laboratory and health care workers accidentally exposed to HIV. ZDV administered to HIV-positive pregnant women during pregnancy and labor, with concomitant administration of ZDV to the infant for a period of six weeks has largely reduced perinatal transmission of HIV, and has become standard practice. Other antiviral regimens are also being evaluated for this purpose. Other approaches currently under development include the evaluation of regimens for their efficacy to reduce viral burden and virus-infected cells in mucosal and genital secretions and the development of virucidal agents for topical use with contraceptives.

Concluding Remarks

Antiviral agents have been highly effective in controlling the ravages of the AIDS epidemic, and have even raised hopes for a cure. Nevertheless, this very success poses even greater challenges for the future. There are problems in evaluating the efficacy of new compounds in the face of currently effective therapeutic regimens, as evidenced by the global debate on the ethics of performing placebo-controlled trials in developing countries. Monitoring treatment efficacy by studying viral dynamics is being challenged by current trends where patients on long-term PI therapy show continuing immunological improvement despite virological failure. Patients on combination therapy are running out of treatment options before new compounds are becoming available. Thus, better use of available antiviral compounds seems far more prudent than relying on new products. This approach includes the development of rational approaches for drug combinations, the development of optimal delivery systems to ensure better treatment compliance. Finally, we have to explore options for customizing treatment on an individual basis to select drugs and adjust dosage regimens based on pharmacological and pharmacokinetics parameters which take into account individual variables including past treatment history, and resistance profiles of viral isolates.

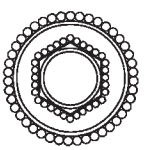
HUMAN T-CELL LEUKEMIA VIRUSES (*RETROVIRIDAE*)



Contents

HTLV-1

Mitsuaki Yoshida, Department of Cellular and Molecular Biology, Institute of Medical Science, University of Tokyo, Tokyo, Japan

History

Human T-cell leukemia virus type 1 (HTLV-1) is the first exogenous retrovirus to have been established in humans. After a long and painstaking search for human retroviruses, HTLV-1 was isolated from adult T-cell leukemia (ATL) at the beginning of the 1980s. ATL was first described in 1976 in Japan as a unique malignancy of T cells affecting only adults. The disease is now known to be endemic in the southwest part of Japan, the Caribbean, South America and Africa. The human retrovirus HTLV was reported in the USA in 1980, by characterization of reverse transcriptase in a T-cell line established from peripheral blood T cells of a patient with T-cell lymphoma. This lymphoma was later diagnosed as ATL. Several T-cell lines were also established from Japanese patients with ATL by co-cultivation of normal cord-blood lymphocytes and leukemic cells from ATL patients, and retrovirus-like particles were detected in these established T cell lines. These cell lines expressed antigens that reacted with sera from ATL patients. These antigens were then identified as proteins encoded by a retrovirus (initially called ATLV), which was newly established by characterization of reverse transcriptase, specific core proteins and the proviral genome integrated in chromosomal

differ serologically. The molecular mechanism has not been resolved yet.

In eukaryotic viruses so far all host cell adaptation is explained by the appearance and selection of viral mutants. It has, however, not been investigated whether phenotypic M/R processes of genetically unaltered viruses do also occur in the kingdom of eukaryotes, possibly explaining the occurrence of reversible changes in the host cell tropism of viruses.

DNA Methylation in Eukaryotic Viruses

There is no unequivocal evidence of the existence of DNA M/R systems in eukaryotic cells. Enzymes resembling pairs of DNA methyltransferases and restriction endonucleases are, however, encoded by viruses infecting eukaryotic algae (*Chlorella* spp.); their biological functions remain still unclear. Other viruses, like Frog virus 3 and lymphocystis disease virus (members of the family *Iridoviridae*), encode their own DNA methyltransferases, and their genomes carry high numbers of 5-methylcytosine residues. Functional consequences of the extensive methylation have to be further elucidated.

In the DNA of eukaryotic cells 5-methylcytosine is usually generated by cellular methyltransferase activities and mainly but not exclusively occurs in CpG dinucleotides. DNA methylation is known to be involved in processes like transcription inhibition, genomic imprinting, cell differentiation and dedifferentiation (carcinogenesis), and hypermutability. Furthermore, DNA methylation is assumed to silence transcription from integrated retroviral genomes, whereas demethylation results in the reactivation of the provirus. For some human pathogenic viruses, such as herpes simplex viruses, cytomegalovirus, Epstein–Barr virus or papillomaviruses, a role of DNA methylation in gene regulation has been demonstrated.

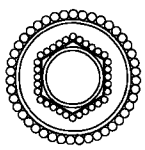
HUMAN IMMUNODEFICIENCY VIRUSES (*RETROVIRIDAE*)



Contents

General Features

Luc Montagnier, Institut Pasteur, Paris, France and Queens College, NY, USA

History

The infectious origin of acquired immunodeficiency syndrome (AIDS) was recognized soon after the identification of the disease itself in 1981. The first AIDS cases diagnosed in 1982 in hemophiliacs

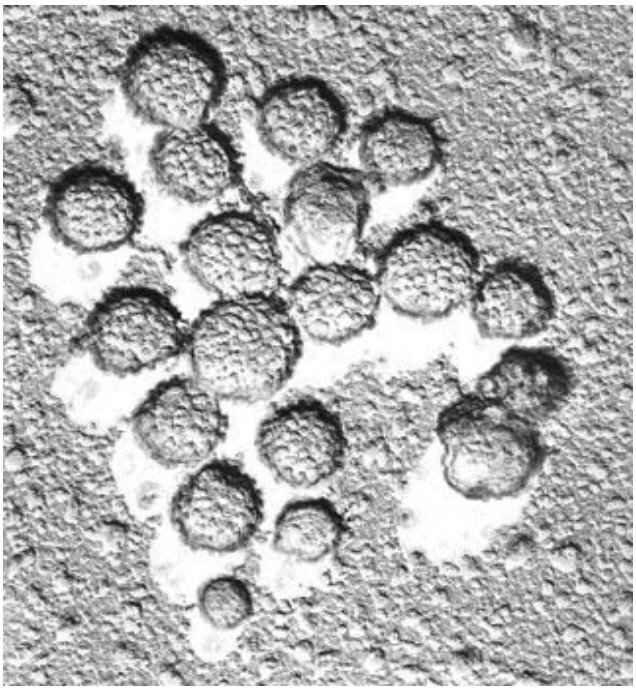


Figure 1 Replica surface of HIV-2 virions, showing the knobs formed by oligomers of the surface glycoprotein. (HIV-1 virions usually shed most of these knobs spontaneously.) (Courtesy of Drs H Gelderblom and M. Özel.)

indicated that filtered Factor VIII concentrates could transmit the disease, suggesting that a virus or a small bacterium which could pass through bacteriological filters was the etiological agent. Indeed a retrovirus was isolated in early 1983 by L. Montagnier, F. Barre-Sinoussi, J. C. Chermann and their colleagues from a culture of activated T-lymphocytes derived from a lymph node biopsy of a homosexual patient with lymphadenopathy. Other similar isolates from full-blown AIDS patients were made by the same group in 1983, who showed, along with D. Klatzmann and J. C. Gluckman, their tropism for CD4+ lymphocytes. The viruses were found not to be antigenically related to human T cell leukemia viruses (HTLVs) but to be more closely related to the animal lentiviruses. This was despite the fact that some other studies (R. C. Gallo) produced data in favor of an HTLV-related variant. In 1984, R. C. Gallo, M. Popovic and their co-workers described, under the name of HTLV-III, a virus which proved to be identical to the virus described by the Pasteur group. The essential role of the virus, now renamed human immunodeficiency virus (HIV), in AIDS was demonstrated by epidemiological studies, particularly in cases of transmission by blood, where HIV was the only detected common factor in the donor and the receiver. A second type of virus, named HIV-2, was isolated in 1986 from West-African patients with AIDS. The discovery of HIV as the etiological agent of AIDS has led to the development of rational therapeutic strategies such as reverse transcriptase inhibitors, protease inhibitors and vaccines.

Taxonomy and Classification

By its morphology, genetic structure, nucleotide sequence, the virus belongs to the second subfamily of retrovirus, the lentiviruses, which includes viruses causing slow pathologies in animals, such as Visna, equine infectious anemia (EIA) and feline immunodeficiency virus.

Retrolentiviruses of primates (SIVs, HIVs) are characterized by a tropism to CD4+ lymphocytes, a property not shared by lentiviruses of ungulates.

Virion Structure

Mature virions (diameter 100–120 nm) have a characteristic spherical morphology with a dense cone-shaped core surrounded by a bilayered phospholipid envelope in which knobs are inserted (**Fig. 1**). There are approximately 80 knobs covering the viral sphere. Each knob is made of several molecules of external glycoprotein, gp120, possibly as trimers or tetramers linked noncovalently to preformed oligomers of the integral membrane protein, gp41.

In the case of HIV-2, dimers or tetramers of the equivalent transmembrane proteins (gp36 or gp41) are so tightly bound that they appear as such (gp80 and gp160) in electrophoretic gels under classical denaturating conditions (heating at 100°C in 1% SDS).

Morphogenesis

Virus assembly takes place at the surface of the plasma membrane of lymphocytes or lymphoid cells and in the membrane of intracytoplasmic vacuoles in the case of macrophages. *Gag* polypeptides are necessary to induce budding, and the subsequent morphogenesis of the virion requires the presence of the precursor glycoprotein, gp 160.

Released immature particles with uncondensed cores are transformed into mature particles with condensed cores by proteolytic cleavage of the p17/p18 protein from the gag precursor, which binds to the inner layer of the viral envelope. As this occurs, the p24 protein wraps around the nucleocapsid, formed by the two RNA molecules and the basic proteins p6 and p9.

The correct morphogenesis and infectivity of the viral particles involves cleavage by a cellular protease

of the glycoprotein precursor, gp160 into gp120 and gp41.

Physical Properties

Virions are sensitive to acidic pH (total inactivation at pH 2), ethanol (20–70%), heat (6 log inactivation at 60°C 30 min, detergents (ionic and nonionic) and chlorine.

Virions are sensitive to radiation including UV light at 260 nM, and X and γ rays at a D10 value of over 500 000 rad (50 Gy).

Genome Structure

The genome is a single-stranded RNA molecule of 9400 base pairs; there are two molecules per virion linked by noncovalent bonds. Lysine tRNA is the primer of the reverse transcriptase, which is Mg^{2+} dependent (optimal concentrations of Mg 10 mM).

The structure of the human immunodeficiency virus genome is reflective of the complex nature of the limitations that are exerted during the replication of these viruses. Such limitations affect mainly the expression of viral genes, in an overall process that seems to optimize and synchronize expression of the viral proteins during acute replication, but could also in some instances control the expression of silent proviruses in chronically infected cells. The genome of HIV-1 and HIV-2 (**Fig. 2**), as well as of the different members of the simian immunodeficiency virus (SIV) group, contains several small genes in addition to the classical retroviral structural genes *gag*, *pol* and *env*. Some of these genes have a critical regulatory function, others appear not to be absolutely required for *in vitro* replication. In addition to these coding elements, the HIV genome is rich in *cis*-acting sequences active at different steps of replication, some of which are target sites for proteins regulating viral gene expression.

DNA Synthesis and Integration

Following entry into the cell, the viral genome, represented by a dimer of two identical genomic RNA molecules, is reverse transcribed into linear, double-stranded DNA. The HIV reverse transcription process does not fundamentally differ from what is known for other retroviruses. One interesting difference, however, is that the second (plus) strand of the viral DNA has two distinct origin sites for its synthesis instead of only one. The plus-strand origin is determined, in all retroviruses, by a polypurine tract (PPT) located at the 5′ boundary of the U3 region of the long terminal repeats (LTR). HIVs and other lentiviruses have a second PPT at the center of their genome, which defines a central discontinuity in the plus strand, reflecting its use as an additional origin site. This second origin appears to improve the efficiency of the reverse transcription process, as shown by a reduced replicative capacity of HIV mutants lacking the central PPT. This feature appears to be common to all lentiviruses and spumaviruses.

During the course of an acute infection, high copy numbers of unintegrated viral DNA molecules, either linear, circular with one LTR, or circular with two LTRs, can be observed in infected cells. Such accumulation of viral DNA appears to be the result of multiple events of infection in individual cells.

Following its synthesis in the cytoplasm, viral DNA is transported to the nucleus and integrated into the host cell genome. This transport is an active process, occurring through nuclear pores, mediated by the interactions of the preintegration complex with cellular proteins. It can occur in nondividing cells, unlike the case of oncoviruses. The integration reaction, which can be reproduced *in vitro*, is mediated by the viral integrase, encoded by the C-terminal region of the *pol* gene. The integrase reacts with the termini of the linear viral DNA molecule and with apparently random sites of the host genome. Integration is regarded as being required for expression of the viral genes.

Regulation of Gene Expression

Transcription

The 5′ LTR of the HIV genome contains the active viral promoter. The transcriptional start site defines the boundary between the U3 and R regions of the LTR. Transcription from the HIV promoter requires the presence of cellular transcriptional activators. Upstream of the transcription start site, surrounded by the usual transcriptional complex recognition signals, two important sets of sequences have been described: these are the three copies of the SP1 transcriptional activator binding site, and two copies of an enhancer element, which reacts with the transcriptional activator NFκB. Initially described as able to control transcription of the gene coding for the kappa chain of the immunoglobulins, NFκB is a ubiquitous transactivator whose components belong to a larger gene family that include the *rel* and *dorsal* proto-oncogenes. This factor can be activated in a number of cell types of the immune system, in particular following activation of the protein kinase C pathway. Further upstream in the U3 region of the LTR, is also found a variety of potential regulatory signals; a large segment of this region, termed NRE

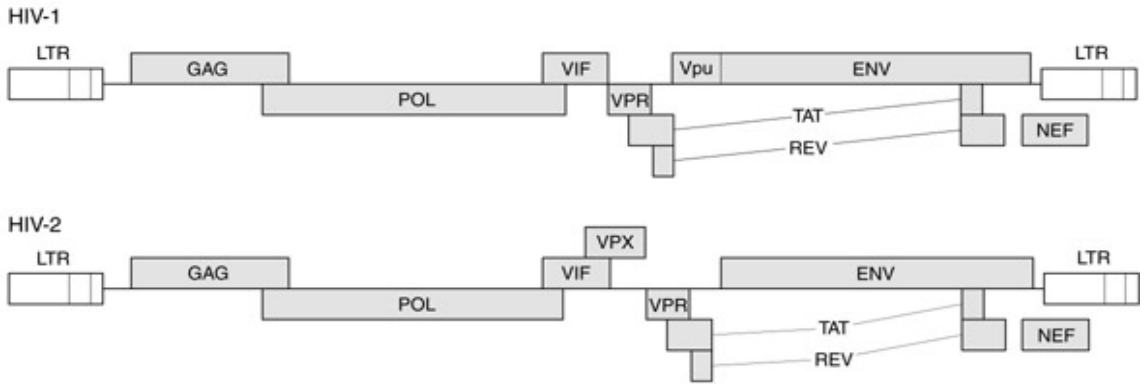

Figure 2 Genome structure of HIV-1 and HIV-2.

(negative regulatory element), has been described as exerting a negative regulatory action on transcription.

Viral regulation of transcription: the Tat system

Transcription of viral RNAs starts at the viral LTR and is mediated by cellular RNA polymerase II. But efficient synthesis of viral mRNAs only occurs in the presence of the viral protein Tat. This protein is produced from multiply spliced RNA, in which the two coding exons of the *tat* gene are linked together. The Tat protein acts by binding to a bulged stem–loop structure present at the 5′ end of all viral mRNAs, called TAR (Tat activation region). This binding is itself mediated by a cellular protein, cyclin T. Like other cyclins, cyclin T is associated with a protein kinase (CDK9) which will phosphorylate the C-terminus of RNA-polymerase II. This phosphorylation will allow efficient elongation of viral RNAs. These Tat cellular cofactors are only present in activated cells. Their absence will allow repression of transcription of proviral DNA which could thus enter a period of latency in T lymphocytes. This is another operative regulation that can allow either high virus production or quasi latency, in addition to the upstream control operated by transcription activators (NFκB) on the LTR promoter.

There is a good crosstransactivation of the HIV-2 LTR by HIV-1 Tat, but HIV-2 Tat is a poor HIV-1 transactivator: this could be consecutive to the presence of a second stem–loop structure on the HIV-2 TAR, required for efficient HIV-2 Tat binding.

Regulation of mRNA processing: the Rev system

In eukaryotic cells, only fully spliced mRNAs are exported to the cytoplasm and are translated. Unspliced RNAs are retained in the nucleus and eventually degraded.

Since HIV contains a single LTR promoter element, it encodes only a single, genome-length primary transcript. Selective expression of different viral genes is determined by differential splicing of this transcript. Splice sites (recognized by cellular proteins) are relatively inefficient, so that a pool of incompletely spliced RNAs could accumulate in the nucleus.

During acute infection, three major classes of viral transcripts can be observed: the 9 kb genomic RNA molecules, producing Gag and Pol proteins, that can also be encapsidated into viral particles; the singly spliced 4.3 kb RNA molecules, coding for the env glycoproteins; and the 1.8–2 kb, multiply spliced RNA molecules, coding for the regulatory proteins. The cytoplasmic export and stability of the unspliced and singly spliced HIV transcripts, coding for the structural proteins, is controlled by the Rev protein.

In the absence of Rev, only multiply spliced messages are seen in the cytoplasm of infected cells. When subgenomic Env constructs are studied, the effect of Rev appears to involve mostly cytoplasmic transport of unspliced RNAs. This restriction, however, seems to be dependent on the presence of splice sites. It is believed that Rev is able to oppose nuclear retention of RNA molecules by elements of the splicing machinery. It has also been suggested that Rev could favor cytoplasmic stability of RNA, association to polysomes, and even translation of unspliced or singly spliced transcripts. The target site for Rev is a complex multi stem-loop structure termed RRE (Rev responsive element), located in the intron separating the *tat* and *rev* coding exon, in the *env* coding region. Rev binds to the RRE but needs to multimerize to be active, which results in a threshold effect in Rev activity. Rev binds to the RRE through its N-terminal domain, whereas its C-terminal domain behaves as a nuclear export signal (NES) which binds to cellular proteins involved in transport from nucleus to cytoplasm.

Table 1 Proteins of HIVs

ORF	*Function*	*Location*	*HIV-1*	*HIV-2*
gag	*precursor*		p55	
	matrix	myristylated, outer virion shell	p17/18	p16
	capsid	virion: core	p24	p26
	nucleocapsid	virion: RNA associated	p7/p9	
	unknown	virion	p6	
pol	protease	virion	p10	
	RT (with RNase II domain)		p66	
	RT		p51	
	integrase		p34	p34
vif	enhances virus infectivity	infected cell	p23	
vpr	arrests cells in G2	virion	p15	
vpx	unresolved	virion (HIV-2, siv)	not found	p16
tat	transcriptional transactivator	infected cell: nucleus	p14	p20
rev	control of RNA splicing and transport	infected cell: nucleus and nucleolus	p19	p19
vpu	controls env-CD4 interaction	infected cell: membrane	p16	not found
env	*precursor*		gp160	gp140
	surface envelope glycoprotein, receptor binding	virion: surface	gp120	gp125
	transmembrane glycoprotein, membrane fusion		gp41	gp36
nef	modulates CD4 surface expression	infected cell: membrane	p27–30	p31

This effect has important consequences: during the early phase of a synchronous acute infection, the first transcripts to accumulate are the short multiply spliced species, followed by singly spliced and unspliced species. This shift from an early to a late phase of HIV expression appears to be under the control of accumulation of sufficient amounts of Rev. Similarly, some cells containing integrated HIV genomes bearing low basal expression levels do not produce structural RNAs; these can accumulate, however, after cell stimulation, in a process that is believed to involve accumulation of Rev. Therefore, the Rev system seems to promote synchronization of particle production during acute infection, and to delay structural protein expression in chronically infected cells, a phenomenon that could favor persistence of the infection in the context of a vigilant immune system.

Structural Proteins

Table 1 summarizes virion proteins, their functions, cellular location and compares HIV-1 with HIV-2 proteins.

Gag and Pol proteins

The Gag and Pol proteins are expressed from the full length, unspliced RNA molecules. In 1:100 of translation events, approximately, translation of *gag* is followed by a frameshift into the *pol* ORF. The Gag or Gag-Pol polyprotein precursors are then packaged into particles where the protease domain of the Gag-Pol precursor will cleave the final Gag and Pol products.

The Gag precursor is cleaved into four proteins. The first Gag protein, from the N-terminus of the precursor, is termed p17/18 for HIV-1 and p16 for HIV-2 (matrix protein); it carries a N-terminal myristic acid, which allows association of both the Gag and Gag-Pol precursors to the cell membrane. The largest Gag protein, p24 (p26 in HIV-2) is the principal constituent of the cone-shaped core characteristic of viruses of the HIV group (capsid protein). The next Gag protein, p7 or p9, is termed the nucleocapsid protein, and is tightly associated with the RNA genome: it has been found to promote both RNA dimerization and encapsidation. The most C-terminal of the Gag proteins is p6; although its function is not known, mutants lacking this protein exhibit a defect in particle budding.

The Pol region can be divided into three main functional elements. The most N-terminal is the protease, which acts as a dimer and cleaves Gag and Pol products during particle maturation. The central element is the reverse transcriptase, which acts as a heterodimer: the smaller component has polymerase activity, and the larger component has both polymerase and RNaseH activities. The action of RNaseH

is required to eliminate the RNA template, with the exception of selected sequences used as primers, and to allow strand transfer events.

env

The envelope glycoproteins of HIV-1 and HIV-2 are translated from a singly spliced RNA species. The glycoprotein is synthesized as a large glycosylated precursor which is then subjected to a series of biochemical rearrangements of its polysaccharide moiety and to a single cleavage event at a specific site carried out by a cellular convertase. This cleaveage separates the larger, outer portion of the envelope glycoprotein (gp 120) from the smaller, transmembrane protein (gp 41).

The gp 120 carries on a specific domain, in the form of a pocket, that binds with high affinity D1–D2 domain of the CD4 molecule present on susceptible cells. The gp 120 binding domain is conformational, involving several regions, which are conserved within HIV variants. Upon binding to CD4, the gp 120 molecule undergoes conformational changes, which exposes some other sites to cellular molecules favoring the tight association of gp 41 transmembrane protein with the plasma membrane. Unlike the CD4 binding site, these sites are located in variable regions or loops of gp 120, particularly the V3 loop. This explains why the virus can choose a variety of cell surface molecules for its entry generally in association but not always, with the CD4 main receptor. Among these surface molecules (called entry cofactors or coreceptors), two main species have been recognized, which are physiological receptors for chemokines: the CCR5 receptor for β chemokines (RANTES, MIP-1α, MIP-1β) and the CXC4 receptor for an α-chemokine (SDF-1).

Very interestingly, the use of each coreceptor corresponds to viruses with different biological properties and pathogenicity. Viruses isolated at the beginning of infection use in most cases the CCR5 coreceptor (R5 viruses). They are not cytopathic *in vitro* (nonsyncytium-inducing viruses) and replicate in macrophages and activated primary T lymphocytes expressing CCR5 and CD4. In full-blown AIDS cases, new viral species appear with high power of replication *in vitro*, cytopathic effect (syncytia and single cell lysis), poor ability to replicate in macrophages and ability to grow in tumor T cell lines. They use the coreceptor CXC4 (X4 viruses). With the characterization of more viral isolates, the situation appears more complex; there are dual-tropic viruses, using both CXC4 and CCR5 coreceptors, or using alternative chemokine coreceptors (CCR3, CCR2, CCR8). There is also evidence of binding of the V3 loop to nucleolin, a nuclear protein whose one isoform is expressed at the cell surface, and with a dipeptidase present on activated T cells, CD26.

The fusion between the viral membrane and the cellular membrane involves a change in the conformation of gp 41, itself induced by the conformational changes of gp 120. It involves exposure of a hydrophobic fusion domain present at the N-terminus of gp41, which enables it to insert itself in the cellular phospholipid bilayer. The transmembrane protein also displays an unusually long intracytoplasmic domain. This domain is particularly interesting in HIV-2 and SIV; indeed, tissue culture propagation of these viruses appears to favor truncation of the intracytoplasmic tail. The correction of this truncation leads to reduced infectivity *in vitro*.

An Important Regulatory Protein: Nef

This third early protein is expressed in far higher levels than Tat and Rev. Most of the protein is myristilated at its N-terminus and associated with the inner side of the plasma membrane. However, there is partial exposure of the C-terminus of the molecule at the outer cell surface and in experimental infections with Nef-expressing vectors, Nef is also in part excreted into the medium.

Expression of the intact Nef protein is not required for *in vitro* infection of peripheral blood leukocytes (PBLs) or of T cell lines. However Nef-deleted mutants of HIV and SIV are much less pathogenic *in vivo*, leading to persistent infection without disease, at least for a long period of time. Studies in the SIV/macaque model have shown that the initial virus load in lymph nodes is reduced by a factor of 10–50, and that formation of germinal centers in response to infection occurs more quickly than with the pathogenic Nef+ strains.

In the productive cycle of viral infection, several functions of Nef have been identified, which contribute to a higher or longer virus production. Nef has been shown to strongly downregulate the expression of cell surface CD4, by connecting CD4 with the cellular endocytic machinery. This prevents reinfection of the infected cell with newly produced virions, which could lead to its premature death.

Nef also downregulates to a lesser extent surface expression of MHG-1, resulting in some inhibition of recognition of the infected cells by specific cytotoxic T lymphocytes (CTL). Nef seems also, by independent, yet unclear, mechanisms, to enhance virion infectivity, perhaps by increasing the stability of the nucleocapsid at its entrance in the cell.

Perhaps the most relevant property of Nef for its role in AIDS pathogenesis is its capacity to activate

CD4+ T lymphocytes by modulating signaling pathways. An extreme case is that of the PBJ14 mutant of SIV which can induce within a few weeks an acute disease in pigtail macaques, and can activate both resting CD8+ and CD4+ lymphocytes *in vitro*. These unusual properties are linked to the creation in Nef by directed mutagenesis (or selection by passage in animals) of a new SH2 (Sarc homologous region 2) binding domain (YXXL motif).

The fact that CD8 cells which are not infectable by SIV are also stimulated, suggests some paracrine effect of Nef expressed or released at the surface of infected CD4+ cells. Nef from 'normally' pathogenic strains of HIV or SIV contains a proline-rich sequence which could bind to the SH3 domain of kinases involved in the activation pathway of T lymphocytes. When mutations are introduced in this region, SIV is no longer pathogenic, unless reversion to the wild-type occurs.

In addition, recombinant Nef protein, in the 10–50 ng/ml range, can act as a costimulatory factor in T lymphocytes in which the T cell receptor was subliminally activated and permits HIV replication in such cells. Thus, Nef produced by HIV-infected cells could recruit for infection neighboring T cells which were on the verge of activation and could not otherwise be susceptible to HIV infection.

This recruitment may be important at the beginning of infection when the number of activated T cells in lymphatic tissues is low and is a limiting factor for HIV expansion.

Other HIV Accessory Proteins: Vif, Vpr, Vpu, Vpx

All these proteins are encoded by single spliced mRNAs and therefore are produced late after sufficient Rev expression.

Vif The Vif protein is expressed at high levels in the cytoplasm of infected cells. Deletion of this gene reduces infectivity of HIV-1 virions in primary T4 cells and some tumor cell lines CH9. Some Vif proteins are also present in mature virions. It is believed that Vif can stabilize the virions upon entry in the cells and favor the formation of the reverse transcription complex.

Vpr This small basic protein is packaged in the virion nucleocapsid in amounts equivalent to the Gag proteins and therefore can be considered as a virion structural protein. Packaging depends on its association with the p6 protein released by proteolytic cleavage from the C-terminus of the p55 Gag precursor.

Two effects of Vpr have been recognized. One, which is controversial, is to contribute to the nuclear import of the preintegration complex, by interacting with nucleoporins, and other cellular proteins, especially in nondividing differentiated cells (macrophages).

The other function is to induce in cycling cells an arrest in G2. This effect is similar to that induced by DNA alkylating agents, and could result in the induction of the DNA repair machinery, which could be useful for integration of the proviral DNA. Rhesus macaques inoculated with a mutant SIV having a deletion in Vpr can still evolve towards AIDS-like disease, although some individuals show more resistance to disease progression.

Vpu The *Vpu* gene is unique to HIV-1 and the related virus isolated from chimpanzees. The product, Vpu, translated from the same mRNA that produces *env*, is an integral membrane protein with a C-terminal intracytoplasmic tail.

Vpu has two functions. The first is to allow selective degradation of CD4 when the latter associates with the viral envelop precursor in the endoplasmic reticulum. This will release the Env protein from this complex and allow its subsequent incorporation into new virions.

The second function is to facilitate virion release from the cell plasma membrane. Vpu-defective mutants show accumulation of intracellular viral particles.

Vpx The *vpx* gene is found only in HIV-2 and SIVs. Like Vpr, the protein is present in mature virions, in amounts roughly equal to that of the major Gag protein p24.

Inside the cell, Vpx is located at the inner side of the cell plasma membrane. Vpx deletion mutants have a reduced capacity to replicate in primary T lymphocytes and macrophages, although they grow normally in T cell lines.

Genetics

One striking feature of the HIVs arose as soon as the nucleotide sequence of several HIV isolates was known: HIVs display a high level of genetic variability. The most variable region of their genome is the outer region of the envelope glycoprotein, where divergence can reach 30%. The most conserved are the *gag* and *pol* genes. The leading cause of such a diversity is reverse transcriptase: this enzyme does not have any proof-correction activity, and appears to introduce errors every 10^4 nucleotides. Another cause is selection: having to replicate in the context of a vigilant immune

system, HIV needs to escape the antiviral immune response. This could explain why the envelope glycoprotein is the most variable region of the genome. It has also been shown that a single infected individual does not carry a single isolate, but a heterogenous population of subisolates, sometimes referred to as 'quasispecies', and that changing the conditions of viral replication (by growing the virus *in vitro*, for example) will modify the balance of that viral population. In addition the biological properties of the virus – as determined in the *in vitro* isolate – change during the course of the disease: in general, isolates made from lymphocytes of asymptomatic patients grow slower and are less cytopathic than isolates made from patients with full blown AIDS. These changes seem to be related to mutations in the envelope protein gp120, but no particular mutation can be assigned to the changes in biological properties.

Within the HIV-1 type, genetic diversity appears to be more striking when African isolates are compared with one another or with Western isolates. This is an indirect indication that African isolates may have evolved longer than their western counterparts.

Based on nucleotide sequence of the variable regions of the envelope protein gp120 (particularly V3), a cladistic classification of HIV-1 isolates is currently being used, using capital alphabetic letters, A to J. They all belong to the group M of HIV-1s (M for major). Since the early 1990s another group of HIV-1 has been described in Central Africa (Cameroun) with some sporadic cases in Europe. This group, which differs from the **M** group by around 50% of nucleotides sequences in the *env* gene, has been termed **O** (for outlayer). All HIV-1s are highly pathogenic but display various geographic locations (see below).

More radically divergent is the HIV-2 group, which was prominent in West Africa in the 1980s, but now tends to be less prevalent than HIV-1. By serology and nucleotide sequences, HIV-2, which also displays several subtypes, is closer to SIVs than to HIV-1. In fact, it probably originates from a SIV naturally infecting sooty mangabeys living in West Africa.

HIV-2 was initially found in some West African patients with AIDS, with symptoms comparable to HIV-1 disease. However, its pathogenic potential seems to be lower than HIV-1, displaying a lower viral load in chronically infected patients and a lower capacity of transmission by sexual contacts.

Origin and Geographic Distribution

HIV-1 seems to have originated in Central Africa. This is suggested by the larger extent of variability found in strains isolated from African patients.

Retrospective serological studies also indicate that the virus was present in the early 1970s in 0.25% of a population of young women living in Kinshasa (Zaïre). However, only retrospective sporadic cases could be detected in Africa before 1980 as well as in Europe and the United States. The HIV-1 directed epidemic started at about the same time in larger cities of Central Africa and of the United States.

Molecular analysis of the virus present in a serum taken from a Zaïrian patient in 1959 indicates that it could be an ancestor of several identified HIV-1 clades: B, which is now prominent in North America and Western Europe, D and F present in Central Africa.

In the phylogenetic trees, two isolates made from chimpanzees are clearly closer to the M group than from the O group, the origin of which cannot be traced to any simian lentivirus. This group may have been circulating in some human populations for a longer time.

In the 1990s HIV-1 infection has become pandemic, rapidly developing in new regions such as India, South-East Asia and South America. In Africa, the infection has spread to the East (Uganda, Kenya, Tanzania, Rwanda, Burundi) and to the North (Ivory Coast). Concerning HIV-2, its spread has been more limited from the areas where it was first detected: Guinea-Bissau, Cap Verde Islands, Senegal. HIV-2 is also present in other countries of the Western part of Africa (Ivory Coast, Burkina Faso, Cameroon, Liberia etc.) and Portuguese-speaking countries (Angola, Mozambique). An outbreak of HIV-2 infection has been detected in prostitutes of the Bombay area, India, suggesting that the virus has also reached Asia.

New rapidly spreading foci of HIV-1 infection have occurred in South Africa, Zimbabwe, Cambodia and China. Some subtypes are becoming prominent, according to the geographic location, such as A in Ivory Coast, C and D in Central and South Africa, E in Thaïland, F in Brazil. As the epidemic progresses, infection of the same individual by two variants becomes frequent, leading to the emergence of recombinants (particularly in the *env* gene) between subtypes.

As of 1998, the number of HIV-infected persons is estimated to be 30–40 million worldwide.

Serologic Relationships

Despite the large spectrum of genetic variability, the prototype strain of HIV-1, isolated at the Pasteur Institute, LAV LAI (otherwise named HTLV-IIIB) can still serve as source of antigen for the detection of HIV-1 antibodies in all geographic regions of the world, including antibodies against the envelope. By

contrast, little crossreactivity exists between SIV/HIV-2 group and HIV-1 glycoproteins, whereas crossreactivity remains important in Gag and Pol proteins of the two viruses.

The lack of crossreactivity in a major epitope of the transmembrane protein (gp41, gp36) has been used to differentiate between HIV-1 and HIV-2 infection, or to detect double infection. So far a few patients have shown, by western blot using HIV-1 and HIV-2 prototypes as antigen, atypical reactivity. Such cases, in which, for instance, no antibodies against the glycoprotein of HIV-1 or HIV-2 could be detected in serum, are probably due to variants distantly related to HIV-1 or HIV-2.

With regards to animal retroviruses, SIV-infected primates do react well with all HIV-2 proteins, confirming the close relationship between SIV (particularly SIV from sooty mangabey) and HIV-2. By contrast, other animal lentiviruses (Visna, CAEV, BIV, FIV) are too distantly related to show antibody crossreactivity, with the exception of equine infectious anemia virus which shows crossreactivity with HIV-1, at the level of the Gag p24 protein.

Host Range and Virus Transmission

HIV-1 has a very limited host range; human and chimpanzee are the only species known so far which can be chronically infected with the virus. However, no disease or deep immune depression have been observed in the hundreds of chimpanzees inoculated with human isolates of HIV-1, with one exception, whereas lack of symptoms is the exception in humans.

HIV-2 can chronically infect some macaque species (rhesus, cynomolgus); an AIDS-like syndrome has been observed in some experiments, but not in a reproducible way.

The two main routes of transmission of HIVs are blood and blood products and sexual contact. The efficiency of blood transmission (transfusion, needles, i.v. drug abuse) depends on several factors: number of virus particles, volume of blood, immune status of the receiver. Infection is particularly efficient in i.v. drug abusers.

Sexual transmission, homosexual and heterosexual, is the major mode of transmission today. All sexual practices are dangerous, but the risk is higher for anogenital intercourse, and is increased by some intercurrent genital infections (herpes, chlamydia etc.).

Transmission from mother to child is also a major mode. In the absence of treatment, 20–30% of seropositive women give birth to an infected child. Infection can occur in the second half of pregnancy, at delivery and also by breast feeding. Severe infection of children results in death in the first year of life. Otherwise the evolution follows that seen in adults.

Role of the Virus in AIDS Pathogenesis

Acquired Immune Deficiency Syndrome (AIDS, SIDA in French and Spanish-speaking countries) was defined in the early 1980s, biologically by a profound defect of cellular immunity associated with a deep shortage of CD4+ T lymphocytes and clinically by the occurrence of opportunistic infections and cancers. In Western countries, the most frequent infections are those of the lungs by *Pneumocystis carinii* and of the brain by toxoplasmas, followed by visceral and retinal infections by cytomegalovirus (CMV). Tuberculosis is frequent in tropical areas (Africa, Asia, South America).

Among cancers, the most frequent are disseminated and aggressive Kaposi's sarcoma caused by human herpesvirus 8 (HHV-8) and B-lymphomas, often caused by Epstein–Barr virus (EBV).

The causal relationship between HIV and the immune depression has been assessed as follows:

1. On the basis of epidemiological studies, particularly in blood donors and recipients;
2. From the tropism and cytopathic effect of HIV and viral glycoproteins on CD4+ cells;
3. On the reproduction of the disease in macaques by virus derived from molecular clones of SIV (close to HIV-2).

The natural history of HIV-1 infection has been thoroughy studied by histological and molecular techniques. Three phases can be distinguished: primary infection, a clinical latency phase, the clinical phase (full blown AIDS).

In the primary infection, entry of the virus through mucosa involves its association with denditric cells which then transport the virus to lymphatic tissues. The virus can rapidly multiply there in activated CD4+ lymphocytes and macrophages. Since the number of activated CD4 lymphocytes is small, it becomes a limiting factor which depends on intercurring microbial infections. Biologically, this phase is characterized by a peak of viral antigens (not always present) and a large number of viral RNA copies in blood, and a peak of γ and α interferons. Specific cytotoxic lymphocytes (CTL) then appear followed by the appearance of antibodies against viral glycoproteins and internal proteins. Clinically, when the level of viral replication is high, symptoms can be detected (fever, adenopathy, headaches). However,

the infection can be sometimes completely inapparent.

This episode is followed by a phase of clinical latency, with no symptoms. However, in a majority of cases, there is a slow and progressive degradation of the immune system, leading finally to clinical AIDS which will last on average ten years, in the absence of treatment. In a minority of individuals (5–10%) (long-term nonprogressors) this degradation does not take place or is very slow. In some others, on the contrary, immune depression can occur very rapidly within 1–2 years.

These variations reflect the complex interaction of HIV with the immune system of the host. In fact, the virus continuously replicates in lymphatic tissues (lymph nodes, spleen), with a rapid clearance from the blood. A relatively small number of infected cells is involved at the beginning and their destruction (either by the virus or by cytotoxic cells) cannot solely account for the large depletion of CD4+ cells. It is likely that indirect mechanisms of cell death are involved, bearing on cells which are not infected, but are in contact with noninfectious viral particles, or gp120 shed from cells or virions. Indeed, interaction of gp120 with the CD4 receptor or coreceptors could induce a wrong signaling leading to apoptotic cell death or anergy, when the T cell receptor is stimulated.

Evidence for the preapoptotic state of a large fractional circulating CD4 cells has been obtained. Defects in antigen-presenting cells, in bone marrow renewal of precursor cells, of faster thymic involution, of high oxidative stress, have also been involved to explain the specific CD4+ cell depletion. It is also clear that a state of chronic activation bearing not only on CD4+ cells, but also on CD8, NK and B cells exists all through this phase, associated with the production of inflammatory cytokines (interferons, interleukin (IL) 6, tumor necrosis factor).

In addition, a small pool of latently infected cells exists and is probably continuously renewed. This pool will escape any kind of treatment.

In the clinical phase, with the occurrence of more pathogenic variants (CXC4 tropic) and the decrease in cell-mediated immune response, the infection from local or regional becomes systemic and precipitates the fatal evolution.

Neurological signs are also frequent, particularly a subacute encephalopathy which can develop into a dementia syndrome and brain atrophy, and seems to be due to the virus itself. Some foci of brain macrophages infected with HIV can be detected in white matter, but neither neurons nor glial cells seem to be productibly infected in the same situation. Some astrocytes express large amounts of Nef protein. Therefore indirect mechanisms for the action of HIV (cytokines, nitric oxide?) have also to be postulated in order to explain the neuronal effects.

Immune Response

An immune response against HIV is mediated by T-helper cells. Antibody response against major HIV structural protein (Gag, Env) and also against Pol proteins and Nef appear within 2–3 weeks after HIV exposure, exceptionally after six months or more. Specific CD8+ cytotoxic T lymphocytes (CTLs) also appear, often earlier than the antibody response, directed against the same proteins. Antibodies against the viral envelope are poorly neutralizing, and are directed against variable regions of gp120, especially the V3 loop.

There is also induction of antiviral cytokines (interferons γ, α) but for unclear reasons, even large amounts of α interferon are not effective to control viral expansion. There is also *in vitro* evidence for viral inhibition by other soluble factors, particularly secreted by CD8+ T lymphocytes; the increase of β chemokines may inhibit by competition the entry of C5 viruses, but some other inhibitory factors produced by CD8+ cells have not yet been identified.

As the infection progresses, the specific CTL response tends to decrease and to lose its efficacy against mutant viruses, although a strong natural killer response (NK cells) can still also play a protective role.

The number and function of CD4+ T lymphocytes decreases progressively with some oscillations during the clinically latent phase. T-helper functions to recalled antigens are precociously affected, in line with a drop of IL-2 and an increase of Th2 cytokines (IL-4). The antibody response against viral proteins decreases at the clinical phase, reaching first the internal proteins. Owing to their higher titers, antibodies against gp120 and gp41 remain detectable even at late stages. These antibodies can also be detected in urine in lower titer.

Treatment

Until 1994, there was no effective treatment of HIV infection and AIDS. Monotherapy using nucleosidic or nonnucleosidic inhibitors of HIV reverse transcriptase gave disappointing results in clinical trials. It was realized that the inhibitory effect on virus replication was not strong enough to prevent the rapid occurrence of resistant mutants. Dramatic improvements appeared in 1995–1996 due to the design of a new class of potent antiviral drugs, the inhibitors of the viral protease, which prevent the

maturation of infectious virions by inhibiting the cleavage of the gag-pol precursor. Another important development was the general acceptance of the concept of combination therapy, in which two, three or even four inhibitors act synergistically and decrease the emergence of resistants. Finally the application of sensitive molecular techniques (polymerase chain reaction, branched DNA) to quantitate the viral load in plasma was an important tool to monitor the antiviral effect of the treatment.

The combined use of two inhibitors (such as azidothymidine (AZT) and 3-thiodeoxycitidine (3-TC)) of reverse transcriptase with a protease inhibitor (such as Ritonavir, Indinavir, Nelfinavir) results generally, in a strong decrease of viral load within weeks (2–4 logs), a slow but consistent increase of CD4+ cells and an improvement of the patient's condition.

Opportunistic infections are much less frequent and there is biological evidence of at least partial restoration of T helper-dependent immune functions (response to recall antigens, drop of apoptosis and cell activation markers). However, this treatment called HAART (highly active retroviral therapy) has some constraints and limitations.

1. It has to be taken daily and indefinitely.
2. Active virus multiplication is not completely suppressed, and multiresistant variants may appear, more rapidly if the patient does not adhere to strict compliance to the treatment.
3. There is a continuously renewed reservoir of cells which are latently infected and therefore have unexpressed proviral DNA which escapes the reverse transcriptase and protease inhibitors.
4. Important side effects, such as mobilization of lipids resulting in hypertriglyceridemia, insulin-resistant diabetes, can occur after long-term treatment.
5. The high cost precludes any generalization of its application for patients in developing countries.

Therefore there is a need for intensive research to develop new types of retroviral inhibitors, to find practical tests to evaluate the spectrum of resistance and sensitivity to available drugs of the patient's virus, to find complementary treatments aimed at reducing the dosage and duration of HAART and at achieving better restoration of the immune system.

Among possible promising developments are the use of: very low doses of IL-2 (a daily subcutaneous inoculation for 6 months); hydroxyurea; and inhibitors of cell activation and a specific immunotherapy against viral proteins.

Prevention and Vaccine

No vaccine is yet available and the only effective prevention at present is education about the ways of transmission, systematic testing of blood donors and the use of condoms. However, an important reduction of transmission from mother to child has been achieved by treatment with AZT of the mother at the end of pregnancy and at the time of delivery and of the newborn in the first weeks of life. A lighter regimen also seems to be effective and applicable to populations of developing countries.

A complete control of the AIDS epidemic cannot be achieved without the availability of a protective vaccine. Although the use of whole virus or whole surface glycoproteins has been disappointing, there are new promising approaches based on the use of DNA, mucosal adjuvants and live vectors, internal and regulatory proteins, and conserved parts of the surface glycoproteins.

Studies of naturally resistant HIV-exposed individuals have shown that cell-mediated immunity and the secretion of soluble inhibitory factors are more important for protection than antibodies, together with a limited role of genetic factors. Individuals homozygous for mutations impairing the expression of CCR5 coreceptors are totally resistant to infections by 'R5 tropic viruses'. However, these are rare (<2%) in the caucasian population. Individuals heterozygous for these mutations can still be infected, but seem to evolve more slowly to the clinical phase of AIDS.

In fact, a large majority of exposed noninfected individuals have acquired a specific immune resistance to infection, based on CTL and specific IgAs, although the role of other genetic factors (HLA) cannot be excluded.

The efficacy trials of candidate vaccine in large populations will raise important logistic and ethical issues difficult to solve, unless an important international mobilization greater than that achieved for vaccinal eradication of poliomyelitis, is achieved.

Human immunodeficiency viruses are members of the family *Retroviridae*, genus *Lentivirus*. The human immunodeficiency viruses (HIV) type 1 and 2 are the causative agents of acquired immunodeficiency syndrome (AIDS). Humans are the hosts for both viruses and they infect mainly CD4+ lymphocytes and monocyte/macrophages also expressing a coreceptor molecule. Characteristic of infection with HIV is an early high level of serum viremia that subsides in response to an aggressive immune response. However, HIV withstands this initial attack, is able to persist, and slowly erodes the immune system of the infected individual by depleting CD4+ lymphocytes at a rate of 2 billion per day. This article describes the molecular determinants responsible for virulence.

Properties of the Virion

HIV particles have a diameter of 100–120 nm and a spherical morphology classical of several other retroviruses. They consist of a dense truncated cone-shaped core surrounded by a membrane bilayer (envelope) decorated with spikes corresponding to the surface glycoprotein (SU). HIV particles are assembled beneath the cell surface. The internal structure of the virus particle rearranges after budding, a result of the proteolytic cleavage of the major structural components by a viral-encoded protease. This process is called maturation. Virions are sensitive to radiation, acidic pH, diluted ethanol, detergents, chorine and temperature (60°C). The genome consists of a homodimer of linear, positive-sense, single-stranded RNA of approx. 9.2 kb in size. The two strands of RNA are capped, polyadenylated, and noncovalently joined through the dimerization domain. Lysine tRNA is found bound to the viral RNA in the particle and serves as a primer for reverse transcription.

Genome Structure

The HIV genome is significantly more complex than the genome of murine retroviruses (**Fig. 1**). This complexity is likely to reflect the dynamic interplay between this virus and its host. Like all other retroviruses, the HIV genome encodes three structural genes *gag*, *pol* and *env*. In addition, it encodes several small genes (*vif*, *vpr*/*vpx*, *tat*, *rev*, *vpu* and *nef*) that regulate gene expression, protein expression, and to a great extent are determinants of virulence. In order to maximize its coding capacity, HIV uses several different means to pack information into a relatively small genome. Differential splicing of the viral genome is used to control in a temporal and advantageous manner the expression of structural and regulatory genes. In addition, the virus genome encodes several *cis*-acting elements involved in virion packaging (Ψ or psi), reverse transcription (primer binding site or PBS, polypurine tracts or PPT), RNA retention in the nucleus (negative regulatory elements or CRS), RNA export and processing (Rev-responsive element or RRE and polyadenylation signal), transcription (TAR), etc.

Virus Replication

The replication cycle of HIV is very similar to that of other retroviruses. However, it is under significantly tighter control. The replication cycle of HIV can be divided into three steps: (1) entry and integration; (2) gene expression; and (3) assembly and budding. Each of these steps involves several specific interactions between virus and cellular proteins. Like all highly capable parasites, HIV skillfully takes advantage of cellular processes to replicate very efficiently and evade destruction by the immune system.

Entry and Integration

The first specific interaction between HIV and its target cell is the binding of the surface viral glycoprotein (SU) to the CD4 molecule, its receptor on the surface of the target cell. For the most part, the interaction between SU and CD4 is required but not sufficient for virus entry. Entry is dependent on a second molecule or co-receptor that binds to a region of the SU protein that becomes accessible after it

Figure 1 Diagram of the HIV-1 genome.

binds to CD4. Whereas all HIV isolates bind CD4, different HIV strains are specific for different co-receptors. These HIV co-receptors also function as receptors for chemokines and are members of the family of receptor proteins characterized by containing seven membrane-spanning segments. The discovery of the role of these co-receptors in HIV entry explained some aspects of HIV tropism that had puzzled investigators for many years and that are highly significant to virus replication and pathogenesis *in vivo*. The 'T' tropic viruses (also known as syncytium inducing or SI) are able to replicate in primary T cells and in cell lines expressing human CD4 but not in primary macrophages. These viruses use the CXCR4 molecule as co-receptor and are inhibited by the natural ligand for this receptor, stromal-derived factor (SDF-1). The 'M' tropic viruses (nonsyncytium inducing or NSI) infect human primary T cells and human monocyte/macrophages but fail to infect almost all human CD4+ cell lines. M-tropic viruses use the CCR5 molecule as co-receptor and are inhibited by its natural ligands the RANTES, MIP-1α, and MIP-1β chemokines.

The co-receptors for HIV are believed to play an important role in the fusion between the membranes of the virus and the cell. After fusion, the virus deposits its genetic information in the cytoplasm in the form of a preintegration complex. The preintegration complex consists of partially reversed transcribed RNA complex with matrix, polymerase, integrase and Vpr proteins. Of particular importance to the transport of the preintegration complex to the

nucleus are the matrix, Vpr and integrase proteins. All three have nucleophilic characteristics that are important for the active transport of the preintegration complex into the nucleus. This active transport mechanism is responsible for the ability of HIV to infect certain nondividing cells such as macrophages. Reverse transcription is completed in the cytoplasm and the finished double-stranded DNA product (provirus) is modified at both ends before integration into the host chromosome. For the most part, the process of reverse transcription for HIV is the same as for other retroviruses. One important exception is the use of a second central polypurine tract to complete the synthesis of the plus-strand. This unique feature of HIV seems to be important as mutations in this region have negative effects on virus replication.

Reverse transcriptases do not have a proof reading activity and therefore introduce nucleotide changes in the provirus with relatively high frequency (10^{-4}–10^{-5} per base incorporated). The error rate of HIV reverse transcriptase is not higher than that of other retroviruses but compounded with the high levels of HIV replication, it plays an important role in the viral diversity seen in patients. The endproduct of reverse transcription is a blunt-ended linear molecule. This molecule is modified by the viral integrase which cleaves the 3′ termini eliminating the terminal two bases from each 3′ end resulting in recessed 3′-hydroxyl groups. In the nucleus, the provirus preferentially integrates in highly bent DNA sites such as nucleosomes. After binding to the cellular DNA, the integrase–provirus complex positions the 3′-OH groups at the ends of the viral DNA to attack phosphodiester bonds on opposite strands of the cellular DNA. Then a *trans*-esterification reaction results in the joining of the proviral and cellular DNA ends. A 4–6 bp gap of mismatched viral 5′ ends are then trimmed, filled in and ligated. These last reactions are believed to be carried out by integrase but a cellular activity can not be ruled out. The net result of the integration process is the permanent incorporation of the provirus into the genome of the host.

Gene Expression

As for all other retroviruses, the HIV primary transcript initiates at the beginning of the R region of the 5′ long terminal repeat (LTR) and ends at the polyadenylation signal at the end of the R region of the 3′ LTR.Unlike most murine retroviruses which have a single splice donor (SD) and acceptor (SA) for the production of two mRNAs, the HIV RNA contains several SD and SA sites that allow for the production of numerous single and multiply spliced mRNAs. However, unlike murine retroviruses which depend solely on the cellular machinery to control the levels and types of viral transcripts, HIV encodes specific proteins that control the level and type of viral RNA expressed (full length, singly spliced and multiply spliced). The HIV LTR contains the typical components of a polymerase II enhancer–promoter which are responsible for the low basal level of transcription observed in the absence of the regulatory protein Tat (*trans*-activator of transcription). Unlike most promoters, the HIV LTR has a downstream activating *cis*-element called TAR (*trans*-acting response element) which is located in the first 80 bp of the transcript. Transactivation by Tat is mediated by the direct interaction between Tat and TAR and involves many different cellular proteins. Tat *trans*-activation results in a change in polarity of the transcripts from mainly short transcripts to fully elongated transcripts. Tat expression initiates a positive feedback loop that maintains high levels of transcription. Tat is encoded by two different exons from a multiply spliced mRNA that express a protein of 102 amino acids. All the known functional domains of Tat (TAR binding and nuclear localization) are found in the first exon. There is no definitive function for the second exon.

Early after infection there are only fully spliced viral RNAs in the cytoplasm of infected cells. These multiply spliced messages encode the Tat, Rev and Nef proteins. This differential distribution of viral RNAs is due to *cis*-acting nuclear retention sequences (CRS) present in the *gag*, *pol* and *env* coding regions of the viral RNA. These sequences are spliced out of the messages encoding Tat, Rev and Nef. As the amount of Rev in the cell reaches a threshold level, there is a significant increase in the levels of singly and multiply spliced messages in the cytoplasm. The transport of these messages into the cytoplasm is mediated by the Rev protein. Rev is a 117 amino acid phosphoprotein that binds to a *cis*-acting element, the Rev *r*esponsive *e*lement or RRE (234 bp) located within the *env* gene and found in all unspliced or singly spliced viral mRNAs. Whereas the exact stoichiometry of the Rev/RRE complex *in vivo* is not known, it is clear that many Rev molecules bind to a single RRE, hence the need for a high threshold level of Rev before export of the viral RNAs occurs. Based on the Rev-dependent export of viral RNA, investigators have divided the life cycle of the HIV into an early and a late phase. In the early phase only Rev-independent messages (*tat*, *rev* and *nef*) are exported and translated. In the late phase both Rev-independent and Rev-dependent (*gag-pol*, *env*, *vif*, *vpr*/*vpx* and *vpu*) messages are exported and translated. Unlike most cellular mRNAs, which are

monocistronic, several HIV mRNAs are multicistronic with open reading frames (ORFs) that partially overlap or are arranged in tandem. Ribosomal frameshift (−1) is involved in the expression of the Gag and Pol proteins from the same mRNA. In most translation events of the gag-pol mRNA, only the Gag protein is translated. At a much lower frequency (approx. 5%) the ribosome falls back one nucleotide at a specific site near the end of the *gag* coding sequence. The ribosome then continues translation of the *pol* ORF. This results in a Gag-Pol fusion protein that is subsequently processed by the virus protease during virion maturation. Other multicistronic mRNAs encode more than one protein and their respective expression levels are determined by the context of the first ATG. For example, all *env* messages also contain the *vpu* ORF. Because the context for the *vpu* ATG is suboptimal, the ribosome can skip over it and find the strong ATG for *env*. This level of control is important to maintain the correct equilibrium between the levels of the different viral proteins.

Assembly and budding

For the most part, assembly of the virus particle takes place on the inner surface of the cell membrane. In certain cell types like macrophages it might also take place in vacuoles. The major virion component is the Gag precursor $Pr55^{gag}$. In the virus particle, the $Pr55^{gag}$ precursor is cleaved into four major proteins: matrix (MA or $p17^{MA}$), capsid (CA or $p24^{CA}$), nucleocapsid (NC or $p7^{NC}$) and $p6^{gag}$. Gag is targeted to the cell membrane by virtue of being postranslationally modified by the addition of a myristyl group. $Pr55^{gag}$ is capable of associating into virion-like particles spontaneously without other viral or cellular proteins. $Pr55^{gag}$ directs the incorporation of the Gag-Pol polyprotein precursor ($Pr160^{gag\text{-}pol}$), the envelope protein, and Vpr. In addition, $Pr55^{gag}$ binds cyclophilin A. The significance of this observation is highlighted by the fact that cyclosporin and some of its analogues disrupt the association of $Pr55^{gag}$ with cyclophilin and inhibit HIV replication. The site of interaction of the Env protein with the forming virion is likely to be the matrix protein. The HIV-1 Env precursor (gp160) is cleaved by a cellular protease into the surface glycoprotein (SU or gp120) and a transmembrane glycoprotein (TM or gp41). Two nonstructural viral proteins Vpr and Nef have also been found in the virus particle. The nucleocapsid domain of Gag interacts directly with the encapsidation sequence (psi) of the HIV genomic RNA via its zinc finger domains. At this point the lipid bilayer begins to surround the viral core and budding occurs. Following assembly and release, proteolytic processing mediated by the viral protease separates the domains of the different polyproteins and sets the appropriate conditions for reverse transcription. Only the mature particles are competent for infection.

Viral Ancillary Genes

As indicated above, in addition to the two essential regulatory genes *tat* and *rev*, the HIV genome encodes several genes that although not essential for *in vitro* replication represent important determinants of virulence. Because these genes do not have an overt *in vitro* phenotype their study has been difficult and progress in these areas is slow. However, significant observations have been made that have partially unraveled their significance.

vif

The *v*iral *i*nfectivity *f*actor ORF overlaps with the 3′ end of *pol* and encodes a 23 kDa protein (Vif) found both in the cytoplasm and the inner portion of the cell membrane. Vif is required for infection of human primary lymphocytes and some cell lines. Whereas the mechanism of Vif action is not well understood, there is a consensus that it affects late events in the viral life cycle such as virus particle maturation. Because certain cells can complement the absence of Vif, the presence of a cellular homologue has been proposed. The infectivity of Vif defective virions produced in non-permissive cells can be 25–100 times lower than wild type. Vif has been found in virus particles at levels similar to Pol. However, since it can also be found in murine leukemia virus particles its incorporation appears not specific. Therefore, any possible significance of Vif incorporation into virions is yet to be determined.

vpr/vpx

The *v*irus *p*rotein *R* (and/or X) ORF encodes a protein (Vpr and/or Vpx) of about 120 amino acids (14 kDa) that is incorporated into the virion via $p6^{gag}$ at levels similar to those of Gag. Vpr is expressed from a singly spliced message which is dependent on Rev for transport into the cytoplasm. In HIV-infected cells, Vpr is found both in the cytoplasm and in the interior of the nuclear envelope. Vpr has two genetically separable functions: facilitating HIV infection of terminally differentiated macrophages and arrest of cells in G2 of the cell cycle. The role of Vpr in macrophage infection is to transport the proviral DNA into the intact nucleus of nondividing cells. This function of Vpr is partially restored by $p17^{MA}$ or integrase. The significance of G2 arrest is not clearly understood, but may result in increased levels of virus

production or perhaps in blocking apoptosis. An amino-terminus domain of Vpr is important for virion targeting and nuclear localization. A carboxyl-terminal domain is important for G2 arrest. Vpx is an additional ORF present in HIV-2 and related simian immunodeficiency virus strains. Vpx is also a virion protein but it does not induce G2 arrest.

vpu

The *v*irus *p*rotein *U* ORF encodes an 81 amino acids protein (Vpu). Vpu is expressed as part of a bicistronic message that also encodes the Env protein and is regulated by Rev. Vpu is a type I membrane protein with two well-described functions: degradation of CD4 in the endoplasmic reticulum and enhancement of virus release from the plasma membrane. The coordinated expression of Vpu and Env is important because CD4 degradation results in the release of Env from a complex with CD4 which otherwise would be retained in the endoplasmic reticulum. Therefore, Vpu expression in CD4+ cells would result in increased levels of Env at the site of particle assembly. A third function has also been described for Vpu, the ability to form a cation-selective ion channel. The role of this ion channel in Vpu activity is presently unknown.

nef

The protein product of the *nef* gene (Nef) was originally described as having a negative effect on virus replication and thus being a *ne*gative *f*actor hence the acronym. Subsequent *in vivo* and *in vitro* studies have shown that Nef has a positive effect on virus replication. The *nef* ORF encodes a 27–29 kDa protein. Nef is expressed from multiply spliced messages that are Rev independent and expressed at high levels early and throughout infection. Nef is myristoylated and phosphorylated in HIV-infected cells. Both post-translational modifications are important for function. Analysis by electron microscopy or immunofluorescence analysis indicates that Nef is found predominantly in the perinuclear region with a small fraction of Nef associated with the inner portion of the cell membrane. Biochemical analysis shows that a large proportion of Nef is associated with membranes through its N-terminus myristyl group. *In vitro* analysis indicates that Nef is a multifunctional protein. There are at least four reproducible functions for Nef: cell surface CD4 and major histocompatability complex (MHC) I downregulation, enhancement of particle infectivity, association with cellular serine/threonine kinases, and cellular activation. These functions of Nef contribute to the high level and efficient replication of HIV *in vivo*, but it is clear that the mechanisms of Nef action remain unknown.

Antiretroviral Agents

Ranga V Srinivas and **Arnold Fridland**, Department of Infectious Diseases, St Jude Children's Research Hospital, Memphis, Tennessee, USA

Introduction

This review attempts to give a brief overview of antiretroviral agents currently used in the control of HIV-1 infections. Compounds in development, as well as other viral targets for the development of potential new drugs are considered briefly. An overview of compounds targeted against various viral gene products is presented and issues that affect the pharmacological response of the various compounds are raised.

Human Immunodeficiency Virus (HIV) Genome and Viral Targets for Drug Development

The HIV genome encodes both structural genes, *gag*, *pol* and *env*, that are common to all retroviruses, as well as additional regulatory/accessory genes unique to lentiviruses. In HIV, these genes include *tat*, *rev*, *nef*, *vif*, *vpu* and *vpr*. *Nef*, *vif*, *vpu* and *vpr* are not essential for virus replication *in vitro* although they play a role in viral pathogenesis. The HIV *gag* gene encodes a precursor polyprotein, which is processed to form the viral capsid which encases the viral

Concluding Remarks

Antiviral agents have been highly effective in controlling the ravages of the AIDS epidemic, and have even raised hopes for a cure. Nevertheless, this very success poses even greater challenges for the future. There are problems in evaluating the efficacy of new compounds in the face of currently effective therapeutic regimens, as evidenced by the global debate on the ethics of performing placebo-controlled trials in developing countries. Monitoring treatment efficacy by studying viral dynamics is being challenged by current trends where patients on long-term PI therapy show continuing immunological improvement despite virological failure. Patients on combination therapy are running out of treatment options before new compounds are becoming available. Thus, better use of available antiviral compounds seems far more prudent than relying on new products. This approach includes the development of rational approaches for drug combinations, the development of optimal delivery systems to ensure better treatment compliance. Finally, we have to explore options for customizing treatment on an individual basis to select drugs and adjust dosage regimens based on pharmacological and pharmacokinetics parameters which take into account individual variables including past treatment history, and resistance profiles of viral isolates.

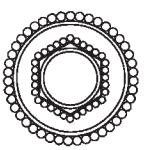
HUMAN T-CELL LEUKEMIA VIRUSES (*RETROVIRIDAE*)



Contents

HTLV-1

Mitsuaki Yoshida, Department of Cellular and Molecular Biology, Institute of Medical Science, University of Tokyo, Tokyo, Japan

History

Human T-cell leukemia virus type 1 (HTLV-1) is the first exogenous retrovirus to have been established in humans. After a long and painstaking search for human retroviruses, HTLV-1 was isolated from adult T-cell leukemia (ATL) at the beginning of the 1980s. ATL was first described in 1976 in Japan as a unique malignancy of T cells affecting only adults. The disease is now known to be endemic in the southwest part of Japan, the Caribbean, South America and Africa. The human retrovirus HTLV was reported in the USA in 1980, by characterization of reverse transcriptase in a T-cell line established from peripheral blood T cells of a patient with T-cell lymphoma. This lymphoma was later diagnosed as ATL. Several T-cell lines were also established from Japanese patients with ATL by co-cultivation of normal cord-blood lymphocytes and leukemic cells from ATL patients, and retrovirus-like particles were detected in these established T cell lines. These cell lines expressed antigens that reacted with sera from ATL patients. These antigens were then identified as proteins encoded by a retrovirus (initially called ATLV), which was newly established by characterization of reverse transcriptase, specific core proteins and the proviral genome integrated in chromosomal

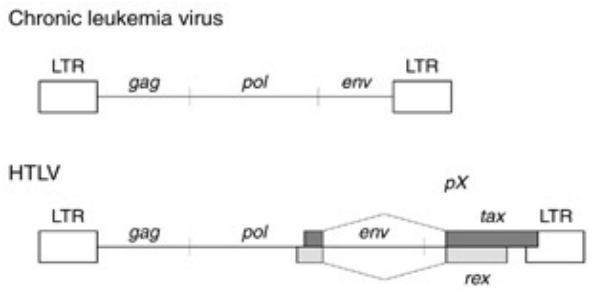


Figure 1 Genomic structures of HTLV and chronic leukemia virus. The pX region of HTLV-1 has overlapping open reading frames for Tax and Rex.

DNA of leukemic cells and established T cell lines. The background of the viral isolation provided strong evidence for the association of HTLV-1 with ATL. The isolation of HTLV-1 has disclosed new aspects of virally induced human cancers, prevention of specific types of leukemia and discovery of new diseases.

Taxonomy and Classification

HTLV-1 is a retrovirus in the genus *Lentivirus* of the *Retroviridae* family (*Gammaretrovirus* genus), with distinct properties from the general C-type retroviruses. The prototype of the retroviruses, chronic leukemia viruses, has the *gag*, *pol* and *env* genes on their genome encoding viral core proteins, reverse transcriptase and surface glycoprotein, respectively. Acute leukemia viruses have an oncogene of cellular origin substituting a part of *gag*, *pol* and/or *env* sequences. The HTLV-1 genome has *gag*, *pol* and *env* genes as general chronic leukemia viruses, but has an extra sequence, pX, in the 3′ terminal region of the genome (**Fig. 1**).

The HTLV-1 genome is very stable and is well conserved among remote endemic areas; however, it is classified into several types according to the restriction maps of the long terminal repeat (LTR). These are Cosmopolitan (C), Japanese (J) and African (A) and Melanesian (M) subtypes. No correlation of these subtypes with their pathogenesis has been observed.

Viruses similar to HTLV-1, simian T-cell leukemia viruses (STLVs), have been isolated from various species of nonhuman primates, including the Japanese macaque, African green monkey, pig-tailed macaque, gorilla and chimpanzee. The STLVs share 90–95% homology of the genomic sequence with HTLV-1 and are also very similar to each other. Although STLVs are widely distributed among monkeys, no leukemia similar to ATL has been commonly observed. Another member of the genus is bovine immunodeficiency virus.

After characterization of HTLV-1, another virus, which is immunologically similar to HTLV-1, was isolated from a patient with hairy T-cell leukemia and named HTLV-2. Similarity of the HTLV-2 genome to that of HTLV-1 is about 60%. HTLV-2 is frequently isolated from intravenous drug abusers, but only three cases have been isolated in patients with hairy T-cell leukemia; thus, its association with a specific disease has not been established.

Molecular Biology

Genome

The proviral genome is 9032 bp long and has a constitution of LTR-*gag*-*pol*-*env*-pX-LTR (**Fig. 1**). The presence of the pX sequence is unique among retroviruses and is essential for efficient replication of the virus. The pX sequence has no significant homology to human chromosomal DNA, and therefore, does not contain any typical oncogene.

The pX sequence contains three open reading frames (ORFs) that overlap each other. Two of these were identified as functional genes, *tax* and *rex*, coding for $p40^{tax}$ and $p27^{rex}$, and the other encodes for $p21^{x}$ whose function is not yet identified. Tax protein, $p40^{tax}$, is a *trans*-activator of transcription of the HTLV-1 genome, and is thus essential to viral gene expression. $p27^{rex}$ is a *trans*-acting modulator of RNA processing and enhances cytoplasmic expression of the unspliced and partially spliced mRNA for Gag and Env. Rex is therefore essential for HTLV-1 gene expression and replication. Regulation with these two viral regulators at the transcriptional and post-transcriptional levels is essential for efficient viral replication and escape from host immune responses. The protein of $p21^{x}$ is composed of the same amino acid sequence as $p27^{rex}$ except deletion at the N-terminal region by initiating translation at the inside of the coding frame for $p27^{rex}$, but its function is unknown.

Gene expression

The HTLV-1 genes are expressed through transcription and splicing of the transcript. The genomic RNA of 8.5 kb, a primary transcript, is the mRNA for Gag and Gag-Pol fusion proteins. A frameshift between *gag* and *pol* sequences suppresses the translational termination for Gag. The primary transcript is spliced into two forms to encode the Env and Tax, Rex and $p21^{x}$, respectively. The first splicing removes the *gag* and *pol* sequences, forming a 4.2 kb mRNA which is able to express Env protein. The second splicing

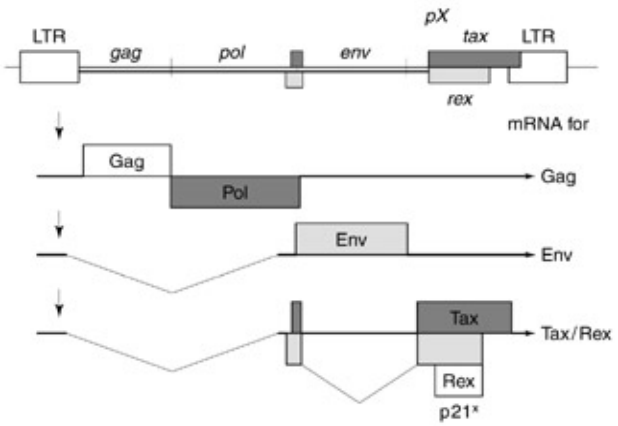

Figure 2 Transcription and splicings for the expression of HTLV-1 genes. Translation for $p21^x$ is initiated at the internal site of the frame for Rex.

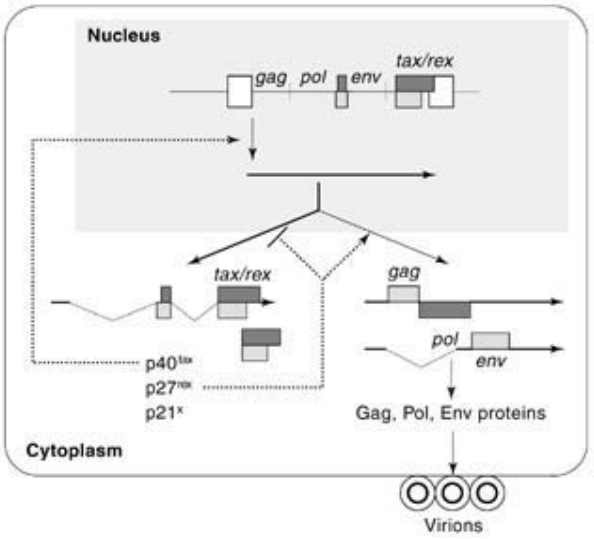

Figure 3 Regulation of HTLV-1 expression at the transcription level and RNA processing by two regulatory proteins, Tax and Rex. Dotted lines with arrow heads and bars represent enhancement and suppression, respectively.

further removes the *env* sequence, forming a 2.1 kb mRNA for the expression of Tax, Rex and $p21^x$ proteins (**Fig. 2**). Therefore, the expression of both unspliced and spliced mRNA in the cytoplasm is essential for viral replication.Transcription of the proviral genome is directed by the LTR. The LTR of HTLV-1 is transcriptionally active; furthermore, its activity is *trans*-activated over 100-fold by the presence of Tax protein. Enhancer sequences, which consist of three direct repeats of the 21 bp sequence containing an imperfect cAMP-responsive element (CRE), are required for *trans*-activation. Although Tax is an enhancer-activating protein, Tax does not bind directly to the 21 bp enhancer. Tax protein binds to CRE-binding protein (CREB) or CRE-modulating protein (CREM), which specifically bind to the 21 bp enhancer. On the other hand, Tax also binds to CREB binding protein (CBP) which is able to bind to CREB only when CREB is phosphorylated, responding to the signal through cAMP and protein kinase A. Therefore, the presence of Tax enables the complex of CREB-Tax-CBP to form even in the absence of cellular stimulation, to form CREB-P-CBP. Complex formation of this sort strongly activates transcription from the LTR.

Modulation of viral RNA processing is *trans*-activated by Rex protein. In the absence of Rex protein, all viral RNA is completely spliced and only the 2.1 kb mRNA for Tax and Rex is expressed in the cytoplasm. Then Rex protein thus expressed suppresses splicing of the viral RNA and enhances the expression of unspliced mRNA in the cytoplasm. Therefore, Rex is essential for the expression of Gag, Pol and Env proteins. This regulation by Rex, in return, reduces the level of spliced mRNA that encodes regulatory proteins, Tax and Rex, consequently resulting in a lower level of viral transcription (**Fig. 3**). In other words, Rex is a positive signal for the expression of viral structural proteins on one hand, but a negative signal for viral gene transcription on the other hand. The combination of these two regulators, Tax and Rex, makes the viral expression transient. This mechanism explains why HTLV-1 is so frequently repressed and how the infected cells are able to escape from the host immune response.

Rex binds to a *cis*-acting element (RxRE) in the target RNA, which is transcribed from the 3′ LTR. The mechanism by which Rex suppresses splicing and enhances the cytoplasmic expression is not clearly understood. The function of Rex is strikingly similar to that of Rev protein of human immunodeficiency virus (HIV), and in fact is able to respond to RvRE to which Rev binds.

Epidemiology

Geographic clustering

Nearly all ATL patients and HTLV-1-infected people have serum antibodies to HTLV-1 proteins, and virus carriers are defined by the presence of antibodies. HTLV-1 antibodies are recognized in 5–15% of adults in southwestern Japan, the Caribbean islands, South America, Central Africa, Papua New Guinea and the Solomon Islands. However, the prevalence of healthy, seropositive adults varies significantly from district to district and even from village to village within these

endemic areas. Why this virus is clustered in such remote regions is not clear; however, migration of races susceptible to HTLV-1 infection has been proposed. This proposal is based on the high conservation of the HTLV-1 genome among all endemic areas, suggesting a single origin of HTLV-1, viral transmission from mother to child, and unique haplotypes of HLA in patients, suggesting different responses of these individuals to HTLV-1 infection. Namely, populations susceptible to HTLV-1 infection moved from Central Asia to East Asia, to South Asia, and to South America through the Bering Strait and North America, and these populations were followed by those relatively resistant to HTLV-1 infection. Thus, the localization of HTLV-1 in such remote areas has been established. ATL and HAM/TSP (see below), which are induced by HTLV-1 infection, are similarly clustered, overlapping HTLV-1. ATL patients and healthy carriers are found sporadically all over the world, but most of them have moved from the endemic areas.

Age-dependent prevalence

The viral prevalence increases with age after 30, reaching a maximum in people between 40 and 50 years of age in Japan. The prevalence is 1.6 times higher in females than in males. This higher prevalence in females over 20 years old is attributed to sexual transmission of HTLV-1 from husbands to wives. Conversely, the findings indicate that HTLV-1 transmission from wives to husbands is infrequent. The age-dependent increase in both sexes was somewhat mysterious, but now is believed to reflect reduced risk of infection at the early stage of life, that is, 40–50 years ago. Artificial milk started to be popular around 40–50 years ago in these areas in Japan, and thus reduced the incidence of breast milk-borne infection of HTLV-1.

Familial aggregation

Familial aggregation of HTLV-1 infection is very apparent. Especially, if a mother is positive, her children are frequently positive. This aggregation is understood to be the result of viral transmission from husband to wife and from mother to child.

Genomic stability

Molecular analyses have demonstrated that the viral genome is well conserved in Japan, the Caribbean and Africa. The viral isolates from Papua New Guinea vary somewhat more but are still 90–95% homologous. The stability of the genome stands in sharp contrast to the highly labile genome of another human retrovirus, HIV.

Infection and Host Range

In vitro infection and transformation

Cell-free viral particles of HTLV-1 show extremely low infectivity *in vitro* and, usually, cannot establish an infection. Co-cultivation with virus-producing cells is able to transmit HTLV-1 to a variety of human and animal cells, human T and B lymphocytes, fibroblasts, and epithelial cells, as well as cells from monkeys, rats, rabbits, and hamsters, but curiously not mice. In these infected cells, the provirus is integrated into random sites in the chromosomal DNA. Only T cells with the CD4+ marker are frequently immortalized on infection with HTLV-1 *in vitro*. The immortalized cells express high levels of the α chain of IL-2R and proliferate in an IL-2R-dependent fashion and mimic leukemic cells *in vivo*.

Natural transmission and *in vivo* infection

Despite the broad range of host cell types *in vitro*, the cells infected *in vivo* are almost exclusively T cells with the CD4+ phenotype. Surprisingly, the vast majority of these infected cells, irrespective of whether or not they are leukemic, do not express the viral information *in vivo*. According to reverse polymerase chain reaction (PCR) analysis of the viral mRNA, over 99% of infected cells are negative for viral gene expression *in vivo*. These *in vivo* cells, however, can express the viral genes soon after cultivation *in vitro*; therefore, the viral latency is not due to structural defects of the proviruses.

HTLV-1 is transmitted through (1) blood transfusion, (2) nursing of infants by infected mothers and (3) sexual relations. Retrospective studies of blood transfusions showed that 60–70% of recipients of fresh, seropositive blood were infected with HTLV-1, but no recipients of seropositive plasma were infected. Thus, the transfer of infected cells from donor to recipient is required for viral transmission. HTLV-1 infection through transfusion is suggested not to induce ATL, but can induce HAM/TSP.

Viral transmission from mother to child was originally suggested by epidemiological studies: most mothers of seropositive children were seropositive and about 30% of the children of seropositive mothers were themselves seropositive. Breast milk is a source of transmissible virus. Milk taken from seropositive mothers could induce antibodies in adult marmosets. More direct evidence was obtained from a practical trial demonstrating that cessation of breast-feeding by seropositive mothers drastically reduced the seropositivity rate of their children.

Wives of seropositive husbands are frequently seropositive. Conversely, the husbands of seropositive wives show the same frequency of seropositivity as

those in the region under study. Thus, the virus appears to be transmitted from husband to wife but not *vice versa*. Infected T cells have been detected in semen and are thought to mediate the viral transmission from male to female.

Pathogenicity

Adult T-cell leukemia (ATL)

The onset of ATL is observed only in adults, most frequently being seen in people in their 40s and 50s. The male/female ratio of incidence of ATL is 1.4/1. Symptoms of ATL are variable and frequently complicated by skin lesions, enlargement of lymph nodes, liver and/or spleen, and infiltration of leukemic cells into various organs. Patients usually have antibodies to HTLV-1 proteins, show an increased level of serum LDH and suffer from hypercalcemia. In addition to the typical, acute form of ATL, smoldering, chronic and lymphoma types have been recognized. In smoldering ATL, patients commonly have a few or several percent of morphologically abnormal T cells in the peripheral blood, but do not show particular signs of severe illness for a long period. Patients with chronic ATL have rather high levels of HTLV-1-infected leukemic cells, but can maintain stable phenotypes for a certain period. In the acute phase, ATL is aggressive and resistant to any treatment; consequently, most patients die within six months of its onset.

Leukemic cells are T cells with the CD4+ phenotype. Frequently, the nucleus of leukemic cells is highly lobulated and this phenotype is unique to ATL. These cells are always integrated with HTLV-1 proviruses, and the site of integration is clonal in a given ATL patient. In most cases of ATL, one complete copy of the provirus is integrated into each leukemic cell. Some cases contain defective proviruses or more than two copies. The leukemic cells frequently express a high level of IL-2Rα on their surface. In almost all cases, leukemic cells carry chromosomal abnormalities, but no abnormality is common among ATL patients.

A causative role of HTLV-1 in ATL development has been proposed based on the clonal integration of the proviral DNA, since it implies that leukemic cells originated from a single HTLV-1-infected T cell. ATL patients are always infected with HTLV-1; therefore, viral infection is prerequisite for ATL development. Furthermore, HTLV-1 can immortalize human T cells *in vitro*, and the phenotypes of the immortalized T cells are similar to those of leukemic cells from ATL patients. The incidence of ATL among HTLV-1 carriers was estimated to be 2–5% over their lifetime.

Although the vast majority of ATL cases are associated with HTLV-1 infection, a form of ATL unrelated to HTLV-1 infection has been described. Patients with this disease are phenotypically indistinguishable both clinically and hematologically from patients with typical ATL, but they have no HTLV-1 antibodies and their leukemic cells carry no HTLV-1 proviral DNA. The etiologic factor in this disease has not been identified.

HAM/TSP and other diseases

HTLV-1 was found to be associated with a slowly progressive myelopathy known in tropical zones as tropical spastic paraparesis (TSP) and, in endemic areas of Japan, as HTLV-1-associated myelopathy (HAM). The unique phenotypes of HAM/TSP are chronic, symmetrical, bilateral involvement of the pyramidal tracts, at mainly the thoracic level of the spinal cord, and include progressive spastic paresis with spastic bladder and minimal sensory deficits. Patients with HAM/TSP are mostly adults; thus, the disease has a long latency after HTLV-1 infection. However, transfusion of seropositive blood can lead to HAM/TSP after an average interval of two years. This feature is different from ATL. However, screening for seropositive blood has greatly reduced the risk of acquiring HAM/TSP through transfusion.

Most patients with HAM/TSP have much higher (frequently one order higher) titers of antibodies against HTLV-1 antigens than asymptomatic carriers and ATL patients. These patients and their family members were reported to have particular types of human leukocyte antigens (HLA). The greater immunological response to HTLV-1 infection may be thus explained.

Despite their strong immunological responses to HTLV-1 infection, most HAM/TSP patients have much larger populations of infected T cells than do HTLV-1 carriers. Some of these infected T cells infiltrate the spinal cord particularly at the site of lesions and also the cerebrospinal fluid. Some of these virus-positive cells produce cytokines including cytotoxic tumor necrosis factor (TNF)-α in the spinal cord. The frequent or infrequent expression of cytotoxic cytokines is proposed to cause accumulation of damage in neuronal tissues as the mechanism of HAM/TSP.

HTLV-1 infection is also proposed to be associated with other diseases such as uveitis, chronic lung diseases, monoclonal gammopathy, and rheumatoid arthritis. The association of uveitis with HTLV-1 infection has been established; however, further

studies are required to elucidate the exact relationship of these diseases with HTLV-1 infection.

Molecular Biology of Leukemogenesis

Viral involvement

ATL cells have clonally integrated HTLV-1 proviruses. However, no common site of integration was observed among ATL patients. Therefore, the role of HTLV-1 in leukemogenesis is independent of its site of integration. In this feature, HTLV-1 differs from other chronic retroviruses of animals, in which integration was commonly adjacent to a proto-oncogene (*cis*-acting effect). As a consequence, a *trans*-acting function of HTLV-1 is postulated in leukemogenesis, and unique genes in the pX sequence have been the focus of interest.

The pX region is able to code for three proteins, $p40^{tax}$, $p27^{rex}$ and $p21^{x}$. Among these protein products, Tax was shown to immortalize human CD4-positive T cells, transform rodent fibroblasts in cooperation with *ras* oncogene, and induce mesenchymal tumors in its transgenic mice. These properties, together with the *trans*-acting functions of Tax protein, suggest that Tax may play critical roles in the development of ATL.

Tax

Tax was originally identified as a *trans*-activator of viral gene transcription as described above, and then also identified as a *trans*-activator of specific cellular genes. It was then identified as a *trans*-repressor of transcription of another set of cellular genes, and also as an inhibitor of tumor suppressor proteins and cell cycle regulators (**Fig. 4**).

Trans-activation of transcription by Tax protein requires a specific enhancer in the target gene; however, Tax itself does not bind to the enhancer directly. The mechanism includes Tax binding to enhancer binding proteins, CREB and CREM, that bind to the 21 bp enhancer of HTLV-1, NF-κB family proteins which bind to NF-κB binding site, and SRF which binds to serum responsive element (SRE). Through the binding to these enhancer binding proteins, Tax *trans*-activates transcription of the viral genome, interleukin (IL)-2Rα, IL-6, GM-CSF, TNF-α, PTHrP, major histocompatability complex (MHC) class I, c-Fos, c-Egr, and others. Abnormal expression of some of these genes obviously enhances abnormal proliferation of infected cells. Activation of IL-2Rα and PTHrP genes by Tax is a reasonable explanation for the abnormal expression of IL-2Rα chain on ATL cells and the high incidence of hypercalcemia among ATL patients, respectively. *Trans*-

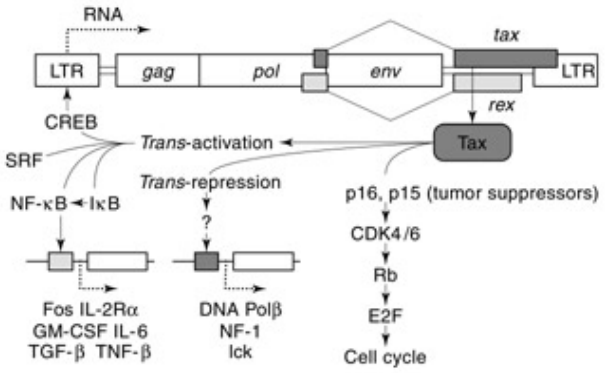

Figure 4 Schematic illustration of Tax action on cellular gene expression and cell cycle regulation.

activation of NF-κB-directed transcription is also achieved by suppression of the inhibitors, IκBα, β and γ, in the cytoplasm. Tax binds to IκBα and induces its rapid degradation, which is normally induced by stimuli for cell growth or differentiation. Consequently, NF-κB regulation is activated by Tax at two distinct steps; one is inactivation of the inhibitor IκB in the cytoplasm and the other is activation of NF-κB protein in the nucleus.

Trans-repression of transcription has been described for DNA polymerase β, NF-1 and lck. More cases will be found on other genes. The mechanism for *trans*-repression is not well characterized; however, the *trans*-repression of DNA polymerase β suggests inefficient DNA repair resulting in a high frequency of mutation. NF-1 gene is a tumor suppressor gene; thus, its suppression might contribute to induction of abnormal cell proliferation.

Inactivation of cell cycle inhibitors is also achieved by Tax; Tax binds to $p16^{ink4A}$ and $p15^{ink4B}$, which are also known to be tumor suppressor proteins, and inhibits their function. These INK family proteins inhibit CDK4 and CDK6, which phosphorylate and inactivate the negative function of Rb protein, and thus, arrest cells at the G1 phase of the cell cycle. Inactivation of these INK family proteins by binding with Tax releases cells from G1 arrest, promoting abnormal cell proliferation. Inactivation by Tax of cell cycle checkpoint protein is also reported at the G2/M phase.

Prevention and Control of Infection

Transfusion of seropositive blood transmits HTLV-1 to the recipients with a risk of two-thirds. With the introduction of HTLV-1 screening systems in blood banks, seropositive blood is now rejected in Japan,

and viral transmission through transfusion has been greatly reduced.

The major natural route of viral transmission is from mother to child via infected T cells in breast milk. Therefore, stopping breast-feeding should prevent infection of children. This possibility is being tested in Nagasaki City, Japan. With consent, pregnant women are surveyed for HTLV-1 antibodies; those who are seropositive are advised to avoid breast-feeding. The trial is still in progress, but the results so far observed indicate a drastic reduction in the incidence of seropositive children. Breast-feeding transmits the virus to the child with a risk of one-third, but bottle feeding reduced the risk to just a few percent. The success of this trial provides direct evidence for viral transmission through milk in humans, but unfortunately, not all children who were bottle-fed remained seronegative. The effect of breast-feeding over a shorter period such as 6 months is under investigation, since breast-feeding would be of great benefit to children.

Future

A regulatory gene, *tax*, of HTLV-1, whose primary role is activation of viral replication, is responsible for induction of abnormal growth of HTLV-1-infected cells. This seems to be facilitated by *trans*-activation or *trans*-repression of transcription of specific cellular genes and also by inhibition of some cell cycle inhibitors and tumor suppressor proteins. However, the long latency in the pathogenesis after infection clearly indicates that Tax alone is not sufficient for the malignant transformation of infected T cells. Abnormal promotion of cell proliferation by Tax basically results in a random population of infected T cells; however, final leukemic cells are always of clonal origin. It is generally accepted that tumorigenesis proceeds through multistep processes. Therefore, it is likely that HTLV-1 infection enhances proliferation of progenitor cells for tumor cells in a random fashion. One of the most critical questions is what kind of molecular events trigger a clonal expansion of infected cell into leukemic cells? Furthermore, there exist smoldering, chronic and acute ATL, and also lymphoma type of ATL. The leukemic cells in these different types of ATL are all clonal; therefore, it is an interesting question as to what kind of genes are involved in these different subtypes of ATL.

Another unique finding of HTLV-1 is its expression *in vivo*. The viral genes are expressed at extremely low levels and are detected only by sensitive PCR. The vast majority of infected T cells do not express any of the viral mRNA, irrespective of whether they are transformed or not. Therefore, most leukemic cells *in vivo* do not express Tax protein at all, suggesting that Tax may not be required for the maintenance of the transformed phenotypes of T cells *in vivo*. What kind of molecular events can mimic the function of Tax in these cells? The solution of these questions would provide clues for understanding ATL as well as cancers in general in humans.

Studies on HTLV-1 and modern technologies have now made it possible to prevent viral transmission, although only in part; however, cessation of breast-feeding might result in more serious problems in children in certain environments. Therefore, the development of an efficient vaccine is an urgent and essential issue for complete irradication of HTLV-1 and its associated diseases.

HTLV-2

Bobbie J Rimel, Joseph D Rosenblatt and **Vicente Planelles**, Departments of Medicine, Hematology-Oncology Unit and Microbiology and Immunology, University of Rochester, Rochester, New York, USA

History

Human T cell leukemia virus type 1 (HTLV-1), the first recognized human retrovirus, was discovered in 1980. HTLV-1 has been linked epidemiologically and molecularly to the pathogenesis of two distinct illnesses, a leukemia called adult T cell leukemia/

lymphoma (ATLL), and a chronic neurologic disease, HTLV-1-associated myelopathy (HAM). Identification of HTLV-1 set the stage for the search for other human retroviruses.

A permanently immortalized T cell line, known as the Mo T cell line, was established in 1976 from the spleen of a patient with an unusual T cell variant of hairy-cell leukemia (HCL). This cell line was shown to contain a second highly related retrovirus distinct from any previous isolates of HTLV-1 by Kalyanaraman and Gallo. Although there was antigenic similarity between the structural gag-encoded proteins, p19 and p24 of HTLV-1 and the virus in the Mo T cell line, a competition radioimmunoassay using HTLV-1 virus lysate demonstrated only partial cross-reactivity. The Mo T cell virus was subsequently cloned and was found to have a similar genomic organization but less than 60% overall nucleotide homology to HTLV-1. Therefore, the virus in the Mo T cell line represented the first isolate of a new and different type of human retrovirus, now known as human T cell leukemia virus type 2 (HTLV-2).

To date, only sporadic cases of leukemia or human disease linked to HTLV-2 have been identified. The patient from whom the Mo T cell line was originally established had a disease characterized as a T cell variant of HCL. Whether the patient in fact had a true T cell HCL variant is still open to question, as direct analysis of leukemia cells was not performed and the T cell phenotype was established from an immortalized T cell line obtained from the patient's spleen. HCL is generally of the B cell lineage, with characteristic cytoplasmic protrusions from atypical lymphoid cells in the peripheral blood and bone marrow. HTLV-2 was again isolated from a second patient thought to have an unusual variant of HCL; however, detailed analysis of this patient demonstrated that he had a biphenotypic malignancy with a monoclonal B cell population with morphological features of HCL and an atypical clonal CD8+ T cell population predominant in the patient's bone marrow and peripheral blood that was infected with HTLV-2. As opposed to HTLV-1, where the virus has been repeatedly isolated from patients with a unique form of leukemia known as ATLL, HTLV-2 has yet to be convincingly associated with any human malignancy, except in anecdotal cases. Nevertheless, owing to its biologic, antigenic and molecular similarity to HTLV-1, HTLV-2 has afforded an excellent model for the study of gene regulation and transformation of infected T cells by both viruses.

Current epidemiologic data suggest that North and South American Indians have a significant prevalence of HTLV-2 seropositivity. High rates of infection have also been documented in populations of intravenous drug abusers (IVDA) in the USA and Europe. Detailed epidemiological studies of these HTLV-2-infected populations may eventually reveal a clearer relationship between HTLV-2 and human disease.

Taxonomy, Classification and General Properties

Retroviruses (*Retroviridae* family) were traditionally divided into three subfamilies, based primarily on pathogenesis rather than molecular data. Using nucleotide sequence relationships and genomic structure, the International Committee on the Taxonomy of Viruses (ICTV) has recently redefined the taxonomy of the *Retroviridae* to recognize seven distinct genera. According to this classification scheme, HTLV-2 is a member of the Deltaretrovirus (bovine leukemia virus (BLV) and HTLV) genus. The biological properties of these viruses and their molecular genetic structure distinguish them from human immunodeficiency virus type 1 (HIV-1) and 2 (HIV-2), which are members of the *Lentivirus* genus of retroviruses. Whereas HIV-1 and HIV-2 have cytopathic effects on human T cells and monocytes in culture, both HTLV-1 and -2 are capable of transforming T cells *in vitro*, resulting in immortalized T cell lines. However, both deltaretroviruses and lentiviruses appear to be capable of prolonged asymptomatic infection *in vivo*.

The molecular organization of HTLV-1, HTLV-2 and BLV is unique, in that all three viruses contain overlapping *trans*-acting regulatory genes located in the 3′ end of the genome. These genes, *tax* and *rex*, are analogous in function to the corresponding transcriptional and post-transcriptional regulators, *tat* and *rev* respectively, in HIV-1 and HIV-2. The *tax*- and *rex*-encoded proteins bear little amino acid homology to analogous lentivirus proteins, and appear to be unique to HTLV and BLV viruses. Additional viral proteins have been recognized by Franchine and co-workers in HTLV-1, and are thought to be encoded by HTLV-2 as well.

As in other retroviruses, the HTLV virion is believed to contain two copies of single-stranded HTLV genomic RNA encased within structural Gag proteins and covered by envelope glycoproteins. The virion also contains reverse transcriptase, integrase and RNase H (*pol* gene products), but not the *trans*-regulatory proteins, Tax or Rex, which are synthesized intracellularly, and, although not a functional part of the virion, are nevertheless crucial for viral replication.

Initial studies comparing genomic sequences of HTLV-2 isolates have clearly demonstrated the existence of two HTLV-2 subtypes: HTLV-2a (for-

merly known as HTLV-2 Mo) and HTLV-2b (formerly known as HTLV-2 NRA). This subtype discrimination is based on relative divergence of nucleotide sequences of the *envelope* (4.3%), *gag* (3.8%), and long terminal repeat (LTR) (5.7%) regions. The predicted amino acid sequence of the HTLV-2a and HTLV-2b Tax protein suggested a possible functional difference between the Tax proteins of these virus subtypes. A two-nucleotide substitution near the 3′ end of the HTLV-2b Tax coding sequence results in an Arg residue instead of the stop codon present in the HTLV-2a Tax protein. In transient transfection assays, HTLV-2b Tax is a fivefold more potent *trans*-activator of the HTLV-2 LTR than the HTLV-2a Tax protein. *In vivo* consequences of this functional difference remain to be established.

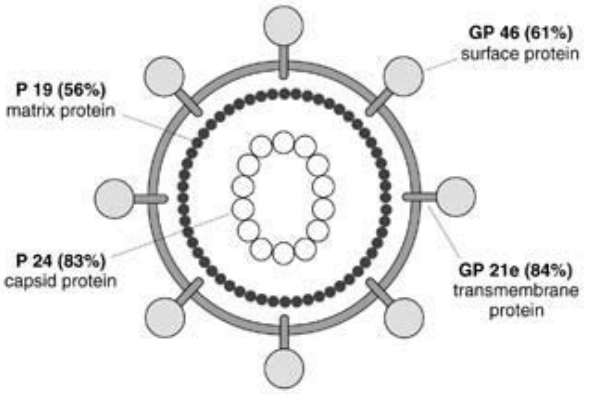

Figure 1 Amino acid homology between viral capsid and envelope proteins of HTLV-1 and HTLV-2. Reproduced with permission from Cann AJ and Chen ISY (1990) HTLV-I and -II. In: Fields BN, Knipe DM, Howley PM *et al.* (eds) *Fields Virology*, 2nd edn, p. 1501, New York: Raven.

Properties of the Genome and Proteins

The genetic organization of HTLV-1 and -2 is distinct from that of other retroviruses. Although the major virion protein components, the *gag*, *pol* and *env* genes common to all replication-competent retroviruses, are preserved, the 3′ end of the genome conserved between HTLV-1 and -2 is not common to replication-competent oncoviruses. This region was originally described in HTLV-1 by Seiki and Yoshida in Japan, and was designated the X region.

Although the epidemiology of HTLV-1 has been extensively studied worldwide and linked to the geographic distribution of HTLV-1-associated diseases, the epidemiology of HTLV-2 is still poorly characterized. Initially found in several patients with T cell leukemia, HTLV-2 was subsequently identified in acquired immune deficiency syndrome (AIDS) patients without associated malignancy, and in IVDA in the USA, UK and, more recently, Italy. A detailed study of IVDA in several locations in the USA by discriminatory PCR analysis of DNA within infected peripheral blood mononuclear cells (PBMC) demonstrated that many IVDAs, found to be seropositive by HTLV-1-based assays, are in fact infected with HTLV-2. A study in 1989 showed that of 23 seropositive IVDAs in New Orleans identified using an HTLV-1-based enzyme-linked immunosorbent assay (ELISA), 21 were found by discriminatory PCR to be infected with HTLV-2, and only two were found to be infected with HTLV-1. These studies highlight the serological crossreactivity of patient sera with HTLV-1 and -2 Gag antigens (see **Fig. 1**), and the need for more discriminatory analyses of seropositive individuals. Routine use of HTLV-1-based ELISA for screening of blood donor samples in the US has demonstrated an overall HTLV seroprevalence of approximately 0.04%.

Random screening of the blood supply with the HTLV-1-based ELISA has identified a number of otherwise healthy seropositive individuals. The use of discriminatory DNA amplification by PCR of mononuclear cell DNA to distinguish between HTLV-1 and -2 has demonstrated that over 50% of HTLV-seropositive random blood donors are in fact infected with HTLV-2. These studies also found that, whereas HTLV-1-infected blood donors tend to have lived in endemic areas or have had sexual contact with individuals from HTLV-1-endemic areas, most HTLV-2-infected donors appear to have come into intimate contact with IVDAs. Several populations that appear to be endemically infected at low rates with the HTLV-2 virus have been identified, including New Mexican Indians, Indians in Florida and, more recently, in Panama, Brazil and Venezuela. Rates of infection have varied from approximately 1% for the New Mexican Indian population to as high as 8% for the Guaymai Indians of Panama. The preliminary epidemiologic evidence would suggest that the indigenous native American population within the US and Central America may represent an endemic reservoir of HTLV-2 infection, and has led to speculation that HTLV-2 is a 'New World' virus. However, the degree of homology between HTLV-1 and HTLV-2 would suggest a common origin, making this speculation highly unlikely.

Since 1991, sporadic cases of HTLV-2 infection have been detected in West and Central Africa, and the presence of such infection in rural isolated populations, including pygmies, suggests a prior presence of HTLV-2 in this area. Recently, HTLV-2

has been isolated from a healthy male from Gabon, a pygmy from Cameroon and a group of Nigerians with sexually transmitted diseases. To date, HTLV-2 has not been detected in Japan or, with any regularity, in the Caribbean basin, both areas of endemic HTLV-1 infection.

A recent survey among Spanish IVDUs indicates that HTLV-2 has been introduced into Spain very recently. Interestingly, IVDUs in prisons showed higher HTLV-2 rates of infection in comparison with unincarcerated IVDUs, perhaps due to increased transmission through needle sharing. Hypothetically, the lack of opportunity to use clean needles in prison offers a unique occasion for the virus to be rapidly transmitted through needle sharing.

Host Range

HTLV-1 and -2 apparently cause disease only in humans, although some other mammalian species can be infected. Rabbits have been successfully infected with both HTLV-1 and -2. HTLV-1-infected rabbits reportedly may develop behavioral changes, but not leukemia. No pathology has been described in HTLV-2-infected rabbits to date.

Few conclusive data are available about cell types infected in humans. A wide variety of cells will support transcription from the HTLV-2 viral LTR, including cell lines of T cell, B cell and nonlymphoid origin *in vitro*. Physical separation of PBMC of carriers into T cell, B cell and adherent-cell populations and PCR analysis for the presence of integrated viral sequences suggested that, in the blood, the primary HTLV-2-infected cells are T cells.

Direct cell-to-cell contact may be required for efficient HTLV infection *in vitro*. In the laboratory, infection of cells with HTLV-1 or -2 is generally performed by cocultivating target cells with irradiated or mitomycin C-treated virus-producing donor cells. In contrast to HIV-1, infection by HTLV-1 and -2 of susceptible T cells appears to be inefficient, with a slow increment in the percentage of productively infected cells *in vitro*, occurring over several weeks to months. Infection of human PBMC by HTLV-1 or -2 results in productively infected T cell lines that are immortalized and can proliferate indefinitely in the absence of IL-2. Only T cells appear to be transformed by HTLV; nevertheless, viral replication can occur in other cell types. Epstein–Barr virus (EBV)-transformed B cell lines have been successfully infected with both HTLV-1 and -2, and HTLV-2 infection results in syncytia formation in the human B cell BJAB lymphoblastoid cell line.

The cellular receptor for HTLV-1 and -2 has not been identified, but it is thought to exist on a variety of human and animal cells, including lymphoid and nonlymphoid cells of primate, feline, rabbit and rat origin. The presence of the HTLV-1 and -2 receptor on these cells has been inferred by the ability to infect these cells with vesicular stomatitis virus (VSV) pseudotypes, which incorporate HTLV-1 or -2 Env proteins into VSV virions. Infection with HTLV-1 VSV pseudotypes can block infection by HTLV-2 VSV pseudotypes and vice versa, suggesting that HTLV-1 and -2 share a similar cellular receptor, which has been localized to human chromosome 17. Productive infection is also observed in several of the cell types identified by VSV studies, including cells of lymphoid and nonlymphoid origin such as human osteogenic sarcoma cells, human fibrosarcoma cells, feline kidney epithelial cells, transformed monkey kidney fibroblasts (COS) and human endothelial cells. Despite the variety of cell types that can be infected by HTLV-1 and -2, both HTLV-1 and -2 appear to preferentially transform T cell lines *in vitro*. These T cell lines have been of both CD4+ and CD8+ antigenic phenotype when transformed by HTLV-2, and will grow indefinitely in the absence of exogenous IL-2. The reasons for cell type-specific T cell transformation are not known. Cell lines doubly infected by HTLV-2 and HIV-1, as well as HTLV-1 and HIV-1, have been established.

Molecular Genetics

Unlike HIV-1, HTLV-1 exhibits an unusual degree of fidelity between viral isolates. Studies of HTLV-1 samples from several African countries, the Caribbean basin and South America showed little or no genetic drift within individuals followed serially over several months and mild intrastrain variation between various HTLV-1 isolates. A high degree of similarity was noted between West African, West Indian, Iranian and French Guyanan HTLV-1 isolates.

Initial sequencing of the LTR from the HTLV-2a and HTLV-2b strains obtained from two different leukemic patients showed approximately 95% homology. Mapping by restriction enzyme analysis demonstrated disparity in approximately 10% of restriction sites sampled between the two isolates. Recently, multiple complete sequences and partial sequences of HTLV-2 isolates have become available. Letourneur *et al.* performed multiple sequence alignments using the transmembrane portion of the glycoprotein gp21 sequence. Phylogenetic analysis of these alignments showed clustering of isolates into three subtypes; a, b, and c (**Fig. 2**).

The lack of variability between isolates of HTLV-1 as compared with the variability of isolates of HIV-1

may be explained by differences between the HTLV and HIV life cycles, kinetics or underlying molecular events. One hypothesis is that HTLV-1 reverse transcriptase (Pol) functions with increased fidelity relative to the HIV-1 reverse transcriptase. Increased fidelity of reverse transcriptase would result in fewer sequence changes in the DNA provirus, and thus, in the progeny virion with each cycle of replication. Alternatively, the reduced variability may be due to the significantly lower levels of HTLV-1/-2 viral replication in infected individuals as compared with HIV-1. Fewer errors with each replication cycle and/or a reduced number of cycles would decrease the mutation frequency of HTLV-1/-2 versus HIV-1. The low rate of replication for HTLV-1 may also reflect the tendency to remain latent in infected individuals. Instead of cycles of reinfection, proviral replication may depend to a degree on T cell division. Since the majority of T cells are resting and nondividing, viral replication *in vivo* would be reduced, and would account for a decreased rate of mutation.

Adapted with permission from Letourneur F, d'Auriol L, Dazza MC (1998) Complete nucleotide sequence of an African human T-lymphotropic virus type II subtype b isolate (HTLV-II-Gab) molecular and phylogenetic analysis. *J. Gen. Virol.* 79: 274.

Serologic Crossreactivity of HTLV-1 and HTLV-2

Although they are distinct viruses, HTLV-1 and -2 are antigenically related. There is a 65% overall nucleic and sequence homology between sequenced HTLV-1 and -2 isolates. In the structural virion proteins, the homology is approximately 56% for p19 (Gag), 83% for p24 (Gag), 61% for gp46 (Env-SU) and 84% for gp21 (Env-TM) transmembrane proteins (**Fig. 1**). The homology is lowest (about 30%) within the viral LTR and the untranslated region in the 3′ end of the genome, increases in *gag* and *env* genes, and is highest within the 3′ overlapping *tax/rex* regulatory genes (about 75–80%). This high degree of homology between HTLV-1 and -2 is responsible for the antigenic crossreactivity between the viruses. The degree of virion structural and coat protein crossreactivity is illustrated in **Fig. 1.** In the past, most known carriers of HTLV-II were serologically detected using HTLV-1-based screening assays, due to cross-reactivity with Gag and Env proteins. Discrimination between HTLV-1 and -2 was performed by PCR assays. An ELISA, which discriminates between HTLV-1 and -2 based on the use of synthetic env peptides, is now commercially available. However, this assay is neither as specific nor as sensitive as PCR-based methods.

Clinical Features of HTLV-2 Infection

HTLV-2 has been found infrequently in the setting of human malignancy. The original isolate of HTLV-2 was obtained from a patient with an atypical T cell variant of HCL, but frank integration of HTLV-2 within leukemic cells *in vivo* was not demonstrated. Other HTLV-2 isolates were obtained from a patient with AIDS and a hemophiliac without coexistent malignancies. Evidence of HTLV-2 infection was seen in two patients with unusual T cell lymphoproliferative disorders and in asymptomatic IVDA in the US and UK.

Three viral mRNA species have been convincingly identified for HTLV-1 and -2. These include full-length genomic RNA encoding the *gag, protease* and *pol* genes, singly spliced *env* mRNA encoding four envelope proteins, and doubly spliced *tax/rex* mRNA encoding the sequences from the 3′ X region. Recently, investigators have suggested the existence of additional viral mRNA subspecies by using polymerase chain reaction (PCR) amplification techniques to detect subtle variations of viral mRNAs.

Two unique regulatory genes have been identified within the X region of HTLV-1 and -2. One gene, referred to as *tax,* encodes a transcriptional regulator of the HTLV LTR. It encodes a 40 kDa nuclear phosphoprotein, p40tax in HTLV-1 and a 37 kDa protein in HTLV-2, p37tax. A second gene, *rex,*

encodes two proteins in HTLV-1, p27XIII and p21XIII, and two protein species in HTLV-2, $p26^{x-b}$ and $p24^{x-b}$, in an alternate, partially overlapping reading frame.

The *gag* gene is translated as a polyprotein precursor with an apparent molecular mass of 70 kDa, which is cleaved to form mature Gag polypeptides. Mature Gag protein species, p19, p24 and p15, have been recognized. These represent the matrix, capsid and nucleocapsid proteins, respectively, of HTLV-1 and HTLV-2. The p24 protein, as noted, has high amino acid homology between HTLV-1 and -2, whereas the p19 protein shows a lesser degree of homology. Nevertheless, both p19 and p24 show considerable crossreactivity to intact proteins between HTLV-1- and -2-infected individuals. The p19 protein is thought to be myristoylated at its N-terminus, and this modification may facilitate association of p19 with the cell membrane.

An intact reading frame for a protease gene was first detected in the HTLV-2 sequence and subsequently described in some HTLV-1 clones. Initial noninfectious clones of HTLV-1 that were sequenced demonstrated stop codons within potential protease open reading frames (ORFs). The function of the protease has been examined for HTLV-2, and it has been demonstrated that, as in other retroviruses, the viral protease is necessary for appropriate cleavage and processing of Gag polyprecursor proteins into mature Gag structural proteins. Apparently the protease undergoes self-cleavage to generate a mature protease molecule. As in some other retroviruses, the protease ORF overlaps both Gag- and Pol-coding sequences. Therefore, in HTLV-1 and -2, the translation of the protease precursor likely occurs following ribosomal frameshifting.

The largest ORF in the HTLV genome is encoded in the polymerase region. In the case of HTLV-2, these sequences could encode a 982-amino acid Pol precursor. As in other retroviruses, the *pol* gene encodes the reverse transcriptase protein, as well as integrase and RNase H functions necessary for completion of the retroviral life cycle. HTLV-1 and -2 share approximately 56% amino acid homology within coding sequences of the *pol* gene. As previously noted, HTLV-1 and -2 show a lower rate of mutation than HIV-1, suggesting a higher fidelity of HTLV reverse transcriptase than that of HIV-1.

In both HTLV-1 and -2, the *env* gene begins upstream of the 3′ end of the *pol* gene and partially overlaps it. In HTLV-2, a high molecular mass glycosylated precursor of approximately 68 kDa is thought to be cleaved into a 46 kDa surface glycoprotein (gp46) and a 21 kDa transmembrane protein (p21). The Env proteins of HTLV-1 and -2 probably interact with similar as yet unidentified cellular receptors to mediate viral entry. The requirement for cocultivation of HTLV-infected cells to obtain efficient infection is unclear. However, the need for cocultivation suggests that HTLV-1 and -2 virions may be unstable in the extracellular milieu, or alternatively, that binding of Env alone to cellular receptors may be insufficient to infect cells. Experiments with both live and heat-inactivated HTLV-1 virions by Duc Dudon and Gazzollo and with HTLV-2 virions by Zack and Chen indicate that the virion coat may act to induce T cell proliferation nonspecifically in culture. This function has been speculatively attributed to Env proteins, although no direct mitogenic effects of Env have been demonstrated.

The *tax* and *rex Trans*-regulatory Genes

Unique genes are found in HTLV-1 and -2 encoded principally by sequences at the 3′ end of the genome, as noted previously. The protein products of these genes do not appear to be packaged within the mature virion. These genes are encoded by a 2.1 kb doubly spliced mRNA containing three exons, which is seen within infected cells. This multiply spliced RNA appears to encode two overlapping genes, designated *tax* and *rex*, respectively. The HTLV-1 *tax* gene encodes a protein of 40 kDa (p40tax), and the HTLV-2 *tax* gene has been demonstrated to encode a protein of 37 kDa (p37tax). These proteins localize primarily to the nucleus of infected cells, although small amounts of Tax have been found in the cytoplasm.

The Tax proteins of HTLV-1 and -2 are crucial to the viral life cycle, and mutations within the *tax* gene of HTLV-1 or -2 abolish viral mRNA transcription. The Tax protein acts to increase transcription from the viral promoter located in the 5′ LTR. A *trans*-acting transcriptional regulator in HTLV-infected cells was first demonstrated by experiments in which the HTLV-2 viral LTR was found not to transcribe efficiently in uninfected cells. Subsequently, several groups studied HTLV transcription by linking chloramphenicol acetyltransferase (CAT), a bacterial indicator gene, to the viral LTR. Cotransfections of the viral LTR linked to the CAT gene with expression plasmids containing Tax- and/or Rex-coding sequences into mammalian cells have demonstrated that expression of *tax* is necessary for efficient transcription from the viral LTR (**Fig. 3**). Similarly, transfection of whole HTLV-2 proviral mutants deficient in Tax and/or Rex have demonstrated that levels of transcription depend primarily on the presence of the Tax protein.

The Tax protein is a 37 kDa nuclear phosphoprotein that acts as a transcriptional activator via three

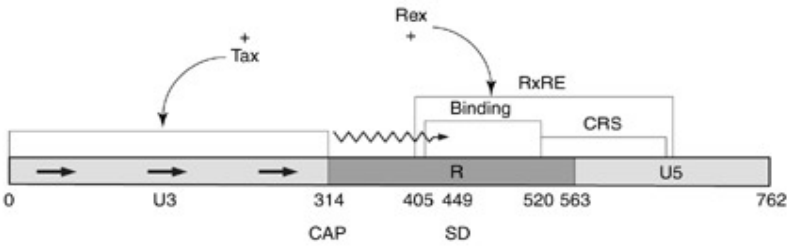

Figure 3 Interactions of *trans*-acting viral regulatory proteins with the HTLV-2 LTR. (Details in text.)

repeated 21 bp enhancer elements upstream of the transcriptional start site. Tax is thought to interact with transcriptional regulatory proteins without directly binding to DNA (**Fig. 3**). The HTLV-2 Rex protein is a 26 kDa phosphoprotein that binds to viral RNA within the Rex-responsive element (RxRE), and is thought to affect splicing and/or nuclear/cytoplasmic transport of viral mRNA. Transport appears to be inhibited in the absence of Rex by an adjacent *cis*-acting repressive element (designated the CRS). Rex function is required for efficient expression of unspliced *gag/pol* mRNA and partially spliced *env* transcripts (**Fig. 3**).

The mechanism by which the Tax protein elicits enhanced transcription from the viral LTR is the subject of extensive investigation. Studies by several investigators have established that Tax does not bind DNA, but rather, acts indirectly via three repeated enhancer elements located within the viral LTR. Tax can apparently interact with a variety of different cellular transcription factors. Investigators have identified transcription factors from the nuclear factor, kb (NF-kappaB), and the cyclic AMP responsive element binding protein (CREB) families, through which Tax appears to act in different promoters. In the HTLV-1 and HTLV-2 LTR, the Tax effect is mediated via three imperfect 21 bp repeat enhancer elements thought to bind CREB-like transcription factors (**Fig. 3**). The mechanism by which Tax interacts with various cellular transcription factors is not known.

CREB binding protein (CBP), thought to be a coactivator of CREB-mediated transcription, has been shown to bind both phosphorylated and unphosphorylated HTLV-1 CREB in the presence of Tax. Recent studies have shown that the CREB binding domain (KIX) domain of CBP can bind with Tax, and that Tax can promote binding of the KIX domain to DNA-bound CREB complexes.

Several heterologous promoters other than the HTLV-1/-2 LTRs, such as the adenovirus E3 promoter, the SV40 enhancer/promoter, the cellular interleukin 2 (IL-2) and IL-2α receptor promoters, the promoter for the c-*fos* oncogene, and the promoter for granulocyte–macrophage colony-stimulating factor (GM-CSF), have all demonstrated *trans*-activation by Tax. The pleomorphic effects of Tax on cellular promoters suggest that Tax may play a role in T cell transformation, and may contribute to the leukemic phenotype. Incorporation of the HTLV-1 *tax* gene into a herpes saimiri-derived expression vector and introduction into T cells resulted in proliferating T cell lines that expressed high levels of the IL-2 receptor but remained dependent on IL-2 for continued proliferation. It should be noted that fully transformed HTLV-1/-2-infected cell lines do not require IL-2 for continuous proliferation.",4> Introduction of HTLV-1 Tax expression vectors into transgenic mice resulted in thymic atrophy in some mice, and development of unusual tumors resembling neurofibromas in others. Thus, several lines of investigation have suggested a potential role for Tax in cellular transformation.

Recent investigations have demonstrated that Tax from HTLV-1 and -2 transactivates the intercellular adhesion molecule 1 (ICAM-1). ICAM-1 is the counter receptor for lymphocyte function-associated antigen (LFA-1). Since these adhesion molecules play important roles in cell-to-cell interactions and signal transduction, upregulation of ICAM-1 could have profound effects on the biology of infected T cells. First, it is possible that upregulation of ICAM-1 plays an important role in cell-to-cell-mediated transmission of HTLV-1. In addition, upregulation of ICAM-1 on HTLV-1 infected cells may facilitate transmission not only by promoting adhesion between infected T cells and target T cells but also by inducing the proliferation of the latter.

The *rex* gene of HTLV-1 and -2 has been demonstrated to encode two protein species in both viruses. In HTLV-1, the Rex 27 kDa and 21 kDa proteins appear to result from the use of alternative initiator methionine codons. However, in HTLV-2, the 26 kDa Rex protein has been shown to be a phosphorylated form of the 24 kDa Rex protein in which phosphorylation occurs on serine residue(s). The *rex* gene

products of HTLV-1 localize to nuclei of infected cells, and are found in the highest concentration within the nucleoli. A short conserved stretch of highly basic arginine and lysine amino acids at the N-terminus of Rex in HTLV-1 and -2 appears to be required for nucleolar localization and the RNA-binding function of the proteins. Studies of both HTLV-1 and -2 Rex suggest that the larger molecular weight species acts post-transcriptionally through *cis*-acting RNA Rex-responsive elements (RxRE) within the viral LTR to regulate viral mRNA transport. Cytoplasmic levels of *gag/pol* mRNA, and in HTLV-1, *env* mRNA, are increased in the presence of Rex.

The Rex protein of HTLV-2 has been purified using a baculovirus expression system, and purified Rex has been found to bind directly to HTLV-2 mRNA transcripts initiated from the 5′ LTR that contain the RxRE. Other investigators have noted that HTLV-1 Rex expressed in bacteria also binds to the corresponding HTLV-1 RxRE. The HTLV-2 Rex-binding domain may form a prominent stem–bulge–loop secondary RNA structure, and is entirely located within the R region of the LTR (**Fig. 3**). This RxRE secondary structure as well as critical sequences located within the 5′ splice site are required for binding, and are consequently necessary for Rex function. Rex may act by binding to the RxRE to increase export and/or prevent splicing of RxRE-containing mRNAs from the nucleus and cytoplasmic accumulation of unspliced *gag/pol* message. The mechanism by which Rex may affect the cellular fate of singly spliced *env* mRNA remains unclear. Additional RxRE and/or binding domains may be present elsewhere in the genome and allow differential processing of *env* mRNA. The net effect of Rex is thought to be accumulation of full-length *gag/pol* and possibly *env* mRNAs. Synthesis of Gag and Env proteins can then predominate in order to facilitate virion assembly.

Recently, the nuclear proteins hnRNP I and hnRNP AI have been shown to bind to cis acting repressive sequence (CRS) and may be involved in Rex regulation of RNA processing. HTLV-2 Rex has also been shown to inhibit early spliceosome assembly. Recent experiments indicate that Rex may also play a role in inhibiting transcription from the HTLV-2 LTR and, possibly, by this mechanism lead to the establishment of latent infection.

The *rev* gene in HIV-1 performs an analogous function. Both HTLV-1 and -2 *rex* can functionally substitute for the *rev* gene of HIV-1 and 'rescue' Rev-deficient HIV-1 clones, but reciprocal substitution of Rev for Rex has not been observed. Although Rex can substitute for Rev, binding of HTLV-2 Rex to the Rev-responsive element (RRE) in HIV-1 is of much lower affinity than to the homologous HTLV-2 RxRE. This indicates that like Tax, Rex may, somewhat nonspecifically, affect processing of other viral and/or cellular mRNAs, although direct evidence has not been obtained, except in the case of HIV-1.

Other proteins encoded by this pX region are not well characterized with regard to their function in HTLV infection or effects on host cell gene expression. HTLV-1 p12 protein shares structural similarity with the bovine papillomavirus E5 protein. Both proteins localize to the cellular endomembranes and are thought to interact with the H+ vaculolar ATPase complex that is involved in proton transport into cellular organelles. The p12 protein has also been shown to bind to subunits of the IL-2 receptor and decrease its surface expression. It has been hypothesized that p12 may play a role in altering cellular responses to IL-2 and other cytokines and thus may be involved in T cell transformation. A similar protein exists in HTLV-2.

Epidemiology

Molecular epidemiological studies have shown that HTLV-2a is the predominant infection in IVDAs in urban North America. HTLV-2b seems to be the predominant subtype in Indian groups in Panama, Colombia and Argentina. Recently, it has been suggested the existence of a third molecular subtype of HTLV-2 – HTLV-2c – in urban Brazilian and Indian populations. HTLV-2c has LTR and *env* nucleotide sequences more closely related to HTLV-2a, but a nucleotide and a predicted amino acid sequence for *tax* similar to that of HTLV-2b.

A second well-characterized isolate of HTLV-2 (HTLV-2b) was obtained from an elderly Caucasian male with HCL whose illness was marked by splenomegaly, inaspirable bone marrow and the presence of circulating tartrate-resistant acid phosphatase-positive (TRAP+) lymphoid cells with hairy cell morphology. The peripheral blood in this patient also contained a large number of atypical lymphoid cells that were TRAP-negative and of T cell origin. The patient's illness was observed over a 2-year period, and he was ultimately found to have two coexisting lymphoproliferative disorders of distinct T and B cell origin. Using cell-fractionation techniques, it was determined that oligoclonally integrated HTLV-2 DNA was detected in a CD8+ T cell-enriched fraction, but not in a CD4+ T cell-enriched fraction, a non-T cell fraction, or in B cells of the affected patient. It was concluded that the patient harbored a TRAP+ B cell malignancy without integrated HTLV-2, and a CD8+ T cell lymphoproliferative syndrome containing oligoclonally inte-

grated HTLV-2, which had arisen from a single virally infected precursor cell, similar to what is observed for HTLV-1 and adult T all leukemia (ATL). This case still represents the most convincing evidence for potential involvement of HTLV-2 in a human malignancy. Other anecdotal cases of T cell malignancy in the setting of HTLV-2 infection, including a case of T cell prolymphocytic leukemia, have been documented. Nevertheless, an etiologic role for HTLV-2 in leukemia/lymphoma remains to be established.

HTLV-2 has also been observed in only two cases of a progressive spastic myelopathy in patients co-infected with HIV-1. Additional cases of myelopathy among HTLV-2-infected New Mexican Indians and African Americans in the US have also been reported. It would therefore appear that like HTLV-1, infection with HTLV-2 might predispose to a spastic myelopathy affecting sphincter control and motor function in the lower extremities. In several patients with neurologic syndromes related to HTLV-2, severe cerebellar dysfunction leading to ataxia was also noted. In a study of HTLV-2-infected IVDA, most carriers were noted to be asymptomatic and have normal absolute lymphocyte counts and immunologic T and B lymphocytic subsets. A modestly elevated absolute lymphocyte count was noted in 4 of 21 HTLV-2-infected IVDA, and several patients had a CD8+ T cell lymphocytosis, as well as an overall increase in the percentage of CD8+ HLA-DR-positive lymphocytes. No overt pathology was demonstrated in this cohort, although several IVDA were also noted to have moderate elevations in serum creatine phosphokinase levels, suggesting possible myositis. This finding was intriguing in view of reports of polymyositis found in association with HTLV-1 infection. Thus, most HTLV-2-infected IVDA have been asymptomatic, and have had no overt hematologic, neurologic or immunologic abnormalities other than occasional lymphocytosis.

Infectious dermatitis has been described in children infected with HTLV-1 and similar cases of prolonged dermatitis and frequent staphylococcal skin infections have been described in IVDA found to harbor HTLV-2. Whether this represents a prototypic illness associated with the virus is unknown. Epidemiologic studies of small populations of New Mexican Indians, identified as an HTLV-2-infected endemic population, have not disclosed an increase in T cell malignancies, B cell chronic lymphocytic leukemia or HCL. Thus, a conclusive link between HTLV-2 and a specific malignant or neurological disease has not yet been established.

Recent studies have shown that HTLV-2-infected individuals had an increased risk of pneumonia, minor fungal infection, abscess and lymphadenopathy and bladder or kidney infections. This new finding of increased prevalence of a variety of infections in HTLV-2-positive donors suggests immunologic impairment. However, whether HTLV-2 has an etiological role in predisposing infected individuals to such infections will require further investigation.

Transformation by HTLV-2

T cell transformation is defined as continuous cellular proliferation *in vitro* in the absence of exogenous IL-2. Both HTLV-1 and HTLV-2 will transform normal human T cells *in vitro*. Infection by HTLV *in vitro* is successful only by cocultivation of irradiated virus-producing cells with PBMC; cell-free HTLV is generally noninfectious. HTLV does not encode a prototypical oncogene, and therefore cannot be classified as an acute transforming retrovirus. HTLV transformation also does not utilize oncogene/promotor-insertion mechanism of transformation, as seen for Moloney murine leukemia virus (MoMuLV) or other animal retroviruses.

The first noticeable change during coculture infection with HTLV is a polyclonal expansion of infected T cell subpopulations approximately two to four weeks after coculture. HTLV-transformed T cells also have increased endogenous expression of IL-2 and cell surface expression of the IL-2R molecule. Increased expression of IL-2 and IL-2R results in autocrine stimulation and is regarded as an important event in T cell transformation by HTLV. Further passage of infected cell cultures results in selective outgrowth of one or a few dominant clones. Although *in vitro* transformation by HTLV provides a model system to examine leukemogenesis by HTLV, there are distinct limitations and differences inherent in the system. Clonal populations of cells that predominate in culture are generally distinct from clonal populations that predominate in the patient. In addition, virus expression is relatively abundant in cells transformed *in vitro*, as well as tumor cells that have been adapted to grow in culture. This is in contrast with the extremely low level of viral RNA expression detected in circulating leukemic cells of patients, with adult T-cell leukemia (ATL).

The mechanism of transformation *in vitro* by HTLV-1 and -2 is unknown. Several hypotheses have emerged from molecular genetic studies of both HTLV-1 and -2. Much attention has focused on the potential role of the HTLV-2 *trans*-regulatory genes, *tax* and *rex*. Since Tax has been demonstrated to enhance transcription of a number of cellular regulatory genes, aberrant cellular gene expression may relate to immortalization of T cells. Tax *trans-*

activates the expression of a particular set of cellular genes, including IL-2, IL-2Rα, GM-CSF, as zinc-finger putative transcription factor, IL-3, IL-4, the proto-oncogenes, c-*sis* and c-*fos*, and the major histocompatability complex (MHC) I antigen. Activation of some of these genes involves induction of NFkappaB activity by Tax. Tax has been shown to repress transcription of the DNA polymerase gene, which encodes a protein involved in DNA repair, suggesting another mechanism that may be involved in transformation. How Rex may relate to transformation is unclear.

Both HTLV-1 and -2 virions are capable of mitogenically stimulating quiescent T cells to divide in the absence of actual viral infection and integration. The specific virion components responsible for the observed proliferative effects on T cells have not been identified, although the most likely mechanism would involve interaction of viral envelope proteins with a cellular receptor. Quiescent T cells infected with HIV-1 can be induced to produce HIV-1 following mitogenic stimulation with HTLV-1 or -2 virions, suggesting possible pathogenic consequences in individuals co-infected with HIV-1.

Detection and Control of HTLV-2

The vast majority of HTLV-2 carriers have been detected during routine screening using ELISA employing HTLV-1 virion lysate. Because of the serological crossreactivity of the viruses, HTLV-2-infected individuals are also detected (**Fig. 2**). Specific serological assays for HTLV-2, based on antigenic epitopes that discriminate between HTLV-1 and -2, have been developed, and their sensitivity and specificity are much improved. At the present time, the most reliable method of differentiating HTLV-1 from -2 infection is by amplification of PBMC DNA using PCR, which will reliably detect and differentiate between HTLV-1 and -2. Southern blotting for HTLV-2 DNA can be performed on cells that have been cultured for several weeks *in vitro*, but it is not practical on a routine basis. Without culture, PCR must be used because the levels of virus in the PBMC DNA are too low for detection by routine Southern blotting.

Discrimination between HTLV-1 and -2 is not a trivial issue, since the potential consequences of infection differ between the two viruses. In the case of HTLV-1, there is a low (4–5%) but documented risk of developing ATLL, and a lower risk of contracting HTLV-1-associated myelopathy. For HTLV-2, the risk of developing pathology is not yet known. If a seropositive individual is identified, counseling should be given with the aim of preventing further transmission of the virus through sexual transmission or breast-feeding. If possible, the individual should be referred to a facility that will perform additional testing to discriminate between HTLV-1 and -2.

The discovery and characterization of the human T cell leukemia viruses types 1 and 2 have led to unique insights into human oncogenesis and retroviral pathophysiology. HTLV-2, although closely related to HTLV-1, is of unknown pathogenic potential. Further identification of infected individuals and longitudinal follow-up of infected cohorts will likely yield clues as to the true pathogenic nature of this virus. The anecdotal reports of leukemia and myelopathy in association with the virus suggest that infection with HTLV-2 may have occasional neurologic or hematologic sequelae. Serological assays to discriminate between HTLV-1 and -2 infection are being developed, and these will undoubtedly provide useful epidemiologic information on a routine basis in the future.

The molecular events underlying HTLV-1/-2 replication and transformation of infected T cells will likely be better understood in the future. Insights gleaned from the study of the *trans*-acting genes of HTLV-2, *tax* and *rex*, have been applicable to the understanding of the regulatory mechanisms of other pathogenic human retroviruses such as HTLV-1, HIV-1 and HIV-2. New animal models for studies of HTLV-1/-2-induced malignancy such as transgenic and SCID-hu mice are being developed and tested.

HYPOVIRUSES (*HYPOVIRIDAE*)

Donald L Nuss, Center for Agricultural Biotechnology, University of Maryland Biotechnology Institute, University of Maryland, College Park, USA

History

Interest in hypoviruses stems chiefly from the observation that they reduce virulence of their pathogenic fungal host, i.e. cause hypovirulence. Although future studies may reveal hypovirus-related genetic elements replicating in a range of fungi, their known natural host range is currently limited to the chestnut blight fungus *Cryphonectria parasitica*. A classic example of the havoc that can result from the introduction of an exotic organism, the North American chestnut blight epidemic, first reported in 1905, caused the destruction of an estimated 4 billion mature chestnut trees by 1950. *C. parasitica* was subsequently introduced into Italy during the 1930s, threatening European chestnut forests and orchards. However, for reasons still to be completely understood, the European chestnut blight epidemic was much less severe than that witnessed in North America. One clear contribution to this reduced severity was the prevalence of *C. parasitica* strains exhibiting a reduced virulence phenotype (hypovirulence), first described by an Italian forest pathologist in the 1950s. French investigators subsequently showed that the hypovirulence phenotype was transmissible following anastomosis (fusion of hyphae) between vegetatively compatible *C. parasitica* strains, implicating a cytoplasmic genetic element as the causative agent of the phenotype. The observation that a hypovirulent strain could produce a curative effect when inoculated on to existing cankers on diseased trees stimulated a successful government-sponsored biological control program using hypovirulent *C. parasitica* strains for management of chestnut blight in French chestnut plantations. Recent studies in Switzerland also support the view that natural hypovirulent strains retard disease progression in European forest ecosystems.

In 1977, Day and coworkers at the Connecticut Agricultural Experiment Station reported that hypovirulent *C. parasitica* strains harbor double-stranded (ds) RNAs, providing the first indication of the nature of cytoplasmic elements responsible for the phenotype. Subsequent surveys of dsRNAs associated with different North American and European hypovirulent strains revealed considerable variations in concentration, number and size of dsRNA components. By the late 1980s, it was clear that a detailed molecular analysis of the dsRNAs associated with a single hypovirulent strain was required to bring some measure of order to the mounting confusion generated by such surveys. This resulted in the cloning and complete sequence determination of the prototypic hypovirus, now designated CHV1-EP713, in 1991. This milestone was followed in 1992 by the construction of an infectious full-length cDNA clone of CHV1-EP713 RNA by Choi and Nuss. This development furnished direct evidence that hypoviruses are indeed the causative agents responsible for transmissible hypovirulence and provided the means for facile manipulation of the hypovirus genome. The subsequent development of a robust hypovirus transfection system using synthetic coding strand transcripts of the CHV1-EP713 dsRNA stimulated efforts to introduce the virus into pathogenic fungal species phylogenetically related to *C. parasitica*, thus expanding host range and virus-mediated virulence attenuation. Current hypovirus research focuses primarily on virus–host interactions, the effective use of natural and transgenic hypovirulent fungal strains for biocontrol and systematic comparative virology.

Taxonomy

A discussion of hypovirus taxonomy must be prefaced by a description of several distinguishing features relative to classic virus families. Hypovirus infection is nonlytic and persistent, resulting in very consistent phenotypic changes of the host. In a sense, these viruses have achieved the goal of contemporary gene

Current hypovirus research focuses primarily on virus–host interactions, the effective use of natural and transgenic hypovirulent fungal strains for biocontrol and systematic comparative virology.

Taxonomy

A discussion of hypovirus taxonomy must be prefaced by a description of several distinguishing features relative to classic virus families. Hypovirus infection is nonlytic and persistent, resulting in very consistent phenotypic changes of the host. In a sense, these viruses have achieved the goal of contemporary gene

therapy, in that they stably alter host phenotype in a predictable and efficacious (hypovirulence) manner. As is observed for fungal viruses generally, hypoviruses exhibit no extracellular phase in their life cycle. Infections cannot be initiated by inoculation with an infected cell extract or enriched fractions. Instead, these viruses are transmitted via cytoplasmic mixing as a result of fusion (anastomosis) between vegetatively compatible strains or to a variable degree in asexual spores (conidia). Unlike most fungal viruses, hypoviruses encode no coat protein and form no discrete particle. Rather, hypovirus genetic information is found predominantly as dsRNA associated with membrane vesicles ranging in diameter from 50 to 80 mm. Based on amino acid comparisons, hypoviruses appear to be related ancestrally to the *Potyviridae* family of plant viruses.

The genus *Hypovirus* within the family *Hypoviridae* (*hypo* from *hypo*virulence) currently consists of three confirmed members. Designations used in the nomenclature include CHV for *Cryphonectria* hypovirus, a number indicating species relatedness and, following a hyphen, the fungal host strain from which the virus was isolated, e.g. EP713. As will be discussed in the next section, the primary nucleotide sequence for the coding strand of the prototypic member of the genus *Hypovirus*, CHV1-EP713, specifies two large open reading frames (ORFs) designated ORF A and ORF B. A second, closely related member, CHV1-EP747, has the same organization and shares approximately 90% identity at the nucleotide level with CHV1-EP713. The third confirmed member of the genus, designated CHV2-NB58, shares only about 60% nucleotide sequence identity with CHV1-EP713 and lacks a portion of ORF A that, for the CHV1 members, encodes a functional *cis*-acting cysteine protease. Preliminary characterizations of several additional hypovirus field isolates have indicated that designations CHV3 and CHV4 will be required in the very near future.

Genetic Organization and Expression Strategy

Although hypovirus genetic information is readily recovered from infected cultures as linear dsRNA, the absence of a discrete virus particle and an extracellular infection phase presents some difficulties in precisely defining the hypovirus genome. Synthetic copies of the coding strand are infectious by electrophoration into fungal spheroplasts, and phylogenetic analyses suggest a common ancestry with a group of positive-strand RNA plant viruses. Thus, one could consider hypoviruses as having a positive-strand RNA genome and the dsRNA as representing

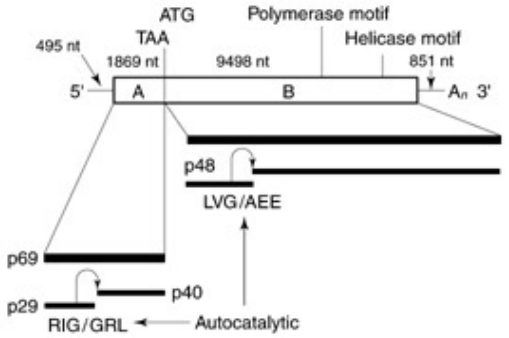

Figure 1 Hypovirus genetic organization and basic expression strategy. Details are discussed in the text. (Adapted from Shapira R, Choi GH, Hillman BI and Nuss DL (1991) *EMBO J.* 10: 741–746 by permission of Oxford University Press.)

accumulated replicative form RNA. Irrespective of this complication, direct analysis of hypovirus dsRNAs, cDNA cloning studies and *in vitro* translational analyses have provided the following view of hypovirus genetic organization and expression strategies. Depending on the species, hypovirus dsRNA ranges in size from 12 to 13 kb. One strand contains a 3′ poly(A) tail, while the complementary strand contains a 5′ poly(U) tract. All of the hypovirus coding information appears to reside within two contiguous ORFs on the polyadenylated strand, which in the case of CHV1-EP713 is 12 712 nucleotides in length, excluding the poly(A) tail (**Fig. 1**). ORF A encodes two polypeptides, p29 and p40, that are released from a polyprotein precursor, p69, by an autoproteolytic event between Gly248 and Gly249, mediated by a cysteine-like protease catalytic domain located within p29. ORF B has the capacity to encode a polyprotein of 3165 amino acids and contains unmistakable RNA-dependent RNA polymerase and helicase motifs. Proteolytic processing of only a portion of the ORF B polyprotein has been elucidated in the form of the autoproteolytic release of a 48 kDa protein, p48, from the N-terminus. This cleavage event occurs between Gly418 and Ala419 and is catalyzed by essential residues Cys341 and His388 within p48. The junction between ORF A and ORF B is defined by the sequence 5′-UAAUG-3′, in which the UAA portion clearly serves as the termination codon for ORF A and the AUG portion is thought to serve as the initiation codon for ORF B. While the mechanism involved in ribosome transition through the junction is not known, this unusual pentanucleotide sequence is found at the ORF A–ORF B junction for all confirmed species within the genus. There is clearly a need for additional fine detailed mapping of the processing cascades for hypovirus-encoded polyproteins.

In most hypovirus-infected C. *parasitica* isolates, the full-length viral dsRNA is accompanied by a constellation of shorter dsRNA species. These ancillary dsRNAs appear to be generated by internal deletion events, are replicated only in the presence of the full-length viral RNA and are not associated with any function or phenotypic effect.

Hypovirus-Mediated Alteration of Host Phenotype

In addition to reduced virulence, hypovirus infection also causes a number of associated phenotypic changes in its host. These can include: convenient experimental markers, e.g. reduced orange pigmentation; vital host functions, e.g. reduced asexual reproduction (conidiation); or a highly complex process, e.g. reduced virulence. Several lines of evidence, including results obtained with the differential mRNA display technique, have clearly indicated a significant and stable alteration in the pattern of host gene transcript accumulation as a result of hypovirus infection. These combined observations led to speculations that hypovirus infection results in alterations in host signal transduction pathways that regulate the constellation of phenotypic traits that are modified in hypovirulent strains. Indeed, results of very recent studies do indicate that a major way in which hypoviruses alter fungal phenotype, including virulence attenuation, is by disrupting G-protein signal transduction.

Following the cloning of the gene for a C. *parasitica* G-protein α subunit of the Gi family, designated CPG-1, Western analysis revealed a reduced accumulation of this subunit in CHV1-EP713 infected cultures. Like hypovirus infection, transgenic cosuppression of CPC-1 accumulation, in the absence of virus infection, was also shown to result in attenuation of fungal virulence. In related studies, hypovirus infection and CPG-1 cosuppression were both shown to prevent the induction of C. *parasitica*-encoded cellulases, enzymes expected to have some role in degrading plant host cell walls during the infection process. Consistent with the prediction that CPG-1, like mammalian Giα subunits, may function to negatively regulate adenylyl cyclase, hypovirus infection and CPG-1 cosuppression were shown to independently result in constitutively elevated cAMP levels. Moreover, effects of hypovirus infection on the accumulation of specific host transcripts could be mimicked by artificial elevation of cAMP levels. Taken together, these results led to the proposal that CHV1-EP713 alters host phenotype primarily through disruption of CPG-1-regulated, cAMP-linked signal transduction. Results of targeted disruption of *cpg-1* were entirely consistent with this view, causing both elevated cAMP levels and a set of phenotypic changes similar to, but more severe than, those observed for CHV1-EP713-infected C. *parasitica* cultures. Mechanisms involved in the apparent hypovirus-mediated reduction in CPG-1 accumulation remain to be elucidated.

Information concerning the role of hypovirus-encoded proteins in host phenotypic alterations is limited. In this regard, the development of a full-length infectious CHV1-EP713 cDNA clone provides powerful approaches with which to identify virus-encoded symptom determinants. For example, deletion of the p29-coding domain within the context of the infectious CHV1-EP713 cDNA clone resulted in a replication-competent viral RNA that caused little reduction in host pigment production and only a moderate reduction in conidiation, relative to the wild-type virus, while retaining the ability to confer wild-type levels of hypovirulence. Thus, while not essential for either viral replication or virulence attenuation, p29 clearly contributes to a number of hypovirulence-associated traits. One can easily imagine an extension of these studies to determine roles for other hypovirus-encoded protein products. The ability to uncouple hypovirulence from associated traits, such as reduced levels of conidiation or reduced pigment production, also established the feasibility of engineering infectious viral cDNA for construction of hypovirulent fungal strains with specific phenotypic traits.

Biological Control

A practical prediction associated with the development of an infectious CHV1-EP713 cDNA clone was that transgenic hypovirulent C. *parasitica* strains would exhibit expanded capacity for hypovirus transmission. Transmission of hypovirus RNA by natural hypovirulent strains appears to be restricted by a vegetative compatibility (v-c) system that regulates the ability of C. *parasitica* strains to anastamose, and is complicated in North American forest ecosystems by a high level of v-c diversity in native fungal populations. C. *parasitica* strains transformed with the CHV1-EP713 cDNA contain a chromosomally integrated copy of the viral cDNA in addition to cDNA-derived cytoplasmically replicating RNA. As a result, these transgenic hypovirulent strains have the capacity to transmit hypoviruses via nuclear inheritance to ascospore progeny. Meiotic transmission to ascospore progeny represents an entirely novel mode of hypovirus dissemination that is expected to circumvent barriers imposed by the vegetative compatibility system. Additionally, since

the ascospore progeny represent a spectrum of different vegetative compatibility groups, launching of the cytoplasmic viral cDNA into these new vegetative compatibility groups should result in the potential for expanded vegetative dissemination of hypovirus genetic information. Stable transmission of virus at a high frequency to asexual spores of transgenic strains has also been demonstrated in the laboratory. These combined transmission properties are, in turn, predicted to confer substantially enhanced biological control potential. In this regard, studies designed to test dissemination and persistence properties of transgenic hypovirulent *C. parasitica* strains under actual field conditions are currently in progress in Connecticut and West Virginia.

Future Perspectives

As more field isolates are characterized it is becoming apparent that there is considerable diversity in the spectrum and severity of symptoms associated with hypovirus infections, even for isolates that are closely related at the nucleotide level. It is anticipated that comparative molecular studies of different hypovirus isolates, now progressing in several laboratories, will reveal fine details of hypovirus genome structure/function relationships and protein function. By incorporating hypovirus infectious cDNA transformation and transfection technologies, such studies may also provide the most effective approach for identifying viral determinants responsible for alterations of host phenotype. The identification of virus-encoded determinants responsible for hypovirulence and the range of hypovirulence-associated traits will, in turn, facilitate engineering of more effective transgenic hypovirulent fungal strains for biomanagement and will drive mechanistic studies of hypovirus-mediated disruption of host signal transduction. Progress in these areas would further strengthen the potential application of hypoviruses for purposes of understanding and controlling fungal pathogenesis.

IDAEOVIRUS

MA Mayo and **AT Jones**, Scottish Crop Research Institute, Invergowrie, Dundee, UK

History

The genus *Idaeovirus* contains a single species, raspberry bushy dwarf virus (RBDV). Bushy dwarf disease became apparent in Scotland in the 1950s, causing widespread damage in the dominant raspberry cultivar 'Lloyd George'. RBDV was consistently associated with this disease, but later work showed that it did not induce the disease itself, but only when it was part of a complex of viruses. However, RBDV is the causal agent of yellows disease in raspberry, and a cause of 'crumbly fruit' in some *Rubus* species and cultivars. Some strains are associated with a lethal disease in some red raspberry cultivars.

Taxonomy and Classification

RBDV is the sole species in the genus *Idaeovirus*. The genus is not classified into a family. However, there are a number of similarities between RBDV and viruses classified in the family *Bromoviridae*. RBDV particles are readily deformed on electron microscope grids and the virus is pollen-transmitted, both features of viruses in the genus *Ilarvirus*, family *Bromoviridae*. The expression strategy for the coat protein gene of RBDV is very like that for the coat protein genes of viruses in all the genera in the family *Bromoviridae* (e.g. alfalfa mosaic virus) (**Fig. 1**). Also, there are some similarities in amino acid sequence between the gene products of RBDV and viruses in most of the *Bromoviridae* genera (**Fig. 2**). Nevertheless, the current official ICTV position is that the genus *Idaeovirus* is distinct by virtue of the bipartite genome of RBDV.

Geographic Distribution

RBDV occurs worldwide, wherever its *Rubus* hosts (raspberry, blackberry, hybrid berry) are grown. This includes Europe, North America, South America, the former USSR and Australasia.

Host Range and Virus Propagation

RBDV has a moderately wide experimental host range but induces symptoms in only a few species. Reported hosts are in 55 species in 12 families of dicotyledonous plants. RBDV is usually propagated in *Chenopodium quinoa* plants. Virus particles can be purified by a combination of clarification and/or precipitation at low pH, followed by polyethylene glycol precipitation and differential and sucrose density gradient centrifugation.

Properties of the Virion

RBDV particles are about 33 nm in diameter but, unless fixed by aldehyde treatment, they often appear distorted when examined by electron microscopy. Particles sediment as a single component of about 100 S. They are readily disrupted by treatment with high salt concentrations or relatively low concentrations of sodium dodecyl sulfate. Particles are assumed to have a $T = 3$ symmetry on the basis of estimates of molecular weights of virion RNA and protein subunits.

Properties of the Genome

Virus particles contain three single-stranded RNA species. The genome of the R15 isolate of RBDV comprises RNA1 of 5449 nucleotides and RNA2 of 2231 nucleotides (**Fig. 1**). Virions contain a third RNA molecule (RNA3) which is a copy of the 3′-terminal 946 nucleotides of RNA2. RBDV RNA molecules do not have 3′-terminal poly(A) and are thought to be capped at the 5′ end. The 3′-terminal sequences of RNA molecules can be folded into highly ordered structures. RNA extracted from infected plants using phenol-based methods contains substantial amounts of double-stranded RNA. This RNA corresponds in size to double-stranded forms of RNA1 and RNA2 (about 6 kbp and 2.5 kbp); no

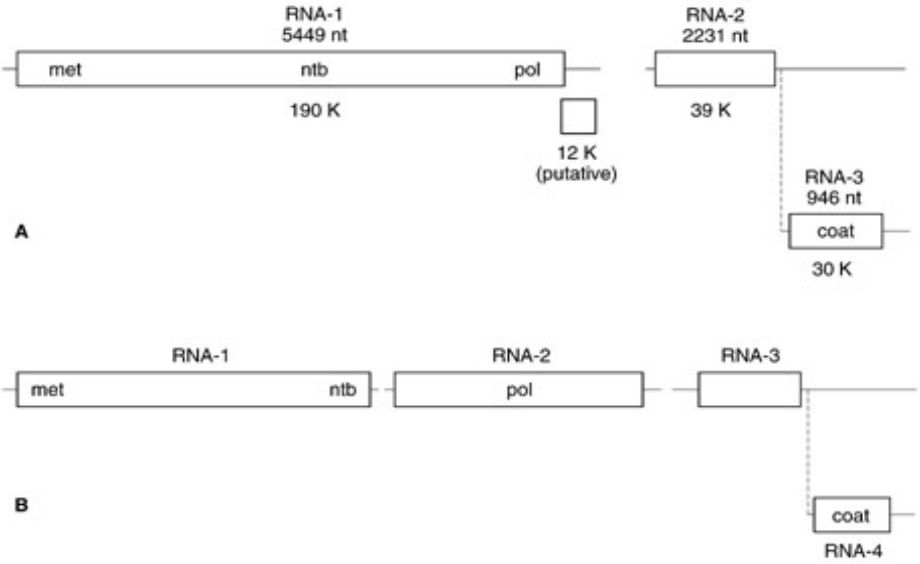

Figure 1 Organization of the bipartite genome of (**A**) raspberry bushy dwarf virus and comparison with the organization of the tripartite genome of (**B**) alfalfa mosaic virus. RNAs are represented as horizontal lines, open reading frames are represented as boxes and the dashed lines illustrate the production of a subgenomic mRNA for translation to yield coat protein. The approximate positions of conserved domains are shown as met (methyl transferase), ntb (NTP-binding) and pol (RNA polymerase).

double-stranded RNA is present that corresponds in size to double-stranded RNA3.

Properties of the Genome (Genes)

RNA1 encodes a large polypeptide with an M_r of *c.* 190 000 (190K), which accounts for most of its coding potential (**Fig. 1**). A small open reading frame is present near the 3′ end of R15 RNA1. It is also present in genomes of a number of other isolates and may therefore be functional. Its product would be a polypeptide with an M_r of about 12 000 (R15 isolate, **Fig. 1**). The 190K polypeptide contains regions with amino acid sequence domains that resemble those thought to be associated with methyl transferase, NTP-binding and RNA-dependent RNA polymerase activities in proteins of other viruses (**Fig. 1**).

RBDV RNA2 encodes two polypeptides. These are a 39K polypeptide at the 5′ end and a 30K polypeptide at the 3′ end (**Fig. 1**). The genes are separated by 118 nucleotides of noncoding sequence. The 39K polypeptide has limited sequence similarities with the

Figure 2 Matrix showing the percentage identities between pairs of corresponding proteins of alfalfa mosaic virus (AlMV), citrus leaf rugose virus (CiLRV), brome mosaic virus (BMV), broad bean mottle virus (BBMV), cucumber mosaic virus (CMV), tomato aspermy virus (TAV), olive latent virus 2 (OLV2) and raspberry bushy dwarf virus (RBDV). Taxonomic relationships among the viruses are shown to the left. Values above and to the right of the diagonal line are comparisons between putative polymerases, values to the bottom and left are for comparisons between putative NTP-binding/methyl transferases.

putative movement proteins of viruses in the family *Bromoviridae*, and the genera *Dianthovirus* and *Furovirus*, which has led to the suggestion that the function of the 39K protein is, at least in part, to facilitate virus movement. The 30K polypeptide is the coat protein. The sequence of RNA3 encodes the coat protein and the gene has a leader sequence of 40 nucleotides. *In vitro* translation of RNA2 yields the 39K protein but not the coat protein. This is produced when RNA3 is translated.

Evolution

The RNA2 of RBDV resembles the RNA3 of viruses in the family *Bromoviridae* in size (*c.* 2 kb), organization (two open reading frames) and expression strategy (coat protein expression from a subgenomic RNA). Some properties of the virions, as well as features of virus transmission (see below), also suggest a link between RBDV and viruses in the family *Bromoviridae*. Pairwise comparisons of whole proteins (**Fig. 2**) or especially conserved domains support this suggestion. These show that the proteins of viruses in the genera *Alfamovirus, Bromovirus* and *Cucumovirus* resemble those of RBDV more than any of these resemble proteins of olive latent virus 2, the type member of the genus *Oleavirus*, which is also classified in the family *Bromoviridae*. These comparisons suggest that the genus *Idaeovirus* could be classified in the family *Bromoviridae*, and more tentatively point to a possible common origin of the viruses in these genera, or at least some of the proteins that they encode.

Serologic Relationships and Variability

Most isolates of RBDV are indistinguishable serologically but minor serological variants are reported from black raspberry. However, some isolates are known that differ in *Rubus* host range. Several of these are able to overcome the RBDV resistance gene *Bu* which is present in some red raspberry cultivars.

Transmission and Tissue Tropism

RBDV spreads from plant to plant in association with pollen. Plants can be infected this way, either as progeny from the pollination (vertical transmission) or as the pollinated mother plants (horizontal transmission). It is not clear how the mother plants become infected following inoculation with pollen from infected plants.

In infected *Rubus* plants, RBDV is often erratically distributed, which can complicate sampling for diagnostic purposes. However, RBDV will multiply in most, if not all, tissues of infected plants.

It is likely that RBDV has been distributed worldwide by the trade in *Rubus* planting material and seed.

Pathogenicity

RBDV can cause significant crop loss in susceptible cultivars of *Rubus*. Recently, in Europe, the emergence of RBDV strains capable of overcoming the principal RBDV resistance gene (*Bu*) has caused further concerns.

Prevention and Control

The only effective control of RBDV infection available currently is the use of certified healthy stock and the exclusion of virus sources near crops, or the cultivation of resistant cultivars. Durable resistance is being sought by both conventional selection breeding and by transgenic methods. Tests with *Nicotiana* plants transformed with cDNA to RBDV genes have shown that transgenes can confer resistance to RBDV multiplication.

Cell Mediated Immune Response

Janice Riberdy and **Peter Doherty**, St Jude Children's Research Hospital, Memphis, Tennessee, USA

General Features

Cell-mediated immunity (CMI) is concerned with the elimination of infected cells from organ sites of virus growth. This terminates the production of new virus, preventing the further spread of the infectious process. While virus-specific immunoglobulin (Ig) molecules are very important for neutralizing free virions, and thus play a central part in resistance to reinfection, antibody transfer experiments indicate that Ig-mediated mechanisms are less prominent in the clearance of virus from solid tissues. Removing the infected cell generally depends on the involvement of virus-specific thymus-derived lymphocytes, or T cells, the effectors of CMI. The immune system has evolved largely to deal with pathogens, optimizing the effective synergism between Ig-mediated and T cell-mediated functions.

There are two broad categories of T cells, each expressing a clonally distributed T cell receptor (TCR) heterodimer characterized as either $\alpha\beta$ or $\gamma\delta$. The $\alpha\beta$ or $\gamma\delta$ TCR molecules are associated with the multimeric CD3 complex, which is involved in mediating the signaling events that control T cell stimulation and differentiation. Most current understanding of virus-specific CMI is concerned with the $\alpha\beta$ T cell subsets, which express either the CD4 or CD8 coreceptor molecules (**Fig. 1**). The $\gamma\delta$ T cells are a minority in mice and humans, constituting less than 5–10% of the peripheral T cells in blood and secondary lymphoid tissue, while they are much more prevalent (20–30%) in pigs, ruminants and chickens. The role of the $\gamma\delta$ T cells in virus infections is not yet understood, though these lymphocytes are known to accumulate in some viral pneumonias and may play a part in regulating the inflammatory process.

The CMI effector mechanism is targeted to the surface of virus-infected cells because the antigen-specific $\alpha\beta$ TCR recognizes viral peptides presented in association with self major histocompatibility complex (MHC) glycoproteins (**Fig. 1**). The developing T cells are selected in the thymus to be tolerant (non-responsive) of self MHC molecules encountered in the thymic microenvironment but reactive, after leaving the thymus, to these same glycoproteins when they are modified by the binding of nonself peptides. This phenomenon is known as 'MHC restriction'. Tolerance of viral peptide–MHC glycoprotein complexes can also be induced if, as in mice infected *in utero* with murine lymphocytic choriomeningitis virus (LCMV), the antigen is encountered during thymocyte differentiation.

A critical lymphocyte in most virus-induced inflammatory processes is the CD8+ $\alpha\beta$ T cell. Lymphocytes of this T cell subset recognize viral peptides presented in the context of the class I MHC glycoproteins, the strong transplantation antigens that are expressed (or can be induced) on most cells throughout the body. The CD8 molecule binds to a constant region of the MHC protein, thereby increasing the avidity of the interaction between the T lymphocyte and the antigen-presenting stimulator or target cell. This may be particularly important at the initial stages of the induction of a primary T cell response. The pore-forming proteins (perforins) and enzymes (granzymes) characteristic of cytotoxic effector function are prominent in the cytoplasm of activated,

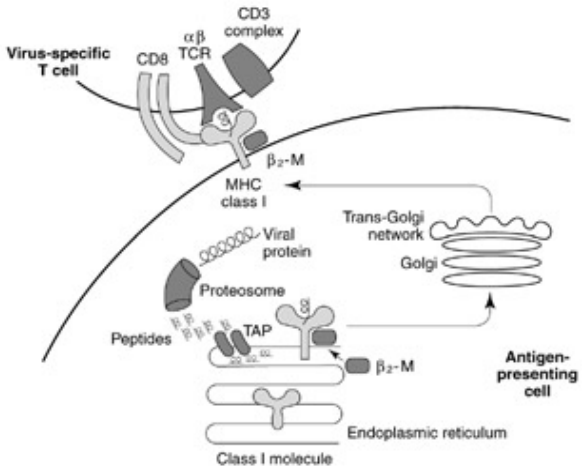

Figure 1 *T cell surveillance.* The virus-infected cell signals that it is abnormal by presenting a nonself peptide in the groove of the MHC class I protein complex. The MHC class I complex comprises an alleleic form of the variant heavy chain bound to the constant β_2-microglobulin (β_2-m) molecule. This is recognized by a clonotypic $\alpha\beta$ T cell receptor expressed on the surface of a recirculating, CD8+T cell. The lymphocyte–target cell interaction is thought to be further stabilized by the concurrent recognition of a conserved region of the MHC molecule by the CD8 dimer. The fact that the great majority of cells thoughout the body express, or can be induced to express, class I MHC glycoproteins makes this monitoring mechanism very effective. *Endogenous processing pathway.* A proportion of the viral proteins produced in the cytoplasm during the course of virus synthesis and assembly are degraded by the proteasome complex and transported into the endoplasmic reticulum, where they form a stable complex with the class I heavy chain and β_2-m. It is this trimeric complex that is ultimately transported to the plasma membrane for recognition by the CD8+T cell.

virus-specific, CD8+ T cells. These cytotoxic lymphocytes (CTLs) apparently make direct contact with the infected cells *in vivo* and lyse the target cells.

CD4+ T cells or helper T cells work in concert with the CD8+ lymphocytes and B cells to provide a complete immune response to viral infections. Secretion of lymphokines such as interferon-γ induces expression of both MHC class I and class II glycoproteins, which in turn enhances the specific recognition of MHC–viral peptide complexes by the T cells themselves (**Fig. 2**). CD4+ T lymphocytes recognize antigenic peptides in the context of MHC class II proteins. MHC class II molecules have a more limited range of expression that includes macrophages, dendritic cells and B cells. This is an important feature that focuses the CD4+ T cell response to cells that specifically require 'help', such as the B cell population. CD4+ 'helper' T cells secrete lymphokines, such as interleukin (IL)-2 and IL-4, which in turn promotes the clonal expansion and differentiation of B cells essential for the generation of the antibody-secreting plasma cells.

The MHC restriction of the $\alpha\beta$ T cells thus focuses the CD4+ and CD8+ subsets into appropriate anatomical niches. The CD4+ helpers encounter high concentrations of class II MHC molecules in lymphoid tissue, where they promote the development of the immune response. The CD8+ effectors recognize modified class I MHC glycoproteins expressed on any cell throughout the body, and act to eliminate these infected cells and thus limit further spread of the pathogen.

Antigen Processing, Presentation and Levels of Response

Whether or not a viral peptide is presented by a class I or class II MHC glycoprotein depends, in large part, whether the antigen is inside or outside the cell. During an infection, viral proteins are made in the cytoplasm of the cell. A portion of these proteins are proteolytically degraded by the proteasome complex and the resulting peptides are transported into the endoplasmic reticulum via a proteinaceous pore formed by the TAP molecules. MHC class I molecules are cotranslationally transported into the endoplasmic reticulum where they bind the nonpolymorphic molecule β_2-microglobulin (β_2-m). This process is mediated by a series of chaperone molecules such as calnexin and calreticulin and results in the binding of MHC class I–β_2-m complexes to the TAP molecules via the tapasin protein. Antigenic peptides transported through the TAP complex can then bind and stabilize the class I–β_2-m complex such that it is now competent for transport to the plasma membrane where it can interact with the TCR of a CD8+ T cell. Whether or not a given peptide has sufficient binding affinity for a class I complex is largely dictated by the structural constraints of the particular class I allele. The endogenous (class I) antigen processing/presentation pathway occurs in all virus-infected cells except the few, such as some categories of sensory neurons, that seem unable to express class I MHC molecules. Whether or not the viral protein that gives rise to the antigenic peptide is ever found on cell surface is irrelevant. Many of the peptides that are important for CMI are derived from early proteins that are internal to both the virion and to the virus-infected cell and thus serve to focus the CD8+ T cells to the surface of infected cells.

Even with very large and complex viruses, the CD8+ T cell response is often dominated by the recognition of a single viral peptide presented in the

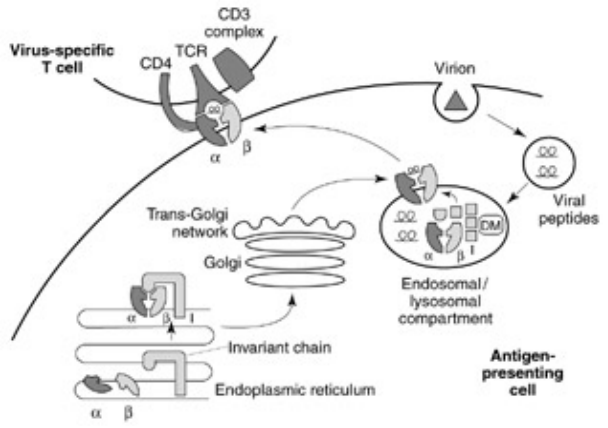

Figure 2 *Exogenous processing pathway.* Invariant chain associates with the α and β chains of MHC class II glycoproteins in the endoplasmic reticulum and blocks peptides from binding the complex. A sorting signal encoded in the invariant chain molecule itself targets the $\alpha\beta$ I complex to an endosomal/lysosomal compartment where the invariant chain is proteolytically degraded. Virions can be taken into cells such as macrophages or dendritic cells by phagocytosis. Alternatively, virions can be specifically endocytosed by clonotypic B cell receptors (Ig). These virions are degraded in lysosomal/endosomal compartments where the resultant peptide fragments associate with MHC class II $\alpha\beta$ heterodimers via interactions with H-2 M (murine) or HLA-DM (human) molecules. The MHC class II–peptide complex is transported to the plasma membrane where it serves as a target for CD4+ helper T cells which secrete lymphokines (IL-2, IL-4) and promote B cell responses and antibody production. Cells that normally express MHC class II molecules, such as dendritic cells, macrophages and B cells, tend to be located in lymphoid tissue with the lymph nodes and spleen providing the 'nurturing' environment necessary during the initial stages of the immune response.

context of one of the 4–6 allelic forms (**Fig. 1**) of the class I MHC glycoproteins (encoded at the HLA-A, B, C loci in humans; H-2K, D, L in the mouse) expressed on the surface of most cells in any individual. Absence of this 'immunodominant' allele may allow the emergence of a response associated with another peptide–MHC complex. The existence of three genetic loci with essentially similar functions, together with the extreme polymorphism of the class I MHC genes, ensures that a state of complete anergy during the course of a virus infection is comparatively rare for the CD8+ T cells. As a consequence, despite the fact that MHC-related effects on patterns of resistance can be measured in virus diseases, these are generally not the main host genes determining susceptibility.

In contrast, exogenous proteins such as virions are taken into the cell as a consequence of phagocytosis and are proteolytically degraded into peptide fragments in an endosomal/lysosomal compartment (**Fig. 2**), shared by the class II MHC molecules (HLA-DP, DQ, and DR in humans; I-A and I-E in mice). MHC class II molecules are comprised of two transmembrane proteins. The α- and β-chain proteins of the class II molecule are also cotranslationally translocated into the endoplasmic reticulum where they associate with a third molecule, the invariant chain. This protein serves two significant functions. First the association with invariant chain prevents the $\alpha\beta$ dimer from binding peptides in the endoplasmic reticulum and also provides a sorting signal to target newly synthesized MHC class II molecules to the endosomal/lysosomal compartment where antigenic peptides from exogenous proteins reside. The invariant chain is proteolytically degraded in the endosomal/lysosomal compartment and antigenic peptide binding is finally mediated by a complex similar in structure to classical class II molecules (termed HLA-DM in humans and H-2 M in mice). At this point, the MHC class II peptide complex is transported to the plasma membrane for recognition by CD4+ T cells. Phagocytosis of exogenous antigens is the typical antigen-presenting route of macrophages and dendritic cells. These cells are critical in initiating the immune response, as they express key costimulatory signals necessary to activate naive T cells.

The B lymphocyte is also a key antigen-presenting cell in the virus-specific immune response. Precursor B cells expressing surface Ig molecules (the B cell receptor) specific for epitopes exposed on a viral coat protein will be crosslinked as a consequence of multipoint binding to these repeated antigenic determinants (**Fig. 2**). The virus–Ig complex is internalized, degraded in lysosomes, and peptides derived from the various viral proteins presented in the context of class II MHC glycoproteins. This process focuses CD4+ T cells to the surface of B cells that have surface Ig molecules specific for viral epitopes. This is critical for the developing B cells to get the appropriate cytokine help needed for progression to Ig secreting plasma cells. In brief, antigen processing and presentation pathways serve to direct cytotoxic T cells to infected targets and helper T cells to B cells that require cytokine signals.

Stimulation of Cell-mediated Immunity

The generation of T cell effectors during the primary phases of the host response to an invading virus usually occurs in organized lymphoid tissue (**Fig. 3**). The architecture of the lymph node constitutes a circumscribed anatomical niche to facilitate contact between the relatively rare, naive B cell and T cell precursors and the antigen-presenting macrophages

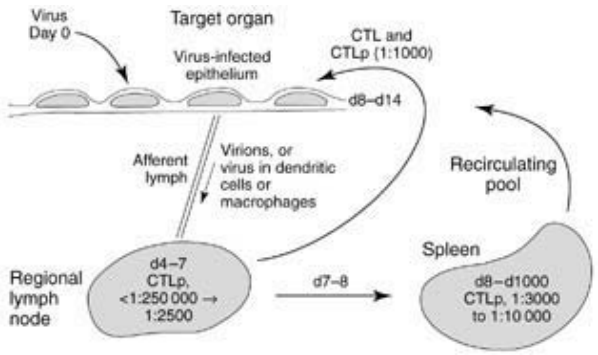

Figure 3 Primary T cell responses are normally generated in organized lymphoid tissue, particularly regional lymph nodes. Viral antigens may reach the lymph node as either free virions, or as processed peptides presented on the surface of dendritic cells or monocytes. The prevalence of virus-specific cytotoxic T lymphocyte precursors (CTLp) greatly increases over 6–8 days, with many of the CD8+T cell effectors then exiting from the lymph node and traveling via the blood to the organ(s) supporting virus growth. Thereafter, at least for the life of a laboratory mouse, there is an expanded pool of virus-specific, memory CTLp.

and dendritic cells. In particular, the microarchitecture of lymph nodes includes delineated T cell and B cell zones, as well as clusters of follicular dendritic cells and germinal centers. All of the factors that contribute to the generation and maintenance of these microstructures are not known, but molecules such as lymphotoxin α are key players in these processes. The functional consequences of this unique microenvironment are particularly important for lymphokines secreted at short range by the CD4+ helper T cells which promote the proliferation and differentiation of antigen-specific B cells and ultimately result in the generation of high-affinity antibodies.

Viral antigens reach the lymph nodes or spleen via blood or lymph, or encounter lymphoid tissue aggregates (the tonsils, Peyer's patches) associated directly with mucosal surfaces. The virus may be in the form of free virions, or processed peptides presented on the surface of monocytes/macrophages or dendritic cells that have traveled from the initial site of infection to the regional lymph node in afferent lymph. Early in the course of the disease process there is a shutdown of T cell recirculation (with resultant lymphopenia) due to the massive recruitment of all classes of lymphocytes into lymphoid tissue. This nonselective process is mediated, at least in part, by the virus-induced production of interferon $\alpha\beta$. The numbers of virus-specific CD8+ CTLp and CD4+ Thp then dramatically increase over the next 6 or 8 days.

Many of the virus-immune CD8+ T cells, and fewer of the CD4+ subset, then leave the lymph node and travel via the blood to the major target organ(s) supporting virus growth. The lymphocytes invade the infected tissue, where the CD8+ effectors generally clear the infectious process completely within 24–48 h. Large numbers of other T cells and monocytes/macrophages are also recruited into the site of pathology. Both CD4+ and CD8+ T cells can promote this delayed-type hypersensitivity response. The inflammatory process resolves after the virus is eliminated, though substantial numbers of lymphocytes and macrophages may persist through the time that tissue repair is continuing.

The immune system incorporates many levels of protection, which at first glance may appear redundant. However, as many viruses evolve to circumvent immune detection, the importance of overlapping features is revealed. For instance, mice that are first depleted of CD4+ T cells and then exposed to a cytomegalovirus (CMV) clear the infection from the lung, but not from the salivary gland. Perhaps an antibody-mediated process, operating via T cell help to responder B cells, is involved in eliminating infected cells that are for some reason inaccessible to (or not recognized by) the CD8+ effectors. Mechanisms dependent on the virus-specific Ig response seem to offer the only possibility for dealing specifically with virus-infected cells that are, for example, constitutively MHC negative.

T Cell-mediated Immunopathology

The almost synchronous destruction of large numbers of virus-infected cells by the emerging CMI response can lead to an acute physiological defect and even, in an extreme situation, to death. The classical model of CD8-T cell mediated immunopathology in a virus infection is murine LCM. The rather nonlytic LCMV grows in cells of the choroid plexus, ependyma and meninges following intracerebral injection of adult mice. Death results when CD8+ class I MHC-restricted CTLs damage the LCMV-infected cells and cause a massive breakdown of the blood–brain barrier. Suppression of the T cell response prevents this process from occurring; the mice survive and become asymptomatic carriers of the virus.

Immunopathology is thus the Janus face of normal CMI. Elimination of cells supporting the growth of a lytic virus is essential if the individual is to survive. Whether or not this process will bring on a crisis depends on the extent of the infection, and how central the infected cells are to maintaining the functional integrity of the organism. Perhaps this is the reason that evolution has favored a mechanism

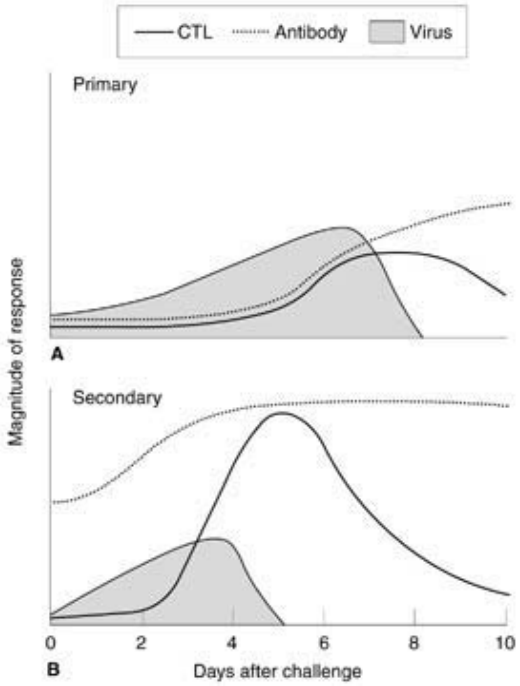

Figure 4 The characteristics of a primary cytotoxic T lymphocyte (CTL) and antibody response are illustrated in (**A**), the important point being that CTL effector function is not maintained for long after the virus is eliminated, though there is a greatly expanded pool of virus-specific, CD8+ memory T cells which are poised to respond should there be a subsequent infection (Fig. 3). Antibody persists, and a secondary response (**B**) to challenge with the same virus will generally result in the neutralization of the virus. However, some viruses (notably the influenza A viruses) share CTL epitopes on internal viral proteins, though their surface glycoproteins are different (e.g. H1N1 and H3N2). Cross-challenge with such viruses will give the secondary CTL response shown in (**B**). It is important to note that there is still a lag phase of 2–3 days before these CTL effectors are available to clear the virus.

that allows many categories of neurons, which cannot be replaced, to remain MHC negative.

T Cell Memory

Before an initial encounter with a virus, there are generally less than 1:250000 virus-specific CTLp in lymphoid tissue. The number increases to 1:2000–1:3000 by 6 or 7 days after infection (**Fig. 3**). Similarly, the frequency of virus specific Thp is greatly elevated during the course of an infection. Enhanced CTLp frequency is maintained for several years without further exogenous antigenic challenge in (for example) mice that have been infected with an influenza A virus, though there seems to be more variation in the magnitude of the Thp. The nature of the homeostatic mechanisms which regulate the size and function of these memory populations are key questions that remain as yet, unanswered.

Immunization to promote T cell memory may clearly be beneficial. However, though memory T cells are both present at higher frequency and more readily stimulated than their naive precursors, it is still the case that such lymphocytes are not usually activated to be fully functional effectors until several days after the secondary challenge (**Fig. 4**). This lag phase means that memory T cells, unlike circulating antibody, do not prevent the establishment of infection, though the process of virus clearance may be somewhat enhanced. For instance, there is evidence from a human study that the presence of such virus-specific CTLp in peripheral blood is correlated with less severe influenza virus infection. Also, there is encouraging preliminary evidence that people immunized with the gp160 of human immunodeficiency virus (HIV) in an alum adjuvant are maintaining a population of HIV-specific CTLp in peripheral blood for a considerable period. Thus, the maintenance of long-term memory populations may well enhance the overall well-being of individuals, but the specific regulation of these lymphocytes remains elusive.

HIV Cell-mediated Immunity

Infection with HIV poses a particular problem for immunity for two reasons. The first is that the viral coat glycoproteins vary greatly, which limits the effectiveness of vaccines depending on the presence of pre-existing neutralizing antibody. The second is that the cell surface receptor for HIV is the CD4 molecule expressed on the helper T cell and, in humans, on some macrophages. Chemokine receptors have recently been identified as coreceptors for HIV infection. The development of the acquired immune deficiency syndrome (AIDS) is associated with the progressive, inexorable loss of the CD4+T cells. At least part of this may reflect elimination of the infected CD4+T cells by the virus-specific CD8+T cells, which remain fully functional CTL effectors during the course of this persistent infection. Also, stimulation of the CD4+T cells activates the virus growth cycle and thereby increases viral load. A further complicating factor is that virus reservoirs persist in association with follicular dendritic cells in the lymph node. This provides a continuous supply of infectious virus as CD4+T cells pass through the lymph node. Relatively few virus-infected CD4+cells are found in peripheral blood, which could indicate that these lymphocytes are being effectively eliminated when they become antigenic in lymphoid tissue.

The lack of CD4+T cells in patients with AIDS results in much greater susceptibility to a variety of opportunistic infections, particularly those caused by fungi and protozoa. Secondary infections with other viruses are not as prominent, presumably because the CD8+T cell response is less compromised, though infection with herpesviruses may eventually become a problem. Herpesviruses, such as Epstein–Barr virus (EBV) and CMV, tend to persist in sites where they cannot be eliminated by CD8+T cells, though such infections are generally controlled in people who are not immunosuppressed. The severely impaired immune function of AIDS patients reflects the necessity of a complete immune system with many functioning branches.

History: or How We Got to Where We Are

Studies in laboratory mice with three different virus systems (LCMV, poxviruses and influenza) have contributed enormously both to our understanding of CMI and to immunobiology in the general sense. The persistent carrier state in mice infected *in utero* with LCMV, characterized by Traub (1939), was one of the factors that led Burnet and Fenner to formulate the concept of immunological tolerance (1949). Burnet (1970) went on to develop the immunological surveillance hypothesis, which he argued in the context of tumor immunity. This is undoubtedly applicable to the lymphoma and nasopharyngeal carcinoma associated with EBV infection, the basic mechanism being that illustrated in **Fig. 1.**

The operational basis of surveillance by class I MHC-restricted CTLs was discovered by Zinkernagel and Doherty (1974), while analysing the immunopathological disease caused by LCMV in previously unexposed adult mice. The 'single T cell receptor/altered self' model developed from these experiments provided an explanation (1975) for both variations in the level of T cell responsiveness associated with the expression of particular MHC alleles (the so-called immune response gene effects), and the extreme polymorphism of the class I MHC genes. Zinkernagel (1978) also used the LCM model to establish the canalizing role of the thymus in the establishment of the class I MHC-restricted T cell repertoire. They were awarded the Nobel Prize for this work in 1996.

The first vaccine, introduced for smallpox by Jenner (1798), depends on CMI effector mechanisms. Systematic analysis of the ectomelia (mousepox) model by Fenner (1947) set the stage for modern studies of CMI, with Blanden showing some years later (1970) that primed Thy-1+ cells promote virus clearance. Recombinant poxvirus (vaccinia) technology has also been used very effectively for the identification of the antigenic proteins/peptides involved in virus-specific T cell recognition. This approach (pioneered by Paoletti and Moss) has led to practical consequences, for example the recombinant rabies vaccine developed by Koprowski and his colleagues for use with feral populations.

An unexpected crossreactivity for virus-specific CD8+ CTLs was discovered independently (1977) in the laboratories of Askonas and Doherty, both of whom were analyzing CMI to the naturally occurring influenza A virus recombinants. These T cells were later found (1984–1985) by Townsend and McMichael, Bennink and Yewdell (using vaccinia virus recombinants) to be specific for conserved, internal proteins of the virus, such as the ribonucleoprotein (RNP). Townsend (1986) then had the major insight that the influenza-specific, CD8+ CTLs were recognizing peptides of the RNP. This made sense of MHC restriction when considered in the context of the emerging understanding of the TCR (Davis and Mak) and the crystallographic analysis of the HLA-A2 molecule by Bjorkman, Wylie, Strominger and colleagues. The new field of antigen processing in the cytoplasmic/endogenous (class I MHC) rather than the lysosomal/exogenous (class II MHC) compartment was opened as a consequence (**Figs 1** and **2**).

The experimental analysis of virus-specific CMI has thus led to several major (and many minor) original findings and pointed the way to some key concepts concerning the nature of immunity. The need to deal with virus infections has obviously been central to the evolution of the immune system. Rigorous analysis of the host response to viruses will continue to provide new insights into general mechanisms in immunity.

INFLUENZA VIRUSES (*ORTHOMYXOVIRIDAE*)

Contents

General Features

Robert G Webster, St Jude Children's Research Hospital, Memphis, Tennessee, USA

History

The highly contagious acute respiratory illness known as influenza has afflicted humans since ancient times. The pattern of outbreaks of respiratory diseases that appear suddenly, persist for a few weeks and then suddenly disappear is sufficiently characteristic to permit the identification of numerous major epidemics in the distant past. One such epidemic was recorded by Hippocrates in 412 BC, and several were described in the Middle Ages. Historical data from 1500–1800 indicate that: (1) epidemics occurred relatively frequently but irregularly, with the disease seeming to disappear for periods of time; (2) epidemics varied in severity but usually caused mortality in the elderly; and (3) some epidemics, such as those in 1781 and 1830, spread across Russia and Asia. There are similarities with our current knowledge of the epidemiology of influenza, including age-related mortality and emergence of epidemics in China.

The 1918 'Spanish influenza' pandemic was particularly severe, killing between 20 and 40 million people worldwide, and partial analysis of the virus genome from a lung sample in a paraffin block of a soldier that died in 1918 supports the belief that the virus originated from swine. In the late 1920s, Richard Shope showed that swine influenza could be transmitted with filtered mucus, suggesting that the causative agent was a virus. Human influenza A virus was first isolated in ferrets in 1933 by Wilson Smith, Sir Christopher Andrewes and Sir Patrick Laidlaw, in the UK. Influenza B was first isolated by Thomas Francis in 1940.

Fowl plague, a lethal form of influenza in chickens, was first reported in Italy in 1878 but it was not until 1955 that Walter Shafer in Germany showed that this disease was actually caused by an influenza virus.

Taxonomy and Classification

Influenza viruses belong to the *Orthomyxoviridae* family of RNA viruses and is constituted of four genera; *Influenzavirus* A, *Influenzavirus* B, *Influenzavirus* C and *Thogovirus*. These viruses have segmented negative-strand RNA genomes enclosed in a lipid envelope derived from the host cell. The particles are covered in a layer of spikes, contained in the envelope, which are of three kinds: a hemagglutinin (HA) which agglutinates erythrocytes, an enzyme neuraminidase (NA) which releases the virus from cells and a small number of copies of the M2 protein that serves as an ion channel. Beneath the lipid envelope is a membrane or matrix (M) protein surrounding a helical complex containing the nucleoproteins (NP) and three poly-

IMMUNE RESPONSE

History

The germ of immunology grew out of the observation in ancient times that those who survived a clinical infection seldom suffered a second, similar sickness. Repeated exposure to a disease like smallpox, which leaves characteristic pock marks after the first attack, strengthened this belief. Some understanding of the mechanisms of protection from a second infection came much later and mainly from the study of bacteria and their products. The discovery in the 1890s that soluble toxins produced by some bacteria induced all the symptoms of the disease led to the finding that the body produced a 'substance' which 'neutralized' the activity of the toxin – the antitoxin or antibody. This in turn led to extensive studies of antigen–antibody reactions and to the use of immune serum therapy. Such studies dominated immunological work in the first half of the twentieth century.

It was also suggested in the late nineteenth century that leukocytes could play a role in the defense of the body, based on the observations of the activity of phagocytic cells. However, the declaration of the Clonal Selection Theory by Burnet in 1957 demolished the earlier ideas of the chemists about the mechanism of antibody formation and production, and ushered in an era of intense study of first B-cell- and later T-cell-mediated immune reactions.

The use of viruses as tools for elucidating immune responses came much later, and has substantially added to our understanding of immunological principles. Infections by viruses containing mosaics of identical protein molecules contributed to our understanding of the importance of antigen conformation and recognition by antibodies. Viruses with RNA genomes which show great antigenic variation illustrated the contribution of individual amino acid residues in influencing the specificity of antigen–antibody reactions. From the mid-1970s until the present day, the use of viruses as infectious immunogens provided the major approach for studying an important cellular response, cytotoxic T cell generation and activity.

Though it is likely that the immune response of vertebrates was largely fashioned by the need to overcome infections, immunologists have taken advantage of this only during the last quarter century.

Nature of Immune Responses

It is convenient to divide 'immune' reactions into two classes: adaptive responses, often called specific responses; and nonadaptive or innate responses. Adaptive responses are mediated by lymphocytes which express two unique characteristics: exquisite specificity and memory. This response is characteristic of vertebrates and reaches its highest development in primates.

Nonadaptive immune responses

In nonimmunized hosts, there is a lag period after infection of at least some days (and sometimes considerably longer, e.g. human immunodeficiency virus, HIV) before components of the adaptive response are detected. It is especially during this period that nonadaptive responses are important for limiting viral responses. In humans and ferrets, a mild influenza virus infection may be limited to the upper respiratory tract, where the mucus contains substances that can inhibit influenza virus infectivity. Infection induces an inflammatory response in which a variety of cells, including monocytes and polymorphonuclear leukocytes, are extruded on to the site of infection. There is a correlation between the extent of fever caused by pyrogens such as interleukin 1 (IL-1) and the rate of decline of viral titer. Activation of natural killer (NK) cells by interferons (IFN-α and IFN-β) results in lower viral titers. Mice bearing the *Mx* gene are resistant to influenza virus infection due to enhanced IFN production. Depletion of NK cells in some strains of mice makes them more susceptible to some viral infections (cytomegalovirus and vaccinia and mouse hepatitis viruses).

Activation of the complement cascade following infection may result in lysis of enveloped viruses such as influenza.

The innate system predates the adaptive system in evolution and it was first thought that the two

Table 1 Some properties of antigen-presenting cells

Molecules expressed	*Dendritic cells*	*Macrophages*	*B cells*
Class I MHC	Constitutive	Constitutive	Constitutive
Class II MHC	High, IFN-γ enhances	IFN-γ enhances	IL-4 enhances
Costimulator	High	Activation enhances	Activation enhances
T cell target	CD4+,CD8+	Mainly CD4+	Activated CD4+

systems are unrelated, but it has become increasingly clear that the activation and maturation of the former may facilitate the effectiveness of the latter. IFN-γ, originally called immune interferon because it was produced by T cells, is now known to be also produced by NK cells. The classical and alternate pathways of complement activation, which differ only slightly in the properties of the first of six components, serve the innate and adaptive systems respectively.

Adaptive immune responses

Role of antigen-presenting cells (APCs) APCs may interact with two classes of lymphocytes: the B or bone marrow-derived lymphocytes, but especially with the T or thymus-derived lymphocytes. APCs process antigen to a form which is recognized by T cells. Noninfectious antigenic material (e.g. inactivated viral particles) is endocytosed into the APC and degraded in lysosomes. Some of the peptides so produced associate with class II major histocompatibility complex (MHC) antigens; the complex is transported to and expressed at the plasma membrane, where it is specifically recognized by a T cell receptor. This response is termed a class II MHC-restricted response and the recognizing cell has the CD4 membrane marker.

In contrast, an infectious particle, e.g. a virus, may recognize and bind to a receptor on the APC, be endocytosed and replicate (either abortively or productively) within the cell. Some of the newly synthesized proteins within the cytoplasm are degraded to peptides, a few of which may associate with class I MHC antigens. Following expression at the cell surface, the complex may be recognized by the receptor on T cells, which also express the CD8 marker. The response is called a class I MHC-restricted response.

In order for T cell activation, differentiation and replication to occur, the APC must also express a costimulator molecule, CD 80, 86 (B7.1 or 7.2), which is recognized by specific receptors on the T cell (CD 28). The activities of APCs can be modified by certain cytokines. **Table 1** lists some properties of three different APCs. Dendritic cells (DCs) are particularly important for CD8+ T cell stimulation, whereas B cells are important antigen presenters to already activated CD4+ T cells (T–B cell interaction).

Activation of T cells There are now known to be subclasses of both CD4+ and CD8+ T cells, each characterized by a particular pattern of cytokine secretion after interaction with APCs and differentiation into helper/effector cells. The properties of these are outlined in **Table 2**. Because of the similarities in expression and secretion of different cytokines, the terms type 1 and type 2 T cell responses have come into general use. Th1 and Tc1 responses are referred to as type 1 responses and Th2 and Tc2 responses as type 2 responses. Two cytokines in particular not only have a dominant role in inducing these responses, IL-12 inducing a type 1 response and IL-4 a type 2 response, but also in suppressing other responses. For

Table 2 Some properties of subclasses of T lymphocytes

Class	*Subclass*	*Cytokine pattern*	*Effector activities*
CD4+	Th1	IL-2, 3; IFN-γ, TNFα, β	Provides help for IgG2a (mice) and IgG1 (humans); mediates DTH, but usually not cytotoxic activity
	Th2	IL-3, 4, 5, 6, 10, 13, TNFα	Provides help for IgG1, IgA and IgE production
	Th0	IL-2, 4, 5, 10, IFN-γ	Provides help to B cells
CD8+	Tc1 (CTL)	IL-2, IFN-γ, TNFβ	Mediates early lysis of virus-infected cells Usually, poor mediator of DTH reactions
	Tc2	IL-4, 5, 10.	Suppresses CTL activity

CTL, cytotoxic T lymphocyte; DTH, delayed-type hypersensitivity; TNF, tumor necrosis factor.

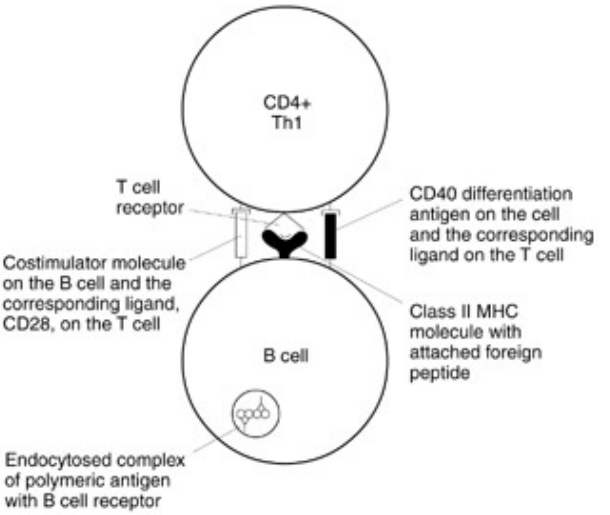

Figure 2 B cell activation by interaction with effector Th cells.

example, IL-4 and Tc2 can suppress the formation/activity of Tc1 cells.

T cells can also be distinguished because of the composition of their receptors for antigen recognition. Most have α,β-peptide chains, but some have γ,δ chains. The latter are a diverse group and are discussed elsewhere.

In vivo, afferent lymphatic vessels convey antigen, some perhaps already taken up by DCs, to the cortical and medullary areas of draining lymph nodes (or to the spleen) via the afferent lymphatics (**Fig. 1**). Particulate material may also be phagocytosed by macrophages in the medullary sinuses. Lymphocytes enter the node via endothelial (postcapillary) venules and T cells localize in the paracortex (T zone), where interaction with APCs occurs.

Activation of B cells An epitope of either a simple, a complex or aggregate of antigens may be specifically recognized by IgM receptors on B cells in the cortex of the lymph node. The complex so formed is endocytosed and degraded within the cell in a fashion thought to be similar to the process in macrophages or dendritic cells. Levels of costimulator molecules as well as class II MHC antigen expression are enhanced and the peptide–MHC antigen complex is transported to the cell membrane. The B cell now migrates to the T zone in the node where the MHC–peptide complex may be recognized by the T cell receptor of usually an already activated T cell. This interaction is illustrated in **Fig. 2**.

In the case of a T cell-independent antigen, e.g. a saccharide, the B cell may secrete IgM antibodies of low affinity, but because of their high avidity, they may be an important early defense mechanism against some pathogens, including viruses.

Early-formed antibody may interact with free antigen and the complex bind via complement receptors to special cells with a very high surface area, the follicular dendritic cells (FDCs) in primary lymphoid follicles (**Fig. 1**). T cell-activated B cells expressing different Ig isotypes (centrocytes) migrate to the follicles and undergo somatic hypermutation, leading to affinity maturation of the Ig receptors. Interaction with antigen held at the surface of FDCs preferentially selects those cells with receptors of higher affinity, and these differentiate into plasma cells. This activity causes morphological changes in the follicle so that they become secondary follicles or germinal centers. The plasma cells enter medullary cords and exit the node via efferent lymphatics. Many migrate to the bone marrow, but most have a relatively short lifespan. Cells not selected by antigen in this way die by apoptosis.

Though there are examples where protective antibodies may be formed to continuous (linear) sequences of a viral antigen, increasing evidence indicates that the most effective neutralizing antibodies recognize conformational epitopes formed by adjacent protein molecules. Examples are the hemagglutinin of influenza virus which exists as a trimer, the VP1 protein multimer of picornaviruses and, more recently, the env antigen of HIV which exists as a trimer. These oligomers/polymers are normally resistant to proteases. This is especially so for glycoproteins, and in the case of a retrovirus, enzymatic removal of the terminal neuraminic acid of the env antigen enhances the susceptibility to protease degradation. In fact, intact HIV particles have been found attached to FDCs. These findings imply that, *in vivo*,

Table 3 Sequence of immune responses following intranasal inoculation of a nonlethal dose of influenza virus to mice.

Type of response	*Events*	*Time period (days)*
Virus	The virus attaches to receptors on epithelial cells, replicates, infects other cells. Maximum titers are reached on days 3–6, thence they decrease and virus is eliminated	0–10
Th cells	CD4+ Th cells are first detected	2
CTLs	CD8+ CTLs are detected, reach peak levels at about 3 days after peak viral titers, then decrease and activity becomes undetectable	4–12
	Memory CTLs are formed and remain at high levels for more than 18 months	14–500+
ASCs	IgM SCs detected at about 7 days, reach peak levels at about 3 months, and are present for about 12 months	7–300+
	IgG SCs detected at about 10 days, reach peak levels at about 3 months and are present for more than 18 months	10–500+
	IgA SCs detected at about 10 days, reach peak levels at about 3 months, and are present for about 12 months; memory ASCs reach peak levels at about 3 months	7–300+

ASCs, antibody-secreting cells; CTLs, cytotoxic T lymphocytes; Th, T helper cells.

these antigens should retain their quaternary conformation while in the extracellular medium, i.e. for selection of B cells and persistence on FDCs. In contrast, once inside an APC such antigens should be more readily degradable to peptides. There is less need for internal antigens of a virus to be protease resistant; often, such antigens (e.g. the nucleoproteins of influenza and lymphocytic choriomeningitis viruses) are a rich source of peptides which bind to class I MHC antigens.

Formation of immunological memory

B cells Some centrocytes in the follicles convert to memory B lymphocytes which circulate around the body. When they later traverse a lymph node or the spleen which contains specific antigen attached to FDCs, the process of activation and selection for cells with high-affinity receptor or reconversion to memory cells begins again. In this way, provided antigen persists for a long period in an appropriate conformation, specific antibody of high affinity may be present for a very long period after an infection or immunization. For example, the H1N1 strain of influenza virus circulated before 1957. It was 'displaced' then by H2N2 and later by H3N2 strains. When the H1N1 strain later appeared in 1977–1978, severe infections mainly occurred in those born since 1957.

An alternative or additional explanation for continued antibody production is the establishment of an idiotypic–anti-idiotypic antibody network, but there is little direct evidence for a long-acting mechanism of this kind.

Compared to naive cells, memory B cells express IgG, IgA or IgE receptors so are readily distinguished from naive B cells. *In vivo*, it is difficult to estimate the number of memory B cells at any one time, but *in vitro* experiments suggest that after an infection the number may be 100-fold or higher, compared with the number of naive cells of that specificity.

T cells The mechanism of formation of T memory cells is shrouded in mystery. There is no indication that it occurs in any special site, affinity maturation of the T cell receptor does not occur, and it is now generally accepted that memory T cells have a long life in the absence of specific antigen. They have a higher level of some cell surface markers, including CD45RO, than naive cells. *In vitro*, limit dilution analyses indicate that after a specific infection or immunization, the numbers of specific Tc1 cells may increase by a factor of 20 or more, but there is some doubt about the validity of such findings *in vivo*, as it is now recognized that memory cells are more readily activated than naive cells. There is also discussion as to whether some memory cells exist in an 'activated' state, whereas others behave more like naive cells.

Sequence of responses in an acute viral infection

Primary response Influenza virus infection in the mouse has been studied in some detail. Following intranasal inoculation of a sublethal dose of influenza virus, some innate responses in the lung can be detected within hours. The subsequent sequence of adaptive responses is outlined in **Table 3**. Specific antibody is the only mechanism for entirely preventing infection (sterilizing immunity), though this probably occurs quite rarely if at all. Many viruses infect via a mucosal surface, such as the gut, and the

respiratory and genitourinary tracts. A special feature is the induction of secretory IgA (sIgA), which is secreted into the lumen from the mucosa. It is very stable, resisting degradation by most proteases, so is ideal as a first line of defense. In cases where viremia may also occur, such as polio virus and measles virus infections, serum Ig forms a second line of defense. Infection must occur for a cell-mediated immune response to develop.

Secondary response If subsequently exposed to virus of an identical or closely similar antigenic specificity, the pre-existing antibody should neutralize the infectivity of nearly all of the incoming virus. Escaping virus would initiate infection, but the progeny in turn would likely be neutralized by the antibody so that the infection would be subclinical. A primary cytotoxic T lymphocyte response should also contribute to clearing the residual infection. However, if the antigenic (B cell) specificity of the challenge virus is different, as occurs especially with influenza virus pandemics, little neutralization of virus will occur, but there will be a more rapid and enhanced cell-mediated immune response, especially cytotoxic T lymphocytes, to the infection because of the memory response to conserved T cell epitopes. Thus, the clinical infection is controlled more rapidly, which could mean the difference between life or death in some cases.

Evading the Immune Response

Viruses may use a number of strategies to evade the immune response.

Evasion of antibody

Antigenic variation Many DNA viruses occur in antigenically different forms, known as serotypes. The number varies from a few (e.g. hepatitis B) to many (e.g. adenoviruses, >40). Each serotype is antigenically stable, and the distribution may vary in different localities. Prior infection with one serotype often does not protect against infection by a different serotype. Owing to the lack of corrective mechanisms for RNA synthesis, RNA viruses sometimes show greater antigenic variation. Mutations leading to changes in the sequence of nucleic acid bases and hence of amino acids, which may occur during viral replication, may persist. This is called antigenic drift and the classical examples are influenza (orthomyxovirus) and HIV (retrovirus). There are also said to be more than 100 serotypes of rhinovirus (an RNA virus) but it seems possible that some are mutants which emerged because of immune pressure. It is not clear why some RNA viruses (e.g. measles, polio) show much less antigenic variation in the field compared to influenza virus. Usually, internal antigens (e.g. nucleoprotein) show much less drift than surface antigens (e.g. influenza), so that they have conserved T cell epitopes. Though HIV shows very high antigenic drift in many proteins, there are some conserved T cell epitopes in the internal antigens.

Viruses with a segmented genome can, in addition, undergo gene reassortment and this may result in major antigenic differences between parent and progeny virus. This process is called antigenic shift and has led to several pandemics of influenza virus.

Immunosuppression Sometimes, antibody formation in response to an infection is poor or delayed or both. For example, HIV possesses suppressor sequences, and synthetic peptides corresponding to these sequences have been shown to inhibit T cell proliferation *in vitro*. In HIV infection, there is often a marked delay before neutralizing antibody is detected.

Evasion of cell-mediated immune responses

Latency Latency is a stage after infection when infectious virus in a cell cannot be detected, but under certain conditions, such as stress, the virus may be reactivated and infectious progeny again produced. Classical examples are herpes viruses, Epstein–Barr virus (EBV) and HIV.

Sanctuary sites Some sites are not easily accessible to the immune system; for example, the brain and epididymis, which are separated from the blood by a barrier, and the kidney. HIV, for example, is present in the brain and semen. This may provide an explanation of why many HIV-infected individuals who generate strong cytotoxic T lymphocyte responses do not clear the virus. Herpes and measles viruses infect neurons and plasmodia infects red blood cells, neither of which express class I MHC. Even lymph nodes can act as a sanctuary. Infectious HIV has been found attached to FDCs in lymph nodes, even though neutralizing antibody was present.

Regulation of class I MHC expression Infection of cells by pox, cytomegalo, herpes and adeno viruses can result in downregulation of class I MHC antigen expression. A variety of mechanisms is used but a common one is the expression in the infected cell of an antigen which binds to the MHC molecule and prevents its expression at the plasma membrane. The net result is that the infected cell is not recognized by cytotoxic T lymphocytes.

Table 4 Putative immune diseases associated with viral infections

Disease	*Agent*
Systemic lupus erythematosus	C-type viruses
Rheumatoid arthritis	Epstein–Barr virus
Autoimmune disease syndrome	HIV
Idiopathic thrombocytopenic purpura	Various viruses
Multiple sclerosis	Parainfluenza, measles viruses, HTLV-1, etc.
Diabetes mellitus	Coxsackie virus B
Thyroiditis	Mumps virus
Postinfectious encephalomyelitis	Measles, rubella viruses

Information courtesy Dr N. R. Rose.

Antigenic drift in cytotoxic T lymphocyte epitopes Like B cell epitopes in some RNA viruses, antigenic drift can occur in T cell epitopes, notably during HIV infection. This may be particularly important if it occurs in a dominant cytotoxic T lymphocyte epitope, as other conserved epitopes may be less well recognized.

Immunological tolerance Infection of neonates by some viruses, such as hepatitis B and lymphocytic choriomeningitis virus (LCMV), results in the persistence of the virus and a carrier state.

Infection of effector cells A wide range of viruses can infect cells involved in immune processes. HIV infects Th cells, DCs and macrophages, and this leads to immune incompetence. The structure of lymph nodes and follicles can be destroyed, and opportunistic infections occur. EBV infection can flourish in immunosuppressed, organ-transplanted people, but transfer of syngeneic cytotoxic T lymphocytes has controlled the infection.

Adverse immune reactions to viral infections

Immune complex formation It is almost inevitable that the immune response to a viral infection will induce some immunopathology. Immune complexes may be deposited in places such as renal glomeruli and the synovium of joints which have filtering basement membranes. If viral antigen is continuously released, such as in a persistent hepatitis B infection, the complexes are deposited over a prolonged period, causing chronic inflammation.

Immune enhancement If a virus replicates in cells which express Fc receptors, then the formation of complexes of virus and nonneutralizing antibody may facilitate infection of the cell by the virus. The classical example of immune enhancement is a dengue virus (flavivirus) infection, leading to immunopathological effects *in vivo*, such as the dengue shock syndrome. Infection-enhancing antibodies have been found in HIV-infected individuals, especially during the later stages of the infection.

Immunopathology There is a variety of experimental models in which a viral infection can cause considerable pathology, sometimes leading to death. Mice injected intracerebrally with LCMV may die due to the formation and activity of cytotoxic T lymphocytes. This does not happen if infection occurs by other routes. Transfer of cloned specific cytotoxic T lymphocytes in small numbers to mice infected intranasally with respiratory syncytial virus enhances recovery; transfer in large numbers enhances disease. Transfer of virus-specific class II MHC-restricted immune cells expressing delayed-type hypersensitivity activity to mice infected with influenza virus can enhance disease.

Molecular mimicry, autoimmunity and autoimmune disease

The presence of similar amino acid sequences between some viral and host proteins is more common than originally supposed. Data-based searches have shown considerable sequence homology, the extent observed increasing with the length of the sequence. Some monoclonal antibodies to viral proteins bind to host proteins. Experimentally, immunization with a peptide from a viral antigen which shared 60% homology with a myelin basic protein induced pathological lesions in the brain. It is important that the homology be not too great.

Autoimmunity is common in human populations and it is very likely that most viral infections induce some autoimmunity. Infection by some viruses may initiate or be associated with a particular autoimmune disease. **Table 4** contains a list of possible

associations. Studies in animal models suggest that Th1-type lymphokines are involved in the genesis of many organ-specific autoimmune diseases.

Cell Mediated Immune Response

Janice Riberdy and **Peter Doherty**, St Jude Children's Research Hospital, Memphis, Tennessee, USA

General Features

Cell-mediated immunity (CMI) is concerned with the elimination of infected cells from organ sites of virus growth. This terminates the production of new virus, preventing the further spread of the infectious process. While virus-specific immunoglobulin (Ig) molecules are very important for neutralizing free virions, and thus play a central part in resistance to reinfection, antibody transfer experiments indicate that Ig-mediated mechanisms are less prominent in the clearance of virus from solid tissues. Removing the infected cell generally depends on the involvement of virus-specific thymus-derived lymphocytes, or T cells, the effectors of CMI. The immune system has evolved largely to deal with pathogens, optimizing the effective synergism between Ig-mediated and T cell-mediated functions.

There are two broad categories of T cells, each expressing a clonally distributed T cell receptor (TCR) heterodimer characterized as either $\alpha\beta$ or $\gamma\delta$. The $\alpha\beta$ or $\gamma\delta$ TCR molecules are associated with the multimeric CD3 complex, which is involved in mediating the signaling events that control T cell stimulation and differentiation. Most current understanding of virus-specific CMI is concerned with the $\alpha\beta$ T cell subsets, which express either the CD4 or CD8 coreceptor molecules (**Fig. 1**). The $\gamma\delta$ T cells are a minority in mice and humans, constituting less than 5–10% of the peripheral T cells in blood and secondary lymphoid tissue, while they are much more prevalent (20–30%) in pigs, ruminants and chickens. The role of the $\gamma\delta$ T cells in virus infections is not yet understood, though these lymphocytes are known to accumulate in some viral pneumonias and may play a part in regulating the inflammatory process.

The CMI effector mechanism is targeted to the surface of virus-infected cells because the antigen-specific $\alpha\beta$ TCR recognizes viral peptides presented in association with self major histocompatibility complex (MHC) glycoproteins (**Fig. 1**). The developing T cells are selected in the thymus to be tolerant (non-responsive) of self MHC molecules encountered in the thymic microenvironment but reactive, after leaving the thymus, to these same glycoproteins when they are modified by the binding of nonself peptides. This phenomenon is known as 'MHC restriction'. Tolerance of viral peptide–MHC glycoprotein complexes can also be induced if, as in mice infected *in utero* with murine lymphocytic choriomeningitis virus (LCMV), the antigen is encountered during thymocyte differentiation.

A critical lymphocyte in most virus-induced inflammatory processes is the CD8+ $\alpha\beta$ T cell. Lymphocytes of this T cell subset recognize viral peptides presented in the context of the class I MHC glycoproteins, the strong transplantation antigens that are expressed (or can be induced) on most cells throughout the body. The CD8 molecule binds to a constant region of the MHC protein, thereby increasing the avidity of the interaction between the T lymphocyte and the antigen-presenting stimulator or target cell. This may be particularly important at the initial stages of the induction of a primary T cell response. The pore-forming proteins (perforins) and enzymes (granzymes) characteristic of cytotoxic effector function are prominent in the cytoplasm of activated,

influenza infection. *Curr. Top. Microbiol. Immunol.* 128: 1.
