The rapid yield to selective pressure by 6S RNA and the Qβ RNA variants reflects the inaccuracy of the Qβ replicase, which has been estimated at between 10^{-3} and 10^{-4} per nucleotide per replication. The presumed absence of a $3' \rightarrow 5'$ exonuclease editing activity in Qβ replicase would be consistent with its relatively low copying fidelity. At the same time the frequency with which deletions occur must also be unusually high.

Rigidity and Plasticity of the Genome Structure

Considering the inaccuracy of phage RNA replication one might expect an endless scale of phage sequences, all fit to survive. This turns out not to be true. The sequences of Qβ and MS2 have, despite many years of laboratory cultivation, not or hardly changed. Similarly it has turned out to be quite difficult to find RNA phages in nature whose sequences diverge substantially from the group prototype. For instance, group I representatives like f2, R17, M12, JP501, all isolated independently in different parts of the world, show more than 90% sequence identity. Thus there seem to be very few solutions that are good enough to coexist. It is assumed that the selection pressure, which discards all potential variants (for instance those having synonymous codons), originates from the contribution of the RNA secondary structure (**Fig. 2**) to phage fitness. Such contributions involve regulatory circuits, RNase resistance, delaying the annealing of positive and negative strands and probably many other parameters.

In spite of this apparent rigidity the genome

structure shows a high degree of flexibility under noncompetitive conditions. Laboratory evolution of phages containing a wanton distortion in RNA structure yields many pseudorevertants presenting us with a large spectrum of structural solutions. These solutions all perform well as long as they do not have to compete with their wild-type counterpart. Then they lose and disappear from the population.

Phylogeny of RNA Phages

An interesting but necessarily most difficult question is that of the origin and kinships of the RNA bacteriophages. It is generally assumed that all of them derive from a common ancester because of the nearly identical genetic organization, the strong resemblance of the replicases, the use of the same host proteins (except Host Factor) as auxiliaries in the copying reaction, and the similarities of several control mechanisms. These properties are more easily explained by divergent than by convergent evolution.

Therapeutic Use of RNA Phages

There is presently renewed interest in DNA phages as combatants of bacterial infections. Early pilot studies showed that *E. coli* adapts to RNA phages by losing its F pili.

Smallpox (Variola) Virus

History

A Chinese account of a disease which was clearly smallpox was written in the 4th century. Over the next two centuries reliable accounts described smallpox in Japan, Korea, India and Egypt. Shortly after this, the Islamic expansion carried smallpox into North Africa and Europe. From the 15th century smallpox was taken to America and southern Africa with the spread of European colonists. According to the Chinese account, smallpox had appeared in China during the first century, but it may have been current in India well before that. A few Egyptian mummies show evidence of a pustular rash which has some resemblance to smallpox, but there are no accounts of such a disease in contemporary Egyptian or Jewish writings.

Taxonomy and classification

Variola (smallpox) viruses belong to the *Orthopoxvirus* genus of the *Chordopoxvirinae* subfamily of DNA viruses in the *Poxviridae* family and have linear, double-stranded DNA genomes of 186 kb. The virions are large (about 250 × 200 nm), brick-shaped particles. Like vaccinia they can be seen as mature, intracellular virions or as enveloped, extracellular virions. When viewed by electron microscopy after dehydration and embedding in Epon, the particles have two lateral bodies and a central core, but the

structure shows a high degree of flexibility under noncompetitive conditions. Laboratory evolution of phages containing a wanton distortion in RNA structure yields many pseudorevertants presenting us with a large spectrum of structural solutions. These solutions all perform well as long as they do not have to compete with their wild-type counterpart. Then they lose and disappear from the population.

Smallpox (Variola) Virus

History

A Chinese account of a disease which was clearly smallpox was written in the 4th century. Over the next two centuries reliable accounts described smallpox in Japan, Korea, India and Egypt. Shortly after this, the Islamic expansion carried smallpox into North Africa and Europe. From the 15th century smallpox was taken to America and southern Africa with the spread of European colonists. According to the Chinese account, smallpox had appeared in China during the first century, but it may have been current in India well before that. A few Egyptian mummies show evidence of a pustular rash which has some resemblance to smallpox, but there are no accounts of such a disease in contemporary Egyptian or Jewish writings.

Taxonomy and classification

Variola (smallpox) viruses belong to the *Orthopoxvirus* genus of the *Chordopoxvirinae* subfamily of DNA viruses in the *Poxviridae* family and have linear, double-stranded DNA genomes of 186 kb. The virions are large (about 250 × 200 nm), brick-shaped particles. Like vaccinia they can be seen as mature, intracellular virions or as enveloped, extracellular virions. When viewed by electron microscopy after dehydration and embedding in Epon, the particles have two lateral bodies and a central core, but the

lateral bodies are not evident when orthopoxviruses are observed by cryoelectron microscopy.

Variola virus has a close antigenic relationship to other orthopoxviruses; it is distinguished as a species by its biological characters and by the characterization of its DNA genome.

Virion structure and properties

What is known about the structure, physical properties and replication of variola virus conforms so closely to the much better studied vaccinia that the reader is referred to that entry. One point of difference is that the variola genome has only a short inverted terminal repeat sequence (ITR) of 725 bp, unlike the 10 kb ITR of vaccinia virus.

Geographic and seasonal distribution

The last natural case of smallpox occurred in 1977; and in 1980 the World Health Organization (WHO) declared that the disease had been eradicated. In its heyday smallpox had a worldwide distribution. The development of effective public health services and the routine practice of vaccination gradually eliminated the disease from North America and most of Europe, but outbreaks, apparently endemic in origin, continued in these parts of the world through the first decades of the 20th century. For a variety of reasons, routine vaccination failed to eradicate smallpox from many tropical and subtropical areas. At the start of the global eradication campaign in 1967 there were still 31 countries in which the disease was endemic.

After smallpox eradication was complete, the number of laboratories maintaining stocks of variola virus was rapidly reduced. At present (1998), variola virus is maintained in just two high-containment laboratories situated in Atlanta, USA and in Novosibirsk, Russia. The WHO is coordinating a program to obtain DNA sequences from representative strains of variola. It is intended that these sequence data shall become the permanent record of this virus and all remaining stocks of the virus shall be destroyed before the end of the 20th century.

Smallpox was maintained entirely by transmission from an active case to another human; latency did not occur. Consequently, active search would reveal cases throughout the year in countries where the disease was endemic. Nevertheless, there were low seasons and high seasons. In tropical areas it seems likely that the seasonal changes in incidence were achieved more through the ease or difficulty of traveling about than from direct effects of climate on survival of virus or susceptibility to it.

Host range and virus propagation

Variola virus had a narrow host range and natural infection was confined to humans. The virus was propagated in laboratories on the chick chorioallantois or in cell cultures, usually of human origin. There was no experimental animal model in which inoculation of variola virus produced clinical disease resembling smallpox and in which the pathology could have been studied. The virus produced a mild disease in some species of monkeys and could be propagated, at least for a time, in baby mice and in rabbits.

Genetics

DNA restriction maps of variola from different geographic areas were remarkably uniform and showed little, if any, variation in viruses from different countries. Consistent differences were found between variola major strains and alastrim strains from South America, but this did not apply to strains of variola minor from Africa. The complete DNA sequence of variola virus strains Bangladesh-1975 and India-1967 and the partial sequences of Harvey-1947, Congo-1970, Somalia-1977 and Garcia-1966 have been determined and are deposited in DNA data banks. There are several instances of some of the individuality of variola virus, but there is at present no evidence that variola encodes any gene which has no counterpart in the genome of another poxvirus.

Comparisons of the entire sequence of a variola virus with that of vaccinia virus has revealed that the central two-thirds of the genomes are highly conserved, with >95% nucleotide identity, but towards the termini the sequences diverge and there are sequences unique to either virus. There are several instances of highly related coding sequences being intact in one virus and truncated or fragmented in the other. Surprisingly, in the majority of cases where coding sequences are disrupted, the sequence is intact in vaccinia and broken in variola. Some open reading frames that at first appeared to be unique to variola have been found to be present in other orthopoxviruses. At present it would appear that the virulence of variola virus for humans probably resided in the combination and variation of multiple genes present in several poxviruses, rather then a 'key' unique virulence gene.

Variola viruses readily recombine with other orthopoxviruses: some of the resulting recombinants were characterized biologically, but work with variola virus ceased before these results were correlated with the exchange of particular segments of the parental genomes.

Evolution

The naturally occurring orthopoxviruses: cowpox, monkeypox and camelpox, currently occupy separate geographic and biologic niches in Europe, Africa and the Middle East. The similarities between the genomes of these three viruses, variola and vaccinia are sufficient to imply a common ancestor. Furthermore, there is evidence that several orthopoxvirus genes, for instance those encoding enzymes for virus transcription and DNA replication, have counterparts in other genera of poxviruses, such as leporipox, capripox, avipox and suipox, molluscipox and yatapox. Two orthopoxviruses that have been identified in America, volepox and raccoonpox, are less closely related to other orthopoxviruses.

Camelpox seems to be most closely related to variola, in biological properties, in some features of the genome, and in its natural infection of only a single species. There is, however, no firm evidence that camelpox virus can infect humans, despite much contact between camels and unvaccinated humans. It is possible that both camelpox and variola viruses having found a single species present in numbers adequate to maintain their survival, have lost the presumed primitive ability of orthopoxviruses to utilize a variety of host species – an ability which has been retained for the survival of cowpox and monkeypox.

Serologic relationships and variability

There was never any evidence for antigenic variability in variola viruses. Indeed it was even difficult to separate variola from other orthopoxviruses by serologic tests. Any strain of vaccinia would protect against variola in any part of the world and in different years. In accord with this, the proteins of the envelope of extracellular virions are highly conserved between vaccinia and variola. Several different antigens of variola virus find their way to the surface of the infected cell before virus release. Because of this and also the length of the incubation period, it is unlikely that minor variation in any particular antigen would confer sufficient advantage to be preferentially selected.

Epidemiology and transmission

The vast majority of smallpox was contracted by direct contact with an infected person. There were rare instances of indirect spread via fomites but animals played no part in sustaining or transmitting the variola virus.

Despite occasional startling incidents, smallpox required close contact for effective transmission and spread mainly within households or to other close contacts.

Those infected with smallpox remained well for the 10–12 days of the incubation period and, during this time, were not infectious to others. In natural smallpox (as opposed to variolation) virus was transmitted by droplet infection. The most usual source was the lesions that occurred in the pharynx or mouth (the enanthem). These ulcerated more quickly than the lesions developing in the skin (the exanthem) and were well situated for distribution to close contacts. Primary lesions were presumed to occur in the respiratory tract but were never seen or demonstrated post mortem. Throat swabs from contacts who subsequently developed smallpox were occasionally found to harbor virus during the incubation period, but there was no evidence that transmission occurred before the end of the incubation period. Nor did those who were subclinically infected pass on the disease.

Cases were potentially infectious until all the lesions had completely healed but virus was not so readily dispersed from dried exudate or scabs. There was no evidence of latency and no spontaneous recurrence. Consequently, once an outbreak had run its course or been controlled in a local community, smallpox would not recur unless reintroduced from outside that community.

Outbreaks varied in severity, but even in a severe outbreak there would be some milder cases. At times whole outbreaks of mild smallpox occurred with little or no fatality. This led to the distinction of two varieties of the disease, variola major and variola minor, and to the presumption that the variola minor outbreaks were caused by a distinct strain of variola virus of lower virulence. In some areas the minor form became established as the endemic strain. The variety of variola minor known as alastrim apparently arose towards the end of the 19th century and produced consistently mild disease. This strain was first described in southeast USA and thence spread through North America, to Europe, to South America and to Australasia. Outbreaks of minor smallpox were still occurring in Europe in the 1950s and in Brazil through the 1960s. Isolates from outbreaks of alastrim in Europe and Brazil shared biologic characters and a DNA restriction pattern which distinguished them from variola major viruses. The position in Africa was less well defined. Outbreaks of major and of minor smallpox continued to occur. Although the endemic variola in some African countries was clinically and epidemiologically variola minor in recent years, virus isolates from these cases could not be distinguished from isolates of variola major virus.

Clinical features

The incubation period of 10–12 days was terminated by the abrupt onset of fever and prostration, often with nausea or vomiting. On the 3rd day of illness a macular rash appeared; this became papular and then vesicular and eventually pustular. The rash tended to be more concentrated on the head and limbs than on the trunk. The lesions were firm and raised but also based deeply in the skin. Scabs formed as the ulcerated pustules dried and gradually separated over 2–3 weeks, leaving depigmented areas. Residual facial scarring, due to destruction of sebaceous glands, was a characteristic feature of the survivors of major smallpox. Blindness was another, not uncommon, sequel. The above description applies to classical cases of major smallpox, in which the fatality rate was 16–30%. Prognosis was worse if the rash was slower in development, with the lesions remaining flat and soft or becoming hemorrhagic. Sometimes the initial prostration was severe, generalized hemorrhagic manifestations appeared on the second or third day and no distinctive rash developed. These patients invariably died, usually between the 5th and 7th day of illness. A more favorable prognosis was signified if the rash evolved more quickly and the lesions were more superficial. This was the usual course of events in people who had been vaccinated, but not recently enough to give complete protection.

When the causative virus was variola minor, prostration was notably less than in patients who had a comparable extent of rash following infection with variola major virus.

Pathology and histopathology

The majority of smallpox lesions were in the skin and mucous membranes of the mouth and oropharynx. The small number of postmortem studies that were done showed few specific lesions in internal organs, except in cases of hemorrhagic smallpox. In the absence of obvious damage in the vital organs it was presumed that death had been due to the profound toxemia. Fuller accounts will be found in the texts cited at the end of this entry.

Immune response

Antibody that neutralized intracellular virus and hemagglutination inhibiting (HI) antibody appeared by about the 6th day of the disease, corresponding to the 18th day after infection. This is slower than the antibody response to primary vaccination and may explain partly why vaccination soon after contact with smallpox often ameliorated the outcome. However, experience with the complications of vaccination showed that a failure to develop cell-mediated immunity was more important than failure to develop antibody. It is presumed that cell-mediated immunity also controlled the development and resolution of smallpox lesions, but this was not adequately investigated.

Recovery left a lasting immunity; although second attacks of smallpox were not unknown. Neutralizing antibody persisted for many years; HI antibody was demonstrable for some months to a few years.

Prevention and control

Successful vaccination gave complete protection against smallpox for at least 3 years and probably 5 or more. Immunity waned after longer intervals, but rarely, if ever, did anyone who had been vaccinated contract fatal smallpox. The International Certificate of vaccination against smallpox was given a validity of 3 years, but those at high risk were normally revaccinated at yearly intervals.

Compulsory routine vaccination should, theoretically, have eradicated smallpox in any area where it was practiced. However, in many countries where the disease was endemic, the fraction of the population that escaped the vaccination program sufficed to maintain a chain of active cases and a reservoir of the virus.

The main factors in containing an outbreak of smallpox were the isolation of cases and the tracing of contacts before the end of their incubation period. These measures were supplemented with vaccination or revaccination in the locality of the outbreak, and were effective in the control and elimination of smallpox introduced into a nonendemic area. The eradication of smallpox from endemic areas was achieved by detecting current outbreaks and containing them. This strategy effectively interrupted the local transmission of the virus and progressively reduced the number of chains of transmission which remained.

Future perspectives

In 1980 the World Health Organization certified officially the eradication of smallpox, and no further cases have come to light in the 18 years that have elapsed since then. This major achievement seems to be firmly established. The only remaining viable variola viruses are the two reference collections of variola strains held in high containment laboratories at Atlanta and Novosibirsk and the possibility that virus might have survived in the bodies of any smallpox victims who were mummified or buried in permafrost conditions. Extrapolation from the known rates of decay of variola virus in smallpox scabs indicates that this possibility is unrealistic.

It has been agreed that the two collections of variola virus strains should be destroyed before the end of the twentieth century. The archival record of variola virus will then be the complete DNA sequence of a small number of representative strains and some fragments of variola DNA which have been cloned into recombinant plasmids. Of course much of the gene pool of variola virus will still remain, in the genomes of other, closely related orthopoxviruses. When the genomes of further orthopoxviruses have been sequenced it will be possible to determine what features of the variola genome were unique to that virus. The section on monkeypox includes a discussion of whether variola virus could emerge again from natural sources.

Monkeypox Virus

History

Monkeypox virus was first described as the cause of an apparently spontaneous outbreak of fever and rash in a colony of cynomolgus monkeys held at the State Serum Institute in Copenhagen in 1958. During the next few years similar outbreaks were reported in monkey colonies in the USA. In 1966 monkeypox infection was introduced into the zoo at Rotterdam. Here the first animals affected were giant anteaters from South America, but the disease spread to various species of apes and monkeys. The viruses isolated from these animals were found to be similar and to represent a species of orthopoxvirus that had not been described before 1958. In two separate incidents in 1970 monkeypox virus was found to have caused a smallpox-like illness in humans in the Democratic Republic of the Congo (formerly Zaire) and in Liberia. Sporadic cases have continued to occur in the African rain forest belt, particularly in the Democratic Republic of the Congo. The virology and epidemiology of monkeypox have been intensively investigated because of the possible threat to the success of smallpox eradication.

Taxonomy and classification

Monkeypox virus is a separate species of the *Orthopoxvirus* genus. Biologically it can be differentiated from other species by the morphology and ceiling temperature of its pocks on the chick chorioallantois and by its pathogenicity to rabbits. Antigenically it crossreacts extensively with other orthopoxviruses but produces a few specific antigens which can be detected with suitably absorbed antisera or monoclonal antibodies. The genome, of approximately 190 kb, has a distinctive restriction map, and DNA sequence data are available for parts of the genome.

Virion properties and replication

There is no reason to believe that replication of monkeypox virus differs significantly from the more extensively studied vaccinia virus.

Geographic and seasonal distribution

The reservoir of monkeypox virus is confined to the tropical rain forest belt of Africa. On current information the reservoir hosts are arboreal rodents, from which sporadic transmissions occur to simians and to humans. Human infections are rare events: most of the reported cases have been in the Democratic Republic of the Congo, which harbors more than half of the present African rain forest. There is no marked seasonal incidence, but some correlation with times of maximum agricultural activity (see Epidemiology).

Partial DNA sequence studies of American and European isolates show identity with isolates from West Africa, thus confirming the presumption that the outbreaks in Europe and America were initiated by subclinical infection in monkeys or other animals exported from West Africa. There have been no outbreaks outside Africa since 1968, following a general tightening of regulations concerning exports of animals. DNA sequence data confirm that the outbreaks in Europe and America were caused by a monkeypox virus originating from West Africa rather than Central Africa.

Host range and virus propagation

Under experimental conditions monkeypox virus is capable of infecting most common laboratory animals and many simian species. The resulting disease is usually mild in African monkeys but Asian and South American monkeys suffer moderate to severe disease. Apes, with the exception of chimpanzees, are seriously affected and the wide range of susceptible exotic animals is illustrated by the two South American giant anteaters which became infected while in transit to the Rotterdam Zoo.

In its natural habitat, monkeypox virus has been recovered from many sporadically infected humans and from one sick squirrel (*Funisciurus anerythrus*) and a chimpanzee. Other information comes from serologic surveys; antibody specific to monkeypox has been detected in a significant proportion of squirrels belonging to the genera *Funisciurus* and *Heliosciurus*. Specific antibody was also detected in seven species of cercopithecus, and also in cercocebus and colobus monkeys. Monkeypox virus was propagated in

laboratories on the chick chorioallantois, where it produced characteristic small pocks with a central hemorrhage. Cell cultures of many different species were susceptible.

Genetics

*Hind*III restriction maps of the monkeypox virus genome confirm the conservation of the central part of the orthopoxvirus genome throughout the genus. Although restriction site maps show more variation in the outer quarters of the genome, DNA fragments from these regions crosshybridize strongly with corresponding fragments of other orthopoxviruses and rule out any long region of sequence that could be unique to monkeypox. There must be short unique stretches to account for the monkeypox-specific antigens that have been demonstrated, but few studies of DNA sequence in monkeypox have yet been reported. There is some variation in restriction site maps of monkeypox isolates from different geographical areas but variants with more dramatic changes in genome structure can readily be isolated in the laboratory. These are the 'white pock' mutants, which also have been described among other orthopoxviruses with a hemorrhagic pock phenotype, such as cowpox.

Evolution

Monkeypox virus, like cowpox virus, appears to be sustained by transmission in small rodents. The present distributions of these viruses do not overlap but the antigenic and genetic similarities among all the orthopoxviruses are such that they must share a common ancestor. Each of these two viruses is known to infect a variety of species under natural conditions, including humans. This could have led to the possibility of further speciation. It has been suggested that monkeypox might be the progenitor of variola. This is ruled out because a gene sequence (ORF) which is present in variola (and vaccinia) has been shown to be degenerate and partially deleted in monkeypox DNA. Also it must be remembered that smallpox appeared in East Asia well before it was current in Africa (see the earlier section on variola virus).

Epidemiology and transmission

In the Democratic Republic of the Congo, sporadic cases of monkeypox infection have continued. Most cases occur in small rural villages in the rain forest belt. The age-specific incidence of primary monkeypox (i.e. excluding spread from person to person) is highest in young children between 1 and 8 years, peaking in the 3–4 year age group. Young children have access to the cleared areas between the village and the forest; in this area also are found squirrels of the genera *Funisciurus* and *Heliosciurus* in which monkeypox antibody is prevalent. The age-specific incidence of secondary cases is more evenly distributed. Most outbreaks are believed to be limited to the primary (and sometimes coprimary) cases. Chains of presumed human-to-human transmission have so far been limited but there is concern that the virus may adapt to become more transmissible in humans. Ongoing surveillance is required. Variation in the reported incidence from area to area and from year to year may well depend on natural fluctuations in the wildlife reservoir but will also be affected by the efficiency of surveillance activities. Transmission from person to person is probably from the enanthem via the respiratory route, but the secondary attack rate among unvaccinated household contacts is much lower than that found in smallpox. Based on experience to date, the basic case reproduction rate does not exceed 1.0 and outbreaks would be self-limiting even in an unvaccinated community.

Clinical features

The incubation period of human monkeypox appears to be about 12 days, the same as for smallpox, but there have been only a few instances where it could be accurately determined. The clinical picture of human monkeypox closely follows that of ordinary smallpox. Most cases in unvaccinated children have been severe, but equivalents of the flat or hemorrhagic types of smallpox have not been encountered. The illness begins with fever, followed in 1–3 days by the rash, and an enanthem is usually present on the oral mucosa. Unlike smallpox, most patients develop a generalized lymphadenopathy or, less often, a regional lymphadenopathy. Mortality in the unvaccinated has been about 11%, though somewhat higher than this in children under 2 years of age. Nearly all deaths have been in children under the age of 9 years.

Pathology and histopathology

This has only been studied in experimental infection of monkeys. Histopathology of the lesions resembled that of smallpox. Following intramuscular inoculation, there was an intense local inflammatory response. Virus spread to the regional lymph nodes and thence to spleen, tonsil and bone marrow. Viremia occurred between the 3rd and 14th days and a generalized rash appeared about the 7th or 8th day.

Immune response

The antibody response to infection with monkeypox virus can conveniently be detected by hemagglutina-

tion inhibition or by ELISA tests. High titers in straight antibody tests suggest a response to monkeypox rather than to vaccination, but a residual titer after absorption with vaccinia virus is required to demonstrate antibody specific to monkeypox. For this reason radioimmunoassay tests have been most useful because of the high titers obtainable from unabsorbed sera by this technique. More specific tests are in course of development.

Prevention and control

Recent vaccination with vaccinia virus effectively protects against monkeypox, and those who had been vaccinated some years previously were susceptible but were less likely to develop severe illness. Widespread routine vaccination would be necessary to protect all who might come into contact with monkeypox; but the incidence of monkeypox is so low that complications arising from the vaccination program might rival the morbidity to be expected from monkeypox itself.

Future perspectives

The main incidence of monkeypox in humans has been in young children. Although this age group is currently unprotected by vaccination, there has not been any evidence of a rising incidence of monkeypox infections. Until recently monkeypox has not presented a public health problem serious enough to require specific action. Significantly more cases of monkeypox have been reported recently, including longer chains of transmission than had previously been recorded. The situation is being closely monitored and recent isolates of the virus will be rigorously compared to see if significant changes have occurred. At this stage it is hard to forecast future developments.

SOBEMOVIRUSES

OP Sehgal, University of Missouri, Columbia, Missouri, USA

History

Southern bean mosaic virus (SBMV) is the archetype of the plant virus genus *Sobemovirus* in the family *Tetraviridae*. SBMV was the subject of intensive biological and physicochemical investigations during the 1940s and was the only virus, other than tobacco mosaic and tomato bushy stunt viruses, that had been well characterized at this early period. In the 1970s through the mid 1980s, SBMV served as a prototype on the applicability of small angle x-ray diffraction and neutron scattering in deciphering virion organization. During the same period, studies with SBMV and turnip rosette virus (TRoSV), yielded vital information on the nature of macromolecular forces that govern virion stability.

Taxonomy and Classification

The International Committee on Taxonomy of Viruses recently established the genus *Sobemovirus* in the family *Tetraviridae* (1995). At present, a number of viruses including SBMV and TRoSV are recognized as members of the sobemovirus genus. These are: blueberry shoe string virus (BSSV), cocksfoot mottle virus (CfMV), lucerne transient streak virus (LTSV), rice yellow mottle virus (RYMV), Rottboellia yellow mottle virus (RoYMV), *Solanum nodiflorum* mottle virus (SNMV), sowbane mosaic virus (SoMV), subterranean clover mottle virus (SCMoV) and velvet tobacco mottle virus (VTMoV). Additionally, seven viruses may be considered as probable members pending availability of additional

tion inhibition or by ELISA tests. High titers in straight antibody tests suggest a response to monkeypox rather than to vaccination, but a residual titer after absorption with vaccinia virus is required to demonstrate antibody specific to monkeypox. For this reason radioimmunoassay tests have been most useful because of the high titers obtainable from unabsorbed sera by this technique. More specific tests are in course of development.

Prevention and control

Recent vaccination with vaccinia virus effectively protects against monkeypox, and those who had been vaccinated some years previously were susceptible but were less likely to develop severe illness. Widespread routine vaccination would be necessary to protect all who might come into contact with monkeypox; but the incidence of monkeypox is so low that complications arising from the vaccination program might rival the morbidity to be expected from monkeypox itself.

Future perspectives

The main incidence of monkeypox in humans has been in young children. Although this age group is currently unprotected by vaccination, there has not been any evidence of a rising incidence of monkeypox infections. Until recently monkeypox has not presented a public health problem serious enough to require specific action. Significantly more cases of monkeypox have been reported recently, including longer chains of transmission than had previously been recorded. The situation is being closely monitored and recent isolates of the virus will be rigorously compared to see if significant changes have occurred. At this stage it is hard to forecast future developments.

SOBEMOVIRUSES

OP Sehgal, University of Missouri, Columbia, Missouri, USA

History

Southern bean mosaic virus (SBMV) is the archetype of the plant virus genus *Sobemovirus* in the family *Tetraviridae*. SBMV was the subject of intensive biological and physicochemical investigations during the 1940s and was the only virus, other than tobacco mosaic and tomato bushy stunt viruses, that had been well characterized at this early period. In the 1970s through the mid 1980s, SBMV served as a prototype on the applicability of small angle x-ray diffraction and neutron scattering in deciphering virion organization. During the same period, studies with SBMV and turnip rosette virus (TRoSV), yielded vital information on the nature of macromolecular forces that govern virion stability.

Taxonomy and Classification

The International Committee on Taxonomy of Viruses recently established the genus *Sobemovirus* in the family *Tetraviridae* (1995). At present, a number of viruses including SBMV and TRoSV are recognized as members of the sobemovirus genus. These are: blueberry shoe string virus (BSSV), cocksfoot mottle virus (CfMV), lucerne transient streak virus (LTSV), rice yellow mottle virus (RYMV), Rottboellia yellow mottle virus (RoYMV), *Solanum nodiflorum* mottle virus (SNMV), sowbane mosaic virus (SoMV), subterranean clover mottle virus (SCMoV) and velvet tobacco mottle virus (VTMoV). Additionally, seven viruses may be considered as probable members pending availability of additional

Table 1 Geographical distribution, natural hosts and insect vectors of sobemoviruses

Virus	*Geographical distribution*	*Natural hosts*	*Vectors*
SBMV	USA, Central and South America, Africa, Asia	Bean, cowpea	Beetles
BSSV	USA, Canada	*Vaccinium corymbosum*, *V. angustifolium*	Aphids
CfMV	Europe, New Zealand	Cocksfoot, wheat	Beetles
LTSV	Australia, New Zealand, Canada	*Medicago sativa* (lucerne)	Beetles
RYMV	Tropical Africa	*Oryza sativa* (rice)	Beetles
RoYMV	Nigeria	Itchgrass	Unknown
SNMV	Australia	*Solanum nodiflorum*, *S. nigrum*, *S. nitidibaccatum*	Mirid, beetles
SoMV	World-wide	*Chenopodium* spp., apple, grapes, *Atriplex suberecta*	Leafminers, aphids
SCMoV	Australia	Subterranean clover, club clover	Beetles
TRoSV	UK	Turnip, swede	Beetles
VTMoV	Australia	*Nicotiana velutina*	Mirid, beetles
Tentative members			
CYMV	Colombia	*Calopogonium mucunoides* (calopo)	Beetles
CMMV	Europe	Cocksfoot	Aphids
CyMV	Europe, New Zealand	*Cynosurus cristatus*	Aphids
GCFV	Asia, Australia, New Zealand	Ginger	Unknown
PMV	USA, Mexico, Africa	Several grasses	Beetles
RgMV	Japan	*Dactylis glomerata* *Lolium multiflorum*,	Unknown
SsbMV	India	*Sesbania grandiflora*	Unknown

information on their properties. These are: calopo yellow mosaic virus (CYMV), cocksfoot mild mosaic virus (CMMV), cynosurus mottle virus (CyMV), ginger fleck virus (GCFV), panicum mosaic virus (PMV), ryegrass mottle virus (RgMV), and sesbania mosaic virus (SsbMV). Olive latent virus 1, a putative sobemovirus, resembles *Necrovirus* species in its genomic organization and expression and should be included in the genus *Necrovirus*. Other tentative virus species are in the genus.

Geographical Distribution, Natural Hosts and Vectors

Most sobemoviruses have somewhat limited distribution, but as a group, they are found throughout the world (**Table 1**). Individual members have few natural hosts but, as a whole, they infect a wide spectrum of plant species. Eight sobemoviruses affect dicotyledonous species, and an equal number affect monocotyledonous species, but none are transmitted to both. Leaf-eating beetles are their most common vectors.

Properties of the Virion

Sobemovirus virions are isometric with a diameter of *ca.* 25–30 nm (**Fig. 1**). Most virions exclude negative stains from penetrating to the core, a reflection of a highly compact capsid organization. SBMV virions exhibit no structural changes even when inactivated (>99%) by exposure to ultraviolet light, heating, freezing and thawing or nitrous acid. However, EDTA treatment, which removes capsid-associated divalent cations, results in virion 'swelling', and such virions are then rendered permeable to negative stains.

Sobemovirions are nonenveloped, and contain *ca.* 21% RNA and 79% protein. SBMV, LTSV and TRoSV virions contain significant amounts of intimately bound divalent cations (calcium, magnesium). The virions sediment sharply as single components in sucrose gradients, with $s_{20,w}$ values ranging from 109S (PMV) to 120S (BSSV). A characteristic feature of most sobemovirions is that they band homogeneously in cesium chloride (densities ranging from 1.34 to 1.39 g ml^{-1}) but heterogeneously in cesium sulfate gradients. The banding heterogeneity in cesium

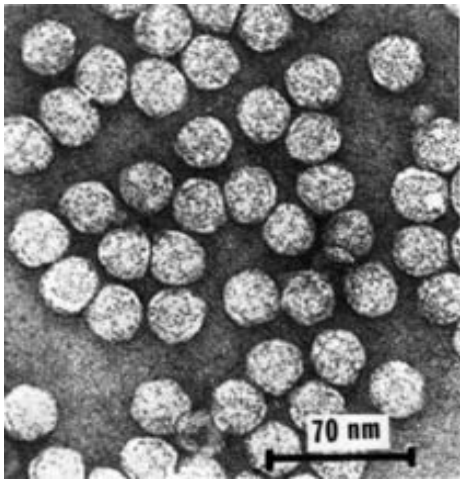

Figure 1 Purified virions of southern bean mosaic virus, bean strain. Uranyl formate was used as the negative stain.

sulfate gradients is a reflection of conformational variations among virions in a population rather than any differences in their chemical composition.

Capsid Organization and Stabilizing Interactions

The sobemovirus capsid is constructed from a protein of about 30 kDa. A proportion of coat protein subunits in SBMV and TRoSV virions exist as stable dimers that are preferentially linked to RNA. The basic SBMV capsid structure is $T = 3$ quasi-symmetry of 180 subunits. High resolution x-ray diffraction has revealed three types of quasi-equivalent subunits, namely A, B and C, which are chemically identical but have different conformations. The A subunits cluster at the fivefold axes, whereas sets of B and C aggregate at the quasi-sixfold vertices. Each subunit consists of a random domain, i.e. the N-terminal 'arm' located towards the virion interior, and the surface domain, which is organized into an eight-stranded antiparallel β barrel and five α helices. Considerable similarity exists between the organization of SBMV capsid with those of tomato bushy stunt, tobacco necrosis, poliovirus type 1 and human rhinoviruses. Sobemovirus virions are extremely stable *in vitro* in their native state. For SBMV and TRoSV, this stability is derived from strong inter-subunit linkages mediated by hydrophobic interactions, divalent cations and pH-dependent bonds. Additionally, protein–RNA linkages contribute to virion stability. Perturbations in the pH-dependent and divalent cation-mediated bonds cause the capsid to relax, rendering it sensitive to proteases, salt or detergents. Only LTSV and CyMV among the sobemoviruses, are sensitive to detergent in their native states.

Properties of the Genome

Sobemovirus genomes are linear, single-stranded RNAs of positive polarities and range in mol. wt from *ca.* 1.3×10^6 to 1.5×10^6. The complete sequences of genomic RNAs of SBMV bean strain (4109 nucleotides (nt)), SBMV cowpea strain (4194 nt), RYMV (4450 nt), CfMV (4038 nt) and LTSV (4275 nt) have been determined. A covalently linked protein (VpG) is present at the 5′ terminus in all of these RNAs; VpG is necessary for the infectivity of SBMV, RYMV and LTSV RNAs. The 5′ end sequence motifs for SBMV and LTSV are ACAAA; for RYMV it is ACAA; whereas for CfMV it is AUAAU. Furthermore, SBMV, LTSV and RYMV genomes contain a polypurine sequence, AG(G)AAA, about 8–10 nt downstream from the ACAA(A) element; for CfMV, the comparable sequence is AGAAAGA. The 3′ ends of sobemoviral genomes lack poly(A) tails and, unlike many other plant viral genomes, are not configured into tRNA like structures.

Encapsidated Subgenomic and Satellite RNAs

Virions of SBMV, GCFV, LTSV, SNMV, SCMoV, TRoSV, VTMoV and CMMV encapsidate minor amounts of heterogeneous subgenomic (sg) or putative sgRNAs. VTMoV virions contain two discrete sgRNAs, RNA-1a (0.63×10^6 Da) and RNA-1b (0.25×10^6 Da), besides the genomic RNA (**Fig. 2**). CfMV virions encapsidate a discrete 0.5×10^6 Da RNA and several intermediate-sized putative sgRNAs. Included among the heterogeneous population of SBMV and TRoSV sgRNAs are the autonomized coat protein cistrons. The sgRNAs of SBMV, RYMV and LTSV possess VpG at their 5′ ends followed by the same sequence motifs as their respective genomic RNAs. LTSV, RYMV, SCMoV, SNMV and VTMoV virions encapsidate discrete, viroid-like satellite (sat) RNAs, in addition to the genomic and subgenomic RNAs. These satRNAs exist in linear and circular forms (**Fig. 2**). Complete sequences are known for satRNAs of LTSV (322 nt), RYMV (220 nt), SCMoV (322 nt and 380 nt), SNMV (377 nt) and VTMoV (366 nt). The satRNAs of SNMV and VTMoV exhibit a high degree of sequence homology and are different from those of SCMoV or LTSV. At 220 nt, RYMV satRNA represents the smallest known, naturally occurring virioid-like RNA. A region comprising 19% of the sequence of RYMV satRNA shows about 93% homology to the

satRNA of a Canadian LTSV isolate. The sobemoviral satRNAs contain a conserved hammerhead structure which is involved in self-cleavage (ribozyme).

Transmission

Sobemoviruses are transmitted readily with sap inoculation, a reflection of their high endogenous concentration and particle stability. Transmission via contact with leaf abrasion during strong wind is possible, but actual proof is lacking. RYMV exuded with guttation fluid may contaminate irrigation water, which then serves as the inoculum source. Some sobemoviruses, SBMV, SCMoV, SoMV and PMV, are transmitted through the seed.

Insects are the principal vectors of sobemoviruses. SBMV, CfMV, CYMV, PMV, RYMV and TRoSV are transmitted by chrysomelid beetles, whereas SNMV and VToMV are transmitted by coccinellid beetles; SBMV is transmitted also by a coccinellid beetle. The mirid bug, *Cyrtopeltis nicotianae,* is the vector of SNMV and VToMV. Aphids have been implicated in the transmission of BSSV, CMMV and CyMV. SoMV is transmitted by the leafminer fly, *Liriomyza langei;* it is carried mechanically on mouth parts and the ovipositor.

SBMV is acquired by the chrysomelid beetle, *Ceratoma trifurcata,* within a few minutes after feeding and transmitted without a latent period. Virions are present in fairly high concentration in the regurgitant fluid, intestines and hemolymph, but there is no evidence of SBMV multiplication in the vector. The virus persists in beetles for about 5–7 days. It is transmitted through contaminated mouth parts, during regurgitation and with reflexive bleeding. The coccinellid beetle, *Epilachna varivestis,* is an efficient SBMV vector, but the virus is not found in the hemocoel. Obviously, systemic transport within the beetle's body is not a prerequisite for SBMV transmission. CfMV is transmitted by a cereal leaf beetle, *Lema melanopa.* It is excreted in the fecal matter and can cause infection if deposited at freshly damaged feeding sites.

Experimental Host Range and Symptomatology

Most sobemoviruses have restricted host ranges and infect only a few species in one or two plant families. For example, RoYMV infects itchgrass (*Rottboellia cochinchinensis*) and corn (*Zea mays*) in the family Gramineae. The host ranges of SBMV, SCMoV and CYMV are restricted to a few species in the family Leguminosae; CfMV is restricted to the family Gramineae, whereas VToMV is confined to the family Solanaceae. SNMV, LTSV and TRoSV infect a few species in 3–4 different families. Additionally, most sobemoviruses have few hosts in common. For example, of the eight sobemoviruses that affect Gramineae, only PMV and RoYMV are transmitted to corn.

Symptoms induced by sobemoviruses are persistent mosaic, mottle or chlorosis, often accompanied by leaf deformities and stunted plant growth. CYMV produces a striking yellow variegation of leaves. BSSV causes shoestring symptoms in which the leaves are transformed into curled, strap-like structures; additionally, flowers show 'breaking', and immature berries exhibit reddish streaking or vein-banding patterns.

The Infection Process

Sobemoviruses enter through wounds caused by mechanical abrasion or insect feeding and, like other plant viruses, usually establish infection in the directly invaded cells. However, SBMV virions introduced by *E. varivestis* at the feeding site move out rapidly via

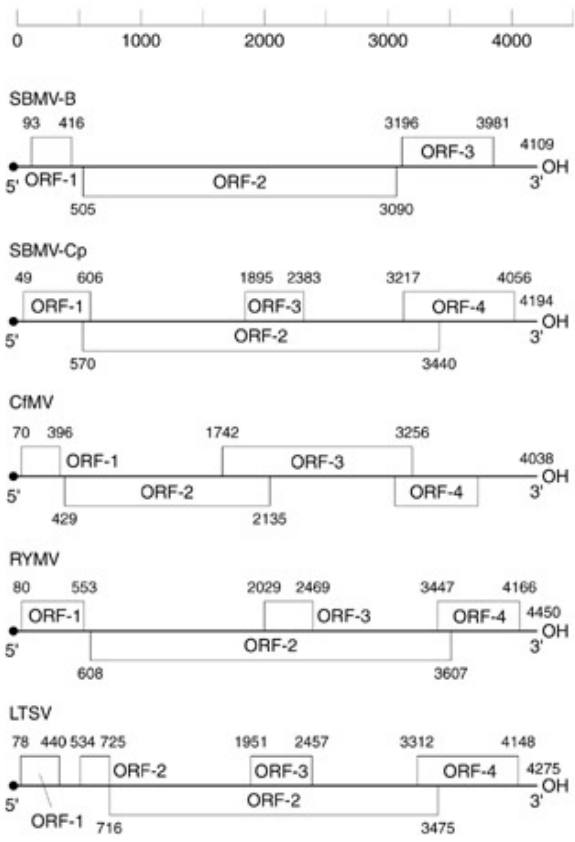

Figure 3 Organization of sobemovirus genomes. The viral RNA is represented by the thick line, and VpG is shown as the solid circle at the 5′ terminus. The open reading frames (ORFs) are shown as boxes.

leaf veins and cause infection in the unwounded cells. Apparently, SBMV virions can enter uninjured cells, although the precise mechanism is unknown. Upon entry into a cell, SBMV virions swell, extruding the 5′ terminus of RNA which is located near the capsid surface. A contact between the exposed RNA region and ribosomes leads to an early translational event, followed by complete capsid disassembly.

Isolated SBMV RNA must exist in a proper configuration to be infective. A marked structural stabilization of SBMV RNA *in situ* occurs when virions are heated, and this altered conformation is retained even when RNA is released from the capsid; this RNA is noninfectious. Upon structural destabilization, however, this RNA regains full infectivity. That SBMV RNA in a conformationally stabilized state is biologically inert, yet is rendered fully competent with denaturation, is a novel and unique phenomenon and underscores the importance of RNA secondary and tertiary structure in the infection process.

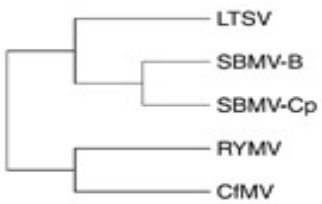

Figure 4 Relationship between coat proteins of sobemoviruses based on alignment by the clustal algorithm of their predicted amino acid sequences.

Replication and Expression of Virion RNAs

Although details are scanty, the replication mode of sobemoviral genomes appears to be typical of viruses that contain ssRNA of positive polarity, i.e. infection by plus strand RNA leads to the production of an intermediate double-stranded RNA complex from which progeny plus-strand RNAs are transcribed. The presence of genomic RNA replicating structures (approx. mol. wt 2.8×10^6) in SBMV and VTMoV infections have been detected in the cytoplasm where most of the virus-specific RNA polymerase activity is located.

Figure 3 is a schematic representation of the expression strategies of sobemoviral genomes. Each genome has three to four open reading frames (ORFs). The size of ORF 1 differs among these viruses and has a potential to encode a 12 kDa to 18 kDa protein; for LTSV ORF 1, two putative coding regions (ORF 1a and ORF 1b) have been identified. The nature or function of protein encoded by ORF 1 is not known, and little sequence similarity exists in this region among the sobemoviruses. ORF 2 encodes a polyprotein containing VpG, serine protease and polymerase domains. The CfMV polyprotein is encoded by two overlapping frames; ORF 2a codes for VpG and serine protease whereas ORF 2b codes for replicase which is expressed via a ribosomal frameshift event. The ORF 3 product has not been identified, and in SBMV-bean strain a comparable ORF is lacking. The viral coat proteins are encoded in ORF 3 of SBMV bean strain and ORF 4 of the other sobemoviruses; however, these coat proteins are expressed from sgRNAs. The transcription initiation sites for some of these sgRNAs have been tentatively identified and are: nt3241 for SBMV cowpea strain; nt3441 for RYMV and nt3285 for LTSV.

The relationship between sobemoviral coat proteins, based on alignment of their predicted amino acid sequences by clustal algorithm, is shown in **Fig. 4**. Among viruses infecting legumes, the SBMV bean and cowpea strains have coat proteins that are more

closely related to each other than to LTSV coat protein. Further, coat proteins of viruses affecting the Gramineae, RYMV and CfMV, appear more closely related between themselves than with the viruses that infect legumes. It will be of interest to ascertain if a similar relationship will hold true when sequence information for coat proteins of other sobemoviruses becomes available.

The replication of sobemoviral satRNAs, which proceeds via the rolling circle model proposed for viroids, is dependent on the presence of a suitable helper sobemovirus. The abilities of sobemoviruses to support satRNA replication, however, differs markedly. LTSV supports replication of satRNAs of SNMV and SCMoV, but SNMV does not support replication of VTMoV satRNA and vice versa. Also, LTSV satRNA replicates in the presence of an appropriate helper sobemovirus in divergent plant species. Thus, it replicates in *Brassica rapa, Raphanus raphanistrum* and *Sinapis arvense* (Brassicaceae) and *Chenopodium amaranticolor* (Chenopodiaceae) in the presence of TRoSV, and in *Triticum aestivum* (wheat) and *Dactylis glomerata* (Gramineae) in the presence of CfMV; all of these plants are nonhosts for LTSV. TRoSV fails to support LTSV satRNA replication in *Thlaspi arvense* or *Nicotiana bigelovii* although these plants are susceptible to TRoSV. Apparently, satRNA replication depends not only on the helper virus polymerase but also on some specific host factor(s).

(**B**) Virions, V, enclosed in a vesiculated structure, ve. (Reproduced with permission from Morales FJ (1995) A sobemovirus hindering utilization of *Calopogonium muconoides* as a forage legume in the lowland tropics. *Plant Dis.* 79: 1220.

Virion Assembly

The sequence of events leading to sobemoviral assembly *in vivo* is not understood. Under *in vitro* conditions, however, a few SBMV coat protein subunits (dimers?) bind with RNA, generating a complex which then serves to nucleate the capsid assembly. The coat protein amino-terminal arm appears to be the site with which RNA interacts first to generate this complex. Some evidence suggests that a stretch of 25 nucleotides (nt1410 to nt1436 in ORF 2) on the genomic RNA of SBMV cowpea strain is the coat protein recognition site; this region is highly conserved among sobemoviruses and configures into a stable hairpin structure. Since several subgenomic and satRNAs are encapsidated with great efficiency, these also must possess putative coat protein recognition site(s).

In Vivo Distribution and Cytopathology

Sobemoviruses are present in most plant parts including epidermis, mesophyll, meristem, xylem and phloem. Virions occur in cytoplasm and vacuoles, and except for BSSV, RYMV and CyMV infections, also in the nuclei. They are not found, however, in the mitochondria and chloroplasts. The cytoplasm of infected cells may contain fibrillar material resembling double-stranded replicative form of RNA, which is either enclosed in discrete membranous vesicles or distributed in diffused patches. Sometimes, virions are enclosed in discrete vesiculated structures (**Fig. 5**). In other cases they are arranged in a crystalline array in cytoplasm and vacuole. Bundles of microtubules are seen in cells infected with BSSV, RYMV and SNMV, but their nature is not known.

Serology

Sobemoviruses are strongly immunogenic. In general, they are neither serologically crossreactive nor are they related to viruses belonging to other groups.

However, SNMV and VTMoV are serologically related and so are SBMV, SsbMBV and CYMV; SCMoV and LTSV are distantly related.

SBMV bean and cowpea strains are serologically similar but not identical. Likewise, RYMV isolates from Kenya and the Ivory Coast are dissimilar. Isolates of CfMV and CyMV from New Zealand, but not those from Europe, are serologically related. No serological variations have been observed among the naturally occurring isolates of TRoSV, GCFV, SoMV or LTSV.

Epidemiology and Control

SBMV and RYMV often reach epiphytotic proportions under field conditions. For SBMV, seed-borne inocula and weeds serve as the primary sources of infection. RYMV incidence is considerably higher in areas of continuous rice cultivation than those with interrupted plantings. This suggests that locally present RYMV inocula contribute largely to disease initiation. The beetle vectors move rapidly from plant to plant spreading RYMV. During the off-season, RYMV survives in volunteer and wild rice (*Oryza longistaminata*) plants, regrowths of harvested crops and in ratoons. Some sources of germplasm for resistance towards SBMV and RYMV are available. In view of the worldwide importance of rice and bean/cowpeas in the human diet, the applicability of gene engineering techniques for developing virus-resistant cultivars needs to be exploited.

Conclusions

The sobemoviruses constitute a homogeneous group based on their physicochemical parameters, including stability characteristics, and genomic expression strategies. These viruses possess relatively simple organizations, and their genomes are the smallest among the plant viruses. Furthermore, sobemoviruses represent a class of genetically stable viruses because few naturally occurring variants or strains have been identified. Also, the markedly divergent and non-overlapping host ranges underscore a high level of biological specificity and host plant adaptability of sobemoviruses.

Though the primary structures of the coat proteins of SBMV and tobacco necrosis virus are largely similar, there is only a limited resemblance in their polymerase sequences around the GDD motif. However, considerable similarities exist in the amino acid sequence motifs of the putative polymerase and nucleic acid helicase proteins between sobemoviruses and members of luteovirus subgroup II. Moreover, presence of the ACAAAA element at the 5′ end of genomic and sgRNAs is a property which sobemoviruses share with members of the dianthovirus group and luteovirus subgroup II. LTSV, RYMV, SCMoV, SNMV and VTMoV can be distinguished from other sobemoviruses because they encapsidate satRNAs. That different sobemoviruses can support replication of a given satRNA is a reflection of the nonspecific nature of such an association. In this regard, LTSV satRNA seems most versatile because it interacts with a suitable helper virus in divergent dicotyledonous and monocotyledonous species. Likewise, LTSV, more than any other sobemovirus, is effective in supporting replication and encapsidation of sobemoviral satRNAs. It is rather interesting that satRNA of RYMV, a virus with host range restricted to the monocotyledons, exhibits structural homology with satRNA of LTSV which affects dicotyledonous species. Finally, RYMV satRNA, the smallest viroid-like RNA associated with a plant virus, possesses retroviroid and viroid-like structures making it a probable candidate as an evolutionary bridge between these classes of subviral plant pathogens. Thus, sobemoviral satRNAs offer attractive possibilities for indepth study of molecular interactions between two distinctive biological entities and on the nature and mode of origin of satRNAs associated with plant viruses.

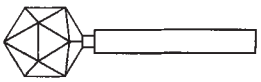
SPO1 PHAGE (*MYOVIRIDAE*)



Charles R Stewart, Department of Biochemistry & Cell Biology, Rice University, Houston, Texas, USA

History

SPO1 is a large virulent phage of the Gram-positive bacterium *Bacillus subtilis* and is in the genus 'SPO1-like viruses' of the *Myoviridae* family. Shunzo Okubo isolated it from soil in Osaka, Japan, during the early 1960s, and brought it with him to Chicago, where he collaborated with Bernard Strauss and Marvin Stodolsky on the first published studies of SPO1. Peter Geiduschek, Stodolsky's mentor, saw in SPO1 the opportunity to test the generality of the lessons then being learned about sequential gene action in the *Escherichia coli* phage T4, and began a series of experiments which illuminated the regulation of SPO1 gene action and stimulated the interest of many others.

Taxonomy and Evolution

SPO1 is a member of a family of *B. subtilis* phages, whose distinguishing feature is the presence of the unusual base, hydroxymethyluracil, instead of thymine in the DNA. All members of the family, which also includes SP82, Φe, 2C, SP8, H1 and SP5c, appear to be descended from a common ancestor, since they show many striking similarities in structure, restriction maps, genetic maps, gene products and gene regulation. However, they also show many differences in detail, and thus have had the opportunity for significant divergence. Perhaps the most striking similarity is the presence, in SPO1, SP82, 2C, and Φe, of a group I self-splicing intron, discovered by David Shub and his colleagues by testing RNAs from phage-infected cells for their capacity to incorporate labeled GTP. Each of these introns includes an open reading frame that specifies an endonuclease that catalyzes the substitution of its intron for the homologous intron in a related phage genome. The greater efficiency of the SP82 endonuclease, when acting on the SPO1 genome, permits SP82 DNA to exclude closely linked SPO1 alleles from the progeny of a mixed infection. These are among the very few introns known in procaryotes. The presence of introns both here and in T4 has been cited as an argument for the existence of introns in ancient evolutionary times, before the divergence of Gram-positive from Gram-negative bacteria. SPO1 is similar to T4 in many other ways as well, including size, structure, overall organization of the life cycle, and the presence of an unusual pyrimidine.

Virion Structure and Proteins

An SPO1 particle includes a single linear double-stranded DNA molecule and at least 53 different polypeptides, organized into an icosahedral head about 87 nm in diameter, a short neck, and a contractile tail of 19 × 140 nm, ending in a complex base plate 60 nm in diameter.

Genome Structure and Gene Function

The single DNA molecule is 145 kb long, with a 12.4 kb terminal redundancy, and with hydroxymethyluracil (hmUra) completely replacing thymine as the base-pairing partner for adenine. The presence of hmUra gives the DNA a CsCl buoyant density substantially higher than that of other DNAs of similar GC content, which has been useful in making experimental distinctions between phage and host DNAs. The two strands of the phage DNA are physically separable on CsCl, a characteristic that has been used extensively to identify the template strand for specific transcripts. Marmur and Greenspan used that property of SP8 to demonstrate for the first time that specific RNAs are complementary to one strand of the DNA from which they were transcribed.

Figure 1 shows a map of the SPO1 genome. Sixty-three genes have been identified by conditional lethal mutations and/or DNA sequencing, and have been mapped into a single linkage group that spans the entire genome. Conditional lethal mutations have permitted analysis of the functions of 40 of the known genes, showing that genes involved in the same function, such as DNA replication, tail formation, head formation, or virion assembly, tend to be clustered together on the map. The 35 genes that have been sequenced, 24 of which, being in the terminal redundancy, are present in two copies, occupy about 31 kb. The genes specifying the 53 known structural proteins are expected to occupy another 61 kb, on the basis of the molecular weight of the proteins, as estimated by gel electrophoresis. The remaining 53 kb may be estimated to include about 56 genes, assuming similar average size and density, for a total of about 144 genes.

Growth Cycle

Under optimal conditions, SPO1 has an eclipse period of 25–30 min, a latent period of 33–40 min, and a

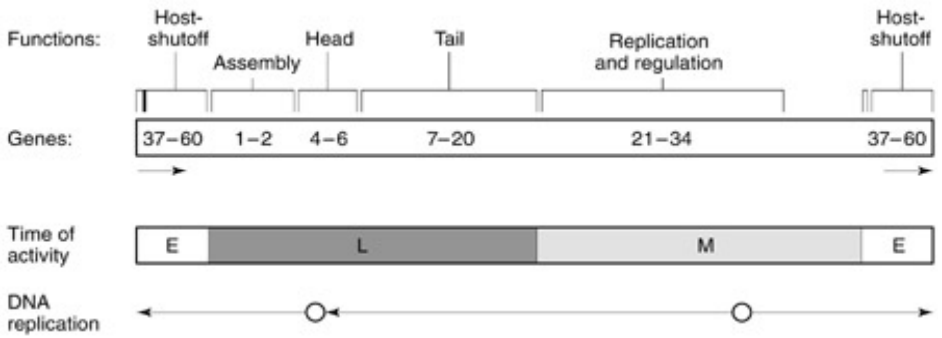


Figure 1 Maps of the SPO1 genome. The 'Genes' box shows the approximate map location of most of the known genes. The position of the terminal redundancy is shown by the arrows under the ends of that box. Genes *37–60*, being located in the terminal redundancy, are indicated twice. Genes *35* and *36*, located in the small portion of the terminal redundancy to the left of gene *37*, are not shown. The clustering of genes according to function is indicated above the 'Genes' box. Most or all of the known genes in each region are believed to specify products involved in the function indicated. Genes for replication and regulation are interspersed among each other, and certain genes are required for both processes. Two genes required for assembly are located in different regions, gene *3* in the head region and gene *35* in the small box to the left of the host-shutoff region. As discussed in the text, the host-shutoff function of genes *37–60* has not been definitively established. Since most of the terminal redundancy has been sequenced, genes *37–60* make up a continuous cluster of known genes. In the rest of the genome, the known genes are interspersed among regions of unknown function, and no genes have been identified between gene *34* and the terminal redundancy. The 'Time of activity' box shows regions predominantly transcribed during early (E), middle (M) or late (L) times, as indicated by the unshaded, lightly shaded and heavily shaded areas, respectively. A minority of each type of transcript is also scattered among the other areas of the genome; for instance, gene *28* is transcribed at early times. The 'DNA replication' line shows the simplest pattern of replication consistent with the data. The two Os represent origins of replication, and the arrows show the directions of replication proceeding from each origin.

burst size of 100–300 phage. Into this brief period is packed a remarkably complex sequence of events. Immediately after infection, some of the SPO1 early genes are turned on, with the others following during the next few minutes. Shortly thereafter occurs the shutoff of host DNA replication and gene expression. By 5 or 6 min after infection, SPO1 middle genes begin turning on and some of the early genes are turned off. The middle genes specify most of the enzymes necessary for SPO1 DNA synthesis, which begins about 10 min after infection. Shortly thereafter, SPO1 late genes begin to function, directing the synthesis of structural proteins, and some of the early and middle genes are turned off. By 25 min after infection, the first infectious phage particles have formed, and lysis begins as early as 33 min, resulting in the destruction of the infected cells. The following sections describe each of these processes in detail.

Regulation of Gene Action

The transitions from early to middle to late gene activity are caused by a cascade of sigma factors. The major host RNA polymerase, with sigma factor A, transcribes from promoters whose −35 and −10 sequences approximate the consensus sequences TTGACA ... TATAAT. The promoters for the SPO1 early genes fit that consensus and thus are transcribed by the host polymerase. One of the early genes, gene *28*, specifies another sigma factor, which substitutes for sigma A on the RNA polymerase, changing the specificity of the polymerase so it then recognizes the promoters of the middle genes, whose consensus sequence is AGGAGA ... TTTNTTT. Two of the middle genes, *33* and *34*, specify proteins which cause the RNA polymerase to recognize the late gene promoters, with consensus sequence CGTTAGA ... GATATT. The sigma factor specified by gene *34* is essential for all late transcription, whereas the accessory protein specified by gene *33* is required for some, but not all, late transcription.

This sequence of events was put together primarily from a series of elegant experiments done by Jan Pero, Peter Geiduschek and their colleagues. RNA pulse-labeled at early, middle or late times showed completely different patterns of hybridization competition and of hybridization to Southern blots of restriction digests of SPO1 DNA. Mutations in gene *28* prevented the transition from the early to the middle patterns, whereas mutations in genes *33* or *34* prevented the middle to late transition. Three different RNA polymerases, A, B and C, were extracted from SPO1-infected cells and used to transcribe SPO1 DNA *in vitro*, producing RNAs which showed the same hybridization patterns as the pulse-labeled early, middle and late RNAs, respectively. Analysis of the polypeptides associated with the three polymerases showed that A contained sigma

A, B contained (instead) the gene *28* product, and C contained (instead) both the gene *33* and gene *34* products.

Thus, the sequential onset of early, middle and late transcription is explained by the sigma cascade. The mechanisms responsible for other regulatory events in the SPO1 life cycle are not yet understood, although, in some cases, gene products that play essential roles have been identified. One of the most interesting is TF1, a type II DNA-binding protein that is synthesized in large quantities during SPO1 infection, and that binds preferentially to specific sites on DNA containing hmUra, causing bending of the DNA. SPO1 mutants deficient in TF1 fail to shut off transcription of certain middle genes and fail to turn on transcription of certain late genes. The bending caused by TF1 may be, in itself, a cause of these regulatory changes, or may make those genes accessible to other regulatory factors.

Certain mutations in two other genes, *22* and *27*, also prevent activity of certain late genes. The effect of the gene *22* mutation may be an indirect result of its prevention of phage DNA synthesis, suggesting that some change in structure, associated with replication, may be necessary for the activation of certain late promoters. The effect of the gene *27* mutation, however, seems to be independent of its effect on replication.

Other regulatory events whose mechanisms are not yet understood include: the delay in the onset of transcription of some early genes relative to others; the turn-on of translation of certain early mRNAs, requiring the activity of one or more SPO1 gene products; the shutoff of two different groups of early genes at two different times; the shutoff of those middle genes for which TF1 is not required; and probably others that are not yet so well defined.

By hybridization of pulse-labeled RNAs to Southern blots of restriction digests of the SPO1 genome, transcription maps have been prepared showing which regions of the genome are transcribed at which times. A summary of the overall trends revealed by such mapping is included in **Fig. 1.** Detailed analysis of individual transcription units, within certain regions of the genome, has been performed by S1 mapping and by *in vitro* transcription, and the results are summarized in the following paragraphs.

Most early transcription takes place in the terminal redundancy, each copy of which contains at least 13 promoters, most of which are very active and some of which are among the strongest promoters known. This high density of active promoters in a duplicated region may be for the purpose of competing effectively with host promoters for RNA polymerase. All 13 promoters direct transcription toward the middle of the redundant region, where two efficient transcription terminators halt transcription from the left and right sides, respectively. Many of the early transcripts of both SPO1 and SP82 undergo processing, by cleavage with RNase III, and six putative sites for RNase III cleavage have been identified within this region of SPO1. This entire region of early transcription has been sequenced, and the roles of its gene products are discussed below.

Most middle transcription occurs in a 60 kb region that occupies most of the right half of the genome. A 28 kb subset of this region includes all five of the regulatory genes mentioned earlier, as well as all the genes known to be required for SPO1 DNA replication. A total of 13 active middle promoters and three relatively weak early promoters have been identified in this region. Each of the early promoters is in a tandem arrangement with a middle promoter, permitting some sequences to be transcribed by both the early-specific and middle-specific polymerases. Eleven of the genes, including all the regulatory genes, have been sequenced.

Most late transcription occurs in the left half of the unique region of the genome. This region includes nearly all the genes known to be directly involved in head or tail morphogenesis, and it is assumed that most late genes specify structural proteins.

DNA Replication

Conditional lethal mutations have identified 10 SPO1 genes as essential for SPO1 DNA replication. Except for gene *28*, most or all of these are middle genes, whose products begin to appear about 7 min after infection. Thus, the time at which replication is initiated, about 10 min after infection, may be determined simply by the time at which all necessary proteins and precursors have accumulated to a sufficient concentration. Genes *23* and *29* are required for the synthesis of hmUra, *32* and *21a* or *b* for initiation of replication, and *22*, *30* and *31* for elongation. Gene *31* specifies the DNA polymerase and is the site of the intron discussed above. Other SPO1 gene products that play a role in replication, but whose genes have not been identified, include DNA gyrase, dCMP deaminase, dTTPase, dTMPase and an inhibitor of thymidylate synthetase.

There are at least two origins of replication, near the opposite ends of the unique region of the SPO1 genome. One growing point proceeds leftward from the right-hand origin, replicating most of the unique region. Another proceeds leftward from the left-hand origin, replicating from there to the end. There must be at least a third growing point to replicate the right end of the genome, but it is not clear whether that

starts above the right-hand origin and replicates rightward or whether there is a third origin, farther to the right, from which replication proceeds bidirectionally. **Figure 1** includes a representation of the simplest interpretation of the data on directions of replication.

As the SPO1 DNA replicates, it forms concatemers of as many as 20 genomes, joined end to end by overlapping terminal redundancies. It has been proposed that concatemer formation is one solution to the inability of DNA polymerase to synthesize the 5′ end of a linear DNA molecule. The two daughters of the replication of a linear molecule would each have protruding 3′ ends which would be complementary to the opposite terminal redundancy. This complementarity would nucleate annealing of the entire terminal redundancies, to form an end-to-end dimer, a process which would be repeated again and again. When the concatemer was broken back down to unit genomes, cleavage would be staggered so as to produce protruding 5′ ends, whose complements could then be synthesized by DNA polymerase. This hypothesis predicts that, after formation of the first dimer, and before the second round of replication has begun, genetic markers in the terminal redundancy should have been replicated only to half the extent of markers in the rest of the genome, a prediction that has been dramatically confirmed, for SPO1, by temperature-shift experiments with temperature-sensitive mutants affected in gene *32*.

Morphogenesis

Little is known about SPO1 morphogenesis. Although many of the known genes are required for head or tail formation or for virus assembly, and 53 proteins have been identified as part of the virus particle, only one gene has been identified with a specific viral protein (gene *6* specifies a particular head protein), and only one morphogenetic process has been studied. The proteolytic processing of a precursor polypeptide to produce the mature form of the major head protein requires the activity of both the gene *5* product and TF1. Nothing is known of the biochemical activity of the gene *5* product, and TF1 may have any of several possible roles. Other type II DNA-binding proteins participate in the wrapping of DNA molecules into chromatin-like structures, suggesting that TF1 might play a similar role in folding SPO1 DNA for packaging into the head, and that processing of the head protein might be an integral part of the packaging process. Alternatively, TF1 might be necessary for expression of gene *5*, or for some other necessary gene.

Effect on the Host Cell

It is to the selective advantage of a virus to shut off the macromolecular syntheses of the host cells, so they will not compete with the comparable viral syntheses for energy, materials and access to biosynthetic machinery. Most synthesis of host DNA, RNA and proteins is shut off within a few minutes after SPO1 infection. The shutoff mechanisms are highly selective, since not only do they have no effect on the synthesis of the comparable phage macromolecules, they also spare certain host syntheses. Host ribosomal RNA continues to be synthesized at nearly normal rates, which seems sensible since the phage has a use for the host ribosomes. The mechanism by which SPO1 distinguishes between host and phage DNAs is not clear. It must be more subtle than the presence or absence of hmUra, since some host genes are unaffected. Unlike T4, which causes the complete degradation of DNA without hydroxymethylcytosine, SPO1 causes no detectable degradation of *B. subtilis* DNA.

Most or all of the 24 early genes in the terminal redundancy are believed to specify components of the host-shutoff machinery, although this belief still awaits definitive confirmation. About one-third of the 24 genes have been tested individually, by expression in uninfected cells, and nearly all are inhibitory to the bacteria, four or five of them to the point of lethality. They affect different host functions, with the two best-characterized acting specifically on RNA polymerase and cell division, respectively. The nucleotide sequence of this 24 gene cluster shows promoters and ribosome-binding sites that are designed for highly efficient expression, and such efficiency has been shown both *in vivo* and *in vitro*. This duplicated cluster of highly expressed genes seems appropriate for specification of the host-shutoff machinery, which must, within a few minutes, cause the cessation of biosyntheses that are occurring at thousands of sites in each infected cell.

Recombination and Mutagenesis

SPO1 has a very active recombination system, producing frequencies of recombination between nearby genetic markers of about 0.001% per base pair. Nothing is known about the mechanisms of recombination or the gene products involved, but the high frequency facilitates several types of experimentation. Cloned SPO1 restriction fragments, as small as 200 bp, undergo significant recombination with the homologous region of the SPO1 genome, resulting in marker rescue of markers as little as 12 bp from the end of the fragment, permitting efficient fine-structure

mapping. Also, new mutations can be constructed *in vitro* and inserted into the SPO1 genome by marker rescue recombination. Mutations of the genes specifying either protein TF1 or E3 were introduced into *B. subtilis* on cloned fragments less than a kilobase in length, and were allowed to recombine with superinfecting wild-type SPO1. By the criterion of plaque-lift hybridization, the frequencies with which the mutations replaced the wild-type alleles ranged from 5×10^{-4} to 4×10^{-3}.

Recombination is also an integral part of the process of transfection by SPO1 DNA (most studies of the phenomenon have been done with the close relative SP82). When a cell is infected with purified DNA, the DNA is damaged by nuclease activity of the host cell. (This activity is inhibited, and therefore causes no problem, during normal infection.) Production of a single intact genome requires recombination between several of the damaged genomes.

Cloning Vehicle

SPO1 can also serve as a cloning vehicle. Entire plasmids, carrying a short region of homology to the SPO1 genome, can be inserted into the SPO1 genome by Campbell-mode integration. At least 5.6 kb of exogenous DNA can be added to the SPO1 genome in this way without apparent effect on the viability of the phage. Although too cumbersome to be used for routine cloning, this procedure offers a way to test the effect on SPO1 infection of adding specific genes to the genome, and to test the effect of the incorporation of hmUra on the functioning of any DNA of interest.

History

Foamy viruses were first recognized in the 1950s as contaminating viral agents which caused cytopathic effects in cultures of rhesus monkey kidney cells. On the basis of morphological, biochemical and genetic properties, foamy viruses are retroviruses; however, recent studies have demonstrated major differences in the replication strategy employed by these viruses and that of conventional retroviruses. Certain aspects of foamy virus replication are similar to hepadnaviruses. Cytopathology in foamy virus-infected monolayer cell cultures is characterized by extensive formation of intracellular vacuoles in multinucleated syncytial cells. By light microscopy, infected cell cultures have a foamy appearance, and hence the Latin term *spuma* for foamy was coined for this group of retroviruses (i.e. spumaviruses). These viruses, also designated syncytium-forming viruses, have been recovered from various mammals, including cats, cows, hamsters, sea

lions, and from various Asian, African and New World primate species (**Table 1**). In some instances, distinct spumavirus serotypes have been obtained from members of a single species (**Table 1**). In 1971, a spumavirus was isolated from a patient with nasopharyngeal carcinoma, and this virus has been designated human foamy virus (HFV), human spumaretrovirus (HSRV) or human spumavirus (HSpV) (**Fig. 1**).

Taxonomy and Classification

Foamy viruses are classified into the genus *Spumavirus* of the *Retroviridae* family. Foamy virus particles are spherical (100–140 nm diameter) and consist of a ring-shaped nucleoprotein core surrounded by a bilayer membrane envelope. The viral genome is dimeric single-stranded RNA that has positive polarity and encodes three genes for virion polyproteins (i.e. *gag*, *pol* and *env*) and additional open reading frames (ORFs). Extra ORFs, or accessory genes, are also a feature of complex retroviruses such as human immunodeficiency virus (HIV) and human T-lymphotropic virus (HTLV). Foamy viruses replicate via reverse transcription and integrate into host cell DNA; long terminal repeats (LTRs) are located at each end of proviral DNA. Viral-coded reverse transcriptase and integrase are packaged into virions. Reverse transcription is largely completed in the virion prior to entry. Although many features are shared with other retroviruses, comparisons of nucleotide sequences and replication strategy indicate that foamy viruses are a unique and distinct group of retroviruses.

Properties of the Virion

Foamy viruses share several morphological features with retroviruses. Extracellular HFV particles are polymorphic. In addition to naked extracellular preassembled cores, two morphologically different types of enveloped particles are observed. The majority of particles are spherical, with a diameter of 100–120 nm, and contain a 40–55 nm pentagon-shaped electron-lucent nucleoprotein core (i.e. nucleoid) with surface spikes, 10–13 nm in length, on the envelope. A second minor population of particles is larger (120–150 nm diameter), with condensed, amorphic cores. It has been suggested that the former type of particle is an immature form, while the second type represents mature virions. While immature in morphology, these particles are highly infectious. Mature virus particles have a bouyant density of 1.16 gm ml^{-1} in sucrose gradients. Immature viral particles in the cell cytoplasm are ring-shaped, measuring 35–45 nm, and consist of an electron-opaque shell and an inner, less dense center. Prominent envelope glycoprotein spikes up to 15 nm long

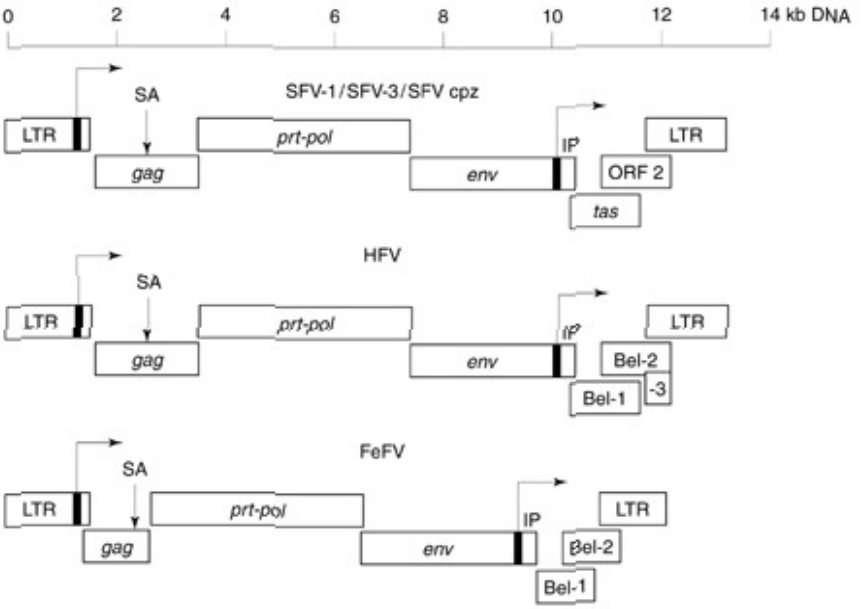

Figure 1 Genetic organization of SFVs, HFV and FeFV. Open reading frames (ORFs) and the long terminal repeats (LTRs) are shown for SFV-1 (rhesus macaque isolate), SFV-3 (African green monkey isolate), SFVcpz (chimpanzee isolate), HFV and FeFV (feline isolate). *tas* and bel-1 are transcriptional transactivators for the respective virus. The genetic organization of SFV-3 and SFVcpz is the same as SFV-1. The horizontal arrows designate viral transcripts that initiate in the 5′ LTR and internal promoter (IP). SA indicates the *prt-pol* splice acceptor.

project out from the virus membrane; the *env* gene encodes the glycoprotein, which has a transmembrane anchor (TM) domain and a surface (SU) domain. The virion core contains two identical copies of single-stranded viral RNA complexed with core proteins derived from the polyprotein precursor encoded by the *gag* gene. Purified extracellular particles contain predominantly unprocessed Gag and Prt-Pol precursor proteins.

Properties of the Genome

Foamy viruses package single-stranded RNA genome in virions. Each virus particle contains two identical copies of genomic RNA; thus, foamy viruses are diploid, as are other retroviruses. Reverse transcription is largely completed in the virion. The retrovirus RNA genome has positive polarity, and the 5′ end contains a cap structure (7-methylguanosine in a 5′–5′ linkage via a triphosphate to a second 2′-*O*-methylated nucleotide). In addition, a poly(A) tail, from about 100 to 200 nucleotides in length, is found at the 3′ end of retroviral RNA genomes. The 5′ cap structure and the 3′ poly(A) tail are features of virion RNA, subgenomic viral transcripts in infected cells, as well as normal cellular mRNA. Virions also contain small RNA molecules derived from the host cell; a cellular transfer RNA species that charges with lysine is bound to a site near the 5′ end of the viral RNA genome and serves as primer for initiating synthesis of plus-strand viral DNA during reverse transcription. In infected cells, the viral genome consists of both unintegrated linear DNA (double-stranded), covalently closed supercoils, and provirus integrated into the host cell genome. LTRs are located at the ends of linear viral DNA molecules; thus, viral genes lie between the LTRs.

Complete nucleotide sequences have been elucidated for SFV-1, SFV-3, SFVcpz, HFV and FeFV; accordingly, the genetic organizations of these foamy viruses are known (**Fig. 1** and **Table 2**). The proviral lengths in base pairs (bp) of SFV-1 (12 952 bp), SFV-3 (13 111 bp), HFV (12 142 bp), SFVcpz (13 246 bp), and FeFV (11 656 bp) are the largest among retroviruses. Sizes for domains in the LTR (i.e. U3, R and U5) and lengths of ORFs are given in **Table 2**. Foamy viruses encode *gag, pol* and *env* genes, each of which specifies a polyprotein precursor for virion proteins. In addition, foamy viruses encode three (SFV-1, SFV-3, FeFV) or two (SFVcpz and HFV) ORFs that extend from the end of the *env* gene into the 3′ LTR (**Fig. 1**). Genomic organizations of SFV-1 and SFV-3 are the same; however, HFV and SFVcpz show an extra ORF (i.e. bel-3; truncated in SFVcpz) (**Fig. 1**). A +1 ribosomal frameshift was presumed to be required for translation through the overlap of the foamy virus *gag* and *prt-pol*

Table 2 Relationships of SFV-1, SFV-3 and HFV[a]

translation frames. Translational frameshifting to produce *gag-prt-pol* polyproteins in other retroviruses is by a −1 ribosomal frameshift event. However, recent studies have demonstrated that foamy virus *prt-pol* expression is independent of *gag* synthesis and requires a spliced mRNA which initiates in the 5′ LTR and is subsequently spliced utilizing a splice acceptor in the *gag* gene; *gag* determinants are removed from this *prt-pol* messenger RNA. Predicted protein-coding regions of SFV-1 and SFV-3 show 54–85% homology (**Table 2**). Similar pairwise comparisons of SFV-1 with HFV reveal 38–76% homology, and alignment of SFV-3 and HFV demonstrates 34–78% homology (**Table 2**). In summary, foamy viruses have complex genomes, encoding genes for virion proteins and accessory genes, as do several other retroviruses such as HIV and HTLV. Also, foamy virus *prt-pol* expression is fundamentally different from that of other retroviruses.

Properties of Viral Proteins

Knowledge of foamy virus proteins is based on direct analysis of virions and infected cells and also on comparisons of predicted protein sequences from other retroviruses. Analysis of HFV cores revealed Gag polypeptides with apparent molecular weight of 78 and 74 kDa and a Prt-Pol precursor protein of 135 kDa. Proteolytic processing of foamy virus Gag precursor proteins is inefficient; only a cleavage event near the C-terminus of Gag, which generates p74 from p78, is observed in infected and in purified virions. Prt-Pol cleavage appears to proceed to a greater extent than Gag processing in infected cells with p80 Pol (reverse transcriptase), p40 (integrase) and p15 (nucleocapsid protein) generated from the p135 Prt-Pol precursor. Domains within the *pol* gene for reverse transcriptase, RNAse-H, and integrase are identified by alignment with other retroviruses. The matrix (MA) protein derived from the N-terminus of the *gag* polyprotein precursor has not been identified for foamy viruses. For all other retroviruses, the C-terminus of the *gag* gene specifies a nucleocapsid (NC) protein which has a conserved motif of several cysteine residues; this motif is a metal-binding finger that mediates the interaction of NC protein to the viral RNA genome. Inspection of the predicted sequences of the foamy virus *gag* gene does not reveal a domain with a cysteine motif; instead, sequences near the C-terminus of the *gag* gene encode an NC protein with a high content of glycine and arginine residues (GR boxes). GR boxes are involved in nucleic acid binding and in a transient translocation of the HFV Gag precursor protein to the nucleus of infected

cells. This motif is not conserved in FeFV, although there is some conservation of positively charged residues. FeFV Gag protein is considerably smaller than SFV and HFV Gag.

The SFV-1 *env* glycoprotein is a heterodimer composed of a 70 kDa SU domain and a 30 kDa TM domain. In cells infected with HFV, three viral glycoproteins with molecular weights 170 kDa, 130 kDa and 47 kDa have been identified; respectively, these may represent the *env* precursor, SU and TM domains. Comparison of the predicted amino acid sequences of the *env* genes of SFV-1 and HFV reveals that the *env* proteins are very similar in size as well as in structure; all cysteine residues and the majority of potential glycosylation sites are conserved. The external portion of the TM domain of SFV-1 and HFV is almost twice as large as those in other retrovirus subfamilies. Thus, the TM domain of foamy viruses may be folded into a structure which is fundamentally different from the other retroviruses. An endoplasmic reticulum retrieval signal has been identified in the foamy virus envelope and is conserved among all sequenced foamy viruses; however, its significance remains to be determined.

Physical Properties

Spumaviruses possess lipid bilayer membranes; therefore, stability is similar to that of other viruses with membrane envelopes. Heat and extremes of pH inactivate infectivity, and detergents and organic solvents disrupt virion structure. Ionizing radiation and x-rays inactivate the spumavirus RNA genome. Infectivity is lost after repeated cycles of freezing and thawing and after prolonged storage at 4°C, although virus is relatively stable in the frozen state.

In Vitro Cell Cultures

Single cycle growth studies of foamy viruses in cell culture reveal an eclipse period of 24 h and a maximum yield of virus attained by 72 h postinfection. Approximately 10% of the HFV yield in human diploid cells is released into the medium; the remainder is cell associated. The rate of adsorption of HFV to human embryonic fibroblasts (HEFs) at 37°C is maximal at 3 h postinfection. Nothing is known about cellular receptors in this early stage of infection. After attachment, the viral particle enters into the cell by either viropexis or direct entry. Whether a fusion factor is involved in the penetration process, as seen in other enveloped virus families, remains to be determined.

As with other retroviruses, foamy virus replication is related to host cell division. Similar to oncoviruses, such as murine leukemia virus (MLV), but unlike the lentivirus HIV-1, foamy viruses require host cell proliferation for productive infection. Productive infection is observed only if the target cells pass through mitosis. The semipermissiveness of heteroploid epithelial cell lines to infection with HFV or SFV-3 was determined to be the result of the methylated state of viral DNA. Treatment of such cell lines with the inhibitor of DNA methylation, 5-azacytidine, enhances viral production.

Strategy of Replication of Nucleic Acid

The pattern of foamy virus replication in tissue culture generally conforms to that of other retroviruses; however, differences are noted with respect to viral DNA synthesis. In contrast to conventional retroviruses, a high proportion of infectious HFV particles contain double-stranded DNA similar in size to full-length provirus, suggesting that reverse transcription takes place in the virion, before new rounds of infection. Most retroviruses initiate plus-strand DNA at one site, the 5′ boundary of the 3′ LTR. Foamy viruses utilize this site and may potentially also initiate at an internal site in the *pol* gene; a gap is located in *pol* in the linear duplex viral DNA intermediate. In acutely infected monolayer cells, very large quantities of linear viral DNA molecules are synthesized. These accumulations of viral DNA are presumed to be a consequence of reinfection; permissive cells are presumed to contain numerous cell receptors, and, thus, endogenously synthesized viral *env* glycoprotein may not be present in sufficient amounts to bind to all cell receptors and block superinfection. Several other retroviruses which induce cytopathology in cell culture systems also show large amounts of unintegrated linear viral DNA. Integrated (i.e. proviral) forms of foamy virus DNA have not yet been rigorously identified; however, the fact that these viruses encode an integrase domain in the *pol* gene supports the notion that integration is a critical step in the foamy virus life cycle.

Transcription

The U3 domains of the LTRs of foamy viruses contain *cis*-acting promoter elements (including the TATA box) which are recognized by cellular transcription factors. In addition, a second viral promoter (the internal promoter; IP) is located near the 3′ end of the *env* gene (**Fig. 1**). Both promoters are dependent on the viral transactivator for full activity. Simian foamy viruses have U3 domains that are longer than those of all other retroviruses; thus, the potential is high for many *cis*-acting regulatory

motifs. In the nuclei of infected cells, viral transcription initiates in the 5′ LTR and in the IP, possibly in a temporally regulated manner. The IP appears to be a stronger promoter in infected cells (basal and transactivated levels). Transcripts with the potential to code for the ORF region gene products originate predominantly from the IP. Subgenomic transcripts derived from either the 5′ LTR or the IP are subject to complex splicing. All subgenomic viral transcripts which initiate in the 5′ LTR have a short 5′ leader (51 nucleotides) specified by the R region in the LTR. Both foamy virus promoters demonstrate very low basal levels of activity in transient expression assays, involving transfection of plasmids containing either the LTR or IP, into mammalian tissue culture cells. ORF 1 of SFV-1, SFV-3, SFVcpz and FeFV and bel-1 of HFV are transcriptional transactivator (*tas*) genes that act through *cis*-acting targets in the U3 domain of the respective LTR, or through sequences immediately 5′ to the IP TATA box, to augment levels of viral transcripts. Mutational analysis of cloned viral genomes has demonstrated that the *tas* gene is required for viral replication. The target sequences for *tas* for each virus are upstream from the TATA box. SFV-1 Tas and HFV Bel-1 proteins interact directly with DNA target elements in each promoter. Foamy virus LTRs lack any significant homology with the LTRs of lentiviruses and other retroviruses; in addition, the *tas* genes are unrelated to the regulatory genes of other retroviruses. The Tas-responsive elements in the LTR and IP of each individual virus also show little overall homology other than a conserved TATA box. Thus, the mechanism of transactivation in the foamy virus system is fundamentally different from that for other viruses, and may be different for a given transactivator acting at the 5′ LTR versus the IP. Functions for the potential genes encoded by the remaining ORFs (i.e. ORF 2; Bel-2,-3) are not yet known. Foamy viruses do not appear to contain a Rev/Rex axis as in the lentiviruses or oncoviruses. The additional ORFs are dispensable for replication in tissue culture cells; only the viral transactivator is required.

Translation

A subgenomic mRNA encodes the Prt-Pol precursor which lacks Gag determinants. No Gag-Pol precursor can be detected in foamy virus-infected cells or virions. The Env polyprotein precursor is translated from a subgenomic spliced mRNA. The subgenomic mRNA for Env is presumed to be translated on membrane-bound cytoplasmic polysomes, and other viral mRNA species may be translated on free polysomes in the cytoplasm. Proteins encoded by *bel-2* and *bel-3* have been identified in infected cells. An abundant protein containing N-terminal sequences from the *bel-1* gene and C-terminal sequences from the *bel-2* gene has been detected in infected cells; however, the function of this fusion protein, designated Bet, is not known.

Post-translational Processing

In conventional retroviruses, the viral *gag*, *pol*, and *env* genes encode polyprotein precursors that are processed by specific cleavages. Viral protease produces the matrix (MA), capsid (CA) and nucleocapsid (NC) proteins from the *gag* gene precursor. Little processing of the foamy virus Gag precursor is observed in infected cells or in virions. Only a C-terminal cleavage of p78 Gag to generate p74 Gag is readily observed in foamy virus-infected cells or in virions. The putative MA protein of foamy viruses (and several other retroviruses) has a glycine immediately after the initiator methionine; therefore, MA is predicted to be myristoylated at the N-terminus by a host cell enzyme. Reverse transcriptase and integrase are cleaved from the *pol* gene precursor, presumably by the viral protease. The *env* precursor is glycosylated by cellular enzymes and cleaved into the SU and TM domains; this cleavage site at two basic residues is recognized by a host cell endopeptidase.

Assembly Site, Release, Uptake, Cytopathology

Assembly of nucleoprotein cores appears to occur in the cytoplasm. Intracellular viral particles are ring-shaped, 35–50 nm in diameter, and consist of an electron dense shell and an inner electron-lucent center. Particles mature by budding through the cell plasma membrane.

The receptor(s) for these viruses has not been identified, and the entry mechanism (i.e. direct fusion of viral and cell membranes or receptor-mediated endocytosis) has not been studied.

Cytopathology in monolayer tissue culture cells is characterized by extensive formation of intracellular vacuoles in multinucleated syncytial cells. Certain hematopoietic cell lines can produce high levels of virus without obvious cytopathology for an extended period of culture.

Geographic and Seasonal Distribution

Isolates of FeFV, representing two serotypes, have been identified in domestic cats from three continents (**Table 1**), and an isolate has also been obtained from a European wildcat. FeFV has been identified in

healthy cats as well as in cats with neoplasms or nonneoplastic diseases. BFV infection in cattle populations also appears to be widespread. Four serotypes of SFV have been isolated from Old World monkeys and three additional serotypes are from New World monkeys (**Table 1**). Two unique serotypes of SFV were recovered from chimpanzees and one unique serotype from prosimians (**Table 1**). A recent SFV isolate from orangutan appears to be serologically distinct. In summary, foamy viruses appear to be endemic in some animal species in certain areas. Recent studies have refuted previous seroepidemiological studies which indicated that HFV may infect a small number of individuals in Africa and certain Pacific islands; however, rare zoonotic infection of humans with SFVs has been documented. Nothing is known about the seasonal distribution of foamy viruses in any mammalian species.

Host Range and Virus Propagation

Foamy viruses have a wide host range in cell culture systems. The SFVs replicate and cause cytopathology in epithelial and fibroblastic cells from primates, rodents and chickens. Lymphoid cells can be persistently infected with no visible cytopathic effects on the host cells. Cytopathology in monolayer cells is generally characterized by multinucleated syncytia at early times and extensive vacuolization at later times; inclusion bodies are not observed. HFV replicates in diploid fibroblast-like cell lines but not in heteroploid epithelial-like cell lines. *In vitro,* SFV-1 establishes a carrier state in HEp-2 (human hepatoma) and BHK (baby hamster kidney) cell lines, and a Vero (monkey fibroblast) cell line harboring SFV-3 in a latent state has been described. Manifestation of cytopathology with respect to time after infection *in vitro* depends on the serotype of the virus, titer, passage history and cell type used to propagate virus. Under optimal conditions, SFVs induce cytopathology and reach maximal titers as early as 4–5 days after infection. Virus is spread by the extracellular route and by cell-to-cell transmission.

Genetics

Although the complete sequences of the SFV-1, SFV-3, HFV, SFVcpz and FeFV genomes have been elucidated, the extent of variation within each virus and the potential for recombination between viruses are not known.

Evolution

Foamy viruses are exogenous agents, as uninfected host cells do not contain sequences related to these viruses. Sequence comparisons reveal that SFV-1 (rhesus macaque isolate) and SFV-3 (African green monkey isolate) are more closely related to each other than either is to HFV. HFV and SFVcpz are highly related. A potential progenitor virus(es) for the primate foamy viruses remains to be identified. Evolutionary relationships of the primate foamy viruses with foamy virus isolates from other species are not yet established.

Serologic Relationships and Variability

Serologic relationships have been determined by analyzing properties of virus neutralizing antibodies in sera of naturally infected animals and rabbits immunized with whole virus preparations. Antibodies to foamy virus isolates from primate, feline, bovine or murine (i.e. hamster) species do not crossreact, and these viruses are immunologically unrelated to retroviruses in other genera. At least 11 simian serotypes and two feline serotypes have been identified (**Table 1**). Serologic patterns of the SFVs are complex, in that a single species may have two or more serotypes, and the same serotype has been isolated from different species (**Table 1**). Antibodies to HFV apparently crossreact with several SFVs. The genetic and molecular basis for serological cross-reactivity (and variability) has yet to be determined; these studies will require sequencing of foamy virus genomes coupled with an analysis of immunologic epitopes on viral proteins.

Epidemiology

SFVs are prevalent in captive and wild-caught primates. Surveys of primates reared in captivity suggest that foamy virus prevalence is extremely high, especially in adults, were rates of infection may approach 100%. Previous seroepidemiological studies revealed that HFV may be present in a small number of humans in parts of Africa and the Pacific islands. Recent re-examination of these populations have been unable to confirm these previous findings, which suggested an association of foamy virus with specific human disease, and also failed to find any evidence of naturally occurring human infection with a foamy virus.

Transmission and Tissue Tropism

Mechanisms which account for spread of foamy viruses are not well defined. Vertical transmission has been described in cats, cows and monkeys. FeFV, BFV and SFV have been isolated from throat washings or nasal swabs from the respective hosts. Thus, it is possible for horizontal transmission to

occur by direct contact and, perhaps, by the respiratory route via aerosolization.

SFVs have been isolated from several organs (e.g. brain and lymphoid cells) and fluids of healthy and diseased primates. Analysis of fractionated monkey peripheral blood mononuclear cells indicated foamy virus infection of diverse cell populations, with the highest proviral burden in CD8+ T cells. In their respective hosts, FeFV and BFV are also distributed in many different tissues. A feature of the virus–natural host relationship is that foamy viruses have not been directly observed by electron microscopy or other means in the tissue from which they were isolated. Recovery of virus has always been achieved by culturing cells from the original tissue *in vitro*. The mechanism(s) of virus activation is still unknown.

Pathogenicity

Although several reports provide tentative links between presence of a foamy virus and certain clinical conditions, the vast majority of naturally infected hosts do not display any disease. Epidemiologic studies suggested an association of FeFV with polyarthritis in cats, yet experimentally infected cats remained free of symptoms. HFV has been recovered from several patients with de Quervain subacute thyroiditis, and additional HFVs have been obtained from individuals with other disease conditions; however, none of these viral isolates have been well characterized. The prototype HFV was recovered from an individual in East Africa who had a nasopharyngeal carcinoma. Whether this HFV is a genuine human retrovirus or a simian foamy virus contaminant remains to be resolved by characterization of additional (independent) foamy virus isolates from humans. Sequence analysis of SFVcpz indicated a close relationship between this chimpanzee isolate and HFV, thus HFV may represent a rare zoonotic infection or SFV contaminant. In summary, reports on foamy viruses in humans represent anecdotal observations, and an etiologic role for a putative HFV in human pathology is not yet established.

Seronegative natural hosts experimentally infected with foamy virus develop antibodies to the virus but show no clinical symptoms. Heterologous hosts inoculated with foamy viruses generally do not present with any disease signs. Rabbits experimentally infected with SFV-1 seroconverted and harbored virus in several tissue for 1–3 weeks postinfection. In another study, rabbits infected with SFV-7 by the intravenous route demonstrated transient suppression of cell-mediated immune functions. Progressive encephalopathy and muscular abnormalities were produced in transgenic mice containing a portion of the cloned HFV genome that includes the ORF (or *bel*) region; this region encodes the transcriptional transactivator (*tas*). This observation in the transgenic animal model intimates a pathogenic potential for foamy viruses, perhaps with respect to neurodegenerative diseases. Whether foamy viruses are cofactors for disease for other infectious agents is not known.

Clinical Features of Infection

Naturally and experimentally infected hosts develop antiviral antibodies, and virus is recoverable from a variety of organs by culturing tissue explants *in vitro* to activate viral gene expression. A clear association between foamy avirus infection and disease has not yet been established (see above, Pathogenicity). Extremely rare zoonotic infection of humans, through occupational exposure (animal laboratory workers), has been documented. Infected individuals appear healthy.

Pathology and Histopathology

Currently there is no significant information available on the pathology and histopathology of foamy virus infections in their natural hosts, as clinical disease has not been convincingly associated with these viruses. Histologic analysis of transgenic mice containing portions of the HFV genome reveals patterns of neurological and muscular degeneration (see above, Pathogenicity).

Immune Response

Naturally infected animals have virus-neutralizing antibodies. Accordingly, the presence of these antibodies may account for viral latency or a low-level persistent infection. Other defense mechanisms, such as interferon, may also subdue viral replication in the host. The role of cell-mediated immunity in foamy virus infection remains to be explored.

Prevention and Control of Foamy Viruses

Foamy virus infections of their natural hosts are not known to cause any major clinical disease; consequently, the development of preventive and control measures are not necessary at this time. However, experimental xenotransplants from nonhuman primates to humans raises the possibility of SFV infection in humans.

Future Perspectives

Many fundamental aspects of foamy virus replication

and virus–host interactions remain to be investigated. The emerging picture of foamy virus replication is one with distinct differences from that of conventional retroviruses, with some features reminiscent of hepadnaviruses. The distribution of foamy viruses in a species and the precise modes of transmission are not well established; these studies will be aided by sensitive techniques for detecting viral genomes (e.g. amplification via polymerase chain reaction) and antiviral antibodies (e.g. ELISA systems and immunoblots with genetically engineered viral antigens). The reason(s) for lack of pathology in animals infected with foamy viruses is not known; it is tenable that these viruses may be associated with long-term, chronic degenerative disease(s). In addition, foamy viruses may be cofactors for other infectious agents. In the host, the precise cell types and organs harboring virus and viral genomes are not well defined. Whether infection is 'persistent' or 'latent' remains to be determined. Additional studies are required to elucidate the mechanism of viral transactivation (*via tas/bel*) and to evaluate the effects of cell-activation signals on viral gene expression. The significance of host immune mechanisms for controlling viral replication and pathogenesis is not determined, and a mechanism(s) which accounts for viral cytopathology has not been elucidated. The extent of strain variation, particularly in the *env* genes of primate foamy viruses, is an area for future study. A cellular receptor for attachment of virus particles has not yet been identified. In addition, the broad host range and apparent lack of pathogenesis are factors which may make foamy viruses useful for the development of retroviral vectors for gene transfer. Transduction of a wide variety of vertebrate cells, including primary hematopoietic progenitor cells, by foamy virus vectors has been reported.

SYNERGISM: PLANT VIRUSES

Vicki Bowman Vance, Department of Biological Sciences, University of South Carolina, Columbia, South Carolina, USA

Mixed Virus Infections are Common in Plants

Mixed virus infections occur in both plant and animal systems, and doubly infected organisms commonly display changes in disease symptoms and in the accumulation of one or both of the co-infecting viruses. However, such infections are relatively uncommon in animal hosts where they are generally associated with depression of the immune response. In contrast, higher plants are frequently infected with multiple viruses. In some cases, the virus interaction is antagonistic and infection by one virus interferes with the subsequent replication or spread of the other virus. This type of interaction is the basis for the phenomenon known as 'cross protection', where a plant is protected from a virulent strain of a virus by prior inoculation with a mild or asymptomatic strain of the same virus. Cross protection is limited to closely related viruses.

In other cases of mixed virus infection in plants, the viral interaction is synergistic and co-infection enhances the replication and/or spread of one or both viruses. The co-infection usually results in a much more severe disease than either virus causes in a single infection, and a number of plant disease syndromes are caused by the interaction of two independent viruses in the same host. In contrast to cross protection, synergistic viral interactions almost always occur between unrelated viruses. Such synergistic interactions offer a unique opportunity to investigate the regulation of viral disease because the accumulation and pathogenicity of one virus are altered when it interacts with a relatively simple genetic element, the genome of the co-infecting virus.

Potyvirus-associated Synergisms

Many synergistic diseases involve a member of the potyvirus group of plant viruses. In these *potyvirus-associated* synergisms, the other virus of the pair may be any of a broad range of unrelated viruses, including pararetroviruses, such as cauliflower mosaic virus, and RNA viruses of both the alphavirus supergroup (for example potato virus X [PVX]) and the picornavirus supergroup (for example cowpea mosaic virus). **Table 1** lists a number of examples of potyvirus-associated synergisms.

Several such potyvirus-associated synergistic diseases have been examined in some detail, and in each, a dramatic increase in host symptoms has been observed in doubly infected plants compared to singly infected plants. The increase in symptoms in doubly infected plants is correlated with an increase in the accumulation of the nonpotyvirus; however, in general, there is no corresponding increase or decrease in the level of the potyvirus.

The PVX/potyvirus Interaction

A model synergism

The interaction between PVX and potato virus Y (PVY, a potyvirus) in tobacco has been well characterized and serves as a model to understand the underlying molecular basis for potyvirus-associated synergistic disease. Plants mechanically inoculated with both viruses develop synergistic disease, which is characterized initially by severe vein clearing and then necrosis of the first systemically infected leaf tissue. The dramatic increase in symptoms in the first systemically infected tissue is correlated with a large (3–10-fold) increase in the level of PVX compared to

Table 1 Potyvirus-associated synergisms

Potyvirus	*Heterologous virus*
Potato virus Y	Potato virus X

Tobacco etch virus	Dodder latent mosaic virus

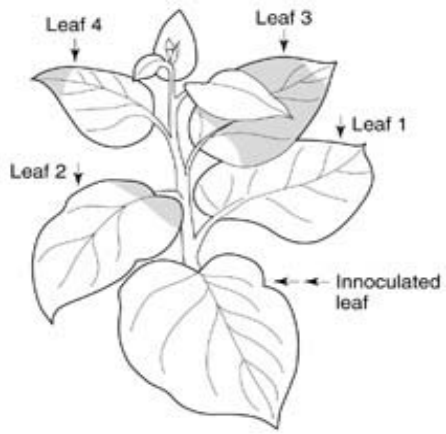

Figure 1 Diagram of a tobacco plant showing the pattern of acute phase synergism symptoms on the bottom of leaf two, all of leaf three and the tip of leaf four above the inoculated leaf. The location of acute phase symptoms is indicated by shading.

the analogous regions of plants singly infected with PVX.

Both the timing of invasion by the two viruses and the developmental state of the host are important for induction of the PVX/PVY synergistic response. PVX must enter the systemically infected cells at a time when PVY is actively replicating and expressing its viral gene products. Outside that window in time, PVX invasion does not lead to the synergistic increase in symptoms or the correlated increase in PVX accumulation. The severe symptoms on first systemically infected leaves are found in a characteristic pattern, confined to the base of the second leaf, over most of the third leaf and at the tip of the fourth leaf above the inoculated leaf (**Fig. 1**). These severely affected tissues are said to be in the acute phase of the synergistic disease. The pattern of acute phase symptoms reflects the developmental state of the plant, since all the affected tissues were at the same level of maturity at the time of viral invasion. The pattern of acute phase disease was one of the first clues that the host may play an important role in the development of synergistic disease. The fact that the timing of PVY invasion was found to be important suggests that an interaction between the potyvirus (or potyvirus gene product) with the host might play a role in mediation of the disease syndrome.

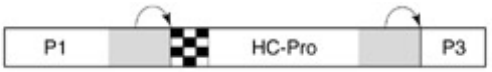
The increase in PVX accumulation in acute phase tissue is due to a change in control of PVX replication. PVX is a (+) strand RNA virus that replicates via production of a complementary RNA, the (−) strand RNA, that is used as a template for production of high levels of the genomic RNA. The genomic RNA encodes five known gene products and serves as mRNA for the 5′-proximal gene product, the 166 kDa putative replicase. The genes that are encoded internally on the genomic RNA are expressed via production of subgenomic mRNAs, each serving as mRNA for the gene encoded at their respective 5′-proximal ends. The virion is rod shaped and consists solely of the genomic RNA encapsidated by the viral coat protein. In the acute phase of PVX/PVY synergism, the levels of infectious PVX particles, PVX genomic RNA, PVX coat protein and PVX coat protein subgenomic mRNA all increase to about the same extent (3–10-fold) over that in the analogous singly infected tissues. In contrast, the level of the PVX complementary RNA, which serves as a template during replication, consistently increases to a level 3-fold above that of the virion and its component parts. Thus, the ratio of (−) strand to (+) strand PVX RNA is increased during synergism and this suggests a change in the regulation of PVX RNA replication. This change in PVX replication does not require replication of the PVY genome, and is mediated by expression of a subset of the PVY genes (see next section).

Although much of the early synergism work centered on the PVX/PVY interaction, a similar synergistic response is induced in co-infections of PVX with several other potyviruses, including the well-studied tobacco vein mottling virus (TVMV) and tobacco etch viruses (TEV). The finding that many different potyviruses could induce the same changes in host response and in PVX replication was important because it was the first hint that the role of the potyvirus in potyvirus-associated synergisms might be the same for all such diseases.

PVX/potyviral synergism is mediated by the potyviral P1/HC-Pro sequence

Two lines of evidence lead to the conclusion that PVX/potyviral synergistic disease does not require replication of the potyviral genomic RNA and that the response is mediated by expression of potyviral sequences in the 5′ proximal one-third of the potyviral genome. The first line of evidence stems from experiments using transgenic plants expressing various subsets of the potyvirus genome. Plants expressing the 5′ proximal region of either the TVMV or the TEV genomic RNA and infected singly with PVX displayed the synergistic increases in symptoms and in PVX RNA replication. These results indicate that the 5′-proximal region of the genomic RNA of either TVMV or TEV is sufficient to mediate synergistic disease.

The second line of evidence stems from experi-



Protein	Domain	Potyvirus function	Synergism △ Replication	Synergism ↑ Symptoms
P1		Replication, polyprotein cleavage	Yes	No
HC-Pro	Zinc finger	Aphid transmission	No	No
	Central	Replication, long distance movement, pathogenicity	Yes	Yes
	Proteinase	Polyprotein cleavage	?	?

Figure 2 Diagram of the potyviral P1/HC-Pro sequence which mediates potyvirus-associated synergisms. Proteinase domains of both P1 and HC-Pro are indicated by shading, whereas the location of the cleavage site for each of these proteinases is indicated by an arrow. The amino terminal zinc finger-like domain of HC-Pro is indicated by a checkerboard pattern. The functions of the P1 and HC-Pro sequences in the potyvirus life cycle, as well as their role in synergism are indicated below the diagram.

ments using PVX as a vector to express this same region of the TEV genome (PVX-5′TEV). An infectious cDNA clone of the PVX genome was engineered to express the TEV sequence under control of a repeated coat protein subgenomic promoter. When inoculated onto tobacco, this engineered PVX induced a characteristic synergistic response with enhancement in both symptoms and in RNA replication. When used to infect tobacco tissue culture cells, expression of the potyviral sequence dramatically prolonged the accumulation of PVX (−) strand RNA over a three-day time-course experiment. This result indicates that the potyviral 5′ proximal sequence induces a synergistic change in PVX RNA replication and confirms that the region is sufficient to mediate synergistic disease.

The region of the potyviral genome that mediates synergism includes the viral genomic 5′ untranslated region (UTR) as well as the coding region for the N-terminal portion of the viral polyprotein, including P1, helper component protease (HC-Pro), and about a quarter of P3 (termed P1/HC-Pro sequence, **Fig. 2**). This region is expressed as polyprotein and subsequently processed by the proteolytic activities of both P1 and HC-Pro.

We can obtain clues for how HC-Pro and P1 might mediate synergism by examining the functions they perform in the TEV infection process (**Fig. 2**). Both HC-Pro and P1 are multifunctional proteins. P1 has proteinase activity that cleaves the potyviral polyprotein, creating the C-terminus of P1 and the N-terminus of HC-Pro. P1 also functions in *trans* as an accessory factor for genome replication and has RNA binding activity. One possibility is that P1 plays a direct role in synergism, perhaps analogous to its role as an accessory factor in TEV replication. Alternatively, it might enhance synergism only indirectly by producing the authentic HC-Pro N-terminus by means of its proteinase activity.

HC-Pro has at least three functional domains: an N-terminal domain required for aphid transmission; a central domain involved in pathogenicity, RNA replication, and leaf-to-leaf movement of the virus through the phloem; and a C-terminal domain required for autoproteolytic processing of the HC-Pro C-terminus. The central domain of HC-Pro is of particular interest because it is involved in the regulation of both pathogenicity and RNA replication of potyviruses, and these are the characteristics that are altered in PVX during synergism.

The potyviral P1/HC-Pro sequence also mediates other potyvirus-associated diseases

The finding that transgenic plants expressing the P1/HC-Pro region of the potyviral genome develop synergistic disease when infected with PVX raised the possibility that many or all potyvirus-associated synergisms might be mediated by this same sequence. To test this hypothesis, two other viruses, tobacco mosaic virus (TMV) and cucumber mosaic virus (CMV), were used to infect transgenic tobacco line U-6B, which expresses the P1/HC-Pro region of the TEV genome. Both viruses can infect tobacco and are known to interact synergistically with a potyvirus. TMV and CMV are both (+) strand RNA viruses in the alphavirus supergroup; however, CMV has a tripartite genome, and many strains also support replication of an associated satellite RNA, whereas the genome of TMV, like that of PVX, is monopartite. The transgenic plants expressing the potyvirus P1/HC-Pro sequence displayed the enhanced symptoms characteristic of synergism when infected singly with either TMV or CMV. **Figure 3** shows enhanced symptoms of PVX, CMV and TMV in the U-6B plants as compared to those in nontransgenic control plants. At the molecular level, infection of the U-6B transgenic resulted in increased accumulation of the genomic RNAs of both of these heterologous viruses. Thus, the response of TMV and CMV to expression of the potyvirus P1/HC-Pro sequence is similar to that previously shown for PVX.

Because both TMV and CMV are capable of

inducing synergistic disease in mixed infections with a member of the potyvirus group, this result supports the hypothesis that all such potyvirus-associated synergistic diseases, which occur in an evolutionarily diverse range of host plants and involve interactions with a large number of viral groups, are mediated by the same potyviral sequence. The fact that expression of this sequence alters disease induction by each of these unrelated heterologous viruses suggests that it affects a step in viral infection that is common to all of these viruses and thus of general significance.

Identification of functional domains within the P1/HC-Pro sequence

The role of P1/HC-Pro in synergism could be mediated by the entire P1/HC-Pro region, either the RNA itself, or the encoded polyprotein. Alternately, the response could be mediated by a part of the RNA sequence or one or a subset of the encoded proteins. Three complementary approaches have been used to delineate the domains of P1/HC-Pro that function in potyviral synergism. The first approach was to use transgenic plants expressing mutant versions of the P1/HC-Pro sequence. Six transgenic lines, three with mutations within the P1 coding region and three with mutations within the HC-Pro coding region, were infected with PVX to assay the ability of the mutant transgene to induce synergism. The three lines with mutations within the P1 coding region all maintained the ability to mediate the synergistic response to PVX. In contrast, two out of three of the mutations within the HC-Pro coding region failed to induce synergistic disease. Both mutations that interfered with the ability to cause synergism were located within the region encoding the central domain of HC-Pro. This result established the importance of the HC-Pro central domain for induction of PVX/potyviral synergistic disease.

A second approach was to use mixed inoculation experiments with a mutant version of TEV. Plants were co-inoculated with PVX and TEV-del-2, a spontaneous deletion mutation of TEV in which the first 65 amino acids of HC-Pro are missing, and assayed for synergistic disease. The mutant TEV interacted with PVX to produce synergistic disease indistinguishable from that produced by mixed infection with wild-type TEV. This result showed that the amino-terminal 65 amino acids of HC-Pro, encoding a zinc-finger-like domain required for aphid transmission of the potyvirus, are dispensable for induction of PVX/TEV synergism.

Although the first two approaches established some sequences required in the induction of synergism, they did not establish the minimal sequence required for the response. The third approach was to use PVX as a vector to express various parts of the P1/HC-Pro sequence and then assay the engineered viruses for the ability to cause disease symptoms and the change in PVX replication characteristic of synergism. This approach revealed that the HC-Pro protein was both necessary and sufficient to cause the synergistic increase in host symptoms. In contrast the synergistic enhancement of PVX replication required both P1 and HC-Pro. This result suggests that the synergistic increase in symptoms and in PVX replication, although correlated in mixed infections, may be mediated via different pathways.

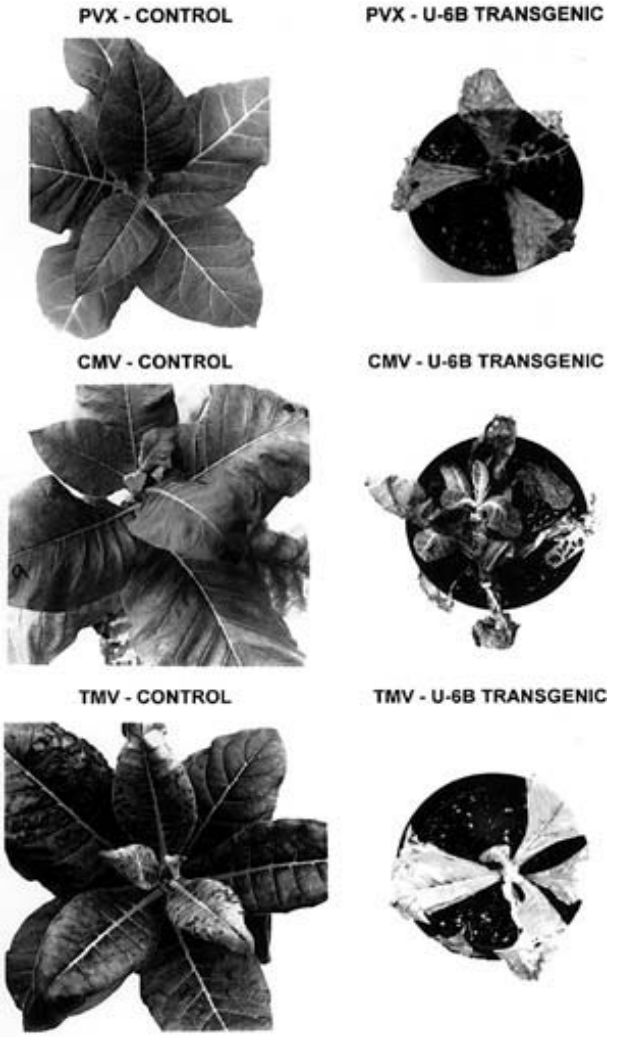


Figure 3 Enhanced pathogenicity of PVX, CMV and TMV in transgenic tobacco expressing high levels of the P1/HC-Pro sequence. The left hand column shows nontransformed tobacco plants infected with PVX (top row), CMV (middle row) or TMV (bottom row). The right hand column shows infection of the P1/HC-Pro expressing transgenic line U-6B infected with the same set of viruses.

Possible mechanisms for potyviral-associated synergism

Potyviral-associated synergisms result in increases in both the accumulation of the nonpotyvirus of the synergistic pair of viruses and in the host symptoms. In the case of PVX/potyviral synergism, these two aspects of the synergistic disease are mediated by different functional domains of the P1/HC-Pro sequence, possibly reflecting action via different pathways. The central domain of HC-Pro is required for both enhanced replication and enhanced symptoms. Since this region of HC-Pro has been shown to prolong replication of the potyvirus in plants and because expression of P1/HC-Pro also prolongs PVX (−) strand RNA accumulation in tobacco culture cells, it is possible that the basis of potyvirus-associated synergism is the ability of HC-Pro to prolong replication not only of potyviruses, but also of a broad range of heterologous viruses.

Although it has been shown that P1/HC-Pro acts to alter replication of PVX, the possibility that the potyviral sequence also facilitates viral movement has not been ruled out. In fact, because the central domain of HC-Pro is required for both movement and replication of the potyvirus and the same domain is also required for the synergistic effect on PVX, a role in movement in addition to the role in replication remains quite possible.

The TEV P1/HC-Pro sequence mediates synergistic disease during infection by viruses from three different groups (PVX, potexvirus; TMV, tobamovirus; CMV, cucumovirus). Therefore, it has been proposed that synergism may occur via an indirect mechanism involving an interaction of the TEV-encoded proteins with one or more host factors common to the different viral infections rather than a direct mechanism involving interactions with different RNAs or proteins from three heterologous viruses.

Two different indirect mechanisms could explain transactivation of viral replication by P1/HC-Pro. The TEV sequence might augment viral replication by enhancing the synthesis, activity or availability of a host factor that affects both TEV and the heterologous viruses in a positive way. It has been shown that host factors may be used as part of the virus replication machinery in plant cells. However, there is no evidence for host factors that act as general positive regulators of virus replication.

Alternatively, the potyviral sequence might interfere with the activity or availability of a negative regulator of viral replication, perhaps part of a host defense system that normally limits the viral infection. Post-transcriptional gene silencing has recently been proposed to act as a general defense system against plant viruses and this system is a candidate for a defense system impacted by P1/HC-Pro. In one post-transcriptional gene silencing model, an RNA targeting system is activated by high level expression of a particular RNA sequence, such as an invading virus. Once activated, the system rapidly destroys the RNA target in a sequence specific manner. The same cellular system is also thought to be involved in post-transcriptional gene silencing of nonviral transgenes in plants. In the case of plant viral synergism, the P1/HC-Pro sequence might interfere with the induction or the action of the post-transcriptional silencing pathway and thus allow a broad range of viruses to overstep the normal host imposed limits of RNA accumulation.

Nonpotyviral Synergisms

A number of plant viral synergisms which do not involve a member of the potyvirus group have been reported (**Table 2**); however, in contrast to the potyvirus-associated synergisms, none of these nonpotyviral synergisms have been well characterized at the molecular level. Probably the best studied of the nonpotyviral synergisms is the interaction of TMV and PVX, which causes the synergistic disease in tomatoes called double streak. This synergistic interaction has been reported to result in an increase in the level of PVX in doubly infected plants. One possibility is that the nonpotyvirus synergisms are mediated by expression of a subset of one viral genome, in a manner similar to that shown for the PVX/potyviral synergism. Interestingly, a high proportion of the nonpotyviral synergisms involve TMV as one member of the pair of interacting viruses, and this raises the possibility that the TMV genome includes a synergism sequence similar in function to the potyviral P1/HC-Pro sequence.

T

T1-LIKE PHAGES (*SIPHOVIRIDAE*)

JR Christensen, Rochester, New York, USA

Natural History

T1 is one of the seven phages collected by Delbrück and renamed T1 through T7; they all make clear-centered plaques on *Escherichia coli* B. T1 is unrelated to any of the others. Its latent period at 37°C is 13 minutes, and the burst size is about 100. T1 also infects some other laboratory strains of *E. coli* (e.g. K-12 and C) and *Shigella dysenteriae*. Out of 290 clinical isolates of *E. coli*, T1 could replicate in two and kill a third without producing phage.

T1's best-known relative is the *Shigella* phage, D20, with which it readily hybridizes. T1-like phages can be isolated from sewage, but none has received much study. Among laboratory strains of T1, there are a few minor differences, revealed by restriction analysis.

The virion is highly stable in the dry state, so that careless technique may cause T1 (like other phages with this property) to become airborne in the laboratory, and to unexpectedly lyse cultures contaminated accidentally.

The Virion

In the electron microscope, T1 closely resembles lambda, with a polyhedral head about 55–60 nm across, and a long, flexible tail about 7 × 150 nm. Fifteen virion proteins have been recognized. One of these, P7, accounts for about 50% of the total protein, and two additional proteins for another 35%.

The genomic molecule is double-stranded DNA with approximately 48 500 bp. Only the four conventional bases are present. About 0.2% of the cytosine residues and 1.7% of the adenine residues are methylated, at the 5 and 6 positions, respectively. The DNA molecule includes a terminal redundancy of about 2800 ± 530 bp (6%), so that the coding capacity is about 46 000 base pairs. Because of the way the genome is packaged during morphogenesis (see below), there is a limited set of cyclic permutations of the nucleotide sequence within a population of virions.

Early Events in Infection

Adsorption of T1 is a two-step process: an initial, reversible interaction with an outer membrane-spanning protein coded by *fhuA (tonA)*, followed by an irreversible interaction involving the *tonB*-coded protein and energy provided by bacterial metabolism.

The exterior loops of FhuA serve as receptor for a variety of ligands, including several iron compounds, phages T1, T5 and ϕ80, and colicin M. Mutation studies indicate that the various ligands bind to non-identical but partially overlapping portions of FhuA.

It has been proposed that TonB serves to transmit inner-membrane energy to FhuA, altering its conformation, and allowing T1 infection (and the transport of certain other ligands, including ϕ80) to proceed. However, a possibly different role for TonB during T1 infection has been proposed (see below). T5 does not require TonB activity, nor indeed does a host-range mutant of T1, T1*hr*.

During the first 1–2 min after infection, there are marked changes in the membrane properties and in the energy state of the bacterium: there is a large efflux of K^+, the proton motive force (PMF) decreases, but does not vanish, and intracellular ATP levels fall, due to the activity of the proton-translocating ATPase. Those transport systems driven by ATP or by the PMF are inhibited, but the activity of the sugar phosphotransferase systems is stimulated. None of these changes requires phage gene activity.

During this same period of time, entry of phage DNA into the cell and shut-off of host protein synthesis occur. A model that puts these observations

together has been proposed (though there is some dispute about it): preinfection, at least two cation gradients contribute strongly to the energized state of the membrane – K^+ is higher inside the cell, and H^+ is higher outside. The entry of T1 DNA is effected by a proton symport that involves *tonB*. This process tends to deplete the PMF, but partial activity is maintained by H^+ efflux, driven partially by ATP hydrolysis and partially by K^+ symport. The resulting fall in intracellular ATP leads to a fall in GTP. This, and perhaps other changes in the intracellular ionic environment, produces an inhibition of translation of host proteins at the initiation level. (Presumably the translation of phage proteins is resistant to these changes.)

Within a few minutes, a 'resealing' process occurs, although it is not clear that the membrane is restored exactly to its original condition. Resealing and the continued maintenance of the remaining level of the PMF are necessary for the infectious process to continue.

Another early event is the appearance of a phage-coded DNA methyl transferase. Although the specificity of this enzyme is identical to the host's *dam* enzyme, it is quite distinct in other enzymological properties, and T1 DNA shows no hybridization to that of the cloned host gene. The phage-coded enzyme almost totally methylates the adenines occurring within 5′-GATC sequences, even when the phage is grown in *dam* mutants. The biological role of this methylation is unclear.

Transcription

T1 depends on the host RNA polymerase for transcription throughout its cycle. Both early and late, all or nearly all transcripts are read from the same strand of DNA. All major regions of the genome are transcribed early, but there is a relative shift at later times towards the regions coding for virion proteins. The basis for the shift remains unknown. Considerable transcription (but not translation) of host genes continues after infection.

Protein Synthesis

The synthesis of 31 phage-coded proteins has been documented in infected cells. From their combined molecular weights, these account for about 80% of the coding capacity of the genome. Five temporal patterns of synthesis have been noted: proteins synthesized only early; only late; continuously but at a declining rate; continuously and steadily; continuously and at an increasing rate. As with the synthesis of host proteins, much of this regulation is probably at the transitional level.

DNA Synthesis

Among virulent, double-stranded DNA phages, T1 is unusual in that is depends on the *polC*-coded α subunit of Pol III for DNA synthesis. This is a property typical of temperate phages. It also depends on most of the other host-coded proteins involved in the elongation phase of DNA synthesis, except for *dnaB*, but does not require host proteins involved in the initiation of DNA synthesis.

Host DNA synthesis is stopped very early in infection. This inhibition requires protein synthesis, presumably for the expression of a phage gene, but the gene responsible has not been identified.

Two sets of phage genes are required for DNA synthesis. Mutants in genes 1 and 2 are totally defective in DNA synthesis. Presumably, the products of these genes function in initiation of synthesis on T1 templates. The continuing function of both of these genes is required throughout the growth cycle. Lysis of the host is delayed after infection by these mutants, but most phage-coded proteins are produced normally.

Two other genes, 3.5 and 4, encode a recombination function called Grn (for general *r*ecombi*n*ation – pronounced 'green'). This function is obligatory for phage production (see below) but, once expressed, it becomes progressively dispensable as the infection proceeds. Under some conditions, the host's RecE or lambda's Red recombination system can substitute, at least partially, for Grn. Evidence suggests that gene 4 encodes an exonuclease, but no such enzyme has been isolated.

Early in infection, the products of DNA synthesis are linear, monomeric molecules. Later, under the influence of Grn, linear, concatameric molecules are produced; these have a broad distribution of sizes up to about 8- to 10-mers, presumably produced mainly by 'head-to-tail' recombination between homologous redundant ends on two molecules. In the total absence of Grn function, no concatamers are found, and DNA synthesis ceases prematurely, about 6 min into the infection. Why synthesis stops under these conditions is not clear, particularly since, once Grn has been expressed, synthesis of both monomers and concatamers continues even though further Grn activity is blocked. In the total absence of Grn, the cells lyse at the normal time, but no phage are released.

As with other virulent phages, T1 infection leads to degradation of the host's DNA. The liberated material provided about two-thirds of the precursors for the synthesis of T1 DNA. Mutants in gene 2.5 are deficient in host DNA breakdown, but phage DNA synthesis proceeds normally.

However, while phage DNA synthesis can proceed

in the absence of host breakdown, the converse is not true. In T1 there is an unusual functional dependence of the degradation of host DNA upon ongoing synthesis of phage DNA. If phage DNA synthesis is prevented, whether by use of mutants or of naladixic acid, degradation of host DNA does not occur. If degradation has already begun, and a synthesis block is imposed, degradation stops. Thus, no conditions have been found under which free degradation products can be detected. With T4 and other virulent phages that have been studied, if phage DNA synthesis is blocked, host DNA degradation nevertheless occurs, with released materials leaking into the medium.

Morphogenesis

Relatively little is known about the pathways of T1 capsid assembly. Some virion proteins, including P7, are cleaved from larger precursors, as occurs during capsid assembly with several other phages. Mature, DNA-filled heads can join to tails and form infectious particles *in vitro*.

More is known about the manner in which DNA becomes encapsidated. Linear genomic concatamers are the substrate for packaging. The process is initiated at a site called *pac,* located between gene 1 and gene 2 on the map, and processive head-filling proceeds toward gene 1 (leftward, as the map is conventionally represented). As mentioned above, a 'headful' is about 1.06 genomes worth of DNA. Only two or three particles are produced from a single initiation event, so that a limited set of cyclic permutations is produced. Thus, about 18% of the genome will, in some of the particles, be represented twice, once at each end of the packaged DNA molecule.

A mutation, *pip,* located between markers in genes 2.5 and 3 (and which likely represents a separate gene), has a marked influence on DNA packaging. If the host happens to be a lambda lysogen, T1*pip* has an enhanced frequency of initiating packaging 'mistakenly' at a site, *esp*-λ, located on the lambda prophage (see Transduction, below). The *pip* mutant is also deficient in processive packaging, so that almost all of the packaged molecules are initiated at *pac* even though, judging by the small burst size, the efficiency of initiation at *pac* is probably reduced by the mutation.

Mutants in most of the genes involved in head production are grossly defective in processing concatameric DNA to monomeric DNA, suggesting that nearly-complete head structures are required for the maturing of concatamers into monomeric 'headfuls'. However, mutants in gene 12 process concatamers normally, though they do not produce heads; presumably they fill DNA normally into head precursors that are unstable due to the lack of the gene 12 product. Finally, *am*383, the sole mutant in gene 13.3, which maps in the head region and encodes a virion protein, is only partially defective in processing concatamers. It is not clear whether this mutation is phenotypically 'leaky', or whether this observation points to some special role for this gene in DNA packaging.

Extracts, prepared from cells infected with T1 bearing amber mutations in both gene 1 and gene 2, are capable of packaging either homologous or heterologous DNA added *in vitro*. Two packaging pathways have been identified.

If the extract is given homologous DNA extracted from virions of T1 (or T1-like phages), it produces phage. Presumably, the pathway involves two steps: the production of concatamers, via recombination, followed by packaging, initiated at *pac*.

Given heterologous DNA extracted from T3, T7 or lambda *nin,* all of which are about 80% the length of T1 DNA and lack any known *pac*-like sites (*esp*-λ is in the *nin* region), the extract produces the corresponding phage by a *pac*-independent pathway. DNA from wild-type lambda is packaged less efficiently than that from lambda *nin,* suggesting that the second pathway prefers shorter molecules. (The first pathway does not act on wild-type lambda DNA, despite the presence of *esp*-λ, as there are no redundant ends to facilitate concatamer formation.)

Mutants and Maps

The current genetic map (**Fig. 1**) contains 23 essential genes, identified by complementation tests between conditional-lethal mutants, and the nonessential gene 2.5, identified by *tar* mutants (which enhance transduction frequency). These are in numerical order, with fractional gene numbers for those genes identified since the first 18 genes were mapped.

At the left end are the genes discussed above: 1, 2, 2.5, 3.5 and 4, as well as *pac* and *pip,* all of which have roles in DNA metabolism. Curiously, also within this cluster is gene 3, which has no role in DNA metabolism – rather it is essential for tail formation. Perhaps it has a regulatory role, rather than coding for a virion protein.

Next come eight more genes, 5 through 11.5, that are required for the production of phage tails. The *hr* mutation, which allows T1 to infect *tonB* (but not *fhuA*) mutant bacteria, maps just to the left of the available gene 5 markers, and may be within that gene. Finally come ten genes, 12 through 18, required for the production of phage heads. Probably there are

at most a very few undiscovered head or tail genes, judging from the number present in the morphologically similar phage, lambda.

Several tail and head genes, plus the *pac* region, have been cloned in the positive selection vector, pLV59. These clones, which together include about one-third of the total genome, have allowed a comparison of the genetic and physical maps (**Fig. 1**). Genetic markers are relatively far apart at both ends, but especially so at the left end. The occurrence of 'head-to-tail' recombination during concatamer formation would be expected to increase genetic distances between markers at the map ends (this does not mean that the genetic map is 'wrong', merely that it represents a different kind of information). But this effect will not be found to the right of *pac*, and so the wide genetic distances between markers in the region form gene 2 to gene 5 cannot be due to this effect. It is almost certain, however, that more genes remain to be discovered, particularly genes for nonessential functions, as these will not be discovered in collections of conditional lethal mutants. Unless these nonessential genes are scattered among the head and tail genes, which seems highly implausible, their likely location is in the leftward portion of the map.

Restriction and Modification

T1 passes freely among such *E. coli* strains as B, K-12 and C, so it is not subject to either B or K restriction. At one time it was felt that the high level of methylation of T1 DNA might account for this, but as 5′-GATC sequences are the main sequence methylated (at least, the total level of adenine methylation is consistent with the number of such sequences that might be expected on a genome of T1's size), and as this sequence is not part of the recognition sequence for either the B or K restriction enzyme, this seems unlikely.

However, in P1 lysogens, T1 grown in a nonlysogen is subject to restriction and modification; P1-modified T1 plates with full efficiency on both lysogens and nonlysogens. When unmodified T1 infects a lysogen, about 80% of phage DNA is degraded and excreted into the medium within 5 min. After this, degradation stops, and several

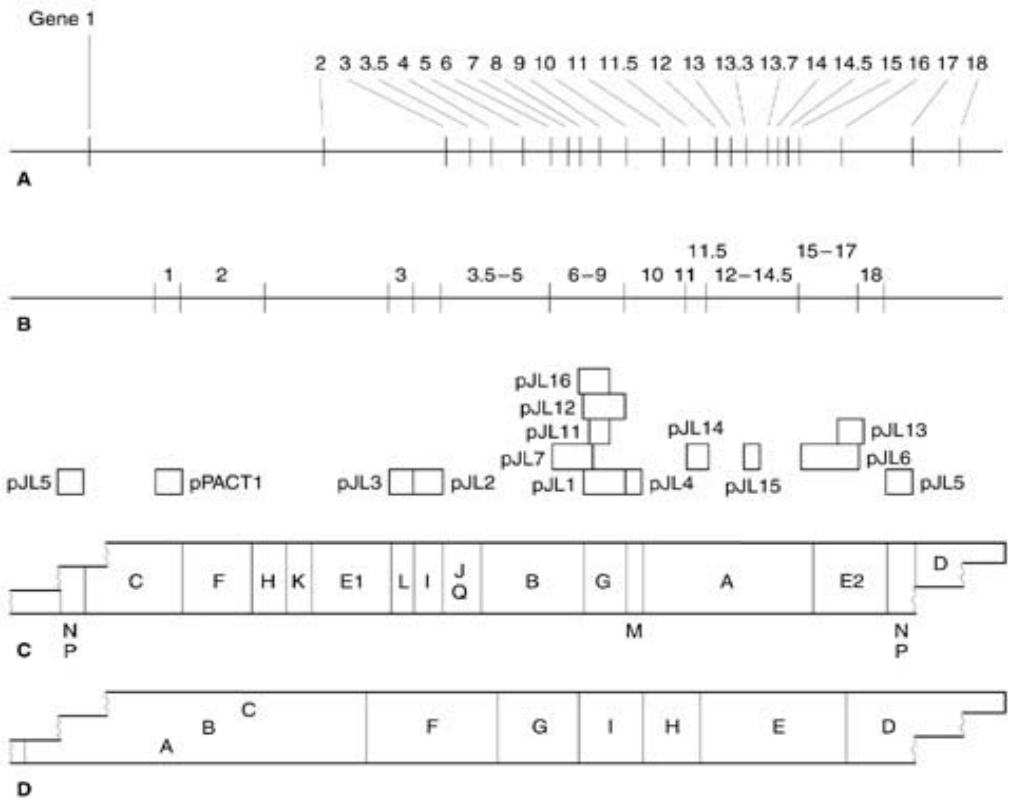

Figure 1 Genetic and physical maps of T1. (**A**) The genetic map, with each gene identified by the *am* or *ts* mutant used to map the gene. (**B**) Positions of the T1 genes on the DNA molecule. Each interval represents the outer limits of the regions occupied by the *am* mutant tested, relative to the physical map below. (**C**) Locations of the T1 cloned fragments relative to the physical map. (**D**) Physical map of T1 DNA with the *Bgl*II (upper) and *Bgl*I (lower) cleavage sites. observations indicate that biologically active fragments of the restricted genome persist in the lysogenic cells for a considerable period of time.

Complementation occurs in 10–25% of the cells when unmodified T1*am* + *hr* and modified T1*amhr* + phage coinfect lysogens. This is true for most of the genes tested but not all. Most of the progeny phage are *amhr* +, so this is not primarily due to marker rescue, though that also occurs (see below). Complementing activity is but little diminished when infection by the modified phage comes 4, or even 9, minutes after infection by the unmodified one.

In co-infection experiments that use plaque-morphology markers to distinguish modified from unmodified phage (no complementation required), recombinational rescue of the alleles of the unmodified parent occurs in a few percent of the cells. Certain markers are rescued more frequently than others are. In three-factor crosses, usually only a single marker is rescued in a given cell. The alleles of the nonmodified phage remain available for rescue for at least 10 min.

In addition, under special conditions, unmodified T1 alone can successfully infect lysogens. The required conditions are high multiplicity of infection (about 10), strong aeration in nutrient medium, and occurrence of protein synthesis during the first few minutes after infection. (These special conditions are not required for the phenomena described above.) Up to 10% of the cells produce phage; this is called cooperative infection. The progeny phage are mostly modified, and they have undergone extensive recombination. Again, dividing the infecting phage into two portions, with up to 6 min intervening, does not interfere with cooperation.

Finally, among the rare (*c.* 1 in 10^4) lysogens that do yield phage after infection by a single, unmodified T1, individual cells lyse and produce their progeny (most of which are unmodified) over a period of 3–5 h.

Transduction

In common with other phage that package DNA by a headful mechanism, T1 is a generalized transducing phage. To demonstrate this, it is necessary to use T1*am* phage (typically a double *am* stock), permissive donors and nonpermissive recipients; otherwise, potential transductants are killed on the assay plate by the large excess of viable, virulent phage in the transducing lysate. The fact that, for a given marker, transduction frequencies are quite reproducible from experiment to experiment makes T1 a good subject for studying various aspects of the transduction process.

Although all markers tested can be transduced, the frequency of transduction varies widely among different markers. It appears likely that packaging of bacterial DNA can be initiated at many sites in the chromosome that mimic, to varying degrees, T1's *pac* site. This idea is strengthened by the discovery of two specific sites that have a special property: markers to one side of the site, but not the other, are transduced at high frequency; this is what would be expected of transductional 'pick-up' initiated at a *pac*-like site. One of these, *esp*, is located between *att*-λ and *gal* on the bacterial chromosome. From this site, *bio* (but not *gal*) markers in nonlysogens, or lambda plaque-forming units (PFUs) in lysogens, are transduced at relatively high frequency. The second site, *esp*-λ, is within lambda, between genes P and Q, and from this site, PFUs are readily transduced from polylysogens. Experiments with tandem heteroimmune dilysogens show that packaging proceeds leftward from this site. While initiation of packaging at *pac*-like sites probably contributes greatly to T1 transduction, *pac*-independent packaging of heterologous DNA can occur *in vitro* (see above), and a similar process may be involved in the transduction of low-frequency markers.

Small plasmids can also be transduced. The frequency is markedly enhanced by cloning *pac* or *esp*-λ into the plasmid. Transducing particles carry head-to-tail multimers of plasmid DNA; perhaps Grn can stimulate circle-into-circle recombination.

The phage-induced degradation of host DNA would be expected to compete with transduction. It does: most of the transducing particles are formed early in the infectious cycle, and *tar* mutations (gene 2.5), which block degradation, enhance the formation of transducing particles.

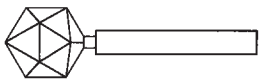
T4-LIKE PHAGES (*MYOVIRIDAE*)



Gisela Mosig, Department of Molecular Biology, Vanderbilt University, Nashville, Tennessee, USA

History and Overview

Bacteriophages T2, T4 and T6 were among the seven *Escherichia coli* phages ('Snow White and the Seven Dwarfs') selected by Max Delbrück to study fundamentals of viral replication. T2, T4 and T6, which are serologically related are called the 'T-even' phages. The genomes of these phages are contained in large (~170 000 bp) linear, double-stranded (ds) DNA molecules, whose termini contain repetitions of 3–5% of the genome, and are randomly permuted over circular maps (**Fig. 1**). The DNA molecules are packaged in elongated 'heads' of quasi-icosahedral symmetry. The heads are connected to tails whose baseplates and attached tail fibers (**Fig. 2**) are instrumental for recognition, adsorption and injection of the DNA into host bacteria. Differences in the tail fiber regions are important for recognition of different receptors in different host strains, which can be used to distinguish different members of the T-even family.

Since the early days of phage research, many phages from different parts of the world have been classified to belong to this family, based on similar genomic organization, regulatory patterns and sequence similarity of their 'essential' genes and on the presence of hydroxymethylcytosine (HMC) instead of cytosine in their DNA. The HMC residues are glycosylated to different extents in different members of the family. The essential roles of these modifications for the developmental strategy of these phages are discussed below (Restriction-Modification and Exclusion).

T-even phages are some of the most successful molecular parasites. Like all viruses, they depend for their propagation on many vital structures and functions of their hosts, e.g. membranes, energy metabolism, transcriptional and translational machines, and they manage to subvert host functions gradually to their own purposes in an exquisite choreography that allows adaptations to different environmental conditions, including different physiological states of the host. In contrast to many other viruses, they encode their own DNA replication, recombination and repair functions, making them particularly suitable for the study of these fundamental biological processes.

The gradual subversion of host functions to phage propagation is achieved at several interconnected levels:

1. A cascade of phage-induced proteins modifies the host RNA polymerase and its accessory proteins (sigma factors) covalently and noncovalently. These modifications together ultimately turn off all host transcription, and allow timed initiation of transcription from different classes of phage promoters and selective processivity of RNA polymerase on HMC-containing DNA.
2. There are no known T4 transcriptional repressors, but RNA processing by phage and host enzymes, translational repressors and still poorly understood modifications of ribosomes modulate T4 gene expression. Translational modulation is thought to be particularly suitable for physiological adjustments during the rapid development of T-even phages: one growth cycle is finished in less than 30 min at 37°C.
3. The host DNA and host mRNA, present at the time of infection, are rapidly degraded, and the breakdown products are efficiently reused to synthesize phage DNA and RNA.
4. The onset of the first phage DNA replication from specific origins requires host RNA polymerase to generate primers and is thereby connected to physiological regulatory processes of the host. Most subsequent initiations of replication forks depend on DNA primers in intermediates of recombination and on phage-encoded recombination proteins, which are entirely phage controlled.
5. During the later stages of development, DNA packaging proteins compete with replication–recombination proteins for the intracellular phage DNA, thereby coordinating replication and packaging.

These processes are interconnected at several levels. For example, late transcription depends on DNA replication, and in turn influences synthesis of and competitions between recombination, replication and packaging proteins. Together with multiple redundant pathways for these processes, the crossconnections allow a flexible development, which is the recipe for the success of the T-even phages.

Most of the recent work with T-even phages has

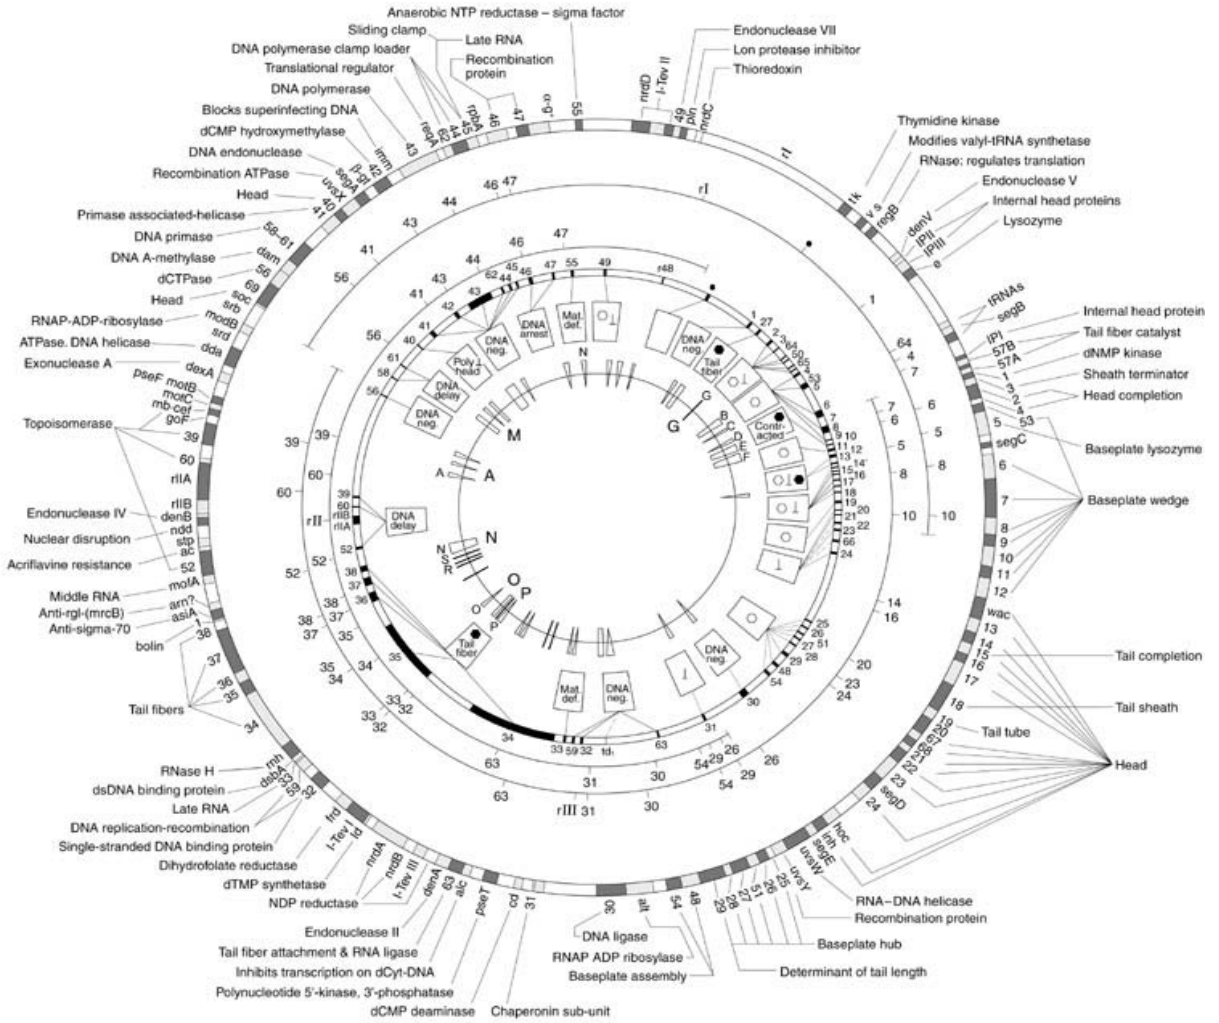


Figure 1 Comparison of several maps of T4 genes. The outermost circle shows the map of known genes and origins of replication, based on the DNA sequence. The next three overlapping circular segments drawn as thin lines show the positions of the indicated genes based on the probability of cutting ends during packaging between these genes and reference markers in *rI*, *rII* and *rIII*. The next circle shows the position of these genes based on recombination frequencies. The rectangles depict mutant phenotypes. The innermost circles represent the heteroduplex loops between T2 and T4 DNA. The substitution loop M is aligned with gene 69 in the outer circle.

been concentrated on T4, mainly because the isolation of a large collection of conditional lethal mutants has provided a powerful impetus for molecular analyses by biochemical and biophysical methods.

Genome Structure and Map

The genome of T4 resides in about 168 000 bp of double-stranded DNA containing glucosylated HMC residues. Using genetic tricks, phage mutants with unmodified cytosine-containing DNA can be isolated. Their DNA has been instrumental in cloning and sequencing the T4 genome.

Mature DNA molecules (chromosomes), packaged into virions, are linear and contain 3–5% of the genome as terminal redundancies at both ends. In contrast, intracellular replicating DNA is highly branched and contains multiple covalently linked (head to tail) copies of the genome. These structures are called 'concatemers'. Mature T4 chromosomes are cut during packaging of intracellular DNA (see below) at nearly random map positions. As a consequence, the ends of different individual chromosomes are almost randomly permuted over the circular genetic map (**Fig. 1**).

Numerous mutations, and their assignments to complementation groups and open reading frames (ORFs) have defined approximately 130 genes with known functions. In contrast to the lambdoid phages, early and late gene clusters and transcription units are

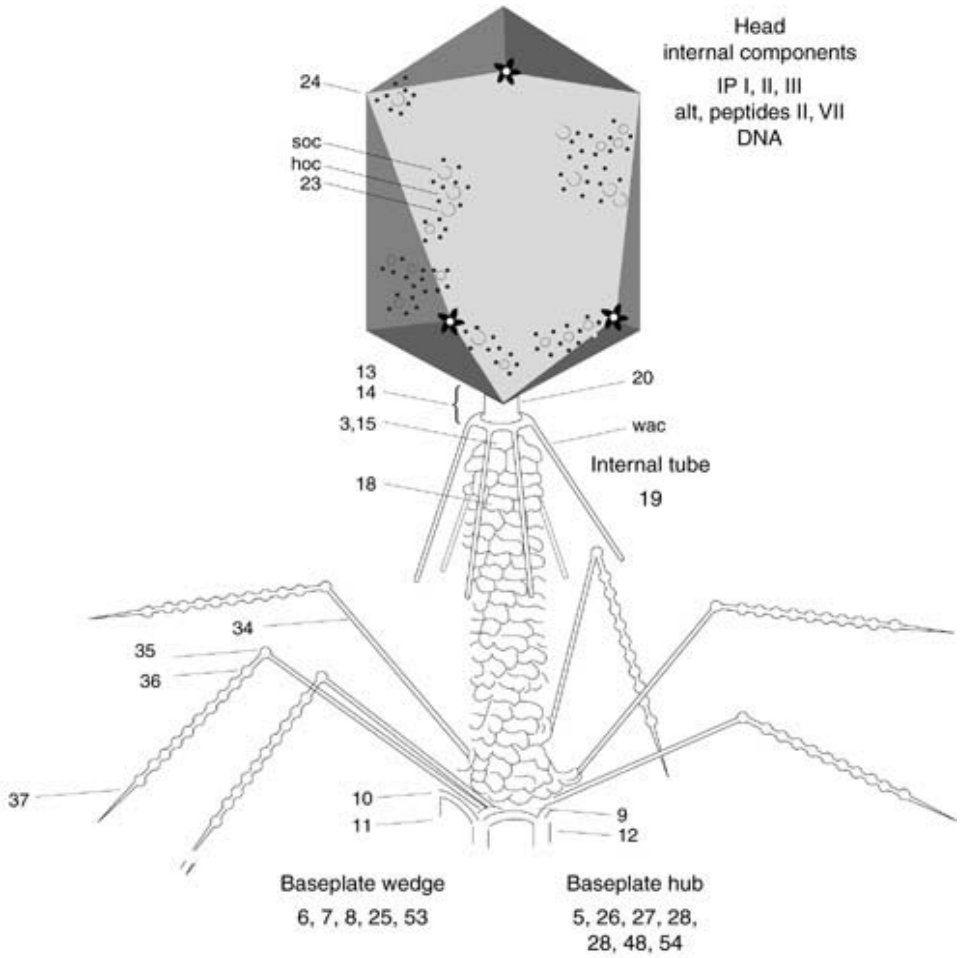

Figure 2 Diagram of the T4 virion, based on electron microscopy at 2–3 nm resolution. Locations of proteins are indicated by the corresponding gene numbers (cf. **Fig. 1**). The portal vertex composed of gp20 is attached to the upper ring of the neck structure inside the head itself. The internal tail tube is inside the sheath and itself contains a structural component in its central channel. The baseplate contains short fibers of gp12; these are shown in stored, folded conformation. (From Karam *et al* (1994) with permission of ASM Press.)

interdigitated, transcribed from multiple promoters, and genes for related or interacting proteins are not necessarily clustered (**Fig. 1**). In this respect, as well as in sequence similarities of certain proteins with the same functions, the T-even phages resemble more the herpesviruses than other phages.

More than 100 additional ORFs were revealed by DNA sequencing; many of them are still in search of functions. There are many overlapping coding regions, many ORFs are very small, and in some regions the two complementary DNA strands code for different proteins. In spite of the large genome size only a few short regions are devoid of coding capacity. These observations suggest that apparently redundant and 'nonessential' genes confer selective advantage, an inference that is supported by other evidence, discussed below.

Particle Structure and its Relationship to Assembly, Infection and Host Range

T-even phages build some of the most complex virus particles, which resemble lunar landing modules (**Fig. 2**). They devote more than 40% of their genetic information to synthesis and assembly of the protein components of these particles. The importance of host functions during assembly became apparent by 'host defective' (*hd*) mutations and compensating phage mutations and led to the discovery of the first chaperonin, now called GroEL.

The complex assembly pathways, revealed by exquisite mutational and biochemical analyses, accommodate efficient packaging of DNA and efficient genome transmission by allowing two-step adsorption to different receptors in the host's cell wall, and

easy release of the DNA during subsequent infection. Complete uptake of phage DNA by a host bacterium is also dependent on membrane potential.

Twenty-four genes are involved in head morphogenesis, more than 25 encode structural components of the tail and tail fibers and five more are needed as morphogenetic catalysts. Heads, tails and tail fibers are assembled in independent pathways and put together after the heads are filled with DNA.

Head shapes and the protein components of heads, tails and baseplates are similar among the T-even phages, except that two nonessential proteins (Hoc and Soc) that decorate and stabilize T4 heads are missing in some members of the family.

Heads

Assembly of heads is complex and has resisted *in vitro* reconstitution. *In vivo* it appears to be initiated on the bacterial membrane. The major head subunits (cleaved gp23) form the bulk of the heads; a related minor cleaved gp24 forms the pentamers at the vertices. Both proteins are converted into an assembly-competent state by a chaperonin composed of a host subunit groEL and a small phage subunit gp31, which takes the place of groES of the bacterial chaperonin. Sequential action of scaffolding proteins and cooperative conformational changes lead to sequential changes in dimensions and shapes of the head precursors while they are being assembled and filled with DNA. Extensive controlled proteolysis by a phage-encoded protease, whose precursor is part of the scaffolding assembly, cleaves head subunits, scaffolding proteins and other packaged proteins, e.g. the ADP-ribosylating Alt protein (see Temporally Controlled Gene Expression During T-even Development, below) and internal proteins bound to the DNA. Together, these processes render head assembly irreversible. Proteolysis *in vivo* is probably triggered by entry of some DNA; *in vitro* it can be achieved by other conditions. In any case, proteolysis is a prelude to rearrangements of the subunits and expansion of the head volume and allows decoration of the heads with Hoc and Soc proteins mentioned above.

Head size is not uniquely determined. The normal T4 head can be described by skewed icosahedral symmetry (T = 13) whose side faces have been elongated (Q = 21). It can accommodate full-length chromosomes with terminal redundancies. Anomalous heads of different sizes and shapes are made in low proportions in wild-type T4 infections, and in higher proportions when infecting phages have mutations in genes for head subunits or scaffolding proteins, or due to incorporation of arginine analogues. Head lengths and shapes are determined at an early assembly stage, prior to formation of the unprocessed proheads.

Small heads ('petites') contain incomplete genomes, which represent nearly random permutations of the genetic map, and recombination between several of them reconstitutes complete genomes with expected frequencies. Most of the larger 'giants' contain oversized chromosomes representing linear concatemers. A small proportion of heads contain more than one DNA molecule; it is not yet known whether these are packaged into the rare anomalous heads containing more than one portal vertex.

The anomalous head sizes and shapes occur because assembly depends on numerous interactions of several proteins, each of which can exist in multiple conformational states and in different concentrations.

Tails

The tails are built like complex cocked mechanical devices with additional catalytic activities. The multifunctional baseplate contains information for building the tail and serves as a perfect valve for DNA entry into bacteria in the next infectious cycle. It consists of a central hub, six outer wedges and six tail spikes, each of these structures being assembled from several different subunits. Baseplate formation combines aspects of catalyzed assembly, self-assembly, concerted conformational changes and proteolysis.

Baseplate components are important for the irreversible second step of phage adsorption. A concerted conformational change of all baseplate components from a hexagon to a star configuration opens a hole in the tail to allow DNA to exit from the particles. It also activates the lysozyme activity of gp5 that actively punctures the host cell wall from the outside.

The tails are of remarkably uniform length, determined by a subunit of the baseplate that acts like a tape measure. Tails have a tubular inner core, through which DNA passes from the head to the baseplate, and an outer sheath that contracts during infection by conformational changes of individual subunits.

Tail fibers

Six bent tail fibers are attached to the tail of each particle. Each fiber consists of two half-fibers whose proteins are joined at an angle. The inner (proximal) half-fibers are attached to the baseplate. The outer (distal) half-fibers contact phage-specific receptors on the surface of the bacterial cell wall during the first, reversible step of adsorption. In many newly formed phage particles this end is transiently attached to the

junction of heads and tails, rendering the fibers less fragile.

Tail fibers of different T-even phages appear superficially similar, but the amino acid sequences and genes are different in the different family members, resulting in recognition of different receptors in the host cell wall. These differences are used to distinguish different T-even phages by their host range. Apparently, illegitimate recombination with other DNA sequences, e.g. those of prophages that reside in the host genome, allow rapid evolution and adaptations to different receptors in different hosts' cell walls under selective pressure.

Temporally Controlled Gene Expression During T-even Development

T-even phages inactivate host translation and transcription in many small steps by multiple redundant mechanisms. The temporal regulation of phage gene expression is likewise exerted at many levels: transcript initiation, elongation and termination; stability, conformation and recognition by ribosomes of the transcripts, and combinations thereof.

Different classes of phage genes are distinguished in terms of timing as early (immediate early, IE), middle (delayed early, DE), or late. Operationally, IE genes are distinguished from the other classes in that they can be transcribed by host RNA polymerase without modification by phage proteins. Expression of all other T-even genes requires phage protein synthesis for several reasons. Successive transcription initiations from early, middle and late promoters are accomplished by a cascade of RNA polymerase modifications: the α subunits are covalently ADP-ribosylated and several accessory proteins bind non-covalently. Moreover, RNA polymerase can be attracted to middle promoters by proteins bound to specific DNA sequences, and it can be activated for initiation at late promoters by another protein bound to DNA, and used in both late transcription and DNA replication, the sliding clamp gp45 (see DNA Replication and Recombination In Vivo, below).

Another classification criterion distinguishes all genes that are expressed prior to the onset of DNA replication as 'prereplicative' or 'early' from 'post-replicative' or 'late' genes whose expression depends on DNA replication.

The distinction between different classes is, however, blurred because most T4 genes are under dual or multiple controls and because of overlapping and interdigitated transcriptional, post-transcriptional and translational control signals. Thus, promoters can be classified as early, middle or late, but genes defy this classification. One example (of ten known T4 regions with overlapping early, middle and late transcripts) is shown in **Fig. 4**. The regulation of T4 gene expression is better described by a web of interacting regulatory networks than by simple progression along a linear timed pathway.

Collectively, prereplicative genes encode: (1) nucleases that degrade the host DNA; (2) enzymes of the deoxyribonucleotide biosynthesis complex; (3) proteins of the replication and recombination machines; (4) proteins that modify the T4 DNA to protect it from degradation by its own nucleases and from other restriction enzymes; (5) several tRNAs; (6) proteins that modify structure and function of the host RNA polymerase; (7) at least one RNase (RegB protein) that selectively destroys certain early transcripts; (8) proteins that repress translation (e.g. RegA protein). In addition some prereplicative transcripts serve as primers for leading strand DNA synthesis in origins of replication (see below).

A T4-encoded sigma factor, gp55, associated with host core RNA polymerase, directs transcription from late promoters. Late transcription requires several additional proteins and concomitant DNA replication, further discussed below.

The late genes code for virion components, for some DNA repair and recombination proteins, and proteins that cut and package the complex vegetative DNA into preformed heads. A soluble lysozyme, different from but evolutionarily related to the baseplate lysozyme, lyses the host bacteria to release the progeny phage particles. Late genes that are under multiple controls (e.g. **Fig. 4**) can be expressed early, particularly when the RNA is broken or when infections occur at high temperatures, i.e. conditions that allow access of ribosomes to the translation initiation regions of late genes in the early RNA.

Transcription

The first set of promoters, early promoters, resembles the consensus sequence of *E. coli* promoters with additional information content (**Fig. 3a**). They are recognized by the *E. coli* RNA polymerase containing the major sigma factor σ^{70}, at a time when the host DNA is still largely intact. T4's early promoters are preferred to *E. coli* promoters, apparently not due to gene dosage effects. Several factors are thought to contribute to such preferential transcription of T4 versus *E. coli* genes:

1. Many early T4 promoters contain upstream polyA tracts, functioning as bendable sequences or as 'promoter UP elements'.
2. Arg265 of one α subunit of the host's RNA polymerase is ADP-ribosylated immediately after infection by the T4 Alt protein that is packaged

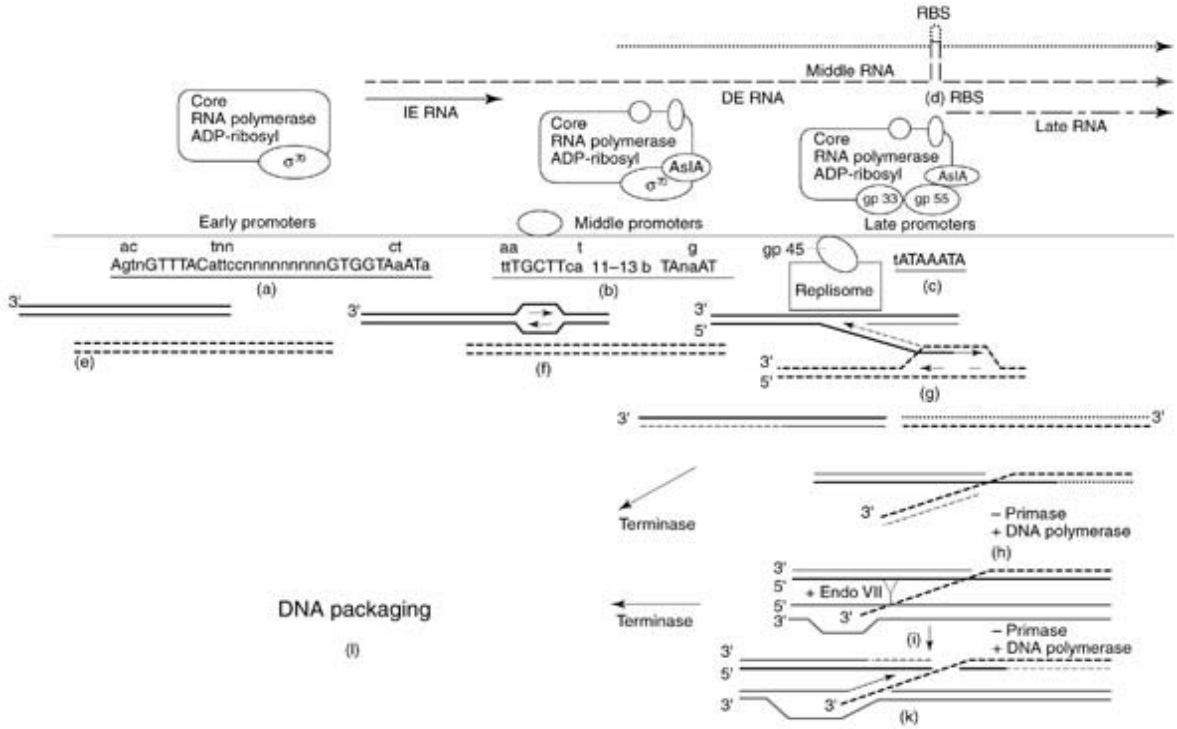

Figure 3 A diagram of transcription, DNA replication, recombination and packaging during T4 development (progressing in time after infection from left to right). The upper panel (a)–(d) shows overlapping early, middle and late transcripts in a 'generic' region, the modifications of host RNA polymerase after infection and the consensus sequences of early, middle and late T4 promoters that are recognized by different forms of the RNA polymerase. Ribosome-binding sites for late proteins in prereplicative transcripts are sequestered in hairpins (d); see also **Fig. 4**. The lower panel shows different stages of DNA replication and recombination. (e) Two infecting permuted T4 chromosomes. (f) Bidirectional origin initiation in one of them. Leading strand synthesis is primed by RNA polymerase-generated transcripts; lagging strand synthesis is primed by short RNAs synthesized by primase. As soon as the first growing point reaches an end (only one is shown), the partially single-stranded 3′ terminus invades the homologous region of another chromosome (g) or the terminal redundancy of the same chromosome (not shown). Join–copy replication is initiated from the invading 3′ DNA end. When an endonuclease cuts at the recombinational junction, join–cut–copy recombination can be initiated from the 3′ ends to allow copying of single-stranded segments of an invading DNA. Together both processes generate branched concatemers, which become increasingly more complex by reiterations. This DNA is processed to mature, unbranched chromosomes during packaging. Parental molecules are drawn as bold lines, filled with different patterns. Newly synthesized DNA is drawn as thin lines. Discontinuous synthesis of Okazaki pieces is indicated by dashed lines, continuous synthesis by solid lines. Arrowheads indicate the directions of RNA or DNA synthesis. (Modified from Mosig *et al* (1995).)

and injected with the phage DNA. This Arg265 is located at the dimer interface of the two α-subunits and it is important for activation of many strong *E. coli* promoters including those for ribosomal RNA. Its modification affects transcription in several ways.

3. At the time of infection, the host DNA is associated with nonspecific (e.g. HU, NS) or semi-specific (e.g. IHF, FIS) DNA binding proteins. In contrast, the infecting phage DNA is at first largely free and may be much more readily accessible to the host's RNA polymerase.

Host transcription is further reduced and the transition from host to phage transcription is accelerated by products of several early phage genes. Some of them disrupt the host nucleoid. Alc protein selectively inhibits transcript elongation on the host DNA but allows elongation on phage DNA, whose cytosine residues are hydroxymethylated and glycosylated (see below). The *asiA* product binds to the C-terminal segment of σ^{70}, interfering with transcription from all host promoters with standard -35 regions, as well as from T4 early promoters. However, phage infection can proceed because most prereplicative genes can also be transcribed from middle promoters (**Fig. 3**).

MotA protein bound to mot-boxes in middle promoters (**Fig. 3b**) recognizes Ast-A-modified RNA polymerase and allows initiation from middle promoters and expression of most prereplicative genes after the AsiA protein has inhibited initiation

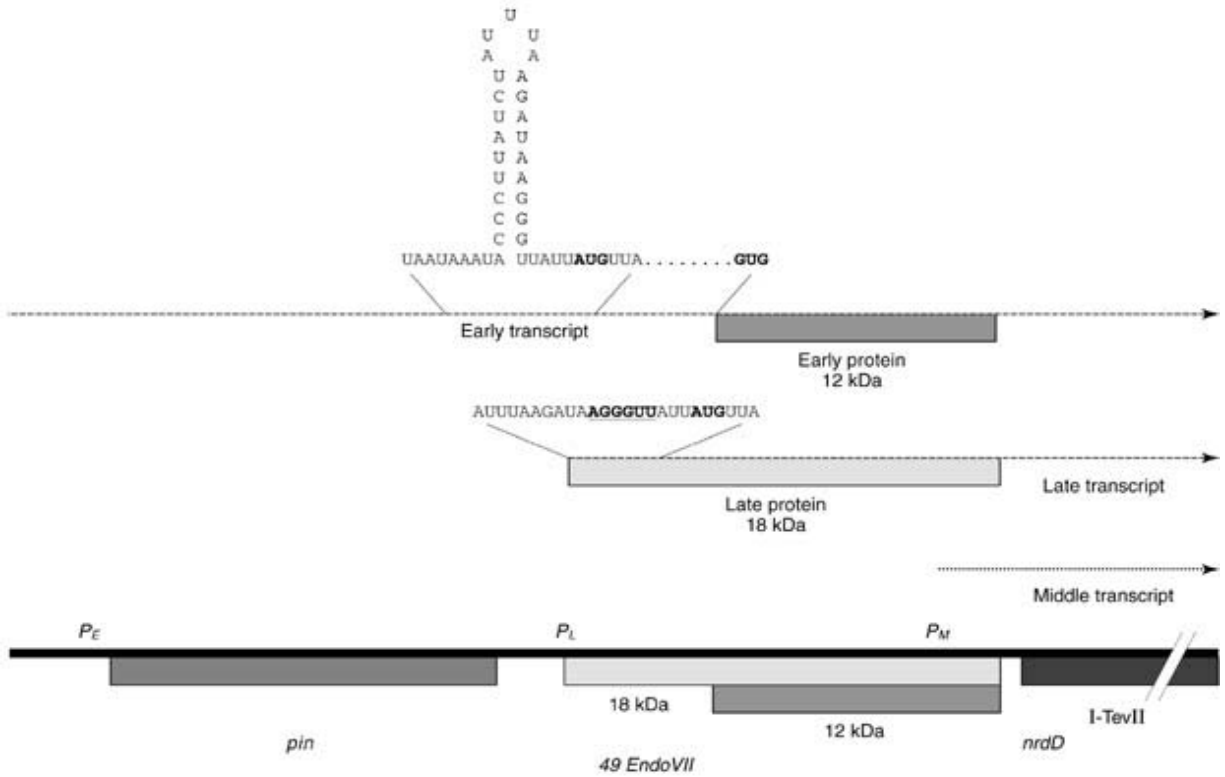

Figure 4 An example of interwoven transcriptional and post-transcriptional controls in the T4 gene *49* region (cf. **Fig. 1**). The locations of early (P_E), middle (P_M), and late (P_L) promoters and the protein-encoding segments of genes *pin*, *49* and *nrdD* are marked. Overlapping transcripts are distinguished by differentially patterned horizontal lined with arrows. The *nrdD* transcripts encode two proteins, one from spliced and the other (a truncated peptide) from unspliced RNA. I-TevII is a self-splicing intron. The late gene *49* transcript is predominantly translated into the 18 kDa EndoVII. In the larger, early transcript the Shine–Dalgarno sequence is sequestered in a hairpin. A shorter 12 kDa protein can be initiated in frame from an internal GUG. (Modified from Karam *et al* (1994).)

from early promoters. Initiation from early and middle promoters can overlap in time, depending on the proportions of RNA polymerase molecules that have been modified. Initiation from late promoters (**Fig. 3c**) requires a phage-encoded sigma factor (gp55), activation by gp45, the sliding clamp of the T4 replisome, and an adapter protein (gp33). In addition it requires concomitant DNA replication, or 'uncoupling' from DNA replication by combinations of certain recombination- and ligase-defective mutations. The critical common aspect of the latter conditions is that single-strand interruptions in the DNA provide entry sites for the sliding clamp, gp45, that is loaded on to the DNA by a complex of gp44 and gp62. The sliding clamp has to track along DNA to activate RNA polymerase bound at late promoters by T4 σ^{gp55}, to form open complexes and initiate transcription.

As indicated in **Figs 3** and **4**, most T4 genes can be transcribed from several promoters belonging to different classes. Genes downstream of any promoter may be poorly expressed because of premature *rho*-dependent transcription termination or because of RNA processing or degradation, or because the ribosome binding sites are sequestered by secondary structures.

Certain *rho* (transcription termination factor) mutations (also called host defective, *hdF* or *nusD*) of *E. coli* prevent growth of wild-type T4 by causing premature termination of many T4 transcripts. Mutations that allow growth in these specific *rho* mutants have been found in three nonessential T4 genes. It was initially thought that the corresponding T4 genes encode transcriptional antiterminators, but current evidence suggests that at least one of them allows T4 growth in the (*nusD*) *rho* mutants, because it stabilizes the few functional transcripts that have not been prematurely terminated.

Several additional phage proteins with unknown functions associate with host RNA polymerase. They are probably important in facilitating transcription initiation and elongation after phage infection under certain stress conditions.

The timing of differential gene expression during

T4 development is modulated by specific nucleases; for example, a T4 *regB*-encoded ribonuclease cleaves early transcripts rather selectively in the ribosome-binding sites of certain early T4 genes, thereby reducing expression of certain early T4 genes, and presumably of some host genes, at the post-transcriptional level. Moreover, several host nucleases and autocatalytic cleavages are important in processing the precursor RNAs for eight T4-encoded tRNAs and two tRNA-like structures of unknown function. The T4 tRNAs supplement host tRNAs during translation and are important for codons that are rare in *E. coli*, but frequent in T4; thereby they help maintain the different codon usages and AT contents of phage and host.

The introns in at least three T4 mRNAs (for thymidilate synthetase, *td*, and aerobic and anaerobic nucleotide reductase genes *nrdB* and *nrdD* respectively, have to be excised by self-splicing. Numerous mutations define the active centers of these ribozymes in exquisite detail.

Translational controls

Due to the interspersion of early and late genes on the T4 map (**Fig. 1**) and the 'sloppiness' of the interdigitated T4 transcription patterns shown in **Figs 3** and **4**, many early and middle transcripts are extended into late genes. Nevertheless, few or no corresponding late proteins are synthesized early at normal growth temperatures of 37°C or below. At higher temperatures there is some early expression of these late genes *in vivo* and early RNA sheared *in vitro* can direct synthesis of these late proteins. It is remarkable that expression of all of ten such late genes investigated so far follows similar patterns: in the long early transcripts a hairpin sequesters the translation initiation region, either the Shine–Dalgarno sequence or the initiation codon, or both. An additional late promoter immediately upstream of the late gene directs synthesis of transcripts that cannot form the hairpin, and these transcripts are efficiently translated (**Figs 3d** and **4**). Remarkably, phage evolution has conserved the early transcription of these late genes, while incorporating other means of preventing their translation. Pausing of RNA polymerase at such hairpins might facilitate access of the T4 σ^{gp55} required for initiation from the late promoters.

Three additional regulatory systems of T4 use translational controls. Expressions of gene *32* for the major single-stranded DNA binding protein (SSB) involved in DNA replication, recombination and repair, and of gene *43* for DNA polymerase, are autogenously regulated by translational repression. A more general, nonessential translational repressor (RegA protein), which binds to several specific transcripts, can reduce translation of several T4 replication proteins and of some host proteins. This repression is most apparent under experimental conditions that prolong early and delay late transcription.

DNA Replication and Recombination *In Vivo*

DNA replication and recombination are tightly interwoven, following several different redundant pathways. The T-even phages provided the first and most compelling evidence for recombination-dependent DNA replication. Redundant alternative modes of replication and recombination ensure that both processes work under many different conditions and during different stages of development. Known interrelationships are shown diagrammatically in **Fig. 3.**

The first round(s) of DNA replication are initiated from one of several potential origins. Because of the circular permutation of chromosomal ends (**Fig. 3e**), in each individual chromosome any origin is located at different distances from the ends. In most chromosomes only one origin is used, perhaps due to limited abundance of replisome components. Different origins share the requirement for transcription from early or middle promoters, generating large transcripts that can serve as primers for leading strand DNA synthesis at one of several sites approximately 1 kb downstream of the promoter. However, each of the four origins that have been closely investigated has a different sequence and overall structure, presumably related to preferred usage under different conditions. Three origins (*A*, *F* and *G*) require transcription from middle promoters, *oriE* depends on an early promoter. **Fig. 3f** depicts initiation from an arbitrary generic origin.

The transition from σ^{70}-dependent prereplicative transcription to T4 σ^{gp55}-dependent late transcription inhibits initiation from these origins, either by default (because the RNA polymerase no longer recognizes origin promoters), or because late protein(s), e.g. UvsW protein, actively prevent transcripts from serving as primers for DNA synthesis, or for both reasons.

Subsequent DNA replication is initiated from intermediates of homologous recombination (**Fig. 3g, i**). The recombinational intermediates are mainly formed by invasion of a single-stranded terminus into the homologous region of another molecule (or at the other end of the same molecule). When T4 chromosomes are broken by radiation damage or by certain

nucleases, single-stranded termini of internal breaks can initiate recombination similarly as natural ends of infecting chromosomes. This is a major reason for the recombinogenic effects of radiation damage.

The recombination intermediates can initiate replication from the 3′ ends of the invading single strand (join–copy recombination, **Fig. 3g**), or, after an endonucleolytic cut at the junction from a 3′ end in the invaded strand (join–cut–copy recombination, **Fig. 3i**). The join–copy mode can start as soon as a growing point has reached an end. The join–cut–copy mode requires an additional endonucleolytic cut, which probably depends on one or more late proteins, and therefore occurs later. This mode can bypass the requirement for primase or topoisomerase in T4 DNA replication and can be used when these enzymes are limiting, e.g. late in infection. Ultimately, reiterations of these processes generate a highly branched concatemeric network in which no individual chromosomes can be distinguished.

Of course, not all recombination junctions need to be converted to replication forks. Some T4 recombination can occur, albeit with delay, when DNA replication is inhibited. Electron micrographs of such T4 DNA intermediates provided the first compelling evidence for the importance of branch migration in homologous recombination. Under these conditions, no viable progeny is produced, because no packagable concatemers are formed; there is little, if any, late transcription, and there are no heads to be filled.

DNA Replication *In Vitro*

Virtuoso biochemical and biophysical characterization of replication proteins, in combination with genetic experimentation, has led to an understanding of functions and interactions of the basic replication proteins in the replisome, a biological machine that moves the replication fork, or through which the replicating DNA is passaged. Seven proteins, corresponding to genes *43* (DNA polymerase), *44* and *62* (sliding clamp loader), *45* (sliding clamp), *41* (DNA helicase), *61* (primase to synthesize primers for lagging strand synthesis) and *32* (single-stranded DNA-binding protein), form an active complex that replicates model templates with *in vivo*-like speed. Leading and lagging strand synthesis are coupled by interactions of primase-helicase with DNA polymerase. These basic reactions and protein functions are similar in all procaryotic and eucaryotic systems; in fact, some of the T4 proteins can partially substitute in eucaryotic *in vitro* systems.

Recombination-dependent initiation by a join–copy mechanism has also been achieved. Consistent with genetic analyses, these *in vitro* reactions require several recombination proteins in addition to the seven basic replication proteins just mentioned: the T4 RecA analogue gpUvsX, the single-stranded DNA binding proteins gpUvsY and gp*59*. The latter protein loads the gene *41* helicase, an enzyme that is important for branch migration in addition to its unwinding function at the replication fork. Initiation by the join–cut–copy mechanism and origin initiation have not yet been achieved *in vitro*.

Many of the T4-encoded DNA enzymes, most importantly DNA ligase, kinase and polymerase, are now standard components of cloning procedures and kits.

DNA Packaging

The ends of mature T4 chromosomes are nearly randomly permuted over the map, and 3–5% of the genome is repeated at both ends as so-called terminal redundancies. Mature chromosomes are generated from the branched concatemeric vegetative DNA during packaging by a terminase, a heteromeric protein encoded by genes *16* and *17* that associates with DNA and with gp20 at the portal vertex of the head (**Fig. 1**) and uses ATPase activities for the head-filling process. Gene *17* produces several proteins of different sizes by initiation from in-frame internal initiation codons. Several of these proteins have nuclease activity; the largest one also binds non-specifically to single-stranded DNA segments. There is controversial evidence as to whether T4 has sequence specific *pac* sites or whether it initiates packaging at such random single-stranded DNA segments. Perhaps both processes can initiate packaging. If the first initiation of packaging is a relatively rare event, processive packaging of 103–105% genome lengths to fill the preformed heads can account for the random circular permutation of the ends in mature virion DNA by either mechanism. Endonuclease VII which cuts Holliday and Y junctions and mismatched base pairs *in vitro* is required *in vivo* to trim the branches of vegetative DNA. It can associate with gp20 and retain nuclease DNA ligase, endonuclease V and topoisomerase are also required, presumably to provide uninterrupted double-stranded DNA as packaged chromosomes.

An *in vitro* packaging system has been developed to package large pieces of foreign DNA.

Restriction-Modification and Exclusion

In the following discussion the term 'restriction' is used in its broadest meaning, not limited to type II restriction enzymes. The complex modification and restriction of T4 DNA and of other DNA by T4 can

best be rationalized as the result of an ongoing evolutionary process that includes exchanges between the phage, its host and prophages resident in the host.

T-even phages destroy dCTP, synthesize dHMCTP and use the latter for DNA synthesis. This modification protects the T4 DNA against T4-encoded restriction endonucleases II and IV that degrade the host DNA as part of the parasitic strategy to usurp the host. However, HMC residues render DNA susceptible to the Mcr restriction systems of the host. These host functions were the first restriction systems (then called Rgl) discovered. They are now called McrA and McrB, because they restrict DNA containing methylcytosine or hydroxymethylcytosine. These restriction functions are overcome when the HMC residues are glycosylated. In T4 DNA, all HMC residues are modified; 70% with α- and 30% with β-glycosyl linkages. In T2 and T6 DNA, there are no α-glycosyltransferases, and 25% of the HMC residues remain unglycosylated. T6 contains many diglycosylated residues. In addition, a T4-encoded early anti-restriction protein (Arn) protects nonglycosylated T4 DNA against one but not all of these host restriction enzymes.

T2 and T4, but not T6, encode a Dam methylase that methylates 0.5–1.5% of the adenine residues at the N^6 positions, mostly but not exclusively at GATC sequences. These enzymes exhibit patches of similarity at the protein level with the *E. coli* Dam methylase and the *Dpn*II methylase of *Diplococcus pneumoniae*. The only proven physiological role of adenine methylation is protection against the phage P1 restriction system, when there is no HMC glycosylation.

Intriguingly, several other 'host' genes that exclude T4 by various strategies are located in resident prophages or their defective derivatives.

The Mcr A system of K12 mentioned above resides in a cryptic prophage-like element, *e14* that is not present in all *E. coli* strains.

Another protein of *e14*, Lit, in combination with a short internal peptide (*gol*) of the major T4 head protein, gp23, cleaves the host's elongation factor EF Tu, thereby inhibiting translation of all late T4 proteins.

The classical example of phage exclusions by genes of resident prophages is that of T4 *rII* mutants in lambda lysogens by lambda's *rexA* and *rexB* genes. This exclusion was elegantly used in Benzer's classical analyses of structure and function of a gene. It occurs at the time of transition from join–copy to join–cut–copy recombination mentioned in the section on DNA replication and recombination, and it involves several enzymes important in the latter mechanism, as well as a putative ion channel produced by lambda's Rex proteins. Probably the otherwise nonessential RII proteins counteract this restriction, but the molecular mechanism is still unknown.

Another cryptic DNA element of certain *E. coli* strains, *prr*, encodes a PrrC protein that excludes T4 RNA ligase/polynucleotide kinase-deficient mutants. PrrC protein is a cryptic RNA endonuclease that is activated by the small (26 residues) T4 Stp protein to cleave the anticodon loop of an essential host $tRNA^{Lys.}$ T4 RNA ligase/polynucleotide kinase can repair this damage, but in the absence of RNA ligase the cleavage of this tRNA is lethal to T4 protein synthesis. Intriguingly, the *prrC* gene is located between three genes of a type IC restriction cassette. The corresponding proteins are thought to inhibit PrrC RNase activity in uninfected cells.

Phage P2 lysogens exclude T4 by two mechanisms: the Tin protein poisons the single-stranded DNA binding protein gp32 that is essential for all T4 DNA replication and recombination, and the P2 Old protein can degrade DNA from ends, nicks and gaps (although the ends of the infecting T4 chromosomes are probably protected by bound T4 gp2).

Evolution

Sequences and map positions of the 'essential' genes whose products have the same functions of most T-even phages are similar. In contrast, genomes of different members of the family have different 'nonessential' genes interspersed between these essential genes (**Fig. 1**). The heterologies contribute to apparent exclusions of alleles of one phage by another, and to the species barriers between different members of the family. They first became evident as insertion or substitution loops in electron micrographs of heteroduplex DNA prepared *in vitro* by annealing single strands of T2, T4 and T6 DNA, and have been confirmed by sequence comparisons in many cases.

In some cases the sequence divergence reflects gene amplifications and permutations of duplicated sequences. The tail fiber genes of different T-even phages appear to have diverged by illegitimate recombinations with genes of other phages, including prophages residing in the host genome. Substitutions of sequence blocks of individual genes by foreign sequences can account for the variability between different members of the family. In turn, these substitutions allow adsorption to different hosts with different receptors, accounting for the remarkable coevolution of viral and host genomes.

Such illegitimate recombinations are not limited to genes for recognition proteins. Illegitimate pairing of partially homologous sequences and join–copy and

join–cut–copy recombination (discussed above) were apparently involved in horizontal gene transfer of nonessential genes adjacent to the essential dCTPase gene, and probably other genes as well. Although inactivating their functions has little or no consequences for phage development in the laboratory, we surmise that these genes are important for viral growth and survival under different physiological conditions, in different hosts with different receptors or containing different prophages, and in the face of various restriction systems imposed by different hosts.

Future Perspectives

The T-even phages have been instrumental in first formulations of several fundamental biological concepts: (1) the unambiguous recognition of nucleic acids as genetic material; (2) the operational distinctions in defining the gene by mutational, recombinational or functional analyses (the concepts of muton, recon and cistron); (3) the demonstration of mRNA; (4) the nature of the triplet code, and the importance of initiation and nonsense codons; (5) homologous recombination as exchange between DNA molecules, and the importance of heterozygotes in this process; (6) the role of homologous recombination in initiating DNA replication; (7) restriction and modification of DNA as important aspects of host–virus interactions; (8) light-dependent and light-independent DNA repair mechanisms; (9) the importance of pathways of macromolecular assemblies (protein machines) in morphogenesis and DNA metabolism; (10) the presence of self-splicing introns and mobile endonucleases in prokaryotes; and (11) the facility of ribosomes to skip unspliced introns in mRNA during translation.

Recent progress towards understanding the importance of redundant pathways and proteins for fundamental processes is bound to lead to better appreciation of the functional significance of web-like interconnections between different processes for development, for virus–virus and virus–host interactions, and for evolution.

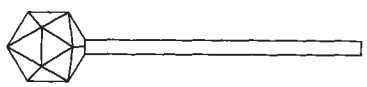
T5-LIKE PHAGES (*SIPHOVIRIDAE*)



D. James McCorquodale, Midwestern University, Downers Grove, Illinois, USA

Classification and Morphology

Bacteriophage T5 and its relatives BF23, PB, BG3 and 29-alpha are in the T5-like viruses genus of the *Siphoviridae* family. They have a general morphology that consists of an icosahedral head and a long noncontractile flexible tail. The head of T5 has an average diameter of 90 nm. The tail is attached to one of the head apices via a head–tail linker protein and has three L-shaped tail fibers attached at a site near its distal end. A ring-like structure is formed at this site as a result of the attachment of these tail fibers. The tubular tail undergoes a transition at the tail fiber attachment site to a conical form, which tapers into a single straight tail fiber. The tail has a diameter of 12 nm with a length of 190 nm. The cone (12 nm) plus

join–cut–copy recombination (discussed above) were apparently involved in horizontal gene transfer of nonessential genes adjacent to the essential dCTPase gene, and probably other genes as well. Although inactivating their functions has little or no consequences for phage development in the laboratory, we surmise that these genes are important for viral growth and survival under different physiological conditions, in different hosts with different receptors or containing different prophages, and in the face of various restriction systems imposed by different hosts.

Future Perspectives

The T-even phages have been instrumental in first formulations of several fundamental biological concepts: (1) the unambiguous recognition of nucleic acids as genetic material; (2) the operational distinctions in defining the gene by mutational, recombinational or functional analyses (the concepts of muton, recon and cistron); (3) the demonstration of mRNA; (4) the nature of the triplet code, and the importance of initiation and nonsense codons; (5) homologous recombination as exchange between DNA molecules, and the importance of heterozygotes in this process; (6) the role of homologous recombination in initiating DNA replication; (7) restriction and modification of DNA as important aspects of host–virus interactions; (8) light-dependent and light-independent DNA repair mechanisms; (9) the importance of pathways of macromolecular assemblies (protein machines) in morphogenesis and DNA metabolism; (10) the presence of self-splicing introns and mobile endonucleases in prokaryotes; and (11) the facility of ribosomes to skip unspliced introns in mRNA during translation.

Recent progress towards understanding the importance of redundant pathways and proteins for fundamental processes is bound to lead to better appreciation of the functional significance of web-like interconnections between different processes for development, for virus–virus and virus–host interactions, and for evolution.

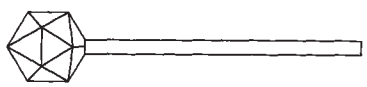
T5-LIKE PHAGES (*SIPHOVIRIDAE*)



D. James McCorquodale, Midwestern University, Downers Grove, Illinois, USA

Classification and Morphology

Bacteriophage T5 and its relatives BF23, PB, BG3 and 29-alpha are in the T5-like viruses genus of the *Siphoviridae* family. They have a general morphology that consists of an icosahedral head and a long noncontractile flexible tail. The head of T5 has an average diameter of 90 nm. The tail is attached to one of the head apices via a head–tail linker protein and has three L-shaped tail fibers attached at a site near its distal end. A ring-like structure is formed at this site as a result of the attachment of these tail fibers. The tubular tail undergoes a transition at the tail fiber attachment site to a conical form, which tapers into a single straight tail fiber. The tail has a diameter of 12 nm with a length of 190 nm. The cone (12 nm) plus

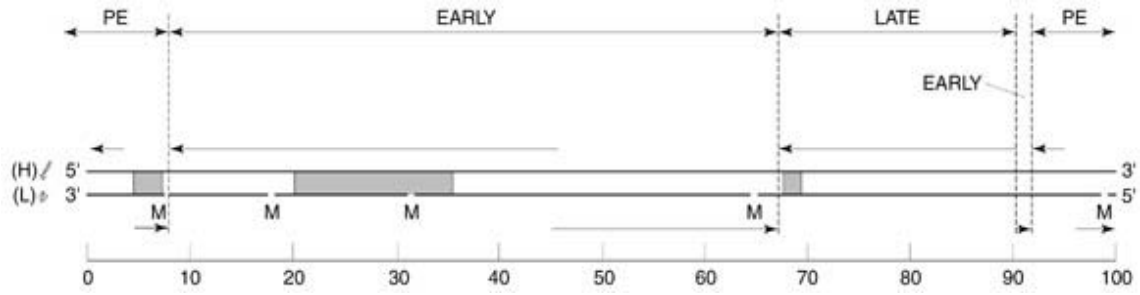


Figure 1 Structure and organization of the genome of T5 and BF23. The heavy double lines represent the two DNA strands of the double-stranded genome. H and L indicate the relative bouyant density of the upper un-nicked strand to that of the lower nicked strand. The script '1' and 'r' indicate leftward transcription from the upper strand and rightward transcription from the lower strand, in agreement with the 3′-5′ polarities of the two strands. Major nicks in the lower strand are indicated by gaps in the heavy line and the letter 'M'. Deletable regions are indicated by shaded regions between the two heavy lines. The distribution of pre-early, early and late genes along the genome is indicated by name and by lines with arrowheads at both ends. The direction of transcription for each class of genes is indicated by directional arrows above and below the two heavy lines. The 0–100 scale at the bottom divides the genome into percentages from left to right.

the single straight tail fiber (50 nm) bring the total length of the tail to about 250 nm. The phage protein (Oad) that binds irreversibly to the host receptor (FhuA) is located in the conical region. The tail is hollow from the head to the cone-shaped structure and provides part of the route for transfer of phage DNA from the phage head to the host cell. A total of 15 different polypeptides have been detected in mature T5 phage particles and the number of copies of each polypeptide per particle depends on the part of the phage structure that it forms. For example, the major head polypeptide is present at 730 copies per particle whereas the straight tail fiber polypeptide is present at only five copies per particle.

Structure of the Genome

The DNA within mature T5 or BF23 particles is linear, double-stranded, and about 121 300 bp long (**Fig. 1**). It contains only the four common bases, adenine, guanine, cytosine and thymine, none of which are methylated. Its AT content is 61%. Two features of the DNA stand out. First, it has unusually long direct terminal repetitions of about 10 100 bp and second, it is nicked at precise sites, and all nicks are in one strand only. The nicks consist of a missing phosphoester bond between the 5′-phosphate group of one nucleotide residue and the 3′-OH group of its adjacent nucleotide residue. Thus, these nicks can be ligated with DNA ligase. The nicks are introduced by a site-specific nicking enzyme coded by genes *sciA* and *sciB*, which map at the right end of the 'late' region of the genetic map (see **Fig. 1**). Nicks are classified as 'major' or 'minor', with major nicks occurring in virtually all phage DNA molecules and minor nicks occurring in only a small fraction of these molecules.

The frequency of the major nicks (four per 111 200 bp) predicts a recognition sequence of seven or eight nucleotides. A prominent sequence on the 5′ side of nicks in T5 DNA is 5′-GCGCGGTG-3′, and the sequence in the unnicked strand around the major nick at 64.8% of the length of DNA from the left end of both T5 and BF23 DNA is 5′-CCCGCGCCC-3′. The left end is defined as the end that always enters the host cell first during normal infections (**Fig. 1**). Thus the sequence most efficiently recognized by the nicking enzyme appears to be

```
intact strand: 5′  (C) | CCGCGCC | C 3′
nicked strand: 3′ G(T) | GGCGCGG | G 5′
                       ↑
                      nick
```

The boxed in sequence would generate major nicks whereas minor variations in this sequence would presumably generate minor nicks.

The DNA can be deleted in three regions without affecting viability (**Fig. 1**). The major deletable region is between positions 20.0 and 35.7%. Although this region spans about 19 kb, only about 13.3 kb can be deleted from the DNA and still be packaged. Larger deletions yield DNA too small to be packaged. This deletable region contains genes that code for at least one tRNA for each of the 20 amino acids found in proteins. Another deletable region is between positions 4.1 and 7.1% (about 3.6 kb) and is therefore in the terminal repetition. It follows that most genes in the right half of the terminal repetition are unessential. The third deletable region is between positions 67.8 and 69.5% and is within a nonessential gene that codes for the L-shaped tail fibers of the

mature phage. Because regions of the T5 and BF23 genomes can be deleted, these phages could be used as cloning vehicles for inserts up to about 19 kb. However, such use has not been developed. Nevertheless, some T5 promoters, because of their strength (see below), are currently being used in expression vectors.

The nucleotide sequences that have been determined in T5 DNA plus those determined in BF23 DNA (not counting overlapping sequences) come to about 30% of their genomes, or about 36 400 nucleotides. Most of this sequencing has been done in the region from 58.3 to 92.2%, which includes some early but mostly late genes, and includes T5 genes *D7-8-9* (the phage DNA polymerase), *D10* (a putative helicase), *D11, D12* and *D13* (nucleoside triphosphate-binding proteins, probably involved with DNA replication, recombination and/or repair), *D14, D15* (a 5′-exonuclease), the *dut* gene (dUTPase), the *1tf* gene (L-shaped tail fibers), the *oad* gene, the *11p* gene (lipoprotein), and BF23 genes 25 (equivalent to T5 gene N4) and 24 (tail proteins). Four other interesting regions of T5 or BF23 have been sequenced. About 1000 bp have been sequenced in the region where the first step of DNA transfer stops (see below), which is very close to the right end of the left terminal repetition (positions 7.4–8.3%). Present in this sequence are several direct repeats and palindromes, DnaA-binding sites and simple repeats with a periodicity suggestive of DNA bending. Another sequence of about 1100 bp (positions 2.4–3.3%) defines gene *A2–A3*, an unidentified open reading frame (ORF) on its right, and the beginning of gene *A1* on its left. The third region (positions 22.4–27.8%) that has been sequenced codes for tRNAs, but contains short ORFs interspersed between the tRNA genes. Lastly, a sequence of about 180 bp defining the left end of BF23 DNA (90% homologous to that of T5 DNA) encodes a strong transciptional stop signal just after the termination codon for the *dmp* gene (5′-deoxyribonucleoside-5′-monophosphatase), which is the leftmost gene in the terminal repetitions.

The genetic maps for both T5 and BF23 have been correlated with their physical genomes such that pre-early genes are located from 0 to 8.3%, and are repeated between 91.7 and 100%, i.e. pre-early genes are in the terminal repetitions. Early genes are located between positions 8.3 and 67.2% as well as in a very short region between 90.5 and 91.5%. Late genes are located between 67.2 and 90.5%.

Restriction maps for T5 DNA have been developed for the restriction endonucleases *Bal*I, *Bam*HI, *Bgl*I, *Bst*EII, *Eco*RI, *Hin*dIII, *Hpa*I, *Kpn*I, *Pst*I, *Sac*I, *Sal*I, *Sma*I, *Sst*I and *Xho*I, and for BF23 DNA for *Bal*I, *Bam*HI, *Eco*RI, *Hpa*I and *Sal*I.

The Infection Process

Attachment of T5 to host cells is facilitated by the L-shaped tail fibers which bind rapidly and reversibly to polymannose O antigens on the outer surface of the outer membrane of the host cell, and move the phage across the outer surface until a receptor is located. The host cell receptor for T5 is *fhuA*, the receptor for ferrichrome, and for BF23 is *btuB*, the receptor for vitamin B_{12}. Irreversible binding occurs between the phage Oad protein and these host receptors, and is accompanied by a covalent cross-linking of three copies of a minor tail protein, pb4. The straight tail fiber, pb2, rearranges to form a channel as does the host cell receptor, thereby providing the route of entry of phage DNA into the host cell. The straight tail fiber is long enough to span the outer membrane, the periplasm, and the inner membrane, but it may also draw the outer membrane to the inner membrane to create contact points where the phage DNA actually enters the host cell through the newly formed channel. Transfer of phage DNA by both T5 and BF23 is unique in that they transfer their DNA in two steps. The left terminal repetition is always transferred first after which DNA transfer stops. DNA transfer resumes only after the pre-early genes in the left terminal repetition have been expressed. The remaining 92% of the phage DNA is then quickly transferred to the host cell such that late genes follow the entry of early genes by only a few seconds.

During transfer of the left terminal repetition (the first step of DNA transfer), the entry channel for DNA is open and low-molecular-weight substances such as K^+ and phosphate leak out of the host cell so that partial depolarization of the periplasmic membrane ensues. After transfer of the left terminal repetition, the channel is closed by Ca^{2+} and the periplasmic membrane repolarizes. When the channel is reopened for transfer of the remaining 92% of the DNA, low molecular weight components of the host cell again leak out and another partial depolarization of the periplasmic membrane occurs. Ca^{2+} again closes the channel, the periplasmic membrane repolarizes, and a successful infection is established. The T5 and BF23 systems therefore both have a Ca^{2+}-requirement, and cannot progress when the concentration of Ca^{2+} is below 0.1 mM.

Pre-early Genes

Since genes in the terminal repetition (**Fig. 1**) are the first phage genes to be expressed in the infected host cell, they have been termed 'pre-early'. Pre-early genes that have been identified include *dmp* (coding for a deoxyribonucleoside-5′-monophosphatase), *A1* (cod-

ing for a protein required for completion of DNA transfer, for shutdown of expression of pre-early genes, and for degradation of host DNA), and *A2-A3* (coding for a protein that is also required for completion of DNA transfer and that binds to DNA, lipopolysaccharide, and host RNA polymerase). Other functions induced by genes in the terminal repetition include the inactivation of host restriction endonucleases, of the host cell reactivation system, of host DNA methylases as well as the total inhibition of host DNA, RNA and protein synthesis. The product of gene *A2-A3* (gp*A2-A3*) is also crucially involved in the abortive response that ensues when either T5 or BF23 infects host cells that harbor a ColIb plasmid or, in some cases, a ColIa plasmid.

Effect on Host Cell Metabolism

Infection by T5 or BF23 results in a rapid and complete degradation of host DNA to individual deoxyribonucleotides, and therefore the synthesis of host DNA, RNA and protein ceases soon after infection. Mutations in gene *A1* prevent this degradation and cells infected with *A1* mutants continue synthesis of host proteins for at least 60 min. The deoxyribonucleotides derived from host DNA are partially degraded to ribonucleosides, free bases and deoxyribose-1-phosphate. The free bases and deoxyribonucleosides are secreted by the infected cell so that all deoxyribonucleoside triphosphates used in the synthesis of phage DNA are synthesized via *de novo* pathways of nucleotide anabolism. A possible reason for the clearance of all nucleotides derived from host DNA is that the phage-induced nuclease that degrades host DNA may only attack methylated DNA. Phage DNA is not methylated and so would be protected from attack, but if any methylated bases derived from host DNA were incorporated into phage DNA, it would be attacked. Thus, the elimination of host-derived bases would be a requirement for a successful infection. This suggestion would also require that a phage function inactivate host DNA methylases, which, as stated above, is known to occur after infection by T5.

Another requirement for a successful infection is the inactivation of host cell restriction endonucleases. Neither T5 nor BF23 DNA contain *Eco*R1 or other common restriction sites in their terminal repetitions but do have them in the central nonredundant portion of their genomes. Thus, inactivation of host restriction endonucleases by the product of one or more pre-early genes, and therefore prior to entry of the portion of the genome containing susceptible restriction sites, allows the susceptible portion of the phage genome to escape the action of host restriction endonucleases. If, on the other hand, the terminal repetition contains even a single restriction site that is cleaved by a host restriction endonuclease, the infection is unsuccessful.

Early Genes

After pre-early genes are expressed, phage DNA transfer resumes and early but not late genes begin their expression as soon as the rest of the phage DNA enters the host cell. Early genes code mostly for enzymes and proteins required for biosynthesis of deoxyribonucleotides, replication of phage DNA and regulation of transcription. Early gene expression begins about 5 min after infection at 37°C, and continues in the case of some early genes until about 20 min after infection, but in the case of other early genes until lysis. Thus, early genes can be divided into two subclasses on the basis of their period of expression.

Products of early T5 genes that have been identified include DNA polymerase (*D9*), deoxynucleoside monophosphokinase (*dnk*), dihydrofolate reductase (*B3*), 5′-exonuclease (*D15*), ribonucleotide reductase (possibly *B1* or *B2*), thioredoxin, thymidylate synthase (*thy*), dUTPase (*dut*), tRNAs (genes within the major deletable region), lipoprotein (*11p*), and RNA polymerase modifying proteins (*C2*, *D5* and *14* and *10* in the case of BF23). This array of early gene products enables the infected cell to initiate phage DNA replication, which begins about 8–9 min after infection and continues until lysis.

Late Genes

Expression of late genes begins at 10–12 min after infection and continues until lysis. Most late genes code for structural proteins of the mature phage particle, and when they begin to accumulate, phage morphogenesis begins using the phage DNA that had begun replication earlier. The eclipse period for T5 and BF23 is about 20 min. Thus, there is a well-regulated temporal sequence for the synthesis of phage DNA and of pre-early, early and late proteins which corresponds to the same temporal sequence for the synthesis of mRNAs. Although most late genes code for structural proteins of the mature phage particle, two late genes (*sci*A and *sci*B) code for the protein that introduces nicks into the phage DNA. Lysis of the infected cell presumably depends on a late gene which codes for a lysis protein, but this has yet to be demonstrated for the T5 system. Lysis exposes the progeny phage to phage receptors liberated from the lysed host cells. To counteract the inactivation of progeny phage by these receptors, the product of early

gene *11p* (a lipoprotein) combines with liberated host receptors to inactivate them.

Regulation of Transcription

The temporal appearance of phage-specified proteins in T5- or BF23-infected cells is regulated at the level of transcription (**Fig. 1**). However, since all classes of T5 or BF23 genes (pre-early, early and late) are efficiently transcribed *in vitro* by unmodified host RNA polymerase (with sigma-70), and this capacity for transcription is the same whether nicked or ligated phage DNA is used as a template, the temporal expression of phage genes *in vivo* must be regulated by mechanisms that prevent the simultaneous expression of all classes of genes if the phage DNA entered the cell in one step. This regulation appears to be accomplished in part by sequential modifications of the host RNA polymerase. On the other hand, expression of pre-early genes is temporally separated from early and late gene expression because of the two-step mechanism of phage DNA transfer, whereby pre-early genes enter the host cell first and must be expressed before early and late genes are able to enter the cell. Pre-early genes are therefore transcribed *in vivo* by the pre-existing unmodified host RNA polymerase. The first modification to host RNA polymerase is the binding of the pre-early proteins coded by gene *A2-A3* (gpA2-A3) and gene *A1* (gpA1). The modification by gpA1 causes shutdown of pre-early gene transcription, whereas the modification by gpA2-A3 prevents the premature transcription of late genes when the phage DNA carrying early and late genes enters the host cell after pre-early genes are expressed. It follows that early genes, but not late genes, can be transcribed by host RNA polymerase modified by gpA2-A3 and gpA1. Transcription of late genes would then require a further modification of RNA polymerase by early gene products, and for T5 they are gpC2 and a 15 kDa protein, whereas for BF23 they are gp10 and gp14. GpA2-A3 is then displaced from the RNA polymerase and late transcription proceeds with the resulting gpC2-15 kDa (for T5) or gp10-gp14 (for BF23) modified RNA polymerase.

DNA Replication

T5 DNA contains multiple origins of replication, which suggests that its DNA is replicated linearly. However, T5 DNA is found in a circular form in infected cells, and the length of such circles is equal to a genome length minus one terminal repetition. Formation of these circles could therefore arise from a recombinational event between the terminal repetitions of a single incoming parental DNA. The occurrence of circles suggests a rolling circle model of DNA replication. Sedimentation studies of replicating T5 DNA from infected cells shows a fast-sedimenting fraction, which could be linear concatemers or the rolling circle intermediate, and a slow-sedimenting fraction that corresponds to genome-length T5 DNA. These findings suggest that excision of genome-length DNA from larger precursors and packaging of phage DNA into immature heads proceed independently of one another.

Morphogenesis

Morphogenesis follows two separate pathways, head formation and tail formation. The immature head is filled with a genome length of phage DNA that is cut from a linear concatemer consisting of phage genomes minus the length of one terminal repetition. The most likely mechanism for excising exactly one genome from such a linear concatemer is by means of two staggered single-strand cuts at each internal terminal repetition in order to generate genome-length DNA with each terminal repetition having a 3′-recess. Filling of each 3′-recess would then generate full, completely double-stranded phage DNA.

Both head and tail morphogenesis involve cleavage of polypeptides that contribute to the formation of these structures. Tails can be connected to heads *in vitro*, but packaging of T5 or BF23 DNA *in vitro* has not yet been accomplished.

Abortive infection in ColIb Hosts

If T5 or BF23 infects a host cell harboring the colicinogenic plasmid, ColIb (or some ColIa plasmids), the infection is abortive. In such infections, the phage adsorbs to the host cell normally, and the phage DNA is transferred into the host cell in the usual two-step manner without being degraded. Pre-early genes are expressed and shutdown normally, but early genes barely begin expression before the host cell prematurely lyses, resulting in death of both the host cell and the infecting phage. Gene products from the phage, the host cell and the plasmid are necessary for this abortive response. The phage gene is pre-early gene *A2-A3*, which binds to both DNA and host RNA polymerase. The host cell genes involved are *cmrA* and *cmrB*, which map suspiciously close to *trkA* and *trkB*, respectively, which code for potassium transport proteins located in the cell membrane. The plasmid gene is *abi* (*ab*ortive *i*nfection), which could code for a polypeptide of 114 amino acids that is strongly hydrophobic and may therefore interact with cell membranes. The putative Abi protein, however, has not yet been detected and is presumably synthe-

sized in very small amounts. How the gene products from three sources interact to cause the abortive response has yet to be elucidated.

Transfection

Transfection of spheroplasts by naked T5 or BF23 DNA provides a means to assess the functional importance, other than that of phage DNA transfer, of the two pre-early proteins, gpA1 and gpA2-A3, which are normally required for transfer of phage DNA into the host cell. Transfection bypasses the normal mechanism, and by so doing, phage DNA with an amber mutation in either gene *A1* or *A2-A3* can produce intact phage (still with the original amber mutation) when transfected into su^- spheroplasts. The efficiency of such phage production is considerably lower than that produced from wild-type phage DNA, but still much higher than that produced from phage DNA with an amber mutation in an essential gene such as T5 DNA polymerase. For a DNA with an amber mutation in gene *A2-A3*, the efficiency was 16%, for one in gene *A1* it was 1.4%, and for one in the essential gene *D9* it was 0%. It thus appears that the role of gpA2-A3 in preventing premature transcription of late genes is important, but not as important as the role of gpA1 in shutting down host macromolecular synthesis by degrading host DNA plus shutting off pre-early transcription.

Interestingly, transfection by T5 or BF23 DNA is a two-hit process in wild-type spheroplasts. Since in transfection, the entire DNA molecule enters the spheroplast in one step, the first DNA molecule to enter inactivates hostile host functions but its non-redundant region is largely degraded. However, such a spheroplast should now be able to accept a second DNA molecule without degradation and a successful infection would follow. One hostile host function appears to be the RecB nuclease since transfection is a one-hit process in $recB^-$ hosts.

Cloning Genes from T5 or BF23

Many restriction fragments from T5 or BF23 DNA are not directly clonable because they either code for lethal products or contain such strong promoters that the cells harboring them cannot survive. The strength of some T5 promoters has prompted their use in expression vectors, some of which are commercially available. Fragments that have been cloned are largely from the region from 58 to 92%, which includes mostly late structural genes with some early genes, and from 21 to 36%, which includes all the tRNA genes that are expressed during the early period. A small fragment from 2.1 to 3.4% in the pre-early region has also been cloned.

T5 genes that have been overproduced from an expression vector include gene *D7-8-9* (coding for T5 DNA polymerase), gene *D15* (coding for T5 5′-exonuclease), and *11p* (coding for a lipoprotein that inactivates host cell receptors). BF23 genes *24* and *25* (coding for a minor and major tail protein, respectively) have also been cloned, sequenced, and expressed.

Future Perspectives

Contributions from the T5 and BF23 systems include the identification and use of some of their gene products. Pre-early gene products that inactivate specific host functions, including restriction endonucleases and DNA methylating enzymes, should show interesting mechanisms of action and prove experimentally useful. Similarly, the availability of the 'nicking' enzyme would add to our battery of enzymes for manipulation of DNA. The nucleotide sequence of all T5 and BF23 promoters and their strength of binding to unmodified and modified forms of host RNA polymerase should sharpen our understanding of promoter function. The elucidation of the mechanims by which the two-step transfer of phage DNA to host cells and the ColIb-directed abortive response is accomplished will probably reveal some unique cellular interactions. Finally, the complete nucleotide sequence of T5 and BF23 genomes would greatly help our understanding of this system.

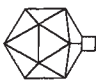
T7-LIKE PHAGES (*PODOVIRIDAE*)



Ian J Molineux, Department of Microbiology, University of Texas, Austin, Texas, USA

General Properties, Ecology and Evolution

Bacteriophage T7 is the prototype of a group of virulent phages having a $T = 7$ icosahedral head approximately 60 nm in diameter, a stubby, noncontractile tail (about 20 nm in length and 10 nm wide) plus six thin tail fibers. It is the type species of the genus 'T7-like phages' in the *Podoviridae* family. The distinguishing characteristic of the group is the synthesis of an RNA polymerase that is both resistant to the antibiotic rifampin and highly specific for phage promoters. T7-like phages that infect one of a variety of Gram-negative bacteria have been described, but none are yet known that infect Gram-positive hosts. Most studies have been performed on the coliphage T7 and properties of other phages are usually described relative to those of T7.

T7 does not form plaques on most *Escherichia coli* strains newly isolated from nature because it does not adsorb to smooth or capsulated bacteria. In *E. coli* B the primary receptor for T7 is the R-core portion of the lipopolysaccharide (LPS) of the outer membrane; in smooth strains the R-core is inaccessible to the phage gp17 tail fibers, which specify the adsorption host-range. The precise adsorption component may be different on *E. coli* K-12 or C strains, on which T7 grows equally well. T7-like phages are known that grow on smooth bacteria; virion-associated hydrolases may degrade cell surface polysaccharides to allow a gp17 homologue to access the primary receptor.

T7 and T3 were isolated in 1945 as phages that grew on *E. coli* B. Similar coliphages have been isolated from different parts of the world and about 60 representatives are known that can be subdivided by the promoter specificity of the phage-coded RNA polymerase. Recombination between phages in a subdivision is very efficient, recombination between those in different subdivisions is extremely rare but undoubtedly highly significant in the evolution of specific phages. Electron microscopic analyses of heteroduplexed DNA of T7-like phages showed varying degrees of homology, some regions exhibiting >90% sequence identity and others with no apparent similarity. These observations suggest that a given phage is the result of multiple recombination events between many T7-like phages.

Genetic Structure

The genetic map of T7 is based on the nucleotide sequence of 39 937 bp. Numbers define genes, ordered sequentially from the genetic left end of the DNA (**Fig. 1**). Three classes of genes have been identified: class I, or early, genes are expressed until about 8 min after infection at 30°C; class II genes are expressed from about 6 to 15 min after infection; and class III genes are expressed from about 8 min until lysis (about 25 min at 30°C). Fifty-six known or potential T7 genes have been described – less than half are essential for phage growth on usual laboratory strains but mutant hosts have allowed the functions of several other genes to be elucidated. There are indications that a few genes may be remnants of homing endonucleases or other mobile elements. More than 90% of the genome is coding and most of the remainder contains recognizable genetic signals. Little overlapping of genes occurs; by means of an internal in-frame initiation gene *4* specifies two distinct polypeptides and programmed ribosomal frameshifting yields two products from gene *0.6*, gene *5.5* (yielding a *5.5–5.7* fusion), and gene *10*. Only the gene *10* frameshift has been well characterized; both gp10A and the longer, −1 frameshifted, gp10B are assembled into wild-type particles but either alone suffices for viability. The frameshifted protein may be biologically significant since a comparable T3 gp10B exists even though the frameshifting sequences have diverged from T7. Other T7-like phages are also thought to contain two forms of their major capsid protein.

Genetic signals include promoters and terminators

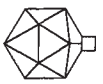
T7-LIKE PHAGES (*PODOVIRIDAE*)



Ian J Molineux, Department of Microbiology, University of Texas, Austin, Texas, USA

General Properties, Ecology and Evolution

Bacteriophage T7 is the prototype of a group of virulent phages having a $T = 7$ icosahedral head approximately 60 nm in diameter, a stubby, noncontractile tail (about 20 nm in length and 10 nm wide) plus six thin tail fibers. It is the type species of the genus 'T7-like phages' in the *Podoviridae* family. The distinguishing characteristic of the group is the synthesis of an RNA polymerase that is both resistant to the antibiotic rifampin and highly specific for phage promoters. T7-like phages that infect one of a variety of Gram-negative bacteria have been described, but none are yet known that infect Gram-positive hosts. Most studies have been performed on the coliphage T7 and properties of other phages are usually described relative to those of T7.

T7 does not form plaques on most *Escherichia coli* strains newly isolated from nature because it does not adsorb to smooth or capsulated bacteria. In *E. coli* B the primary receptor for T7 is the R-core portion of the lipopolysaccharide (LPS) of the outer membrane; in smooth strains the R-core is inaccessible to the phage gp17 tail fibers, which specify the adsorption host-range. The precise adsorption component may be different on *E. coli* K-12 or C strains, on which T7 grows equally well. T7-like phages are known that grow on smooth bacteria; virion-associated hydrolases may degrade cell surface polysaccharides to allow a gp17 homologue to access the primary receptor.

T7 and T3 were isolated in 1945 as phages that grew on *E. coli* B. Similar coliphages have been isolated from different parts of the world and about 60 representatives are known that can be subdivided by the promoter specificity of the phage-coded RNA polymerase. Recombination between phages in a subdivision is very efficient, recombination between those in different subdivisions is extremely rare but undoubtedly highly significant in the evolution of specific phages. Electron microscopic analyses of heteroduplexed DNA of T7-like phages showed varying degrees of homology, some regions exhibiting >90% sequence identity and others with no apparent similarity. These observations suggest that a given phage is the result of multiple recombination events between many T7-like phages.

Genetic Structure

The genetic map of T7 is based on the nucleotide sequence of 39 937 bp. Numbers define genes, ordered sequentially from the genetic left end of the DNA (**Fig. 1**). Three classes of genes have been identified: class I, or early, genes are expressed until about 8 min after infection at 30°C; class II genes are expressed from about 6 to 15 min after infection; and class III genes are expressed from about 8 min until lysis (about 25 min at 30°C). Fifty-six known or potential T7 genes have been described – less than half are essential for phage growth on usual laboratory strains but mutant hosts have allowed the functions of several other genes to be elucidated. There are indications that a few genes may be remnants of homing endonucleases or other mobile elements. More than 90% of the genome is coding and most of the remainder contains recognizable genetic signals. Little overlapping of genes occurs; by means of an internal in-frame initiation gene *4* specifies two distinct polypeptides and programmed ribosomal frameshifting yields two products from gene *0.6*, gene *5.5* (yielding a *5.5–5.7* fusion), and gene *10*. Only the gene *10* frameshift has been well characterized; both gp10A and the longer, −1 frameshifted, gp10B are assembled into wild-type particles but either alone suffices for viability. The frameshifted protein may be biologically significant since a comparable T3 gp10B exists even though the frameshifting sequences have diverged from T7. Other T7-like phages are also thought to contain two forms of their major capsid protein.

Genetic signals include promoters and terminators

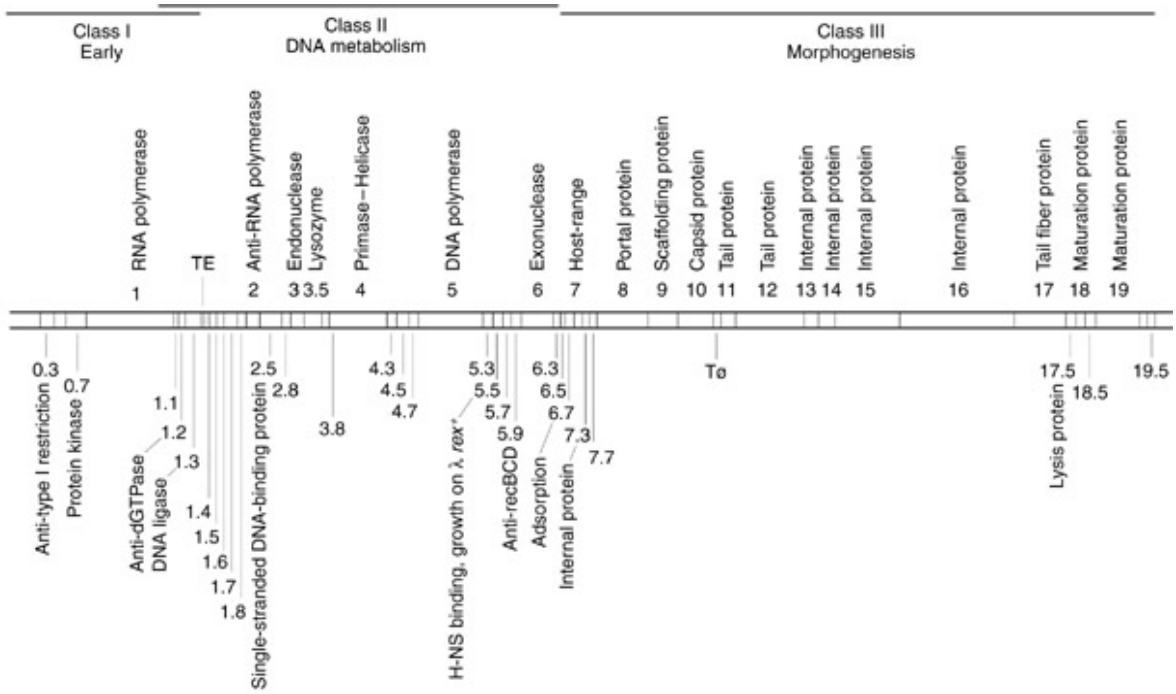


Figure 1 Genetic map of bacteriophage T7.

for the host and phage RNA polymerases, RNase III recognition sequences, the primary origin of DNA replication, and a terminal repetition of 160 bp used in forming concatemers during replication. The terminal repeat of different T7-like genomes is different in both length and sequence. The sequence GATC (a major regulatory sequence in *E. coli*) is distinctly underrepresented; this sequence, statistically expected 156 times in a 40 kb genome, occurs only six times in T7, 10 times in T3, and not at all in BA14. T7 and T3 inactivate type I restriction enzymes but remain susceptible to cells harboring type II and III enzymes. However, susceptibility to the latter enzymes may not be universal among the T7 group: some members contain restriction sites in their genomes but grow despite the presence of the cognate enzymes. The phage gene(s) responsible for type II and III enzyme inactivation are unknown.

Class I genes

Class I genes are those transcribed by *E. coli* RNA polymerase immediately after infection; the biochemical functions of five gene products are known. Type I restriction enzymes are inactivated by gp0.3 (which, for some T7-like phages, also harbors *S*-adenosyl methionine hydrolase activity). gp0.7 is a serine–threonine protein kinase that phosphorylates many host proteins, including RNA polymerase, RNase III, some ribosomal proteins and several translation factors. gp0.7 is also responsible for shut-off of host-catalyzed transcription, although this function is separable from kinase activity. Since host-catalyzed transcription is inactivated and the upstream T7 promoter ϕOL is poorly utilized during infection, early phage genes are also shutoff. Although class I mRNAs are stable, their translation (and those of residual host mRNAs) abruptly ceases about 8 min after infection; how inhibition is achieved is unknown.

gp1 is the T7 RNA polymerase, gp1.2 inhibits *E. coli* dGTPase, and gp1.3 is DNA ligase. Of class I genes, only gene *1* is essential, the remainder are required only in certain hosts or under adverse conditions. In the first few minutes of infection, T7 gene products thus inactivate some potentially deleterious host enzymes and, via inhibition of *E. coli*, and synthesis of T7, RNA polymerase, subsume all intracellular nucleotides and the translation machinery for the exclusive benefit of phage development.

Class II and class III genes

Class II and III genes are transcribed by T7 RNA polymerase; they are distinguished by a selective shut-off of class II transcription and translation about 15 min after infection. Class II genes function primarily in T7 DNA metabolism; they comprise the last three class I genes, *1.1–1.3*, plus genes *1.4–6.3*. In addition to their role in concatemer formation and

resolution, the gp3 endonuclease and the gp6 exonuclease also degrade host DNA to mononucleotides; these are subsequently utilized for T7 DNA synthesis. More than 80% of the nucleotides in progeny phage originated from the host chromosome. *In vitro*, gp3 and gp6 degrade T7 DNA and their activities must be regulated *in vivo;* regulation may involve gp2 but the mechanism is not well understood. The gene 3.5 lysozyme is also multifunctional: its location among the class II genes reflects its role in replication and transcriptional regulation rather than in cell lysis.

Expression of the late class III genes is independent of DNA replication; times of appearance, rates of synthesis and final accumulation of class III proteins are unaffected by preventing phage replication. Essentially all class III genes are involved in phage morphogenesis and maturation or in cell lysis.

Phage Particle

The phage capsid is composed of 415 copies of gp10A or gp10B. At one vertex of the icosahedron, 12 molecules of gp8 form a portal through which the phage genome can pass. The portal also serves as the connector for the phage tail, consisting of six copies of gp12 and 12 or 18 copies of gp11. Six tail fibers, each comprised of gp17 trimers, are attached to the tail just below its junction with the capsid. The particle also contains several internal proteins – three forming a hollow cylindrical core structure, coaxial with the tail, that is attached to the inner surface of the capsid and the portal. This internal core is important during both DNA packaging and ejection. Functions of other particle proteins are incompletely understood, although gp6.7 is essential for adsorption and gp13 for an early stage of infection. Cryoelectron microscopy shows the 40 kb T7 genome spooled around the tail-specified axis in a close-packed, quasi-crystalline array.

T7 Infection Cycle

Aside from lysis, the T7 infection cycle has been modeled as a linked set of differential equations, directly derived from experimental data. The computer simulation accurately displays genome translocation into the cell, gene expression and its regulation, DNA replication and morphogenesis.

DNA Ejection

Following adsorption to *E. coli* K-12 the infection is initiated by degradation of the internal head proteins gp7.3 and gp13. The stubby T7 tail cannot directly penetrate the cell cytoplasm and a channel across the outer envelope must form to allow DNA translocation. The internal core of the head dissociates and its constituent proteins enter the cell (**Fig. 2**). gp14 localizes to the outer membrane; the N-terminal region of gp16 shares homology with a bacterial lytic transglycosylase and may enlarge a hole through the peptidoglycan. This presumed activity of gp16 is important only when cells are at high density or low temperature, conditions likely favoring increased crosslinking of the peptidoglycan. Much of the 143 kDa gp16 presumably spans the periplasm but the protein also penetrates the cytoplasmic membrane to complete the DNA translocation channel. gp15 appears to be cytoplasmic at this stage of infection but its function is unknown.

Only when channel assembly is complete does the phage genome exit the capsid. gp16 appears to be one component of an enzymatic motor, fueled by the proton motive force, that ratchets T7 DNA at a constant rate from the capsid into the cell. About 850 bp enters the cytoplasm by this mechanism; in the absence of transcription DNA translocation normally aborts at this stage. Therefore, neither the classic syringe model for phage DNA ejection nor the concept of packaged DNA resembling a compressed coiled spring apply to T7. It should be noted that these two widely held ideas have no direct experimental support in any phage–host system.

Within the 850 bp that enter the cell lie three *E. coli* RNA polymerase promoters. Transcription from these promoters causes 19% of the genome to be pulled into the cell, simultaneously causing expression of the nine early genes. One of these codes for T7 RNA polymerase, responsible not only for translocating the remaining 81% of the genome but also for all class II and class III gene expression. Complete internalization of the T7 genome occupies one-third of the latent period; the slow transcriptional mode of entry both ensures gp0.3 synthesis with consequent inactivation of type I restriction enzymes before cognate sites enter the cell, and may also help regulate temporal gene expression.

Transcription

All transcription of T7 DNA *in vivo* goes from left to right on the genetic map (**Fig. 3**). The three *E. coli* RNA polymerase promoters are all active, the A1 promoter being among the strongest known. Additional minor promoters identified by *in vitro* transcription studies or predicted from the nucleotide sequence are not known to be biologically significant except for mutant phages. Transcription from the major promoters usually terminates at the early terminator TE to produce three RNAs differing at

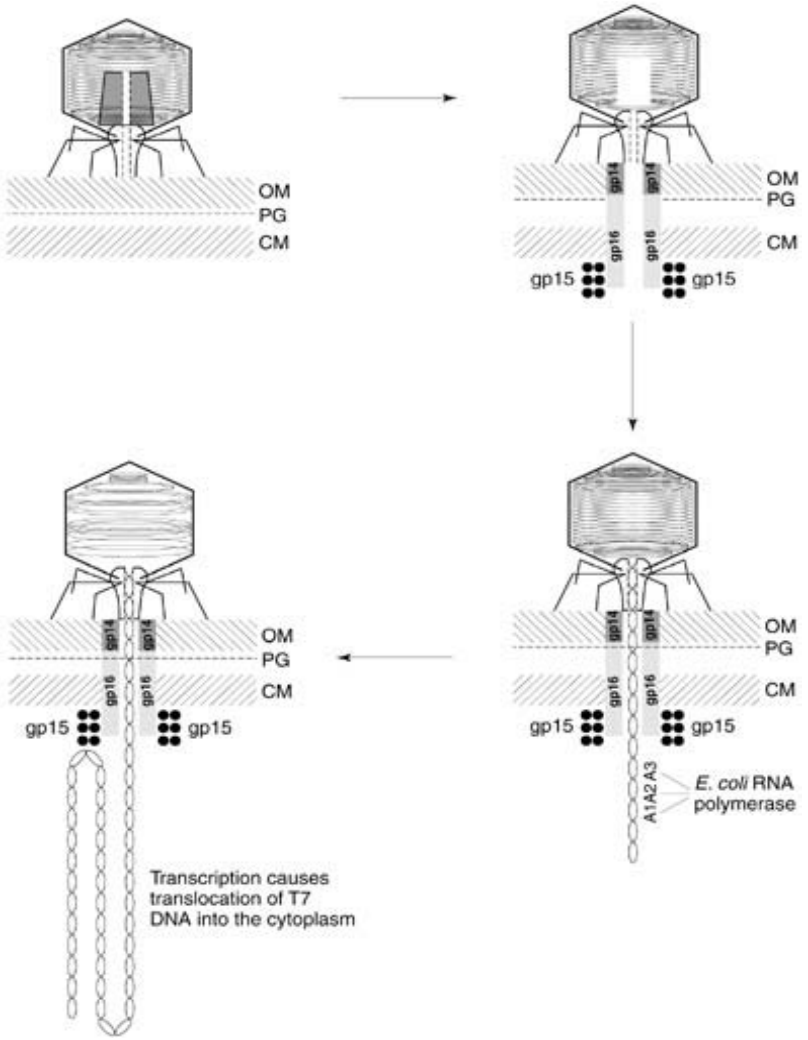

Figure 2 T7 DNA translocation into the bacterial cytoplasm. OM, outer membrane; PG, peptidoglycan; CM, cytoplasmic membrane.

their 5′ ends but containing identical coding information. Transcription that reads through TE terminates inefficiently near the 3′ end of gene *3.5*, distal to gene *10* at the T7 RNA polymerase terminator, or at the genome end.

Processing of primary transcripts by the host enzyme RNase III is a major feature of T7-infected cells, although nonessential for phage development. Early RNAs are processed into a noncoding initiator RNA and five mRNAs, only one of which is monocistronic. Processing of late transcripts also occurs but all RNase III-generated RNAs remain polycistronic. The stability of T7 RNAs during infection is likely due, in part, to the formation of base-paired structures at their 3′ ends by RNase III processing.

T7 RNA polymerase promoters consist of a highly conserved 23 bp segment that runs from −17 to +6, relative to the transcription start. Seventeen promoters exist in the T7 genome, ten expressing class II and class III genes and five expressing only class III genes. The *φOL* and *φOR* promoters may function more in replication or maturation than in mRNA synthesis but neither are essential for phage viability. T3 contains a similar, though not identical, set of promoters.

Transcription from class II promoters and the first three class III promoters terminates distal to gene *10* at T*φ* and results in a nested set of polycistronic RNAs that differ at their 5′ ends. Termination at T*φ* is about 80% efficient – in T7 the essential genes *11* and *12* are expressed only from readthrough RNAs; these, together with transcripts from *φ13* and *φ17*, terminate near the genome end.

The significance of synthesizing such a complex array of transcripts, in particular over the class II

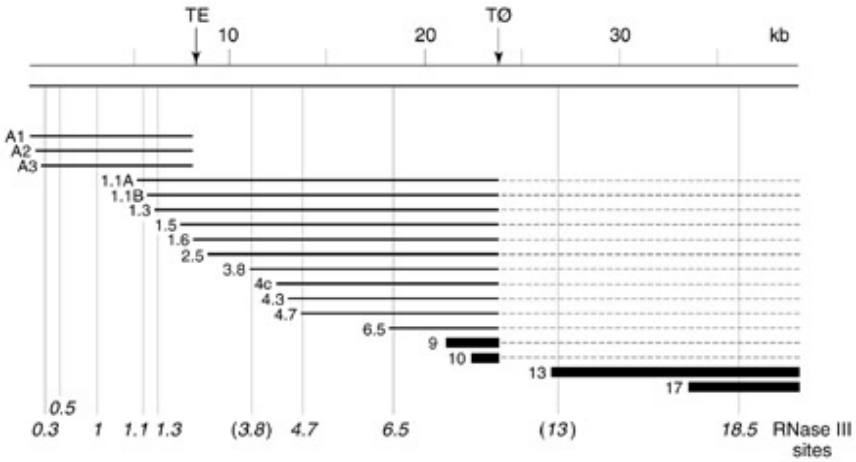

Figure 3 T7 RNAs. Promoters are indicated at the 5′ ends of transcripts. Horizontal dashed lines represent the major readthrough RNAs. Vertical lines indicate the positions of cleavage by RNase III; sites are named by the gene following the site. Sites where cleavage is inefficient are in parentheses.

region, is unclear; however, it does provide a means of selectively producing large quantities of gene *9* and especially gene *10* RNAs. These are partly responsible for the high levels of gp9 and especially gp10 in the infected cell. A leader sequence on gene *10* mRNA and the initial gene *10* codons both also appear designed to maximize gp10 synthesis: during infection perhaps 100 000 gp10 molecules can be made from a single T7 genome in about 20 min.

The sequences of the five class III promoters are identical; these promoters are stronger than class II promoters, whose sequences differ from consensus at 2–7 positions. Promoter strength differences are manifest by the frequency of abortive initiation, which is higher at class II than at class III promoters. gp3.5 lysozyme also complexes with T7 RNA polymerase to inhibit the conformational change necessary for polymerase to switch from the initiation to the processive elongation mode of synthesis. One consequence of gp3.5–gp1 complex formation is then to effect the selective shut-off of class II transcription. Since gp3.5 is itself a class II product, its synthesis is autoregulating and high-level expression of gene *3.5* inhibits phage growth. gp3.5–gp1 complex formation also stimulates DNA replication, perhaps by providing primers via abortive transcription initiation over an origin sequence or by facilitating replication complex assembly on the separated strands of the transcription bubble. Transcripts originating from *φOR* encounter a strong transcriptional pause site that is prolonged by gp3.5 on concatemeric DNA immediately 3′ of the terminal repeat. Enhanced pausing at this site may aid assembly of the machinery for DNA packaging. Gene *3.5* is thus central to several aspects of T7 development.

Promoter specificities

The RNA polymerases coded by other T7-like phages are similar to that of T7. A single amino acid change allows T7 RNA polymerase to specifically recognize T3 promoters, and *vice versa*. RNA polymerases coded by *Salmonella* phage SP6 and *Klebsiella* phage K11 have diverged more extensively from the T7 enzyme, although their respective promoters retain substantial homology to T7. However, there is little recognition of these enzymes for noncognate promoters. Of likely evolutionary significance is the homology between these phage-coded enzymes and the *Saccharomyces cerevisiae* mitochondrial RNA polymerase.

DNA Replication

Replication *in vivo* requires T7 RNA polymerase, DNA polymerase, primase/helicase, single-stranded DNA binding protein (gp2.5), endonuclease and exonuclease. There is no requirement for topoisomerase activity as no closed circular species of the T7 genome form. Even though *E. coli* RNA polymerase is transcriptionally inactive when replication begins, it can interfere with DNA maturation and packaging and gp2 is required to alleviate inhibition. Other than thioredoxin, which forms a 1:1 complex with gp5 in T7 DNA polymerase, no host proteins are known to be required for phage replication. A crystallographic structure of T7 DNA polymerase, bound to a primer-template and nucleoside triphosphate, has been reported.

Replication *in vivo* is normally initiated at an A+T-rich region located 15% from the left end,

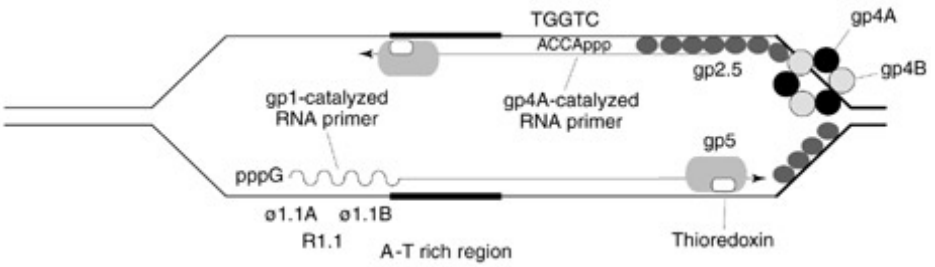

Figure 4 Initial events at the primary origin of DNA replication. Not all protein:proteins are indicated.

although deletion mutants lacking this origin grow well in most laboratory hosts. Replication is bidirectional on the linear genome, the replication 'bubble' enlarges, providing a Y-shaped molecule, before further elongation yields two linear molecules (**Fig. 4**). Replicated linear molecules necessarily contain unreplicated 3′ ends; T7 circumvents replicated genome erosion by forming linear concatemers via its terminal 160 bp repeats. As replication proceeds, fast-sedimenting DNA molecules appear that consist mainly of linear concatemers and branched, recombining molecules. The fast-sedimenting DNA complex, containing >100 genome equivalents, is ultimately converted by the gp3 resolvase into concatemeric molecules that are substrates for the packaging machinery. Although incorporation of thymidine into T7 DNA can be detected for about 20 min, the >200-fold increase in T7 DNA mass resulting from replication is achieved much more rapidly, fluctuations in nucleotide pool sizes as bacterial DNA is degraded and reutilized confound analyses of precursor incorporation data. The rate of T7 DNA mass increase is suggestive of numerous replication forks, consistent with the idea that recombination intermediates may be converted into replication forks, as is the case with T4. Recombination rates in T7-infected cells are very high; wild-type recombinants have been detected between mutants altered in adjacent nucleotides. Recombination is independent of the host RecA but requires most T7 replication proteins. Single strands may be formed by gp6 exonuclease or during replication; strand exchange is catalyzed by gp2.5 and the gp4 helicase, and gp3 resolves Holliday junctions.

Plasmid-based assays *in vivo* have revealed secondary replication origins that may function in later stages of phage replication. Plasmids containing the promoters *ϕ6.5* and *ϕ13* are replicated following T7 infection as efficiently as plasmids containing *ϕ1.1A* or *ϕ1.1B* and the primary origin; those containing *ϕOR* are replicated even more. Furthermore, plasmids containing both *ϕOR* and a packaging signal are packaged after replication, yielding particles that transduce the plasmid DNA. Plasmids containing other promoters are, at best, poorly replicated after infection, but what makes a promoter functional in DNA replication is not understood.

In vitro, bidirectional replication from the primary origin has been achieved using purified T7 RNA and DNA polymerases, gp2.5, and the heterohexameric primase–helicase complex of gp4A and gp4B. RNA polymerase synthesizes primers of 10–60 nucleotides from both promoters immediately upstream of the origin. The gp4 hexamer forms a sliding clamp that translocates 5′ to 3′ to unwind unreplicated DNA using ribo- or deoxy-NTP (preferring dTTP *in vitro*) hydrolysis for energy. The clamp also interacts with both gp2.5 and DNA polymerase, making DNA synthesis more processive. Whereas gp4B has only helicase activity, gp4A also serves as a primase; the N-terminal 63 residues not present in gp4B contain a zinc-finger motif that interacts with the sequences 3′-CTGG(G/T)-5′ or 3′-CTGTG-5′ in single-stranded DNA. Primers, 5′-ACC(A/C) or 5′-ACAC are synthesized that initiate lagging strand DNA synthesis. gp2.5 interacts with both DNA polymerase and primase–helicase to stimulate lagging strand synthesis and to promote bidirectional replication from the primary origin. Although *E. coli* SSB stimulates T7 DNA polymerase activity *in vitro*, it cannot substitute for gp2.5 for bidirectional replication from the primary origin and T7 SSB is an essential protein.

Capsid Assembly and DNA Packaging

Detailed information on morphogenesis has been obtained with both T7 and T3. It is assumed that the mechanism of particle assembly is common to both phages.

Packaging of T7 DNA starts with the assembly of a DNA-free procapsid. The major capsid protein gp10 assembles around a gp9 scaffold in a reaction that has been accomplished *in vitro* using purified proteins. One vertex of the icosahedral procapsid is modified by the addition of gp8 to form the portal. In addition, the procapsid contains the internal protein core, and also the maturation protein gp19. The latter is likely outside the procapsid, as it recognizes the gp8 portal

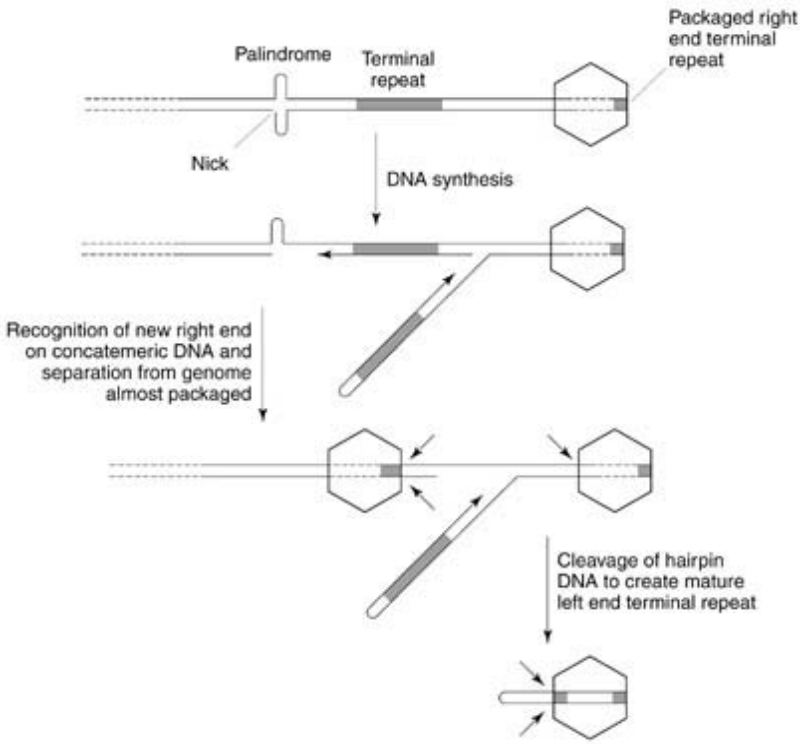

Figure 5 Pathway for duplication of the terminal repeat during packaging from concatemeric DNA.

protein and, perhaps in conjunction with gp18, interacts with concatemeric DNA before packaging. Both gp18 and gp19 are required for packaging, though neither are found in the mature phage particle. Packaging of a single genome from concatemeric DNA is estimated to take about 90 s, a rate that has been achieved *in vitro*.

During packaging of DNA, the procapsid undergoes a conformational change characterized by an increase in size and a conversion from rounded to icosahedral morphology. The gp9 scaffolding protein likely exits the procapsid as these changes occur. After association of the procapsid with concatemeric DNA, packaging proceeds from a genomic right end leftwards in an incompletely understood process. A series of reactions is necessary for duplication of the 160 bp terminal repeat that in concatemers is present in only one copy between genomes. The DNA is nicked by an unknown nuclease at a palindromic sequence located to the left of the right terminal repeat, creating a hairpin primer for DNA polymerase (**Fig. 5**). Extending the hairpin through the terminal repeat and into the genome being packaged provides duplex DNA that could be converted into a mature left end. On the remaining concatemeric DNA, primase-initiated synthesis on the displaced strand proceeds through the terminal repeat, providing sequences that could be converted into the mature right end of the next genome to be packaged. However, the nicking site and palindromic sequences are nonessential, although the obligatory alterations in the packaging mechanism are unknown.

The nuclease recognizing the termini of mature T7 DNA is unknown, although gp19 possesses a nonspecific endonucleolytic activity that is suppressed by gp18, and both proteins are required to create the mature termini. T7 RNA polymerase is also required for DNA packaging; it seems likely that gp3.5-enhanced pausing of transcription near the concatemer junction may recruit gp19 for initiation of packaging.

The final stage of phage development is lysis of the host cell, a process poorly understood. Genes *3.5* and *17.5* are required, perhaps together with another component (gp18.5 and/or nucleic acid?). gp17.5 may be a holin that disrupts the cell membrane, allowing gp3.5 lysozyme to lyse the cell or to release phage from cell debris. The potential role of DNA in lysis is unclear, but replication-defective mutants are as lysis defective as gene *3.5* amber mutants, even though replication does not affect gene expression.

Host Functions in T7 Development

A number of natural *E. coli* or other enterobacterial hosts are nonpermissive for many members of the T7

group of phages. In most cases the host genes involved are unknown. Several prophages or resident plasmids are known to have the potential to inhibit growth of T7 by a process(es) distinct from adsorption or DNA restriction; however, the incoming phage often contains a gene that prevents inhibition. The λ *rex* genes exclude certain missense mutants of T7, perhaps by a comparable (but unknown) mechanism to that of exclusion of T4 *r* II mutants. The Col Ib plasmid inhibits growth of *0.7* mutants; the basis of exclusion is not understood but may involve the failure to inactivate *E. coli* RNA polymerase. Most T7-like phages are also excluded from growth in F plasmid-containing cells, although T3 is an exception. The *pifA* gene of F interferes with the normal functions of T7 genes *1.2* and *10*; interaction of either gene with *pifA* causes inhibition of all macromolecular synthesis and membrane functions. The rapid loss of metabolic potential of the abortively infected, F-containing *E. coli* suggests that some key cellular component(s) is inactivated by the interaction of T7 and *pif* genes. This component is unidentified but can be protected from PifA and gp10 (or gp1.2) by increased synthesis of the *E. coli* membrane protein FxsA, a protein with no known independent function.

Expression Systems Based on T7 RNA Polymerase

The specificity of T7 RNA polymerase for its promoter has allowed the development of high-level, regulated expression systems for cloned DNA in both procaryotes and eucaryotes. Typically, the gene *10* promoter is employed, with or without gene *10* translational start sequences; T7 RNA polymerase is supplied from the cloned gene or by phage infection. Epitope-tagged expression vectors to aid in product purification are available. A phage display system based on the capsid protein accommodating both high and low levels of display has also been developed.

Future Perspectives

The utility of the expression and display systems alone will ensure continued research on bacteriophage T7. Our understanding of, in particular, mechanisms of DNA replication and transcription will continue to be furthered using T7 as a model. The mechanisms of DNA translocation across membranes and the morphogenesis and structure of complex nucleoprotein assemblages are two additional fields of research where the T7 model can be expected to make significant contributions.

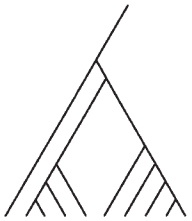
TAXONOMY, CLASSIFICATION AND NOMENCLATURE OF VIRUSES



Claude M. Fauquet, The Scripps Research Institute, Division of Plant Biology, La Jolla, California, USA

History of Virus Classification and Virus Nomenclature

Humans feel the need to classify natural entities and the viruses are no exception. As in other biological systems, virus classification is an approximate and imperfect exercise. Like any other type of classification, it is a totally artificial and human-driven activity without any natural base. However, science requires workable descriptions of living systems and their constituent parts, and, when achieved properly, classifications are extremely useful for showing similar characteristics and properties across populations. Unfortunately for virus taxonomy no fossil record exists and so evolutionary relationships are very speculative, meaning that only a logical and precise virus classification can provide indications of the evolution of viruses. Appropriately chosen classification criteria are also informative in the case of newly discovered viruses. In theory, nomenclature and classification are totally independent, but for viruses both issues are often considered at the same time. As a result, taxonomic names for the viruses have always been the subject of passionate discussions and the taxonomic status of viruses is a sensitive and critical issue.

Virus classification is a relatively new exercise, as the first evidence for existence of a virus was only presented at the end of the nineteenth century by Beijerinck in 1898. It was not until 1927 that Johnson, a plant virologist, drew attention to the need for a system of virus nomenclature and classification. First efforts to classify viruses utilized a range of ecological and biological criteria, including pathogenic properties in the case of human and animal viruses, and symptoms for plant viruses. For example, viruses sharing the pathogenic properties causing hepatitis (e.g. hepatitis A virus, hepatitis B virus, yellow fever virus, and Rift Valley fever virus) were grouped together as 'the hepatitis viruses'. Virology developed substantially in the 1930s and early classifications for the viruses reflected these advances. In 1939, Holmes published a classification of plant viruses dependent on host reactions and differential host species, using a binomial-trinomial nomenclature based on the name of the infected plant; however, only 89 viruses were described and classified in this way. With the development of electron microscopy and biochemical studies in the 1950s, the first virus groupings based on common virion properties emerged: like the Herpesvirus group described by Andrewes in 1954, the Myxovirus group by Andrewes *et al*, in 1955, and the Poxvirus group by Fenner and Burnet in 1957. During this period there was also an explosion of newly discovered viruses; in response, several individuals and committees independently proposed virus classification systems but none was widely adopted by the scientific community. It became obvious that only an international association of virologists could propose a comprehensive and universally acceptable system of virus classification.

At the 1966 International Congress for Microbiology held in Moscow, the International Committee on Nomenclature of Viruses (ICNV) was established by an international group of 43 virologists. An international organization was set up with the aim of developing a taxonomy and nomenclature system for all viruses that would be recognized worldwide. The name of the ICNV was changed in 1974 to the more appropriate International Committee on Taxonomy of Viruses (ICTV), which remains active today. ICTV, the unique official committee of the Virology Division, is now considered the international official body for all matters related to taxonomy and nomenclature of viruses.

Since the founding of the ICTV, all virologists have agreed that the hundreds of viruses isolated from different organisms should be classified together in a unique system, but separate from other microorganisms such as fungi, bacteria and mycoplasma. However, there was much controversy on the way to do it. Lwoff, Horne and Tournier argued for the adoption of a system classifying viruses into subphyla, classes, orders, suborders and families. Descending hierarchical divisions would have been based on nucleic acid type (DNA or RNA), strandedness (single or double), presence or absence of an envelope, capsid symmetry, and so on. The hierarchy of this system has never been recognized by the ICTV; nevertheless, the types of criteria used became the basis of the universal taxonomy system now in place, and all ICTV reports have used this scheme. Until 1990, no hierarchical

classification level higher than the family was used, however, the system has recently begun to move in this direction. A first order, *Mononegavirales*, was accepted in 1990, and another two, *Caudovirales* and *Nidovirales*, were adopted in 1996. In its nonlinnean structure, the scheme is quite different from that used in the taxonomy of bacteria and other organisms. Nevertheless, the usefulness of the scheme is being demonstrated by its wide application. It has replaced all competing classification schemes for all viruses and no one would now dispute with the ICTV the international mandate to name and classify viruses.

Since its establishment, a total of seven virus taxonomic reports (also known by the names of the ICTV Presidents acting as Editors in Chief of the reports) have been published by the ICTV: Wildy in 1971; Fenner in 1976; Matthews in 1979; Matthews in 1982; Francki *et al* in 1991; Murphy *et al* in 1995; and van Regenmortel *et al* in 1999. At the first meeting in Mexico City in 1970, two families with a corresponding two genera and 24 floating genera were adopted to begin the grouping of the vertebrate, invertebrate and bacterial viruses. In addition, 16 plant virus groups were designated, as reported by Matthews in 1983. The fifth ICTV report, edited by Francki *et al* in 1991, described one order, 40 families, nine subfamilies, 102 genera, two floating genera and two subgenera for vertebrate, invertebrate, bacterial and fungal viruses, and 32 groups and seven subgroups for plant viruses. While most virologists shifted to placing viruses in families and genera, plant virologists retained the term 'groups' until 1993. It was only in 1995, as described in the sixth ICTV report, that the ICTV proposed a uniform system for all viruses, with two orders, 50 families, nine subfamilies, 126 genera, 23 floating genera and four subgenera encompassing 2644 assigned viruses. Most recently, at the 28th meeting of the ICTV in March 1998 in San Diego, California, the Universal Virus Classification was adopted; this comprises three orders, 56 families, nine subfamilies, 203 genera, 30 floating genera and a total of 3954 species, strains and/or serotypes of species and tentative species. It is a general trend that the number of described taxa and the number of species of viruses is increasing steadily, easily explained by the increasing complexity of the virus classification and by the amount of data available to demarcate viruses.

With precise and complete descriptions available for a large number of virus families, this classification now constitutes a valuable source of information for new 'unknown' viruses. Therefore, the ICTV classification is not only a taxonomic exercise for virus evolutionists but also a valuable diagnostic tool and educational system for virologists, teachers, medical doctors and epidemiologists.

How does the ICTV operate?

The ICTV is a committee of the Virology Division, which is in turn part of the International Union of Microbiological Societies. The ICTV is a nonprofit-making organization composed of prominent virologists representing countries from throughout the world who work to designate virus names and taxa through a democratic process. The ICTV operates through a number of committees, subcommittees and study groups consisting of more than 492 eminent virologists with expertise in viruses infecting humans, animals, insects, protozoa, archaea, bacteria, mycoplasma, fungi, algae, yeasts and plants. Taxonomic proposals are initiated and formulated by individuals or by the study groups. These proposals are revised and accepted by the corresponding subcommittees and presented for executive committee approval. All decisions are then ratified at a plenary session (or also now by postal vote) held at each Virology Congress where all members of ICTV and more than 50 representatives of national microbiological societies are represented. At present, there are 47 study groups working in concert with six subcommittees – namely, the vertebrate, invertebrate, plant, bacteria, fungus and virus data subcommittees. The ICTV does not impose any taxonomic terms or taxa but ensures that all propositions are compatible with ICTV rules for homogeneity and consistency. The ICTV regularly publishes reports describing all existing virus taxa with a list of classified viruses as well as descriptions of virus families and genera. An Internet web site, where the most important information relative to virus taxonomy is made available, is updated regularly. The sixth report was published by Murphy *et al* (1995) and the seventh by van Regenmortel *et al* (1999).

The increasing number of virus species and virus strains being identified, together with the explosion of data on many descriptive aspects of viruses and viral diseases, and particularly sequence data, has led the ICTV to launch an international virus database project. This project, termed ICTVdB, is scheduled to be fully operational and accessible to the scientific community around the year 2000. The ICTVdB, in addition to the taxonomic descriptions of all the taxa, will comprise all the information available about each virus species, and later each virus strain, for all the descriptors necessary to identify and recognize all viruses.

A Universal System for Virus Classification

There are currently two systems in use for classifying organisms: the linnean and the adansonian systems.

The former is the monothetic hierarchical classification applied by Linnaeus to plants and animals, while the adansonian is a polythetic hierarchical system initially proposed by Adanson in 1763. In 1984 Maurin and collaborators suggested applying the linnean classification system to the viruses. Although convenient to use, this system has shortcomings when applied to the classification of viruses. Firstly, it is difficult to appreciate the validity of a particular criteria. For example, it may not be appropriate to use the number of genomic components as a hierarchical criteria. Secondly, there are no obvious reasons for prioritizing criteria, and in consequence it is difficult to rank all the available criteria. For instance, is the nature of the genome (DNA/RNA) more important than the sense of the coding sequence of the genome or the shape of the virus particles?

The adansonian system considers all available criteria at once and makes several classifications, taking the criteria into consideration successively. The criteria leading to the same classifications are considered as correlated and are therefore not discriminatory. Subsequently, a subset of criteria are considered, and the process is repeated until all criteria can be ranked to provide the best discrimination of the species. This system has not been used frequently in the past owing to its labor-intensive nature, but this situation has changed as a result of the power and availability of today's computer technology. Furthermore, qualitative and quantitative data can be simultaneously considered when generating such a classification. In the case of viruses, it was determined by Harrison and collaborators in 1971 that at least 60 characters could be used for a complete virus description (**Table 1**). Thus, the limiting factor for applying the adansonian system is now not its labor-intensive nature but the lack of data for many of the viruses.

In addition, the increasing number of viral nucleic acid sequences being reported, in combination with the appropriate computer software, allows the comparison of viruses to generate different phylogenetic trees, according to the gene or set of genes used, as for example proposed by Koonin in 1991, Dolja and Koonin in 1991 and Dolja *et al* in 1991. However, to date, none of them has satisfactorily provided a clear classification of all viruses. A multidimensional classification, taking into account all the criteria necessary to describe viruses, would probably be the most appropriate way of representing a virus classification, but again the shortcomings of data for some viruses would prevent the use of this system in the foreseeable future.

For almost 25 years, the ICTV has been classifying viruses essentially at the family and genus levels using a nonsystematic polythetic approach. Viruses were clustered first in genera and then in families. A subset of characters, including physicochemical, structural, genomic and biological criteria, is then used to compare and group viruses. This subset of characters may change from one family to another, according to the availability of the data and the importance of a particular character for a particular family. It is obvious that there is no homogeneity in this respect throughout the virus classification and that virologists weigh the criteria differently in this subjective process, leading to the generation of a nonhomogeneous classification. Nevertheless, over time we can see stability of the current ICTV classification at the genus and family level. When sequence, genomic organization and replicative cycle data are subsequently used for taxonomic purposes, they usually confirm the actual classification. It is also obvious that hierarchical classifications above the family level will encounter conflicts between phenotypic and genotypic criteria and that virologists will have to consider the entire classification process in order to progress in this direction.

Currently, and for practical reasons only, virus classification is structured according to the presentation indicated in **Tables 2** and **3**. This 'Order of Presentation of the Viruses' does not reflect any hierarchical or phylogenetic classification but only a convenient order of presentation of the virus taxa. Since a taxonomic structure above the level of family (with the exception of the orders *Mononegavirales*, *Caudovirales* and *Nidovirales*) has not been developed extensively, any listing must be arbitrary. The order of presentation of virus families and genera follows four criteria: (1) the nature of the viral nucleic acid; (2) the strandedness of the nucleic acid; (3) the use of a reverse transcription process (DNA or RNA); and (4) the positive or negative sense of gene coding on the encapsidated genome. These four criteria give rise to six clusters comprising the 86 families and floating genera of viruses. In the past, two other criteria were also taken in account: the presence or absence of a lipid envelope and the segmentation of the genome as mono-, bi-, tri-, tetra- or multipartite. However, it has become clear that the presence of an envelope was entirely related to the nature of the host and that families could comprise genera having viruses with segmented or nonsegmented genomes, but sharing all other properties, including genome organization and sequence homology. These criteria have been therefore abandoned.

The Virus Species Concept and its Application

In 1991 the ICTV accepted the concept that viruses

Table 1 Virus family descriptors used in virus taxonomy

I Virion properties

A Morphology properties of virions

1 Size
2 Shape
3 Presence or absence of an envelope and peplomers
4 Capsomeric symmetry and structure

B Physical properties of virions

1 Molecular mass
2 Buoyant density
3 Sedimentation coefficient
4 pH stability
5 Thermal stability
6 Cation (Mg^{2+}, Mn^{2+}) stability
7 Solvent stability
8 Detergent stability
9 Radiation stability

C Properties of genome

1 Type of nucleic acid DNA or RNA
2 Strandedness: single-stranded or double-stranded
3 Linear or circular
4 Sense: positive, negative or ambisense
5 Number of segments
6 Size of genome or genome segments
7 Presence or absence and type of 5′ terminal cap
8 Presence or absence of 5′ terminal covalently linked polypeptide
9 Presence or absence of 3′ terminal poly(A) tract (or other specific tract)
10 Nucleotide sequence comparisons

D Properties of proteins

1 Number
2 Size
3 Functional activities (especially virion transcriptase, virion reverse transcriptase, virion hemagglutinin, virion neuraminidase, virion fusion protein)
4 Amino acid sequence comparisons

E Lipids

1 Presence or absence
2 Nature

F Carbohydrates

1 Presence or absence
2 Nature

II Genome organization and replication

1 Genome organization
2 Strategy of replication of nucleic acid
3 Characteristics of transcription
4 Characteristics of translation and post-translational processing
5 Site of accumulation of virion proteins, site of assembly, site of maturation and release
6 Cytopathology, inclusion body formation

III Antigenic properties

1 Serological relationships
2 Mapping epitopes

IV Biological properties

1 Host range, natural and experimental
2 Pathogenicity, association with disease
3 Tissue tropisms, pathology, histopathology

Table 1 Continued

4 Mode of transmission in nature
5 Vector relationships
6 Geographic distribution

Adapted from ICTV guidelines for family descriptions.

exist as species, in a similar manner to other organisms, and adopted a definition for a virus species proposed by van Regenmortel in 1990: 'A virus species is a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche.' This simple definition and the position taken by the ICTV has already had, and will continue to have, a profound effect on virus classification. Effectively, in the sixth ICTV report virus names were indicated in 'List of species' but they were in fact a 'List of virus names' with undefined taxonomic status. In the seventh ICTV report, according to the polythetic nature of the species definition, a 'List of species-demarcating criteria' is provided for each genus, indicating how virus species can be identified in this particular genus. Viruses are then differentiated in species and tentative species according to this list of criteria and the availability of information to demarcate the species.

First, it is intended to define for each genus the criteria demarcating a virus species, and, second, to compare these criteria from one genus to the next, searching for homogeneity throughout the virus classification. Naturally this list of criteria should follow the polythetic nature of the species definition and more than one criteria should be used to determine a new species. It is obvious that most of the criteria in the list of demarcating criteria are shared amongst the different genera, within and across families; namely, host range, serological relationships, vector transmission type, tissue tropism, genome rearrangement and sequence homology (**Table 4**). However, if the types of criteria are similar, the levels of demarcation clearly differ from one family to another. This may reflect differences in appreciation from one family to another but also the differential ranking of a particular criterion in different families. The huge differences (up to 30%) in sequences among nucleoproteins of species of lentiviruses does not have the same biological significance as small differences in capsid protein sequences (1–10%) of species of potyviruses, and therefore universal levels of sequence identity for similar genes may not exist for viruses! The levels of demarcation may even change from one gene to another within the same family. Homogenization of the application of the species definition concept throughout the virus definition will be the next challenge of ICTV for the eighth report to be published by 2002. This, in turn, will contribute to homogeneity of the genus and family demarcation criteria (**Table 4**) and will permit creation of new families or merging of existing families. However, it is important to note that the nature of the demarcating criteria at the genus level will probably not change as these have passed the test of time. Despite the fact that they were mostly established using biochemical and structural criteria, they remained valid when correlated with genome organization and sequence data.

The Universal Virus Classification

The present universal system of virus taxonomy is set arbitrarily at hierarchical levels of order, family (in some cases subfamily), genus and species. Lower hierarchical levels, such as subspecies, strain, serotype, variant, pathotype and isolate are established by international specialty groups and/or by culture collections, but not by the ICTV. However some of them may be indicated in the ICTV report for information or because in the past these names were listed as 'viruses' in previous reports.

Virus species

The species taxon is always regarded as the most important taxonomic level in classification but it has proved to be the most difficult to apply to the viruses. ICTV definition of a virus species was long considered to be 'a concept that will normally be represented by a cluster of strains from a variety of sources, or a population of strains from a particular source, which have in common a set or pattern of correlating stable properties that separates the cluster from other clusters of strains' as stated by Matthews in 1982 and by Francki *et al* in 1991. This was a general definition, which was in fact not very useful for practically delineating species in a particular family. Furthermore, this definition directly addressed the definition of a virus strain, which had never been attempted in the history of virus taxonomy. In 1991, the ICTV Executive Committee accepted a definition proposed by van Regenmortel in 1990 (see above). This definition states: 'A virus species is a polythetic class of viruses that constitutes a replicating lineage

Table 4 List of criteria demarcating different virus taxa

I Order
Common properties between several families including:
Biochemical composition
Virus replication strategy
Particle structure (to some extent)
General genome organization
II Family
Common properties between several genera including:
Biochemical composition
Virus replication strategy
Nature of the particle structure
Genome organization
III Genus
Common properties within a genus including:
Virus replication strategy
Genome size, organization and/or number of segments
Sequence homologies (hybridization properties)
Vector transmission
IV Species
Common properties within a species including:
Genome rearrangement
Sequence homologies (hybridization properties)
Serological relationships
Vector transmission
Host range
Pathogenicity
Tissue tropism
Geographical distribution

and occupies a particular ecological niche.' The major advantage in this definition is that it can accommodate the inherent variability of viruses and is not dependent on the existence of a unique characteristic. Members of a polythetic class are defined by more than one property and no single property is absolutely essential and necessary. Thus in each family it might be possible to determine the set of properties of the class 'species' and to check if the family members are species of this family or if they belong to a lower taxonomic level. The ICTV is currently conducting this exercise throughout all virus families. This exercise should ultimately result in an excellent evaluation of a precise definition of each virus species in the entire classification.

Several practical matters are related to the definition of a virus species with the goal of improving the usefulness of virus classification. These include: (1) homogeneity of the different taxa; (2) diagnosis-related matters; (3) virus collections; (4) evolution studies; (5) biotechnology; (6) sequence database projects; (7) virus database projects; and now (8) intellectual property rights.

Virus families and genera

There is no formal definition for a genus, but it is commonly considered as: 'a population of virus species that share common characteristics and are different from other populations of species'. Although this definition is somewhat elusive, this level of classification seems enduring and useful; some genera have been moved from one family to another over the years, but the composition and description of the genera has remained stable. The characters defining a genus differ from one family to another and there is a tendency to create genera with fewer differences between them. Upon examination, there is more and more evidence that the members of a genus have a common evolutionary origin. The use of subgenera has been abandoned in current virus classification.

Notwithstanding the creation of the ICTV, plant

virologists continued to classify plant viruses in 'groups', refusing to place them in genera and families. However, owing to obvious similarities, plant reoviruses and rhabdoviruses had been integrated into the families *Reoviridae* and *Rhabdoviridae* (**Table 2**). This position was mostly due to plant virologists' refusal to accept binomial nomenclature. Since this form of nomenclature was withdrawn from the ICTV classification rules in 1995, they subsequently accepted the placing of plant viruses into species, genera and families as shown in the sixth ICTV report. However, there are still 30 of so-called 'floating genera' that do not pertain to any family. This is mostly due to the fact that plant virologists prefer to accumulate data on virus species and genera before clustering appropriate genera in families. It is remarkable that this attitude has also been adopted by other virologists as a convenient way of classifying viruses, without having to move genera out of families when it becomes apparent that they are part of a distinct family. For example, the members of the floating genus 'cricket paralysis-like viruses' share enough properties with picornaviruses to be included in the family *Picornaviridae;* however, they also possess properties that would justify their classification in a separate family. Only new data or new viruses will permit a definitive position, therefore for the time being it remains a floating genus. Similarly the same strategy is used to create a floating genus 'ictalurid herpes-like viruses', within the family *Herpesviridae*, although in this case it is a floating genus within the family because of uncertainty as to whether the members of this genus should be classified in one of the existing subfamilies or to a new subfamily.

Virus orders

As mentioned above, the higher hierarchy levels for virus classification are extremely difficult to establish. Despite several propositions in the past, only three have been accepted: *Caudovirales, Mononegavirales* and *Nidovirales*. The first virus order, *Mononegavirales*, was established in 1990 and comprises the nonsegmented single-stranded RNA negative-sense viruses, namely the families *Bornaviridae, Filoviridae, Paramyxoviridae* and *Rhabdoviridae*. This decision was taken because of the great similarity of many criteria between these families, including their replication strategy. A second order, *Caudovirales*, contains all the families of double-stranded DNA phages possessing a tail, including the families *Myoviridae, Podoviridae* and *Siphoviridae*. A third order, *Nidovirales*, comprising the families *Coronaviridae* and *Arteriviridae*, was accepted in 1996 because of the impossibility of grouping together these two taxonomic entities, which share many properties and yet are so different, as a single family. Many members of the ICTV advocate the creation of many more orders, but it has been decided to proceed cautiously to avoid creation of short-lived orders. The creation of formal taxa higher than the orders, for example, kingdoms, classes and subclasses, has not been considered by the ICTV.

Virus Taxa Descriptions

Virus classification continues to evolve with the technologies available for describing viruses. The first wave of descriptions, those before 1940, mostly took into account the visual symptoms of the diseases caused by viruses, along with their modes of transmission. A second wave, between 1940 and 1970, brought together an enormous amount of information from studies of virion morphology (electron microscopy, structural data), biology (serology and virus properties) and physicochemical properties of viruses (nature and size of genome, number and size of viral proteins). Since 1970, the third wave of virus descriptions has included genome and replicative information as well as molecular relationships with virus hosts. There is a correlative modification of the list of virus descriptors and **Table 1** lists the family and genera descriptors which are used in the current ICTV report. **Figures 1–5** are diagrammatic representations of families and genera of viruses infecting vertebrates, invertebrates, plants, fungi, yeasts, protozoa and bacteria. The most recent wave of information used to classify viruses is naturally nucleotide and amino acid sequences. It is becoming more and more prevalent in virus taxonomy, as exemplified by the presence of a significant number of 'phylogenetic trees' in the seventh ICTV report, and by the huge number of scientific publications on this topic. Some scientists promote the concept of 'quantitative taxonomy' aimed at demonstrating that virus sequences contain all the coding information required for all the biological properties of the viruses. This is in complete agreement with the polythetic concept of the virus species definition, as demonstrated for example by Padidam *et al* in 1995, van Regenmortel *et al* in 1997, Hyppia *et al* in 1998, and Aleman *et al* in 1999.

The impact of descriptions on virus classification has been particularly influenced by electron microscopy and of the negative staining technique for virions. This technique had an immediate influence on diagnostics and classification of viruses. With negative staining, viruses could be identified from poorly purified preparations of all tissue types, and informa-

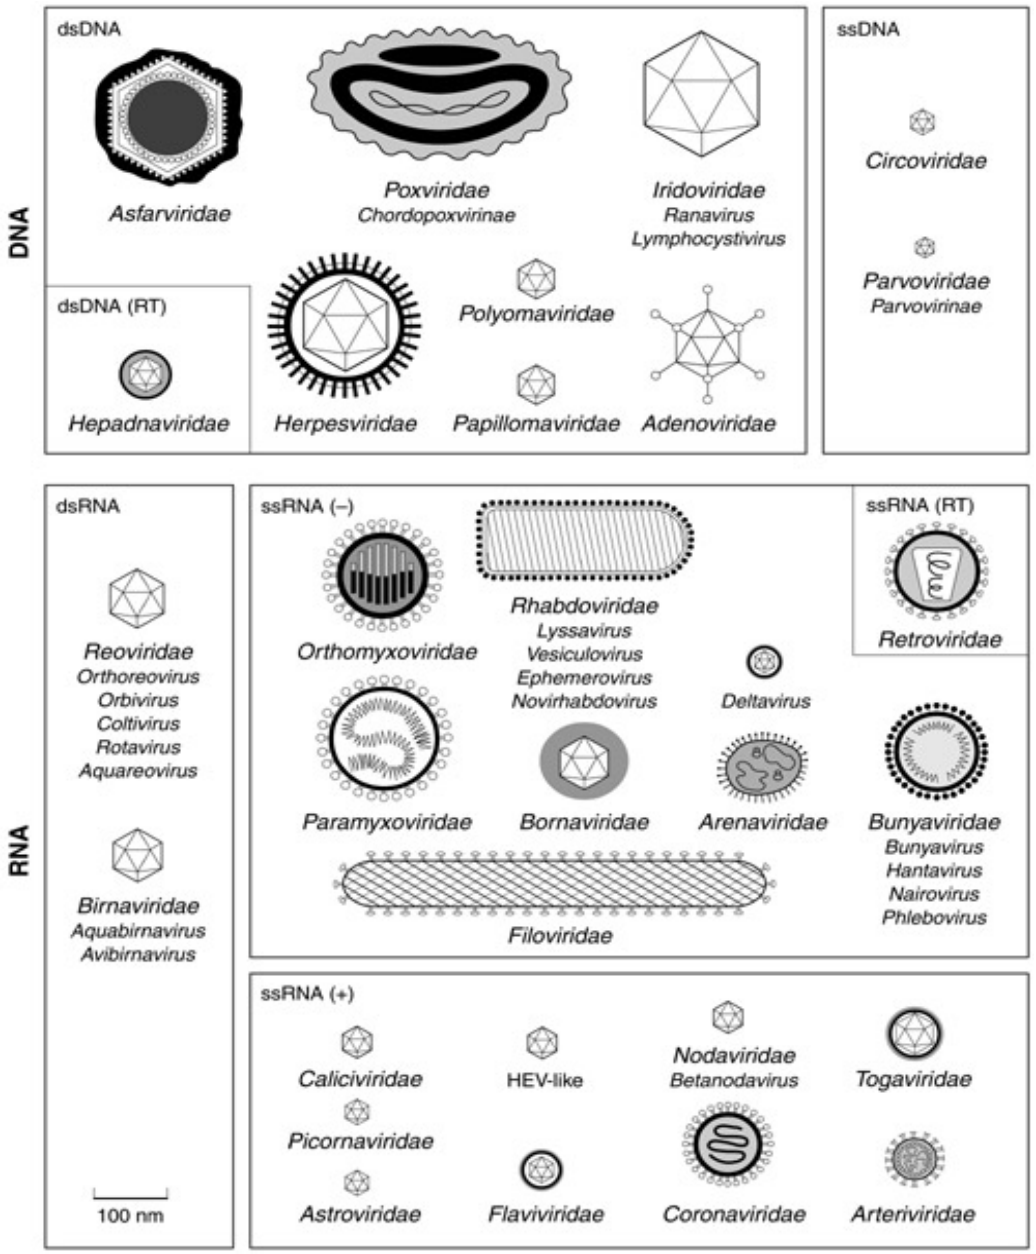

Figure 1 Families and genera of viruses infecting vertebrates.

tion about size, shape, structure and symmetry could be quickly provided. As a result, virology progressed simultaneously for all viruses infecting animals, insects, plants and bacteria. Thin sections of infected tissues brought a new dimension to virus classification by providing information about virion morphogenesis and cytopathogenic effects. These techniques, in conjunction with the determination of the nature of the genome, provided a major source of information for the system of virus classification established in the 1980s, as shown by the large number of viruses listed in the fifth ICTV report in 1989.

In many instances the properties of viruses belonging to the same genus are correlated. Thus, the classification of a few of them will likely be sufficient to allow the classification of a new virus into an established genus. For example, a plant virus with filamentous particles of 700–850 nm and transmitted by aphids is likely to be a member of the genus *Potyvirus*. Establishment of new genera in the future will require more information. Most of the properties listed in **Table 3** will have to be precisely analyzed to warrant the formation of a new genus.

Table 3 lists 45 different categories of properties but each category includes many items. Lists of virus descriptors usually comprise 1000–2000 descriptors.

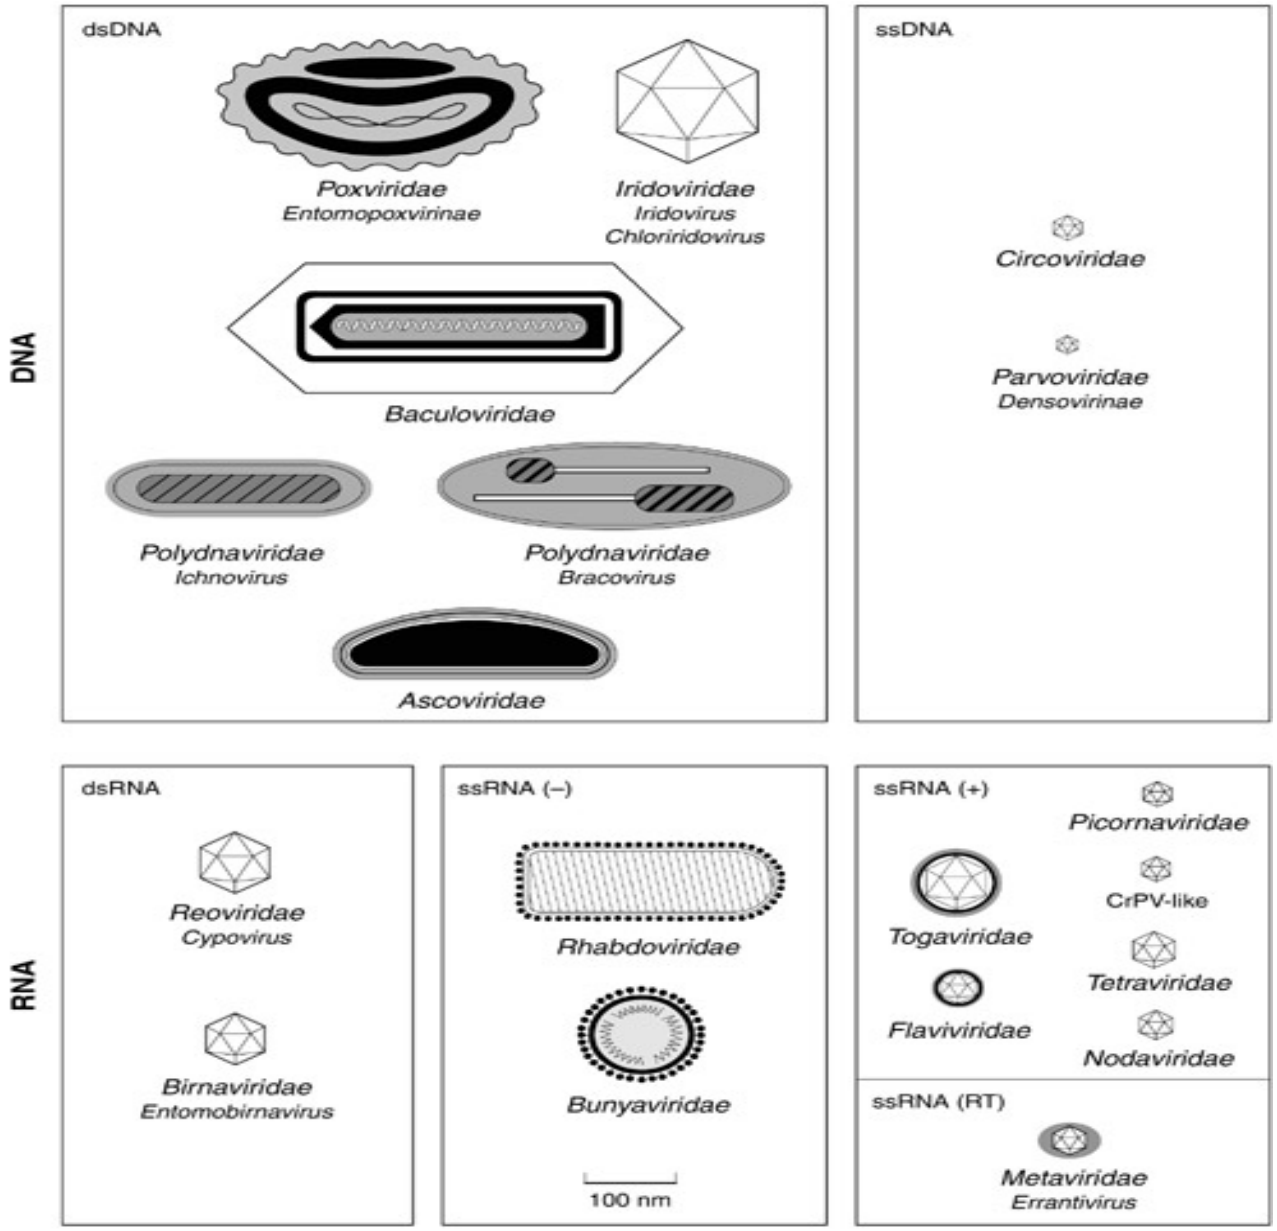

Figure 2 Families and genera of viruses infecting invertebrates.

The establishment of a universal list of virus descriptors is under way and should be adopted by ICTV around 2000 with the establishment of the ICTVdB. It will contain a common set of descriptors for *all* viruses and subsets for specific viruses in relation to their specific hosts (human, animal, insect, plant and bacterial).

A Uniform Nomenclature of Viral Taxa

When a genus is approved by ICTV, a type species is designated. However, none of these type species have received a new international name and only English names are used. Latinized binomial names for virus names have been supported by animal and human virologists of ICTV for many years, but have never been implemented. This suggestion was in fact withdrawn from ICTV nomenclature rules in 1990 and consequently such names as *Herpesvirus varicella* or *Polyomavirus hominis* should not be used. For several years, plant virologists have adopted a different nomenclature, using the vernacular name of a virus but replacing the word 'virus' by the genus name; for example, *Cucumber mosaic cucumovirus* and *Tobacco mosaic tobamovirus*. Though this usage is favored by many scientists, and examples of such practice can

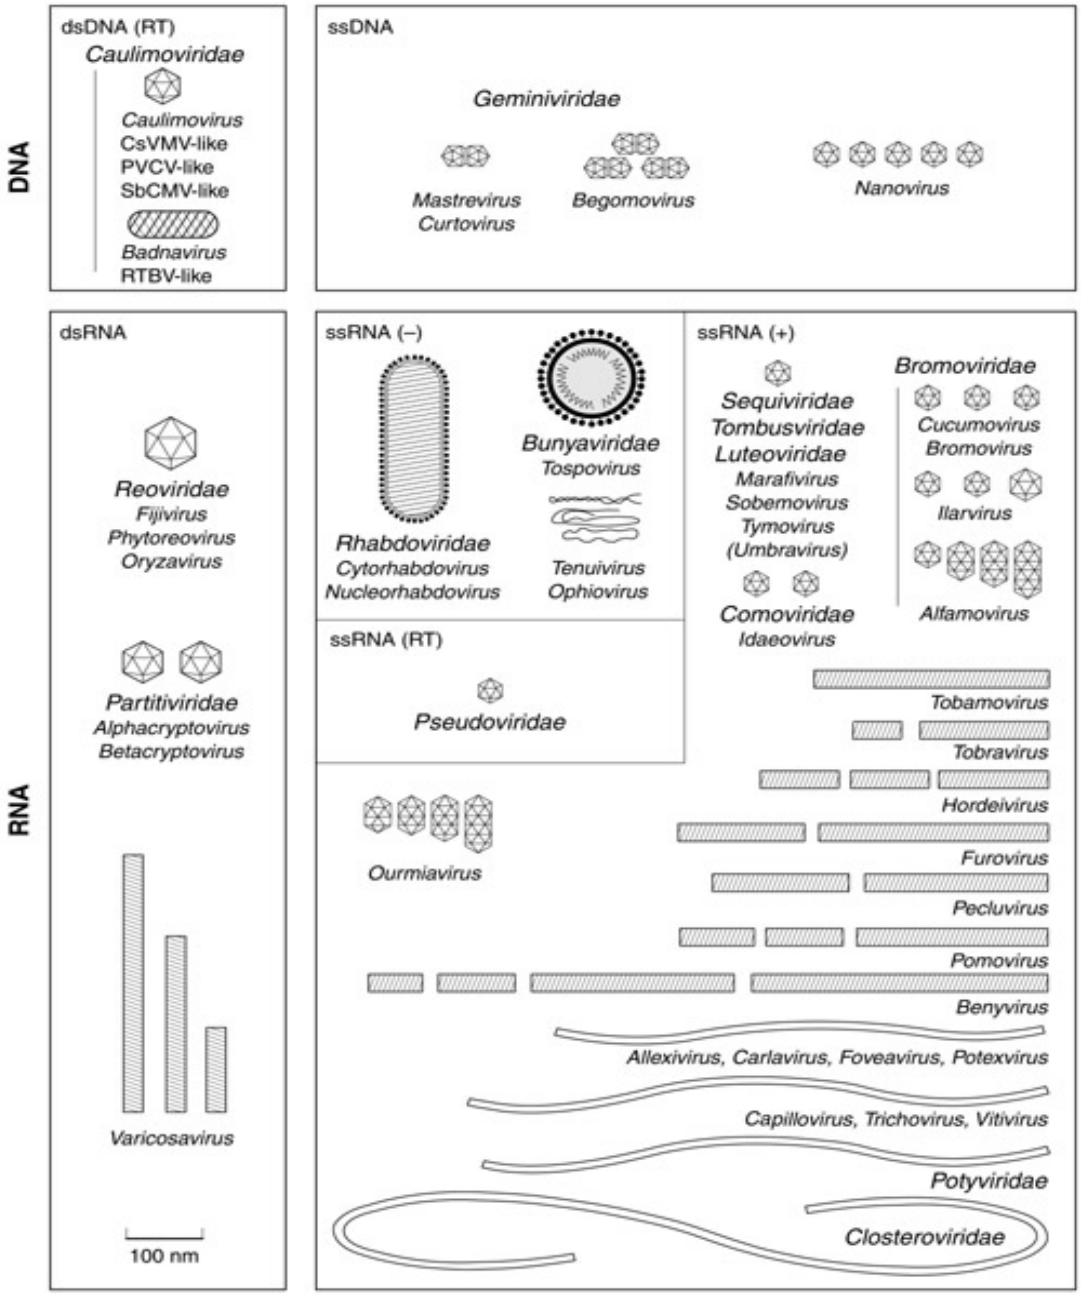

Figure 3 Families and genera of viruses infecting plants.

be found for human, animal and insect viruses (e.g. *Human rhinovirus, Canine calicivirus, Acheta densovirus*...), it has not been universally adopted by the ICTV.

The ICTV has set rules for virus nomenclature and orthography of taxonomic names that are regularly revisited and improved. The last word of international virus species names is 'virus', the international genus names universally end in '...virus', the international subfamily names end in '...virinae', the international family names end with '...viridae', and the international order names are ending in '...virales'. In formal taxonomic usage, the virus order, family, subfamily, genus and species names are all printed in italics (or underlined) and the first letter is capitalized. For all taxa except the species names, new names are created *de novo* following ICTV guidelines, but in the case of virus names English vernacular form is used. In formal usage, the name of the taxon precedes the name of the taxonomic unit; for example, 'the family *Picornaviridae*' or 'the genus *Rhinovirus*'. In informal vernacular usage, order,

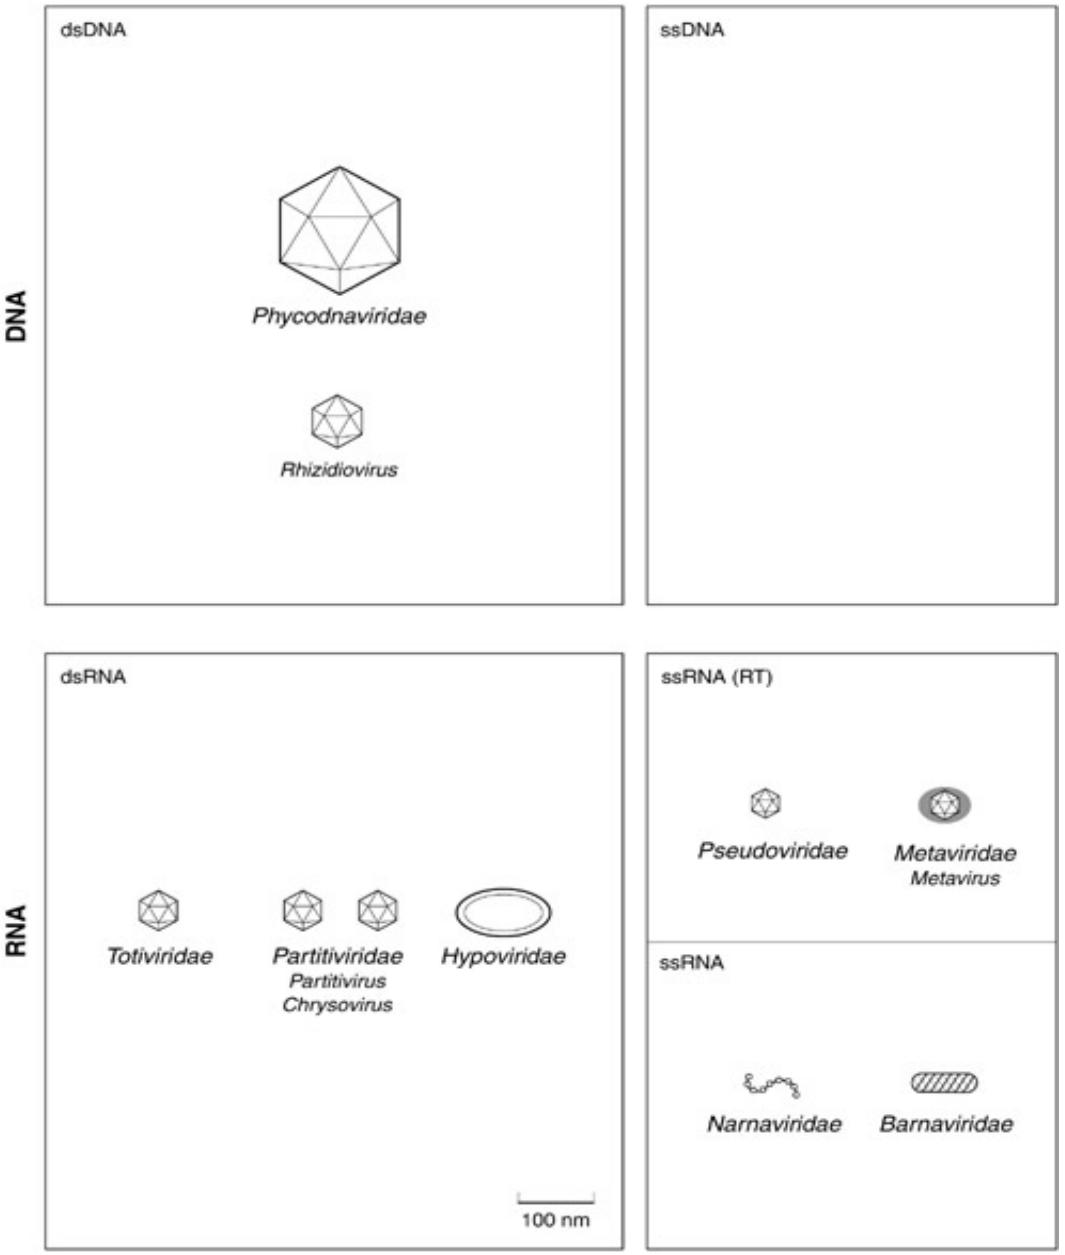

Figure 4 Families of viruses infecting algae, fungi, yeasts and protozoa.

family, subfamily, genus and species names are written in lower case Roman script; they are not capitalized nor italicized (or underlined). Additionally, in informal usage, the name of the taxon should not include the formal suffix, and it should follow the term for the taxonomic unit; for example, 'the mononegavirales order', 'the adenovirus family', 'the avihepadnavirus genus' or 'the tobacco mosaic virus' species. Virus names are often abbreviated for convenient reasons, but ICTV has not set up guidelines to generate such abbreviations. The ICTV reports list abbreviations most commonly used by specialists and the ICTV reports help virologists to identify duplicates of abbreviations in order to decrease the number of such duplicates. In 1988 plant virologists initiated the publication of such lists and have indicated guidelines for the creation of new virus names and new abbreviations. These guidelines were last published in 1991 by Fauquet and Martelli and will be updated again in 1999.

To avoid ambiguous virus identifications, it has been recommended to journal editors that published papers follow ICTV guidelines for proper virus identification and nomenclature, and that viruses should be cited

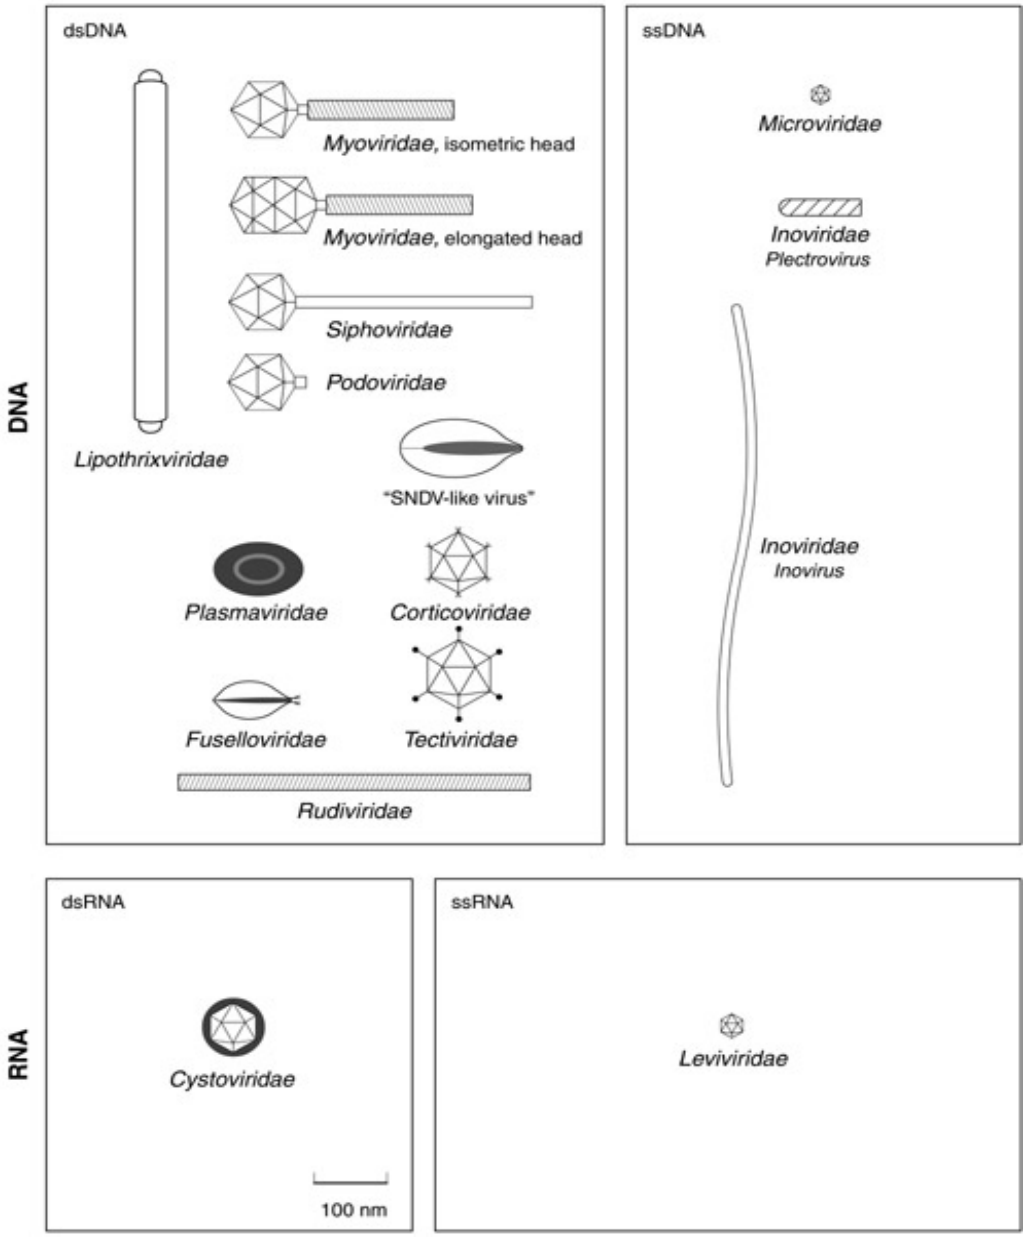

Figure 5 Families and genera of viruses infecting bacteria.

with their full taxonomic terminology when they are first mentioned in an article. For example:

- Order *Caudovirales*, family *Podoviridae*, genus 'T7-like viruses', species *Enterobacteria phage T7*.
- Order *Mononegavirales*, family *Paramyxoviridae*, subfamily *Paramyxovirinae*, genus *Rubulavirus*, species *Mumps virus*.
- Order *Nidovirales*, family *Coronaviridae*, genus *Coronavirus*, species *Avian infectious bronchitis virus*.
- Family *Iridoviridae*, genus *Iridovirus*, species *Chilo iridescent virus*.
- Family *Picornaviridae*, genus *Enterovirus*, species *Poliovirus*, serotype Human poliovirus 1.
- Genus *Tobamovirus*, species *Tobacco mosaic virus*.

TENUIVIRUSES

Bryce W. Falk, Department of Plant Pathology, University of California, Davis, California, USA

History

The viruses in the genus *Tenuivirus* (tenuiviruses) have been recognized as important plant pathogens since the early 1900s. However, in 1977 it was first recognized that rice stripe virus (RSV)-infected rice (*Oryza sativa* L.) plants contained unusual fine-stranded particles. These appeared as circular or branched filaments and were distinctly different from particles associated with other plant viruses. Subsequent work showed that plants infected by several other viruses contained similar particles. This and the somewhat unique biological properties shared by these viruses led to the early grouping together of RSV and other plant viruses, including maize stripe virus (MSpV) and rice hoja blanca virus (RHBV). Since 1995, RSV and related viruses have been grouped together by the International Committee on Taxonomy of Viruses (ICTV) as members of the genus *Tenuivirus* (tenuiviruses).

Taxonomy and Classification

There are currently six species within the genus *Tenuivirus*, and at least five tentative species (**Table 1**). The definitive tenuiviruses are: rice stripe virus (RSV; the type species of the genus); MSpV; RHBV; rice grassy stunt virus (RGSV); *Echinochloa* hoja blanca virus (EHBV) and *Urochloa* hoja blanca virus (UHBV). All tenuiviruses exhibit similar properties, and in recent years molecular biological analyses have shown that they are quite distinct from other currently recognized plant viruses. The genus *Tenuivirus* is not placed within a formally recognized virus family; however, tenuiviruses appear in some ways to be more closely related to viruses in the genus *Phlebovirus* of the family *Bunyaviridae*, than they are to other plant viruses.

Biology, Host Range and Vector Transmission

The plant host ranges of all tenuiviruses are limited to monocotyledenous plant species within the family Poaceae, including many plants which are important food crops (i.e. rice (*Oryza sativa* L.) and maize (*Zea mays* L.)). The symptoms induced in infected plants are generally similar for the different tenuiviruses and includes general leaf striping, a distinct white coloring of the leaf stripes and stunting (**Fig. 1**).

Tenuiviruses generally are not mechanically transmissible to their plant hosts; however, mechanical transmission has been reported in limited instances but only under specific conditions. All tenuiviruses are transmitted to plants by specific planthoppers (Homoptera: Delphacidae, see **Table 1** and **Fig. 2**). Transmission of a given tenuivirus is specific and may be limited to planthoppers of a single species. Compared to other vectors of plant viruses (i.e. aphids or whiteflies), delphacid planthoppers are not generally thought of as common vectors; however, they are perfectly adapted to be vectors of tenuiviruses. Delphacid planthoppers which vector tenuiviruses

TENUIVIRUSES

Bryce W. Falk, Department of Plant Pathology, University of California, Davis, California, USA

History

The viruses in the genus *Tenuivirus* (tenuiviruses) have been recognized as important plant pathogens since the early 1900s. However, in 1977 it was first recognized that rice stripe virus (RSV)-infected rice (*Oryza sativa* L.) plants contained unusual fine-stranded particles. These appeared as circular or branched filaments and were distinctly different from particles associated with other plant viruses. Subsequent work showed that plants infected by several other viruses contained similar particles. This and the somewhat unique biological properties shared by these viruses led to the early grouping together of RSV and other plant viruses, including maize stripe virus (MSpV) and rice hoja blanca virus (RHBV). Since 1995, RSV and related viruses have been grouped together by the International Committee on Taxonomy of Viruses (ICTV) as members of the genus *Tenuivirus* (tenuiviruses).

Taxonomy and Classification

There are currently six species within the genus *Tenuivirus*, and at least five tentative species (**Table 1**). The definitive tenuiviruses are: rice stripe virus (RSV; the type species of the genus); MSpV; RHBV; rice grassy stunt virus (RGSV); *Echinochloa* hoja blanca virus (EHBV) and *Urochloa* hoja blanca virus (UHBV). All tenuiviruses exhibit similar properties, and in recent years molecular biological analyses have shown that they are quite distinct from other currently recognized plant viruses. The genus *Tenuivirus* is not placed within a formally recognized virus family; however, tenuiviruses appear in some ways to be more closely related to viruses in the genus *Phlebovirus* of the family *Bunyaviridae*, than they are to other plant viruses.

Biology, Host Range and Vector Transmission

The plant host ranges of all tenuiviruses are limited to monocotyledenous plant species within the family Poaceae, including many plants which are important food crops (i.e. rice (*Oryza sativa* L.) and maize (*Zea mays* L.)). The symptoms induced in infected plants are generally similar for the different tenuiviruses and includes general leaf striping, a distinct white coloring of the leaf stripes and stunting (**Fig. 1**).

Tenuiviruses generally are not mechanically transmissible to their plant hosts; however, mechanical transmission has been reported in limited instances but only under specific conditions. All tenuiviruses are transmitted to plants by specific planthoppers (Homoptera: Delphacidae, see **Table 1** and **Fig. 2**). Transmission of a given tenuivirus is specific and may be limited to planthoppers of a single species. Compared to other vectors of plant viruses (i.e. aphids or whiteflies), delphacid planthoppers are not generally thought of as common vectors; however, they are perfectly adapted to be vectors of tenuiviruses. Delphacid planthoppers which vector tenuiviruses

Table 1 Tenuiviruses, their planthopper vectors and plant hosts, and geographic range

Virus	*Vector*[a]	*Plant hosts*[b]	*Range*[c]
Rice stripe virus (RSV)	*Laodelphax striatellus*	Rice (*Oryza sativa*)	Asia, Far East
Maize stripe virus (MSpV)	*Peregrinus maidis*	Maize (*Zea mays*)	Worldwide tropics and subtropics
Rice grassy stunt virus (RGSV)	*Nilaparvata lugens*	Rice	Asia, Far East
Rice hoja blanca virus (RHBV)	*Tagosodes oryzicola*	Rice	American tropics and subtropics
Echinochloa hoja blanca virus (EHBV)	*Tagosodes cubanus*	Rice, *Echinochloa colona*	American tropics and subtropics
Urochloa hoja blanca virus (UHBV)	*Caenodelphax teapae*	*Urochloa* spp.	

[a] All Tenuivirus insect vectors are planthoppers in the Delphacidae. The name indicates the main vector.
[b] Indicates the primary economically important host. All tenuiviruses have more extensive experimental host ranges (Falk and Tsai, 1998).
[c] Indicates the main natural geographic distribution.

are phloem feeders, and colonize plants within the family Poaceae. The planthopper vector can acquire the corresponding tenuivirus by feeding from a virus-infected plant and, once acquired, the planthopper generally retains the ability to transmit the corresponding tenuivirus for the remainder of its life. Immediately after acquisition there is a defined incubation period before subsequent transmission to new host plants is possible. This incubation period is fairly long, measured in days, and is suggestive that viral multiplication in the planthopper is a prerequisite before the tenuivirus can subsequently be transmitted to new plant hosts. Further evidence supporting the replication of tenuiviruses in their planthopper vectors is that RHBV, RSV and MSpV can be transovarially transmitted from viruliferous female planthoppers to their progeny, and RHBV can be paternally transmitted to offspring.

Proof for multiplication of tenuiviruses in their planthopper vectors has been demonstrated by using different approaches. For example, RHBV has been maintained in *Tagosodes orizicola* planthoppers for up to ten generations, and RSV has been maintained in *Laodelphax striatellus* planthoppers for 40 generations. Serological analyses have been used to show definitively that MSpV antigens increase over time in *Peregrinus maidis* planthoppers after MSpV acquisition (either by plant feeding or intrathoracic injec-

tion), providing conclusive evidence that MSpV replicates in *P. maidis*.

Even though transmission of a given tenuivirus is specific, it appears that vector specificity may be even further affected by the genetic composition within the vector species population. There are 'transmitters' and 'nontransmitters' for RHBV within *T. oryzicola* populations. The transmitters are competent RHBV vectors, while the nontransmitters are not, and transmitters are capable of supporting RHBV replication, whereas nontransmitters are not. By making crosses between individuals of these two types, the ability to support RHBV replication, and thus transmit RHBV to plants, was shown to be due to a single recessive gene. The above characteristics show that Tenuivirus transmission by planthopper vectors can be classified as circulative-propagative, and is highly specific. Furthermore, the host ranges of tenuiviruses include plants and animals, the latter being their planthopper vectors.

Geographic and Seasonal Distribution

Tenuiviruses are not universally common plant viruses, but they are generally somewhat limited in their geographical distribution, probably due in part to limits for the natural geographical ranges of their planthopper vectors. RSV and RGSV appear to be limited to rice growing areas of Asia, and RHBV and EHBV are limited to tropical and subtropical rice growing regions of the Americas. Only MSpV is found in both the New and Old Worlds. MSpV has been reported from North, Central and South America, Australia and parts of Africa. However, MSpV and its planthopper vector, *Peregrinus maidis*, are limited to subtropical and tropical maize-producing regions in these areas.

Even though they are somewhat limited in their natural incidence, the tenuiviruses are still of considerable economic importance. Their primary host plants are important food crops including rice (*Oryza sativa*) and maize (*Zea mays*), and disease incidence can be severe. For example, RHBV, which causes the only virus disease of rice in the western hemisphere, has sporadically affected rice production in many tropical and subtropical rice production areas of the Americas, and yield losses of 25–50% have been reported. When RHBV was identified in Florida, USA, in the 1950s, a quarantine on Florida rice production was implemented in hopes of preventing RHBV spread into rice producing areas of nearby states. Rice production in southern Florida did not resume until the late 1970s, and now it is a minor crop. RHBV is still of considerable importance in the rice growing regions of Latin America. In their respective geographic regions, RSV and RGSV cause similarly important diseases in rice. RSV has been reported to affect as much as 19% of the total rice acreage in Japan. MSpV causes annual losses in maize in various regions, and losses of 80% have been reported in specific maize growing regions.

Virus Structure and Composition

The name tenuivirus is derived from the nature of the slender (tenuous), filamentous ribonucleoprotein particles (RNPs) associated with the tenuiviruses. RNPs have been identified by electron microscopy in cells of tenuivirus-infected plant and insect hosts. The RNPs also have been purified from plants infected by several different tenuiviruses, including MSpV, RSV, RGSV, EHBV and RHBV. Electron microscopic analysis has shown the RNPs to be threadlike, very thin in diameter (8–10 nm; **Fig. 3**) and often without defined lengths. Frequently the RNPs appear circular, but under various conditions they can exhibit varying degrees of supercoiling.

Rate-zonal sucrose density gradient centrifugation analysis has shown that RNP preparations for specific tenuiviruses can be resolved into four or five distinct RNPs. The sedimentation coefficients of the five MSpV RNPs range from about 70 to 190 S for the slowest to fastest sedimenting RNPs, respectively. Biochemical analyses have shown that RNPs are composed of single-stranded RNA encapsidated

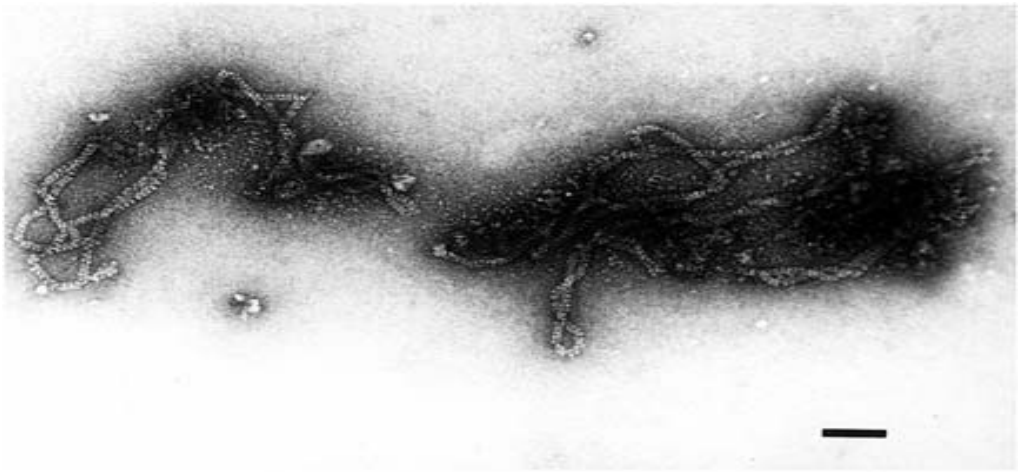

Figure 3 Transmission electron micrograph showing purified rice hoja blanca virus (RHBV) RNPs. Note circular filamentous nature of the particles. Bar = 50 nm. (Courtesy of Dra. A. M. Espinoza Esquivel, University of Costa Rica.)

essentially by a single protein species, the nucleocapsid (N) protein. The N proteins for all tenuiviruses are similar in size, about 32 000–35 000 mol.wt. In addition to the N protein, purified RNP preparations often contain small amounts of a large protein of greater than 200 000 mol.wt which is believed to be the tenuivirus RNA-dependent RNA polymerase.

Four or five distinct genomic RNAs have been isolated from purified RNPs of different tenuiviruses. The overall pattern and sizes of the RNP RNAs for different tenuiviruses, as determined by denaturing agarose gel electrophoresis, are very similar. For MSpV, sizes are estimated to be about 8.3, 3.3, 2.4, 2.2 and 1.3 kb for RNAs 1–5, respectively. Northern hybridization and nucleotide sequence analyses have shown that each of these RNAs is largely distinct, and representative of a single genome segment. Thus the multipartite genomes of tenuiviruses like MSpV are among the largest (*c.* 18 kb) genomes for the plant viruses.

Analysis of individually purified MSpV and RSV RNPs has shown that the different sized genomic RNAs are separately encapsidated in different RNPs. The smallest RNA (RNA 5) can be isolated from the slowest sedimenting RNP, with larger RNAs being found in faster sedimenting RNPs, respectively. Furthermore, careful studies with RSV have shown that the circumference of the filamentous, circular RNPs is proportional to the size of the encapsidated RNA. The five RSV RNPs are estimated to be *c.* 290 nm, 510 nm, 610 nm, 840 nm and 2110 nm in circumference for RNPs 1–5, respectively.

The RNP RNAs are believed to be single-stranded. However, under appropriate conditions, both single- and double-stranded RNAs have been detected in RNAs extracted from purified RNPs of MSpV, RGSV, EHBV and RSV. This was somewhat surprising when originally discovered, as it seemed unlikely that both single- and double-stranded RNAs would be contained within the RNPs. It is now believed that only single-stranded RNAs are encapsidated, but that for each size RNA (e.g. RNA 1), complementary molecules are separately encapsidated in different RNPs. This is supported by data which show that mostly single-stranded RNAs are detected when MSpV RNPs are disrupted with detergent and the RNAs immediately analyzed by gel electrophoresis. However, when RNP RNAs for MSpV and RSV are isolated using SDS and phenol, concentrated by ethanol precipitation, and subsequently analyzed by nondenaturing gel electrophoresis, both single- and double-stranded RNAs are detected. The double-stranded RNAs presumably arise *in vitro* by hybridization of complementary strands for each RNA.

Nucleic acid hybridization data support the above observations. Opposite polarity, complementary molecules for each of the five MSpV RNAs have been identified from purified RNPs. However, unequal amounts of the complementary molecules for all five MSpV RNAs are present. Northern hybridization studies of denatured and nondenatured MSpV RNP RNAs suggested that each of the five RNP RNAs is represented primarily as one polarity; however, smaller amounts of the complementary polarity molecules for each RNA are also present. Thus, upon annealing *in vitro*, some double-stranded RNA is formed while the RNA in excess then remains as single-stranded RNA. For a given genomic segment,

that polarity which is most abundant is referred to as vRNA, while that which is less abundant is referred to as vcRNA (viral complementary RNA).

The above characteristics are consistent and characteristic features of the tenuiviruses; however, the properties of the RNPs and the molecular biology of tenuiviruses (see below) suggest that the circular RNPs may not be true virions, but possibly they are components of a more complex virion. At this time the exact nature of tenuivirus virions remains in question.

Genome Composition and Structure

The different sized Tenuivirus RNAs are distinct genome components. Infectivity experiments demonstrating whether or not all five of the tenuivirus RNAs are necessary for competent infections have not been done. However, nucleic acid hybridization analyses have shown that for a given tenuivirus the genomic RNAs do not have a high degree of nucleotide sequence homology with each other, and nucleotide sequence analyses show that the individual genomic RNA segments have distinct organizations encoding different proteins.

The genomic RNAs of several tenuiviruses have been sequenced and characterized. While the terminal structures on the Tenuivirus genomic RNAs have not been definitively identified, the 5′ termini do not contain a VPg, nor are they capped. Genomic RNAs of both RSV and MSpV can be readily radiolabeled *in vitro* by using polynucleotide kinase. Similarly, the 3′ ends of the RSV genomic RNAs have been labeled using T4 RNA ligase, suggesting that the 3′ terminus is an OH group. Nucleotide sequence analyses also have shown that the tenuivirus genomic RNAs have conserved and complementary 5′ and 3′ termini. There are 11 nucleotides at the 5′ termini and ten nucleotides at the 3′ termini, which are largely conserved not only among the five genomic RNAs of a given tenuivirus, but also between different tenuiviruses (**Fig. 4**). The minor exceptions are that RSV RNA 1 and MSpV RNA 5 have only 9 of the 10 conserved nucleotides at their 3′ termini. It is also of interest that the terminal eight nucleotides at both the 5′ and 3′ termini are identical to those found in the vertebrate-infecting viruses of the genus *Phlebovirus* (family *Bunyaviridae*). The genomic RNA 5′ and 3′ terminal nucleotide sequences also are complementary (**Fig. 4**). The 3′ 17 terminal nucleotides are complementary to 17 of the 18 5′ terminal nucleotides. A model has been proposed for RSV which allows the 11th nucleotide from the 5′ end to bulge out so that the 17 complementary nucleotides at each terminus could base pair and form a hairpin structure.

Figure 4 Terminal nucleotide sequences of *Tenuivirus* and *Phlebovirus* RNAs. For the conserved and complementary 5′ and 3′ nucleotide sequences for tenuivirus genomic RNAs, the nucleotides shown in bold are conserved among the RNA sequences determined so far. For the *Phlebovirus* sequence, the nucleotides shown in bold are those which are identical to those found for tenuiviruses. The asterisk (*) in the 3′ terminal sequences represents a space inserted so as to align 5′ and 3′ nucleotides for complementary base pairing.

Such complementarity of RNA terminal nucleotide sequences is largely unique among the plant viruses, with the exception that the genomic RNAs of tomato spotted wilt virus (genus *Tospovirus*, family *Bunyaviridae*) also exhibit this feature. The feature is common among vertebrate-infecting viruses with segmented, negative-sense RNA genomes in the families *Bunyaviridae, Arenaviridae* and *Orthomyxoviridae*.

It is of interest to note that for La Crosse virus (genus *Bunyavirus*, family *Bunyaviridae*) the complementary genomic RNA termini exist in infected cells and in RNPs as base paired, stable panhandle structures. It is believed that because the La Crosse virus RNA termini are base paired within the RNPs, this could play a role in determining the circularity of the RNPs. Interestingly, the tenuivirus circular filamentous RNPs are morphologically very similar to those of La Crosse virus, and it is tempting to speculate that the tenuivirus RNA 5′ and 3′ termini are also base paired, and that this feature, at least in part, contributes to the circular nature of the characteristic tenuivirus RNPs.

Nucleotide sequence analyses have shown that the different tenuivirus genomic RNAs exhibit different genetic organizations and encode different proteins. RSV vRNA 1 is 8970 nt and of negative polarity. The vcRNA1 potentially encodes for a protein of 336 860. The smallest tenuivirus genomic RNA, RNA 5

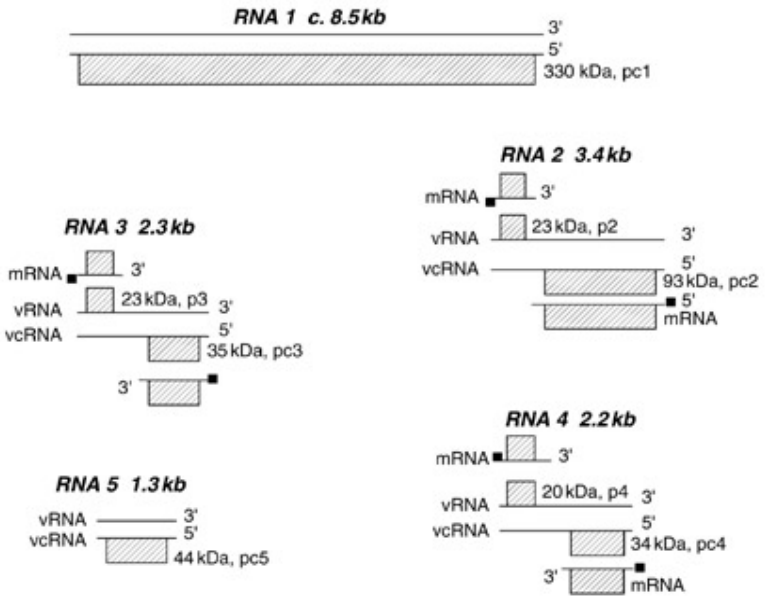

Figure 5 Generic genome map and expression strategy for viruses in the genus *Tenuivirus*. Five tenuivirus genomic RNAs and their approximate sizes (kb) are indicated. vRNA and vcRNA indicate the viral and viral complementary RNAs, respectively. Hatched boxes indicate ORFs. For the ambisense RNAs (RNAs 2, 3 and 4), mRNAs are indicated below or above the vRNA or vcRNA. Black boxes indicate capped 5′ termini on these mRNAs. No caps are shown on the monocistronic RNAs, but it is likely these mRNAs are also capped. Names and sizes of proteins (kDa) are shown.

(1317 nt) is also of negative polarity. MSpV vcRNA 5 encodes a protein, pc5, of 44 000 mol.wt. Analyses of pc5 show it to be highly basic in nature, containing 21% arginine and lysine, but as yet its function is unknown.

The organizations of tenuivirus genomic RNAs 2, 3 and 4 is more complex. Both the vRNA and vcRNAs for each genomic segment encode proteins, thus the coding strategy is ambisense (**Fig. 5**). MSpV vRNA 2 encodes a small hydrophobic protein (23 500 mol.wt) while vcRNA 2 encodes a 93 900 mol.wt protein. Because the vRNA and vcRNA each encode proteins, the terminology used to refer to the respective proteins is determined by whether they are encoded by vRNA or vcRNA. The vRNA 2-encoded protein is designated p2, while the vcRNA 2-encoded protein is pc2 (the c for a protein encoded by the vcRNA). Thus, for the remaining ambisense MSpV genomic RNAs, RNAs 3 and 4, p3 is 22 700 mol.wt, pc3 is 35 000 mol.wt, p4 is 19 800 mol.wt and pc4 is 31 900 mol.wt.

The functions of all of the tenuivirus-encoded proteins are not known. The pc1 is believed to be the RNA-dependent RNA polymerase (RDRP). Amino acid sequence analyses have shown that pc1 contains features characteristic of RDRPs, and it exhibits significant similarity to the RDRPs (L proteins) found for viruses in the genus *Phleobvirus*. The function of p2 is unknown, but computer predictions suggest it to be membrane-associated within infected host cells. The second RNA 2-encoded protein, pc2, exhibits significant similarity to the virion membrane glycoproteins found for viruses in the genus *Phlebovirus*. Interestingly, so far no membrane-bound virions have yet been identified for tenuiviruses. The pc2 is *c.* 94 000 mol.wt and for MSpV contains the proteolytic cleavage sequence conserved among the glycoproteins for Phleboviruses. VcRNA 3 encodes the *c.* 35 000 mol.wt nucleocapsid (N) protein. The vRNA 3 encodes p3, a protein of *c.* 23 000 mol.wt and for which no function is yet identified. The vRNA 4 encodes p4, a protein of *c.* 20 000 mol.wt. P4 is the most abundant protein found in tenuivirus-infected plants (see below). The vcRNA 4 encodes pc4, a protein of *c.* 32 000 mol.wt and of unknown function. Some of these proteins are discussed in more detail below, under Virus–Host Relationships or Serological and Nucleic Acid-Based Relationships.

Gene Expression Strategies

The tenuivirus full-length genomic RNAs are not mRNAs. During tenuivirus infection and replication, specific subgenomic mRNAs are generated for the ambisense genomic RNAs (RNAs 2, 3 and 4; see **Fig. 5**), and for MSpV, with the exception of that for p4,

subgenomic mRNAs have been identified both in MSpV-infected plants and planthoppers. As tenuivirus genomic RNAs 1 and 5 are monocistronic, it is likely that mRNAs for pc1 and pc5 are essentially full-length, but probably are modified from those found in RNPs.

The subgenomic mRNAs representing the RNA 2, RNA 3 and RNA 4 open reading frames (ORFs) have been detected in MSpV-infected tissues, but not in purified RNPs. The sizes of the RNA 2, RNA 3 and RNA 4 subgenomic mRNAs are *c.* 700 and 2600 nt for p2 and pc2; 650 and 1350 nt for p3 and pc3; and *c.* 950 and 1000 nt for p4 and pc4, respectively. In agreement with the polarities of the ORFs contained in each of the ambisense genomic RNAs, the subgenomic mRNAs for a given RNA segment are of opposite polarity to each other, and it is likely that subgenomic mRNAs for a given genomic RNA are not overlapping. The opposing ORFs on a specific genomic RNA are separated by relatively large A-U rich intergenic regions (>350 nt). Whether or not these intergenic regions play a role in mRNA transcription termination is not yet known.

The subgenomic mRNAs correspond in nucleotide sequence with the 5′ regions of the genomic RNA segments; however, the 5′ terminal nucleotide sequences for a given genomic RNA (i.e. vRNA 4) and the corresponding mRNA (i.e. that for the p4 ORF) are not identical. The 5′ termini for several tenuivirus mRNAs have been shown to contain short leader sequences of heterogeneous nucleotide composition, and these are immediately 5′ of the viral RNA sequence. Furthermore, and in contrast to the tenuivirus genomic RNAs, the mRNAs have a 5′ cap. It is believed that these capped leader sequences are generally of host mRNA origin and originate by 'cap snatching'.

Cap snatching is a feature which was first described for influenza virus, and which was subsequently shown to occur for other vertebrate-infecting viruses such as those in the families *Orthomyxoviridae, Arenaviridae* and *Bunyaviridae*. During mRNA transcription, host mRNAs are recruited and a virus-encoded cap-specific endonuclease cleaves the host mRNA several nucleotides downstream of the 5′ cap. The resulting 5′-capped sequence is then used as a primer for mRNA synthesis. A few of the 3′ nucleotides base pair with the mRNA template (the 3′ end of the full-length RNAs) and the short, capped ribonucleotide serves as a primer for transcription. Thus, the mRNA gains the 5′ cap and short leader sequence of the donor mRNA. The specificity of donor RNAs that can serve as mRNA primers is not yet known, but generally the capped leader sequences are short, only 10–16 nt.

Virus–Host Relationships

One of the most diagnostic features of tenuivirus infections of plants is the presence of large amounts of the tenuivirus-encoded p4 protein in plant tissues. P4 is the most abundant protein in MSpV-infected plant tissues and can be found at levels exceeding $10\,mg\,g^{-1}$. P4 can easily be detected from tenuivirus-infected plants by using serological methods, or directly by light and/or electron microscopy. Within infected plant cells, p4 aggregates into large crystalline structures or inclusion bodies which can occupy significant portions of the plant cell (**Fig. 6**). Similar p4 aggregates can be formed *in vitro*. The inclusion bodies found in the cell cytoplasm are not viroplasms or sites of tenuivirus replication, and p4 is not associated with Tenuivirus RNAs or the RNPs. As such, p4 has been referred to as the major noncapsid protein (NCP). The p4-containing inclusion bodies are detectable by light and/or electron microscopy and are of various morphological types. Light microscopic analysis has shown inclusion bodies to be needle-shaped, ring-like and even in figure-of-eight amorphous structures. Transmission electron microscopy has revealed that these structures can have two types of substructure. The amorphous, semielectron opaque inclusion bodies are the most abundant, sometimes appearing to fill almost the entire cytoplasm. Filamentous, electron-opaque bodies also can be seen but are generally less abundant. All of the above seem to be composed only of p4, and thus the various types may represent different developmental stages. Despite its abundance in tenuivirus-infected plants, p4 has not been detected in MSpV-infected *P. maidis*, the MSpV planthopper vector. The reason for the differential abundance of p4 in plant as opposed to insect hosts is not known; however, RNA hybridization analyses have shown that the p4 ORF subgenomic RNA is highly abundant in MSpV-infected plants, but has not been found in MSpV-infected *P. maidis*. In contrast, other tenuivirus-coded proteins, such as the nucleocapsid protein (N protein; pc3), and their respective subgenomic RNAs can be detected both in MSpV-infected plant and insect hosts.

Serological and Nucleic Acid-Based Relationships

Antibodies to two tenuivirus proteins, p4 (the NCP) and pc3 (N protein), have been generated for most tenuiviruses, and some serological comparisons have been done. Using stringent serological tests, antibodies to each of these proteins have generally shown positive reactions only with corresponding proteins of

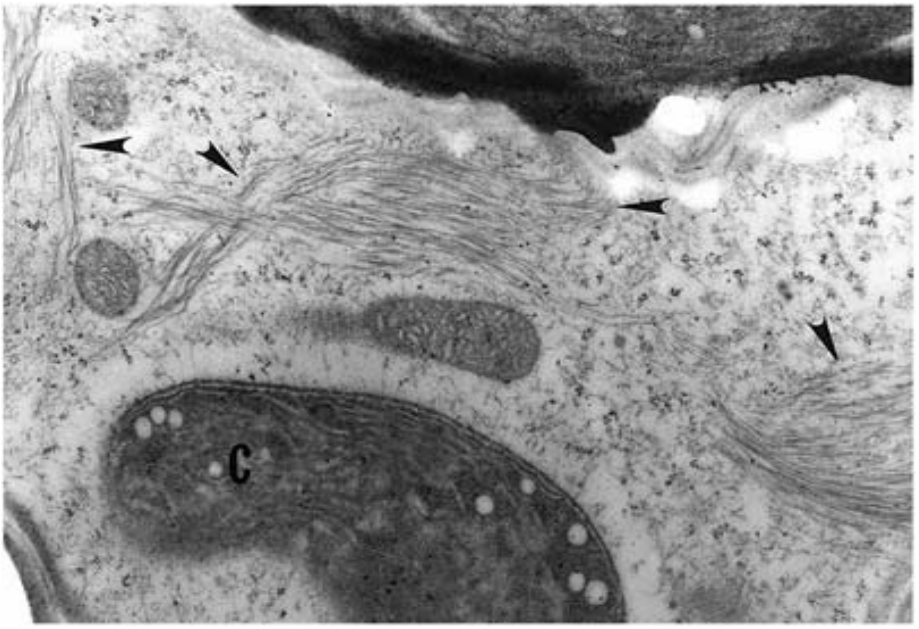

Figure 6 Transmission electron micrograph of a cell of a MSpV-infected *Zea mays* plant. C indicates a chloroplast. Arrows indicate the MSpV typical p4 (NCP) needle-shaped inclusions.

their respective tenuivirus. However, by using less stringent serological tests, slight serological cross-reactions have been obtained between similar proteins encoded by different tenuiviruses. The N proteins of RSV and MSpV are distantly serologically related, as are those of RSV and RGSV. However, the MSpV N protein does not show a serological relationship to those of RGSV or RHBV. Only slight serological crossreactions were detected when the MSpV and RHBV NCPs were compared. Thus, current data suggest that these respective Tenuivirus-encoded proteins are generally serologically distinct from each other.

More recently, computer-based comparisons of tenuivirus genomic RNA nucleotide sequences, and comparisons of deduced amino acid sequences for tenuivirus-encoded proteins have shown that the tenuiviruses are closely related, and they have some specific similarities with some vertebrate-infecting viruses. The genome organizations are similar for all tenuiviruses, and the respective encoded proteins exhibit detectable degrees of similarity. However, some of the tenuivirus-encoded proteins exhibit similarity to related proteins of other viruses. Tenuivirus pc1, pc2 and pc3 all show similarities with proteins encoded by the genomes of viruses within the genus *Phlebovirus*. The RSV pc1, the putative RDRP, shows *c.* 30% identity, between residues 493–2026, with the L protein of viruses in the genus *Phlebovirus*. RSV pc1 also contains other features found in phlebovirus L proteins, including the four conserved polymerase motifs. The MSpV pc2 shares features found for the phlebovirus glycoproteins, including a putative conserved cleavage site, and pc3 (the N protein) showed significant similarity to the N proteins for two viruses in the genus *Phlebovirus*.

Biologically the viruses in the genera *Phlebovirus* and *Tenuivirus* are distinct, but still have some general similarities. Phleboviruses infect their invertebrate vectors as well as their vertebrate hosts, while tenuiviruses infect their invertebrate vectors (planthoppers) and plants. Distinct membrane-bound spherical virions are typical for phleboviruses. Within these are three RNPs containing the three genomic RNAs. No similar virions are yet found for tenuiviruses, but RNPs similar to those of the phleboviruses are common, and these separately contain the five tenuivirus genomic RNAs. The genomic RNAs of tenuiviruses and phleboviruses have eight identical nucleotides at their 5′ and 3′ termini. Finally, viruses in these two genera exhibit somewhat similar genome organizations, coding arrangements and expression strategies, and some of their gene products show significant similarity. Thus, tenuiviruses and phleboviruses appear to have a common evolutionary lineage.

Epidemiology and Control

Tenuivirus epidemiology is determined in part by the biology and behavior of their planthopper vectors. Delphacid planthoppers are wing dimorphic, having both short- and long-winged adult forms (**Fig. 2**). Short-wing forms are capable of spreading tenui-

viruses over short distances by walking from plant to plant. Long-winged forms can disperse by active flight and as such can spread tenuiviruses over long distances (several kilometers). Planthopper vector populations fluctuate seasonally, and corresponding tenuivirus-induced diseases also fluctuate seasonally and from year to year. However, when crop incidence corresponds with high planthopper populations or activity, diseases caused by tenuiviruses often result. For example, in Florida MSpV disease in *Z. mays* occurs in fall-planted maize crops. *P. maidis* populations build up on alternate grasses during the summer months. As the fall-planted maize plants emerge, planthoppers move into the young succulent plants and severe disease can result. Later fall, or winter or spring plantings are not as severely affected. A similar situation has been reported from Japan for RSV, and when high planthopper populations coincide with young plants, resulting disease can be severe.

Tenuivirus disease control strategies based upon epidemiological data (i.e. late planting to avoid planthopper activity) may offer some help in controlling diseases caused by tenuiviruses; however at present, forecasting tenuivirus epidemics has not proven to be reliable, and thus this has hampered using tactics such as delayed planting. Both plant-derived and genetically engineered forms of resistance to tenuiviruses in plants have been described. Genetic resistance seems to be the most useful and effective strategy for attempting to control RHBV, RGSV and RSV in rice. Continued plant breeding efforts will probably be necessary to provide long-term tenuivirus disease control.>

TETRAVIRUSES (*TETRAVIRIDAE*)

Terry N Hanzlik and **Karl HJ Gordon**, CSIRO Entomology, Canberra, Australia

Introduction and History

The *Tetraviridae* are a family of viruses isolated exclusively from lepidopteran insects (moths, butterflies) that have a positive-sense, single-stranded (ss) RNA genome encased in an icosahedral capsid. They were initially isolated and characterized in Australia and South Africa in the 1960s from cadavers of emperor moths. The extensive work on the viruses isolated from the South African *Nudaurelia capensis cyntherea* (pine emperor moth) led them to being known for a while as the *Nudaurelia* β-like group. The distinctive $T = 4$ quasi-symmetry of the capsid's icosahedral structure focused initial attention on the group and engendered the family's present name (from the Greek *tettares*, four). Tetraviruses have been difficult to study because of their limited availability, which was restricted to field-collected insect cadavers, and because of the inability to culture them in cell lines. These difficulties, combined with a perceived lack of economic importance, served to hinder work on the group until new strategies allowed new ways of looking at, and working with, tetraviruses. These studies indicate that the virology of tetraviruses has general implications and that it can be exploited in exciting new ways for agriculture and medicine.

Taxonomy and Serology

Earlier, viruses were classified as members of the family on the basis of a positive serological reaction to sera raised against a few well-characterized tetraviruses. Most of the members noted in **Table 1** have been classified on this basis. Now, however, analysis of physical characteristics is the favored approach, with serology usually used at a later stage. Once an icosahedral capsid containing an ssRNA genome has been ascertained, two strong indicators of tetraviruses

viruses over short distances by walking from plant to plant. Long-winged forms can disperse by active flight and as such can spread tenuiviruses over long distances (several kilometers). Planthopper vector populations fluctuate seasonally, and corresponding tenuivirus-induced diseases also fluctuate seasonally and from year to year. However, when crop incidence corresponds with high planthopper populations or activity, diseases caused by tenuiviruses often result. For example, in Florida MSpV disease in *Z. mays* occurs in fall-planted maize crops. *P. maidis* populations build up on alternate grasses during the summer months. As the fall-planted maize plants emerge, planthoppers move into the young succulent plants and severe disease can result. Later fall, or winter or spring plantings are not as severely affected. A similar situation has been reported from Japan for RSV, and when high planthopper populations coincide with young plants, resulting disease can be severe.

Tenuivirus disease control strategies based upon epidemiological data (i.e. late planting to avoid planthopper activity) may offer some help in controlling diseases caused by tenuiviruses; however at present, forecasting tenuivirus epidemics has not proven to be reliable, and thus this has hampered using tactics such as delayed planting. Both plant-derived and genetically engineered forms of resistance to tenuiviruses in plants have been described. Genetic resistance seems to be the most useful and effective strategy for attempting to control RHBV, RGSV and RSV in rice. Continued plant breeding efforts will probably be necessary to provide long-term tenuivirus disease control.>

TETRAVIRUSES (*TETRAVIRIDAE*)

Terry N Hanzlik and **Karl HJ Gordon**, CSIRO Entomology, Canberra, Australia

Introduction and History

The *Tetraviridae* are a family of viruses isolated exclusively from lepidopteran insects (moths, butterflies) that have a positive-sense, single-stranded (ss) RNA genome encased in an icosahedral capsid. They were initially isolated and characterized in Australia and South Africa in the 1960s from cadavers of emperor moths. The extensive work on the viruses isolated from the South African *Nudaurelia capensis cyntherea* (pine emperor moth) led them to being known for a while as the *Nudaurelia* β-like group. The distinctive $T = 4$ quasi-symmetry of the capsid's icosahedral structure focused initial attention on the group and engendered the family's present name (from the Greek *tettares*, four). Tetraviruses have been difficult to study because of their limited availability, which was restricted to field-collected insect cadavers, and because of the inability to culture them in cell lines. These difficulties, combined with a perceived lack of economic importance, served to hinder work on the group until new strategies allowed new ways of looking at, and working with, tetraviruses. These studies indicate that the virology of tetraviruses has general implications and that it can be exploited in exciting new ways for agriculture and medicine.

Taxonomy and Serology

Earlier, viruses were classified as members of the family on the basis of a positive serological reaction to sera raised against a few well-characterized tetraviruses. Most of the members noted in **Table 1** have been classified on this basis. Now, however, analysis of physical characteristics is the favored approach, with serology usually used at a later stage. are a particle diameter of 35–41 nm and a density in CsCl of $<1.30\ g\ mL^{-1}$. These characteristics are not definitive, however, and so the International Committee on the Taxonomy of Viruses distinguishes them in its key from similar RNA viruses, such as caliciviruses, on the basis of their being an insect virus, having a major coat protein component of M_r >60 000, and the production of a coat protein from a separate RNA.

The family is unique for positive-strand icosahedral viruses in having two genera, *Betatetravirus* (β-type viruses) and *Omegatetravirus* (ω-type viruses), distinguished by the number of ssRNAs comprising their genomes. The ω-type genus has a bipartite genome and has the Nudaurelia ω-virus (NωV) as the type virus; the β-type genus has its complete genome on a single RNA strand and has the Nudaurelia β-type (NβV) virus as its type virus. Some confusion about classifying β-type viruses can result when a second RNA is extracted from their purified virions; this proves to be a coencapsidated subgenomic RNA, corresponding to the 3′ region of the genomic RNA. Particle morphology viewed from high-resolution electron micrographs may also be used to distinguish virus particles from the two genera on a tentative basis. Reconstructed images at 32 Å resolution may show three distinct pits in planar faces of β-like particles, which are not visible in the ω-like particles (**Fig. 1**).

Serological relationships among the viruses belonging to the two groups show a contrasting pattern. The β-type viruses show a wide relationship, with each member having a positive serological reaction to at least one other member of the genus. This is despite low sequence similarity, as viewed by hybridization at low stringency. However, the two known ω-type viruses do not show a serological relationship, even though they are highly similar at the sequence level.

Physical Properties

Properties of the structural proteins

As is apparent in **Table 2**, data obtained for many tetraviruses show only one major protein, usually with an M_r of >60 000. However, these data were

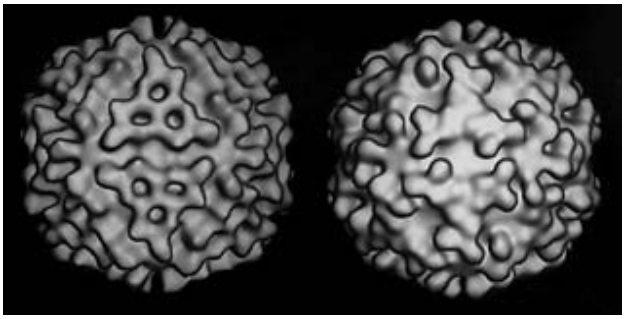

Figure 1 Image reconstructions of frozen hydrated particles of NβV (left) and NωV (right) analyzed by electron microscopy. (Courtesy of Norman Olson and Tim Baker).

obtained before more precise measurements on some tetraviruses showed the equimolar presence of a minor protein with an M_r of 7000–8000. Virions of all tetraviruses are now believed to have this protein constituent. While the minor protein is unmodified, the major protein has an N-terminal block of unknown structure. Also seen in SDS-PAGE profiles of tetravirus proteins extracted from purified virions are small amounts of a protein slightly larger than the major protein. This is a residual amount of an uncleaved protein that is the precursor to both the major and minor proteins. The cleavage takes place upon assembly of the capsid by a mechanism believed to be similar to that detailed for nodavirus capsids. The cleavage occurs towards the C-termini of the precursor proteins between Asn and Phe residues in ω-type tetraviruses and between Asn and Gly residues in β-type tetraviruses.

Properties of the genome

RNAs found encapsidated in tetravirus particles have the lengths shown in **Table 2.** As noted previously, a second species of subgenomic RNA of 2–3 kb in length may be found in minor amounts in β-type RNA, even though this group has a monopartite genome. The genomic RNA strands are capped on their 5′ ends, similarly to most mRNAs, but are not polyadenylated at the 3′ end. However, strong evidence indicates an intriguing tRNA-like secondary structure with a valine anticodon located at the 3′ terminus. The tetraviral tRNA-like structures are the only ones known for an animal virus and are distinct from the plant virus tRNA-like structures by not having a pseudoknot in the aminoacyl stem. Extensive secondary structure elsewhere on the tetraviral genomic RNAs is also likely.

Properties of the virion

Biophysical characteristics of tetravirus particles are listed in **Table 2.** The most precisely measured particle diameters are those of the type viruses, 39.7 nm for NβV and 41.0 nm for NωV. Measurements for other tetraviruses vary slightly below these values, which may be due to less precise measurements in photomicrographs. The equilibrium densities are generally at the low end of the range of densities ($<1.30\,g\,ml^{-1}$) displayed by unenveloped icosahedral viruses with ssRNA genomes. Tetraviral particles appear to be robust. They are resistant to chloroform extraction and retain stability upon exposure to a wide range of pH (3–11).

The distinctive structure of the tetraviral capsid has drawn much attention to the family, for it is the only capsid solely organized with $T = 4$ quasi-symmetry which allows 240 protein subunits to comprise the capsid. Other, more complex viruses have only substructures organized with this motif, while most other viruses with unenveloped icosahedral capsids have $T = 3$ quasi-symmetries that allow only a 180 subunit composition. Low-resolution studies from image reconstructions of electron micrographs show the 240 protein subunits are arranged in Y-shaped trimers on the surface of the particle (**Fig. 1**). Four each of the trimers compose the irregular triangles seen in **Fig. 1**, which have planar faces separated by deep grooves. The planar faces of the two β types studied in this manner (NβV and TeV) show the three distinct pits apparent in **Fig. 1**.

Further details of the unique character of the tetravirus capsid emerge from the high resolution (2.8 Å) structure of the NωV capsid determined by x-ray diffraction methods (**Fig. 2**). The protein subunit has three distinct domains located on the interior, middle and exterior of the capsid. The conformation of exterior domain is that of a c-type immunoglobulin-like (Ig-like) domain, making the tetravirus capsid the only known example of this structure found in an unenveloped icosahedral virus (one other Ig-like structure has been found on the more complex, enveloped dengue fever virus). The Ig-like structure and its association with binding, as well as its prominent location on the capsid's exterior, suggest that this domain is as least partly responsible for the tropism of NωV. The middle region of the NωV capsid protein is the canonical 'jelly-roll' possessed by all proteins forming icosahedral capsids and forms the contiguous shell of the capsid. The interior domain consists of the cleaved minor protein and the termini of the major protein. The minor protein is mostly helical in structure and appears to interact with the genomic RNAs, as does the N-terminus of the major protein. A hypothesis has been formed in which the helix of the minor protein forms a conduit at the fivefold axis for RNA to exit the capsid through a membrane during the uncoating process.

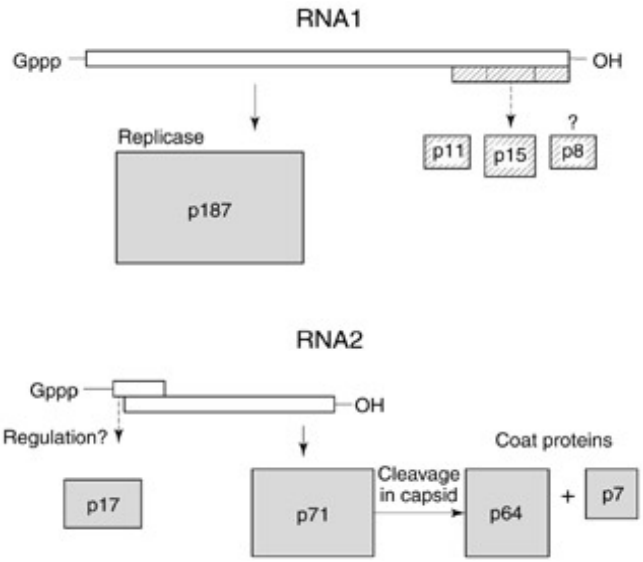

Figure 3 Genome organization and replication strategy of the ω-like tetravirus, HaSV. The genomic RNA1 and RNA2 with their ORFs are represented as open boxes above arrows leading to their functional protein products, represented as shaded rectangles enclosing their molecular weights. Dotted arrow indicates little, if any, production; question mark indicates incomplete understanding, while crosshatched rectangles indicate no evidence for expression.

Molecular Biology

Complete sequences are available for both β-type (NβV) and ω-type (HaSV) viruses. Comparison between the two sequences indicate a clear but distant relationship between the two genera. Detailed analysis of certain domains within the tetraviral sequences indicate the *Tetraviridae* belong to the α-like superfamily of RNA viruses. Analysis of the sequences give the major insights into how tetraviruses replicate, as experimental work is made difficult due to the lack of a cell culture system. However, new strategies for producing viral mutants and studying replication and coat protein assembly have given some insights into tetravirus virology.

ω-like genome organization

The complete sequence of the two RNA strands (RNA1 and RNA2) of the ω-like virus, HaSV, is available, while only RNA2 and a partial sequence of RNA1 exist for the only other known member of this genus, NωV. This information shows the gene products of the two viruses to be highly similar, except at certain key areas of the primary sequences of the coat proteins, as discussed below. Nearly the full length of HaSV RNA1 is accounted for by a single open reading frame (ORF) of 1704 codons encoding the 187 kDa replicase (**Fig. 3**). Experimental evidence exists for the function of this protein through its expression with recombinant baculoviruses (described below). It is not known whether the protein is processed into smaller fragments. Three smaller ORFs exist at the 3′ end of RNA1 out of frame with the replicase ORF which could encode proteins of 99, 140 and 73 amino acids. However, there is no evidence for a subgenomic RNA which could express them, nor is there a discernible relationship to other proteins to indicate their function, if any.

RNA2 of HaSV has two out-of-frame ORFs that overlap each other, with a 'leaky scanning' mechanism for ribosomal translation as the likely means of expressing both genes from the same RNA. The first gene has its initiating AUG at base 283 in poor context for translation initiation, which would allow most ribosomes to scan through to the second AUG in good context at base 366, which initiates the second gene. The function of the 16 522 Da product of the first gene remains unclear, although there is experimental evidence to suggest it is involved in the regulation of strand synthesis. The second gene encodes the 647 residue, 70 670 Da precursor protein for the major and minor coat proteins of HaSV. The coat protein gene for NωV encodes a slightly smaller protein than that of HaSV (644 residue) but the two are highly homologous (>67% overall identity) except for three regions of the primary sequence. The

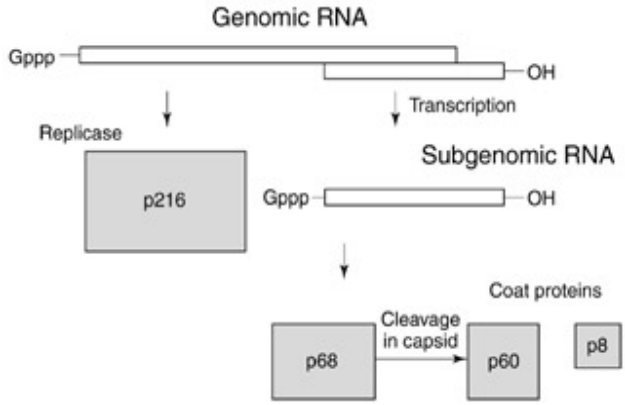

Figure 4 Genome organization of the β-like tetravirus, NβV. The NβV genomic RNA and its subgenomic RNA with their ORFs are represented as open boxes above arrows leading to their functional protein products, represented as shaded rectangles enclosing their molecular weights.

two terminal regions (amino acids 1–48 and 601–647) have 40% and 53% identity and correspond to the interior domain, while the 145 amino acid region in the middle of the primary sequence (amino acids 274–419) has only 33% identity and corresponds to the exterior Ig-like region. These dissimilar sequences in otherwise highly similar coat proteins are consistent with the putative functions of their corresponding structural domains, i.e. binding a different host cell for the exterior domain and interacting with a different RNA sequence for the interior domain.

β-like genome organization

The sequence of the NβV genomic RNA shows it to have only two genes which overlap each other (**Fig. 4**). The larger gene located at the 5′ end produces a 1925 amino acid protein with a calculated molecular weight of 216 kDa and is the RNA-dependent RNA polymerase (replicase), as determined by homologies to those of other viruses. It is not known at present whether further processing of the product of the replicase gene into smaller proteins occurs. The smaller gene located towards the 3′ end of the NβV genome encodes the 68 549 Da coat protein precursor which is cleaved upon capsid assembly to the major and minor coat proteins. This gene is able to be translated by scanning ribosomes through the production of a subgenomic RNA encoding 2.5 kb of the 3′ end of the genomic strand. This subgenomic strand is not capable of being replicated as only one species of double-stranded RNA with the length of the genomic strand is extracted from NβV infected larvae.

Genetic manipulation of tetraviruses

The lack of a cell culture system necessitated the development of a novel means of producing and examining effects of specific mutations in the genomes of tetraviruses. The strategy for producing HaSV mutants exploits its inactivity outside a host gut cell and the ability of the components of many simple icosahedral viruses like HaSV to assemble into virions in a wide variety of environments. Thus, by arranging the presence of the three main component types of HaSV (RNA1, RNA2 and coat protein) inside a plant cell where the virus is inactive, the two RNAs are able to assemble with coat protein to form a virion capable of infecting larvae. This is accomplished in a transient plant protoplast expression system (*Nicotiana plumbiganofolia*) by transfecting three plasmids, two producing the RNA strands by *in vivo* transcription off a modified plant promoter and the other expressing the coat protein precursor. The RNA-producing plasmids are constructed with cDNA copies of the viral RNAs behind a modified cauliflower mosaic virus 35S promoter designed to produce capped transcripts starting at the first viral base. An intact 3′ terminus for the RNA strand is achieved with a *cis*-acting ribozyme engineered to cleave the transcribed RNA after the last 3′ viral base. The third plasmid is engineered to express the coat protein precursor ORF behind an unmodified 35S promoter and without a ribozyme. Upon transfection of the three plasmids, the protoplasts are incubated for 3 days to allow assembly of the components and then fed to insect larvae to replicate and amplify the virus. Virus mutants are produced by site-directed mutagenesis upon the RNA-producing plasmids.

Replication

To counter the difficulty of the lack of a cell culture system to study the replication of HaSV, a system dependent on expressing tetraviral components with two different recombinant baculoviruses was developed. The first baculovirus expressed the HaSV replicase in Sf9 cells behind the polyhedrin promoter to the degree it was readily detected on an immunoblot of Sf9 cells. The high quantity of enzyme apparently compensated for a low level of activity, as replication of RNA2 templates presented to it by a second co-infected baculovirus was detected. The second baculovirus was engineered to produce precise transcripts of RNA2 using a similar strategy to the protoplast expression of tetraviral RNAs with the use of the same ribozyme and a modified *Drosophila* hsp70 promoter. Indicating replication was occurring with this system was the observation that no RNA2 transcript occurred on Northern blots unless the

RNA1 virus was present. By examining the effect of specific deletions of RNA2, this system is being used to examine which elements on RNA2 are important for its replication.

Studies of coat protein assembly

Similar to the coat proteins of many other small icosahedral viruses, assembly of virus-like particles (VLPs) occurs upon expression of only the tetraviral coat protein ORF in nonhomologous expression systems (yeast and baculoviruses). Of particular interest, however, are the observations indicating that the tetravirus coat proteins, without any other viral proteins, are able to perform all four generic functions of viral coat proteins: (1) binding each other to form a stable particle; (2) binding and incorporation of specific RNAs; (3) binding of host cells with subsequent entry; and (4) uncoating of RNA for translation. Experimentation has shown that VLPs display the assembly-dependent cleavage of the precursor, they are able to incorporate RNAs with viral sequences, and they bind specifically to a larval midgut receptor similar to native virions. Furthermore, purified VLPs can carry mRNAs of the reporter genes into gut cells of larvae where the reporter gene shows activity. VLPs carrying reporter gene mRNAs can be produced from Sf9 cells co-infected with two baculoviruses, one expressing the coat protein ORF and the other expressing a transcript having the reporter gene ORF in front of RNA2 sequences which allowed the transcript's encapsidation into the VLPs.

Pathobiology

Host range

Lepidopteran insects are the only known hosts for tetraviruses. A systematic survey of approximately a thousand diseased insects from different orders showed tetravirus hosts were confined largely to noctuid, saturniid and lymacodid moths of the Heterocera suborder of the Lepidoptera. Tetraviruses appear to differ in the breadth of the range of species they are able to infect. HaSV appears unable to infect species outside the subfamily Heliothinae, while *Tricoplusia ni* virus (TnV) and *Dasychira pudibunda* virus (DpV) are able to infect insects outside the family of their nominal host. Closely related viruses may have very distinct host ranges, as exemplified by NωV and HaSV. The former is able to infect a saturniid host, yet is unable to infect the noctuid heliothine host of the latter, despite having a high degree of relationship (>90% for the replicase).

No replication in other animals has been detected. Numerous animals injected with high titres of tetraviruses for antibody production have failed to show any abnormal response or disease symptoms. A detailed pathological study of mice injected with TaV showed no evidence that the virus was in any observable way harmful to them. Transfection of vertebrate cell lines with HaSV genomic RNA also showed no activity. However, studies on serological reactions by vertebrates (including humans) towards particles of tetraviruses, done in the 1970s, suggested that tetravirus specificity was more broad as positive reactions were noted. However, these reactions are believed to be nonspecific, owing to the type of serological test involved and indications that the reaction is not due to replication. Further work is required to consolidate these findings, especially in view of the large body of evidence showing the specificity of tetraviruses for insects and their potential widespread use in agriculture (see below).

Transmission and symptoms

Horizontal transmission via ingestion by larvae has been demonstrated for several tetraviruses. Interestingly, the range of symptoms from this means of transmission varies greatly. Few or no symptoms (only slight growth retardation at high doses) can be seen upon infection of several hosts by TnV. On the other hand, NβV displays a marked pathological effect upon larvae 7–9 days postinfection, with infected larvae in all stages ceasing to feed, becoming moribund, discolored and flaccid, and, upon death, remaining hanging by their prolegs. The cadavers are distinct from those infected with baculoviruses because an internal liquefaction occurs which leaves the integument intact. A dependence upon the larval life-stage can also be seen. HaSV is highly active against neonate larvae, with as little as 5000 particles causing them to cease feeding within a day and to die within 4 days. Surprisingly, HaSV infection of later instar larvae shows little effect. It has not been clearly demonstrated whether adults or pupae are capable of being infected by tetraviruses, although NβV was reported to be isolated from these stages.

Vertical transmission of tetraviruses is also believed to occur. It has been impossible to remove HaSV from a laboratory-bred colony of its host despite stringent sanitation procedures. Evidence from studies of HaSV pathology in early instar larvae show subpathogenic, low-level infections exist for this virus, which is highly virulent at higher doses. TnV appears to be vertically transmitted under artificial conditions and there is evidence for vertical transmission of the more virulent DpV. Symptoms of infection from this route are difficult to detect, with the most obvious being slow-growing larvae. The

evidence for vertical transmission, however, remains undefinitive and further work needs to be done to establish it. The most likely mechanism for vertical transmission, should it occur, is transovum, as tetraviruses appear to infect only midgut cells (see below).

Histopathology and tropism

All the available evidence points to the larval midgut as the exclusive site of infection of tetraviruses. Examinations by light and electron microscopy for several viruses have shown their particles only in midgut tissues. In a definitive experiment showing this phenomenon, Northern blots of RNA extracted from infected larvae showed the presence of HaSV RNA only in midgut tissue, even after infection by injection into the hemocele. This experiment also shows that the tissue tropism of HaSV is not due to the lack of exposure to the virus by other host tissues. The marked tropism of HaSV which prevents its culture in continuous cell lines appears to be a function of both the abilities of the particles to bind and enter cells and a restriction on the activity of the replicase in cells other than those of the midgut. Binding studies using the histochemical detection of HaSV particles on cross-sections of larval midguts show exclusive binding to outer cell membranes, particularly the goblet cell apical membrane. However, even when cellular uptake mechanisms for particle entry are bypassed in cultured cells (including those of the cotton bollworm host, *Helicoverpa armigera*) by transfection of HaSV genomic RNA, no replication activity is seen.

In the most detailed pathology study for a tetravirus, HaSV was seen to infect all three major cell types of the lepidopteran midgut: goblet, columnar and regenerative stem cells. Infected cells showed crystalline arrays of particles, which were associated with a massive increase in the rate of cells detaching from the basal membrane and shedding into the lumen. Cells were shed to the extent that few, if any, remained in midguts of insects with advanced infections; this phenomenon was correlated to an increased rate of apoptosis. Hence the rapid loss of infected gut cells may be a cellularly mediated defense that protects the insect against more extensive viral infection.

Ecology

Only informal reports are available to describe the broader interactions between tetraviruses and their hosts in the wild. Hence much must be surmised and inferred from laboratory studies and the limited reports of agricultural use. The broad range of disease symptoms and possible dual means of transmission suggest a complicated picture.

Tetraviruses are readily found in insect hosts with other tetraviruses and other virus types, including cytoplasmic polyhedrosis viruses, baculoviruses and other small RNA viruses. Persistence in wild populations of *Nudaurelia* for decades in South Africa has been described for NβV and NωV, with the latter succeeding the former in prevalence in recent times. This succession may have contributed to the recent decline of the host population to the point where few moths have been observed in areas formerly inundated. The persistence of tetraviruses is probably due to their ability to initiate sublethal infections and to be transmitted vertically, as well as the apparent robust nature of the particle, which would favor its vertical transmission.

At high densities of host populations, horizontal transmission is the main mode of viral spread through dispersed cadavers and frass in which tetraviruses have been shown be present. The *Nudaurelia* populations recorded large-scale epizootics at high densities, at times displaying up to 90% mortality nearly every year for at least four decades. In contrast, no HaSV epizootics have been observed in the low density *H. armigera* populations in closely scrutinized Australian cotton fields, and yet the virus clearly has the capacity for virulence. The few infected *H. armigera* larvae found in the wild are likely to be the result of vertical transmission.

Economic Use and Future Perspectives

Tetraviruses, as well other small RNA viruses of insects, have been little used in Western agriculture as biological control agents for pests. However, SaV and DtV have been used to great effect in Malaysian oil palm plantations to control limacodid caterpillar pests, which can reach very high densities. Production and dispersal of these viruses was accomplished by suspension of naturally infected cadavers in water and spraying. Laboratory tests with purified HaSV on larvae of *H. armigera* strongly indicate their potential for the control of this major pest. Furthermore, the association of NωV with the decline of *Nudaurelia* populations indicates that long-term effects on pest populations with the use of tetraviruses are possible.

There is more interest in the economic use of tetraviruses, however, when the group is looked at through the lens of biotechnology. One major obstacle to their use for insect control has been the difficulty of producing them. However, the simplicity of the tetraviral genome makes production of viral particles in nonhost cells feasible (see above, Molecular Biology). The assembly of HaSV in plant

Figure 5 Tobacco made transgenic with genes that produce a tetravirus. The genes introduced into the transgenic tobacco plant on the right were designed to produce the protein and RNA components of the tetravirus, HaSV. These components were able to assemble into infectious virions, as indicated by the stunted, HaSV infected larva encircled below the leaf on the right. The larger larvae feeding on the control leaf on the left were not infected.

protoplasts described above suggested that transgenic crop plants could also accomplish the same feat. To test this hypothesis, the three genes required for HaSV assembly were placed into the genomes of tobacco plants by *Agrobacterium*-mediated transgenesis. The plants were screened for antifeeding activity and several showed they could induce stunted larvae, which subsequently were shown to be infected with HaSV (**Fig. 5**). This experiment indicates a new approach to the control of the world's most economically important group of insect pests, the heliothine caterpillars. Assembly of HaSV is also being tested in yeast with the same three gene strategy. Production of tetraviruses by yeast fermentation would make the virus available cheaply for spraying purposes.

Biotechnology may have another use for tetraviruses that may impact on medicine as well as agriculture. Their particles have the potential to be used as versatile vehicles for the targeted delivery of nonviral RNAs to new cell types. The tetravirus virion can be viewed as a delivery vehicle for viral genes that employs an Ig-like domain to bind specifically to a particular cell surface epitope, allowing its entry into midgut cells. This suggests that its exchange for another Ig-like domain having affinity towards another surface epitope of another cell type would change the destination of the particle's RNA contents to the other cell type. This potential targeting ability, combined with the already demonstrated ability to produce functional VLPs with nonviral mRNAs (described above), makes for a potentially versatile system for delivering transient gene activities to specific cells. Possible medical uses include a novel form of gene therapy or immunotoxins where toxin mRNAs are delivered to cancer cells, allowing more specific expression of toxicity than the present forms. In agriculture, mRNAs for insect-specific toxins could be targeted more quickly to a particular insect. This approach would preclude the use of a virus for every pest insect, and such a system could be made more acceptable to consumers and regulatory authorities.

THEILER'S VIRUSES (*PICORNAVIRIDAE*)

Howard L Lipton, Division of Neurology, Evanston Hospital, Evanston, Illinois, USA

History, Geographic Distribution and Host Range

The mouse encephalomyelitis viruses are enteric pathogens of mice. Discovered by Max Theiler in the early 1930s and originally called murine poliovirus, these agents are frequently referred to as Theiler's murine encephalomyelitis viruses (TMEV). Theiler initially recovered isolates from mice with spontaneous paralysis housed in a research colony; subsequently the TMEV have been found in virtually all nonbarrier mouse colonies, where they cause asymptomatic intestinal infections. While the TMEV are widely distributed throughout the world in mouse colonies, their host range is quite narrow, and includes only mice and rats. Serological evidence indicates that *Mus musculus*, the feral house mouse, is the natural host, but several other species of voles and possibly rats may also serve as hosts. As is the case for other picornaviruses, following peripheral routes of infection, TMEV spreads to the central nervous system (CNS) producing encephalitis, or more commonly, spontaneous paralysis, i.e. poliomyelitis. The incidence of spontaneous paralysis is low, around one paralyzed animal per 1000–5000 mice in a colony reported in the older literature. Since the TMEV may go undetected unless appropriate serological tests for the virus are performed, these agents are a potential hazard for investigators using mice in biomedical research.

In recent years, this group of viruses has assumed additional importance because TMEV infection in mice provides one of the few available experimental animal models for multiple sclerosis. TMEV-induced demyelinating disease is a relevant animal model for multiple sclerosis because: (1) chronic pathological involvement is virtually limited to the CNS white matter; (2) myelin breakdown is accompanied by mononuclear cell inflammation; (3) demyelination results in clinical disease, e.g. spasticity, from involvement of upper motor neuron pathways; (4) myelin breakdown is in part immune-mediated; and (5) the disease is under multigenic control with a strong linkage to certain major histocompatibility complex (MHC) genes.

Classification and Serologic Relationships

Based on the complete nucleotide sequence and genome organization, TMEV have been classified in the genus *Cardiovirus* of the family *Picornaviridae* along with encephalomyocarditis virus (EMCV) and Mengo virus (**Table 1**). TMEV are a separate serological group of cardioviruses, as polyclonal antisera show no crossneutralization between TMEV and EMCV or Mengo virus. Because the coat proteins share a high level of amino acid sequence identity with the other cardioviruses, crossreactions are seen on ELISA when disrupted virions are used as antigens and on complement fixation tests.

Group C: Vilíuisk virus[a]

[a] Vilíuisk virus is either a divergent TMEV or it belongs in a separate group as shown here.

Three-dimensional Virion Structure

Picornavirions have a relative molecular mass of $\sim 8.5 \times 10^6$ Da, of which ~30% is RNA. The spherical virus particles have an external diameter of about 30 nm. The capsid proteins are arranged in icosahedral symmetry with 60 protomers, each composed of a single copy of VP1, VP2, VP3 and VP4.

The three-dimensional structures of the GDVII, BeAn and DA strains have been determined at ~0.3 Å resolution by x-ray crystallography. The overall architecture is quite similar to that of other picornaviruses whose structures have been determined, and closely resembles that of Mengo virus. Each of the three major capsid proteins VP1, VP2 and VP3 consist of a wedge-shaped eight-stranded antiparallel β barrel, as demonstrated for other picornaviruses. The N-termini of the capsid proteins form an extensive, intertwined network on the inner surface of the protein shell. The loops connecting the β strands form the outer surface features of the protein shell and provide the surface differences with Mengo virus. The pit which has been proposed as the viral receptor is a broad depression on the virion surface at the junction between VP1 and VP2 along the twofold axis. The TMEV surface structures can be differentiated from that of Mengo virus in having: (1) a larger VP1 CD double loop, with loop I containing an extra five residues and shifted more toward the VP2 EF puff at the twofold axis, while loop II points more toward the fivefold axis; (2) an 11 residue insertion in the VP2 EF puff forming a double loop in which the inserted loop interacts with the VP1 FMDV GH loop; and (3) the tip of the VP3 knob (a loop inserted in βE) points straight outward on the rim of the pit.

Properties of the Genome

The genetic component of the virion is a positive-sense, single-strand RNA molecule that has a sedimentation coefficient of 35 S and is 8100 nucleotides long. Virion RNA has a poly(A) tract on the 3′ end and a small basic protein, VPg, covalently linked to the 5′ end. The complete genomes of the GDVII, DA and BeAn strains have been cloned and sequenced. With the notable absence of a poly(C) tract in the 5′ noncoding region, the organization and sequence of the TMEV genome is remarkably similar to that of EMCV. The polyprotein of the BeAn strain, a typical TMEV, initiates at the AUG codon at nucleotide 1065 and extends for 6909 nucleotides (or 2303 codons), ending at the single UGA termination triplet at base 7972. The polyprotein-coding region is flanked by 5′ and 3′ noncoding sequences of 1064 and 125 nucleotides, respectively. In BeAn the 5′ noncoding region contains a stretch of 11 pyrimidines interrupted by a single purine before the AUG at nucleotide 1065. In picornaviruses, the 5′ noncoding region mediates cap-independent translation and also serves as an internal ribosome entry site (IRES), e.g. when experimentally present in the intercistronic region in a bicistronic mRNA. The TMEV 5′ noncoding sequences have been predicted to form stable secondary structures, which in the 500 nucleotides upstream of the authentic AUG (at 1065) are nearly identical to those predicted for EMCV and foot-and-mouth disease virus. In BeAn, eight AUGs precede the initiator AUG, but none of them has an optimum Kozak context sequence. Hence, it could be argued that selection of the authentic initiator AUG after binding of ribosomes to TMEV RNA does not involve internal ribosome binding. However, BeAn nucleotides ~500–1065 determine a structure that serves as an IRES in bicistronic mRNAs both *in vitro* (rabbit reticulocyte lysate) and *in vivo* (BHK-21 cells). A poly(A) tail of indeterminate length is present on the 3′ end of the viral genome.

Polyprotein and Post-translational Processing

As is the case for other picornaviruses, the final TMEV gene products are the result of post-translational cleavages of the polyprotein. The 2303 amino acid polyprotein has a calculated molecular weight of 255 990. (This applies to BeAn virus; the polyprotein of GDVII virus contains no insertions or deletions; however, two VP1 amino acids are deleted in that of DA virus.) The processing scheme follows the standard L–4–3–4 picornavirus polypeptide arrangement, i.e. the leader peptide (L), four capsid polypeptides in part one (P1) of the genome, three polypeptides in P2 and four polypeptides in P3 (**Fig. 1** and see below). The coding limits of individual polypeptides have been predicted by analogy with those of EMCV, as the only confirmation to date of the deduced sequence is that of the N terminus of 1D. The eight amino acids flanking the putative cleavage sites are highly conserved for the two viruses. All of the cleavage sites in the polyprotein except for two, 1A/1B and 2A/2B, are processed by the viral protease 3C. The TMEV 3C protease therefore processes Q–C, as well as Q–S and Q–A, dipeptides and, in addition, the E–N dipeptide at the 1D/2A cleavage. However, only 6 of 8 Q–G, 2 of 13 Q–S and 1 of 7 Q–A dipeptides in the polyprotein are cleaved by 3C, indicating that involvement of secondary, tertiary, or both types of structure is also important for recognition of these particular dipeptides. The 2A/2B site is probably autocatalytically cleaved, as in EMCV.

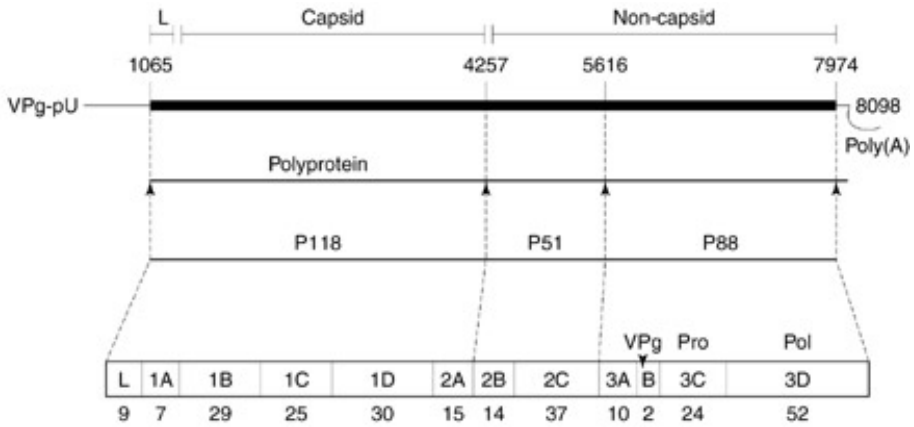

Figure 1 TMEV-specific protein cleavage scheme. The intermediate cleavage products are not shown. The numbers below the 11 final gene products are the molecular weights (in thousands) of each of the proteins as calculated from their predicted amino acid sequences.

Cleavage of the polyprotein gives rise to three primary products, the first of which (116 530 mol. wt) contains the leader protein (8593 mol. wt), the P1 capsid proteins, and the first P2 polypeptide 2A (15 353 mol. wt). Thus, the initial precursor released from the polyprotein is like that of the other cardioviruses and differs from that of other groups of picornaviruses. The capsid proteins are arranged in the following order: 1A (VP4; 7102 mol. wt), 1B (VP2; 29 433 mol. wt), 1C (VP3; 25 463 mol. wt), and 1D (VP1; 30 457 mol. wt). The second processing precursor (2BC) is 51 708 mol. wt and gives rise to 2B (14 863 mol. wt) and 2C (36 845 mol. wt). The P2 proteins 2A, 2B and 2C have not been assigned functions as yet for the cardioviruses. The third or C-terminal precursor protein is 87 950 mol. wt and is processed into the four mature proteins 3A (9934 mol. wt), 3B (2169 mol. wt), 3C (23 612 mol. wt) and 3D (52 235 mol. wt). Protein 3B, also designated VPg, is a small basic protein which is 20 amino acids in size and is found covalently linked to the 5′ end of viral RNAs. This peptide may be important in viral replication. By analogy with other picornaviruses, the 3C polypeptide is a viral protease and 3D is the viral polymerase.

Physical Properties

Since the TMEV do not have an envelope they are more resistant than lipid-containing viruses to chemicals and physical agents. They are insensitive to chloroform, ether, nonionic detergents (such as deoxycholate, NP40 and Tween-80) and the ionic detergent sodium dodecyl sulfate, but are inactivated by 0.3% formaldehyde and HCl 0.1 mol l^{-1}. TMEV are rapidly destroyed at temperatures over 50°C and lose some infectivity upon lyophilization. Purified virions can be stored for long periods of time at −70°C without loss of infectivity, but slowly lose infectivity on storage at −20°C.

As enteroviruses the TMEV require stability at low pH to pass through the acidic conditions of the stomach. The TMEV are stable over the entire pH range from 3 to 9.5. However, in contrast to the other cardioviruses, such as Mengo virus and EMCV, they are not highly thermolabile in the presence of 0.1 mol l^{-1} chloride or bromide in the pH range 5 to 7.

Theiler's virions have a sedimentation coefficient of 150 S by velocity centrifugation in sucrose and a buoyant density of 1.34 g ml^{-1} by isopycnic centrifugation in cesium salts.

Replication

The reader is referred to entries on human poliovirus and cardioviruses for the strategy of picornavirus RNA replication as no information is available on this topic for the TMEV.

Mapping Genomic Determinants Important in Pathogenesis

The existence of two distinct TMEV neurovirulence groups makes the TMEV particularly useful for molecular pathogenesis studies. The difference in virulence (LD_{50}) between the highly virulent and less virulent TMEV groups is of the order of 10^5 plaque-forming units. Further, full-length cDNA clones of the highly virulent GDVII and the less virulent DA and BeAn viruses have been assembled in different laboratories, and viral RNA transcribed from these cDNAs has been demonstrated to be infectious upon transfection of mammalian cells. To identify the

PFU, plaque-forming units.

determinants important in pathogenesis, e.g. virulence and persistence, recombinant viruses between parental cDNAs have been assembled and analyzed *in vitro* and after inoculation of mice.

Neurovirulence and persistence have been mapped primarily to the P1 region encoding the leader and the coat proteins. These results suggest that the mechanism for the pathogenetic properties of virulence and persistence are likely to involve the exterior surface of the virus, and immunological or receptor-mediated events may be involved. Chimeric virus constructs in the coat protein region, resulting in the interaction of potentially disparate protomeric subunits of two parental viruses, have been found to be prone to assembly defects. Such chimeric viruses may exhibit compromised growth *in vitro*. Thus, the pathogenetic phenotypes of chimeric viruses need to be interpreted with caution and require analysis of their growth properties *in vitro*.

Transmission and Tissue Tropism

TMEV are transmitted by the fecal–oral route but can be separated into two biological groups based on neurovirulence (**Table 2**). The first group, consisting of three isolates, GDVII, FA and Ask-1, is highly virulent and causes a rapidly fatal encephalitis in mice. The other TMEV, some 10–20 isolates, that include viruses recovered from the CNS of spontaneously paralyzed mice and from the feces of asymptomatic mice, form a second, less virulent group. Experimentally, the less virulent viruses produce poliomyelitis (early disease) followed by demyelinating disease (late disease). When cell culture-adapted less virulent TMEV are used to inoculate mice, the poliomyelitis phase is subclinical; brain-derived stocks produce both of the less virulent disease phases.

Pathogenesis

Little information is available about the pathogenesis of TMEV infection following peripheral routes of infection, including feeding of virus. In general, isolates from either of the TMEV neurovirulence groups do not readily produce CNS disease following peripheral routes of inoculation, with the exception of one strain, TO(B15). TO(B15) is a mutant selected for its invasiveness from the intestinal tract. When mice are inoculated intracerebrally with the highly virulent strains, the virus replicates throughout the brain and spinal cord, causing encephalitis or encephalomyelitis. Thus, neurons as well as glial cells (astrocytes and probably oligodendrocytes) are infected in the cerebral cortex, hippocampus, basal ganglia, thalamus, brainstem and spinal cord. Affected mice develop a hunched posture and hind limb paralysis. The rapid demise of these animals is the result of widespread lytic infection. The following sections focus on the pathogenesis of the biphasic disease produced by the less virulent TMEV, which provides a model system for multiple sclerosis.

Clinical Features of Infection

Although TMEV are enterically transmitted, the pathogenesis of the infection has been primarily studied using the intracerebral route of inoculation which maximizes the incidence of neurological disease. Following intracerebral inoculation, the less virulent strains produce a distinct biphasic CNS disease in susceptible strains of mice, characterized by poliomyelitis during the first few weeks postinfection, followed by chronic, inflammatory demyelination that begins during the second or third week postinfection and becomes manifest clinically between 1 and 3 months postinfection. Mice with polio-

myelitis develop flaccid paralysis, usually of the hind limbs; only one limb may be affected, or paralysis may spread to involve all limbs and lead to death. In contrast to the fatal outcome of paralysis produced by the Lansing strain of human poliovirus type 2, complete recovery from TMEV-induced poliomyelitis is usual. Occasionally, residual limb deformities are seen as the result of extensive anterior horn cell infection and severe paralysis (early disease).

Gait spasticity is the clinical hallmark of the demyelinating or late disease. Late disease is first manifest by slightly unkempt fur and decreased activity, followed by an unstable, waddling gait. Subsequently, generalized tremulousness and ataxia develop, and the waddling gait evolves into overt paralysis. Incontinence of urine and priapism are commonly seen. As the disease advances, prolonged extensor spasms of the limbs can be induced followed by difficulty in righting. Weight loss is not seen until mice are severely paralyzed. The clinical manifestations of late disease are progressive and lead to an animal's demise in several to 14 months.

Pathogenesis and Histopathology

Motor neurons in the brainstem and spinal cord are the main targets of infection during poliomyelitis (early disease), but sensory neurons and astrocytes are also infected. TMEV do not replicate in endothelial and ependymal cells. A brisk microglial reaction is elicited, with the appearance of numerous microglial nodules, particularly in the anterior gray matter of the spinal cord. Examples of neuronophagia are quite frequent at this time, but very little lymphocytic response is seen. The poliomyelitis phase lasts 1–4 weeks, after which time little residual gray matter involvement is apparent other than resolving astrocytosis.

As early as 2 weeks postinfection, inflammation of the spinal leptomeninges begins to appear, followed by involvement of the white matter. Initially, the inflammatory infiltrates are almost exclusively composed of lymphocytes, but at later times plasma cells and macrophages are numerous. The influx of macrophages is in close temporal and anatomic relationship with myelin breakdown. Both light microscope and ultrastructural studies show that myelin breakdown is related to the presence of mononuclear cells, which either actively strip myelin lamellae from otherwise normal-appearing axons or are found in contact with myelin sheaths undergoing vesicular disruption. Foci of inflammation and myelin destruction extend from the perivascular spaces into the surrounding white matter, leading to sharply demarcated plaques of demyelination. The ultrastructure of oligodendrocytes during the initial phase of myelin breakdown has not shown alterations in oligodendroglial loops, which are in close apposition with naked but otherwise normal axons, suggesting that myelin injury may not be directly related to oligodendrocytopathology.

Sites of TMEV persistence

The sites of TMEV persistence are still disputed; however, TMEV persistence clearly involves active virus replication, as infectious virus can be readily isolated from the CNS of infected mice. *In situ* hybridization has revealed two populations of CNS cells positive for viral genomes. Virus replication in the majority of these cells (>90%) appears to be highly restricted, as they contain <500 viral genomes. A small percentage of CNS cells contain >1500 genomes, possibly as many as 10^4–10^5, and are probably productively infected. Highly restricted virus production has been demonstrated in macrophages isolated from the CNS of diseased mice; therefore, macrophages appear to be the primary target for persisting virus. It is also possible that some of the cells with restricted infection are astrocytes. The kinetics of virus replication in the CNS cells with restricted infection remains to be elucidated, such as the length of the replicative cycle and whether the cells are lysed or continue to produce infectious virus for longer times. *In vitro,* TMEV infection only occurs in monocytes once they have differentiated into macrophages. The infection of macrophage cell lines is highly restricted but with normal levels of viral translation, as substantial amounts of viral antigen are produced; ultimately infected macrophages undergo apoptosis. In contrast, oligodendrocytes appear to be productively infected, as an ultrastructural study has shown crystalline arrays of virions in oligodendrocytes in demyelinating lesions. Oligodendrocytes may correspond to the CNS cells containing large numbers of viral genomes by *in situ* hybridization. These data suggest that a lytic infection of oligodendrocytes contributes to demyelination along with immune-mediated mechanisms of damage.

Immune Response

During the first week, TMEV-infected mice mount a virus-specific humoral immune response that reaches a peak by 1 to 2 months postinfection and is sustained for the life of the host. Neutralizing and other virus-specific antibodies have been measured. The majority of the antiviral IgG response in persistently infected, susceptible mice is of the IgG2a subclass, with little antiviral IgM detected by day 14 postinfection, whereas IgG1 antiviral antibodies appear to pre-

dominate in resistant and immunized mice. Murine CD4+ T cells of the Th1 subset mediate delayed-type hypersensitivity (DTH) and regulate IgG2a production via interferon γ production, whereas CD4+ Th2 cells regulate IgG1 and IgE production via interleukin 4. Thus, the predominant IgG2a antiviral response in susceptible mice may be an *in vivo* measure of preferential stimulation of a Th1-like pattern of cytokine synthesis. Recently, virus-specific CD8+ cytolytic T cell responses have also been shown help in virus clearance during the acute phase of the infection, and may be responsible for the resistance of certain strains of mice to the demyelinating disease.

When infected, susceptible mice also produce substantial levels of virus-specific CD4+ T cell responses. T cell proliferation and DTH appear by 2 weeks postinfection and remain elevated for at least 6 months. Both DTH and T cell proliferation have been shown to be specific for TMEV and mediated by CD4+ class II restricted T cells. A temporal correlation has also been found between the onset of demyelination and the appearance of these virus-specific T cell responses, as well as for high levels of virus-specific DTH and the susceptibility of mice of different genetic backgrounds and mixes. DTH and T cell proliferative responses in infected and immunized SJL mice (a susceptible strain) are directed toward immunodominant regions (peptides) in each of the three major coat proteins. T cell responses to these epitopes in VP1 and VP2 are believed to participate in the immunopathology (see below).

Although mice mount virus-specific humoral and cellular immune responses early in the infection and peak virus titers fall by 100–1000-fold, TMEV somehow evade immune clearance to persist at low levels indefinitely in the CNS of the host, as described above. Extraneural persistence has not been observed. Current dogma holds that humoral immunity is more important than cellular immunity in clearing infections by nonenveloped viruses, such as picornaviruses, but this has not been established for TMEV; evidence has been presented for a role for both neutralizing antibodies and cytolytic T cells in TMEV clearance. The precise mechanism by which TMEV evade immune surveillance is not known but does not appear to involve antigenic variation. Although complement and virus-antibody deposition in the CNS parenchyma have not been detected, extracellular transport of virus as infectious virus-antibody complexes, in aggregates, or contained or enveloped within cell membranes are means whereby virus could be protected from TMEV-specific immune responses and continue to replicate. This is an area for further study to enable a better understanding of how TMEV evade immune surveillance.

Immune-mediated Mechanism of Demyelination

Appropriately timed immunosuppression can prevent the clinical signs and pathological changes of TMEV-induced demyelinating disease, indicating that the immune response participates in myelin breakdown. A number of different immunosuppressive modalities have proven to be effective, including cyclophosphamide, antilymphocyte serum, antitumor necrosis factor antibodies, and monoclonal anti-IA, CD4+ and CD8+ antibodies. If given too early in the course of early disease, the infection in neurons is potentiated and results in encephalitis and a high mortality rate. Thus, immunosuppression may be most effective when administered after the first week of infection. The incidence of demyelinating disease is increased in SJL mice infected with a dose of virus that normally produces a low incidence of disease and adoptively

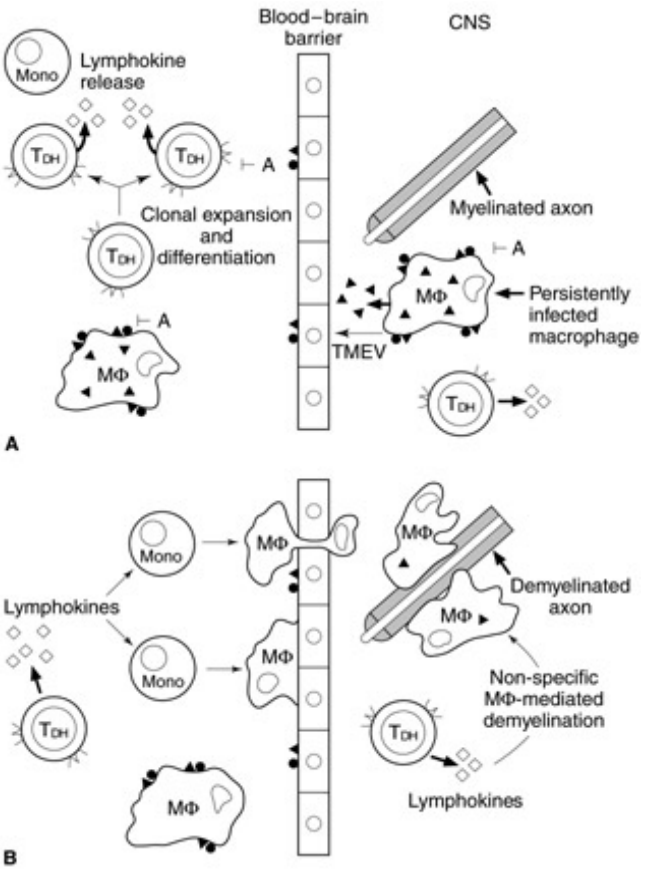

Figure 2 Proposed DTH-mediated mechanism of TMEV-induced demyelination. (**A**) Virus antigen presentation to Th1 lymphocytes, here designated T_{DH} cells, by antigen-presenting cells in either systemic lymphoid organs (left) or inside the blood–brain barrier (right). (**B**) Th1 lymphocyte response resulting in the recruitment of monocytes into the CNS and their differentiation into macrophages (MΦ) which then mediate demyelination.

immunized with TMEV VP2-specific T cell line. This observation supports a role for CD4+ T cells in mediating TMEV-induced demyelinating disease.

The effector mechanism by which a nonbudding virus, such as TMEV, might lead to immune-mediated tissue injury is unknown. Because TMEV antigens have been primarily found in macrophages, it has been proposed that myelin breakdown results from an interaction between virus-specific T cells trafficking into infected areas of the CNS and the virus. Thus, myelinated axons may be nonspecifically damaged as a consequence of a virus-specific immune response, i.e. an 'innocent bystander' response. In this circumstance, cytokines produced by MHC class II-restricted, TMEV-specific T_{DTH} cells primed by interaction with infected macrophages lead to the recruitment and activation of additional macrophages in the CNS, resulting in nonspecific macrophage-mediated demyelination (**Fig. 2**). This hypothesis is consistent with the CNS pathology observed in mice exhibiting TMEV-induced demyelinating disease and the fact that antigen-specific T cells and T cell lines have been shown to cause bystander CNS damage via macrophage activation in other model systems. Alternatively, in the case of extensive infection of oligodendrocytes, demyelination might result from immune injury to these myelin-maintaining cells expressing TMEV antigens in conjunction with H-2 class I determinants. CD8+ T cells would then be the likely T cell to kill infected oligodendrocytes; however, widespread degeneration of oligodendrocytes has not been observed.

TOBAMOVIRUSES

Dennis J. Lewandowski and **William O. Dawson**, Department of Plant Pathology, Citrus Research and Education Center, University of Florida, Lake Alfred, Florida, USA

Introduction

Early research in the late 1800s on the causal agent of the mosaic disease of tobacco led to the discovery of the phenomenon of viruses. Thus tobacco mosaic virus (TMV), the type member of the tobamovirus group, became the first virus to be discovered, and since then has had a central role in many fundamental discoveries in virology. The first quantitative biological assay for plant viruses was the use of *Nicotiana glutinosa*, which produces necrotic local lesions when inoculated with TMV. TMV was the first virus to be purified and crystallized, which led to the discovery of the nucleoprotein nature of viruses and determination of the atomic structure of the coat protein and the virion. TMV was the first virus to be visualized in the electron microscope, confirming the predicted rigid rod shape. The genetic material of TMV was shown to be RNA, a property previously thought to be restricted to DNA. TMV was the first virus to be mutagenized. The first viral protein for which an amino acid sequence was determined was the coat protein of TMV. Subsequent determination of coat protein sequences from a number of strains and mutants helped to establish the universality of the genetic code. Methods of infecting plant protoplasts with viruses were developed with the tobacco–TMV combination, creating a synchronous system to study events in the infection cycle.

Taxonomy and Classification

Tobamoviruses are in the genus *Tobamovirus*; they have not been assigned to a family. There are 15 members within the *Tobamovirus* genus (**Table 1**). Although tobamoviruses are one of the most intensively studied groups of viruses, the taxonomy is often confused. Historically, plant viruses with rigid virions of approximately 18 × 300 nm were classified as a strain of TMV. Many viruses originally referred to as strains of TMV are now recognized as distinct tobamoviruses. For example, the tobamovirus that has been referred to as the tomato strain of TMV, and which is approximately 80% similar to TMV at the nucleotide sequence level, is actually tomato mosaic tobamovirus. Different tobamoviruses for which the entire nucleotide sequence is known are less than 90% identical similar to TMV at the nucleotide level.

Virus Structure and Composition

Tobamovirus virions are straight tubes of approximately 18 × 300 nm with a central hollow core 4 nm in diameter. Virion composition is approximately 95% protein and 5% RNA. Approximately 2100 individual subunits of a single coat protein are arranged in a right-handed helix around a single RNA molecule, with each subunit associated with three nucleotides.

Purified coat protein and viral RNA assemble into infectious particles *in vitro*. Protein–protein associations are the essential first event of virion assembly. Coat protein subunits assemble into several types of aggregates. Coat protein monomers and small heterogeneous aggregates of a few subunits are collectively referred to as 'A-protein'. The equilibrium between A-protein and larger aggregates is primarily dependent upon pH and ionic strength. The larger aggregates that have been characterized are disks, which are composed of two individual stacked rings of coat protein subunits, and protohelices. Protohelices contain approximately 40 coat protein subunits arranged in a spiral around a central hollow core, similar to the arrangement within the virion.

A sequence-specific stem-loop structure in the RNA, the 'origin of assembly', initiates encapsidation and prevents defective packaging which could result from multiple initiation events on a single RNA

Table 1 Definitive tobamoviruses

TMV	Tobacco mosaic virus

SOV	Sammon's Opuntia virus
UMMV	Ullucus mild mosaic virus

molecule. The origin of assembly is located within the open reading frame (ORF) for the movement protein of most tobamoviruses and within the coat protein ORF of sunn-hemp mosaic (SHMV) and cucumber green mottle mosaic (CGMMV) tobamoviruses. Subgenomic mRNAs containing the origin of assembly are encapsidated into shorter virions that are not required for infectivity. The level of expression of a particular subgenomic mRNA containing the origin of assembly determines the relative proportion of that particular virion species. Consequently, in most tobamoviruses, in which the origin of assembly is located within the movement protein ORF, subgenomic mRNAs account for only a minor fraction of the total virion population. In contrast, where the origin of assembly is located within the highly expressed coat protein subgenomic mRNA, as in SHMV and CGMMV, a significant proportion of smaller virions are produced. Hybrid nonviral RNAs containing an origin of assembly will also assemble with coat protein into virus-like particles of length proportional to that of the RNA.

Virion assembly initiates as the primary loop of the origin of assembly is threaded through a coat protein disk or protohelix with both ends of the RNA trailing from one side. The conformation of the coat protein protohelix changes as the RNA becomes embedded within the groove between the two layers of subunits. Elongation is bidirectional, proceeding rapidly towards the 5′ end of the RNA as the RNA loop is extruded through the elongating virion and additional coat protein disks are added. There is disagreement about the mechanism of elongation towards the 3′ end of the RNA, but it appears that this slower process involves the addition of smaller protein aggregates.

Genome Organization

The tobamovirus genome consists of one single-stranded (ss) positive-strand RNA of approximately 6400–6600 nucleotides (**Fig. 1A**). There is a methylguanosine cap at the 5′ terminus, followed by an AU-rich leader approximately 70 nt in length. The 3′ nontranslated end of the RNA consists of sequences that can be folded into a series of pseudoknot structures, followed by a tRNA-like terminus. The tRNA-like terminus can be aminoacylated *in vitro*, and in most cases specifically accepts histidine. The exception is SHMV, which accepts valine and appears to have arisen by a recombination event between a tobamovirus and a tymovirus.

Four ORFs that are contained within the tobamovirus genome (**Fig. 1A**) correspond to the proteins found in infected tissue. Two overlapping ORFs begin

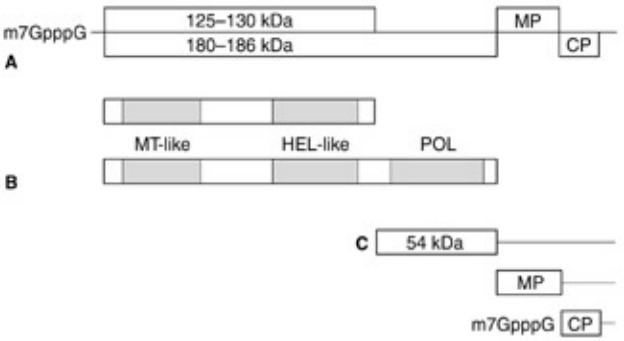

Figure 1 Tobamovirus genome organization and gene expression strategy. (**A**) Tobamovirus genome organization. ORFs designated as open boxes. Untranslated regions designated as solid lines. (**B**) Nonstructural proteins involved in tobamovirus replication. Domains of amino acid sequence similarity to viruses within 'alphavirus supergroup' are designated as hatched boxes. (**C**) Subgenomic mRNAs with 5′ proximal ORF labelled. MP, movement protein; CP, coat protein; MT, methyltransferase; HEL, helicase; POL, polymerase.

at the 5′ proximal start codon. Termination at the first inframe stop codon produces a 125–130 kDa protein. A 180–190 kDa protein is produced by readthrough of this termination codon approximately 5–10% of the time. Both proteins are necessary for efficient replication.

The remaining proteins are expressed from individual 3′ coterminal subgenomic mRNAs, from which only the 5′ proximal ORF is expressed (**Fig. 1C**; **Fig. 2**). The next ORF encodes the movement protein, which has RNA binding activity and is required for cell-to-cell movement of the virus. The 3′ most ORF encodes the coat protein (17–18 kDa). A subgenomic mRNA containing an ORF for a 54 kDa protein that encompasses the readthrough domain of the 180–190 kDa ORF has been isolated from infected tissue, although no protein has been detected.

Within the protein-coding regions of the genome, there are nucleotide sequences that have additional functions as *cis*-acting elements, such as subgenomic mRNA promoters and the origin of assembly. The promoter elements for subgenomic mRNA synthesis are located on the genomic length complementary RNA, presumably upstream from the respective initiation sites. Gene expression from subgenomic mRNAs is regulated both temporally and quantitatively. The movement protein is produced early and accumulates to low levels, whereas the coat protein is produced late and in massive quantities. Several factors are probably involved in regulation of gene expression from the various subgenomic mRNAs. The subgenomic mRNA for the movement protein is not capped and has a long 5′ leader, whereas the coat protein

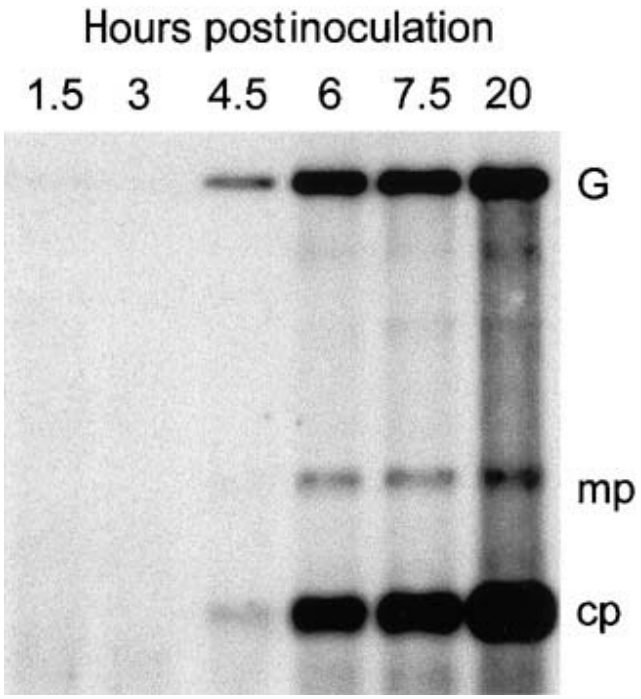

Figure 2 Northern blot of accumulation of TMV positive-stranded RNAs in tobacco protoplasts. Total RNA was extracted from tobacco protoplasts transfected with *in vitro* RNA transcripts of an infectious TMV cDNA clone at the times indicated. G, genomic RNA; mp, subgenomic mRNA for movement protein; cp, subgenomic mRNA for coat protein.

subgenomic mRNA is capped, has a short AU-rich leader, and is an efficient mRNA. Also, the levels of movement protein and coat protein production in TMV mutants are directly related to distance from the 3′ terminus. There are no obvious sequence similarities between the promoters for the movement and coat protein subgenomic mRNAs, suggesting that secondary structure may be important for recognition.

Viral Proteins

The TMV 126/183 kDa proteins are involved in efficient viral replication. Both are contained in crude replicase preparations, and temperature-sensitive replication-deficient mutants map to these ORFs. There are three domains of amino acid sequence similarity shared with replicase proteins from other ssRNA plant and animal viruses (**Fig. 1B**). The N-terminal domain of the 126/183 kDa proteins has sequence similarity with a domain having methyltransferase activity associated with viral RNA capping. The C-terminal domain of the 126 kDa protein (also shared with the 183 kDa protein), is proposed to have helicase activity, based upon conserved sequence motifs. The third domain, which has a signature sequence for RNA polymerase function, is located within the readthrough region of the 183 kDa protein. Additionally, the 126/183 kDa proteins are symptom determinants, as mutations in mild strains map to these ORFs.

The movement protein has a plasmodesmatal binding function associated with its C-terminus and a single-stranded nucleic acid-binding domain associated with the N-terminus. The movement protein–host interaction determines whether the virus can systemically infect some plant species.

Although principally a structural protein, the coat protein is also involved in other host interactions. Coat protein is required for efficient long-distance movement of the virus. Coat protein is also a symptom determinant in some susceptible plant species and an elicitor of plant defense mechanisms in other plant species.

Interactions between Viral and Host Proteins

Available evidence suggests that the interactions of viral proteins with host factors are important determinants of viral movement and host ranges. Amino acid substitutions in the movement protein can alter the movement function in different hosts. Some viruses, including tobamoviruses, can assist movement of other viruses that are incapable of movement in a particular plant species. These interactions suggest that there are more precise associations of viral proteins with host factor(s) than with viral RNA. Additionally, precise coat protein–plant interactions are required for movement to distal positions within the plant.

Virus Replication

Virions or free viral RNA will infect plants or protoplasts. Since tobamoviruses have a genome consisting of messenger-sense RNA that is infectious, one of the first events is translation of the 5′ proximal ORFs to produce the proteins required for replication of the genomic RNA and transcription of subgenomic mRNAs. When virions are the infecting agent, the first event is thought to be cotranslational disassembly, in which the coat protein subunits at the end of the virion surrounding the 5′ end of the RNA loosen, making the RNA available for translation. Ribosomes then associate with the RNA, and translation of the 126/183 kDa ORFs is thought to displace coat protein subunits from the viral RNA.

After the formation of an active replicase complex, a complementary minus-strand RNA is synthesized from the genomic positive-stranded RNA template. Minus-strand RNA serves as template for both

genomic and subgenomic mRNAs. Negative-stranded RNA synthesis ceases early in infection, while positive-stranded RNA synthesis continues. This results in an asymmetric positive- to negative-stranded RNA ratio. Early in infection, genomic RNA functions as template for minus-strand RNA synthesis and as mRNA for production of the 126/183 kDa proteins. Later in the infection cycle, most of the newly synthesized genomic RNA is encapsidated into virions. Subgenomic mRNAs transcribed during infection function as mRNA for the 3′ ORFs that are not translated directly from the genomic RNA.

Within an infected leaf, replication proceeds rapidly between approximately 16 and 96 h postinfection within a cell, after which replication ceases. Even though the infected cells become packed with virions, these cells remain metabolically active for long periods of time. During the early stages of infection of an individual cell, the infection spreads through plasmodesmatal connections to adjacent cells. This event requires the viral movement protein that modifies plasmodesmata to accommodate larger molecules. Movement through plasmodesmata does not require the coat protein. A second function of the movement protein appears to be binding to the viral RNA to assist its movement through the small plasmodesmatal openings. The movement protein also appears to associate with the cytoskeleton. As the virus spreads from cell to cell throughout a leaf, it enters the phloem for rapid long-distance movement to other leaves and organs of the plant. This process requires the coat protein.

Cis-acting Sequences

The 5′ nontranslated region contains sequences that are required for replication. This region has also been shown to be an efficient translational leader. The 3′ nontranslated region contains *cis*-acting sequences that are involved in replication. Certain deletions within the pseudoknots are not lethal, but result in reduced levels of replication. Exchanges of 3′ nontranslated regions between heterologous tobamoviruses result in viable viruses, suggesting that these are structural elements. The 3′ nontranslated region appears to be a translational enhancer, both in the viral genome and when fused to heterologous reporter mRNAs. Sequences encoding the internal ORFs for the movement and coat proteins are dispensable for replication.

The coat protein subgenomic mRNA promoter is better defined than the movement protein subgenomic promoter. Duplication of the coat protein subgenomic promoter results in transcription of an additional new subgenomic mRNA. Subgenomic promoters from heterologous tobamoviruses are recognized and are active. Foreign sequences inserted behind tobamovirus subgenomic mRNA promoters can be expressed in plants and protoplasts.

Satellite Tobacco Mosaic Virus

Satellite tobacco mosaic virus (STMV), a tobamovirus-dependent satellite virus, has been isolated from *Nicotiana glauca* infected with the tobacco mild green mosaic tobamovirus (TMGMV). The genome consists of one plus-sense ssRNA of 1059 nucleotides. The 240 3′ nucleotides share approximately 65% sequence similarity with TMGMV and TMV, contain two pseudoknot structures and have a tRNA-like terminus. No sequence similarity to tobamoviruses exists over the remainder of the genome. Two overlapping ORFs that are expressed in *in vitro* translation reactions are present in the genomic RNA of most STMV isolates. The 5′ proximal ORF encodes a 6.8 kDa protein that has not been detected *in vivo*. The second ORF encodes the 17.5 kDa coat protein, which is not serologically related to any tobamovirus coat protein. The 17 nm icosahedral virions are composed of a single STMV genomic RNA encapsidated within 60 STMV coat protein subunits. Replication of natural populations of STMV is supported by other tobamoviruses, but at lower levels than with the natural helper virus, TMGMV. The host range of STMV parallels that of the helper virus. No effects on symptom expression by any of the helper tobamoviruses have been observed.

TOBRAVIRUSES

Peter B Visser, Alexander Mathis and **Huub JM Linthorst**, Institute of Molecular Plant Sciences, Gorlaeus Laboratories, Leiden, The Netherlands

Taxonomy and Classification

The tobraviruses (type virus: tobacco rattle virus) are bipartite plant viruses which are members of the genus *Tobravirus* (a family has not been assigned). These are (1) tobacco rattle viruses (TRV), (2) pea early browning viruses (PEBV) and (3) pepper ringspot virus (PRV), which was formerly known as the CAM strain of TRV. The first two viruses contain several to numerous distinguishable strains or isolates, whereas only one PRV has yet been identified. Their classification into one genus of tobraviruses was originally based on common properties such as particle morphology, transmission vector and the unusual ability to cause a systemic infection in plants with only part of the genome. Recently this grouping has been supported by molecular studies. Comparisons based on molecular characteristics have also indicated that the tobraviruses are members of the supercluster of Sindbis-like viruses. Another plant virus member of this superfamily is the tobamovirus tobacco mosaic virus (TMV), which, both in morphology and genome organization, closely resembles the tobraviruses.

Virus Structure

The tobravirus genome is composed of two single-stranded RNA molecules of positive polarity, which are capped at the 5′ termini and which fold into a tRNA-like tertiary structure at the 3′ termini. However, this tRNA-like structure cannot be aminoacylated, as is the case in other viruses showing such a structure at the 3′ terminus.

The RNAs, designated RNA1 and RNA2, are separately encapsidated by coat protein subunits. The structure of the virions is determined by a helical array of coat protein molecules surrounding the RNA helix, which is very similar to that of tobacco mosaic virus. The virions are rigid rod-shaped particles with similar diameter (20–23 nm) but with a different length. The L (large) particles of TRV, PEBV and PRV have a similar size (180–210 nm); they encapsidate RNA1. The length of the S (small) particles varies considerably (50–110 nm), even between different strains in one subgroup. This difference in size of the S particles reflects the difference in length of the encapsidated RNA2.

During a normal infection cycle, both L particles and S particles are generated, and homogenates of infected plants are highly infectious (M-type infections, where 'M' stands for 'multiplying'). However, sometimes a second type of natural infection is apparent in which no particles are formed (NM-type infections, 'non-multiplying'). While homogenates of plants with NM-type infections are not or hardly infectious, infectious RNA is produced, as is evident after phenol extraction. The recent advancement of our knowledge of plant viruses has made it possible to explain this unique property of the tobraviruses in molecular genetic terms and to relate it to the specific way in which the genes are separated over the two genome segments.

Genome Organization and Molecular Biology

RNA1 molecules are highly homologous between isolates within the same subgroup, but little homology was identified between TRV, PEBV and PRV. RNA2 molecules are very variable in size. Generally, RNA2 of different isolates shows little sequence homology, except for the 3′-terminal region, which is also homologous to the 3′ terminus of RNA1 (**Fig. 1**).

For each of the three tobraviral subgroups, cDNA clones corresponding to the two genomic segments have been characterized. Both RNA1 of TRV strain SYM and RNA1 of PEBV strain SP5 were completely sequenced and shown to encode four open reading frames (ORFs). The first ORF of TRV strain SYM terminates at a UGA stop codon and encodes a protein of 134 kDa. Suppression of this UGA termination codon results in a readthrough protein of 194 kDa. Also, the first two ORFs of PEBV strain SP5 are fused by a UGA termination codon, which, upon suppression, allows the translation of two partially overlapping polypeptides. *In vitro* translation studies have indeed shown that both TRV RNA1 and PEBV RNA1 code for two polypeptides with sizes corresponding to the ones deduced from the nucleotide sequences. Similar mechanisms of genome expression via readthrough translation have been found with viruses belonging to several groups, among which are plant viruses from the tobamo-, luteo-, tymo- and carmovirus groups. The 3′-terminal one-third of

tobraviral RNA1 contains two ORFs encoding smaller proteins (29 kDa and 16 kDa for TRV, and 30 kDa and 12 kDa for PEBV), which are probably expressed via subgenomic mRNAs.

These data, supplemented with partial sequence data from other tobraviruses, have indicated that extended similarities exist between the various proteins encoded by the different members of the tobravirus group and even with viruses from other plant virus groups. For instance, the 134 and 194 kDa TRV-SYM proteins contain regions with high homology with similar regions in the TMV 126 and 183 kDa proteins and in the proteins encoded by RNA1 and RNA2 of the tricornaviruses. Based on these similarities, functions have been inferred for the different encoded proteins. The second half of the 134 kDa TRV RNA1-encoded peptide contains a nucleotide-binding motif present in helicases, whereas the readthrough portion of the 194 kDa protein accommodates a so-called 'GDD box', which is present in the catalytic subunit of RNA-dependent RNA polymerases. The presence of these motifs is a strong argument in favor of the involvement in genome replication of the large tobravirus RNA1-encoded proteins.

The 29 kDa protein encoded by TRV RNA1 has homology with the TMV 30 kDa movement protein. The functional homology of these two proteins was proven by mutation analysis. A TRV mutant with a defect in the gene for the 29 kDa protein could not infect whole tobacco plants completely. This defectiveness can be complemented by transgenic expression of the TMV 30 kDa protein. The TRV 29 kDa protein may also play a role in symptom induction as this same mutant, complemented with TMV 30 kDa protein, did not produce necrotic spots on test plants, as does the wild-type TRV.

The small proteins encoded by the 3′-terminal ORF in RNA1 of PEBV (12 kDa) and TRV (16 kDa) are homologous. Both polypeptides contain a cysteine-rich putative zinc-finger structure but lack homology with proteins encoded by other plant viruses. TRV infected protoplasts accumulate large amounts of the 16 kDa protein. Infectious transcripts of TRV RNA1 containing mutated 16 kDa ORFs indicated that this protein is not required for replication. While combinations of infectious transcripts of PEBV RNA1 and RNA2, lacking an intact 12 kDa ORF, were highly infectious and the resulting virus accumulated to high levels in leaves and pods, virus could not be detected in pollen grains and ovules, and seed transmission of the mutant was less than 1% of that of the wild-type virus.

Thus, the combination of replication and movement functions allows RNA1 to replicate and spread on its own to give rise to the NM-type infections.

In contrast to similarity in size of RNA1, RNA2 is more variable in both size and nucleotide sequence. However, in all instances the 5′-proximal gene encodes the coat protein. The coat protein of TRV strain TCM is over 90% similar to the coat protein of known isolates of PEBV at the amino acid sequence level. Likewise, coat protein genes of TRV strains PLB, PSG and PpK20 share over 90% homology, whereas the similarity between coat proteins of TCM and PLB is about 40%. The PRV coat protein cistron has only 40% homology with coat proteins of both TCM and PLB.

The variability in length of RNA2 is due both to the presence of additional genes on the larger molecules and to a variable sized 3′-terminal region homologous with that of the corresponding RNA1 (**Fig. 1**). Northern blot hybridization using probes complementary to different regions in RNA2 of TRV strain PpK20 showed that various subgenomic RNAs are produced which enable separate translation of the three RNA2-derived proteins, including the 5′-proximal coat protein. Similarly, ORFs of PEBV strain SP5 also appear to be produced from subgenomic RNAs.

Computer database analysis revealed that the 29.6 kDa product of PEBV RNA2 has 35% overall

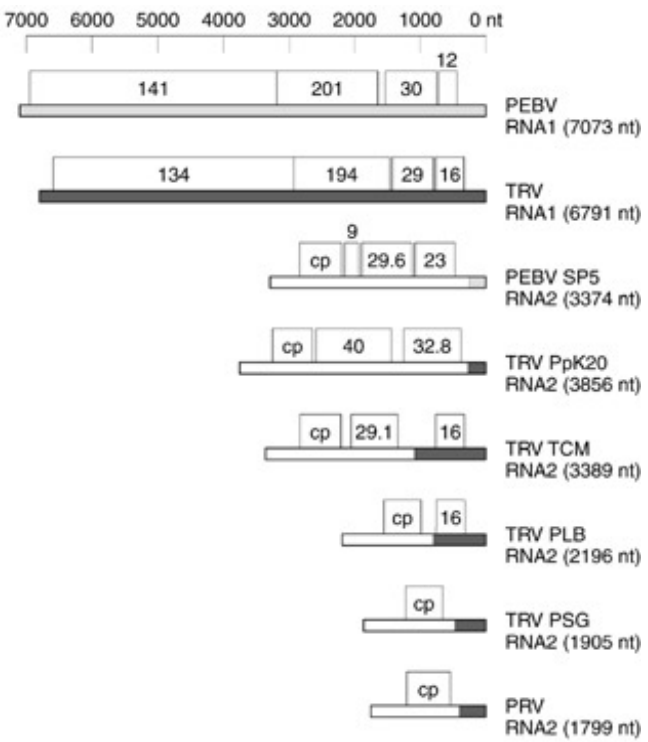

Figure 1 Genomic organization of TRV and PEBV RNA 1 and six tobraviral RNA2 molecules. Relative positions are given of the coat protein and other ORFs (with numbers indicating the molecular weight of their potential products). Shaded bars at the 5′ termini of RNA2 correspond with nucleotide sequences homologous with RNA1.

amino acid sequence homology with the 29.1 kDa putative protein of TRV strain TCM. Apart from that, no other homologies with previously described proteins were found for the other putative proteins encoded by RNA2.

Since TRV strain PSG is infectious by mechanical inoculation and its RNA2 does not contain any ORF in addition to that of the coat protein, the extra genes present on RNA2 of other strains probably have no function in replication. However, strain PSG (but also PLB and TCM which do contain extra ORFs in RNA2) lack the ability to be transmitted by any known nematode vector. Recently, infectious cDNA clones of nematode transmissible isolates became available: PEBV TPA56 and TRV PpK20. Sequencing PEBV TPA56 revealed that this isolate is nearly homologous with the nontransmissible PEBV SP5 strain, with only 11 differences out of 3374 nucleotides. Deletions or frameshifts in the nonstructural genes of PEBV TPA56 RNA2 abolished the transmission of this virus by its associated vector nematode *Trichodorus primitivus*. Also, mutations that affected the 40K gene of TRV strain PpK20 abolished nematode transmission by *Paratrichodorus pachydermus*, whereas a large deletion in the 32.8K gene had no effect on transmission. None of the mutations in the nonstructural genes interfered with encapsidation or replication of the virus. From these experiments it could be concluded that at least some of the RNA2 encoded nonstructural proteins of the tobraviruses are involved in transmission by their vector nematodes. Functions of the other nonstructural proteins encoded by RNA2 remain unknown, but it was suggested that they might play a role in the transmission of tobraviral strains by as yet unidentified species of nematode vectors.

Virus Genetics

In all tobraviruses sequenced up till now, very high homology at the 3′ terminus between both genomic RNAs of each isolate was found. The homologous sequence varies between about 500 and 1100 nucleotides (TRV isolates) and was found to be 266 nucleotides in PEBV-SP5 and 459 in PRV. Whereas these sequences are identical in the RNAs of the TRV strains and in PRV, there are nine differences in the PEBV-SP5 homologous stretch. In tobraviruses, the acquisition of the 3′ terminus of RNA1 by RNA2 is thought to have occurred by recombination based on a copy-choice mechanism of the viral replicase. The junction between RNA2- and RNA1-specific sequences shows a sequence that closely resembles the one that occurs at 5′ termini of subgenomic TRV RNAs.

The nature of the selection pressure that leads to perfect or almost perfect homologous 3′-terminal sequences between RNA1 and RNA2 is not known. Earlier work with pseudorecombinants, which are the experimental combination of RNA1 (or RNA1-containing L particles) from one strain with RNA2 (or S particles) from another, suggested that identical 3′-terminal sequences of the two genomic RNAs are essential for virus stability, maybe by playing a role in template recognition of the viral replicase. It was found that the ability to form pseudorecombinants is independent of serological relationship between the strains used, but is only possible within one subgroup, e.g. between different TRV strains but not between a TRV strain and a PEBV strain. However, replication studies on recombinant tobraviruses showed that only the 5′-noncoding region of TRV RNA2 or PEBV RNA2 is sufficient in hybrid RNAs to permit their replication by, respectively, TRV RNA1 or PEBV RNA1, regardless of the origin of the 3′-terminal region. Thus, the specificity of template recognition is determined by the 5′-noncoding, but not by the 3′-noncoding region and, at least under laboratory conditions, nonhomologous 3′ termini between RNA1 and RNA2 do not affect virus stability.

The susceptibility of TRV RNA2 for recombination was demonstrated by analyzing the so-called 'anomalous' isolates. These isolates combine properties of TRV (symptom expression, ability to create pseudorecombinants with other TRV isolates) and PEBV (serological relationship). The genome of the 'anomalous' isolates was shown to consist of an RNA1 molecule with extensive similarity to that of other TRV isolates, whereas RNA2 appeared to contain PEBV-like coding regions with 3′- and/or 5′-terminal sequences homologous with TRV RNAs.

Thus, by maintaining the terminal homology with TRV RNA1 and capturing internal (coding) sequences of PEBV RNA2 by recombination, it seems that TRV has evolved a flexible mechanism to adapt itself to environmental changes. Laboratory experiments confirm TRV RNA2's proneness to recombination. When the RNA of strain PpK20 was serially passed in tobacco plants by using phenol-extracted RNA as the inoculum in each transfer, several defective interfering (DI) RNAs rapidly accumulated. All DI RNAs were found to have deletions in the coding sequences of the RNA2. In most cases the coat protein gene and the 40K gene was lost completely, whereas part of the 32.8K gene remained translatable, sometimes as a fusion protein with coat protein sequences (**Fig. 2**). Two DI RNAs were found to be recombinants containing a 5′ sequence derived from RNA2 and a 3′ sequence derived from RNA1, which emphasizes the importance of the noncoding terminal

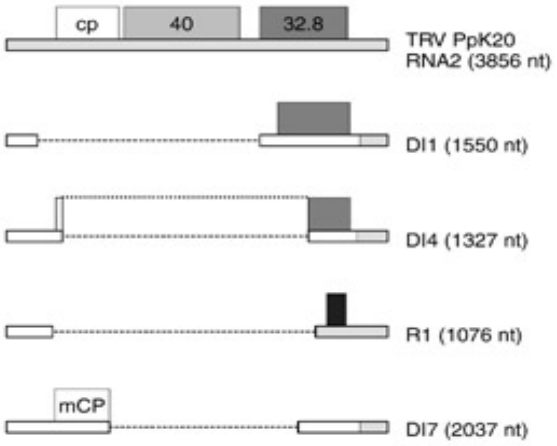

Figure 2 PpK20 defective interfering RNAs and wild-type PpK20 genomic RNA2. The relative positions of the ORFs are shown. Shaded bars at the 5′ termini of the RNAs correspond with nucleotide sequences homologous with RNA1. The dashed lines represent the deleted sequences. The dotted line in DI4 joins the N-terminal and C-terminal regions of a potentially encoded fusion protein. The mutated coat protein encoded by DI7 has been designated mCP (Hernández *et al*, 1996).

sequences for virus stability. When serial passage of TRV strain PpK20 was carried out using leaf homogenates as inocula in each transfer, accumulation of a single DI RNA with a truncated but functional coat protein gene was observed (DI 7). This DI RNA rapidly outcompeted the full-length RNA2, resulting in loss of nematode transmissibility. RNA recombination may explain why most laboratory strains, which have been maintained through the years by mechanical passages, have lost their nematode transmissibility and contain RNA2 molecules of widely varying lengths.

Diseases Caused

Tobraviruses have wide host ranges, infecting herbaceous and a few woody plant species. They cause several types of disease. One of the diseases led to the name of this virus group: when the wind blows through a heavily infected tobacco field a rattle-like sound is produced by the TRV-infected dried-out leaves.

Among tobraviruses, TRV has by far the widest host range, probably the widest of any plant virus. TRV infects more than 100 species in nature, including several common weed species (e.g. *Stellaria media, Capsella bursa-pastoris, Senecio vulgaris*). Experimentally, it was shown that more than 400 plant species in over 50 families can be infected with TRV by inoculation with sap. In about half of these infected plant species, the virus can spread systemically.

In many naturally infected species the virus remains localized at the initial site of infection. Other species are invaded systemically but remain symptomless (as *Stellaria media*) or may develop a wide variety of symptoms. On leaves, symptoms range from necrosis to all kinds of yellow markings (blotching, mottling, mosaic, ringspot), often accompanied by a variable degree of distortion. Of economic importance is the damage caused in bulbous ornamental crops such as tulip, narcissus, lily and crocus, in which leaves become mottled, and gladiolus, which develops notched leaves. Symptoms on underground plant parts include corky arcs in potato tubers (spraing), which lowers the value of the crops, and necrotic spots (malaria) in hyacinth bulbs. Furthermore, vigor and yield are decreased in tomato, sugarbeet, spinach, tobacco, artichoke, celery, pepper and lettuce.

The PEBV subgroup includes the tobravirus isolates that systemically infect leguminous plants. Only four crop species (pea, bean, broad bean and lucerne) are reported to become naturally infected. Symptoms caused by PEBV include large necrotic spots on pea leaflets, leaf distortion with chlorotic V-shaped markings in lucerne and mosaic in bean leaves. Only early browning of pea is known to be a widespread disease. PEBV probably also has hosts among weed species, but these have not been well studied.

No extensive data are available for PRV. This virus is of local concern in Brazil and was reported to cause leaf markings in artichoke and tomato. In addition, wild plants are known to be hosts.

Tobraviruses, especially TRV and PEBV, exist as many serological variants and are known to be very variable in type and severity of symptoms produced. This variability in symptoms may be the result of the specific transmission of tobraviruses by trichodorid nematodes (see below), with different viral strains being transmitted by different nematode species. Furthermore, variation in symptom expression on one host species is well known to occur independently of antigenic variation of the viruses. Experimentally, it was shown that 14 TRV isolates of the same serotype which are naturally transmitted by the same nematode species produced symptoms ranging from severe systemic malformation to mild chlorotic spots on the mechanically inoculated leaves only.

Detection and identification of tobraviruses is further complicated by the existence of NM-type isolates (in which only RNA1 replicates without RNA2). Such infections rapidly spread from cell to cell but only slowly systemically; the symptoms caused are usually more severe than those induced

by M-type isolates (in which both RNA1 and RNA2 are present).

Geographic Distribution

TRV is the most widespread of the tobraviruses and has been recorded throughout Europe, in North America, New Zealand and in Japan. PEBV is known to occur in Europe and North Africa, whereas PRV has only been described in South America (Brazil).

Virus Transmission

Nematode transmission

Tobraviruses are naturally transmitted by root-feeding nematodes of the genera *Trichodorus* and *Paratrichodorus*. At present, seven species within the genus *Paratrichodorus* and four within *Trichodorus* are known to be vectors of tobraviruses.

Acquisition of virus particles takes place together with ingestion of the cytoplasm when the vector nematode is feeding on root cells of infected plants. Nematodes remain viruliferous for long periods of time, for example, more than 1 year in *Trichodorus* spp., but not after molting. There is no evidence for multiplication of tobraviruses in the nematodes, nor for passage to progeny nematodes.

Release of the virus particles from the nematode feeding apparatus is thought to occur by a change in pH caused by saliva flow produced when the nematode starts feeding on a new plant.

In nematodes, TRV particles have been observed throughout the length of the esophageal lumen adsorbed to the cuticular lining of the lumen. This particular region has been shown to stain for carbohydrate, suggesting that lectin-like structures are involved in binding the virus particles to the nematode pharynx. Nuclear magnetic resonance studies on tobraviral particles revealed that protruding, flexible elements are present at the particle surface. Further studies indicated that these flexible elements are formed by a number of amino acid residues at the extreme C-terminus of each coat protein subunit, and that the length and amino acid composition of these flexible ends is strain-specific. Therefore, it is assumed that differences between the C-terminal sequences may reflect differences in transmissibility between virus strains. However, there is genetic evidence that, in addition to the coat protein, other viral proteins are involved in the transmission process. Deletions and frameshifts in the reading frames of RNA2 coding for the non-structural proteins of the transmissible isolate PEBV TPA56 showed that the 29 kDa and 23 kDa proteins, and possibly the 9 kDa protein, are necessary for virus transmission by *Trichodorus primitivus*. Similar experiments with TRV isolate PpK 20 showed that the 40 kDa non-structural protein, but not the 32.8 kDa protein plays a role in the transmission of this virus by *Paratrichodorus pachydermus*. It is suggested that these nonstructural proteins might link the nematode surface to virus particles, perhaps by bridging between the carbohydrate-containing material and the protruding C-terminal part of the virus coat protein. These nonstructural proteins could then be considered as helper components, functionally similar to the helper component of potyviruses or the aphid transmission factor of caulimoviruses.

The factors that determine the specificity of viral transmission have hardly been elucidated. A highly specific relationship has been found between TRV strains and the nematode species involved in their transmission: individual species of *(Para)Trichodorus* transmit serologically distinct isolates of tobraviruses. In addition, certain species are able to transmit more than one virus within the tobravirus group.

Seed transmission

Seed transmission of TRV is not known to occur in crop plants but is possible in several weed species. PEBV and PRV are reported to be seed-borne in pea and tomato, respectively. As described above, there is evidence that the RNA1 encoded 3′-terminal ORF of PEBV is involved in seed transmission, perhaps by allowing passage of the virus over the border between nongenerative and generative tissue.

Virus Epidemiology and Control

The occurrence of tobraviruses depends on the distribution of their nematode vectors, which tend to be prevalent on lighter, sandy or loamy soils. Tobraviruses can survive at sites in three main ways: they can persist in the nematode vector, in perennial plants and in infected seeds.

Viral spread at a site depends on the number, activity and transmitting efficiency of vector nematodes. The number of trichodorids depends mainly on the type of previous crops and on the degree and type of weed infestation (as nematodes multiply differently on different host plants). Weed infestation is also of importance in determining the proportion of nematodes that carry viral particles. A wide range of weed species (e.g. *Stellaria media*) can harbor TRV, with a high incidence of systemic infection. Such plants are a constant source of viral particles to transmitting nematodes. Tests on naturally occurring *Stellaria media* plants are a reliable indication of whether or not TRV occurs at a site.

The activity of nematodes is mainly determined by

soil water content as nematodes need a water film on soil particles to be able to move through the soil. Therefore, incidence of tobravirus-caused diseases is increased after wet periods or in irrigated crops. Optimum temperature for transmission was found to be 15–20°C with little transmission occurring at 4°C.

In Scotland it was shown that 80% of the trichodorid populations in arable land were carrying TRV. The rate of viral transmission by populations of viruliferous nematodes was found to be rather low. This probably reflects the small proportion of virus-carrying individuals. Experiments with single nematodes, however, revealed that, once a nematode has acquired viruses, subsequent transmission to healthy plants can be very efficient.

Another factor affecting the spread of tobraviruses is the vertical and horizontal distribution of vector nematodes. Infected plants typically are patchily distributed in crops. These patches do not necessarily represent the horizontal distribution: as trichodorid nematodes seem to occur in considerable numbers in somewhat deeper soil layers (below the depth of cultivation) but above hard layers, such patches may occur where the topsoil is shallow.

As nematodes move only small distances laterally (probably less than 50 cm per year), spread of virus-carrying nematodes to new sites occurs by agricultural activities. Transport of vector nematodes in wind-blown soil is probably inefficient, as the nematodes are very susceptible to desiccation. Virus-infected seed and vegetative plant material can also be carried for long distances to sites with previously virus-free populations of vector nematodes. Thus it could be observed that trichodorids appeared soon after colonization of a sand dune by grasses but TRV was not recorded until the flora included *Viola tricolor*, in which the virus is seed-borne.

The control of tobraviruses depends largely on the use of tolerant or resistant cultivars (potato, pea) and on the application of expensive nematode-controlling chemicals to vector-infested land. Weeds are both a virus source and a vehicle for virus spread (via seeds). Rigorous control of weeds in order to eliminate virus sources, however, can actually increase TRV infections because virus-carrying trichodorids that may prefer to feed on weed roots are then obliged to feed on crop plants.

Virus dissemination can be minimized by using virus-free planting material (pea, flower bulbs).

TOMBUSVIRUSES

DM Rochon, Agriculture and Agri-Food Canada, Pacific Agri-Food Research Centre, Summerland, British Columbia, Canada

Taxonomy and Classification

Tombusviruses are 30 nm nonenveloped isometric plant viruses which consist of a monopartite positive-sense RNA genome of about 4.7 kb and 180 copies of an approximate 41 kDa coat protein. The *Tombusvirus* genus presently consists of 13 type species. These are listed in **Table 1** along with a brief description of the geographic distribution and transmission of each member.

Table 1 Natural hosts and geographic distribution of definitive and tentative tombusvirus species[a]

Virus	*Acronym*	*Natural host(s)*	*Geographical distribution*	*Transmission*[b]
Definitive species				
Artichoke mottled crinkle virus	AMCV	Artichoke	Mediterranean	+M
Carnation Italian ringspot virus	CIRV	Carnation, sweet cherry	UK, Italy, USA, Germany	+G, +M
Cucumber necrosis virus	CNV	Cucumber	Canada	+C, +F (*Olpidium bornovanus*), +M, +So
Cymbidium ringspot virus	CyRSV	Cymbidium, white clover	UK	+C, +M, −Se
Eggplant mottled crinkle virus	EMCV	Eggplant, *Solanum capsicastrum*	Lebanon, India	+G, +M
Grapevine Algerian latent virus	GALV	Grapevine, pear, plum	Algeria, Italy, Germany	+M, found in river water in Germany and Sicily
Lato river virus	LRV	Unknown	Unknown	+M, found in water in Lato River, Italy
Moroccan pepper virus	MPV	Pepper, tomato, eggplant, pelargonium	Morocco, Germany	+G, +M,
Neckar river virus	NRV	Unknown	Unknown	+M, found in water in River Neckar, Germany
Pelargonium leaf curl virus	PLCV	Pelargonium	Eurasia, Mediterranean, N. America	+G, +M, −S
Petunia asteroid mosaic virus (=TBSV-Ch)	PAMV	Petunia, cherry, spinach, grapevine, hop, pepper, plum, privet, tomato	Eurasia, Czechoslovakia, Germany, Spain, Switzerland, UK, former Yugoslavia, Korea	+M,+P, +Se (some hosts)
Sikte waterborne virus	SWBV	Unknown	Unknown	From water from River Sitke, Germany
Tomato bushy stunt virus	TBSV	Tomato, pepper, eggplant, lettuce, spinach, tulip, apple, pear, fringe tree	Europe, Mediterranean, N. and S. America	+M, +G, +Se (some hosts)
Tentative species				
Cucumber leaf spot virus	CLSV	Cucumber	Germany, Greece, Jordan, UK	−C,+F (*O. bornovanus*), +M, +Se
Pothos latent virus	PoLV	Pothos(?)	Southern Italy	+M, found in hydroponic solution

[b]Abbreviations for modes of transmission: C, contact between plants; F, fungus transmitted; G, graph transmission; M, mechanical transmission; P, pollen transmitted; Se, seed transmission; (+) indicates known means of transmission; (−) indicates that this means of transmission has been ruled out. Note that most tombusviruses are assumed to be soil-transmitted (see text).

Complete nucleotide sequences have been obtained for the genomic RNAs of artichoke mottled crinkle virus (AMCV), carnation Italian ringspot virus (CIRV), cucumber necrosis virus (CNV), Cymbidium ringspot virus (CyRSV) and the cherry strain of tomato bushy stunt virus (TBSV-Ch). The genomes of these viruses have highly similar structures (see **Fig. 1**) and considerable sequence identity exists between comparable regions at both the nucleic acid and protein level (see **Table 2**). The high level of similarity has prompted the suggestion that some of the tombusviruses currently classified as separate species should instead be classified as strains.

Recently, genome sequences of two other potential tombusviruses, cucumber leaf spot (CLSV) and pothos latent virus (PoLV), have been determined. The predicted genome structures are similar to the genome structures of the definitive species (**Fig. 1**). A high level of sequence identity exists between the protein products of these two viruses, however, three of the five viral encoded proteins share only limited similarity with the corresponding proteins of definitive tombusviruses (**Table 2**).

The family *Tombusviridae* encompasses the genus *Tombusvirus* and seven other distinct genera including *Carmovirus*, *Dianthovirus*, the monotypic *Machlomovirus* and *Necrovirus*. The oat chlorotic stunt virus is in the genus *Avenavirus* and panicum mosaic

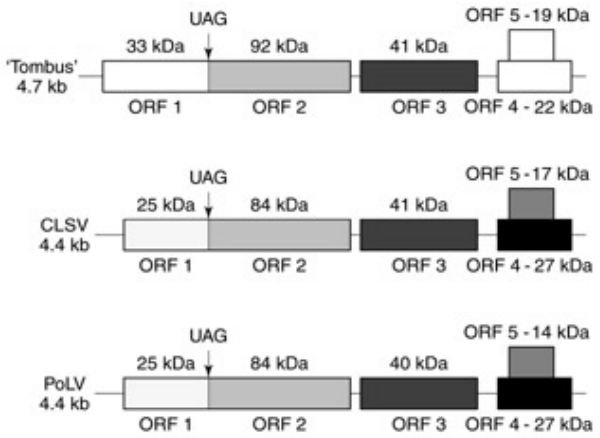

Figure 1 Comparison of the genomic structures of tombusviruses, CLSV and PoLV. The typified 'tombusvirus' genome structure is described in **Fig. 5** legend. The CLSV and PoLV genomic structures are shown individually. Similarly shaded ORFs indicate that the encoded proteins have greater than 30% amino acid sequence identity.

virus in the genus *Panicovirus*. Shared features of the *Tombusviridae* include similar particle morphology, similar genome organizations and expression strategies and also a significant level of amino acid sequence identity in the RNA-dependent RNA polymerase (RdRp) and coat proteins. **Figure 2** shows a dendogram depicting relationships among the RdRps of several members of the *Tombusviridae*. Phylogenetic trees derived from RdRp sequence alignments of *Tombusviridae* are generally reliable indicators of the taxonomic positions of individual members as defined by other criteria. This is in contrast to phylogenetic trees obtained using aligned coat protein (CP) sequences (**Fig. 3**). *Tombusvirus* CP sequences (and notably the P domains, *see also* **Virus Structure**) are the most variable in the genome. This hypervariability likely accounts for antigenic distinctions observed between otherwise very closely related viruses.

A phylogenetic study of the RdRp sequences encoded by several positive-strand RNA viruses has shown that tombusviruses (and other *Tombusviridae* genera) group together with members of the animal pesti- and flaviviruses and the bacterial leviviruses forming one of three major supergroups of RNA viruses.

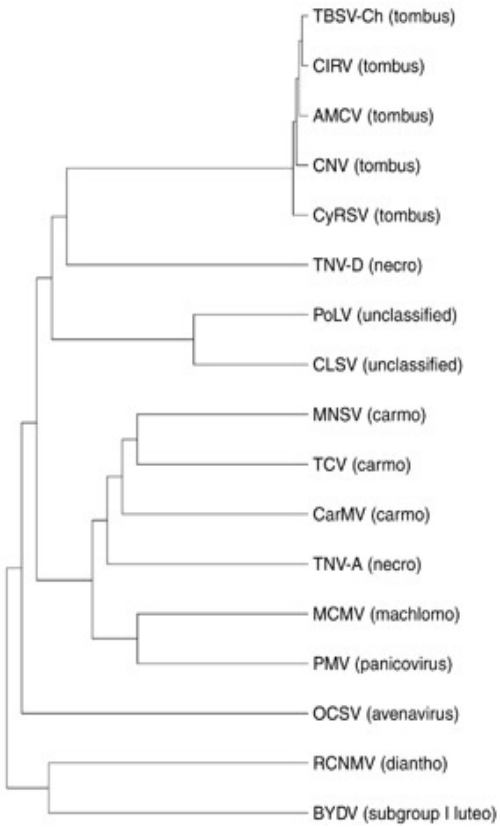

Figure 2 Dendrogram depicting relationships among the RdRps of several definitive and tentative *Tombusviridae* members. Only the readthrough or frameshifted region is aligned. The genus to which the virus belongs is indicated in parentheses. PoLV and CLSV are unclassified. Abbreviations: TBSV-Ch, tomato bushy stunt virus; CIRV, carnation Italian ringspot virus; AMCV, artichoke mottled crinkle virus; CNV, cucumber necrosis virus; CyRSV, Cymbidium ringspot virus; TNV-D, tobacco necrosis virus strain D; PoLV, pothos latent virus; CLSV, cucumber leaf spot virus; MNSV, melon necrotic spot virus; TCV, turnip crinkle virus; CarMV, carnation mottle virus; TNV-A, tobacco necrosis virus strain A; MCMV, maize chlorotic mottle virus; PMV, panicum mosaic virus; OCSV, oat chlorotic stunt virus; RCNMV, red clover necrotic mosaic virus; BYDV, barley yellow dwarf virus.

Table 2 Percentage of identical amino acid residues in pairwise comparisons of proteins encoded by ORFs 1–5 of several tombusviruses, CLSV and PoLV

	ORF 1[a]	*ORF 2*	*ORF 3*[b]	*ORF 4*	*ORF 5*
Tombus/Tombus[c]	53–94	93–97	34–87	84–98	72–92
Tombus/CLSV or PoLV[d]	21–25	43–45	30–53	19–20	12–20
CLSV/PoLV[e]	60	80	33	71	61

[a]The CIRV alignments gave unusually low identity scores. All other alignments gave values between 80 and 94%.

Symptomatology, Host Range and Geographic Distribution

Table 1 summarizes the natural host range, geographic distribution and modes of transmission of the definitive tombusviruses and also PoLV, CLSV and Sikte waterborne virus (SWBV). Tombusviruses as a whole share a wide geographic distribution having been reported in North and South America, several locations in Europe and the Mediterranean and also in Algeria. Individual members of the tombusvirus group, however, generally have a restricted geographic distribution with the exception of TBSV and pelargonium leaf curl (PLCV) which was likely spread internationally through infected pelargoniums. Most tombusviruses naturally infect only a single or a few hosts. This is in contrast to their experimental host range which is wide and diversified. Tombusviruses systemically invade naturally infected plants but remain localized in the majority of experimentally infected plants; common exceptions to this rule are the experimental hosts *Nicotiana clevelandii* and *N. benthamiana*. Tombusvirus-infected crops generally show stunting and diffuse mottling and malformation of leaves. Characteristic lesions associated with the indicator plants basil, globe amaranth and *Chenopodium quinoa* can be used to identify tombusviruses. Further verification can be obtained using antisera or cloned cDNA probes which are widely available. Several tombusviruses have been found associated with defective interfering (DI) RNAs in laboratory infections raising the possibility that DI RNAs can modulate symptoms in natural infections. Finally, many tombusviruses can be inactivated *in vivo* by growing plants at elevated temperatures (ca. 36 °C).

Recent studies have shown that the protein products of open reading frames (ORFs) 4 and 5 are important symptom determinants (see below, Molecular Biology).

Serologic Relationships

Most tombusvirus members are serologically interrelated with cross reactivities ranging from strong to nearly undetectable. CNV and SWBV are the only members which show no detectable serological reaction with other tombusviruses. The tentative species, CLSV, is also serologically unrelated to all tested tombusviruses.

Transmission

Tombusvirus particles are very stable and reach high concentrations in infected tissues. In addition, tombusviruses are efficiently spread and can become established in diverse environments. Different tombusviruses have been shown to be spread in nature by a number of means (see **Table 2**) including seed and pollen transmission, transmission through propagation material and possibly mechanical transmission. Experimentally, tombusviruses are readily sap transmissible and infected leaf extracts retain infectivity after freezing for several years. It is very likely that several tombusviruses are spread through the soil and probably also through irrigation water but attempts to transmit them (except CNV, see below) by soil-borne vectors have not been successful. In addition, attempts to transmit different tombusviruses using aphids, whiteflies or mites have also been unsuccessful.

Several reports have identified tombusviruses in association with rivers and lakes throughout the world and there is evidence suggesting that tombusviruses can enter a field through irrigation water. TBSV is infectious after passage through the human alimentary tract suggesting that tombusviruses may possibly enter rivers through sewage treatment of infective feces.

CNV is the only definitive member of the *Tombusvirus* genus which has been demonstrated to have a specific soil-borne vector. The tentative member, CLSV, is similarly transmitted. Transmission of these viruses is facilitated by zoospores of the Chytrid fungus, *Olpidium bornovanus* (formerly *Olpidium*

radicale). Transmission is mechanistically similar to that demonstrated for the transmission of tobacco necrosis necrovirus by *Olpidium brassicae*. Virus particles and *Olpidium* zoospores are released independently into the soil from roots of infected plants and virus particles adsorb to the axonemal sheath of the zoospore flagellum. Virus gains entry into plants following zoospore infection of plant roots. Different *O. bornovanus* isolates transmit CNV and other viruses in a highly specific manner suggesting that a specific recognition mechanism exists between particles and zoospores. It is possible that this high specificity has precluded the identification of fungal vectors for other tombusviruses.

Molecular studies of CNV transmission by *O. bornovanus* have shown that the CNV coat protein contains determinants which specify transmission. Further studies have shown that a single amino acid change in the coat protein shell domain significantly reduces transmission without altering infectivity, particle stability or viral RNA accumulation. This mutation also affects the level of binding of virus particles to zoospores *in vitro* suggesting that the reduction in transmissibility is at least partly due to less efficient recognition between virus particles and a putative zoospore receptor.

Cytopathology

Cytopathic inclusions known as multivesicular bodies (MVB) and virus-containing bleb-like evaginations of the tonoplast are associated with infection by tombusviruses (**Fig. 4**). MVB are composed of vesicles intermingled with or surrounding granular electron-dense material and are believed to originate from either mitochondria, peroxisomes and/or chloroplasts depending on the virus/host combination examined. Clumps of densely staining amorphous material found scattered or loosely aggregated in the cytoplasm of systemically infected cells (dense granules) are also found in tombusvirus-infected cells but not in all virus–host combinations tested. MVB are believed to be sites of RNA replication and dense granules to be accumulations of excess CP subunit.

Experiments using hybrid genomes created between CyRSV and CIRV, which induce MVB from peroxisomes and mitochondria, respectively, have delineated the MVB-inducing region to a portion of the protein encoded by ORF 1.

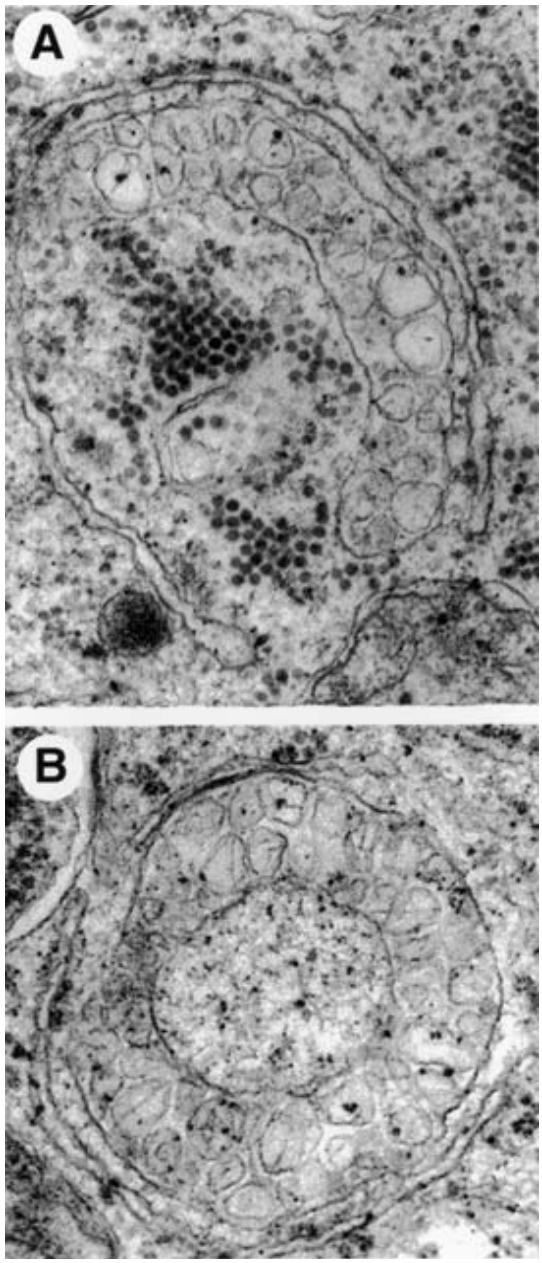

Figure 4 Electron micrographs showing multivesicular bodies formed in CNV-infected *N. clevelandii*. Magnification (**A**) 65 000×; (**B**) 75 000×.

Particle Structure

The structure of TBSV has been determined by x-ray crystallography and is diagrammatically represented in **Fig. 5**. The particle is a $T = 3$ icosahedron approximately 30 nm in diameter which consists of 180 identical CP subunits. Each of the subunits folds into three major domains: an N-terminal highly basic inward-facing RNA binding domain (R); a tightly bonded globular shell domain (S) and a C-terminal outward facing protruding domain (P). The R domain is connected to the S domain by the arm (a) and a five amino acid hinge connects the S and P domains. The P domain projects from the surface of the particle in 90

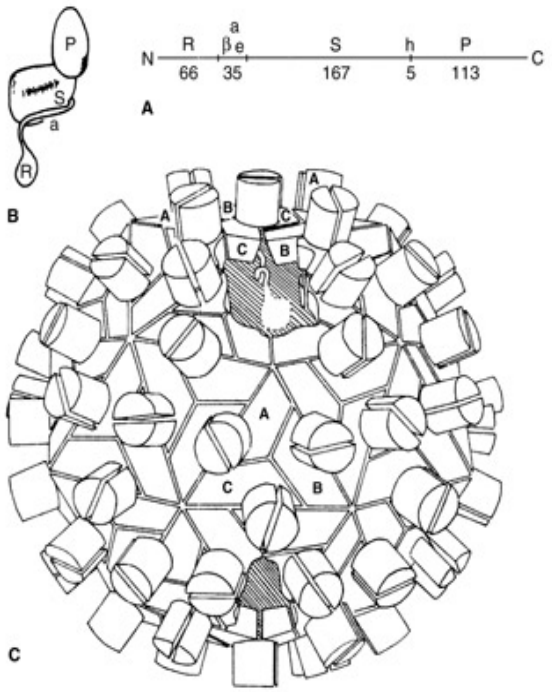

Figure 5 Architecture of the TBSV particle. (**A**) linear arrangement of domains (designated R, a, S, h and P) in the subunit polypeptide. The number of amino acid residues comprising each domain is indicated. (**B**) Schematic diagram of the folding of the polypeptide chain. (**C**) Arrangement of subunits in the virus particle. A, B and C denote the three packing environments of the subunit. (Reprinted with permission from Olson AJ, Bricogne C and Harrison SC (1983) Structure of tomato bushy stunt virus IV. *J. Mol. Biol* 171: 61–93.).

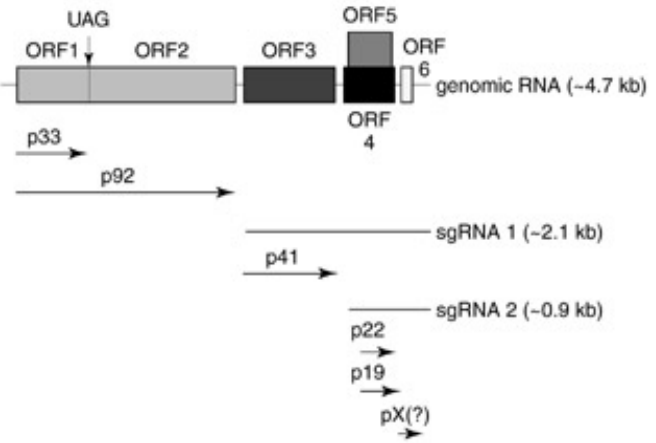

Figure 6 Structure and expression of the tombusvirus genome. The similar structure and expression strategies adopted by tombusviruses is shown. The five major ORFs are indicated by open boxes and the proteins encoded by each ORF by horizontal arrows beneath the ORF. Subgenomic RNA is indicated by a bar beneath the portion of the genome it is derived from. The approximate sizes, in kb, for genomic and sgRNA is indicated. Sizes of proteins may be approximate since they vary slightly from tombusvirus to tombusvirus (i.e. the CIRV 'p33' is actually p36, the CIRV 'p92' is p95, the CNV 'p22' is p21 and the CNV 'p19' is p20).

pairwise clusters. The subunit adopts three conformational states (A, B, C) in the particle due to flexion of the hinge and either an ordered or disordered arm.

TBSV swells at alkaline pH in the absence of calcium ions due to repulsive forces of adjacent negatively charged carboxylate groups. Calcium ions may be important in the release of virion nucleic acid in an infected cell. P domain dimer contacts may also contribute to tombusvirus particle stability. *In vitro* mutagenesis studies show that viral particles do not accumulate when the CNV P domain is deleted. These observations are consistent with a role for the tombusvirus P domain in particle stability. The P domain may also be involved in aggregate formation during particle assembly.

The tombusvirus CP subunit and particle structure shares features in common with several small spherical plant and animal virus particles including those of picornaviruses, black beetle virus, southern bean sobemovirus, turnip crinkle carmovirus and cowpea mosaic and bean-pod mottle comoviruses. Similarities include overall subunit architecture (jelly-roll topology), subunit packing, role of arm domain in coordinating assembly and transition to an expanded virion. The P domain, however, is a feature unique to tombusviruses, carmoviruses and dianthoviruses.

Tombusvirus Molecular Biology

Genome structure

The *Tombusvirus* genus represents one of the most extensively characterized plant virus genera. The genome is a monopartite, plus sense, single-stranded RNA of ~4.7 kb. The genomic sequences of five tombusviruses (AMCV, CIRV, CNV, CyRSV, TBSV-Ch) have been completed and highly infectious transcripts are available for AMCV, CNV, CyRSV and TBSV-Ch. The genomic structure and expression strategy utilized by tombusviruses is highly similar and is summarized in **Fig. 6**. The genome contains five long ORFs (ORFs 1–5) and encodes proteins with approximate molecular weights of 33, 92, 41, 22 and 19 kDa (designated p33, p92, etc.). The sizes of these proteins vary slightly from tombusvirus to tombusvirus (see **Fig. 6** legend) but these designations will apply hereafter. An additional small ORF (ORF 6) located at the 3′ terminus of the genome has been suggested as a possible protein-encoding region. Short

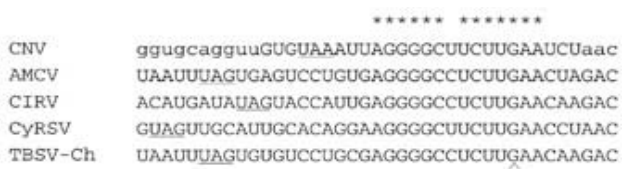

Figure 7 Sequences surrounding the CNV sgRNA2 promoter and comparison to the putative promoters of other tombusviruses. Sequences comprising the core CNV sgRNA promoter are shown in capital letters. Asterisks indicate identity in all five tombusviruses. The sgRNA start site is indicated with a caret and the underlined sequences correspond to the upstream coat protein terminator codon.

intercistronic regions separate ORFs 2 and 3 and ORFs 3 and 4. The 5′ noncoding region ranges in size from 77 to 180 nucleotides (nt) and the 3′ noncoding region (which includes ORF 6) from 338 to 351 nt. The 3′ terminus of the tombusvirus genome does not contain a poly(A) tail and it is presently uncertain as to whether the 5′ end contains a cap structure or some other modification. It is noted that highly infectious transcripts of the tombusvirus genome can be obtained *in vitro* without capping.

Genome expression

ORF 1 initiates with the first AUG codon at the 5′ terminus and terminates with an amber codon to produce p33. The amber codon can be readthrough to produce p92. ORF 2 encodes the CP (p41) and is expressed from the first AUG codon at the 5′ terminus of a ~2.1 kb subgenomic mRNA (sgRNA 1). ORF 5 is nested within ORF 4 in a different reading frame. The respective p19 and p22 translation products are both produced from a single bifunctional ~0.9 kb sgRNA (sgRNA 2; see below).

Genomic plus and minus strand synthesis Most of the data on *cis*-acting sequences required for genomic RNA synthesis rely on studies using defective interfering RNAs (see below, Defective Interfering RNAs).

sgRNA synthesis Subgenomic RNAs accumulate to high levels during tombusvirus infection and are assumed to arise through internal initiation on (−) sense genomic RNA. In CNV and AMCV, synthesis of sgRNA 2 occurs before that of sgRNA 1. A sgRNA which could encode pX is easily detected in CNV-infected plants and protoplasts. Sequences comprising the core promoter for CNV sgRNA 2 have been determined. The promoter lies within a region located 20 nucleotides upstream and six nucleotides downstream of the sgRNA start site. Comparison of sequences within the CNV promoter with the analogous region of other tombusviruses shows strict conservation of 13 of 26 nucleotides (**Fig. 7**). There is little similarity between the sgRNA 2 promoter and the 5′ terminus of the genome or the region surrounding the sgRNA 1 start site. In addition, sequences similar to the ICR2-like motifs found in the promoters of several alphavirus-like (supergroup III) plant and animal viruses are not apparent.

Leaky scanning sgRNA 2 is a bifunctional mRNA capable of encoding distinct proteins *in vitro* and *in vivo* from nested ORFs (ORFs 4 and 5). In CNV, ORF 4 initiates with the first AUG codon on sgRNA 2 16 nt from the 5′ end. ORF 5 initiates at the second AUG codon 29 nt downstream of the ORF 4 AUG. Mutations which increase or decrease the ability of ribosomes to recognize the ORF 4 AUG codon have an inverse effect on ORF 4 expression suggesting that its AUG codon is accessed by leaky ribosomal scanning. Further studies showed that longer sgRNA 2 leader lengths increased expression of ORF 4 relative to ORF 5.

Protein function

p33 and p92 The readthrough portion of p92 contains the canonical 'GDD' motif and surrounding amino acids present in the polymerase domains of positive-strand RNA viruses. Although direct biochemical evidence that these proteins form part of the replicase is absent, genetic evidence is convincing. Methyltransferase, nucleotide binding or helicase motifs have not been identified in either of these two proteins or in any other tombusvirus-encoded protein. The absence of a helicase motif in tombusviruses suggests that a host component may fulfill this function during viral RNA replication.

Immunological analyses of CyRSV- and TBSV-Ch-infected cells have shown that both p33 and p92 accumulate during infection with p33 being approximately 20-fold more abundant than p92. Both proteins are associated with the membrane fraction consistent with a proposed role in viral RNA replication. Mutational analyses of p33 and p92 suggest that both proteins are required for RNA replication but strict evidence for the involvement of p33 is still lacking. Protoplasts from transgenic plants expressing CyRSV p33 and p92 support replication of CyRSV-defective interfering RNAs. In addition, CyRSV deletion mutants lacking ORFs 3, 4 and 5 can replicate in protoplasts. These results provide evidence that ORFs 1 and 2 are the only virus-encoded proteins necessary for viral RNA replication. Tom-

busviruses are believed to replicate in the membranous structures of MVBs formed during virus infection. Evidence exists that p33 is involved in determining the origin of MVB (see Cytopathology).

CP Mutational analyses of the CNV, CyRSV and TBSV-Ch *CP* genes indicate that the *CP* gene is dispensable for viral cell-to-cell and systemic movement. However, systemic spread of coat-protein mutants is not as efficient as wild-type virus as exhibited by delays in the onset of systemic symptoms, a lower percentage of systemically infected plants, or a reduction in the severity of systemic invasion. It is possible that virion formation is required for efficient entry into the vascular system.

The CP P domain (see Virus Structure) is a feature unique to tombusviruses, carmoviruses and dianthoviruses. Deletion of all or part of the P domain coding sequence in CNV (see Particle Structure) results in the absence of particle formation suggesting a role for the P domain in virus particle stability and/or in the formation of particle assembly intermediates. Interestingly, CNV P domain deletion mutants (but not shell domain mutants) rapidly further delete most of the remaining viral CP sequences during infection. The deletion derivatives likely arise through RNA recombination. It is possible that the deletion derivatives have a higher capacity for cell-to-cell movement due to increased production of the cell-to-cell movement protein.

The CNV CP has been found to contain elements involved in the specificity of fungus transmission (see Transmission for additional details).

p22 Several lines of evidence show that the tombusvirus ORF 4 product (p22) encodes the cell-to-cell movement protein. p22 is not required for RNA replication but is required for accumulation of viral RNA in inoculated plants. In addition, histochemical assays of plants inoculated with TBSV-Ch p22 mutants which contain the GUS gene in place of the CP gene show that infection is limited to single cells. Amino acid sequence comparisons of tombusvirus p22 proteins with known and putative viral movement proteins has shown limited but significant similarity. Finally, TBSV-Ch p22 has been found associated with the membrane fraction of plant cells, consistent with its role in viral cell-to-cell movement.

Potato virus X (PVX) derivatives which express the TBSV-Ch p22 gene produce local lesions in *Nicotiana glutinosa* and *N. edwardsonii* rather than the mild mosaic symptoms typical of PVX. These results indicate that p22 is the primary determinant responsible for local lesion formation in these two host plants. As described below, TBSV-Ch p19 and its analogue in other tombusviruses is the primary symptom determinant in other hosts.

p19 Mutations which affect ORF 5 expression in CNV, CyRSV and TBSV-Ch cDNA result in an attenuated phenotype without affecting viral accumulation in plants. In addition, expression of p19 using a heterologous viral vector, PVX, showed that p19 induced a generalized necrosis on infection of *N. benthamiana* and *N. clevelandii* and local necrotic lesions in *N. tabacum*. These symptoms occurred in place of the mild mosaic associated with PVX infection. These results provide evidence that p19 is a major symptom determinant in tombusviruses and further suggest that p19 may interact with host-specific resistance genes present in related *Nicotiana* species.

Start and stop codon mutations which abolish production of the p19 analogue in CNV (p20) lead to loss of necrotic symptoms on inoculated leaves as well as a highly accelerated rate of defective interfering RNA production in plants. The basis for the enhanced rate of *de novo* DI RNA production requires further investigation.

pX Computer assisted analyses of the 3′ terminal regions of several tombusviruses has suggested the existence of a possible sixth small ORF (ORF 6) in tombusviruses leading to production of a small protein (pX) which is between 3.5 and 7.6 kDa. Mutational analyses of the CyRSV ORF 6 have shown that if pX is produced during infection it is not essential for viral infectivity. However, certain mutations in ORF 6 result in nonviable mutants, suggesting that the pX ORF may harbor important *cis*-acting replication signals. A role for pX in viral infection remains to be established.

Defective Interfering (DI) RNAs

DI RNAs

DI RNAs have been found in association with CIRV, CNV, CyRSV and TBSV-Ch and have been extensively characterized in terms of structure, mechanism of formation and mode of interference. DI RNAs occur naturally in plants infected under laboratory conditions and are also generated *de novo* from genomic RNA. DI RNAs are associated with a marked attenuation of the severe symptoms typical of tombusvirus infections.

DI RNA structure DI RNAs correspond to conserved, noncontiguous portions of the tombusvirus genome and range in size from approximately 400 to

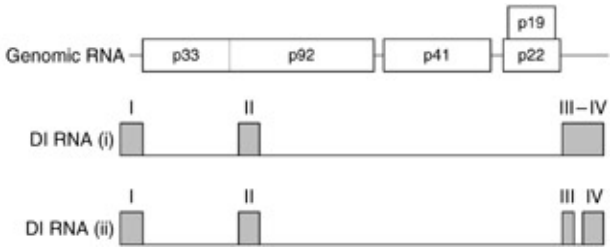

Figure 8 Structure of a prototypical tombusvirus DI RNA. The tombusvirus genome structure is at the top and the two major types of DI RNAs are shown below. Genomic RNA sequences retained in the DIs are indicated by boxes in the DIs whereas horizontal lines correspond to deleted sequences. The four major regions (I–IV) found in DI RNAs are indicated. (Adapted from White (1996).)

800 nt. A prototypical tombusvirus DI RNA consists of four segments of the viral genome designated regions I through IV (**Fig. 8**). Region I corresponds to the 5′ terminal noncoding region and regions III and IV correspond to contiguous or noncontiguous segments at the 3′ terminus of the genome. Region II corresponds to an internal portion of the genome. DI RNAs differ from each other in the amount of sequence deleted between different regions, in the extent of internal deletions within regions, or through duplications of regions or portions of regions. In CNV and CyRSV, head-to-tail dimers of complete monomeric DI RNA units have been observed in plants. The significance of the dimers is not known but dimers can be formed from monomers and it is possible that dimers are templates for the formation of monomers during DI RNA replication.

DI RNA formation A stepwise deletion model for the formation of DI RNAs from genomic RNA has been proposed. In this model, DI RNAs are formed following a series of deletion events as a result of a copy choice mechanism of RNA recombination. Both primary and secondary sequence elements as well as selection for replication competence contribute to the final structure.

Sequences/structures involved in DI replication The smallest DI RNA molecules (~400 nt) tolerate little sequence or structural change suggesting that the retained sequences contain the minimal essential elements for replication/accumulation. A putative stem–loop structure contained within the 3′ terminal 77 nucleotides of CyRSV RNA has been suggested to be important in negative strand synthesis of DI RNA as well as genomic RNA.

Interference DI RNAs are associated with reductions in virus-induced symptoms and virus accumulation. At least two mechanisms account for the observed symptom attenuation. One is that DI RNAs compete with genomic RNA for the viral replicase resulting in reduced viral RNA synthesis. The other is that the presence of DI RNA results in preferential suppression of sgRNA 2 levels relative to genomic RNA. This suppression leads to lower levels of p22 and p19 and consequently reduces symptoms.

Satellite RNAs

A satellite RNA associated with CyRSV has been characterized and found to be composed of 621 nucleotides. Two regions of the satellite RNA show homology to genomic RNA: 9 of the first 14 nt are shared and 49 of 53 nt of the satellite RNA are similar to a segment in the 5′ noncoding region of genomic RNA. These conserved regions are also present in tombusvirus DI RNAs suggesting an important role of these particular sequences in the replication process.

Virus-Resistant Transgenic Plants

Plants transformed with portions of viral genomes often show resistance to viral infection in a specific manner. Transgenic *N. benthamiana* plants expressing the CyRSV CP are resistant to infection but only at very low virus inoculum concentrations. No resistance occurs at higher inoculum concentrations or when plants are inoculated with RNA. Selected transgenic plant lines expressing CyRSV p92 show resistance when inoculated with RNA or virus. Resistance is specific and inversely correlated with the level of expression of transgene mRNA suggesting resistance is RNA-mediated. Transgenic plants expressing CyRSV DI RNAs were found to be protected from the apical necrosis and subsequent plant death normally associated with infection by this virus. Interestingly, transgenic plants expressing CyRSV satellite RNAs actually increased symptom severity. It was suggested that the expressed satellite RNA sequences may interfere with the ameliorating effects of naturally occurring DI RNAs.

TOROVIRUSES (CORONAVIRIDAE)

Marian C Horzinek, Virology Unit, Veterinary Faculty, Utrecht, The Netherlands

History

Toroviruses were defined in the early 1980s as a result of a trilateral, partly collaborative study between groups in Berne, Switzerland (isolation in cell culture), Ames/Iowa, USA (discovery of Breda virus and propagation in calves) and Utrecht, The Netherlands (biologic and molecular characterization).

An equine torovirus (ETV), originally referred to as Berne virus, was accidentally isolated in equine kidney cells in 1972 from a rectal swab taken from a horse with diarrhea. Upon post-mortem examination pseudomembranous enteritis and miliary granulomas and necrosis in the liver were diagnosed; Salmonella Lille (O, 6, 7, Z_{38}) was considered to be the causative agent. ETV can be propagated in lines of equine dermis or embryonic mule skin cells, where it causes a cytopathic effect that results in cell lysis. The virus was not neutralized by antisera against known equine viruses. Serologic crossreactions were observed in neutralization and ELISA with sera from calves that had been experimentally infected with morphologically similar particles, the Breda viruses.

A bovine torovirus (BTV), first described as Breda virus was discovered in 1979 during investigations in a dairy herd in Breda (Iowa), in which severe neonatal calf diarrhea had been a problem for three consecutive years. Despite repeated attempts, BTV has not been adapted to growth in cell or tissue culture, which has hampered its biochemical, biophysical and molecular characterization. The pathogenesis and pathology of BTV infections have been studied in gnotobiotic calves.

Torovirus-like particles have been seen in EM preparations from fecal samples of pigs and humans (children and adults); proof that the observed structures are not artefacts was obtained when toroviral RNA sequences were found in the feces of piglets and in stools from humans with diarrhea.

Taxonomy and Classification

The name of the viruses assembled in this genus is derived from the term *torus* (Latin) which designates the lowest convex molding in the base of a column or pilaster. It refers to the biconcave disk or doughnut shape of the virion that is determined by a tubular capsid of helicoidal symmetry, which is surrounded by a peplomer-bearing envelope. In addition to the unique toroid form, virions may also appear as straight or bent rod-shaped particles.

Analysis of the genetic information and replication mode of the prototype ETV showed that toroviruses are evolutionarily related to the *Coronaviridae* and, to a lesser extent, to the *Arteriviridae*. However, the lack of sequence homology in the structural genes and the absence of antigenic relatedness with coronaviruses justify their separate taxonomic position as a genus, *Torovirus*, in the *Coronaviridae* family.

The families *Coronaviridae* and *Arteriviridae* form the Order *Nidovirales* (from *nidus*, Latin for 'the nest' – alluding to the nested set of subgenomic RNAs transcribed during replication), the second order recognized in animal virus taxonomy so far.

Virion Properties

Extracellular ETV particles possess a helical nucleocapsid coiled into a hollow tube (diameter 23 nm, average length 104 nm, periodicity 4.5 nm) which is either straight or bent into an open torus. A tightly fitting envelope, 11 nm thick, surrounds this structure. Consequently, the virion may assume an erythrocyte-like or a kidney shape, depending on whether the envelope follows the small curvature of the nucleocapsid or not. The largest diameter of ETV is estimated at 120–140 nm. Club-shaped projections (average length 20 nm) are present on the particle surface.

TOROVIRUSES (CORONAVIRIDAE)

Marian C Horzinek, Virology Unit, Veterinary Faculty, Utrecht, The Netherlands

History

Toroviruses were defined in the early 1980s as a result of a trilateral, partly collaborative study between groups in Berne, Switzerland (isolation in cell culture), Ames/Iowa, USA (discovery of Breda virus and propagation in calves) and Utrecht, The Netherlands (biologic and molecular characterization).

An equine torovirus (ETV), originally referred to as Berne virus, was accidentally isolated in equine kidney cells in 1972 from a rectal swab taken from a horse with diarrhea. Upon post-mortem examination pseudomembranous enteritis and miliary granulomas and necrosis in the liver were diagnosed; Salmonella Lille (O, 6, 7, Z_{38}) was considered to be the causative agent. ETV can be propagated in lines of equine dermis or embryonic mule skin cells, where it causes a cytopathic effect that results in cell lysis. The virus was not neutralized by antisera against known equine viruses. Serologic crossreactions were observed in neutralization and ELISA with sera from calves that had been experimentally infected with morphologically similar particles, the Breda viruses.

A bovine torovirus (BTV), first described as Breda virus was discovered in 1979 during investigations in a dairy herd in Breda (Iowa), in which severe neonatal calf diarrhea had been a problem for three consecutive years. Despite repeated attempts, BTV has not been adapted to growth in cell or tissue culture, which has hampered its biochemical, biophysical and molecular characterization. The pathogenesis and pathology of BTV infections have been studied in gnotobiotic calves.

Torovirus-like particles have been seen in EM preparations from fecal samples of pigs and humans (children and adults); proof that the observed structures are not artefacts was obtained when toroviral RNA sequences were found in the feces of piglets and in stools from humans with diarrhea.

Taxonomy and Classification

The name of the viruses assembled in this genus is derived from the term *torus* (Latin) which designates the lowest convex molding in the base of a column or pilaster. It refers to the biconcave disk or doughnut shape of the virion that is determined by a tubular capsid of helicoidal symmetry, which is surrounded by a peplomer-bearing envelope. In addition to the unique toroid form, virions may also appear as straight or bent rod-shaped particles.

Analysis of the genetic information and replication mode of the prototype ETV showed that toroviruses are evolutionarily related to the *Coronaviridae* and, to a lesser extent, to the *Arteriviridae*. However, the lack of sequence homology in the structural genes and the absence of antigenic relatedness with coronaviruses justify their separate taxonomic position as a genus, *Torovirus*, in the *Coronaviridae* family.

The families *Coronaviridae* and *Arteriviridae* form the Order *Nidovirales* (from *nidus*, Latin for 'the nest' – alluding to the nested set of subgenomic RNAs transcribed during replication), the second order recognized in animal virus taxonomy so far.

Virion Properties

Extracellular ETV particles possess a helical nucleocapsid coiled into a hollow tube (diameter 23 nm, average length 104 nm, periodicity 4.5 nm) which is either straight or bent into an open torus. A tightly fitting envelope, 11 nm thick, surrounds this structure. Consequently, the virion may assume an erythrocyte-like or a kidney shape, depending on whether the envelope follows the small curvature of the nucleocapsid or not. The largest diameter of ETV is estimated at 120–140 nm. Club-shaped projections (average length 20 nm) are present on the particle surface.

In the cell, predominantly rod-shaped particles are encountered. Cross-sections through tubular virions appear as three concentric circles of high electron density with an electron-lucent center.

Negatively stained BTV virions appear to be either kidney- or C-shaped, measuring 30–120 nm, or approximately circular, measuring 75–90 nm in diameter. Their envelope bears prominent drumstick-shaped peplomers (17–24 nm), and a fringe of shorter spikes 8–10 nm in length. The short projections represent the hemagglutinin esterase protein, which is present on the surface of bovine torovirions. In intestinal cells of calves killed 48–96 h after infection, tubules of 21 nm diameter and indeterminate length were found both in the cytoplasm and in nuclei.

In thin-sectioned preparations, intracellular torovirions show a bacilliform morphology (rods with both ends rounded – in contrast to the circular outline of coronavirions); extracellular particles may reveal twin circular structures resulting from cross-sections through both limbs of the C-shaped tubular nucleocapsid.

A model of a torovirion is given in **Fig. 1**.

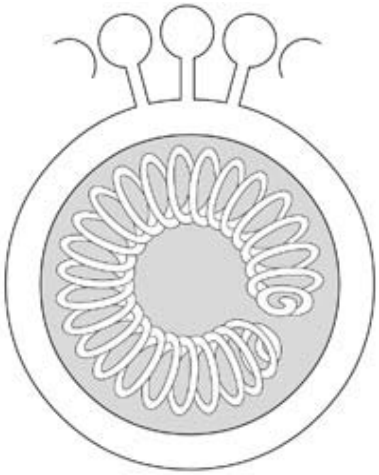

Figure 1 A schematic model of a torovirion. Illustration by Ank Klein-Willink.

Genome

ETV virions (sedimentation coefficient 380S) contain one species of polyadenylated RNA of positive polarity; in agarose gel electrophoresis its length appears as $\geq$20 kb. When assayed under hypertonic transfection conditions genomic RNA is found infectious and RNase-sensitive.

Proteins

Proteins with molecular weights of 20 kDa, 22 kDa, 37 kDa, and 80–100 kDa are identified in labeled ETV virions. Detergent treatment releases the 22, 37 and 80–100 kDa species from the virion, which indicates their association with the envelope. Only the 20 kDa protein is present in purified ETV nucleocapsids and was accordingly named nucleocapsid (N) protein. The heterogeneous, N-glycosylated 80–100 kDa protein is recognized by both neutralizing and hemagglutination-inhibiting monoclonal antibodies and is therefore identified as the peplomer (P) protein. Another membrane-associated polypeptide is the non-glycosylated envelope protein (E; 22 kDa); the 37 kDa molecule also occurs in close association with the viral membrane, but its virus specificity could not be established.

From the deduced amino acid sequence of the nucleocapsid (N) protein gene a basic protein of 18.3 kDa is predicted. *In vitro* transcription and translation, followed by immunoprecipitation, were used to identify the gene. Identification was confirmed by metabolic labeling, using the knowledge that cysteine residues are absent from the amino acid sequence of the N protein. Smaller N-related polypeptides encountered in ETV-infected cell lysates are products of aberrant translation, due to initiation on AUG codons further downstream in the N protein gene.

The 26.5 kDa product of the ETV membrane (M) protein gene was identified by *in vitro* transcription and translation. Computer analysis revealed the characteristics of a class III membrane protein lacking a cleaved signal sequence but containing three successive transmembrane α-helices in the N-terminal half. Only small portions of either end of the polypeptide are exposed on opposite sides of the vesicle membranes; the C-terminus protrudes at the cytoplasmic side of the membrane. The M protein accumulates in intracellular membranes, predominantly those of the endoplasmic reticulum.

The nucleotide sequence of the peplomer or spike (S) protein gene encodes an apoprotein of 1581 amino acids with an M_r of about 178 kDa. The deduced amino acid sequence contains domains typical for type I membrane glycoproteins: an N-terminal signal sequence, a putative C-terminal transmembrane anchor, and a cytoplasmic tail.

Since BTV has not been labeled in cultured cells, its protein composition was studied by means of surface radioiodination of purified virus. Polypeptide species of 105, 85, 37, and 20 kDa were identified, of which the former two probably represent the BTV peplomeric surface structures. Rabbit antisera raised against purified BTV recognize the ETV S protein in immunoprecipitation experiments.

Physical Properties

Buoyant densities of 1.16, 1.18 and 1.14 g ml^{-1} are reported for ETV, BTV serotype 2 and human toroviruses, respectively.

Under experimental conditions ETV is remarkably stable, even to the action of phospholipase C or deoxycholate; Triton X-100 and organic solvents destroy its infectivity. BTV1 appears to be less stable than ETV, as changes in its sedimentation behavior and density have been observed after prolonged storage at −70°C. The infectivity of a fecal preparation containing BTV1 was lost completely after 3 weeks at 4°C whereas ETV in cell-free supernatant remained stable for 92 days. Two cycles of freeze–thawing of purified BTV2 resulted in loss of peplomers.

Replication

Equine torovirus (strain Berne) replication occurs in the cytoplasm via a 3′-coterminal nested set of five subgenomic mRNAs. Preformed tubular capsids bud through membranes of the Golgi stack and of the endoplasmic reticulum. A host cell nuclear function seems to be required since UV preirradiation of cells, actinomycin D and α-amanitin reduce virus yields.

Transcription

In ETV-infected cells five virus-specific polyadenylated RNA species are found with >20.0, 7.5, 2.1, 1.4, 0.8 kb.

Northern (RNA) blot hybridizations with restriction fragments from cDNA clones showed that the five ETV mRNAs form a 3′-coterminal nested set. Sequence analysis revealed the presence of four complete open reading frames of 4743, 699, 426 and 480 nucleotides, with initiation codons coinciding with the 5′ ends of ETV RNAs 2 through 5, respectively; RNA 5 is contiguous on the consensus sequence. ETV RNAs 1, 2 and 3 are transcribed independently, as shown by UV transcription mapping. Upstream of the AUG codon of each open reading frame a conserved sequence pattern is encountered, probably a core promoter sequence in subgenomic RNA transcription. In the area surrounding the core promoter region of the two most abundant subgenomic ETV RNAs, a number of homologous sequence motifs occur.

Translation

The 7.5, 2.1 and 0.8 kb RNAs encode a 151 kDa product (possibly the precursor to the S protein), the M protein, and the N protein, respectively, as shown by *in vitro* translation.

The 3′ part (8 kb) of the polymerase gene of ETV contains at least two open reading frames (designated ORF 1a and ORF 1b) which overlap by 12 nucleotides. The complete sequence of ORF 1b (6873 nucleotides) is known. Like corona- and arteriviruses, ETV expresses its ORF 1b by ribosomal frameshifting during translation of the genomic RNA; also the predicted tertiary RNA structure (a pseudoknot) in the frameshift-directing region is similar. The amino acid sequence of the predicted ETV ORF 1b translation product contains homologies with the ORF 1b product of coronaviruses. Four conserved domains are present: the putative polymerase domain, an area containing conserved cystein and histidine residues, a putative helicase motif, and a domain apparently unique for toro- and coronaviruses.

Post-translational Processing

The *N*-glycosylated peplomer protein is derived from processing of a 200 kDa precursor present in infected cells but not in virions. Eighteen potential *N*-glycosylation sites, two heptad repeat domains, and a possible 'trypsin-like' cleavage site exist in the peplomer gene. The mature S protein consists of two subunits and their electrophoretic mobility on endoglycosidase F treatment suggests that the predicted cleavage site is functional *in vivo*. The heptad repeat domains are probably involved in the generation of an intra-chain coiled-coil secondary structure; similar interchain interactions can play a role in the formation of the observed S protein dimers. The intra- and interchain coiled-coil interactions may stabilize the elongated ETV peplomers.

Assembly

About 10 h after infection ETV particles are seen within parts of the unaltered Golgi apparatus and extracellularly. At that time, tubular structures of variable length, diameter and electron-density appear in the cytoplasm and in the nucleus of infected cells, probably representing preformed nucleocapsids. It is unknown whether the accumulation of nucleocapsids in the nucleus reflects a nuclear phase in the replication of ETV or some sort of defective assembly.

Viruses predominantly bud into the lumen of Golgi cisternae. The preformed nucleocapsid tubules approach the Golgi membrane with one of both rounded ends and attach to it along one side. During budding the nucleocapsid is apparently stabilized, leading to a higher electron density and a constant diameter (23 nm).

Intracellular BTV virions are rod-shaped with rounded ends; they measure 35–40 nm in diameter and are 80–100 nm long.

Defective Interfering Virus

Defective interfering (DI) genomes of ETV can be generated by serial undiluted passages. Isokinetic sucrose gradient analysis showed that they are packaged into virus-like particles with lower S values than standard virions. DI RNAs contain sequences from the presumed 5′ end and the proven 3′ end of the ETV genome. Using probes from the 5′ end, a consensus nucleotide sequence of about 800 nt and the 5′ end of the putative ETV polymerase gene were identified. A conserved sequence motif, probably involved in subgenomic RNA transcription, is situated immediately downstream of the 5′ end of the DI RNAs. There is no evidence for the presence of a common leader sequence in ETV RNAs.

In the gut of a BTV-infected calf, a wave of simultaneous infections progresses through a population of susceptible cells. In view of the immense particle numbers encountered in the feces, enteroabsorptive epithelial cells are probably infected at high multiplicities; DI particles may also be generated *in vivo* and may play a role in modulating the pathogenesis of torovirus infections.

Geographic and Seasonal Distribution

Toroviruses in cattle have been evidenced by ELISA serology in Europe, North America and Asia. Seasonal patterns of infection have been described in calves in relation to herd management (pasture/stable). Most adult horses in Switzerland possess neutralizing antibodies to ETV. Possible human toroviruses have been found in France, Great Britain, The Netherlands and the USA.

Host Range and Virus Propagation

By using the neutralization assay, antibodies to ETV were found in sera from horses, cattle, goats, sheep, pigs, rabbits and feral mice, but not in humans or in carnivores. Torovirus-like particles have been seen in fecal samples of cats with a transmissible diarrhea, but neither serologic nor molecular identification was obtained.

By electron microscopy, pleomorphic virions have been observed in the feces of children and adults with diarrhea; the particles were coated and aggregated after the addition of anti-BTV calf sera. The stool specimen reacted in an ELISA for the detection of BTV antigen in calves, and possessed a low titer of hemagglutinin for rat erythrocytes, which was blocked by antisera to BTV.

Toroviral RNA sequences have been evidenced in the stools from humans with diarrhea. The use of fresh material (avoiding freeze/thawing) is essential for obtaining unequivocal results. Sequence analysis of RNA extracted from specimens of pediatric patients and amplified by reverse transcriptase–polymerase chain reaction (RT-PCR) showed a high degree of identity with the corresponding ETV sequence. This is surprising in view of the observation that the divergence between porcine and bovine/equine torovirus sequences is greater than between human and bovine/equine torovirus sequences. If confirmed, this would indicate occasional spillover of the infection from ungulates to humans, rather than human-to-human transmission.

Cultured cells of equid origin (horse, mule) can be infected with ETV; no other cell species tested supports viral growth. Bovine toroviruses could not be propagated in any culture of primary cells or permanent lines and had to be passaged in gnotobiotic calves. Putative torovirus isolations from young calves with respiratory symptoms (pneumonia) in MDBK cells have been challenged, and a bovine coronavirus was identified in the culture.

Genetics

No information is available.

Evolution

Toroviruses and coronaviruses are ancestrally related by divergence of their polymerase and envelope proteins from common ancestors. In addition, their genome organization and expression strategy, which involves the synthesis of a 3′-coterminal nested set of mRNAs, are comparable. Four domains of amino acid sequence homology exist in the product of ORF 1b of the *POL* gene, which underlines the existence of an evolutionary relationship. In view of these findings, toro- and coronaviruses have been classified as separate genera in the family *Coronaviridae,* which, together with the *Arteriviridae* forms the order *Nidovirales.*

Nucleotide sequence analysis of the ETV genome has revealed the results of two independent non-homologous RNA recombinations: ORF 4 encodes a protein with significant sequence similarity (30–35% identical residues) to a part of the hemagglutinin esterase proteins of coronaviruses and of influenza virus C. Although this gene is truncated in ETV, it is intact and translated into a functional, enzymatically active protein in BTV; this product is visible as a

second fringe of (short) projections on the viral envelope.

The sequence of the C-terminal part of the predicted ETV polymerase ORF 1a product contains 31–36% identical amino acids when compared with the sequence of a nonstructural 30/32 kDa coronavirus protein. The cluster of coronaviruses which contains this nonstructural gene does not express it as a part of their polymerase, but by synthesizing an additional subgenomic mRNA.

Serologic Relationships and Variability

One strain of ETV has been isolated (and re-isolated from the same material), but all attempts to obtain a second equine isolate were fruitless.

Two strains of BTV have been reported in addition to the original isolate by Woode and colleagues: one had been detected in feces from a 5-month-old diarrheal calf in Ohio, and a second Iowa strain was recovered from a 2-day-old experimental animal. On the basis of their reactivity in ELISA, immune electron microscopy and hemagglutination/hemagglutination inhibition assays using rat erythrocytes the three isolates were assigned to two serotypes: BTV1, represented by the Iowa 1 isolate, and BTV2 comprising the Ohio and the second Iowa isolate.

The occurrence of antigenically different toroviruses is not unlikely. Two serotypes of BTV have been described and more probably exist. It is anticipated that serologically unrelated toroviruses will be identified with the aid of nucleic acid probes.

Epidemiology

The high prevalence of BTV antibodies in cows cannot be explained by the few infections found in calves and cows with diarrhea. The viruses may circulate in herds through inapparently or chronically infected animals, as described for rota- and coronaviruses. The level of maternal BTV-specific antibodies influences the clinical outcome of the infection, as differences in the severity of diarrhea were observed between colostrum-fed and colostrum-deprived animals.

With the aid of solid-phase immune-electron microscopy, torovirions can be identified in fecal material; without this selection, virion pleomorphism makes diagnosis by electron microscopy ambiguous.

Transmission and Tissue Tropism

Toroviruses probably spread through feco-oral contact. In feces samples from experimentally BTV-infected calves HA titers in excess of 10^7 units ml^{-1} are measured which would correspond to particle concentrations of $>10^{11}$. Therefore, once an outbreak is under way the infection spreads rapidly, especially when highly susceptible animals are on the premises (e.g. in the calving season).

Using RT-PCR, torovirus sequences were obtained from fecal samples of weaning piglets; an association with weaning diarrhea has not been established.

Pathogenicity

Torovirus infections play a role in diarrhea of breeding calves up to two months of age, and in winter dysentery of adult cattle. Torovirus was detected four times more often in diarrheal calves than in healthy animals. Torovirus-associated diarrhea of calves started later (average 12.7 days of age) than enteritis due to rota- or coronaviruses (average 7.7 and 8.3 days, respectively). Seroconversion was found significantly more often after winter dysentery outbreaks than on farms without a disease history; coronavirus seroconversion was less common.

Clinical Features of Infection

Seroconversions to ETV occurred in all horses between 10 and 12 months of age, but without symptoms. Experimentally infected animals (intravenous route) seroconverted without clinical signs. To the author's knowledge oral infection experiments in horses have not been reported so far.

All BTV strains are pathogenic – although with varying virulence – for newborn gnotobiotic and nonimmune conventional calves after oral infection. Most calves develop anorexia, a watery, yellow–green diarrhea that lasts 4–6 days, and shed virus for 3–4 days. In some calves the diarrhea is preceded by a mild temperature reaction (40°C). In the calves with a normal intestinal flora the diarrhea is generally more severe than in gnotobiotic calves. Reduction of D-xylose resorption may reach 65% in severely affected calves. In some animals depression and dehydration is observed, occasionally with shivering, hyperpnea and watery eye discharge. Mortality in experimental infections approaches 25%.

Pathology and Histopathology

Target organs of BTV in calves are the lower half or two-thirds of the small intestine and the entire large intestine, particularly the spiral colon. There is little macroscopic evidence of the infection. Histological examination shows villous atrophy and epithelial desquamation from the mid-jejunum to the lower small intestine, and areas of necrosis in the large intestine. Both crypt and villus epithelial cells contain antigen as shown by immunofluorescence. The

watery diarrhea is probably a result of loss of resorptive capacity of the colonic mucosa, combined with malabsorption in the small intestine. Infection of crypt epithelium may affect the duration of diarrhea, as regeneration of villus epithelium starts in the crypts. The germinal centers of the Peyer's patches are depleted of lymphocytes and may occasionally show fresh hemorrhage. The dome epithelial cells, including the M cells, display the same cytopathic changes as seen in the absorptive cells of villi. Virions are found in cells of both the small and large intestine. Extracellular virus is closely associated with microvilli of absorptive cells and in the coated pits between microvilli, indicating receptor-mediated endocytosis. In addition, virions are found between enterocytes at the basal and lateral plasma membranes. Virions in various stages of degradation are found within macrophages in the lamina propria.

Antigen is detected as early as 48 h after infection in epithelial cells of the lower half of the villus and of the crypts of the affected areas, as well as in dome epithelium. Fluorescence is cytoplasmic (although a few nuclei may be faintly stained) and generally most pronounced in the intestines with the least tissue damage. The mid-jejunum is infected first, the infection eventually reaching the large intestine. Diagnosis by immunofluorescence test (IFT) should be performed preferentially on sections of the large intestine from calves killed after the onset of diarrhea (i.e. several days after the infection of epithelium).

Immune Response

Up to the age of 4 months, all calves in a sentinel experiment regularly excreted BTV in the feces. They showed early serum IgM responses despite the presence of IgG1 isotype maternal antibodies, but no IgA seroconversion. Antibody titers then decreased below detection, persistent IgG1 titers developed in only a few animals. After introduction into the dairy herd at 10 months of age, all calves developed diarrhea and shed virus. Seroconversion for all antibody isotypes was observed at this stage, indicating lack of mucosal memory. In contrast, coronavirus infection in the presence of maternal antibodies leads to isotype switch and a memory response.

Prevention and Control

No control strategies have been implemented.

Future

The pathogenic significance of toroviruses for animals and humans, also as agents of nonenteric infections needs to be established. Diagnostic procedures for the discovery of more distantly related viruses of this cluster will have to include procedures for the recognition of nucleotide sequence motives.

TOSPOVIRUSES (*BUNYAVIRIDAE*)

James W. Moyer, Department of Plant Pathology, North Carolina State University, Raleigh, North Carolina, USA

History

Diseases incited by tomato spotted wilt virus (TSWV) were first reported in 1915 and were considered to be of viral etiology by 1930. This taxon of plant viruses was categorized as a monotypic virus group consisting of a single virus (tomato spotted wilt virus; TSWV) until the report of Impatiens necrotic spot

virus (INSV) in 1990. Thus, most of the characteristics on which the *Tospovirus* genus is defined were obtained through investigations of TSWV. Although TSWV was originally associated with tomato (*Lycopersicon esculentum*), by the 1950s it had one of the largest known host ranges of any plant virus. By 1998 the known natural and experimental host range exceeded 900 plant species and spanned both monocotyledonous and dicotyledonous plant species. TSWV was known by 1930 to be insect vectored by thrips. It was not until the mid 1960s that the enveloped virion morphology was revealed and the molecular characterization and genome organization did not occur until after 1990. In addition, understanding of the virus–vector biology, cytopathology of both the plant and insect hosts and virus genetics have developed rapidly since 1990. However, efficient *in vitro* cell culture systems for either plant or thrips systems are not available nor is there a system for reverse genetics.

Table 1 List of tospoviruses and serogroups

Tospovirus species	*Abbreviation*
TSWV serogroup:	
Tomato spotted wilt virus	TSWV
Groundnut ringspot virus	GRSV
Tomato chlorotic spot virus	TCSV
WMSV serogroup:	
Watermelon silver mottle virus	WSMV
Watermelon bud necrosis virus	WBNV
Groundnut bud necrosis virus	GBNV
Serologically unrelated	
Chrysanthemum stem necrosis virus	CNSV
Impatiens necrotic spot virus	INSV
Iris yellow spot virus	IYSV
Peanut yellow spot virus	PYSV
Peanut chlorotic fan-spot virus	FCFV
Physalis severe mottle virus	
PSMV Zucchini lethal chlorosis virus	ZLCV

Taxonomy, Classification and Serological Relationships

Tospovirus constitutes the only plant-infecting genus in the *Bunyaviridae*. Tospoviruses are characterized by a quasi-spherical, enveloped virion containing a tripartite RNA genome typical of the family. A single open reading frame (ORF) in the viral complementary-sense (negative) is located on the large RNA (L) and two ORFs in an ambisense (see Molecular Biology) orientation are on both the middle (M) and small (S) segments. The presence of two ambisense RNAs is the defining molecular characteristic that distinguishes this genus from the other genera in the *Bunyaviridae*. Biologically, the tospoviruses multiply in plants and in their insect (thrips) vectors. However, their individual host ranges are highly variable. Some tospoviruses have an extremely large host range (e.g. TSWV) whereas others such as iris yellow spot virus (IYSV) are known to infect only a small number of plant species.

The discovery of INSV led to the current scheme for classifying viruses within the *Tospovirus* genus that is based on nucleic acid sequence homology between nucleocapsid genes. New viruses are named consistent with rules of the International Committee on Taxonomy of Viruses with each virus equivalent to a species. Newly discovered tospoviruses were classified in serogroups, e.g. serogroup I, II etc., and this system was used in the literature. However, the proliferation of viruses and number of monotypic serogroups prompted the abandonment of the numerical system. Distinct viruses are not classified as a group until more than one virus is identified in that group. The serogroup is then identified by the type virus, e.g. tomato spotted wilt virus serogroup (**Table 1**). This system currently distinguishes at least 12 different viruses (**Table 1**). Although the sequence homology between tospoviruses varies with the gene, sequence differences between the nucleocapsid genes are accepted as a measure of overall relatedness. The nucleocapsid protein was chosen not only because it is abundant, but also because of its putative role in regulating the switch from transcription to replication, function in the replication complex and encapsidation of the genome based on viruses with negative strand genome organization. Serological relatedness based on ELISA or Western blot analysis of the nucleocapsid protein is used to classify viruses within serogroups and, as expected, is generally consistent with homology of the nucleocapsid genes. This is distinct from the serological relatedness in other genera of the *Bunyaviridae* that have been measured by neutralization or hemagglutination assays that are indicative of functions mediated by viral glycoproteins which reside in the envelope.

Isolates in the *Tospovirus* genus with greater than 90% nucleocapsid sequence homology are classified as strains of the same virus. Serologically related isolates with 80–90% sequence homology are subjectively classified as strains or as distinct viruses depending on additional criteria. Isolates with less than 80% homology to all of the other known viruses are classified as distinct viruses or species. Those viruses exhibiting serological relatedness are classified in the same serogroup. For example, groundnut chlorotic spot virus is a distinct virus with 78%

homology to TSWV and a distant serological relationship, was formerly classified in serogroup II, but is now classified as a member of the TSWV serogroup. Homology with TSWV for distinct viruses range from about 60% for INSV to less than 40% for watermelon silver mottle virus (WSMV).

Properties of Virion

Tospovirus virions are quasi-spherical, enveloped particles 80–120 nm in diameter. Two viral-coded glycoproteins, G1 and G2, are embedded in the viral envelope. Ribonucleoprotein (RNP) particles consisting of the viral RNA encapsidated in the nucleoprotein and a small number of polymerase molecules are contained within the envelope. Intact virions as well as carefully prepared RNPs retrieved from sucrose or $CsSO_4$ gradients are infectious. There are several reports of TSWV and INSV isolates that are defective for virion formation, but remain infectious.

Properties of Genome

Tospoviruses have a single-stranded, tripartite RNA genome with segments designated as L, M and S in order of decreasing length. The termini of each of the RNA segments consist of an eight nucleotide sequence (5′ AGAGCAAU 3′) that is conserved throughout the genus on each segment of the viral genome. The first 12 to 15 nucleotides at the termini of each segment are complementary with a high degree of complementarity extending throughout the terminal untranslated regions. The base pairing at the termini results in a panhandle structure that may initiate encapsidation and regulation of transcription. The L RNA is approximately 8.9 kb and codes for the RNA-dependent RNA-polymerase (RdRp) that is translated from the viral complementary sense RNA. The M RNA is approximately 4.8 kb with two ORFs in an ambisense arrangement. The ORF nearer the 5′ terminus codes for the 33.6 kDa nonstructural protein (NSm) in the viral sense and is followed by an A-U rich, 200–250 nucleotide intergenic region. The second ORF codes for the G1/G2 precursor protein in the viral complementary sense. The S RNA is 2.9–3.0 kb with two ORFs in a similar ambisense arrangement. A nonstructural protein (NSs) is coded from the ORF nearer the 5′ terminus in the viral sense and the nucleocapsid gene from the ORF in the viral complementary sense located near the 3′ terminus. The two ORFs are separated by an A-U rich intergenic region of variable length. The S segment from isolates of TSWV may vary in length by as much as 100 nucleotides and is due entirely to insertions and deletions in the intergenic region. In addition, highly conserved sequences are embedded within the intergenic region. In one group of isolates, a 33 nucleotide duplicate sequence was associated with reduced competitiveness of the S RNA from those isolates.

Full-length molecules of the M and S ambisense RNA segments are found in infected tissue and purified virions in both the viral and viral complementary sense (approximate ratio of 10:1) which is consistent with ambisense segments from other viruses. Defective interfering RNAs (DIs) associated with attenuated symptoms are also frequently observed. DIs in TSWV infected tissue are the result of a single deletion event in the L RNA. The formation of DIs is favored by repeated passage in certain hosts, high inoculum concentration and low temperatures. Available evidence supports the hypothesis that secondary structure rather than sequence is the primary determinant of the site of deletion as is viral RNA recombination. There is also a high frequency of DIs that maintain the original reading frame resulting in translation of truncated proteins whose existence was confirmed in nucleocapsid preparations.

Properties of Proteins

A 330 kDa protein encoded by the L RNA has been identified as the putative RdRp through sequence homology. RdRp activity has been associated with TSWV virions. Full length and truncated RdRp molecules have been associated with virions containing DIs. The 33.6 kDa NSm protein encoded by the M RNA has been shown to induce tubule structures from protoplasts and cell surfaces from plants and insects, respectively. Induction of tubules and association with the plasmodesmata in plant cells is evidence that this protein is involved in cell-to-cell movement. The G1/G2 precursor protein is also coded for by the M RNA. These proteins occur in the viral envelope and have been associated with recognition by the thrips. The NSs protein (54 kDa) encoded on the S RNA accumulates to high levels as loose aggregates or paracrystalline arrays of filaments, but has not been linked with any function. The nucleocapsid (N) protein, also encoded by the S RNA, ranges in size from 29 to 31 kDa depending on the virus. This protein encapsidates the viral RNA segments and has been demonstrated to have RNA binding properties. It is highly abundant and is the predominant protein detected in serological assays.

Replication

The RNA of this virus, similar to other negative strand viruses is not infectious and recombinant DNA

techniques have not been applied to elucidate genome function. As yet there are no efficient systems for detailed molecular investigations of tospoviruses, although there are reports of infection of plant protoplasts and insect cells. It is known that replication of viral RNA and assembly of virions occurs in the cytoplasm. The RNP containing the L RNA is hypothesized to replicate similar to other negative-strand viruses. The viral RNA is the template for replication and the viral complementary strand serves as the template for translation of the RdRp protein. The S and M ambisense RNAs also replicate similar to negative-strand RNAs. However, translation of these proteins probably occurs from subgenomic mRNAs. Subgenomic mRNAs of appropriate size for each of the ORFs on these two RNAs, have been detected in infected plants. The subgenomic RNAs are capped at the 5′ terminus with 12–20 nucleotides of nonviral origin indicating that tospoviruses utilize a cap-snatching mechanism to regulate transcription. Virions are assembled in the cisternae of the endoplasmic reticulum. Initially they are double-membraned particles that soon coalesce to become groups of virions with a single membrane surrounded by another membrane.

Geographic Distribution

Tospoviruses are found worldwide. However, individual viruses may have limited distribution. In general, they are found in temperate regions colonized by their thrips vector. Exceptions are the viruses (e.g. watermelon silver mottle group) transmitted by *Thrips palmi*, that is found in subtropical regions. TSWV has the most extensive host range and is found worldwide. Conversely, INSV has been of greatest concern in greenhouse-grown floral crops in North America, Central America and Europe. Viruses in the watermelon silver mottle serogroup have been identified in India, Japan and Taiwan, although their vector is found in other parts of the world. IYSV has been reported in Israel, Brazil and western North America. Collectively, tospoviruses have been included among the 'emerging viruses' due to their wide and rapid distribution and the severity of the diseases they incite.

Host Range and Virus Propagation

TSWV has one of the most diverse host ranges of any plant-infecting virus. The virus infects over 900 plant species which include both monocotyledonous and dicotyledonous plants. Other tospoviruses have much narrower host ranges and thus the broad host range of TSWV is not characteristic of the genus. Tospoviruses also replicate in their thrips vectors but distinct from viruses in other genera of this family, are not transmitted transovarially or by plant seeds. These viruses can be transmitted mechanically for experimentation or by their thrips vector. There are no robust plant or insect culture systems for these viruses. However, plant protoplasts have been successfully inoculated.

Genetics and Evolution

The knowledge base for genetics and evolution of tospoviruses has been derived almost exclusively from TSWV. TSWV is unusually adept at adapting to new hosts as well as losing phenotypic characters following repeated passage in experimental hosts, especially *Nicotiana benthamiana*. The virus occurs in plants as a heterogeneous mixture of isolates that have been distinguished by symptom phenotype and more recently with molecular markers. As many as five stable variants have been isolated from a single thrips inoculation site. TSWV has also been shown to form new phenotypes from the mixture. These complex populations provide a reservoir of genetic information that could account for the rapid adaptation. Recombination (sensu reassortment) was shown via classical genetics to be a possible mechanism for reassembling the genetic information among isolates in 1961. TSWV has now been shown to use reassortment of genome segments as a mechanism for adaptation to resistant hosts. The determinants of adaptation to resistance in tomato and pepper have been mapped to the M and S segments, respectively.

Transmission and Epidemiology

Tospoviruses are transmitted from plant to plant by a small number of thrips species. Among the more common vectors are *Frankliniella occidentalis*, *F. fusca*, *F. schultzei*, *Scirtothrips dorsalis*, *Thrips palmi*, *T. setosus* and *T. tabaci*. Thrips feed on the cytoplasm of plant cells. The contents of infected cells are ingested and the virus is transported along the lumen of the digestive tract to the midgut. The virus is then transported by endocytosis across the membrane of endothelial cells which line the midgut of the thrips. This process of acquisition only occurs in thrips in the larval stage of development. Evidence for replication of the virus in the insect vector is based on the accumulation of nonstructural protein (NSs) and the visualization of other inclusions in endothelial cells, muscle cells and the salivary glands. Viral inoculum is introduced into plants in the insect saliva coincident with feeding on the plant. Although the virus is maintained trans-stagially throughout the life

of the insect, there is no evidence for transovarial transmission. Thus, each generation of thrips must acquire the virus during the larval stage of development.

The primary mechanisms for virus increase in plant populations is by the thrips vector and dissemination of infected somatic tissue in vegetatively propagated crops. Transmission of the virus through plant seed is not recognized as a significant factor in the epidemiology of tospoviruses. These viruses are thought to move long distances in thrips carried by wind currents. They may also survive in commercial agricultural systems in weeds that serve as a bridge between crops. Secondary spread within a crop can only occur in crops that support virus infection and reproduction of the vector as only the larval stage can acquire the virus for transmission. The recent emergence of these viruses as serious pathogens in crops has been attributed to the increased prevalence of thrips as agricultural pests on a worldwide basis. For example, *F. occidentalis*, the western flower thrips, is a highly efficient vector of several tospoviruses. Its emergence in the floral crop industry was closely followed by the emergence of INSV in the late 1980s.

Pathogenicity and Histopathology

Tospoviruses are noted for the severity of the diseases they cause in plants. Symptoms include chlorotic or necrotic lesions or line patterns on inoculated and systemically infected leaves. Systemic invasion of plants is frequently nonuniform. Many plants exhibit chlorotic, concentric rings as a characteristic symptom. Stems and petioles may exhibit necrotic lesions. Symptoms are sufficiently severe and atypical that many syndromes observed on many plants mimic disease and injury caused by other stresses such as bacterial or fungal pathogens or chemical injury. Infection of younger plants result in severely stunted plants and are frequently lethal. The pathology of infected thrips has not been thoroughly examined, however, preliminary studies indicate that infected thrips have reduced reproductive rates and longevity.

Although tospoviruses also induce characteristic cytopathic structures, it should be noted that the occurrence of these structures, even virions, vary from plant to plant and virus to virus. In addition to virions, inclusions or viroplasms consisting of the nonstructural protein (NSs) and nucleocapsid proteins may be abundant in the cytoplasm. NSs accumulates as a filamentous structure that may aggregate in loose bundles (e.g. TSWV) or in highly ordered paracrystalline arrays (e.g. INSV). Excess nucleocapsid protein occurs in granular electron-dense masses. NSs and nucleocapsid protein inclusions have been observed in infected plant and insect cells.

Prevention and Control

Tospoviruses can be effectively managed in well-defined cropping systems such as glasshouses by obtaining plant propagules known to be free of the virus, implementing a preventative thrips control program in high risk areas together with constant monitoring of production areas for infected plants and the vector. However, these strategies are costly and require intensive management. Control of the viruses in field crops is problematic due to the array of external sources of inoculum. Vector control is generally ineffective against the introduction of virus from external sources, however, it may be more effective against secondary spread within the field. Deployment of resistant cultivars has provided temporary benefits. Although little is known about the benefits of host resistance against most of the tospoviruses, TSWV defeated nearly every resistance gene deployed against it in many crops. Pathogen-derived resistance utilizing the nucleocapsid and NSm genes has been effective in some greenhouse and field tests. However, isolates have recently been obtained that overcome nucleocapsid-mediated resistance. The impact of these viruses on agricultural production is in large part due to the absence of highly effective control measures.

TOTIVIRUSES (*TOTIVIRIDAE*)

Contents

General Features

Said A Ghabrial, Department of Plant Pathology, University of Kentucky College of Agriculture, Lexington, Kentucky, USA

Jean L Patterson, Department of Virology and Immunology, Southwest Foundation for Biomedical Research, San Antonio, Texas, USA

Introduction

The discovery of the killer phenomenon in the 1960s in the yeast (*Saccharomyces cerevisiae*) and in the smut fungus (*Ustilago maydis*) eventually led to the discovery of the isometric double-stranded (ds) RNA mycoviruses with undivided genomes, presently classified in the family *Totiviridae*. Yeast or smut killer strains secrete a protein toxin to which they are immune, but which is lethal to sensitive cells. The killer toxin is encoded by a satellite dsRNA which is dependent on a helper virus with undivided dsRNA genome (totivirus) for encapsidation and replication. Unlike the helper totiviruses associated with the yeast and smut killer systems, the member viruses in the family *Totiviridae* that infect filamentous fungi and parasitic protozoa are not known to be associated with killer phenotypes. However, purified preparations of some of these viruses are often associated with dsRNA species suspected of being satellite or defective dsRNAs. Viruses with nonsegmented dsRNA genomes of approximately 5200 bp in length have been identified in over 13 strains of the new world parasitic protozoa, *Leishmania braziliensis* and in one strain of the old world parasite, *L. major*. These viruses have recently been placed in the genus *Leishmaniavirus* in the family *Totiviridae*.

The yeast and smut totiviruses and associated killer systems, as well as the totiviruses infecting the parasitic protozoa *Giardia lamblia*, are considered in separate entries in this text. This entry will focus on the totiviruses infecting filamentous fungi and parasitic protozoa, with special emphasis on *Helminthosporium victoriae* 190S virus (Hv190SV) and the totiviruses infecting the protozoa *Leishmania* spp.

Taxonomy and Classification

The family *Totiviridae* comprises three genera, *Totivirus*, *Giardiavirus* and *Leishmaniavirus* (**Table 1**). Viruses in the genus *Totivirus* infect fungi, whereas those belonging to the genera *Giardiavirus* and *Leishmaniavirus* infect parasitic protozoa. The isometric dsRNA totiviruses are unique among dsRNA viruses in that their genomes are undivided, whereas the genomes of all other dsRNA viruses are segmented.

Virion Properties

The sedimentation coefficients $s_{20,w}$ (in Svedberg units) for members of the totivirus genus are in the range of 160–190 S. Particles lacking nucleic acid sediment at the rate of $s_{20,w}$ = 98–113 S. Buoyant density in CsCl = 1.40–1.43 g ml^{-1}. Isolates of ScV-L-A and UmV-H1 may have additional components, containing satellite or defective dsRNAs, with different sedimentation coefficients and buoyant densities.

Virion Structure and Composition

The totiviruses have isometric particles, approximately 40 nm in diameter, with icosahedral symmetry. The capsids are single-shelled and comprised of a single major polypeptide. The capsids consists of 120 capsid protein (CP) subunits of molecular mass in the range of 69–88 kDa, arranged in $T = 1$ lattices.

Although the capsid of Hv190SV, like other totiviruses, is encoded by a single gene, it is comprised of two closely related major CPs, either p88 and p83 or p88 and p78. The capsids of all other totiviruses so far characterized appear to contain only a single major CP. Purified Hv190S virion preparations contain two types of particles, 190S-1 and 190S-2, that differ in sedimentation rates and capsid composition. The 190S-1 and 190S-2 virions are believed to represent different stages in the virus life cycle. The 190S-1 capsids contain p88 and p83, occurring in approximately equimolar amounts, and the 190S-2 capsids are comprised of similar amounts of p88 and p78. p88 and p83 are phosphoproteins, whereas p78 is nonphosphorylated.

The virions of totiviruses encapsidate a single mol-

Table 1 Virus members in the family *Totiviridae*

Genus	*Virus (Alternative name)*	*Abbreviation*	*Accession number*
Totivirus	Saccharomyces cerevisiae virus L-A	ScV-L-A	J04692
	(Saccharomyces cerevisiae virus L1)	ScVL1	X13426
	Saccharomyces cerevisiae virus La	ScV-La	U01060
	(Saccharomyces cerevisiae virus L-BC)	ScV-L-BC	
	Ustilago maydis virus H1	UmV-H1	V01059
	Helminthosporium victoriae 190S virus	Hv190SV	U41345
	Aspergillus foetidus virus S[a]	AfV-S	
	Aspergillus niger virus S[a]	AnV-S	
	Gaeumannomyces graminis virus 87-1-H[a]	GgV-87-1-H	
	Mycogone perniciosa virus[a]	MpV	
Giardiavirus	Giardia lamblia virus	GLV	L13218
	Trichomonas vaginalis virus[a]	TVV	U08999
Leishmaniavirus	Leishmania RNA virus 1-1	LRV1-1	M92355
	Leishmania RNA virus 1-4	LRV1-4	U01899
	Leishmania RNA virus 2-1	LRV2-1	U32108

ecule of dsRNA 4.7–6.7 kbp in size. Some totiviruses may additionally contain satellite dsRNAs or defective dsRNAs, which are encapsidated separately in capsids encoded by the totivirus genome. The complete nucleotide sequences of eight totiviruses belonging to three genera have been published and the GenBank accession numbers are listed in **Table 1**.

Genome Organization and Expression

The genome organization and expression strategy of the totiviruses infecting fungi and protozoa are similar: each virus genome contains two large open reading frames (ORFs); the 5′ proximal ORF encodes a CP and the 3′ ORF encodes an RNA-dependent RNA polymerase (RDRP). Except for LRV2-1, the RDRP ORF overlaps the CP ORF and is in the −1 frame (ScV-L-A, ScV-La, Hv190SV and GLV) or in the +1 frame (LRV1-1, LRV1-4 and TVV) with respect to the CP ORF. The RDRP ORF of LRV2-1 does not overlap the CP ORF, and is separated from it by a stop codon.

Expression of RDRP as CP-RDRP (*gag-pol*-like) fusion protein via −1 ribosomal frameshifting has been well documented only for ScV-L-A. Virion-associated CP-RDRP has been detected as a minor protein in the case of ScV-L-A, ScV-La (L-BC) and GLV. The RDRP of Hv190SV (and possibly that of LRV1-4) is present as a nonfused separate virion-associated minor protein. Although CP-RDRP fusion proteins were not detected *in vivo*, nor associated with virions of TVV, LRV1-1, LRV1-4 or LRV2-1, expression of RDRP as a fusion protein by +1 ribosomal frameshifting (TVV, LRV1-1 and LRV1-4) or ribosomal hopping (LRV2-1) has been proposed.

The overlap region (16 nt) between the two ORFs of Hv190SV dsRNA (**Fig. 1**) is considerably smaller than that in ScV-L-A (130 nt), LRV1-1 and LRV1-4 (71 nt), and GLV (122 nt). The overlap region of these totiviruses contain sufficient information (structures necessary for ribosomal frameshifting, including a slippery site and a pseudoknot structure involving a predicted stem–loop structure) to promote fusion of ORF1 and ORF2 *in vivo*. The overlap region in the Hv190SV dsRNA genome, on the other hand, lacks a heptamer slippery site and a potential pseudoknot structure cannot be predicted from the secondary structure of the sequences flanking the 3′-terminal region of the CP gene. These observations suggest that expression of RDRP occurs by a mechanism different from translational frameshifting. The finding that the termination codon of the CP ORF (nucleotide position 2605-AUG-2607) overlaps with the predicted

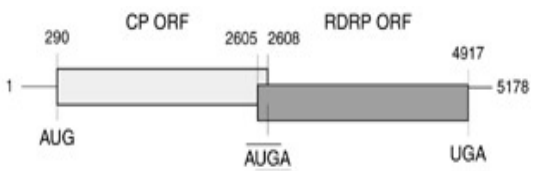

Figure 1 Genome organization of Helminthosporium victoriae 190S virus (Hv190SV) dsRNA. Two large overlapping open reading frames (ORFs) with the 5′ ORF encoding a capsid protein (CP) and the 3′ ORF encoding an RNA-dependent RNA polymerase (RDRP). Note that the termination codon of the CP ORF overlaps the initiation codon of the RDRP ORF in the tetranucleotide sequence AUGA.

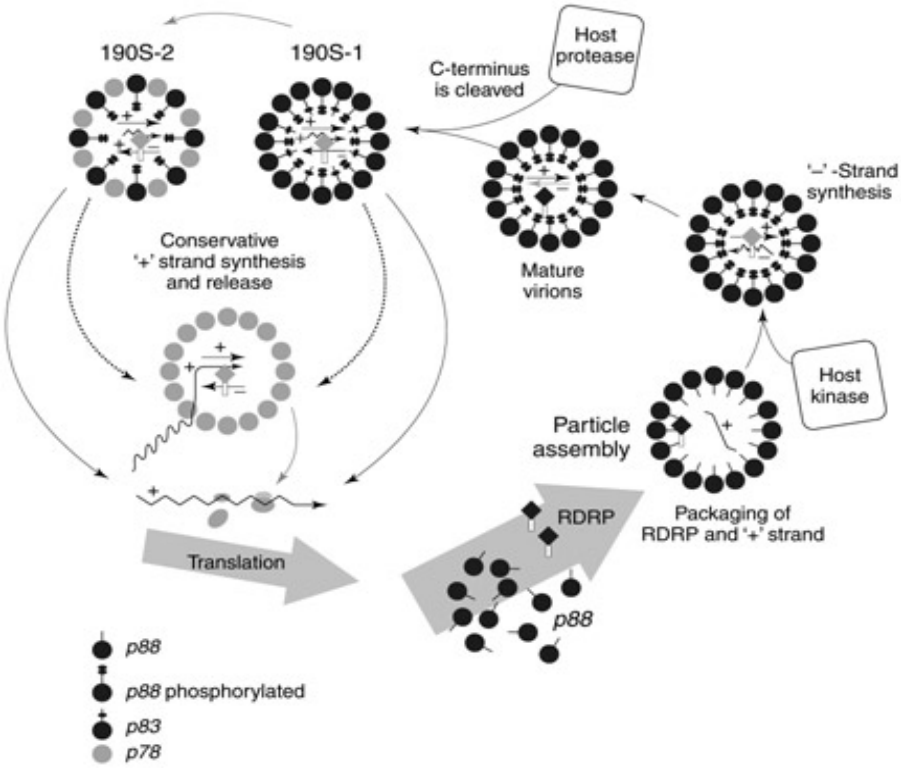

Figure 2 Life cycle of Hv190SV. Mature virions contain a single dsRNA molecule and their capsids are composed entirely or primarily of the capsid protein (CP) p88. Virions representing different stages of the virus life cycle can be purified from the infected fungal host *Helminthosporium victoriae* including the well-characterized 190S-1 and 190S-2 virions. These two types of virions differ in sedimentation coefficient, phosphorylation state and CP composition; 190S-1 capsids contain p88 and p83, whereas the 190S-2 capsids contain p88 and p78 (p88 is the primary translation product of the *CP* gene; p83 and p78 represent post-translational proteolytic processing products of p88 at the C-terminus). p88 and p83 are phosphorylated, whereas p78 is nonphosphorylated. The virions with phosphorylated CPs (p88 + p83) have significantly higher transcriptase activity *in vitro* than those containing the nonphosphorylated p78. Transcription occurs conservatively and the newly synthesized (+)-strand RNA is released from the virions. Phosphorylation of CP is catalyzed by a host kinase, and is proposed to play a regulatory role in transcription/replication. A host-encoded protease catalyzes the proteolytic processing of phosphorylated p88; this occurs in two steps, leading first to p83 (the generation of the 190S-1 virions) and then to p78 (190S-2 virions). The conversion of p88 → p83 → p78 is proposed to play a role in the release of the (+)-strand RNA transcripts from virions. The released (+)-strand RNA is the RNA that is translated into CP and RNA-dependent RNA polymerase (RDRP) and packaged in capsids assembled from the primary translation product p88. It is not known whether p88 is phosphorylated before or after assembly. Synthesis of (−)-strand RNA occurs on the (+)-strand RNA template inside the virion; phosphorylation may be involved in turning on the replicase activity.

start codon for the RDRP ORF (2606-UGA-2608) in the sequence AUGA (**Fig. 1**) suggests that RDRP is translated by an internal initiation mechanism.

Double-stranded RNA Replication

Information on the replication cycle of totivirus dsRNA has mainly been derived from *in vitro* studies of virion-associated RNA polymerase activity and the isolation of particles representing various stages in the replication cycle. In *in vitro* reactions, the RNA polymerase activity associated with virions of the fungal totiviruses ScV-L-A, UmV-H1 and HvV-190S, isolated from lag phase cultures, catalyzes end-to-end transcription of dsRNA, by a conservative mechanism, to produce mRNA for capsid polypeptide, which is released from the particles. Purified ScV-L-A virions, isolated from log phase cells, contain a less dense class of particles which package only (+)-strand RNA. In *in vitro* reactions, these particles exhibit a replicase activity that catalyzes the synthesis of (−)-strand RNA to form dsRNA. The resultant mature particles, which attain the same density as that of the dsRNA-containing virions isolated from the cells, are capable of synthesizing and releasing (+)-strand RNA.

A proposed life cycle of Hv190SV is depicted in **Fig. 2**. Host-encoded protein kinase and protease have been shown to be involved in post-translational modification of CP. Phosphorylation and proteolytic

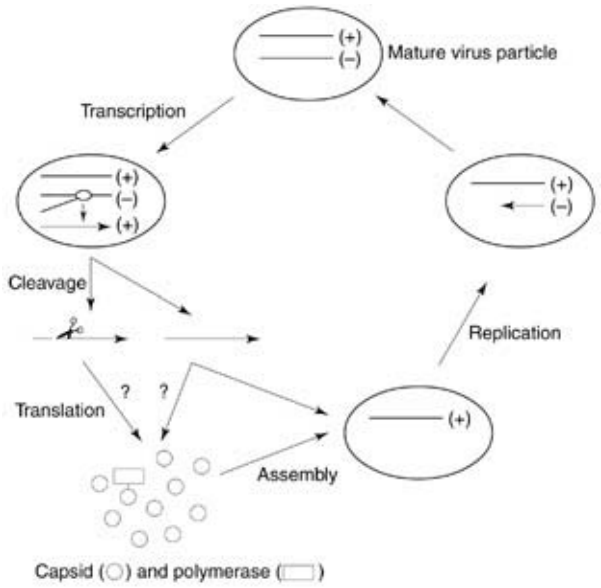

Figure 3 Replication cycle of leishmaniaviruses.

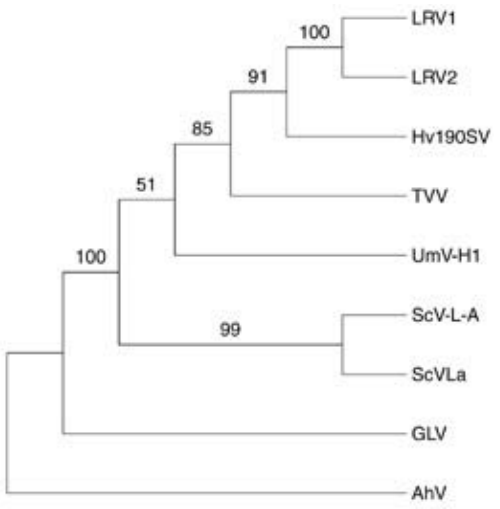

Figure 4 Phylogeny estimates of totiviruses derived from aligned deduced amino acid sequences of RDRP. The resulting consensus tree of 100 bootstrap replicates is shown; the number above each node indicates the percent of bootstrap replicates in which that node was recovered. Tree was outgroup-rooted to the partitivirus Atkinsonella hypoxylon virus (AhV). See **Table 1** for abbreviations of totivirus names.

processing are proposed to play a role in the virus life cycle; phosphorylation of CP may be necessary for its interaction with viral nucleic acid and for subsequent assembly into virions, and/or phosphorylation may regulate dsRNA transcription/replication. Proteolytic processing and cleavage of a C-terminal peptide, which leads to dephosphorylation and the conversion of p88 to p78, may play a role in the release of the (+)-strand RNA transcripts from virions (**Fig. 2**).

Leishmaniaviruses have a slight variation in their life cycle from the other totiviruses. The CP has endoribonuclease activity which is responsible for cleaving 320 nt from the 5′ end of the full-length single-stranded (+)-sense RNA. It has been hypothesized that the cleavage activity generates the functional message by removing translation inhibitory sequences. The proposed life cycle is depicted in **Fig. 3**.

Evolutionary Relationships among Totiviruses

Sequence comparison analysis of the predicted amino acid sequences of totivirus RDRPs indicated that they share significant sequence similarity and characteristically contain eight conserved motifs. This sequence similarity was common to the totiviruses that infect the yeast and smut fungi as well as those infecting parasitic protozoa. The RDRP of Hv190SV, a recently characterized totivirus that infects a filamentous ascomycetous fungus, was also found to contain the same eight conserved motifs. The sequence similarity among the RDRPs of these viruses infecting simple eucaryotes extends beyond the highly conserved eight motifs. Of the 70 amino acid positions contained in these conserved motifs, the Hv190SV RDRP is identical in 48, 47, 46, 40, 38 and 21 positions, respectively, to the RDRPs of LRV1, TVV, ScV-L-A, UmVH1, ScV-La and GLV.

Phylogeny estimates derived from multiple alignments of totivirus RDRP ORFs (**Fig. 4**) indicated that the two leishmaniaviruses LRV1 and LRV2 (percent sequence identities of 46%) are most closely related to each other. This is also true for the two yeast viruses ScV-L-A and ScV-La (identity of 32%). It is of considerable interest that Hv190SV, a mycovirus infecting a filamentous fungus, was found to be a sister clade to the leishmaniaviruses and not to the yeast viruses (**Fig. 4**).

Transmission and Host Range

There are no known natural vectors for the transmission of the fungal totiviruses. They are transmitted intracellularly during cell division, sporogenesis and cell fusion. Although the yeast viruses are effectively transmitted via ascospores, the totiviruses infecting the ascomycetous filamentous fungi, e.g. GgV-87-1-H, are essentially eliminated during ascospore formation. The leishmaniaviruses are not infectious and are propagated during cell division. Like other totiviruses, the leishmaniaviruses have no extracellular phase to their life cycles. Successful transfection of the

protozoa *Giardia lamblia*, however, has been accomplished via electroporation with (+)-strand RNA transcribed *in vitro* from GLV dsRNA.

There are no known experimental host ranges for the fungal totiviruses because of the lack of suitable infectivity assays. As a consequence of their intracellular modes of transmission, the natural host ranges of totiviruses are limited to individuals within the same or closely related vegetative compatibility groups. Furthermore, mixed infections with two or more unrelated viruses are common, probably as a consequence of the ways by which fungal viruses are transmitted in nature. Dual infection of yeast with ScV-L-A and ScV-L-BC is an example of mixed infection involving totiviruses. Leishmaniaviruses have been found in *L. braziliensis*, *L. guyanensis* and *L. major*.

Virus–Host Relationships

The yeast killer system, comprised of a helper totivirus (ScV-L-A) and associated satellite dsRNA (M-dsRNA), is one of a very few known examples where virus infection is beneficial to the host. The ability to produce killer toxins by immune yeast strains confers an ecological advantage over sensitive strains. The use of killer strains in the brewing industry provides protection against contamination with adventitious sensitive strains.

Totiviruses maintain only the genes that are essential for their survival (*RDRP* and *CP*), but make efficient use of host proteins. The host cells have evolved to support only a defined level of virus replication, beyond which virus infection may become pathogenic. Because of amenability to genetic studies, the yeast–virus system has provided significant information on the host genes required to prevent viral cytopathology. A system of six chromosomal genes, designated superkiller (or *SKI*) *SKI2*, *SKI3*, *SKI4*, *SKI6*, *SKI7* and *SKI8*, negatively control the copy number of the ScV-L-A totivirus and its satellite M-dsRNAs. The only essential function of these genes is to block virus multiplication. Mutations in any of these *SKI* genes lead to the development of the superkiller phenotype as a result of the increased copy number of M-dsRNA. The *SKI* genes affect primarily the initiation of translation rather than the stability of mRNA, and are thus part of a cellular system that specifically blocks translation of nonpolyadenylated mRNAs (like the (+)-strand transcripts of totiviruses). About 30 chromosomal genes, termed *MAK* genes (for maintenance of killer), are required for stable replication of the satellite M-dsRNA. Only three of these *MAK* genes are necessary for the helper virus (ScV-L-A) multiplication. Mutants defective in any of 20 *MAK* genes show a decreased level of free 60S ribosomal subunits. Since the *mak* mutations affecting 60S subunit levels are known to be suppressed by *ski* mutations, and since the latter are now known to act by blocking translation of nonpolyadenylated mRNAs, the level of 60S ribosomal subunits is believed to be also critical for translation of nonpolyadenylated mRNAs.

The Hv190S totivirus that infects the plant pathogenic fungus *Helminthosporium victoriae* utilizes host-encoded proteins (a protein kinase and a protease) for post-translational modification of its CP. Phosphorylation and proteolytic processing of CP may play a role in regulating transcription and the release of (+)-strand transcripts from virions (**Fig. 2**).

Ustilago Maydis Viruses

Jeremy Bruenn, Department of Biological Sciences, SUNY/Buffalo, Buffalo, USA

Taxonomy

The *Totiviridae* is a remarkable family of fungal and protozoan viruses. These viruses have a single essential double-stranded RNA (dsRNA) and are recognizably related to each other as viewed by comparison of their RNA-dependent RNA polymerases (RDRPs). They have been discovered in at least four genera of protozoans (*Leishmania*, *Eimeria*, *Giardiavirus* and *Trichomonas*) and nine genera of fungi (*Saccharomyces*, *Ustilago*, *Helminthosporium*, *Gaeumannomyces*, *Mycogone*, *Yarrowia*, *Aspergil-*

lus, Thielaviopsis, and probably *Agaricus*). *Ustilago maydis* viruses are in the *Totivirus* genus of the *Totiviridae* family.

Characteristics of the Host Fungus

The fungus *Ustilago maydis* belongs to the class Basidiomycetes and the family Ustilaginaceae. Its life cycle has three phases: diploid, haploid and dikaryon. While dikaryon formation and development is restricted to host tissue, the diploid and haploid mycelia may grow rapidly in a yeast-like manner in laboratory media. A transient dikaryon (or heterokaryon) may be formed between compatible strains on laboratory medium. *U. maydis* is heterothallic. Sexual reproduction between two haploid strains depends on two unlinked genes. The *a* gene has two alleles and the *b* gene has multiple alleles. Cells with opposite *a* alleles will fuse under appropriate conditions to form a heterokaryon which will infect the host and allow the completion of the life cycle only if the *b* alleles are also different. The *a* gene can, therefore, be regarded as the mating type locus homologous to the simple two-allele mating systems of most yeasts, whereas the *b* gene controls the development of the dikaryon in infected host cells, which is the only place that sexual development can proceed.

Virion Structure and Composition

All the dsRNA viruses are now known to have at least one capsid polypeptide present in 120 copies per virion. This is unique among icosohedral viruses and superficially appears to violate the Caspar and Klug rules for assembly of isometic virus particles. However, in the one case where the x-ray crystal structure of the virion has been determined (Bluetongue virus, or BTV), this apparent $T = 2$ symmetry is really a twofold $T = 1$ symmetry, in which 60 of the subunits adopt one configuration and 60 another. Hence, even though there are 120 copies of the virion protein, half of them are in one conformation and half in the other.

The totiviruses are small icosohedral viruses. *Ustilago maydis* virus (UmV) is about 41 nM in diameter, sedimenting at 172 S and with a buoyant density in CsCl of 1.42 g ml^{-1}. In UmV the capsid polypeptide is about 75 kDa, but no accurate estimate of its size is available. In the one case where the sequence of its coding RNA is known (P1H1), the C-terminus of the protein appears to be generated by cleavage, and the cleavage site has not been determined. Electron microscopy, in the case of UmV and *Saccharomyces cerevisiae* virus (ScV), has demonstrated that there are 120 copies of a single polypeptide in their capsids, arranged as 12 pentamers of dimers of the capsid polypeptide. Presumably, as in BTV, these adopt two configurations in equal numbers in the capsid. In ScV, two of the capsid monomers are thought to be the N-terminal portions of a capsid polypeptide–RDRP fusion protein. Since the P1H1 capsid polypeptide is initially synthesized as such a fusion prior to (presumed) cleavage, this is likely for UmV as well.

Ustilago Maydis Viruses

Most fungal dsRNA viruses do not confer on their host cells any characteristic phenotype. They are persistent, segmented dsRNA viruses whose segments are separately encapsidated and whose only means of transmission is mitosis or meiosis. However, ScV and UmV are known to encode killer toxins, which are thought to provide a selective advantage to cells harboring the responsible viruses.

Interstrain inhibition (the killing phenomenon) in *U. maydis* was discovered by Puhalla during heterokaryon experiments. The inhibitory factor (killer toxin) was shown to be a secreted protein or proteins. Crosses and heterokaryon transfer experiments showed that the inhibitory effect is caused by cytoplasmically inherited factors, which are now known to be single dsRNA segments present in some multisegmented dsRNA viral genomes (see below). A small proportion of *U. maydis* cells (about 1%) can produce killer toxins, to which they are resistant; sensitive cells are the majority in wild populations. There are also some cells that do not have killing ability but are resistant to one toxin. Killer toxins are known in eight genera of yeasts, but the killer toxins of *Ustilago* are the only ones known in a filamentous fungus. The *U. maydis* killer toxins are effective against species in the family Ustilaginaceae, including those that are known as pathogens to wheat, oats and barley.

There are three killer types: KP1, KP4 and KP6, which secrete KP1, KP4 and KP6 toxins, respectively. Correspondingly, there are three groups of resistant cells, in which the resistance is determined by three independent recessive nuclear genes: *p1r, p4r* and *p6r*. In KP1, cytoplasmically inherited factors also confer immunity to the KP1 killer toxin. KP4 probably has no cytoplasmically determined immunity, and recent experiments show that KP6 has no cytoplasmically determined immunity. Cells cannot produce the KP6 toxin unless they have the p6r gene, and the same is probably true of KP4. The *p1r, p4r* and *p6r* genes are thought to encode cellular (membrane, or membrane–cell wall) receptors for the toxin. Since these putative receptors are different in each case, there is no crossresistance to the toxins. The KP6 receptor is

apparently recognized by cytoplasmic toxin polypeptides as well as by toxin in the medium. There are no single resistance alleles that confer simultaneous resistance to all three toxins.

Structure and Function of the Killer Toxins

KP6

The three-dimensional structures of two of the *Ustilago* toxin polypeptides have been determined. The crystal structure of KP6α (space group $P6_322$, a = 48.3 Å, c = 124.8 Å) was determined by use of heavy atom isomorphous techniques and by selenomethionine substitution (R-factor = 0.169, resolution 1.8 Å). The monomer has a three finger structure similar to neurotoxins and cardiotoxins and is composed of a four stranded antiparallel β sheet with two α helices on one side, an additional β strand, and a small α-helix segment at the N-terminus. Three intermolecular salt bridges link monomers of KP6α into trimers organized around a threefold segment axis. The trimer has a funnel shape that is wide across the mouth and narrows to a 3.2 Å opening just large enough to permit an ion to pass.

The trimer has many structural features that have been postulated to be critical elements in pore domains of mammalian ion channels, including a solvent-filled funnel lined with charged amino acid residues that could be a selectivity screen for specific ions and a network of salt bridges that stabilize the timer. The 3.2 Å funnel bore is lined by six phenyl rings. These phenyl rings arise in part from a GFG sequence in KP6α that may correspond to a G(Y/F)G sequence that is conserved in K^+ channels. These phenyl groups in KP6α form a cage similar to one postulated to be responsible for K^+ selectivity relative to Na^+ on the basis of *ab initio* calculations. In crystals two trimers are related by a twofold axis perpendicular to the funnel axis, generating a symmetric pair of funnels. The hexamer has dimensions and characteristics that suggest it is a self-assembling ion pore closely resembling the pore (H5) commonly found in voltage-gated and inwardly-rectifying ion channels. The open ends of the two funnels would lie on the bilayer surface and the narrow bore would be at the center of the bilayer. The salt bridges that hold the trimers together are separated by 30 Å and portions of the funnel would extend well out of the membrane.

KP6β may be a functional analogue of the transmembrane strands that are thought to flank the pore in mammalian ion channels and facilitate entry of the pore into the membrane. The structure of KP6β has been modeled upon that of KP6α by examining sequence similarities. Examination of the stereochemical topology of the KP6α hexamer and the KP6β monomer and the charge distribution on their surfaces suggested a model for a dodecamer composed of six molecules of KP6α (as observed in the crystal structure) surrounded by six molecules of KP6β. The resultant KP6$\alpha_6\beta_6$ dodecamer has an outer surface that is essentially neutral and compatible with membrane insertion. The interface between the observed hexamer of KP6α and the modeled hexamer of KP6β exhibits excellent complementarity in surface charge and stereochemistry. Preliminary experiments with planar lipid bilayers are consistent with the KP6 toxin functioning as a channel-former.

KP4

The structure of KP4 was determined to 1.9 Å resolution and is now refined to 1.4 Å using a single isomorphous derivative, with phases improved using real space averaging. KP4 belongs to the α/β sandwich family of proteins and has a double split β-α-β motif. The toxin has a total of seven β strands and three α helices, with the major secondary structure elements consisting of five antiparallel stranded β sheets (β1, β3, β4, β6, β7) with two antiparallel α helices (α2, α3) lying at approximately 45° to the strands in the β sheet. The *U. maydis* KP4 killer toxin and the *Pichia farinosa* KK1 toxin have no evident primary sequence similarity, but their tertiary structures are essentially identical even though KP4 is a single polypeptide and KK1 is two polypeptides. Thus KP4 appears from its structure to be a tandem duplication of one sequence which has subsequently diverged, and it could easily have arisen from two polypeptides processed by Kex2p by a single deletion of the genomic sequence encoding the intervening sequence and the cleavage sites in the prepropolypeptide. This would conveniently explain the absence of Kex2p processing of KP4.

The scorpion toxins are a family of neurotoxins with some interesting similarities to KP4. Albeit about half the size of KP4, the long toxins are similar to KP4 in that they are all highly basic proteins that are stabilized by an extensive network of disulfide bonds. The core motif of the α and β neurotoxins are quite similar and the functional differences between them may lie in the length and orientation of protruding loops extending from this core region. In light of this tenuous similarity to the scorpion toxins, KP4 killing efficacy was tested on sensitive *Ustilago* cells. Cells were rescued by very small concentrations of Ca^{2+} but not with similar concentrations of monovalent cations.

These rescue experiment results strongly suggested

that KP4 affects Ca^{2+} channels. Therefore, the effect of KP4 was tested on mammalian cells lines where more is known about the types and kinetics of cationic channels. Standard whole-cell patch clamp techniques were used to examine the effects of KP4 on voltage-activated Na^+, K^+, Ca^{2+} currents in PC12, GH_3 and adrenal chromaffin cells, and the prevalent action of KP4 was inhibition of voltage-activated Ca^{2+}-channel currents.

Genome Structure and Translation

The UmV viral genomes consist of three distinct size groups of dsRNAs. They are heavy (H), medium (M) and light (L). Three original isolates (named after the killer toxins they encoded) were named P1, P4 and P6. Cells may have as few as three viral dsRNAs (some isolates of P6 strains) or as many as seven viral dsRNAs (some isolates of P4 strains). The H segments appear to encode the essential viral polypeptides: a capsid polypeptide and an RDRP. One of the H1 segments has been sequenced: P1H1 is 6099 bp, and encodes on one open reading frame (540–5999) a polypeptide of 1820 amino acids with a putative capsid polypeptide in the N-terminal region and a typical RDRP sequence in the C-terminal thousand amino acids. P1H1 and P6H1 are nearly identical in sequence, while P1H1 and P1H2 share about 31% amino acid sequence identity in the RDRP region. This is consistent with there being at least two totiviruses in *Ustilago* (H1 and H2), which is similar to the ScVL1 (ScVL-A) and ScVLa (ScVL-BC) viruses in *S. cerevisiae*. Processing of the P1H1 polypeptide is proposed to occur by self-cleavage.

One or more of the M segments in each subtype encode the toxin. By sequence analysis of both the toxin polypeptides and P6M2 and synthesis of toxin in heterologous (yeast and tobacco) and homologous cDNA expression vectors, as well as immunological evidence, the KP6 coding region in P6M2 has been completely defined. P6M2 is 1234 bp, encoding a preprotoxin of 219 amino acids, which is subsequently processed by signal peptide cleavage after residue 19, Kex2p cleavage after residues 27, 108 and 138, and Kex1p cleavage after residue 137 to yield two polypeptides, α of 79 amino acids (8.6 kDa), and β of 81 amino acids (9.1 kDa).

Similarly, P4M2, of 1006 bp, encodes the KP4 preprotoxin of 127 amino acids, which is processed solely by signal peptidase cleavage after residue 22, yielding a toxin of 105 amino acids (11.1 kDa). The KP4 toxin has been expressed from cDNA clones in yeast, tobacco and *Pichia pastoris*.

P1M2, of 1034 bp, encodes the KP1 toxin, which is synthesized as a preprotoxin of 291 amino acids. The KP1 preprotoxin is processed by signal peptidase (24), Kex2p (142 and 173), and Kex1p (141), resulting in an α peptide of 117 amino acids and a β peptide of 118 amino acids (13.4 kDa). Only β is necessary for activity.

All the *Ustilago* toxin peptides are small, highly stable proteins in which all the cysteines appear to be in disulfides. KP6α has four disulfides, KP6β three, KP4 five, and KP1β three. None of the *Ustilago* toxin polypeptides is glycosylated, although KP6α and KP1β have possible *N*-linked glycosylation sites, and the KP6α site is utilized in *S. cerevisiae*. None of the M segments (including P1M1) have detectable sequence similarities at either the nucleotide level or the protein level, except in the 3′ region of the plus strand, from which the L segments are derived.

The L segments (355 bp) are derived from the 3′ ends of the plus strands of M segments: P6L from P6M2, P1L from P1M1, and P4L from P4M2. Neither the mode of synthesis of these segments nor their function is understood. All the L segments share a great deal of sequence identity (50–95% at the nucleotide level). In general, homologous P1 and P4 segments are very close in sequence (the L segments are 95% identical), while the homologous P6 segments are more divergent. The highest conservation of sequence among P6M2, P1M1 and P4M2 is within 20 bases on either side of the region of M encoding the 5′ end of the L plus strand. This suggests that the L segments are derived by replication of cleavage products of M plus strands (see below).

Complete sequences are known for the following *Ustilago* dsRNAs: P1H1 (6099 bp), P6M2 (1234 bp), P6L (355 bp), P4M2 (1006 bp), P4L (354 bp), P1M1 (1504 bp), P1M2 (1034 bp) and P1L (354 bp). Partial sequences are available for P6H1 and P4H1. P1M1 could encode two secreted polypeptides of 81 amino acids and 143 amino acids after signal peptidase and Kex2 cleavage, but neither peptide has been detected as a component of the P1 toxin (**Fig. 1**).

Replication and Transcription

All dsRNA viruses separate transcription from replication by packaging. Viral plus strands are synthesized in viral particles and extruded into the cell cytoplasm. These have two fates: translation and packaging. Viral plus strands that are packaged into nascent particles are subsequently replicated (by synthesis of the minus strand) after packaging is complete. In ScV, the packaging signal is a small (20 base) sequence. The identity of the packaging signal in UmV is unknown. However, all sequenced UmV

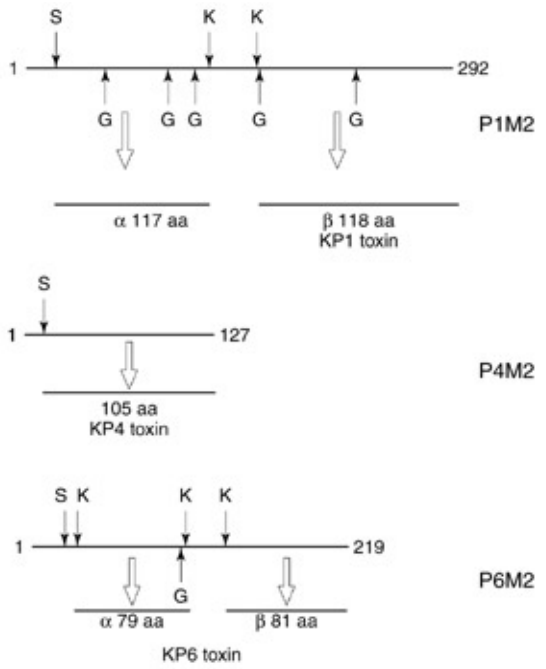

Figure 1 Processing of the KP1, KP4 and KP6 killer toxins, encoded by P1M2, P4M2 and P6M2 respectively. Processing by signal peptidase is indicated by S and processing by Kex2 by K. Possible sites of *N*-linked glycosylation are shown by G, but none of these sites is glycosylated in the mature peptides.

RNAs have the sequence GAAAAA at the 5′ end and $AUGCA_{OH}$ at the 3′ end of the plus strand, except for the L segments. These have the sequence UCCG at the 5′ end of the plus strand. Since the 5′ sequence GAAAAA is common among the fungal dsRNA viruses, and since the complementary region of the minus strand is required for transcriptase activity at least in ScV, this has been taken to be the required start for transcription.

The absence of this sequence in the L segments and their highly conserved sequences around the position of the 5′ end of the L plus strand within M probably indicate that the L segments are generated by cleavage of the M plus strand followed by replication. This hypothesis is further supported by the presence of a long putative double-stranded region (a stem) immediately adjacent to the putative site of cleavage. In P4M2, this stem is a remarkable 23 uninterrupted base pairs in length.

Replication and transcription in dsRNA viruses may be either conservative or semiconservative. That is, the plus strand extruded during transcription may be either the parental strand (semiconservative) or the newly synthesized strand (conservative). Replication is conservative in ScV, but for at least one UmV segment, the M2 dsRNA, replication is semiconservative.

Evolution

Due to the extant similarities among totiviruses present in divergent phyla, ranging from protozoans parasitic to animals (*Leishmania*) to fungi parasitic to plants (*Ustilago*), and the fact that these viruses are not infectious but have only vertical transmission, they are thought to have originated very early in evolution, prior to the differentiation of multicellular from single-celled eucaryotes. Sequence relationships among the totivirus RDRPs support this model. For instance, the closest relative of UmVP1H2 is ScVLa, even though UmVP1H1 and UmVP1H2 are present in the same *Ustilago* cells while ScVLa and ScVL1 are present in the same *S. cerevisiae* cells. Similarly, another fungal totivirus (from *Helminthosporium*) is more closely related to the protozoan totiviruses than to the other fungal totiviruses. Although the totiviruses are noninfectious, the closely related *Giardiavirus* is infectious, and both ScV and UmV have been shown to be infectious, albeit very inefficiently, to spheroplasts. These experiments have selected for transformation by *S. cerevisiae* or *U. maydis* DNA plasmids in the presence of purified virus, using recipient cells lacking the viruses. A small percentage of the selected transformants carry the virus. Hence the cell wall (in fungi) or the cell membrane (in protozoans) seems to limit infection.

Geographic Distribution

The same UmV isolates are present in *Ustilago* from Mexico, the USA, the UK, Poland and China. So far only three toxin specificities have been found. Protein purification and sequencing has demonstrated a toxin with the same N-terminus as KP4 in Korea.

Economic Significance

Ustilago is a pathogen on a number of grain crops, the most important of which is maize. It does cause major crop losses of sweet corn. Although UmV has no apparent effect on the virulence of its host, it may be possible to introduce the viral killer toxin genes into the plants, making them resistant to the fungus. The UmV toxins of *U. maydis* are particularly attractive as biological control agents because they have no known effects when ingested. The UmV toxins can be effective against a wide range of *Ustilago* species known to be crop pathogens, including pathogens of maize, wheat, oats and barley. The UmV toxins should therefore be very useful as a means of introducing novel resistance to the ustilaginales into plants, provided the toxins can be expressed at high levels, are correctly processed, and end up in cellular

or extracellular compartments where they can inhibit growth of the fungus.

The KP6 and KP4 toxins have been successfully expressed in transgenic tobacco plants, so this may be a possible strategy. Tobacco plants are capable of correctly synthesizing, processing and secreting KP6 toxin polypeptides with the same activity and specificity as the authentic KP6 toxin produced by *U. maydis*. The activity of toxin produced is rather low (about 200-fold lower than in *Ustilago*), possibly due to incorrect processing of the C-terminus of α. Tobacco plants produce about 500 times as much KP4 activity from the same expression vector as that used for KP6. Toxin activity is easily detected at the surface of leaves of transgenic KP4 tobacco plants. Transgenic maize plants expressing genes for both KP4 and KP6 toxins could be resistant to all but a fraction of a percent of the natural *U. maydis* population. Since ingested UmV toxins have no toxic effects on human cells, they would be safe for consumption and have less environmental impact than the fungicides currently used to deter fungal pathogens.

Introduction

The observation that certain viruses rapidly and reproducibly induce tumors in the host was first made nearly a century ago. The ability to accurately duplicate this process in tissue culture has made possible the investigation of neoplastic transformation *in vitro*. This, in turn, has allowed the techniques of molecular biology and genetics to be applied to the problem of cancer, especially cancer induced by viruses. Much of our current knowledge of the molecular mechanisms of cancer today is derived from the study of virally induced tumors. Virus-induced tumors are not only important as laboratory tools for investigation of the fundamental mechanisms of tumor formation; some human cancers, including hepatocellular carcinoma, cervical carcinoma, Burkitt's lymphoma and acute T-cell leukemia, appear to have a viral etiology.

The types of viruses that are capable of inducing tumors are remarkably diverse, and include viruses with RNA and DNA genomes. Nonetheless, certain common features have emerged from the study of neoplastic transformation by different viruses. The first is that tumor formation induced by viruses is the result of the acquisition by the host cell of the viral genome. In all cases of virally induced tumors so far described, at least a part of the viral genome is

or extracellular compartments where they can inhibit growth of the fungus.

The KP6 and KP4 toxins have been successfully expressed in transgenic tobacco plants, so this may be a possible strategy. Tobacco plants are capable of correctly synthesizing, processing and secreting KP6 toxin polypeptides with the same activity and specificity as the authentic KP6 toxin produced by *U. maydis*. The activity of toxin produced is rather low (about 200-fold lower than in *Ustilago*), possibly due to incorrect processing of the C-terminus of α. Tobacco plants produce about 500 times as much KP4 activity from the same expression vector as that used for KP6. Toxin activity is easily detected at the surface of leaves of transgenic KP4 tobacco plants. Transgenic maize plants expressing genes for both KP4 and KP6 toxins could be resistant to all but a fraction of a percent of the natural *U. maydis* population. Since ingested UmV toxins have no toxic effects on human cells, they would be safe for consumption and have less environmental impact than the fungicides currently used to deter fungal pathogens.

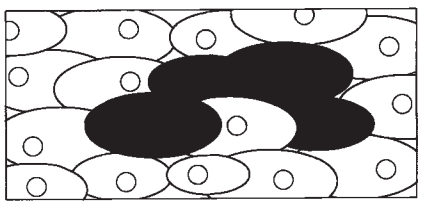
TRANSFORMATION – ANIMAL VIRUSES



Ron Wisdom, Department of Biochemistry, Vanderbilt University School of Medicine, Nashville, Tennessee, USA

Inder M Verma, The Salk Institute, San Diego, California, USA

Introduction

The observation that certain viruses rapidly and reproducibly induce tumors in the host was first made nearly a century ago. The ability to accurately duplicate this process in tissue culture has made possible the investigation of neoplastic transformation *in vitro*. This, in turn, has allowed the techniques of molecular biology and genetics to be applied to the problem of cancer, especially cancer induced by viruses. Much of our current knowledge of the molecular mechanisms of cancer today is derived from the study of virally induced tumors. Virus-induced tumors are not only important as laboratory tools for investigation of the fundamental mechanisms of tumor formation; some human cancers, including hepatocellular carcinoma, cervical carcinoma, Burkitt's lymphoma and acute T-cell leukemia, appear to have a viral etiology.

The types of viruses that are capable of inducing tumors are remarkably diverse, and include viruses with RNA and DNA genomes. Nonetheless, certain common features have emerged from the study of neoplastic transformation by different viruses. The first is that tumor formation induced by viruses is the result of the acquisition by the host cell of the viral genome. In all cases of virally induced tumors so far described, at least a part of the viral genome is

present. Furthermore, the continued expression of at least a part of the viral genome is required for the transformed phenotype to be present. In the case of the transforming RNA viruses, the viral genome is present in the form of a DNA provirus integrated into the host genetic material. An important consequence of the presence of the viral genetic material is the fact that the transformed phenotype induced by the virus is heritable.

Cancer cells show many properties that distinguish them from normal cells. The hallmark of malignant cells is their ability to grow in the absence of appropriate signals from the extracellular environment. While the extracellular signals that are either not sensed or not required may vary from tumor to tumor, the property of malignancy is cell autonomous, that is, it is a property of the transformed cell and not the surrounding normal tissue. Genetic events that give rise to cancer, then, alter the cellular response to external stimuli. The investigation of cancer over the last decade has served to outline a cell signaling pathway that allows cells to respond to changes in the external environment. Support for the idea that this signaling pathway is the direct target for cancer-inducing mutations has been found in a wide range of both viral and nonviral tumors.

Retroviruses

The study of retroviruses has contributed more to our understanding of cancer than the study of any other group of viruses. The relevant features of the retroviral life cycle involve reverse transcription of the RNA genome into double-stranded proviral DNA, integration of the proviral DNA in the host genome, and expression of the viral genome from the chromosomal site of integration. The retroviruses have been of particular importance for several reasons. First, the small size of the retroviral genome and the small number of proteins expressed from the retroviral genome (a transforming retrovirus frequently encodes only one protein) has made them experimentally favorable for molecular analysis. Second, the proteins that produce neoplastic transformation are not required for the virus to complete its life cycle. Third, the retroviral transforming genes are mutated forms of normal cellular genes, giving their study direct relevance to nonviral forms of tumor formation.

Retroviruses can be divided into those that induce transformation acutely (in days to weeks) and form polyclonal tumors, and those that induce transformation over long periods of time (months) and form monoclonal or oligoclonal tumors. The distinction is important because the mechanism of tumorigenesis is fundamentally different in the two cases. Acutely transforming retroviruses consist of a mixture of replication-defective viruses that contain the transforming activity, and replication-competent nontransforming (helper) viruses that serve to propagate the transforming virus. The transforming virus in these cases often encodes only a single protein, and it is this protein that has the oncogenic activity. These transforming viruses are potent carcinogens, in the sense that the infection of a cell is sufficient to induce transformation with a very short latency. The transforming viral genes are transduced mutated copies of cellular genes, and the transforming proteins correspond to mutant versions of the corresponding cellular proteins. Structural and functional analyses of the viral and cellular forms of transforming proteins allow elucidation of the features that convert a normal cellular protein into an oncogenic one.

In contrast to the acutely transforming retroviruses, the retroviruses that induce tumors only after long latency have several important distinctions. They are replication-competent viruses that have not transduced cellular genes and so do not contain a transforming gene. Tumor formation by these viruses is often the result of the mutation of cellular genes during the integration process. Expression of cellular proto-oncogenes may be transcriptionally activated by the occasional nearby integration of retroviral promoter and enhancer elements, as in the case with c-*myc* activation by avian leukosis virus (ALV) and murine leukemia virus (MLV). As retroviruses integrate into a wide range of sites in the host DNA, only rare integration events will give rise to the activation of a protooncogene, explaining the long latency and the monoclonal nature of the tumors. In addition to being potentially tumorigenic, the juxtaposition of the retroviral transcriptional control signals with cellular protooncogenes may be of importance for a second reason. It is likely that production of a fusion virus–oncogene mRNA is the first step in the viral transduction event that results in the generation of an acutely transforming retrovirus through an aberrant viral recombination event.

Cell signaling

The ability of cells to respond to their external environment is mediated by the interaction of factors outside the cell (peptide and nonpeptide hormones and growth factors, cell matrix and other cells) with specific receptors located on the cell surface. These cell surface receptors contain at least two distinct functions. First, they contain a ligand-binding function which allows sensing of the presence or absence of the appropriate factor in the external environment,

and second, they contain or control some type of enzymatic activity that generates an intracellular change in response to the presence of the ligand. Often, this signal is in the form of reversible phosphorylation in response to ligand. The initial signal frequently generates a cascade of intracellular events, which include the generation of small molecule second messengers, such as cyclic nucleotides, calcium ions, and phospholipids, the activation of signals generated by the small GTP-binding proteins, and the activation of other protein kinases. Any long-lasting change in cell behavior, such as growth, requires new gene expression, and an important consequence of the signaling cascade is the activation of a set of transcription factors that directly influence the expression of genes required to alter cell behavior. Theoretically, it should be possible to generate mutant cells defective in the response to extracellular changes by alteration or mutation in any part of the signaling pathway, and the last ten years has witnessed the experimental confirmation of this idea. Thus, neoplastic transformation can be due to mutations in proteins that function as autocrine growth factors, growth factor receptors, membrane-bound and cytoplasmic components of the cell signaling apparatus, and transcription factors, all the normal activities of which are subject to control by changes in the external environment.

Growth factors and receptors

The simian sarcoma virus (SSV) contains a single open reading frame and encodes a single protein (v-Sis). This protein is a fusion protein between the retroviral *env* gene product and the product of a gene derived from the c-*sis* gene of the SSV host, the woolly monkey. The *env* sequences comprise little besides the signal sequence of the Env protein, and the remainder of the protein is the product of the transduced c-*sis* gene. Nucleotide sequence analysis has shown that c-*sis* is the platelet-derived growth factor (PDGF) B chain gene. The v-Sis protein is therefore a form of PDGF, a peptide mitogen for a number of cell types. That the v-*sis* gene product functions as an autocrine growth factor to induce transformation is supported by several lines of evidence. Transformation by v-Sis is limited to cells that express the PDGF receptor. The PDGF receptor is a protein tyrosine kinase the activity of which is dependent on the presence of ligand. In v-Sis-transformed cells, there is increased activity of the PDGF receptor and an increase in total cellular phosphotyrosine-containing proteins when compared to nontransformed cells. As both the v-Sis protein and the PDGF receptor are present in the endoplasmic reticulum, binding and activation of the receptor may occur at sites other than the cell surface. That this is the case is suggested by the observation that activated intracellular forms of the receptor can be found in v-Sis-transformed cells, but not in cells exposed to PDGF. Therefore, the v-*sis* gene product functions as an autocrine growth factor in susceptible cells.

A second class of oncogenic mutations predicted from the cell signaling model outlined above are mutations that separate activation of growth factor receptors from the binding of ligand. The first described example of such a mutation was the v-*erbB* gene of avian erythroblastosis virus (AEV). The v-*erbB* gene is a virally transduced mutant form of the cellular epidermal growth factor (EGF) receptor. AEV infection of chickens results in the rapid induction of erythroblastosis, and although AEV carries a second gene (v-*erbA*), expression of v-*erbB* is necessary and sufficient for the induction of erythroblastosis. The EGF receptor is typical of many growth factor receptors in its molecular architecture. It contains an extracellular domain involved in ligand (EGF) binding, a hydrophobic membrane-spanning domain, a cytoplasmic domain that contains protein tyrosine kinase activity and a C-terminal region involved in regulation of the kinase activity. Several observations suggest that the v-ErbB protein is a constitutively active form of the EGF receptor. In comparison to the EGF receptor, v-ErbB has suffered several structural changes. These include deletion of the extracellular ligand-binding domain and alterations of the C-terminal regulatory region. Molecular analysis has shown that both of these alterations are important for the transforming activity of the protein. Consistent with its proposed function, v-ErbB shows protein tyrosine kinase activity in the absence of EGF, and AEV-transformed cells show increased phosphotyrosine-containing proteins when compared to nontransformed cells. All mutations that impair the kinase activity of v-ErbB impair the transforming activity of the virus in a coordinate manner. Thus, the v-*erbB* oncogene product is a ligand-independent form of the EGF receptor.

Intracellular signal transduction molecules

A number of retroviral oncogenes have been identified that function as intracellular effectors of changes in the external environment. The v-Src protein of Rous sarcoma virus (RSV) is a cytoplasmic tyrosine kinase anchored to the inner surface of the plasma membrane by an N-terminal modification by myristic acid addition. The v-Src protein contains several mutations when compared to c-Src. Important among these is mutation of a C-terminal tyrosine in c-Src that serves as a negative regulator of the c-Src tyrosine

kinase activity. Although it is not known what the physiologic mechanisms are for activating c-Src tyrosine kinase activity, v-Src functions as a constitutively activated enzyme, and RSV-transformed cells contain increased amounts of phosphotyrosine-containing proteins. An additional important feature in the Src protein is the presence of regulatory sequences known as SH2 and SH3 domains. These domains were initially recognized as conserved motifs in other proteins, first in tyrosine kinases and then in other molecules, including the v-*crk* oncogene and a number of substrates for tyrosine kinase enzymes, such as phospholipase C, phosphatidylinositol 3′-kinase (PI3 kinase), and the *ras* GTPase-activating protein (GAP). The investigation of the v-*crk* oncogene has been particularly instructive. The transforming protein, v-Crk, is composed only of SH2 and SH3 sequences, without any tyrosine kinase catalytic domain. However, v-Crk-transformed cells contain elevated levels of phosphotyrosine-containing proteins. Investigation of this phenomenon has led to the realization that SH2 domains function as ligands for proteins containing phosphotyrosine. As all active tyrosine kinase enzymes are themselves phosphorylated on tyrosine, potential substrates may bind through their SH2 domains to the active phosphotyrosine-containing forms of the enzymes. This may be a way of controlling availability of substrates for these enzymes, and the presence of SH2 domains on the substrates of tyrosine kinases is likely to accelerate the identification of substrates, a process that until now has been frustratingly slow.

A second class of cytoplasmic signaling molecule that can be rendered oncogenic by mutation is the Ras family of proteins. Initially identified as v-Ras, the transforming proteins of Harvey murine sarcoma virus (Ha MuSV), the Ras proteins have been conserved as essential functions from yeast to man, with very little sequence variation. The Ras proteins are small GTP-binding proteins with GTP-hydrolyzing activity. The GTPase activity is essentially a way to control the signaling activity, as only the GTP-bound form is active. Recent genetic and biochemical evidence suggests that at least one function of Ras proteins is to mediate the signals generated by protein tyrosine kinases. In contrast to the normal cellular form of Ras, the oncogenic v-Ras contains two point mutations that impair the GTPase activity and so trap the molecule in an 'on' or signal-generating state. Unfortunately, the nature of the signals generated by active Ras remains elusive.

Studies of the regulation of Ras GTPase activity have revealed a second mechanism of oncogenic activation through the Ras signaling pathway. The intrinsic GTPase activity of Ras proteins is augmented by GTPase-activating proteins, or GAPs. The GAP molecules increase the hydrolysis of GTP, and so convert active Ras to inactive Ras. An important observation has been the realization that the gene that confers predisposition to neurofibromatosis (NF1), an inherited form of cancer, encodes a GAP. Inactivating mutations in NF1 GAP are associated with a decrease in GAP activity, a consequent increase in the amount of Ras protein in the active (GTP-bound) state and the formation of tumors.

Cell signaling through transcription factors

The generation of second messengers and cytoplasmic signals by external factors eventually results in changes in gene expression. Several retroviral oncogenes are transduced forms of cellular transcription factors involved in regulating the response to external factors. The transcription factor AP1 is a heterodimeric transcription factor with sequence-specific DNA-binding activity composed of peptides derived from the Fos and Jun families of proteins. The *fos* family of genes was identified as the cellular homologues of v-*fos*, the transforming gene of FBJ MuSV, while the *jun* family was identified by homology to v-*jun*, the transforming gene of avian sarcoma virus (ASV) 17. AP1 activity is tightly regulated, and is rapidly and transiently induced by a wide variety of mitogens, including the peptide mitogens PDGF and EGF. The induction of AP1 activity requires *de novo* protein synthesis, and is a consequence of the early induction of the *fos* and *jun* genes in response to mitogens. Several lines of evidence suggest that transformation by v-Fos is due to overexpression of AP1 activity. Overexpression of either c-Fos or v-Fos protein is sufficient to result in neoplastic transformation, and mutant proteins that are unable to bind AP1 target DNA sequences are nontransforming. Cells transformed by Fos protein show increased levels of AP1 activity compared to nontransformed cells, consistent with the idea that transformation is the result of activation of a specific set of genes that contain AP1 regulatory sequences in their upstream regions. The identification of the relevant genes the activation of which is important for transformation has proven to be difficult.

A somewhat different situation is represented by the transforming gene, v-*rel*, of the reticuloendotheliosis virus (REV-T). The Rel family of proteins constitute a large family of proteins with NF-KB activity. NF-KB is a transcription factor that is involved in the response of lymphoid cells to a variety of external stimuli. NF-KB activity is regulated by a number of complex mechanisms, but an important form of regulation appears to be retention in the

cytoplasm through its interaction with specific inhibitor proteins. External stimuli then result in the dissociation of the inhibitor and allows translocation of NF-KB to the cytoplasm. An usual feature of transformation by v-Rel is that mutant v-Rel proteins that are localized in the cytoplasm can induce transformation. This suggests that direct transcriptional activation by v-Rel is not the mechanism of neoplastic transformation, and suggests that v-*rel* may function as a dominant negative allele of c-*rel*, and this idea has received some experimental support. According to this model, NF-KB activity would function to promote cellular differentiation and inhibit cell growth, and oncogenesis would be the consequence of decreasing NF-KB activity.

Oncogene cooperation

Spontaneously occurring tumors are recognized to be the result of a multistage process in which multiple mutations arising at different times conspire to produce a tumor. On the other hand, neoplastic transformation due to infection with the acutely transforming retroviruses usually occurs as the result of the introduction of a single gene. Yet even the acutely transforming retroviruses contain examples of cooperativity among oncogenes. AEV contains two genes, v-*erbA*, a transduced mutant form of the thyroid hormone receptor gene, and v-*erbB*, a constitutively active form of the EGF receptor gene. Although v-*erbB* is sufficient to direct neoplastic growth of infected erythroid cells, the expression of v-*erbA* is required for growth of the erythroid cells under some culture conditions. Thus, the fully transformed phenotype is the product of a cooperative interaction between the two genes. This theme of cooperation between various oncogenic proteins has been extensively documented in the process of neoplastic transformation of primary cells.

Transformation by human retroviruses

Retroviruses may acquire transforming activity by transduction of cellular proto-oncogenes, they may activate cellular proto-oncogenes by insertional mutagenesis, or they may transform through the action of regulatory genes required for the viral life cycle to proceed. The causative agent of acute T-cell leukemia, human T-cell leukemia virus (HTLV-1), appears to operate through the last type of mechanism. The viral gene *tax* is a regulator of transcription from the viral long terminal repeat, as well as from certain cellular promoters. Interestingly, Tax activates both the interleukin 2 (IL-2) promoter and the IL-2 receptor promoter, generating a loop with potential autocrine activity in T cells. The mechanism of Tax activation of transcription remains unclear. It is able to activate transcription directed by NF-KB and cyclic AMP-responsive sites, although there is no evidence that Tax itself binds DNA. The mechanism of transformation induced by HTLV-1 is likewise unclear; the tumors arise only after a long latency, sometimes 20 years, and are monoclonal.

DNA Tumor Viruses

Several classes of DNA viruses are able to induce neoplastic transformation in culture. In contrast to the situation with transforming retroviruses, in which transformation is the result of the activation of a gene that is not required for the completion of the viral life cycle, transformation by DNA viruses is the result of expression of proteins intimately involved in the replication of the viral genome.

Simian virus 40 (SV40)

Transformation by SV40 is associated with nonproductive infection and is the result of the expression of a single viral protein, the SV40 large T antigen (T Ag). In contrast to productively infected cells in which the SV40 genome is episomal, in transformed cells the viral genome is integrated into the host DNA in a manner which allows for expression of T Ag. T Ag is a multifunctional protein that forms noncovalent interactions with a number of cellular proteins. Key among these are the products of the cellular tumor suppressor genes p53 and Rb. Oncogenic activation of the p53 and Rb genes is associated with loss, rather than gain of function. p53 was initially identified as a protein stably associated with T Ag in transformed cells. The normally rapid turnover of p53 in uninfected cells is greatly reduced by virtue of complex-formation with T Ag, giving rise to increased levels of the protein in transformed cells. The net result of this interaction is not to increase p53 function, however, but rather to sequester it in an inactive complex. The protein product of the retinoblastoma susceptibility gene, pRb, is also noncovalently associated with T Ag, and this complex results in loss of pRb function. Transformation by T Ag has therefore served as the mechanism of identification of one tumor suppressor gene (p53), and has been the entry point for biochemical investigation of another (pRb).

Adenovirus

Transformation by the human adenoviruses has been observed only *in vitro*. As is the case with transformation by SV40, transformation by adenovirus is the result of a nonproductive infection. DNA transfection experiments reveal that the expression of two different viral genes, E1a and E1b, is required for full

transformation. E1a is a multifunctional protein with a bewildering array of activities. The important feature for transformation appears to be the ability to interact with pRB. Expression of the E1a gene alone is sufficient for immortalization of primary cells, but not for full transformation, which requires expression of the E1b gene. The product of the E1b gene is complexed physically with p53. Thus, the combined activities of E1a and E1b are reminiscent of the activities of SV40 T Ag.

Human papilloma virus

Investigation of the transforming activities of the human papillomaviruses (HPV) is of interest for reasons of medical importance as well as scientific interest. Nearly all human cervical carcinomas are associated with the presence of DNA from either HPV 16 or HPV 18. Completion of the life cycle of the HPVs is unusual in that the early and late stages of the life cycle appear to take place in different stages of epithelial cell differentiation, and complete viral replication takes place only in benign papillomas, or warts. This feature has so far made it impossible to grow the HPVs in culture, a problem that has slowed analysis. However, molecular analysis has been informative. Cervical carcinomas are associated with the presence of the viral genome integrated into the host DNA in a manner that allows for expression of the early region of the viral genome. This region is quite complex, with at least eight open reading frames; there is evidence that at least five are involved in generating the transformed phenotype. In a scenario reminiscent of adenovirus, the products of the E6 and E7 open reading frames are physically associated with p53 and pRB respectively. These interactions result in the functional inactivation of p53 by accelerated proteolysis, and pRb by sequestration.

Hepatitis B virus

The hepadnaviruses should be mentioned because of their potential role in human cancers. The hepatitis B virus, especially when acquired by vertical transmission, is associated with the development of hepatocellular carcinoma. At this point, there is no decisive evidence that this association is causal, but strong circumstantial data are present. Experimental evidence suggests two potential mechanisms: activation of cellular oncogenes by integration in a manner similar to insertional mutagenesis by retroviruses, and repetititive mitogenic stimulation due to the toxic effects of chronic exposure to the surface antigen proteins.

Epstein–Barr virus

Nonproductive infection with Epstein–Barr virus (EBV) is associated with Burkitt's lymphoma, a malignancy of B lymphocytes. Once again, there is no decisive evidence for a causal role, but the ability of the virus to immortalize human B lymphocytes suggests a potential mechanism. Infection with EBV may result in the generation of a large pool of preneoplastic cells that are predisposed to further oncogenic mutations.

Future Perspectives

Much of what we understand about the molecular mechanisms of cancer is the result of investigation of virus-induced tumors. This area of investigation has demonstrated, clearly and convincingly, that cancer is a disease caused by mutations in specific genes. We have learned the identity of many of these genes, whether they are carried by the virus, activated by viral insertion, or inactivated by the physical association of their products with viral proteins. The products of these genes form a network of signaling elements that allows cells to respond to the external environment. Where understood, oncogenic mutations result in the production of proteins that propagate mitogenic signals in the absence of appropriate monitoring of the extracellular environment, a result consistent with the proposed normal functions of these proteins. Although many oncogenes were initially identified by virtue of their presence in viral genomes, it is now clear that these genes are also the targets of oncogenic mutations in tumors of nonviral origin. It seems certain that future investigations of virus-induced transformation will further contribute to our understanding of cancer, an understanding that does not appear to be as elusive as a decade ago.

TRANSPLANTATION AND VIRUS INFECTIONS

Robert A Krance, **Helen E Heslop** and **Malcolm K Brenner**, Stem Cell Transplantation Program, Shell Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, Texas, USA

Introduction

Organ transplantation is being used to correct an ever broader range of medical abnormalities. In large part the expanding application and success of transplantation has been based on improved methods of producing immunosuppression in the recipient, which allow acceptance of a genetically disparate graft. This is particularly true following bone marrow transplantation (BMT), where immunosuppression must be especially profound, since the aim is not only to prevent rejection of the graft by the host but to prevent the incoming immune system from 'rejecting' the recipient to produce graft-versus-host disease (GVHD).

Unfortunately, the immunosuppression required by transplant recipients has a number of adverse consequences. Among the most important of these is the suppression of host immune responses directed against endogenous and exogenous microorganisms. Suppression of immune surveillance allows invasion by opportunist fungi and by protozoa and permits recrudescence of those endogenous viruses which are usually maintained in the latent state. Immunosuppression may also increase the severity of infection after exposure to exogenous viruses. All transplant recipients are vulnerable to virus infections, but bone marrow transplant recipients who are the most intensely immunosuppressed, are the most vulnerable of all. Notwithstanding, the introduction of a number of different therapeutic agents, viral disease remains one of the leading causes of morbidity and mortality after transplantation.

Herpesviruses

The herpes viruses, *Cytomegalovirus*, Epstein–Barr virus, herpes simplex and varicella/zoster represent the greatest potential threat to transplant recipients. All four are present in the latent state in a high proportion of individuals, and all four can cause serious or fatal disease in the immunocompromised host.

Cytomegalovirus (CMV)

Background In a normal individual, defense against CMV is mediated by specific cytotoxic T lymphocytes, by production of specific antibody and perhaps also by MHC unrestricted cellular effector mechanisms. In the transplant recipient, immunosuppression-mediated impairment of these defense mechanisms places the recipient at risk of CMV disease. Depending on location and socioeconomic status, 40–90% of transplant recipients have a past history of primary CMV infection and are at risk of viral reactivation. The remaining seronegative recipients are at risk of acquiring primary infection, either from the donor tissue or from blood products required during the post-transplant period. CMV reactivation or infection does not always lead to CMV disease in the transplant recipient and it is important to distinguish between these phenomena.

Although detection of CMV is not always predictive of disease, there may be a high probability that disease will subsequently occur in patients receiving intensive immunosuppression. Following solid organ grafts, the risk of CMV disease rises with the intensity of the immunosuppression administered and is especially increased by the use of monoclonal anti-T cell antibodies, such as OKT3. Bone marrow recipients who have had their own immune system ablated as part of the conditioning regimen and who have not yet regenerated a donor-derived system are particularly likely to develop CMV disease.

Incidence of CMV infection/reactivation and CMV disease *From blood product support* The risk of a seronegative recipient of seronegative donor tissue acquiring CMV infection from blood product support was previously significant, but the incidence of this mode of transmission has been substantially reduced by the use of CMV seronegative or, more commonly, leukocyte poor blood products and is now less than 5%.

From solid organ grafts Seropositive recipients have a 50–80% chance of developing evidence of viral reactivation, and 10–25% of these individuals will develop evidence of CMV disease. The donor organ is also a source of infection and 50–100% of seronegative recipients will develop infection if they receive a

transplant from a seropositive donor. Disease occurs in up to one-half of such patients.

From BMT About 50–60% of both allograft and autograft recipients who are seropositive or have a seropositive donor will have evidence of either primary infection or reactivation, with a peak incidence in the first three months post-transplant. Patients receiving autologous marrow have a low incidence of disease with less than 5% of seropositive recipients developing pneumonitis. By contrast, half of the allograft recipients who develop a primary infection or reactivation will, in the absence of treatment, develop pneumonitis which is fatal in 80–90%. The presence of moderate to severe graft-versus-host disease markedly increases the risk of CMV disease, especially pneumonitis and some studies have shown a reduced incidence of CMV in allograft recipients who receive more effective graft-versus-host disease prophylaxis.

Pathogenesis CMV initially infects a variety of cells including fibroblasts, marrow stromal cells and hemopoietic progenitors. The mechanism of latency is not well understood, but reactivation results in viral shedding. In some situations, such as in AIDS patients, viral replication alone results in disease, but in the transplant patient an immunopathological component is implicated, and both host-versus-graft and graft-versus-host reactions correlate with CMV disease. For example, a host-versus-graft relationship is seen in recipients of liver transplants, who are particularly likely to develop CMV hepatitis. In allogeneic bone marrow transplant recipients, there is evidence that damage to the lungs in CMV pneumonitis results from an abnormal response to antigen, and that this is exacerbated by graft-versus-host disease. The activated immune system may also damage or destroy uninfected 'bystander cells', since antiviral agents which eliminate viral shedding and prevent antigen expression have limited effect on disease progression (see below under Treatment).

Diagnosis CMV infection may be diagnosed either by serological means or by direct isolation of the virus or its DNA. The virus is generally cultured from blood, throat, urine or tissues. CMV is cultured on human fibroblasts and it usually takes 1–4 weeks for the characteristic cytopathic effect to become evident. The use of monoclonal antibodies directed at early or intermediate antigens in conjunction with centrifugation of the specimen on to monolayers of fibroblasts – the shell vial technique – allows diagnosis within 24–48 h. The presence of the virus can be diagnosed even more rapidly by the use of the polymerase chain reaction (PCR) to amplify CMV DNA and RNA, but how accurately detection of viral infection/reaction by such sensitive methodology predicts subsequent CMV disease remains in dispute.

Serological evidence of infection is usually obtained using ELISAs or indirect fluorescence. Diagnosis requires a fourfold rise in titer and may be problematic after BMT when patients are so severely immunocompromised that antibody production is impaired.

Clinical aspects CMV infection in the immunosuppressed host ranges from an asymptomatic illness similar to that in normal individuals to disseminated disease. However, there is a higher incidence of diffuse organ involvement which may present with a variety of clinical manifestations including hepatitis, enteritis, pneumonitis, fever and bone marrow suppression. Disease presentation may also vary according to the organ transplanted. In recipients of renal transplants, pneumonitis is rare and patients are more likely to present with mononucleosis-like symptoms or hepatitis. Recipients of lung, heart or liver transplant have a higher risk of more severe CMV infections such as pneumonitis. Liver transplant recipients are particularly at risk of CMV hepatitis which is more common after primary infection and may be difficult to distinguish from rejection. Finally, following allogeneic bone marrow transplantation, pneumonitis is the most common presentation of CMV disease and will occur in 40–50% of recipients with evidence of infection on blood culture. Pneumonitis presents with fever, cough dyspnea and chest radiograph shows an interstitial pattern. About 80–90% of BMT recipients who develop CMV pneumonitis will die of this complication.

Treatment A number of measures have been used to treat established CMV disease. All are of most benefit after solid organ grafting, and of least value after BMT. Interferon has antiviral activity and may reduce morbidity in renal transplant recipients, but has little effect in BMT patients. Similarly, acyclovir and gancyclovir may reduce viral shedding and may be effective in CMV disease in solid organ recipients, but given alone they do not significantly modify morbidity and mortality from CMV disease in allogeneic BMT recipients.

Intravenous immunoglobulin (IVIg) as a single agent is also ineffective in most studies. However, the combined use of gancyclovir and IVIg in allogeneic BMT recipients with CMV pneumonitis results in disease resolution in around 50–70%. This response rate appears significantly better than the 10% response rate of historical controls, though no

Table 1 Effect of prophylaxis in preventing CMV reactivation/disease

	Effect on		
Prophylactic regimen	*Reactivation/Infection*	*Disease*	*Mortality*
CMV-negative blood products	+	+	+
Acyclovir (low dose)	+/−	+/−	−
Acyclovir (high dose)	+	+	+/−
Gancyclovir	− (see text)	+	+
Intravenous immunoglobulin	−	+	+/−

randomized trials have been performed and the improved survival may in part reflect changes in diagnostic criteria and techniques. Indeed, subsequent studies where the drug combination was administered to patients who were ventilated yielded lower response rates.

Prophylaxis (Table 1) The most effective preventative measure is to use CMV-negative blood products for seronegative recipients who receive seronegative organ grafts. Several studies have convincingly shown that this policy can almost completely eliminate CMV disease. Seronegative recipients of seropositive allogeneic marrow also benefit from seronegative blood products. It has been suggested that seropositive recipients should also receive CMV-negative products to reduce exposure to new strains. In practice most blood banks do not have enough CMV-negative products to supply all these populations and leukocyte-poor products – prepared by filtration of blood – are used instead. It appears that leukocyte-poor products are just as effective – at least in low risk patients.

Antiviral agents have also been explored as prophylactic agents. Acyclovir in renal transplant recipients reduces the rate of CMV infection and disease but did not improve survival. Neither α-interferon nor low-does acyclovir have any convincing effect in BMT recipients. Some studies suggest that acyclovir may reduce the incidence of both CMV infection and invasive disease, but these results are not confirmed in other studies. Gancyclovir effectively reduces the incidence of CMV disease in allograft recipients with CMV infection detected by shell viral technique or by PCR, and more recent studies using prophylactic or pre-emptive gancyclovir have shown that the drug may be used to prevent viral reactivation. Unfortunately, resistant strains of CMV are now beginning to be detected, and CMV disease may also occur once gancyclovir prophylaxis has been stopped. Foscarnet may be an acceptable, non-cross-resistant, substitute for gancyclovir, although the relative efficacy of this drug in BMT patients remains uncertain.

IVIg administered after BMT, resulting in passive transfer of specific antibody, does not reduce the rate of viral reactivation or infection but does decrease the incidence of pneumonia and death. Such treatment may therefore be justified in seropositive recipients. The expense of IVIg does not appear to be justified in seronegative recipients receiving seronegative blood products, in whom risk of CMV infection and disease is negligible. Similarly, in seronegative renal recipients receiving a seropositive graft, IVIg reduces the incidence of CMV disease though not the rate of viral isolation or seroconversion. Neutralizing human monoclonal antibodies are currently being evaluated in phase III trials.

Immunomodulation Several studies have correlated the pattern of CMV infection in allogeneic BMT recipients with the ability to generate CMV specific $CD8^+$ cytotoxic T lymphocytes, which may allow the host to control CMV infection. These observations suggested that adoptive transfer of specific cytotoxic T lymphocytes (CTLs) (expanded *in vitro*) to high risk patients may allow long term protection from overt disease, without the risk of developing chemoresistant strains of virus. Initial studies of this approach have produced promising results.

Epstein–Barr virus (EBV)

Background Even though more than 90% of adults have serological evidence of EBV infection, disease produced by reactivation of this herpesvirus has, until recently, been less prevalent in transplant recipients than disease produced by CMV. However, the development of more aggressive and effective techniques for immunosuppression has not only increased the success of tissue transplantation, but has also substantially increased the incidence of the lymphoproliferative syndrome associated with uncontrolled EBV reactivation in the immunocompromised host.

This complication is particularly common in patients receiving mismatched or unrelated donor BMT, in seronegative neonatal recipients of seropositive liver and in patients receiving small bowel transplants.

Incidence Following solid organ grafting, up to 60% of patients may show evidence of EBV reactivation or infection, assessed on the basis of rising antibody titers to viral proteins. Less than one-third of these patients will develop the clinical features of a viral illness. The incidence of lymphoproliferative syndrome is between 1 and 13%, and is lowest in patients receiving renal allografts and highest in those receiving heart–lung double transplants. Within each group, patients receiving the most intensive immunosuppression, with CSA, antilymphocyte globulin or anti-T cell monoclonal antibody (e.g. OKT3), have the highest incidence.

After BMT the incidence is even more variable. At one extreme, adult patients receiving major histocompatibility complex (MHC) identical sibling allografts as treatment for leukemia have an incidence of 0.25%. At the other extreme, children transplanted for congenital immunodeficiency syndromes who receive marrow from an MHC nonidentical or unrelated donor have a 100-fold greater incidence of lymphoproliferative disease, which occurs in up to 25% of such recipients. This wide variation is in part attributable to the increased immunosuppression required by recipients of mismatched/unrelated marrow, but probably also reflects the long delay in immune reconstitution exhibited by patients receiving a genetically disparate immune system. Because the numbers of mismatched/unrelated donor BMT are steadily rising, some recent BMT series show that death from EBV-induced lymphoproliferation now exceeds that from CMV disease.

Pathogenesis and diagnosis The primary pathologic process is uncontrolled proliferation of mature B lymphocytes. Analysis of proliferating lymphoblasts following solid organ transplant using restriction fragment length polymorphisms (RFLPs) or minisatellite probes, has shown that EBV lymphoproliferation in these patients almost always arises from recipient B cells. In contrast, lymphoproliferation after BMT commonly arises from cells of donor origin. In all cases, the transformed B cells closely resemble morphologically and phenotypically, the lymphoblastoid cell lines generated *in vitro* when human B cells are exposed to EBV in the absence of T cells. The infected lymphocytes may have an immunoblastic or plasmacytoid appearance and are usually CD19, CD20, CD21 and CD24 positive (see below under Treatment). Like Burkitt lymphoma cells, the lymphoblasts are positive for EBV nuclear antigens 1 (EBNA1) but unlike Burkitt lymphoma cells they usually express all of the five other virus-encoded latent cycle nuclear antigens and are positive for most latent membrane proteins. Again in contrast to Burkitt lymphoma cells, lymphoblasts in transplant patients express a number of cell adhesion molecules and ligands. All these phenotypic features would make them intensely vulnerable to cytotoxic T cell killing in a normal individual, and it is only the profound suppression of the immune system after transplantation which permits their outgrowth.

The B cell proliferation may be oligoclonal or monoclonal, and may be associated with production of oligoclonal or monoclonal peaks of immunoglobulin which can be detected by serum electrophoresis. Within the B cells, the virus may be present in linear (replicative) or circular (latent) form. Analysis of these attributes may predict the response to therapy.

Clinical manifestations Early in the illness, fever, malaise and circulating atypical lymphocytes are usually seen. The proliferating lymphoblasts may then produce a number of disease patterns. They may diffusely infiltrate a number of different organ systems, including lungs, liver, kidney, gut, bone marrow and central nervous system. Infiltration may be so extensive that organ failure results. Alternatively, a classical 'lymphoma' pattern is observed, with lymphadenopathy, hepatosplenomegaly, and a biopsy appearance of a diffuse immunoblastic lymphoma. Rarely, a predominantly leukemic picture occurs. Although these distinctive clinical patterns may be seen in isolation, a combination of features often evolves (**Fig. 1**).

Clinical course Initial reactivation of EBV, associated with an 'infectious mononucleosis'-like illness, may resolve spontaneously. But once viral induced-lymphoprolipherative syndrome (LPS) has occurred, the course is generally rapidly progressive. Death may result from renal, hepatic or pulmonary failure, from hemorrhage due to ulceration of bowel tumor, or from central nervous system (CNS) involvement.

Treatment Withdrawal of immunosuppression is associated with spontaneous remission of the tumors in up to 50% of recipients of solid organ grafts; regression is more likely to occur in oligoclonal then in monoclonal tumors. Withdrawal of immunosuppression alone is rarely effective when the LPS has occurred after BMT.

Acyclovir may disrupt the replicative lytic cycle of the (linear) virus and interferon may prevent infection of fresh lymphocytes, but neither approach can signi-

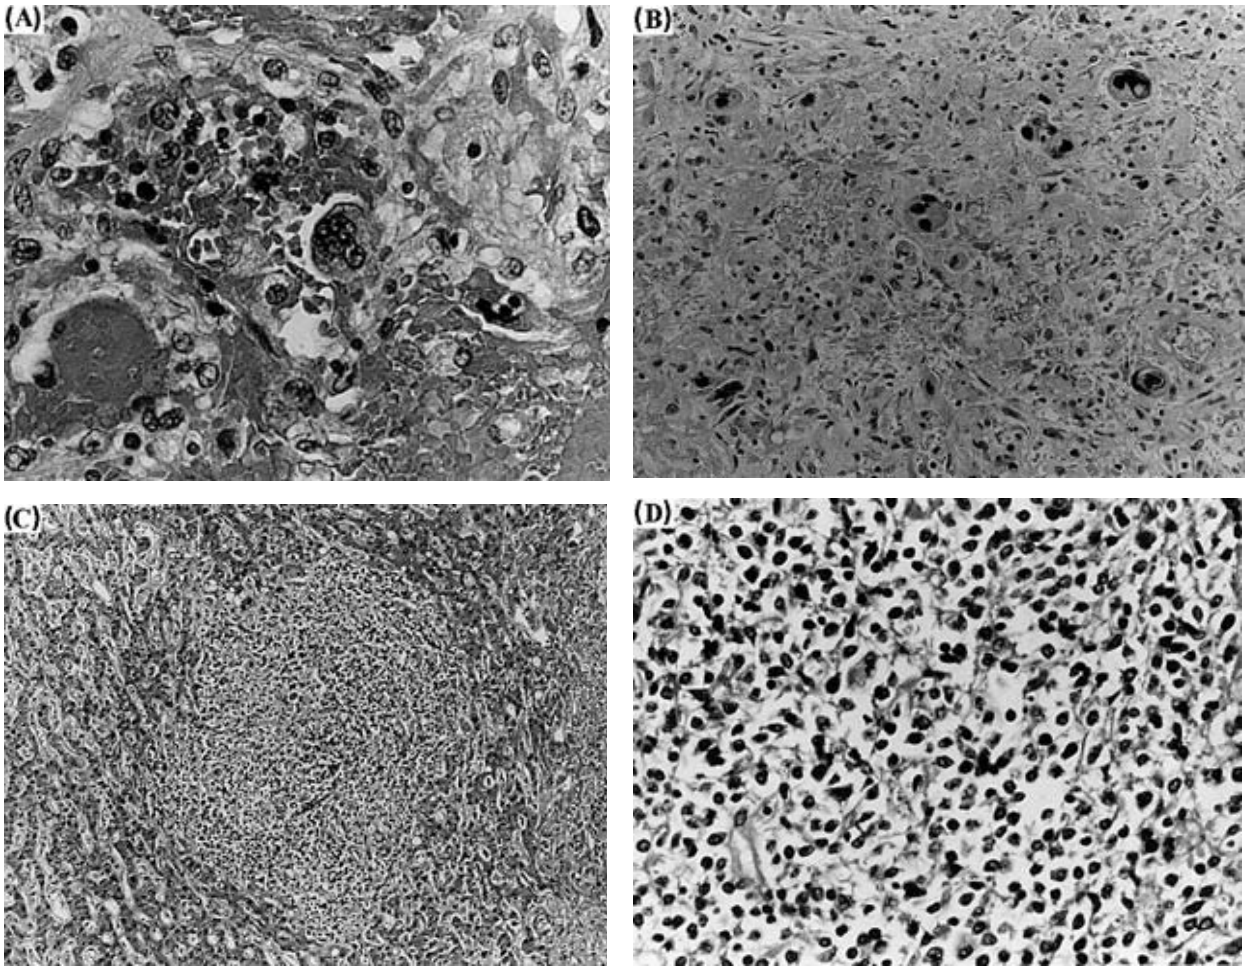

Figure 1 (**A**) Section of lung, infected with CMV, containing intraalveolar hemorrhage and multinucleated giant cell. This is a histologically atypical infection producing only scattered cells with relatively small intranuclear and intracytoplasmic inclusions and no large cells with 'owls-eye' nuclei (hematoxylin and eosin stain; ×315). (**B**) Same infection as in (A) demonstrating numerous cells positive for CMV antigen using monoclonal antibody and immunoperoxidase technique (avidin–biotin complex technique; ×315). (**C**) (EBV low power) Section of liver with lymphoid infiltrate (EBV infection) causing portal expansion (hematoxylin and eosin stain; ×80). (**D**) Same infection as in (C). The portal infiltrate is polymorphous and contains cells ranging from small mature lymphocytes to larger immunoblasts (hematoxylin and eosin stain; ×315).

ficantly modify the growth of already transformed B cells which contain nonreplicating (circular) virus. Nonetheless, remissions have been reported in response to both drugs, although these are more likely in recipients of solid organ grafts and if the tumor is oligoclonal. More recent reports suggest that infusion of monoclonal antibodies to CD21 and CD24 – molecules present on lymphoblasts – may rid the patient of infected B lymphocytes. As with other treatments, this approach seems most effective in solid organ recipients with oligoclonal LPS.

At present the most satisfactory approach to prophylaxis and treatment in BMT recipients is to attempt to restore immunocompetence to EBV by the adoptive transfer of immune T cells. The majority of individuals are EBV seropositive, and between 1 in 1000 and 1 in 10 000 of their circulating CTLS are EBV specific. Transfer of marrow donor T cells therefore regularly produces disease response in patients with uncontrolled lymphoproliferation. Unfortunately, because donor T cells also contain significant numbers of alloreactive CTLs, response may be associated with the development of severe graft-versus-host disease. More recently, it has proved possible successfully to prevent and treat EBV disease by transferring virus-specific CTLs, without the development of graft-versus-host-disease. Alternative approaches have used bulk T cell populations genetically modified to include a thymidine kinase suicide gene. Should graft-versus-host disease develop, these modified cells may be destroyed by administration of gancyclovir.

Finally, the development of mouse models in which proliferating human lymphoblasts can be studied may help in the development and assessment of novel therapeutic strategies.

Varicella Zoster virus

Incidence Reactivation of herpes zoster virus (VZV) infection occurs in 5–25% of solid organ transplant recipients and in as many as 50% of bone marrow transplant patients. Primary infection develops only rarely, and usually in children.

Epidemiology and pathogenesis Like other herpesviruses, the probability of VZV reactivation is increased when cell-mediated immunity is compromised. In solid organ transplant recipients, the eruption of clinical shingles often follows the initiation or increase of medications to prevent graft rejection. The risk of VZV reaction in bone marrow transplant patients is even greater because the attendant immune deficiency is more severe and prolonged than that of solid organ transplant patients. Unlike herpes simplex virus (HSV) reactivation where patients with high HSV antibody titer are more likely to develop reactivation, pretransplant VZV antibody titer does not predict post-transplant infection.

Although VZV infection may develop in the first weeks after transplantation, the median time to reactivation is four to five months for patients not receiving prophylactic acyclovir. Late graft rejection requiring aggressive immunosuppressive measures is frequently accompanied by VZV reactivation in solid organ transplant patients. In allogenic bone marrow transplantation, VZV infection may be more common in patients with graft-versus-host disease, whereas for autologous transplantation VZV infection is more common in patients with Hodgkin's disease or non-Hodgkin's lymphoma.

Manifestations and treatment Classical cutaneous herpes zoster (shingles) is the most common manifestation of VZV infection among transplant patients. Depending on the dermatome affected, VZV reactivation may cause post-herpetic neuralgia, cutaneous scarring or corneal opacification. Solid organ transplant recipients rarely develop disseminated or invasive VZV infection.

In bone marrow transplant patients, VZV infection may present as typical dermatomal herpes zoster, as herpes zoster with cutaneous dissemination, or even as varicella. Serology in these patients indicates past VZV infection. Prior to the availability of acyclovir, cutaneous zoster infection progressed to invasive disease in up 50% of patients, and 10% died. The consequences of visceral dissemination included hepatitis, pancreatitis, and encephalitis; however, VZV pneumonia was the usual cause of death.

Intravenous acyclovir is the most effective and least toxic therapy for VZV infection in transplant patients. In bone marrow transplant patients, prophylactic administration of acyclovir can prevent VZV reactivation, but reactivation is common upon discontinuing the drug. Consequently, prophylactic administration of acyclovir to prevent VZV infection is not recommended. Vidarabine and α-interferon are effective against VZV infections but they are secondary treatments since they are more toxic and less efficacious. Their use is limited to situations when VZV resistance to acyclovir is suspected.

In those patients without prior VZV infection, varicella zoster immune globulin administered within 72 h of VZV exposure may prevent or modify illness. Varicella vaccine is a promising therapy for children who may require transplantation but have not yet acquired their primary immunity.

Herpes Simplex virus

Incidence Reactivation of latent herpes simplex virus (HSV) infection has occurred in 30–90% of seropositive transplant patients. The majority have suffered a mild, usually self-limited illness, with fever accompanied by lesions of the oral or genital mucosa. However, in patients undergoing bone marrow transplant HSV disease has been more severe.

Epidemiology and pathogenesis Less than 5% of HSV illness following transplantation has been due to primary HSV infection. There are two possible sources of primary HSV exposure: intimate contact with an individual shedding HSV or transfer of HSV through the transplanted organ. Transfer of HSV by liver, pancreas, heart and kidney transplantation has been documented. Presumably, the virus, latent in neural tissue within the organ, became reactivated and initiated primary HSV illness in the host.

Between 30% and 100% of adults are HSV seropositive, and 15–30% of these experience recurrent vesicular eruptions. Although the events leading to HSV reactivation are incompletely understood, the combination of high prevalence of HSV seropositivity and iatrogenic immunosuppression have undoubtedly promoted HSV illness among transplant patients. Interestingly, a high antibody titer to HSV pretransplant has been linked to a high risk of viral reactivation.

Clinical manifestations and treatment The incidence of HSV infection peaks during the first weeks after transplantation when cell-mediated immunity is

most suppressed. The classic perioral vesicular eruption is the typical manifestation of HSV infection in solid organ transplant recipients. Genital HSV infection is also common. In bone marrow transplant patients, the diagnosis of HSV infection may be problematic because the classic lesions are often superimposed on mucositis caused by the pretransplant chemotherapy and/or radiotherapy.

Visceral dissemination of HSV has been rare following kidney and liver transplantation, more frequent following heart, lung and heart–lung transplantation, and most common following bone marrow transplantation. Manifestations of visceral dissemination include esophagitis, pneumonia, hepatitis and encephalitis; HSV esophagitis and pneumonia are thought to develop from contiguous spread of oral/perioral disease. HSV has been isolated from 5% of bone marrow transplant patients with pneumonia. Often a co-isolate with cytomegalovirus (CMV), the role of HSV in the pathogenesis of pneumonia is unclear.

The incidence of hepatitis or encephalitis due to HSV has been less than 0.5%. Unlike HSV pneumonia or esophagitis, the onset of hepatitis has not always followed oral/perioral lesions. In the first weeks after liver transplantation, immediate liver biopsy is recommended for patients who develop hepatic dysfunction, since prompt initiation of acyclovir has arrested the progression of HSV hepatitis to fulminant and usually fatal liver failure.

Treatment Acyclovir is the principal treatment for HSV infection. It is effective for prophylaxis as well as treatment of established infection. Because the likelihood of disseminated HSV disease is enhanced by immunosuppression, acyclovir prophylaxis may be used routinely in seropositive recipients of bone marrow transplantation, although gancyclovir (given primarily for prophylaxis of CMV as described above) may be substituted. In solid organ transplantation, where immunosuppression is neither as intense nor as prolonged, opinion is divided on the necessity for prophylaxis. If prophylaxis is used, HSV reactivation often occurs once acyclovir is discontinued. In addition, approximately 10% of patients develop HSV reactivation even while receiving prophylaxis.

Disconcerting reports of acyclovir-resistant HSV, particularly among human immunodeficiency virus (HIV)-infected patients, have been confirmed. Vidarabine and foscarnet, an investigational agent, may be effective alternatives.

Other Herpesviruses

In the last few years several new herpesviruses, HHV-6, HHV-7 and HHV-8, have been identified. Only HHV-6 has so far been recognized as a pathogen in transplant patients. HHV-6 is an endemic virus with over 90% of healthy adults seropositive. It infects CD4 cells and therefore also predisposes to the reactivation of other viruses. Infection occurs in 30–60% of transplant recipients usually in the early post-transplant period. Many patients are asymptomatic and marrow suppression, pneumonitis and encephalitis are the most common disease manifestations. The antiviral susceptibility of HHV-6 is similar to CMV and the organism is sensitive to foscarnet and gancyclovir.

Hepatitis Viruses

Hepatitis A virus or hepatitis delta and epsilon viruses have been uncommon sources of hepatitis in transplant patients. In contrast, infections with hepatitis B virus (HBV) or hepatitis C virus (HCV) have been frequent. Transplant patients may be more susceptible to the complications of HBV and HCV infection, but the uncertainty regarding epidemiology and pathogenesis of these infections complicates decisions regarding the suitability of patients with hepatitis for transplant.

There have been many impediments to an understanding of the consequence of hepatitis. Until the recent development of the anti-HCV assay, the course of patients with HCV infection could not be distinguished from the course of patients with other hepatic abnormalities. Even though patients with HCV can now be identified, the current assay is insensitive. Meanwhile, assays for HBV infection, long considered sensitive and specific, do not adequately detail the potential for HBV reactivation and infectivity. Thus, the outcome of patients previously infected with HBV or HCV and reexposed to one or both of these viruses during transplantation is presently hard to predict on an individual basis, although it is evident that their overall risk of continued and progressive liver dysfunction is increased fourfold or more over uninfected patients. Transplant patients may also have serologic evidence of infection by both viruses and distinguishing the active agent by serologic assays is difficult. Finally, liver dysfunction in the post-transplant patient is a common event and other sources of hepatic injury are often present concurrently.

Incidence

The incidence of hepatitis B surface antigen (HBsAg) positivity varies widely. In Taiwan where 15–20% of the population are HBsAg positive, 93% of bone marrow recipients were positive prior to transplant. In the USA and Italy, 0.1% and 6% of bone marrow

transplant patients, respectively, were antigen positive. Among renal dialysis patients, 3% in the USA and 46% in France were chronically infected. The prevalence of HBsAg seropositivity among liver transplant recipients is skewed by the particular admission requirements to transplant centers. Because of the high rate of HBV reactivation and subsequent hepatic failure, HBsAg-positive patients are not accepted for liver transplantation in some programs. Nonetheless, HBV chronic active hepatitis with hepatic failure is among the most common indications for liver transplantation.

Non-A, non-B chronic active hepatitis with cirrhosis is the most commonly diagnosed condition in patients undergoing liver transplantation. Anti-HCV has been identified in half of these patients. In addition, 37% and 27% of patients undergoing transplant for Laennec's cirrhosis and chronic HBV infection, respectively, were seropositive for HCV. Among kidney transplant patients, up to 26% tested positive for anti-HCV before transplantation. The incidence of HCV infection in bone marrow recipients is uncertain. The widespread use of intravenous immunoglobulin preparations has been blamed for the prevalence (up to 100% of bone marrow transplant patients) of anti-HCV seropositivity; however, immunoglobulin concentrates have not been implicated as a source of HCV transmission.

Epidemiology and pathogenesis

HBV or HCV infection during transplantation is either due to transmission through infected blood or transplanted organ in a previously uninfected patient or more commonly to reactivation or progression of illness in a previously infected patient. There is little evidence that prognosis differs following either primary or secondary infection. Virus reactivation is fomented by the immunosuppression required to establish the allograft. Reactivation does not immediately lead to changes in liver function, and indeed laboratory evidence of hepatocellular injury may not emerge until withdrawal or reduction of immunosuppression.

Within the HBV-infected group, patients at greatest risk for reactivation are asymptomatic HBsAg-positive carriers. Anti-HBs-positive but HBsAg-negative patients are considered immune. However, the intensive immunosuppression administered for bone marrow transplantation, has promoted HBV reactivation in 'immune' patients.

Transmission of HCV by allograft has also been documented, but the frequency of this event has not yet been established. Transfusion of contaminated blood has been assumed to be a major source of HCV infection in transplant patients. Infection by other routes is possible.

Details of HCV pathogenesis are largely unknown. The assay for anti-HCV antibody has not proved enlightening in that regard, since anti-HCV does not appear for weeks to months after infection, and seropositivity may persist for years without evidence of clinical disease. Alternative assays may provide the missing details. For example, serum HCV RNA can now be measured and its presence correlates with infectivity. Although prolonged viremia is common in patients with chronic hepatitis, it remains to be determined whether clearance of HCV viremia indicates permanent immunity or merely a subclinical state capable of reactivation.

Clinical manifestations and treatment

Hepatitis B virus The reported incidence of HBV reactivation following bone marrow transplantation has been 5–12%. However, these figures undoubtedly underestimate the true incidence of reactivation.

Most HBsAg-positive bone marrow transplant recipients develop transient abnormalities in liver function tests, but clinically significant hepatic dysfunction is uncommon. Patients who were HBsAg positive pretransplant rarely cleared antigenemia post-transplant, whereas antigenemia appearing post-transplant persisted for months but almost always resolved. Regardless of whether HBsAg was cleared, intermittent elevation of liver enzymes persisted in over half these patients. The long-term prognosis for these patients is presently unknown. Currently, HBsAg seropositivity is not an absolute contraindication to bone marrow transplantation.

By eight years after kidney transplant, 25–40% of HBsAg-positive patients have developed chronic active hepatitis, cirrhosis, or hepatocellular carcinoma. Data from one study in which HBV reactivation was documented by PCR showed that HBV DNA was detected post-transplant in the 20% of HBV immune patients. Although these patients remained HBsAg negative, their incidence of chronic hepatitis was equivalent to HBsAg-seropositive patients.

Following orthotopic liver transplantation, more than 80% of HBsAg-positive patients will develop reinfection. Overall survival in these patients was significantly reduced compared to other liver transplant patients. HBV-immune patients have not developed reinfection, and this has led to therapies designed to eradicate HBsAg antigenemia: passive immunization with anti-HBs immunoglobulin, active immunization with HBV vaccine, combined active and passive immunization, and α interferon. It appears that HBV reinfection can be delayed by

passive and combined immunization, but late reinfection has occurred. Non-hepatic reservoirs of HBV have been implicated as the cause of reinfection.

Hepatitis C virus There are few reports that document the course of HCV infection in transplant patients. In one, 22% of renal transplant recipients tested repeatedly positive for anti-HCV; 50% of these developed chronic hepatitis. Cirrhosis would be the expected outcome in half of the patients developing chronic hepatitis. Transplantation of solid organs from HCV-seropositive donors has infected over half the recipients. Typically, liver disease progressed to subfulminant hepatic failure or became chronic. At present, transplantation of organs from anti-HCV-positive donors is contraindicated.

Therapy

Some patients with chronic hepatitis secondary to HBV or HCV infection have responded to α-interferon therapy, and this response was occasionally sustained once therapy was completed. Whether α-interferon will improve survival is unknown. Vidarabine and acyclovir have also been effective in a proportion of patients with chronic HBV although their activity was less predictable and vidarabine was more toxic than α-interferon. α-Interferon may enhance graft-versus-host mechanisms in bone marrow transplant recipients. Limited use of α-interferon in patients undergoing orthotopic liver transplantation has failed to prevent HBV reinfection. More recently, the antiretroviral agent lamivudine has been used successfully in small series of transplant patients, where it reduced antigen load and appeared to prevent progression of liver disease due to HBV.

Prevention

Prevention of HBV and HCV infections is the single most effective means of controlling post-transplant hepatitis. In France, immunization against HBV infection has not been the common practice; 46% of chronic dialysis patients are HBsAg positive and 71% of the HBsAg-negative patients are anti-HBs positive. In the USA, measures to prevent HBV infection including isolation of infected patients and HBV immunization have reduced the prevalence to 2.7% and 12% for HBsAg and anti-HBs, respectively. The ability to test blood for anti-HCV will further reduce the incidence of transmitted hepatitis.

Polyomavirus

Primary and usually clinically undetected infections with BK virus (BKV) and JC virus (JCV) occur during childhood, since measurable antibodies to JCV and BKV are present in 70% and 90% of adults, respectively. Such persistence of seropositivity suggests equal persistence of infection, and autopsy studies have identified the viral genome – presumably in a latent state – in various tissues including the kidney. Thus most infections with JCV or BKV in transplant patients are attributed to viral reactivation. However, seronegative renal transplant recipients have acquired primary infection from the transplanted kidney.

Situations in which host immunity, especially cell-mediated immunity, are compromised favor the reactivation of BKV and JCV. Four to eight weeks following kidney transplantation, 26–44% of patients develop viruria. The incidence is higher in patients treated with antilymphocyte serum to prevent graft rejection. Up to half of bone marrow transplant patients also develop viruria with BKV or JCV. Viruria onset has been noted between weeks 2 and 8 and typically persisted for 3–4 weeks. JCV was isolated from 6.7% of seropositive patients, and 55% of BKV seropositive patients excreted the virus. This disparity between the frequency of JCV viruria and BKV viruria is unexplained and contrasts with the experience in renal transplant patients where the incidence of viruria is similar.

BKV or JCV reactivation has been associated with stenosis of the ureteral anastomosis in kidney transplant patients, since virus has been identified in the tissue at the stenosis site. In bone marrow transplant patients, BKV has been linked to hemorrhagic cystitis, with more than 80% of viruric patients developing this complication, an incidence four times that of patients who were not viruric. Compared to autologous or syngeneic transplants, the likelihood of hemorrhagic cystitis was markedly increased among viruric patients undergoing allogeneic bone marrow transplantation. The explanation for this is not apparent. Presumably the more profound immunosuppression that occurs with allogeneic transplantation contributes to the virulence of BKV reactivation.

BKV/JCV have also been identified in the lesions of multifocal leukoencephalopathy, a progressive encephalitis which occurs in a minority of patients on long-term immunosuppression. The contribution of these viruses to the disease state is unclear, but responses to intrathecal cytosine arabinoside have been reported. In general, however, there is no effective therapy identified for BKV or JCV.

Respiratory Viruses

Respiratory syncytial viruses

Infection with parainfluenza and respiratory syncytial virus (RSV) can lead to severe, even fatal, pulmonary

disease in transplant patients. Although RSV is a common pathogen among children, infection confers only transient resistance; most adults will be susceptible at the time of transplant. About 20–50% of patients exposed to RSV in the hospital will be nosocomially infected and RSV infection in transplant patients has coincided with community outbreaks of RSV disease. The communicability of RSV emphasizes the need for stringent isolation measures.

Pneumonia is the most serious consequence of RSV infection. RSV pneumonia has seldom been fatal in solid organ transplant recipients, but the mortality rate among bone marrow transplant patients has been 50%. The importance of RSV as a pathogen appears to be increasing. In one transplant center, RSV was identified in 27% of patients with pulmonary disease.

After BMT, the onset of pneumonia is early in the post-transplant course, usually before bone marrow engraftment. Sinusitis and otitis media often precede the pulmonary symptoms, an important diagnostic clue, since other viral pneumonias are not accompanied by these upper respiratory tract findings. Diagnosis of infection before the onset of pneumonia has been made by finding RSV antigen in upper airway secretions. RSV infections that occur after 100 days post-transplant have not been fatal.

Identification of RSV prior to the onset of pulmonary symptoms and treatment with nebulized ribavirin has arrested disease progression. Once the lower respiratory tract is clinically involved, ribavirin treatment has been less effective. Improved methods of drug delivery, including intravenous ribavirin, may improve the outcome in this latter group.

Adenovirus

Incidence

Adenovirus has been isolated in 5–10% of patients after solid organ transplantation and in 5–25% of patients undergoing allogeneic bone marrow transplantation. Less than half the patients in whom adenovirus was isolated had symptoms of viral infection and in some that were ill, cytomegalovirus or herpes simplex virus was isolated concurrently, confusing the assignment of cause. Nonetheless there is undeniable evidence that adenovirus has caused invasive and fatal disease in transplant recipients.

Pathogenesis and epidemiology

Most patients are seropositive for adenovirus prior to transplant. Tonsils, adenoids, other lymphoid tissue and kidneys are recognized as latent virus reservoirs. This plus the absence of a contagious source suggest that reactivation of latent virus may often be the cause of adenovirus infection following transplantation. Rarely latent virus residing in the transplanted tissue has been implicated as an infectious source.

Although many adenovirus serotypes have been isolated post-transplant, not all isolates have been associated with invasive disease. Several serotypes, notably types 11, 12, 34 and 35, which rarely cause community outbreaks, have been isolated in immunosuppressed patients with pneumonia. Adenovirus type 5, implicated as a cause of intussusception and sporadic cases of hepatitis, has commonly been recovered from liver transplant recipients with adenovirus-associated hepatitis. The disproportionate representation of certain serotypes in transplant patients with invasive disease is unexplained.

Immunosuppression promotes adenovirus infection. In liver transplant patients, invasive disease has been most common when additional therapy was needed to prevent graft rejection. Severe graft-versus-host disease, which is immunosuppressive in itself and is managed by immunosuppressive agents, has been noted to promote adenovirus infection in bone marrow transplant patients. The frequency of adenovirus infection has also increased with increasing numbers of alternative donor stem cell transplants.

Clinical manifestations and treatment

Adenovirus infections have occurred as early as the second week or as late as several months after transplantation. The virus has been isolated from the throat, stool, urine, blood and from tissue parenchyma. Manifestations include gastroenteritis, hemorrhagic cystitis, hepatitis, pneumonia, meningoencephalitis and hemophagocytic syndrome. In some circumstances, infections have been mild and recovery complete. Renal dysfunction suggestive of kidney allograft rejection has followed adenovirus viruria and hemorrhagic cystitis. Renal failure requiring dialysis has complicated the course of bone marrow transplant patients, and in these patients adenovirus was isolated from the renal parenchyma. Adenovirus hepatitis following liver transplantation and pneumonia following bone marrow transplantation have been almost uniformly fatal.

At present there is no specific therapy for adenovirus infection. Treatment consists in aggressive support. There are anecdotal reports of successful management of disseminated adenovirus infection with immunoglobulin, ribavirin, gancyclovir or with adoptive transfer of immune lymphocytes (see EBV disease above). One patient, after undergoing liver transplant, developed adenovirus hepatitis and liver failure and was successfully retransplanted. Undoubt-

edly measures such as these will prevail until adenovirus specific treatment is available.

Immunization

Vaccination

Although viral illnesses occur with high frequency and often devastating effect in transplant recipients, vaccination presently has only a limited role in disease prevention. There are a number of reasons why this should be so. Transplant patients are heavily immunosuppressed, and make poor antibody or T cell responses to killed/subunit vaccines. Administration of live attenuated vaccines, which are potentially more immunogenic, is fraught with peril, since the immune response may be so feeble that even attenuated viruses may produce fatal disease. Finally, effective vaccines to herpes viruses in humans are simply not available. Since it is precisely that virus group which is responsible for most viral-related morbidity and mortality after transplantation, vaccination can at best have a limited impact on outcome. For example, several studies have examined the effect of attenuated Towne strain in renal transplant recipients. Unfortunately, the vaccine induces minimal specific cytotoxic T lymphocytes in seronegative renal transplant recipients, many of whom also fail to make antibody. In clinical trials there was no benefit to seropositive recipients, and no change in the incidence of infection in seronegative recipients. Morbidity was, however, decreased in seronegative recipients.

Despite these limitations, vaccination should still be considered for all transplant patients. In particular, killed or subunit vaccines to poliomyelitis and hepatitis B are readily justified and often produce protective levels of antibody. After BMT, antibody responses to vaccines may be greatly enhanced by immunizing both donor and recipient pre-BMT to allow adoptive transfer of high titer responses. In contrast, live vaccines should be withheld while patients are receiving immunosuppression. After BMT especially, such vaccines should not be given for at least two years; in the presence of chronic graft-versus-host disease this time period may need to be extended indefinitely.

Passive immunization

Although vaccination has a limited role after transplantation, it has been repeatedly suggested that passive immunization with pooled immunoglobulins reduces the incidence or severity of disease associated with viral infection or reactivation after transplantation in general and after BMT in particular (see section on CMV above). These claims have yet to be fully substantiated.

TREE SHREW HERPESVIRUSES (*HERPESVIRIDAE*)

Christian A Tidona and **Gholamreza Darai**, Institute for Medical Virology, University of Heidelberg, Heidelberg, Germany

History

The tree shrews (*Tupaia* sp., family Tupaiidae) belong to a group of primitive higher mammals (*Proteutheria*) and are classified as a separate order (*Scandentia*). The first discovery of herpesvirus-like particles in the tree shrew was reported by Mirkovic in 1970. This *Tupaia* herpesvirus (THV-1), which was isolated from a spontaneously degenerating lung tissue culture from an apparently healthy animal, was characterized by McCombs in 1971 by electron microscopy. Subsequently six additional THV isolates (THV-2 to -7) were obtained and characterized. THV-2 was isolated in 1979 from a degenerating lymphoma cell culture which had been established from a moribund 8-year-old tree shrew. Similarly, THV-3 was isolated from a degenerating cell culture of a Hodgkin's sarcoma (Hodgkin's disease, lymphocytic depletion type) from a moribund 9-year-old tree shrew. The other four THVs (THV-4 to -7) were isolated from spleen tissues of moribund animals aged 4–11 years.

Taxonomy and Classification

THVs are still-unclassified members of the family *Herpesviridae*; however, the recent analysis of the primary structure of the THV-2 genome clearly indicates that these viruses belong to the beta-subfamily of herpesviruses.

Properties of the Virion

Naked viral capsids have a diameter of about 100 nm. Extracellular herpesvirus particles comprise an envelope studded with small surface projections (**Fig. 1A**). Beneath this envelope, an electron dense area is detectable. Some of the enveloped particles contain several viral capsids. The diameter of the envelope usually ranges from 200 to 350 nm (**Fig. 1B**).

Properties of the Genome

THV genomes have attracted attention because they consist of a unique linear double-stranded DNA molecule without any detectable long inverted repeat sequences greater than 40 bp within or at either end of the viral genome. The DNAs of the THV isolates 1–4 were subjected to analytical ultracentrifugation and a specific buoyant density of 1.724 g ml^{-1} was determined. From the UV-absorbance/temperature profile of the viral DNA in 15 mmol l^{-1} NaCl, 1.5 mmol L^{-1} sodium citrate a melting temperature (T_m) of 81.2 ± 0.8°C was calculated. This corresponds to an overall G+C content of 64.5 ± 1.9%, which is in agreement with results obtained from DNA nucleotide sequence analysis.

Measurement of the contour length of viral DNA molecules by electron microscopy revealed molecular sizes of about 194.8 ± 5, 200.8 ± 3, 196.3 ± 3 and 196.3 ± 5 kbp for THV isolates 1, 2, 3 and 4, respec-

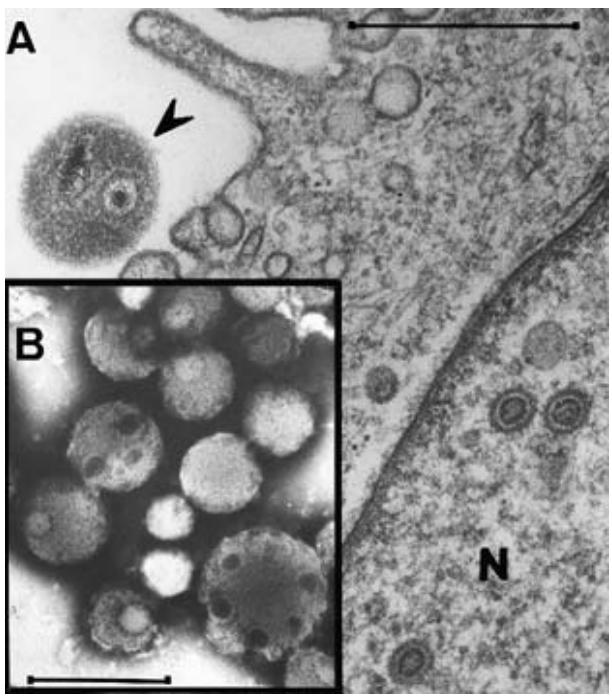

Figure 1 Electron micrographs of *Tupaia* herpesvirus 2 particles. Bars = 500 nm. (**A**) Ultrathin section of a *Tupaia* embryonic fibroblast cell 5 days after infection with THV-2. In the nucleus (N) three virus capsids are present and the mature extracellular virion (arrow) contains two capsids. (**B**) Negative staining of pellets of THV-2 infected tissue culture supernatants using 2% phosphotungstic acid at pH 7.2 reveals the relatively high purity of such materials. Envelope structures are remarkably stable and contain different numbers of capsids.

tively. Physical maps of the THV-2 genome have been constructed.

THV-2 DNA synthesis reaches a maximum between 24 and 36 h post infection, preceded by a transient stimulation of host cell DNA synthesis. Linear concatemeric and circular viral DNA molecules are found during DNA synthesis. The nucleotide sequence of terminal DNA regions of the molecularly cloned THV-2 genome is characterized by a relatively high G+C content of about 75%. Furthermore, the termini contain numerous short repeat elements. A sequence ($A_3C_8AAAGGCAC_6G_5$), postulated to be a consensus signal for site-specific endonucleolytic cleavage in terminal regions of the genomes of herpes simplex virus 1 and 2 (HSV-1, HSV-2), Epstein–Barr virus (EBV) and varicella-zoster virus (VZV), is present at the terminal region of the THV-2 genome. It was found that the signal sequences of HSV and THV-2 are located at similar distances from the genomic termini (at nucleotide positions 432 and 470 bp). This consensus sequence, in combination with several short repeats, which are asymmetrically bracketed by GC-rich arrays, may play a role in forming the mature ends of the THV DNA. Alternatively, this consensus sequence could be the target site for the processing of concatemeric viral DNA molecules into unit-length segments and for the packaging of the processed unit-length molecules into viral capsids.

It was found that THV-1 to -4 genomic DNAs cause infections in tree shrew embryonic fibroblasts.

Viral Proteins

The polypeptide patterns of THV-1 to -3 are remarkably similar, each consisting of at least 35 polypeptides with similar apparent molecular masses ranging from 120 to 230 kDa. While the majority of analogous polypeptides of the three viruses are of indistinguishable electrophoretic mobility, some (e.g. 82–86 kDa polypeptides) showed small differences in apparent molecular mass which were characteristic of the viral strain. By comparative sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) it is possible to distinguish the THV isolates from each other. At least five glycoproteins are found in purified THV virions. Two-dimensional electropherograms reveal at least 47 discernible protein spots, some of which are specific for a given THV isolate and which are detectable in lysates of THV-infected cells.

Viral Enzymes

A protein kinase activity is associated with THV. Divalent cations such as Mg^{2+} or Mn^{2+} are necessary as well as ATP. The predominant sites of phosphorylation are the free hydroxyl groups of serine and threonine residues. Distinct THV polypeptides (molecular masses of 100, 82, and 53 kDa) were found to be targets of phosphorylation in the presence of 5 mmol l^{-1} Mg^{2+}. At a higher Mg^{2+} concentration (20 mmol l^{-1}), additional viral proteins (220, 71, 31 and 20 kDa) were phosphorylated. The gene encoding the viral DNA polymerase was identified by nucleotide sequence analysis.

Geographic and Seasonal Distribution

THV infection of tree shrews is endemic only to south and southeast Asia, corresponding to the geographic distribution of the animal. Seasonal dependence for viral isolation has not been documented.

Host Range and Virus Propagation

The host range of the different THV strains *in vitro* clearly shows that tree shrew embryonic fibroblasts are the most susceptible cells for viral replication. Primary rabbit kidney cells, human foreskin fibroblasts and marmoset skin fibroblasts are less susceptible than tree shrew cells, whereas THVs do not replicate in rodent cell lines. Tree shrew embryonic fibroblasts are the cells of choice for propagation of THVs.

Genetics

A high degree of DNA sequence homology between the different THV isolates has been detected using DNA/DNA hybridization, heteroduplex mapping of the viral DNA molecules, and generation of intratypic recombinant viruses. This indicates the close genetic relationship between the individual THV strains. The seven isolates of THV are genetically grouped into five strains according to DNA fragmentation patterns. THV strains 1, 2, 3 and 5 comprise isolates 1, 2, 3 and 7 respectively, whereas isolates 4, 5 and 6 together represent THV strain 4. However, minor differences between the individual members of THV strain 4 are detectable in respect of slight size variations of specific restriction fragments.

Evolution

The tree shrew, which is the original host of THVs, is thought to have diverged at the basis of the evolutionary tree of mammals. THVs may therefore be fundamental representatives of mammalian herpesviruses. This is supported by the fact that the THV

genome does not contain complex terminal repeat elements and does not occur in different isomeric forms such as modern herpesviruses (e.g. herpes simplex virus).

Serologic Relations and Variability

Serological crossreaction between different THV strains can usually be demonstrated. Crossreaction is sufficiently strong and can be detected with antisera against individual viral strains; however, it is possible to distinguish THV strains from each other in neutralization tests by significant differences in the resulting titers.

Epidemiology

THV epidemiology has not been the subject of intensive studies but analysis of the sera of a limited number of apparently healthy animals in captivity reveals that less than 1% of tree shrews have neutralizing antibodies against THVs.

Transmission and Tissue Tropism

The natural route of transmission of THVs is probably the same as for other herpesviruses. Most infections occur as a result of contact between open lesions and/or moist surfaces; however, spontaneous reactivation of latent virus should also be considered. The target organ for latent THVs is the spleen, as this is the only organ from which infectious viruses can be recovered even after a long period of chronic infection of tree shrews (24 months) and rabbits (14 months). Analysis of the genomes of recovered viruses by different restriction enzymes shows the same DNA fragment patterns when compared to the DNA of the originally inoculated viruses.

Pathogenicity

The pathogenicity of THV-1 to -4 for tree shrews as their indigenous host was studied using juvenile, young adult and adult animals inoculated intravenously or intraperitoneally. *In vivo* pathogenicity studies show that the tree shrew is highly susceptible to these viruses. Intravenous inoculation is always lethal (lethality 100%). In contrast, the majority of intraperitoneally inoculated animals survive the infection (lethality 25%). The major pathology is inflammatory hemorrhagic necrosis of the lungs. High virus titers are detectable in the tissues and whole blood of the infected animals.

It is remarkable that two of the five known THV strains were directly isolated from metastasizing tumors, in one case from a malignant lymphoma and in the other case from a Hodgkin's-like disease. However, only one malignant lymphoma has been induced experimentally in a tree shrew using THV-2. The tumor developed 3.5 years after intraperitoneal administration of the virus. Infectious virus that was genetically identical to the original inoculum was recovered from cultured tumor cells. The failure to routinely induce malignant lymphomas in the tree shrew after experimental inoculation with THV-2 and -3 is probably due to the short period of observation, as tree shrews can reach an age of 14 years.

The response of rabbits to THV-1, -2, -3 and -4 infections is well documented. THV-2 and -3 induce hyperplasia of the thymus in newborn New Zealand rabbits (80%), which in 8% of all cases develop malignant thymomas. Infectious virus can be recovered only from established spleen cultures of the infected rabbits. The spontaneous degeneration of the rabbit splenocyte cultures always develops by the first or second tissue culture passage. The genomes of the recovered viruses are identical when compared with the genome of the originally inoculated viruses.

Clinical Features of Infection

Clinical illness usually appears in juvenile animals infected with THV-1 to -4 on the second day after inoculation. The general symptoms worsen. Intravenous inoculation of these viruses leads to death of the infected animals. Death occurs from day 5 to day 18 post infection as a result of inflammatory hemorrhagic necrosis of the lungs. High virus titers are detectable in the tissues and whole blood of infected animals.

Pathology and Histopathology

It is of particular interest that THV-2 and -3 were isolated from degenerating cultured tumor cells from a high-grade malignant lymphoma and a Hodgkin's-like sarcoma, respectively. The lymphoma was detected in an adult (8-year-old) female tree shrew. Histopathological investigations revealed a discordant hyperplasia of lymphoreticular tissues with formation of nodal follicle-like proliferates. Two types of cells were observed. The first was small with polymorphic nuclei of clear appearance and small nucleoli; the second was of medium to large size with large rounded nuclei. The chromatin showed marginal aggregations with marginal nucleoli. Mitosis was relatively frequent. Several thick reticulin fibers were sparsely distributed after silver staining. Tumor cell infiltration was observed in the parenchyma of the pancreas, the peribronchial lymph follicles, the connective tissue of the pelvis of the kidney, the subserous

membrane of the duodenum, and the cerebral meninges.

A generalized lymphoproliferative disorder resembling human Hodgkin's disease was observed in a female tree shrew of 9 years of age. Histological examination revealed hyperplasia of the lymphoreticular tissue with a polymorphic cellular population consisting of immunoblasts, numerous Hodgkin-like cells and Reed–Sternberg-like cells, eosinophilic granulocytes, and a marked lymphocytic depletion. The spleen showed a diffuse infiltration pattern; liver and peripelvic tissue of kidneys were likewise infiltrated.

Future Perspectives

Many interesting aspects of THV replication, such as transcription, post-transcriptional and post-translational processing, viral enzyme activity, etc., are still not understood and deserve intensive study in the future. Furthermore, genetic analysis of other tree shrew viruses, such as tree shrew retro-, rhabdo-, paramyxo- and adenovirus, is necessary for the final determination of their evolutionary roles.

TRICHOVIRUSES

Sylvie German-Retana and **Thierry Candresse**, Station de Pathologie Végétale, INRA, Villenave d'Ornon, France

History

The genus *Trichovirus* was established for plant viruses characterized by an elongated very flexuous and open particle morphology and a small genome size (<8.5 kb) as compared to other members of the *Closteroviridae* family which share an essentially similar particle morphology but have much larger genomes, in general in excess of 15 kb. The name 'tricho' is derived from the Greek 'thrix' meaning hair. The genus was approved by the International Committee of Taxonomy of Viruses in 1993, at the 9th International Congress of Virology, in Glasgow and has recently been placed in the family *Closteroviridae*.

Apple chlorotic leaf spot virus (ACLSV), the type member of the *Trichovirus* genus, had been previously classified in the subgroup A of closteroviruses, according to the morphology of its flexuous and filamentous viral particle. ACLSV was the first clostero-like virus whose genome was completely sequenced and genomic organization determined. When molecular information became available on other closteroviruses, it became evident that there were very significant differences in genome properties and structure between ACLSV and beet yellows virus (BYV) the type member of the *Closterovirus* genus. These molecular differences, when added to the differences in particle and genome length, vector transmission, tissue tropism and cytopathic effects, led to the splitting of the *Closterovirus* genus and to the establishment of a new viral genus typified by ACLSV and for which the name *Trichovirus* was coined.

Taxonomy and Classification

The genus *Trichovirus* contains nine viral species (including seven tentative members) with similar biological, morphological, and ultrastructural properties. ACLSV and potato virus T (PVT) are definitive members of the genus, whereas grapevine virus A (GVA), grapevine virus B (GVB), grapevine virus C

membrane of the duodenum, and the cerebral meninges.

A generalized lymphoproliferative disorder resembling human Hodgkin's disease was observed in a female tree shrew of 9 years of age. Histological examination revealed hyperplasia of the lymphoreticular tissue with a polymorphic cellular population consisting of immunoblasts, numerous Hodgkin-like cells and Reed–Sternberg-like cells, eosinophilic granulocytes, and a marked lymphocytic depletion. The spleen showed a diffuse infiltration pattern; liver and peripelvic tissue of kidneys were likewise infiltrated.

Future Perspectives

Many interesting aspects of THV replication, such as transcription, post-transcriptional and post-translational processing, viral enzyme activity, etc., are still not understood and deserve intensive study in the future. Furthermore, genetic analysis of other tree shrew viruses, such as tree shrew retro-, rhabdo-, paramyxo- and adenovirus, is necessary for the final determination of their evolutionary roles.

History

The genus *Trichovirus* was established for plant viruses characterized by an elongated very flexuous and open particle morphology and a small genome size (<8.5 kb) as compared to other members of the *Closteroviridae* family which share an essentially similar particle morphology but have much larger genomes, in general in excess of 15 kb. The name 'tricho' is derived from the Greek 'thrix' meaning hair. The genus was approved by the International Committee of Taxonomy of Viruses in 1993, at the 9th International Congress of Virology, in Glasgow and has recently been placed in the family *Closteroviridae*.

Apple chlorotic leaf spot virus (ACLSV), the type member of the *Trichovirus* genus, had been previously classified in the subgroup A of closteroviruses, according to the morphology of its flexuous and filamentous viral particle. ACLSV was the first clostero-like virus whose genome was completely sequenced and genomic organization determined. When molecular information became available on other closteroviruses, it became evident that there were very significant differences in genome properties and structure between ACLSV and beet yellows virus (BYV) the type member of the *Closterovirus* genus. These molecular differences, when added to the differences in particle and genome length, vector transmission, tissue tropism and cytopathic effects, led to the splitting of the *Closterovirus* genus and to the establishment of a new viral genus typified by ACLSV and for which the name *Trichovirus* was coined.

Taxonomy and Classification

The genus *Trichovirus* contains nine viral species (including seven tentative members) with similar biological, morphological, and ultrastructural properties. ACLSV and potato virus T (PVT) are definitive members of the genus, whereas grapevine virus A (GVA), grapevine virus B (GVB), grapevine virus C

Table 1 Properties of definitive and tentative trichoviruses

Virus	Particle length (nm)	Coat protein (kDa)	Genome (nt)	Mechanical transmissibility from natural host	Tissue localization in natural host	Vector
Definitive species						
ACLSV	720	22	7555	Easy	Parenchyma	Unknown
PVT	640	27	c. 7600	Easy	Parenchyma	Unknown
Tentative species						
GVA	800	22.5	7349	Difficult	Phloem	Mealybugs
GVB	800	23	7599	Difficult	Phloem	Mealybugs
GVC	725	25.7	nd	Difficult	Phloem	Mealybugs
GVD	825	20.5	c. 7600	Difficult	Phloem	Mealybugs
GBINV	740	22	c. 7600	Easy	Parenchyma	Unknown
HLV	730	22	nd	Easy	nd	Aphids
CMLV	760	20.5	c. 8200	Easy	nd	Mites

nd = not determined.

(GVC), grapevine virus D (GVD), grapevine berry inner necrosis virus (GBINV), cherry mottle leaf virus (CMLV) and heracleum latent virus (HLV) have properties that qualify them as tentative members of the genus (**Table 1** and see below).

Note added in proof: GVA, GVB, GVC, GVD, CMLV and HLV have recently been split from trichoviruses to create a new genus, Vitivirus. ACLSV, PVT and GBINV thus remain as the only members of the trichovirus genus (see below).

Geographic Distribution and Host Range

Trichoviruses differ in the extent of their geographical distribution. ACLSV, GVA and GVB are found worldwide, whereas PVT has been reported only in the Andean region of South America, GBINV in Japan and HLV in Scotland. CMLV appears to be distributed over North America, but the precise identity of European isolates of CMLV remains to be evaluated. Information is still lacking on the extent of the geographical distribution of GVC and GVD. The natural host range of trichoviruses is restricted to either a single host (PVT, HLV, GVA, GVB, GVC, GVD, GBINV), or to a somewhat wider host range in the case of ACLSV which naturally infects most temperate rosaceous fruit crops.

The experimental host range for ACLSV includes dicotyledonous hosts from a few families and includes 'general purpose' hosts such as *Chenopodium quinoa, C. amaranticolor, Phaseolus vulgaris* and *Nicotiana occidentalis*. Experimental host reactions to GBINV inoculation are quite similar to those of ACLSV except that *C. amaranticolor* is not infected by GBINV. PVT shows a similarly rather restricted experimental host range. The experimental host range for HLV contains hosts corresponding to over nine families and includes also one monocotyledonous host, *Zea mays*. GVA, GVB and GVD and CMLV have a very narrow experimental host range including only *Vitis* and a few *Nicotiana* in the case of the grapevine viruses and *Prunus* and *Chenopodium* for CMLV.

Particle Structure and Composition

Although resembling that of some other flexuous elongated plant viruses such as potex- and carlaviruses, the very flexuous and open particle structure is the most conspicuous characteristic of trichoviruses. This unusual morphology is, however, shared with members of the *Closterovirus* and *Capillovirus* genera. Particles have, in general, a diameter of about 12 nm, with a length of 640–825 nm, depending on the virus considered. The RNA content is usually 5–6% and a single type of coat protein subunit is observed with a molecular weight of 20.5 kDa (CMLV)–27 kDa (PVT), although the calculated weight has been found to be as low as 17.6 kDa in the case of GVD.

The pitch of the primary helix, which can usually be measured from the obvious crossbanding of the particle, has been found to be in the range 3.4–3.8 nm, giving estimated ratios of four nucleotides per protein subunit and of about 10 protein monomers per turn of the helix. However, PVT particles differ slightly from those of ACLSV in having a slightly larger

diameter (13–14 nm) with a pitch of the helix (3.4 nm) at the lower end of the range for trichoviruses. Correlated with the very open structure of the particle, the genomic RNA of several of these viruses, such as ACLSV and HLV, has been found to be sensitive to RNases in their encapsidated forms. Genome size has been found to be directly correlated with particle length and is reported to vary from 7.3 kb to about 8.2 kb.

An unusual property of the coat proteins of ACLSV, HLV, GBINV, GVA, GVB and GVD, is that they are devoid of tryptophan. This probably explains the high (1.4–1.8) A_{260}/A_{280} absorbance ratios of the corresponding viruses.

Genome Structure

In all cases examined, the genome of trichoviruses has been found to consist of a single molecule of single-stranded (ss) RNA. The genomic RNA of ACLSV is infectious and those of ACLSV, GVA and GVB have messenger activity *in vitro*. Thus, trichoviruses should be regarded as having monopartite ssRNA genomes of positive polarity. The genomic RNAs of the type member ACLSV (in fact, four strains of ACLSV differing in their original host and geographical origin), and two tentative members, GVA and GVB, have been totally sequenced, and the sequences of the 3′ terminal regions of PVT, GVD and GBINV genomes have been determined. Relevant sequence database accession numbers are: ACLSV-P863 (M31714), ACLSV-Bal1 (X99752), ACLSV-P205 (D14996), GVA (X75433), GVB (X75448), PVT (D10172), GVD (Y07764) and GBINV (D88448). The genomic RNAs have a polyadenylated 3′ terminus and are capped at their 5′ end.

Genome Organization and Expression: Affinities with other Virus Groups

Genomic organization of the trichoviruses for which sequence information is available is shown in **Fig. 1.** The ACLSV RNA (7.5 kb) contains three open reading frames (ORFs) encoding proteins with approximate molecular weights of 216 kDa, 50 kDa and 22–28 kDa. The partial sequences available for PVT and GBINV fit the same pattern: the extremity of the large replication-associated protein is followed by two smaller ORFs of 39 kDa (GBINV) or 40 kDa (PVT), and 22 kDa (GBINV) or 27 kDa (PVT).

The large, 5′-located ORF 1 codes for a protein that contains three signature sequences, typical of replicase-associated proteins of the 'Alpha-like' super group of plant viruses: the methyl transferase (MT), the nucleotide binding site of the helicase (HEL) and the RNA-dependent RNA polymerase (RdPd) signatures. Homologies with putative papain-related proteinases of positive-strand RNA viruses such as tymo- and furoviruses, are also found in a block of amino acids preceding the HEL domain (**Fig. 1**).

The ORF 2 of ACLSV shares distant similarities with the cauliflower mosaic virus gene I and TMV 30K movement proteins. The ORF 2-encoded protein has been included in the proposed family I of movement proteins (MP), which also includes the MPs of tobamoviruses, tobraviruses, comoviruses, caulimoviruses and geminiviruses. Furthermore, it has been shown that the ORF 2 protein of ACLSV can be detected in both cell wall and cell membrane fractions prepared from infected *Chenopodium quinoa* tissues, and is phosphorylated *in vivo*. All these properties fit with the assignment of this protein as the movement protein of the virus.

The capsid protein (CP) ORF is located at the 3′ terminus of the genomic RNA. The CP contains amino acids that are highly conserved in the CP of filamentous virus, and hypothesized to be involved in the formation of a salt bridge, assumed to play a key role in structure formation.

As shown in **Fig. 1**, the complete sequences of GVA and GVB contain five ORFs, including two that are absent from ACLSV, PVT and GBINV. ORF 1 which is the large replication-associated protein shows clear homologies and a similar arrangement of the conserved signature sequences with the ORF 1 of ACLSV. ORF 2 codes for a 20 kDa polypeptide with unknown function and for which no significant homology has been found in protein databases. ORF 3 encodes a 36.5 kDa (GVB) or 31 kDa (GVA) protein possessing the conserved motifs of the family I of movement proteins, and recent results show that

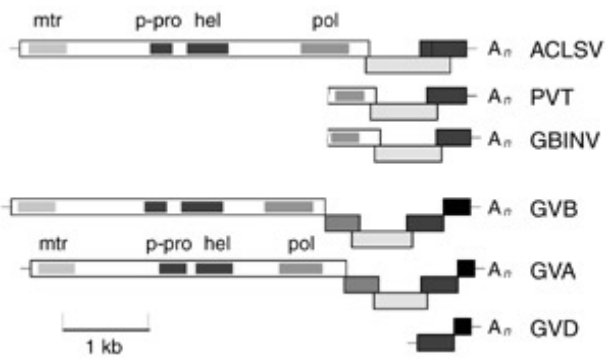

Figure 1 Genomic organization of trichoviruses. ACLSV, apple chlorotic leaf spot virus; PVT, potato virus T; GBINV, grapevine berry inner necrosis virus; GVA, grapevine virus A; GVB, grapevine virus B; GVD, grapevine virus D. mtr, methyl transferase domain; p-pro, papain-like proteinase domain; hel, helicase domain; pol, RNA-dependent RNA polymerase domain.

these proteins are associated with the cell wall, sometimes at the level of plasmodesmata, supporting the hypothesis of their role in the cell to cell movement of the virus. ORF 4 (21.5–21.6 kDa) is the CP cistron showing again low but clear homologies with the CPs of ACLSV, PVT and GBINV. ORF 5 codes for a small (10–14 kDa) protein homologous to the small cystein-rich nucleic acid binding-proteins found in the genome of other plant viruses, such as hordeiviruses and carlaviruses. In the 3′ end of the GVD genome, two ORFs were identified, encoding a cystein-rich 10 kDa protein and the 17.6 kDa CP, respectively; the genome of GVD is thus assumed to follow the same organization as that of GVA and GVB.

Subgenomic messenger RNAs (sgRNAs) have been observed for ACLSV and allow the expression of the ORFs located downstream of the 5′-most ORF. Although there is conflicting evidence for proteolytic processing of the 216 kDa protein of ACLSV, a possible proteolytic maturation of the 216 kDa protein is hypothesized, from the presence of the conserved papain-like protease signature sequence. *In vitro* translation experiments using the genomic GVB RNA as a template have tentatively shown that the 195 kDa viral replicase could undergo proteolytic cleavage.

Comparative analysis of proteins of definitive and tentative trichoviruses showed that they are all phylogenetically related. However, distinct clusters can be observed, in particular, when analyzing the movement and capsid proteins. In particular, GVA, GVB and GVD are much closer to each other than to ACLSV, PVT and GBINV.

Virus Host Relations: Cytopathic Effects

All trichoviruses can be experimentally transmitted by sap inoculation and by grafting. Mechanical transmission from natural host is easy for ACLSV, PVT, HLV, GBINV and CMLV, whereas sap inoculation is difficult for GVA, GVB, GVC and GVD. It is not surprising that the viruses that are easiest to transmit mechanically are also those that do not appear to be phloem-restricted. GVA, GVB, GVC and GVD are phloem-restricted in their natural host, grapevine, whereas ACLSV, PVT and GBINV seem to multiply primarily in parenchyma cells. However, GVA and GVB can invade the parenchyma of artificially infected herbaceous hosts and become mechanically transmissible under these circumstances. Most trichoviruses are not seed-borne, but PVT has been reported to be transmitted rather efficiently in this manner from a number of hosts and ACLSV may be seed-transmitted at a low frequency in apricot.

The cells of plants infected by GVA, GVB and GVD show conspicuous alterations. Virions accumulate in large bundles or paracrystalline aggregates in infected cells. The vascular bundles of systemically infected leaves of *N. occidentalis* have a strongly affected cytology with some cells in stage of necrosis. The cytoplasm shows membrane proliferation, vesiculation, and secondary vacuolation. Vesicular evaginations of the tonoplast contain finely fibrillar material. Mitochondria are damaged and chloroplasts are rounded and swollen, with a disrupted lamellar system and enlarged starch grains.

GBINV particles are found in vascular parenchyma and mesophyll cells. Particles exist as aggregated masses in the cytoplasm, but not in the nucleus or vacuole. No virus-specific inclusion bodies are observed. These modifications are comparable to those observed with ACLSV, except that ACLSV particles are sometimes found in the nucleus.

Viral Transmission

The mode of natural transmission differs substantially between the species of *Trichovirus*. No natural vectors are known for ACLSV, PVT and GBINV, natural dissemination probably being mediated by vegetative multiplication of propagation material.

In the case of HLV, aphid-transmission in a semipersistent manner is assisted by a helper closterovirus [Heracleum virus 6 (HV6)]. Cherry mottle leaf virus (CMLV) is transmitted by the scale mite *Eriophyes inaequalis*. Grapevine trichoviruses appear to be transmitted by several species of mealybugs in a nonspecies-specific manner. Both GVA, GVB and GVD are transmitted in nature by several species of the pseudococcid mealybug genera *Pseudococcus* and *Planococcus* (*Planococcus ficus*, *Pseudococcus longispinus*, *Pseudococcus citri* and *Pseudococcus affinis*). Studies of the acquisition and transmission of GVA by *Ps. longispinus*, showed that *Ps. longispinus* can acquire GVA in a short time (15 min) when feeding on *N. clevelandii*. The virus can be retained for up to 48 h when the insect is fasting. There is no latent period for the inoculation of GVA to *N. clevelandii* after a 30 min feeding. Such properties are consistent with a semipersistent mode of transmission.

Diseases and their Economic Significance

The economic importance of ACLSV is largely due to its worldwide distribution. Although it is more or less symptomless in pome fruits, it is responsible for serious diseases in stone fruit trees such as pseudopox (false plum pox) and bark split of plum, butteratura

and viruella of apricot. In addition ACLSV includes incompatibility problems and bud failure following grafting of infected material, which can result in important losses in nurseries.

Infection by PVT or HLV induces little or no symptoms. The main disease for PVT has been reported only for potato (*Solanum tuberosum*) in which it is usually latent, but can produce a mild leaf mottle. HLV occurs commonly in Scotland in wild *Heracleum sphondylium* (hogweed) plants, without causing any symptoms.

Cherry mottle leaf virus (CMLV) is associated with a disease of both economic and quarantine importance in sweet cherry. The symptoms are irregular chlorotic mottling and distortion of the terminal leaves. In some cultivars, both the quality and the quantity of fruits are affected, the fruits being tasteless, and showing delayed ripening.

GVA, GVB, GVC and GVD are currently thought to be involved in the etiology of the rugose wood complex of diseases, an economically important problem in grapevine. At least four different disorders participate (corky bark, Rupestris stem pitting, Kober stem grooving and LN33 stem grooving). Individual disorders can be distinguished by indexing on specific *Vitis* indicators, but not in the field, due to the absence of specific symptoms. Rugose wood-affected vines are less vigorous, show a more or less pronounced swelling at the bud union and a marked difference between the diameter of scion and rootstock. The affected vines may decline and die within a few years. The major characteristic features of the disease are symptoms of pitting and grooving in the woody cylinders of the scion, rootstock, or both. There are cases in which the scion also shows an atypical production of corky tissues, just above the graft union, called 'corky rugose wood'. Unraveling the etiology of rugose wood appears to be a very complex problem that has not yet been solved. Circumstantial evidence points to GVA and GVB being the probable agents of, respectively, Kober stem grooving and corky bark diseases.

Grapevine berry inner necrosis, reported in Japan, and originally called mosaic disease, is one the most economically important virus diseases of grapevines in Japan. The diseased grapevines grow less vigorously, sprout late in spring, and show inner necrosis in shoots, shortened internodes and various mosaic patterns on leaves. Berries are small, show external discoloration and interior necrosis.

Serological Relationships and Molecular Variability

Very limited serological relationships have been detected between the trichoviruses. It has been recently reported that GVA, GVB and GVD are distantly serologically related, the shared antigenic determinant between GVA and GVD corresponding probably to a cryptotope. GVA and HLV have also a distant serological relationship. No other serological relationship has been reported between other members of the genus.

The type member of the genus, ACLSV, is characterized by a large biological diversity. Polymerase chain reaction (PCR) has been used to study the variability of ACLSV in the region of overlap between the 50 kDa movement protein and the coat protein genes. Extensive variability is observed between isolates at the nucleotide sequence level, most isolates evaluated showing divergence rates in the 10–20% range from each other. However, at the protein level, the CP is highly conserved between the isolates and variations in the 50 kDa movement protein explain most of the variations in the nucleotide sequence. These results are in keeping with the large biological diversity and the low serological diversity observed between ACLSV isolates. No information on the molecular variability of other trichoviruses has been reported so far.

Virus Epidemiology and Control

In most cases, natural transmission by vectors is not the main cause of long-distance dispersion of the viruses, which is mostly due to human distribution of contaminated material. In regions from which a given virus is absent, quarantine measures are the best protective measure. In affected regions, viral infection is usually controlled through the production and use of virus-free propagation material, along with control of insect vector populations and destruction of virus reservoirs. The most frequently used detection techniques for certification of propagation and planting material include bioassays on susceptible hosts and enzyme-linked immunosorbent assays (ELISA). In addition, detection of dsRNAs associated with viral infection (ACLSV, GVA, GVB, GVD), immunoelectron microscopy (IEM), molecular hybridization and PCR detection methods have been reported for several of these viruses. In the case of ACLSV, it has been possible to obtain virus-free plants through the use of meristem tip culture, thermotherapy or a combination of both, eventually coupled with chemotherapy using agents such as virazole (ribavirin, a cap structure analogue). For GVA and GVB, it is possible to eliminate the viruses from grapevine with the use of meristem tip culture, although with great difficulty, as

these viruses are among the hardest to eliminate from the grapevine.

Future Perspectives

Differences in molecular organization, biological and epidemiologic behavior, between definitive (ACLSV, PVT) and tentative (GVA, GVB, GVC, GVD) trichoviruses, seem to be wide enough to warrant the splitting of the *Trichovirus* genus. The creation of a new genus named *Vitivirus*, which would contain GVA, GVB, GVC, GVD, HLV and CMLV, has recently been approved by the Executive Committee of the ICTV.

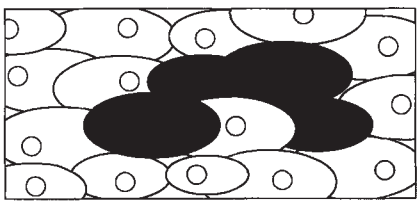
TUMOR VIRUSES – HUMAN



Herbert Pfister, Institute for Virology, University of Koln, Koln, Germany

Bernhard Fleckenstein, Institute for Clinical and Molecular Virology, Friedrich-Alexander University, Erlangen, Germany

Criteria for Causal Relationship between Virus and Cancer

Although there are numerous animal models for viral oncogenesis, only in rare cases is the virus sufficient by itself for tumor induction. In those systems, experimental infection may lead to sizeable tumors within a few weeks, thus leaving no doubt about the etiologic role of the particular pathogen. In humans, none of the viruses incriminated as being oncogenic appear to be independent of other factors. Many years, and often several decades, pass by before tumors develop from primary infection in a small number of infected individuals. Monoclonal tumors arise from the pool of virus-infected cells. This suggests that the virus is, at best, one of several factors that together increase the probability of a cell undergoing malignant transformation. Possible cofactors are chemical or physical carcinogens. Furthermore, the oncogenic activity of the virus may be restricted to a specific genetic background of the patient or to a susceptible stage of cell development. These complex interrelations and the ethical ban on experiments in humans render it extremely difficult to prove the causative role for the virus.

Viruses may contribute to tumor development at various stages of the multistep carcinogenesis process and by different mechanisms. If viral activity is necessary, the virus should be found at some stage in every case in which the tumor occurs. Viral footprints do not, however, have to appear in cancer cells. Human immunodeficiency virus (HIV), for example, significantly increases the risk of development of Kaposi sarcomas and B-cell lymphomas, probably because of its suppressive effect on the immune system. For some herpesviruses and papillomaviruses, a 'hit and run' mechanism has been proposed, which implies virally induced irreversible damage at some point early in tumorigenesis, but no role later on in the maintenance of the malignant phenotype; the virus may therefore completely disappear from the cancer. Viruses may act as mutagens or, even more indirectly, by increasing the risk of mutations via induction of cell proliferation in the course of chronic inflammatory reactions. The etiologic significance of a virus is very difficult to prove in this case. Large-scale and long-term prospective epidemiological studies are the only way to define the risk of a given infection. As the virus may be present for short periods only, the infection is best monitored by the detection of specific antibodies. Previous studies focused on anticapsid antibodies, but with many DNA viruses the production of particles and oncogenic transformation appear to be mutually exclusive,

these viruses are among the hardest to eliminate from the grapevine.

Future Perspectives

Differences in molecular organization, biological and epidemiologic behavior, between definitive (ACLSV, PVT) and tentative (GVA, GVB, GVC, GVD) trichoviruses, seem to be wide enough to warrant the splitting of the *Trichovirus* genus. The creation of a new genus named *Vitivirus*, which would contain GVA, GVB, GVC, GVD, HLV and CMLV, has recently been approved by the Executive Committee of the ICTV.

Criteria for Causal Relationship between Virus and Cancer

Although there are numerous animal models for viral oncogenesis, only in rare cases is the virus sufficient by itself for tumor induction. In those systems, experimental infection may lead to sizeable tumors within a few weeks, thus leaving no doubt about the etiologic role of the particular pathogen. In humans, none of the viruses incriminated as being oncogenic appear to be independent of other factors. Many years, and often several decades, pass by before tumors develop from primary infection in a small number of infected individuals. Monoclonal tumors arise from the pool of virus-infected cells. This suggests that the virus is, at best, one of several factors that together increase the probability of a cell undergoing malignant transformation. Possible cofactors are chemical or physical carcinogens. Furthermore, the oncogenic activity of the virus may be restricted to a specific genetic background of the patient or to a susceptible stage of cell development. These complex interrelations and the ethical ban on experiments in humans render it extremely difficult to prove the causative role for the virus.

Viruses may contribute to tumor development at various stages of the multistep carcinogenesis process and by different mechanisms. If viral activity is necessary, the virus should be found at some stage in every case in which the tumor occurs. Viral footprints do not, however, have to appear in cancer cells. Human immunodeficiency virus (HIV), for example, significantly increases the risk of development of Kaposi sarcomas and B-cell lymphomas, probably because of its suppressive effect on the immune system. For some herpesviruses and papillomaviruses, a 'hit and run' mechanism has been proposed, which implies virally induced irreversible damage at some point early in tumorigenesis, but no role later on in the maintenance of the malignant phenotype; the virus may therefore completely disappear from the cancer. Viruses may act as mutagens or, even more indirectly, by increasing the risk of mutations via induction of cell proliferation in the course of chronic inflammatory reactions. The etiologic significance of a virus is very difficult to prove in this case. Large-scale and long-term prospective epidemiological studies are the only way to define the risk of a given infection. As the virus may be present for short periods only, the infection is best monitored by the detection of specific antibodies. Previous studies focused on anticapsid antibodies, but with many DNA viruses the production of particles and oncogenic transformation appear to be mutually exclusive,

so it might be more promising to screen for antibodies against early nonstructural viral proteins.

Following the classical concepts of virus-induced cell transformation, a tumor virus induces new genetic material into host cells by establishing a persistent infection. The expression of one or more viral oncogenes may then affect cell proliferation and/or differentiation. This can be tested *in vitro* by transformation assays which may result in cells that are tumorigenic in nude mice. If a virus acts in this way, one has to find viral genomes as well as virus-specific transcripts and oncogenic proteins in transformed cells and also in cancer cells if the viral functions are essential for maintaining the malignant phenotype. Tumor viruses may alternatively contribute to carcinogenesis by inserting viral transcription control elements in the vicinity of cellular proto-oncogenes. Viral DNA has to be detectable in these cases adjacent to relevant proto-oncogenes of cancer cells. A harmful integration is typically a very rare event among many random insertions, which is selected for by tumor growth *in vivo*. This mechanism cannot be mimicked by *in vitro* transformation assays.

The physical association of viral genes with tumor cells, in combination with data on oncogenic activity from cell culture or animal experiments, is usually regarded as a most convincing evidence for a role for a virus in human carcinogenesis; however, even better proof of the effective contribution of the virus is obtained from longitudinal epidemiological studies. Finally, the most convincing argument in favor of a necessary role for a tumor virus will be cancer prevention by intervention directed at the virus, such as specific vaccination.

Burkitt's Lymphoma

The malignant lymphoma that was recognized by Denis Burkitt in 1958 as a distinct disease entity in Africa was the first human neoplasm to be linked with a viral etiology. Burkitt's lymphoma (BL) is the most frequent type of childhood tumor found in some hot and humid lowland areas of Central and Eastern Africa, but sporadic cases of the disease, defined by the peculiar histopathology and chromosome translocations, occur throughout the world. Although, in the majority of cases, BL presents in younger children around 8 years of age as a unilateral swelling of the jaw, the disease is usually multifocal at diagnosis due to early metastasis; it characteristically involves liver, kidneys, ovaries or testes, lymphoid tissues in the gut, and endocrine or exocrine glands. In older children and young adults, mostly in the sporadic cases outside Africa, abdominal masses are the first sign of disease.

Lymphoid tumor cell lines derived from BL biopsies led to the discovery in 1964 by Epstein and colleagues of a new herpesvirus, termed Epstein–Barr virus (EBV). The cell lines usually contain EBV genomes as nonintegrated covalently closed circular double-stranded DNA (dsDNA) genomes of about 172 kb in high multiplicity; some lymphoblastoid cell lines carry the EBV genomes integrated into the cellular genomes. EBV is capable of immortalizing human B lymphocytes. The transformed cells express a viral nuclear antigen complex, termed EBNA, which consists of at least six proteins, and in addition latent membrane proteins (LMP). Genetic experiments identified EBNA-2 and LMP as the growth-transforming factors. BL-derived lymphoblastoid cell lines typically express EBNA-1, while, remarkably, the other EBNA proteins and LMP are not detectable. Some lymphoblastoid lines are in a semipermissive state; they produce mature herpesvirus particles spontaneously or can be induced to do so by substances such as the tumor-promoting phorbol ester, phorbol 12-myristate 13-acetate (PMA). BL lymphoma cells and lymphoblastoid tumor cell lines have the surface antigen markers of B lymphocytes; this correlates with a narrow host range of the virus; *in vitro* the virus selectively adsorbs and penetrates by binding of the virion envelope glycoprotein gp350/220 to the complement receptor 2 (CR2; CD21) of B lymphocytes or their precursors. In epithelial cell lines, transcripts encoding CD21 have been detected; however, expression of this receptor on primary epithelial cells remains to be demonstrated.

Indirect immunofluorescence testing with EBV-producing lymphoblastoid cell lines provided the basis for seroepidemiology. It showed that EBV is a ubiquitous virus that occurs in the majority of populations on a worldwide scale. Primary infection can lead to infectious mononucleosis or may remain inapparent without overt disease. BL typically follows early seroconversion during infancy; tumor-bearing children have high antibody titers against structural and early EBV proteins.

In spite of a general association between development of BL and the viral markers, the exact role of EBV in tumor pathogenesis has remained controversial. More than 90% of the tumors in areas of endemic BL contain EBV DNA and express EBNA, and the children have generally high titers of antibodies; however, in sporadic forms of BL that occur in other parts of the world the viral DNA and protein markers are present in only about 15–20%, and elevated antibody titers are not observed in the case of tumors devoid of viral markers. Thus, the presence of EBV persisting in certain compartments of B cells or their precursors may be a risk factor for the develop-

ment of BL, but it cannot be the sole driving force for oncogenesis. So far, it is also difficult strictly to exclude the possibility that EBV is only a passenger of the tumor without contributing to its generation. Common denominators of all BL forms, endemic and sporadic, are certain chromosome translocations. Typically, the gene locus for the proto-oncogene c-*myc* (chromosome 8q29) is juxtaposed to the immunoglobulin heavy chain locus on the long arm of chromosome 14. The break points on the c-*myc* gene are located upstream of the promoter, in the first exon, or between the first and second exon of the proto-oncogene. Less frequently, c-*myc* is translocated to the immunoglobulin (chromosome 2p11) or (chromosome 22q11) light chain genes. It is generally believed that the translocations result in some form of c-*myc* deregulation, perhaps at the level of transcriptional control, mRNA processing or protein synthesis. A unifying concept to explain the role of EBV in BL proposes that the virus initiates the process of tumorigenesis through growth stimulation of a certain B-cell population. Polyclonal B-cell expansion, possibly favoured by malaria-induced impairment of T-cell functions, may enlarge the number of target cells for the necessary key event, chromosome translocation and deregulation of the proto-oncogene c-*myc*. An alternative may be the immortalization by EBV of a malaria-amplified pool of pre-existing c-*myc*-translocated B-cells. In both cases, early EBV infection and viral persistence would be an important risk factor for BL, primarily in its endemic forms.

EBV-Associated Lymphoproliferative Syndromes Other than BL

While primary infection with EBV usually remains without overt disease or manifests as benign infectious mononucleosis, rare cases develop into fatal lymphoproliferations with features of malignant B-cell lymphoma. About half of these cases occur in boys or male adolescents with an inherited defect in the immune system, termed X-linked lymphoproliferative syndrome (XLPS) or Duncan syndrome. The other cases are sporadic without a sex preponderance. Proliferating cells were shown to contain persisting EBV DNA and to express the viral latency genes EBNA and LMP. The infiltrating B-cell derivatives have been shown to be polyclonal in some cases; other processes appeared oligoclonal. The defects of the immune system leading to XLPS or fatal mononucleosis are not precisely known, as the children are not generally immunodeficient. Possibly it relates to functional impairment of natural killer (NK) cells, cytotoxic T cells or changes in the B cells that are the targets of EBV-induced growth stimulation. Notably, some of the patients do not have the normal antibody response to EBV antigens, particularly EBNA-1.

EBV sometimes induces fatal lymphoproliferative disease or lymphoma in globally immunodeficient individuals, either in cases of severe congenital immunodeficiencies or acquired immunosuppression in transplant recipients. Diffuse B-cell lymphomas, often localized in the central nervous system or other extranodular sites, are a frequent cause of morbidity and mortality in acquired immunodeficiency disease (AIDS). The tumors are often polyclonal initially, as they arise from several independent transformation events; they gradually evolve into an oligoclonal or even monoclonal proliferation. The tissues usually have the markers of persisting and actively transforming EBV, including EBNA and LMP expression. Similarly, the lymphomas of owl monkeys (*Aotus trivirgatus*) and cotton top marmosets (*Saguinus oedipus*) that are experimentally inoculated with EBV are considered to be immediate outgrowths of EBV-transformed B lymphoblasts. Presumably, deficiency in certain immune effector mechanisms, genetically determined or acquired, which are necessary to eliminate EBV-transformed B lymphoblasts from the body, leads to progressive lymphoproliferative diseases. On occasion it has been reported that human lymphomas with T-cell markers, such as nasal T-cell lymphomas, contain persisting EBV. A viral etiology of those tumors remains difficult to establish; the cell surface receptor for EBV on T cells is not yet known.

EBV genomes have been detected more recently in a large proportion (up to 60%) of cases of Hodgkin's disease. Distinct LMP-specific membrane and cytoplasmic staining has been found exclusively in Hodgkin and Reed–Sternberg cells of virus DNA-positive specimens, while EBNA-2 is not detected. This suggests a pattern of EBV gene expression different from that of B lymphoblastoid cells and BL. In view of the transforming potential of the LMP gene, it suggests a causal role of EBV in the case of Hodgkin's disease. Viral persistence and preferential expression of LMP has also been seen in some cases of CD30+ anaplastic large cell lymphoma, a heterogeneous group of high-grade malignant lymphomas at the borderline between Hodgkin's and non-Hodgkin's lymphomas. The role of EBV in angioimmunoblastic lymphoadenopathy remains to be determined.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinomas (NPCs) are highly malignant neoplasms which mostly occur in adults between the ages of 20 and 50 years. Though the incidence is generally low in Europe and North

America, NPC is a frequent tumor in southern parts of China, in Tunisia, Central Africa and in the native population of Alaska. The prognosis is poor; most frequently, NPCs present with early metastasis into cervical lymph nodes and the skull. The association of EBV with NPC has been clearly established. Viral DNA is regularly found in all cases of poorly differentiated or lymphoepithelial NPC. Studies on the structure of the persisting episomal EBV genomes have indicated that the neoplastic epithelial cells contain a single clone of EBV in each case. Carcinoma cells consistently express EBNA-1 and, frequently, latent membrane proteins, while the EBNA-2 gene is not transcribed. There is a strong serological association between EBV and NPC. The sera of patients with NPC typically have high titers of immunoglobulin A (IgA) antibodies to structural viral components, latency proteins and replicative antigens. A similar association was found between EBV and several rare tumor forms that are also assumed to be derived from embryonic branchial cleft remnants. High IgA titers against EBV proteins and persisting viral DNA in the tumors have also been found in some forms of neoplasms from the parotid, thymus and lymphatic tissue of the oropharynx.

T-Cell Leukemia

Adult T-cell leukemia (ATL) was the first human disease to be causally linked to a retrovirus. ATL, first described as a frequent tumor form in southern regions of Japan, is a distinct disease entity that occurs in many other parts of the world, including Central Africa and the Caribbean basin. Epidemiology clearly demonstrated the association with human T-cell leukemia virus type 1 (HTLV-1). Serological surveys showed that antibodies against HTLV-1 were regularly found in leukemia patients, and frequently in their close contacts. Tumor cells mostly contain integrated proviral DNA; clonality of the tumor correlates with the monoclonal or oligoclonal integration pattern of the viral genomes. HTLV-1 can be detected by polymerase chain reaction (PCR) in peripheral lymphocytes of latently infected persons and ATL patients. If peripheral mononuclear blood cells are infected with HTLV-1 in cell culture, T cells are immortalized, resulting in continuous growth in suspension culture. The cell surface marker phenotype largely resembles the tumor cells which express high levels of IL-2Rα (α chain of the interleukin-2 receptor) and CD4. HTLV-1 has also been shown to be oncogenic in animal model systems.

ATL usually develops 30–50 years after perinatal infection with HTLV-1. The virus is most frequently transmitted by breast feeding and sexual contacts. The malignancy, arising after the long carrier phase, may be manifested as a lymphoma or acute leukemia, with high white blood cell count and a poor prognosis, usually being fatal within 6–8 months. Smoldering and chronic forms of ATL can convert into an acute course. Approximately 3% of the perinatally infected will develop ATL during their lifetime. Unlike retroviruses of other subgroups, HTLV-1 contains a 1.6 kb proviral genomic region coding for at least two regulatory polypeptides, the 40 kDa transcriptional transactivator Tax and the 27 kDa phosphoprotein Rex, which is required for the cytoplasmic targeting for structural protein mRNAs. Tax, a transactivator of the viral promoter and modulator of numerous cellular genes, appears to mediate the oncogenic effects of the virus; it induces polyclonal expansion of CD4+ T lymphocytes. The early virus-induced helper T-cell proliferation may precede a long period of tumor progression as growth becomes autonomous, turning independent of Tax expression.

HTLV-2, which frequently occurs in some tribes of native Americans, has been isolated repeatedly from the T-cell variant of hairy cell leukemia, but the etiology of T-cell malignancies by HTLV-2 has not been substantiated further until now. Like type 1, HTLV-2 is increasingly spread among intravenous drug abusers in European and American cities.

Genital Cancer

Clinical studies, and especially data from molecular biology, suggest that certain types of human papillomavirus (HPV) are of etiological importance for genital cancer. In developing countries, carcinoma of the cervix uteri is the most frequent type of female cancer. HPV DNA can be found in 80–90% of the tumors, and the early genes E6 and E7 are usually expressed. The most prevalent type in epidermoid carcinomas is HPV 16. HPV 18 may be preferentially associated with adenocarcinomas. Other types like HPV 31, 33, 35, 39, 45, 51, 52 or 56 have been detected in a few cases of squamous cell carcinoma each. HPV DNA was also demonstrated in the less prevalent carcinomas of the vulva, the vagina, the penis and the anus; HPV 16 is again the most frequent type, followed by HPV 18, HPV 6 and HPV 11. The significantly elevated prevalence of individual HPV types in cancers compared with the normal population led to the concept of HPVs with higher (HPV 16, 18, 45) and lower (HPV 6, 11) carcinogenic potential. This grouping is supported by first follow-up studies of the natural history of precancerous lesions associated with different HPVs and by differences in the *in vitro* transformation of keratinocytes.

HPV 16 and other members of the high-risk

papillomavirus group immortalize primary human keratinocytes and induce resistance to differentiation stimuli. Histological abnormalities can be observed in stratifying keratinocyte cultures that resemble those in precancerous, intraepithelial lesions *in vitro*. The cells are not tumorigenic in nude mice initially, but quickly change to an aneuploid karyotype, which is in keeping with frequently occurring abnormal mitoses in HPV 16-positive lesions. At higher passage level, malignant clones reproducibly arise, which indicates that HPV infection is sufficient to induce cancer cells in combination with additional spontaneous or virus-induced modifications. The viral genes E6 and E7 are required to trigger these effects. They encode proteins that are transactivators of transcription and are able to interact with the cellular proteins p53 and p105-RB (the retinoblastoma protein), respectively. The known cell-cycle regulating functions of these proteins are likely to be disturbed by this complex formation with the viral proteins. The E6 and E7 proteins of low-risk viruses display much lower affinities to the cellular proteins, in parallel with a lower or not detectable transforming potential *in vitro*.

Much attention has been paid to the possible role of viral DNA integration in tumor progression. HPV 18 DNA appears integrated into the cellular genome in almost all cervical cancers, and HPV 16 DNA in about two-thirds of the cases. This is in contrast with benign and premalignant lesions, where the viral DNA usually persists extrachromosomally. There is no evidence for a specific integration site, but HPV DNA has been repeatedly detected in the vicinity of the *myc* proto-oncogene in combination with an overexpression of the cellular gene.

The opening of the circular viral genome during integration frequently disrupts the regulator genes E1 and/or E2. Engineered mutants in these genes revealed increased transformation efficiency *in vitro*, so that naturally occurring inactivation may quantitatively enhance cell transformation.

In addition to the disruption of viral control mechanisms, there seems to be a failure of a cellular regulation of viral gene expression in malignant cells. The analysis of hybrids between HPV DNA-positive cervical cancer-derived cells and primary keratinocytes suggested that an inducible control system, possibly encoded by chromosome 11, can normally suppress viral transcription.

The persistence of viral DNA and the continual expression of transforming genes in advanced cancers suggest that HPV functions are also involved in the maintenance of the malignant phenotype. An experimental suppression of E6 and E7 expression inhibited the proliferation of HPV-positive cervical cancer cell lines and reduced the cloning efficiency in semisolid medium, thus indicating that the viral proteins are still modulating the growth of malignant cells.

The genital tract HPVs are also responsible for many HPV infections at extragenital mucosal sites such as the oral cavity and most notably the larynx. However, cancers arising in this field only rarely harbor HPV DNA. Case reports describe the presence of HPV 2, 6, 11, 16 or 30 in carcinomas of the tongue, the oral and nasal cavities, the larynx, the hypopharynx and the lung. The reason for the striking difference between the genital and aerodigestive tracts is not known. Either the etiology of oral and laryngeal cancers is unrelated to HPV, or the relevant HPV types are not yet characterized or the viral DNA is no longer necessary for cancer cells and is finally lost.

Skin Cancer

HPVs induce various proliferative skin lesions that are benign, like plantar, common and flat warts. An association between HPV and skin cancer becomes obvious in epidermodysplasia verruciformis (EV). EV patients are infected with a subgroup of HPVs, which induce characteristic persisting macular lesions disseminated over the body. Many EV patients develop squamous cell skin carcinomas, mainly at sun-exposed sites, which suggests a cocarcinogenic effect of ultraviolet light. The DNA of HPV 5 or 8 persists extrachromosomally in high copy number in more than 90% of the cancers. HPV14, 17, 20 or 47 were occasionally detected. The prevalence of specific HPVs is in striking contrast with the plurality of HPV in benign lesions and has been interpreted as reflecting a higher oncogenic potential of these types.

Oncogenes of EV-HPVs were mainly identified by their effects on rodent fibroblasts. The E6 gene induces altered morphology, reduced serum requirement, and anchorage-independent growth. In contrast with genital HPV, no complex formation could be detected between HPV8 E6 and the cellular p53 protein, which suggests different strategies of transformation. The HPV8 E2 gene, which encodes a transactivator of transcription, leads to reduced serum requirement and growth in soft agar. There is some indication of an increased transforming activity of E6 from HPV5, 8 and 47 when compared with E6 from related HPVs, which have not yet been detected in carcinomas.

A high prevalence of HPV DNA in squamous and basal cell carcinomas of the skin, particularly of immunosuppressed but also of immunocompetent patients, has most recently been demonstrated by highly sensitive PCRs. Evidence is accumulating for many novel HPV types related to EV HPVs and

cutaneous types. Genital mucosal HPV types have also been found. That there is a strong association between genital HPV16 and squamous cell neoplasms from the finger is remarkable. Individual skin tumors were frequently noted to be infected by several HPVs. No single HPV type predominates in skin cancers of non-EV patients, so far as is known. The need for highly sensitive detection methods suggests that HPV DNA persists at very low concentrations in many skin cancers, perhaps at less than one genome copy per cancer cell. The relevance of these findings to the pathogenesis of cutaneous cancer remains to be determined. The possibilities discussed above for carcinomas of the aerodigestive tract are also valid for skin carcinomas.

Hepatocellular Carcinoma

Primary liver cancer is among the most common fatal malignancies of humans worldwide. An association with hepatitis B virus (HBV) from the hepadnavirus family was suggested by the geographical coincidence of a high incidence of hepatocellular carcinoma in southeast Asia and equatorial Africa with high rates of chronic HBV infections, generally contracted congenitally. Prospective studies demonstrated about a hundredfold increased risk of hepatoma among carriers of the HBV surface antigen (HBsAg). Integrated HBV DNA can be detected in a large proportion of the tumors from high-risk areas and in hepatoma-derived cell lines.

Liver cancer usually develops only after several decades of chronic HBV-induced hepatitis and may thus be triggered by accumulating genetic damage due to inflammation and continuous cell regeneration. A specific contribution of HBV might be expected from *cis* effects following integration of viral DNA, but except for a few case reports no consistent evidence has been obtained for the activation of particular proto-oncogenes. A transactivation of transcription may be more relevant; this can be achieved by the viral X protein, the large surface protein and a truncated $preS_2/S$ protein. The viral $preS_2/S$ gene, which normally encodes a surface protein, appears frequently disrupted in cancers as a consequence of DNA integration and then gives rise to the transactivator. All HBV transactivators exert pleiotropic effects via the protein kinase C/raf-controlled signal pathway, finally activating transcription factors such as AP-1 and NF-κB and proliferation. The analysis of viral integration patterns and functional assays suggest that at least one transactivator may function in most hepatomas. Multifocal nodular hyperplastic liver disease developed in mice transgenic for the HBV surface protein genes, and liver cancer arose in mice transgenic for the X gene. Mutations in the p53 tumor suppressor gene occur in about 30% of human hepatomas. They are observed more often in countries with dietary contamination by mutagenic aflatoxin and seem to be a late event in liver carcinogenesis. The complex formation between p53 and X protein as well as truncated $preS_2/S$ may be relevant to p53 inactivation in patients with wild-type p53. The X protein was also shown to interact with elements of the DNA repair system, which may increase the mutation rate of p53.

HBV is the first human tumor virus against which vaccination programs have been initiated on a broad basis. First signs of a decrease in the incidence of hepatoma in populations vaccinated in the 1970s substantiate the viral role in cancer development.

More recently, seroepidemiological evidence was obtained for a correlation between hepatitis C virus (HCV) infections and hepatoma. Antibodies against HCV were detected in between 13% and over 80% of liver cancer patients around the world. Over 60% of acute hepatitis C becomes chronic and may progress to cirrhosis and hepatocellular carcinoma. Latency periods between primary infection and cancer are usually measured in decades but in some cases the intervals are rather short (5–10 years). The cumulative prevalence of hepatoma in cirrhotic HCV-infected patients is over 50%, indicating that HCV substantially increases the risk of hepatocellular carcinoma. HCV is related to flaviviruses and pestiviruses and is the first human tumor-related virus with an RNA genome and no DNA intermediate during replication. The role of the virus in carcinogenesis is not yet clear. Liver injury during chronic hepatitis may be responsible for malignant conversion but there is also some evidence that HCV is more directly involved. HCV appears to persist and replicate in hepatocytes during malignant transformation. The core protein has been shown to cooperate with the *ras* oncogene in transformation of primary rat embryo fibroblasts, to activate transcription of the c-*myc* proto-oncogene and to suppress the c-*fos* promoter. As regulation of cell death is now appreciated as an important factor in the pathogenesis of human malignancies, it is interesting to note that the HCV core protein can suppress cisplatin-mediated apoptosis in human cervical epithelial cells. Core gene variants that predominate in cancerous versus noncancerous lesions may point to a different oncogenic potential of various representatives of the HCV quasispecies. Experimental expression of the nonstructural protein NS3, a serine proteinase, leads to transformation of NIH3T3 cells and it has been speculated that NS3 may cleave and activate cellular proto-oncogene products.

Kaposi's Sarcoma

Kaposi's sarcoma (KS) was first described by Moriz Kaposi as 'multiple idiopathic pigmented sarcoma of the skin' in 1872. It is a multifocal, proliferative lesion of spindle-shaped cells with slit-like vascular spaces in skin and mucous membranes of the oral cavity, gastrointestinal tract and pleura. The tumor cells, termed KS spindle cells, are thought to be of endothelial origin. These tumor cells are likely not monoclonal in the early stages of KS. The 'classic' form of KS is a rare and often benign tumor of elderly males, mostly of Mediterranean or Jewish descent. Usually, the skin lesions of classic KS arise multifocally on the lower limbs and develop from patches to plaques and nodules over several years.

More aggressive, disseminated forms of KS have been described in Africa in the 1950s, and later in immunosuppressed organ transplant recipients. The etiology of this peculiar semimalignant neoplasia has always been an enigma, the favored hypothesis being a model where proliferation and transformation of endothelial cells are triggered in a paraendocrine manner by a host of proinflammatory cytokines and growth factors. Although this model is in agreement with some of the clinical features of this uncommon malignancy, it does not answer the question of what initiates the abnormal release of cytokines. An early hypothesis linked KS to infectious agents. The epidemiology of KS amongst patients with AIDS favored the latter hypothesis.

During the first decade of the AIDS epidemic, KS was at least 20 000 times more common in patients with AIDS than in the general population. Most notably, 20% of homosexual and bisexual patients developed KS, but only 1% of men with hemophilia. By employing the PCR-based representational difference analysis (RDA), Chang, Moore and colleagues searched for DNA sequences present in KS lesions but absent from uninvolved skin. This work resulted in the identification of DNA fragments of a novel human herpesvirus, now termed human herpesvirus 8 (HHV-8) or Kaposi's sarcoma-associated herpesvirus (KSHV). Numerous studies soon revealed that HHV-8 DNA is invariably found in all types of KS, where the majority of KS spindle cells are positive for HHV-8 DNA and transcripts. Searches in normal and diseased tissues other than KS showed that, at least in Northern Europe and the USA, HHV-8 DNA is infrequently detected in Caucasians. Only body cavity-based lymphomas (BCBL) and multifocal Castleman's disease, two rare B-lymphoproliferative disorders, were unequivocally HHV-8 DNA positive.

HHV-8 cell lines established from AIDS-associated cases of BCBL allowed for first studies of HHV-8 serology. In summary, the numerous studies available today clearly show that HHV-8 seropositivity closely reflects the risk of KS development. Antibodies against HHV-8 are usually detectable in 75–95% of KS patients but only in 1–5% of healthy blood donors in Northern Europe and the USA. Although the virus appears to be much more prevalent in Africa and Southern Europe, HHV-8 is closely linked to Kaposi's sarcoma. This is based both on seroepidemiology and DNA detection by PCR and *in situ* hybridization, suggesting a causal relationship between HHV-8 infection/reactivation and KS development.

Studies of HHV-8 genome structure and function also support the hypothesis of viral etiology. The complete genomic sequence revealed that HHV-8 belongs to the rhadinovirus subgroup of herpesviruses, whose best-characterized member is herpesvirus saimiri, an oncogenic virus of New World primates. The HHV-8 genome encodes an unusually high number of genes that have been captured from the host cell. Amongst them are several genes known to be involved in regulation of cell growth (D-cyclins) and apoptosis (bcl-2, v-Flip), signal transduction (IL-6, β-chemokines, IL8-receptor, interferon regulatory factor). Several HHV-8 genes have been found to have transforming potential in cell culture. Although further studies are required to substantiate the mechanism of oncogenesis by HHV-8, it becomes increasingly evident that HHV-8 is a causal factor for KS development.

Future Perspectives

Some two decades ago, only one human virus, EBV, was accepted as a candidate human tumor virus. Since then, the oncogenic potential of human papillomavirus, hepadnavirus and retrovirus has been clearly established. Now it has become evident that virus infections that may result in tumor formation are quite frequent. On a worldwide scale, more than 20% of all malignant tumor forms in females and about 8% of the tumors in males may be the late consequence of a previous virus infection. In most cases, long latency periods of many years or several decades elapse between primary infection by tumor viruses and first symptoms of cancer (**Table 1**). All human tumor viruses are widespread in the world population. They contribute to tumor disease, mainly by initiation of oncogenesis, but are not sufficient by themselves to cause a tumor. Thus, all human tumor viruses are important risk factors for cancer, but require additional events. This implies that mere proof of an infection with a tumor virus is of limited value for the management of patients and cancer prevention. Specific diagnostic tests have to be

Table 1 Latency periods for virus-associated tumors

Virus	*Tumor*	*Latency period (years)*
Hepatitis B virus	Hepatocellular carcinoma	30–50
Human T-cell leukemia virus type 1	T-cell leukemia	20–50
Human herpesvirus 8	Kaposi's sarcoma in immunosuppression	3–10
Human papillomavirus 5, 8	Squamous cell skin carcinoma of patients with epidermodysplasia verruciformis	5–15
Human papillomavirus 16, 18	Cervical cancer	5–25
Human papillomavirus 16, 18	Penile and vulval carcinoma	20–50
Epstein–Barr virus	Burkitt's lymphoma	3–12
Epstein–Barr virus	Nasopharyngeal carcinoma	30–40

Modified from zur Hausen H (1986) Intracellular surveillance of persisting viral infections. *Lancet* ii: 489.

designed which evaluate parameters of the viral infection more closely related to malignant conversion. Often the viruses cannot be traced unambigously in the tumor; conventional virus isolation procedures usually remain unsuccessful: tumor tissues are usually not infectious. The neoplastic phenotype of HPV-positive genital carcinoma cells seems to be affected by viral functions, which raises the prospect of virus-specific pharmacological interference for adjuvant cancer therapy. In many cases, however, continuous viral expression is not detectable in malignant tumors. Primary infection and initial growth transformation apparently lead, through tumor progression, to a constitutive form of proliferation where viral gene products are not necessary for growth and the receptor molecules may no longer be functional. Thus, even in the longer term, antiviral gene therapy may not be successful for the treatment of the tumors, as they have become autonomous. Also in the distant future, the most efficient method for prophylaxis of virus-induced human tumors will probably be vaccination trials to prevent primary infection with the viruses.

TYMOVIRUSES

Adrian Gibbs, Research School of Biological Sciences, Australian National University, Canberra, Australia

History and Distinguishing Features

Yellow mosaic and vein clearing diseases of several species of brassica found in the UK in the 1940s, were found to be caused by a stable sap and beetle-transmitted virus that was named turnip yellow mosaic virus (TYMV). Other similar viruses have been isolated since and found to form a clearly definable virus genus, which has been named *Tymovirus*, after the first found and type species. They have not been assigned to a family.

Around twenty tymoviruses are known. They infect dicotyledonous angiosperms, cause yellow mosaic diseases, are transmitted by beetles, but rarely by seed. They are readily transmitted experimentally by sap inoculation. Their virions are isometric and 25–30 nm in diameter. Their genomes are single molecules of single-stranded messenger-sense RNA about 6300 nucleotides long; 34–42% cytidylic acid. Their 5′-termini are capped, and most have a tRNA-like 3′-terminus. Their genomes replicate in small vesicles which form as invaginations of the outer membrane of chloroplasts.

Geographic Distribution

Tymoviruses have only been isolated from dicotyledonous plants, most of them wild. Most tymovirus species have natural and experimental host ranges restricted to one or a very few plant families and their geographic ranges are also mostly restricted. The species (and their normal geographic ranges) are Andean potato latent (the Andes), belladonna mottle (Europe), cacao yellow mosaic (Sierra Leone), calopogonium yellow mosaic (Malaysia), chayote mosaic (Central America) clitoria yellow vein (East Africa), desmodium yellow mosaic (USA), desmodium yellow mottle (Singapore), dulcamara mottle (UK), eggplant mosaic (Antilles), erysimum latent (Europe), kennedya yellow mosaic (Australia), melon rugose mosaic (Yemen), okra mosaic (Ivory Coast), ononis yellow mosaic (UK), passiflora yellow mosaic (Brazil), physalis mosaic (USA) (this virus was first called belladonna mottle virus-Iowa strain), plantago mottle (USA), scrophularia mottle (Germany), turnip yellow mosaic (Australia and Europe), voandezia necrotic mosaic (West Africa) and wild cucumber mosaic (USA) viruses, and also poinsettia mosaic virus (worldwide), which is a tentative tymovirus species.

Poinsettia mosaic virus has been carried internationally by the horticultural trade, and closely related, but distinct populations of turnip yellow mosaic virus have been found in Europe and Australia. However, every other tymovirus species seems to be confined to a single continent, and reports of wider distributions result from the use of serological tests, which do not adequately distinguish between tymovirus species. For example belladonna mottle virus was initially reported from both Europe and the USA, and clitoria yellow mosaic virus from both East Africa and Malaysia. However, in both instances, gene sequencing showed that the second record was not the same species; these are now known as physalis mosaic and calopogonium yellow mosaic viruses, respectively.

Host Ranges

Tymoviruses have been isolated from dicotyledonous plants; there is only one unconfirmed report of a tymovirus experimentally infecting a monocotyledonous plant. Most infect plants that use the C3 photosynthetic pathway, and only a very few C4 plants are susceptible. Individual tymoviruses have restricted natural host ranges and usually infect a few species from one family. Most have been isolated from wild plants, whereas species of all other genera/groups of plant viruses have mostly been isolated from crop plants. Most viruses that naturally infect wild plants cause few or no symptoms and do not affect growth, however tymoviruses cause bright yellow mosaic symptoms, and depress the growth of their wild natural hosts, but at least one such species, kennedya yellow mosaic virus, compensates for such damage by protecting its wild plant host against herbivores.

Tymoviruses have broader, but still restricted, experimental host ranges. They infect more species from the family of their natural hosts than from other families, and also a greater proportion of plant species from the same major division of the dicotyledons as their natural hosts than species from other divisions.

Molecular Biology

Virions

Tymoviral virions are isometric c.28 nm in diameter. Their shells are regular icosahedra of 180 subunits of a single protein species that cluster in fives or sixes in the surface of the virion shell to form the 32

morphological subunits, which can be seen in negatively stained virions. Purified virions sediment as two components. Those which sediment at 110–120S are nucleoprotein and each contains a single copy of the viral genome, which constitutes 35% of their mass. Some also contain a variable number of tRNA or virion protein mRNA molecules, and a variable number of polyamine molecules. The other virion component sediments at 50–55S and consists of the protein shell of the virion, and those of the solanaceous tymoviruses and ononis yellow mosaic virus also contain variable amounts of nongenomic RNA molecules.

Genome and encoded proteins

Tymoviral genomes are single molecules of about 6300 nucleotides of single-stranded RNA, and, when separated chemically from the virions, they are infectious. The genomes have a characteristic nucleotide composition; G 15–20%, A 17–24%, C 31–42% and U 20–29%. There are untranslated regions of the genome at both termini and between some open reading frames (ORFs) but these constitute only about 3% of the genome. They have a 5′-terminal m7GpppGp cap structure. Most tymovirus genomes also have a 3′-terminal sequence that can form a tRNA-like structure and that can be specifically valylated, but three tymoviruses, belladonna mottle, dulcamara mottle and erysimum latent, have a 3′-terminal sequence that can only form part of a tRNA-like structure, and dulcamara mottle has a 3′-terminal poly(A) sequence. All tymovirus genomes have three ORFs that are of similar size and arrangement in the genome. The largest is also the most conserved and spans most of the genome. It encodes a large replicase protein (RP: 1747–1874 residues, M_r 194 000–210 000) that has sequence motifs (NH_2- to -COOH-) characteristic of a *N*-methyltransferase, a papain-like protease, a helicase/nucleotide-binding fold and a replicase. Overlapping the 5′-terminal third of the RP, and always starting seven nucleotides to the 5′ side of the RP start codon, is an ORF that encodes an overlapping protein (OP) of variable length (440–750 residues, M_r 49 000–82 000) that is the least conserved of the proteins encoded by the virus. The OPs are very basic (pI 10.9–11.9), and may aid systemic spread of the virus in the plant. The third ORF, at the 3′ end of the genome, is of the virion protein (VP: 188–202 residues, M_r 19 600–21 500). The VP ORF is in different reading frames, relative to the RP/OP gene doublet, in different tymoviruses, and, in some, overlaps by a few nucleotides the 3′-terminal region of the RP ORF.

A region of about 50 nucleotides to the 5′ side of the start of the VP ORF, and hence in the 3′-terminal part of the RP ORF, is similar in all tymoviruses and two blocks of it are particularly conserved. One, which has been named the 'tymobox', is probably the VP mRNA promoter. It is 28–44 nucleotides from the start of the VP ORF and is 16 nucleotides in length. Eleven tymoviruses have tymoboxes with the same sequence (-GAGUCUGAAUUGCUUC-), there is a single nucleotide difference in three, and there are four differences in the tymobox of wild cucumber mosaic virus. Part of the tymobox sequence encodes the sequence, -ELL-, found near the C-terminus of all tymoviral RPs. The second conserved region occurs between the start of the VP ORF and the tymobox, seven or eight nucleotides from the latter. This is the translation initiation box -CAAU- (-CAAG- in one), and includes the 5′-terminal -AAU- found in the VP subgenomic mRNA of three tymoviruses.

The tymobox is useful as a genus-specific target for oligonucleotide probes and primers to isolate and sequence the VP gene of most tymoviruses.

Virion protein structure

The structure of the genome-containing virions of TYMV has been determined to a resolution of 0.32 nm. Each virion has a shell built from 180 identical VP molecules surrounding the folded genome. Each VP molecule is of 189 amino acid residues arranged as an elongated eight-stranded antiparallel β-barrel (jellyroll). The VP molecules are arranged in the shell as pentameric or hexameric clusters at the vertices of an icosahedron with deep furrows at the quasi-threefold axes; the outer radius of the shell is 15.9 nm from its center with the furrows at 12.1 nm. The C-termini of the VP molecules are external to the virion, and the N-termini are internal, and those grouped around the sixfold axes interact to form an annulus. During infection, histidine residues inside the VP may become deprotonated to aid disassembly. The genomic RNA also has some defined structure, possibly partial icosahedral symmetry, and there is a solvent-filled space of radius 2.5 nm at the center of the virion.

Only 73 of the amino acid residues of the VP are exposed at the surface of the virion, however not all are equally immunogenic or antigenic, indeed, despite being internal, the N-terminal peptide is a dominant immunogen. Thus the serological behavior of tymovirus virions is complex, involves only a small number of the amino acid residues of the VP, and may be an unsubtle indicator of tymovirus relationships.

Replication Strategy

Tymovirus genomes probably replicate in the vesicles

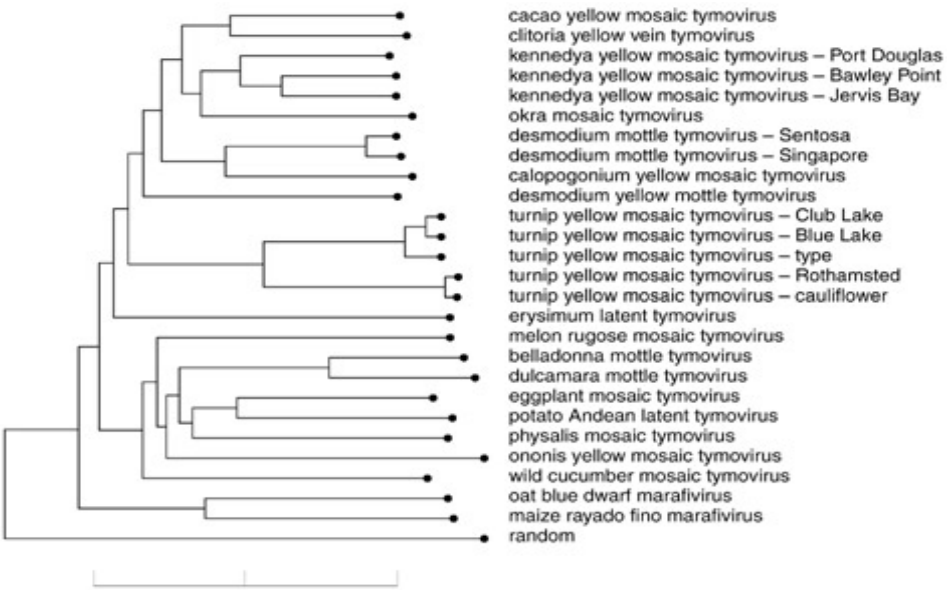

Figure 1 A neighbor-joining tree calculated from the percentage nucleotide differences (excluding gaps) between the virion protein genes of 24 tymovirus isolates and two marafiviruses aligned by the program CLUSTAL V (using default parameters). A random sequence was generated from the alignment by choosing randomly among the different nucleotides that occurred at each position in the alignment, and this was used as an outgroup. The bar represents a 20% nucleotide difference uncorrected for multiple changes.

that form in the margins of the chloroplasts of tymovirus-infected plants; these vesicles have been shown to contain the viral replicase complex and double-stranded RNA 'replicative intermediate' of the virus. It is probable that the OP and RP ORFs are translated directly from genomic RNA, but that of the VP from a subgenomic mRNA is transcribed from the negative genomic strand using the tymobox sequence as a promoter. Tymovirus proteins are produced by cytoplasmic ribosomes. The RP polyprotein is probably *cis*-hydrolyzed into its component parts by a viral protease in the central region of the RP; the first cut is between the helicase and replicase regions, and then the helicase and protease are separated.

Virions of the virus assemble at or near where the chloroplast vesicles connect with the cytoplasm. Virions and genome-free virion shells are found particularly around patches of vesicles, but also throughout the cytoplasm and all parts of infected plants. Virion shells may also accumulate in large numbers in nuclei.

Taxonomy and Evolution

Figure 1 shows a neighbor-joining tree calculated from the nucleotide sequence differences of the virion proteins of 24 tymoviruses. It can be seen that different isolates of each tymovirus species always cluster together, and that species fall into larger groupings that mostly correlate with the family of the plant from which they were isolated. The largest of the groups includes most of the tymoviruses isolated from legumes (**Fig. 1**), these form a sister group to the brassica-infecting tymoviruses, and the remaining major group includes all those isolated from solanaceous plants and cucurbits. The tymoviruses form a sister group to the marafiviruses. The replicase genes are known for seven tymoviruses and one marafivirus and their sequence relationships are totally congruent with those shown by the virion protein genes.

Tymoviruses are variable. Tymovirus isolates that infect the same range of plant species and cause closely similar symptoms are considered to be isolates of a single species. However, they may have virions that differ serologically and in their surface charge, and have genomes with sequence differences of up to 27% (turnip yellow mosaic virus). Some species have distinct subspecies, for example there are two subspecies of turnip yellow mosaic (the type and cauliflower subspecies), and three of kennedya yellow mosaic (the Port Douglas, Jervis Bay and Bawley Point subspecies).

The marafiviruses, which include oat blue dwarf (OBDV), maize rayado fino and Bermuda grass etched line viruses, form a 'sister' genus of the tymoviruses, and are closely related to them. All have particles of

similar size and morphology, and the genome of OBDV has been found to be similar in size (6.509 kb), composition (42.8% C) and sequence to those of the tymoviruses; the complete replicase polyproteins of five tymoviruses differ from one another by up to 65% in sequence, whereas that of OBDV differs from the tymoviruses by 70%. The OBDV genome has a 'tymobox' sequence with 13/16 nucleotide identity to those of most tymoviruses and it encodes the same -ELL- motif. Marafiviruses differ from tymoviruses in several biological features. They mostly infect monocotyledonous plants (only OBDV is known to infect dicotyledons), they seem only to replicate in the phloem or in enations formed by hyperplasia of the procambium of the phloem, and their replication is not associated with chloroplasts or other cell organelles. They have leafhopper vectors and replicate in those vectors. Marafiviruses also differ significantly from tymoviruses in their molecular biology. Their genome does not encode an overlapping protein like that of the tymoviruses, and their virions have proteins of two sizes, that are mostly identical in sequence; the larger is produced by hydrolysis of the genomic transcript and the smaller is transcribed from a subgenomic mRNA, and lacks the N-terminal sequence of the larger protein.

The sequence motifs of the replicase protein (RP) of tymoviruses and marafiviruses also show clear similarities to those of the RPs of the capilloviruses, carlaviruses, closteroviruses and potexviruses, indicating that the RPs of all these viruses have a common ancestor; the RPs of the tymoviruses and OBDV differ from those of potato X and other potexviruses by 90–95% in sequence. The sequence motifs of the RPs also indicate that they may be very distantly related to the 'alpha-like viruses', which include alpha-, furo-, hordei-, rubi-, tobamo-, tobra- and tricornaviruses. Some of these viruses have isometric or bacilliform virions, which may have virion proteins that have a similar β-barrel (jellyroll) structure to those of the tymoviruses, and hence their VP genes may have a shared ancestor. However, all the viruses with filamentous or rod-shaped virions probably have four-stranded α-helix virion proteins encoded by genes unrelated to those encoding the jellyroll VPs. None of the viruses with replicase genes related to those of the tymoviruses has an overlapping (OP) gene, and hence the OP gene probably arose *de novo* in the 'proto-tymovirus'.

Epidemiology and Transmission

The known natural vectors of tymoviruses are all chrysomelid beetles (Halticidae and Galerucidae) except that of TYMV in Australia, which is a pill beetle (Byrrhidae). The vector beetles prefer feeding on plants that are tymovirus-infected rather than virus-free. A few tymoviruses are transmitted by the seed of a limited number of plant species, but not by their pollen. All may be transmitted by sap inoculation, but none by plant contact.

Pathogenicity and Symptoms

Tymoviruses cause yellow mosaics, vein-clearing and mottles. All plants infected with tymoviruses develop small characteristic vesicles within their chloroplasts attached to their outer membranes. These vesicles form as invaginations of the outer chloroplast membranes, and the bilayer membranes of those membranes and the vesicles are confluent.

Prevention and Control

Tymoviruses have mostly been found in uncultivated plants, and none is known to cause economically important diseases of crops.

UMBRAVIRUSES

DJ Robinson and **AF Murant**, Scottish Crop Research Institute, Invergowrie, Dundee, UK

History

Several of the viruses now placed in the genus *Umbravirus* have been known since the early days of plant virology but, because of their peculiar properties and the attendant difficulties in working with them, most have been little studied. The first to be described was tobacco mottle virus (TMoV), reported from Zimbabwe and Malawi by K. M. Smith in 1946. TMoV was shown to be mechanically transmissible but to depend on a helper virus that is not mechanically transmissible, tobacco vein distorting virus, for transmission by aphids in a persistent (circulative) manner. The two viruses together caused a disease in tobacco called 'rosette'. Several virus complexes with similar properties are now known and the dependent viruses in these complexes are placed together in the genus *Umbravirus*. The name was coined from Latin, *umbra,* meaning 'shade', 'shadow' and from English, *umbra,* 'a shadow', 'an uninvited guest accompanying an invited one'. All the helper viruses that have been identified are definitive or tentative members of the family *Luteoviridae*.

Most attention has been paid to umbraviruses associated with two diseases of major economic importance, carrot motley dwarf, which is damaging worldwide, and groundnut rosette, which is very serious and epidemic in Africa. The umbravirus carrot mottle virus (CMoV) was first described in 1964 from motley dwarf-diseased carrots in the UK. A similar but distinct umbravirus, called carrot mottle mimic virus (CMoMV), has recently been found in carrots in Australia. In both instances the helper virus is carrot red leaf luteovirus (CaRLV). In 1969, groundnut rosette virus (GRV) and its helper luteovirus, groundnut rosette assistor virus (GRAV), were recognized as causal agents of groundnut rosette disease, but it was not until 1988 that a satellite RNA of GRV was shown to be the main cause of the symptoms of rosette disease. Recently, pea enation mosaic virus (PEMV), a virus hitherto considered to have a bipartite genome and classified as the sole member of the genus *Enamovirus,* has been shown to be a complex of two viruses. PEMV-1, formerly PEMV RNA-1, is classified in the genus *Enamovirus,* family *Luteoviridae,* and PEMV-2, formerly PEMV RNA-2, is considered to be an umbravirus. The above-mentioned umbraviruses and others which are of lesser or unknown importance, are listed in **Table 1**, together with their helper viruses, where known, and their aphid vectors. The tentative members have either not been adequately characterized, or their putative helper virus has not been detected or identified.

Taxonomy and Classification

Umbraviruses have monopartite single-stranded RNA (ssRNA) genomes with a characteristic arrangement of open reading frames (ORFs) (**Fig. 1**). Amino acid sequence comparisons show that the putative RNA-dependent RNA polymerases encoded by the genomic RNA molecules of CMoMV, GRV and PEMV-2 belong to the so-called supergroup 2 of RNA polymerases, as do those of viruses in the genera *Carmovirus, Dianthovirus, Luteovirus, Machlomovirus, Necrovirus* and *Tombusvirus*. These enzymes are the only universally conserved proteins of positive-strand RNA viruses, and their affinities suggest that the genus *Umbravirus* might be considered to be in or close to the family *Tombusviridae*. Presently *Umbravirus* remains a genus unassigned to a family.

Virus Properties

In plants infected by umbraviruses unaccompanied by the helper virus, no particles of the kind associated with most plant viruses can be found by electron microscopy in leaf extracts, but infected leaves yield abundant infective ssRNA. However, the infectivity of CMoV and GRV in buffer extracts of leaves is surprisingly stable, surviving for about a day at room

Table 1 Umbraviruses, their helper luteoviruses and their main aphid vectors

Umbravirus	*Helper luteovirus*	*Main aphid vector*

Tobacco yellow vein virus (TYVV)	Tobacco yellow vein assistor virus (TYVAV)	*M. persicae*

temperature and for up to 15 days at 4–5°C. It is, however, very sensitive to treatment with organic solvents, and this suggests that the infective RNA is protected in lipid-containing structures. Vesicular structures about 50 nm in diameter occur in the cell vacuoles of CMoV-infected *Nicotiana clevelandii*, often associated with the tonoplast, and have also been found in partially purified preparations. Similar structures have been seen in plant cells infected with bean yellow veinbanding virus (BYVBV), lettuce speckles mottle virus (LSMV) and GRV. At first it was thought that these structures might be virus particles of a kind unusual among plant viruses but it now seems likely that they may be involved in virus replication and/or serve to protect the RNA. The present view is that umbraviruses do not form conventional virus particles but depend on the coat protein of the associated luteovirus for encapsidation and for transmission by the aphid vector of the helper.

Properties of the Genome

The genomes of umbraviruses consist of one linear segment of ssRNA. They are probably not polyadenylated at their 3′ends, but there is no information about structures at their 5′ends. The genomic RNA sequences of CMoMV, GRV and PEMV-2 comprise 4201, 4019 and 4253 nucleotides, respectively. Gel electrophoresis of double-stranded RNA (dsRNA) forms indicates that the genomes of other umbraviruses are of similar size.

The genomes of CMoMV, GRV and PEMV-2 each contain four ORFs (**Fig. 1**). A very short 5′noncoding region is followed by ORF 1, which codes for a potential product of M_r 31 000–37 000. ORF 2 overlaps ORF 1 in a different reading frame and could encode a product of M_r 64 000–65 000. The function of the ORF 1 product is unknown, but the potential ORF 2 product contains sequence motifs characteristic of viral RNA-dependent RNA polymerases. An untranslated region separates ORF 2 from the remaining two ORFs (3 and 4), which overlap one another almost completely in different reading frames. The putative products of these two ORFs are of M_r 26 000–29 000, and the ORF 4 product contains sequences typical of plant virus movement proteins. The ORF 3 products of CMoMV, GRV and PEMV-2 have 42–50% similarity to each other but no significant similarity to any other viral or nonviral proteins. The sequence of the predicted ORF 3 product therefore gives no clue to its possible function.

All three genomes lack genes for plausible coat proteins.

Replication

Strategy of replication of nucleic acid

Leaf tissue of plants infected with umbraviruses contains abundant dsRNA, including a prominent species of about 4.2–4.8 kbp corresponding in size to that expected for a double-stranded form of the genomic RNA. Replication of umbravirus RNA therefore presumably involves the ORF 2-encoded RNA-dependent RNA polymerase and a dsRNA

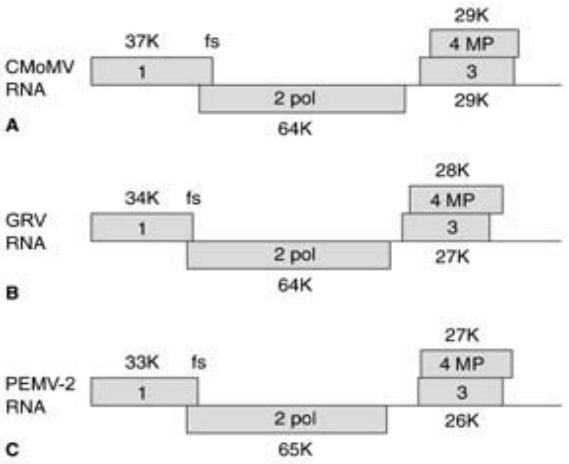

Figure 1 Diagram showing the arrangement of the ORFs in (**A**) CMoMV RNA, (**B**) GRV RNA and (**C**) PEMV-2 RNA. In each case the continuous horizontal line represents the RNA and the numbered blocks the correspondingly numbered ORFs. The M_r of the predicted translation product is shown adjacent to each ORF. ORFs that encode probable RNA-dependent RNA polymerases are marked 'pol', and those that encode probable cell-to-cell movement proteins are marked 'MP'. The positions of probable frameshift events are marked 'fs'. (Adapted from Taliansky M, Robinson DJ and Murant AF (1997) Complete nucleotide sequence and organization of the RNA genome of groundnut rosette umbravirus. *Journal of General Virology* **77:** 2335.)

intermediate, but no further details of the replication mechanism have been elucidated. A second prominent species of dsRNA, present in all plants infected with umbraviruses that have been examined, is of 1.1–1.5 kbp, and may be an intermediate in the synthesis of subgenomic RNA.

Characterization of translation

ORFs 1 and 2 are probably translated from genomic RNA as a single polypeptide of M_r 94 000–98 000 by a mechanism involving a −1 frameshift. ORF 2 does not have an appropriately positioned AUG initiation codon. Moreover, a 'shifty' heptanucleotide sequence is present just upstream of the ORF 1 termination codon and is flanked by sequences that could form stable stem–loop structures. These features are similar to ones associated with frameshifting sites in the genomes of several other plant and animal viruses.

The 1.1–1.5 kbp dsRNA found in umbravirus-infected plants is of the size expected for a subgenomic RNA for ORFs 3 and 4. For CMoMV, this dsRNA has been shown to include the sequences of ORFs 3 and 4, and the 3′ untranslated region. For GRV, corresponding ssRNA has been identified, which runs as two closely spaced bands in gel electrophoresis. Thus it is uncertain whether ORFs 3 and 4 are translated from the same subgenomic RNA species or two different ones.

Satellite RNA

Additional dsRNA species are associated with infection by some umbraviruses and, in the case of GRV, this dsRNA is known to represent a satellite RNA. GRV satellite RNA is found in all naturally occurring isolates of GRV, and is largely responsible for the symptoms of rosette disease in groundnut plants. Different variants of the satellite are responsible for different forms of the disease. Thus the agents of groundnut rosette disease comprise three components: the satellite RNA, GRV acting as a helper for replication of the satellite RNA, and GRAV acting as a helper for the encapsidation and aphid-transmission of GRV and its satellite RNA. Furthermore, for some reason that is not understood, the satellite RNA is also required for the GRAV-dependent aphid transmission of GRV, i.e. unlike most satellites, it is essential for the biological survival (though not the replication) of its helper virus. Most satellite RNA variants do not affect replication of the helper virus but at least one variant strongly downregulates GRV RNA synthesis.

Evolution

As mentioned above, umbraviruses have some affinities with viruses in the family *Tombusviridae* but whether they have lost or never had coat protein genes is idle speculation. Dependence of one virus on another for one or more gene functions is a fairly common feature among plant viruses. In most instances, the dependence of umbravirus on luteovirus is not reciprocated, but the PEMV complex appears to be a notable exception. Like other members of the family *Luteoviridae*, PEMV-1 lacks the ability to move outside the vascular system of infected plants but can 'borrow' the cell-to-cell movement function encoded by the umbravirus PEMV-2. It is thereby released from the confinement to the phloem that is typical of its family and as a result becomes transmissible by manual inoculation. Another member of the *Luteoviridae*, beet western yellows virus, has been reported to acquire limited manual transmissibility when in the presence of LSMV, and this may represent another example of the same phenomenon. The PEMV complex may perhaps illustrate the development of mutual interdependence that may have led to the evolution of multipartite genomes in other virus genera.

Serology

Because umbraviruses do not encode their own coat proteins but depend on their helper viruses for encapsidation, there is no information about serological relationships among umbraviruses.

Geographic Distribution

Carrot motley dwarf and pea enation mosaic diseases occur worldwide wherever their crop hosts are grown. However, it is unclear which of the viruses CMoV or CMoMV is associated with carrot motley dwarf disease in different parts of the world. Groundnut rosette disease occurs only in Africa, south of the Sahara. BYVBV is reported only from Europe, and LSMV only from California, USA. All other umbraviruses are reported only from Africa.

Host Range and Virus Propagation

Individual umbraviruses are confined in nature to one or a few host plant species. Their experimental host ranges are broader but still restricted. The host ranges of umbraviruses overlap, but do not necessarily coincide, with those of their helper viruses. The symptoms induced in infected plants are usually mottles or mosaics.

Experimentally, umbraviruses can be transmitted by manual inoculation, although sometimes with difficulty. They can be propagated in their natural hosts, but often an experimental host is more convenient. *Nicotiana benthamiana* and *N. clevelandii* have proved useful for propagation of CMoV, CMoMV, GRV and several other umbraviruses.

Transmission

In nature, umbraviruses are transmitted by aphids (**Table 1**), but only from plants that also contain a helper virus (**Table 1**). All helper viruses that have been characterized are definitive or tentative members of the family *Luteoviridae*. The mechanism of the dependent transmission is the encapsidation of the umbravirus RNA by the coat protein of the luteovirus. Transmission of the dependent umbravirus therefore occurs in the same persistent (circulative, nonpropagative) manner as that of the helper virus.

Epidemiology

Between crop growing seasons, umbraviruses must survive in plants that are also both hosts of the helper virus and feeding hosts of the vector. Sometimes the aphid vector too will survive on the same plants, but in cold winters in temperate climates, it may survive only in the form of eggs, and these may be laid on an alternate host that is not a host of the viruses. For example, the aphid *Cavariella aegopodii*, the vector of the CMoV/CaRLV complex, lays its eggs on willow (*Salix* spp.), which is not a host of either virus. The aphids produced on willow in the spring are therefore nonviruliferous and must re-acquire the virus complex from a perennial umbelliferous host such as *Anthriscus cerefolium* (cow parsley, Queen Anne's lace), or from overwintering carrot plants.

The components of the pea enation mosaic virus complex infect a wide range of leguminous plant species, of which the most important as overwintering hosts are probably *Medicago sativa* (alfalfa, lucerne) and *Vicia sativa* (common vetch). No nonleguminous natural hosts are known. The most important vector in nature is the pea aphid (*Acyrthosiphon pisum*).

Groundnuts, which originated in South America, are affected by rosette disease only in Africa south of the Sahara, and not in any other parts of the world to which they have been introduced. The causal viruses, GRV and GRAV, must therefore have come from wild plants indigenous to Africa. However, attempts to find an African plant species that is a host of both viruses have so far been unsuccessful. The viruses may now survive in overseasoning groundnut plants. Groundnut rosette is present in most seasons, but periodically becomes epidemic, causing devastating losses of great economic and social importance. The factors that determine the onset of epidemics are not understood, but are undoubtedly linked with the biology of the vector, *Aphis craccivora*.

Little is known about the ecology and epidemiology of other umbraviruses.

Pathology and Histopathology

Although all umbraviruses depend on a helper virus for transmission by vector insects, several of them are equally or more important than their helpers in the causation of disease symptoms. The umbravirus of greatest economic importance is GRV, which causes the most devastating virus disease of groundnut in Africa. However, in this case, as already mentioned, it is a GRV-dependent satellite RNA that is the actual cause of the symptoms.

Umbraviruses, even in the absence of their helper viruses, exhibit rapid systemic spread in plants. They infect cells throughout the leaf, though presumably the aphid-transmissible particles are restricted to the same tissues (in most instances the phloem) as the luteoviruses that provide their coat protein. In mesophyll cells infected with CMoV there is extensive development of cell wall outgrowths sheathing elongated plasmodesmatal tubules.

Prevention and Control

Vector Control

Preventing the spread of umbraviruses by controlling the aphid vector is rarely practical commercially, because severe disease outbreaks are erratic and difficult to predict. Also, especially in the case of GRV, which occurs mostly in the poorer African countries, use of insecticides may be too expensive. However, in many countries, carrot crops are sprayed intensively with insecticides, primarily for the prevention of carrot fly (*Psila rosae*) infestation, and this incidentally provides effective control of carrot motley dwarf disease.

Avoidance of Infection

For the avoidance of pea enation mosaic disease, it is sometimes recommended that pea or faba bean crops should be sited away from alfalfa or clover fields. In Africa, early planting and close spacing of groundnut are effective ways of avoiding rosette disease, because the flying aphid vector has difficulty in recognizing the crop once the plant cover is complete. This approach is also effective against tobacco rosette disease.

Host Plant Resistance

If resistant plant cultivars are available, this is undoubtedly the best approach. Resistance to GRV, inherited as a double recessive character, is found in some groundnut germplasm, and groundnut lines possessing this resistance have been developed, though they are often not preferred for commercial or cultural reasons.

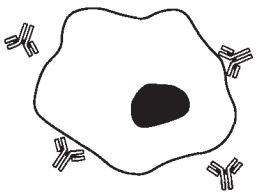
V

VACCINES AND IMMUNE RESPONSE



Gordon L Ada, Australian National University, Canberra, Australia

History

Any history of vaccination to control viral infections, however brief, begins with the story of smallpox and its final eradication. There were bicentenary celebrations in 1996 to celebrate the famous experiment of Edward Jenner in which he inoculated a boy, James Phipps, with cowpox material and demonstrated that he subsequently resisted a challenge with smallpox. Almost 100 years later, Louis Pasteur developed the rabies virus vaccine, and in 1935, an attenuated viral preparation to combat yellow fever was made and remains to this day a safe and effective vaccine. The first inactivated influenza virus vaccine became available in 1936. The production of these two vaccines was possible because of the newly developed technique of growing virus in the embryonated eggs of chickens.

However, the major event that accelerated viral vaccine development was the ability to grow many viruses in tissue culture. This began in the 1920s, but it was the studies by John Enders and colleagues in successfully growing polioviruses in cell culture which initiated an explosion of activity in this field. Jonas Salk produced the trivalent formalin-inactivated poliovirus vaccine and this was followed shortly afterwards by the oral live attenuated polio vaccines of Albert Sabin. Most viral vaccines in use today and those in clinical trials and probably close to registration (**Table 1**) are attenuated preparations.

A subunit preparation consisting of the surface glycoproteins of influenza virus, was subsequently made and is widely used because of its lower reactogenicity compared to whole virus. A new era of viral vaccine development was initiated when the hepatitis B surface antigen, originally isolated from infected blood, was prepared from DNA-transfected yeast cells for use as a vaccine.

Smallpox was declared eradicated in 1980, three years after the last case of endemic smallpox was detected, and nearly 14 years after the World Health Organization (WHO) had begun an intensified campaign to eradicate this disease. In 1985, the Pan American Health Organization (PAHO) initiated a program to eradicate indigenous wild-type polio from the Americas, and eradication was declared in 1994, three years after the last case was detected. WHO has declared the year 2000 as the target date for global eradication and there is a reasonable chance that this will be achieved. Following elimination of indigenous measles from some countries (e.g. Finland, the Caribbean Islands), PAHO has nominated the year 2000 as the date for eradication of this disease from the Americas.

Two Main Requirements of a Vaccine

The safety of a candidate vaccine has become of prime importance. Most of the vaccines listed in **Table 1** are very safe, but two in particular are less so. During the eradication campaign, most smallpox vaccines (vaccinia virus) had a level of side effects which made them unacceptable for current use. Safer preparations have since been made by the deletion of specific DNA sequences. Type 3 poliovirus in OPV can revert to virulence, and poliomyelitis occurs at the rate of about 3×10^6 doses of vaccine in recipients or their close contacts. Attenuated live vaccines may pose a risk to immunodeficient or -compromised people, but at least in the case of measles virus, even this is a very low risk.

The second requirement is efficacy, which is assessed as the ability to protect recipients from disease after a subsequent exposure to the wild-type infectious agent. Vaccine efficacy depends almost entirely on the nature and persistence of the induced immune response. Vaccines are usually given prophylactically and, as the time interval between vaccination and the subsequent exposure to challenge may be short (weeks) or long (years), efficacy depends on stimulation of the adaptive immune response, the

lymphocytes, which have immunological memory. If a vaccine is used therapeutically, which may be deliberate or occur naturally if the vaccine is used in an endemic area, activated innate components may contribute to a protective effect. The efficacy of many vaccines may be predicted by the level of protective antibodies induced by vaccination, but where antigenic variation occurs, a high level of cell-mediated immune (CMI) responses may indicate a degree of protection.

Roles of antibodies

Specific antibody has three main roles: (1) to neutralize the infectivity of a virus; (2) to lyse infected cells which express viral antigens at the cell surface; and (3) to complex with viral debris from infected cells and help in its removal. Following vaccination, the continuing presence of specific antibody of increasing affinity which will bind to virus and prevent infection is regarded by vaccinologists as the most critical requirement of a vaccine. Many viruses naturally infect via a mucosal surface, and here, secretory immunoglobulin A (s.IgA) fulfills this role. In contrast, many vaccines are given parenterally, in which case, the IgM and IgG formed does not prevent the initial infection, but should prevent systemic spread, eg. polio and measles infection.

The mechanism of infectivity prevention by antibody varies between viruses, and even different immunoglobulin isotypes may have different effects. Viral replication may be prevented whether the antibody prevents virus adsorption to the cell, entry into the cell or expression of the viral genome.

Antiviral antibody may bind to antigens expressed on the infected cell plasma membrane and cause lysis – antibody-dependent cellular cytotoxicity (ADCC). Alternatively, lysis may be caused by certain antibody isotypes binding complement and the complex then binds to complement receptors on the infected cell surface. Antibody has been shown to clear some viral infections in T cell-deficient mice, eg. influenza and vaccinia virus infections. In contrast, antibody is inefficient at clearing ectromelia, lymphocytic choriomeningitis virus (LCMV) or Theiler's virus, which are natural pathogens of mice. However, in persistent infections such as LCMV in mice, antibody can prevent virus reaching sites such as the epidermis where CTLs are less effective.

Viral epitopes recognized by protective antibodies Generally, only one or a few antigens of a virus, those exposed to the medium, contain epitopes recognized by neutralizing antibodies. For the virus to survive extracellularly, it must be resistant to enzymes, particularly proteases, and this is usually achieved by having polymers of viral antigens – trimers (influenza hemagglutinin and human immunodeficiency virus envelope) or multimers (VP1 of polio) – so that the important epitopes are usually discontinuous sequences.

Roles of effector T cells

There are two classes of T cells – CD4+ (class II MHC-restricted) and CD8+ (class I MHC-restricted) – and two subclasses of each – CD4+Th1 and Th2, and CD8 + Tc1 and Tc2. They are distinguished by their patterns of cytokine secretion. Because of similarities in these patterns, Th2 and Tc2 are called type 2 T cells, and Th1 and Tc1, type 1 T cells (*see also* **Immune Response, general features**). The main role of Th2 cells is 'helping' B cells make antibody. Th1 cells do this to a lesser extent, but in contrast to Th2 cells, they mediate delayed-type hypersensitivity reactions. From a vaccine development point of view, a major role of Tc1 is their ability to lyse virus-infected cells a long time before viral progeny is formed, so they are frequently called cytotoxic T cells (CTLs). **Table 2** lists some examples of viral infections in mice where there has been clearance or control of virus replication following transfer of specific CTLs.

Table 2 Examples of clearance or control of virus replication in infected mice following transfer of specific CD8+ cytotoxic T cells (CTLs, Tc1)

Orthomyxovirus (influenza virus)
Paramyxovirus (Sendai virus)
Poxvirus (vaccinia virus)
Pneumovirus (respiratory syncytial virus)
Arenavirus (lymphocytic choriomeningitis virus)
Alphaherpesvirus (herpes virus)
Betaherpesvirus (cytomegalovirus)

There are 'experiments of nature' which suggest a protective role for CTLs in infected people. In four situations where people were known to have been exposed to HIV but who were seronegative and virus could not be isolated, CTLs specific for known HIV CTL epitopes could be isolated from their blood.

Though cultured or cloned Th1 cells may also be cytotoxic, primary cells (without *in vitro* culture) are rarely so. Th (presumably Th1) cells have been shown to be protective in a herpes 2 virus infection – the zosteriform spread model. *In vitro,* CTL production is usually enhanced by the presence of TH1 cells, but *in vivo,* there are several examples where 'normal' levels of CTL activity were found following a viral infection in doctored mice lacking CD4+ T cells. However, it has also been shown that if the virus infection persists, CTL activity decreases over time compared to the situation in normal mice, which is similar to what occurs in many HIV-infected individuals when levels of CD4+ T cells greatly decrease and CTL activity disappears.

Sources and properties of T cell epitopes In contrast to the restricted number of viral antigens possessing epitopes recognized by neutralizing antibodies, potentially many viral antigens may contain T cell epitopes. They may be detected as follows.

1. Individual antigens are screened, sometimes using cells infected by a chimeric live vector.
2. A series of overlapping peptides is synthesized and each is tested for its ability to sensitize a target cell for lysis by CTLs.
3. Whereas peptides binding to class II MHC antigens vary considerably in length, averaging about 15 amino acids, those binding to class I MHC antigens are more homogeneous, the great majority being nonamers. The nonamers have a motif specific for MHC molecules of different allelic specificities, possessing two anchor positions that are critical for ligand binding. This has allowed protein sequences to be screened to find ligands potentially specific for different MHC antigens.
4. Peptide ligands can be 'stripped' from an infected cell and sequenced.

There were some general findings.

1. Where comprehensive studies have been made, e.g. influenza virus and HIV, the great majority of antigens possess potential CTL epitopes. With flaviviruses, the nonstructural proteins are the major source of CTL epitopes.
2. With both influenza and HIV, the internal antigens contain conserved sequence epitopes.
3. Not infrequently, one or a few epitopes may be dominant and these may be in a variable region or subject to mutation, both being potential mechanisms for the virus to escape immune control. A vaccine might need to include less dominant epitopes from conserved regions where mutations do not occur.
4. Even though a peptide will bind firmly to a MHC antigen of a given specificity, not all people with that allelic specificity but differing in the rest of the haplotype will respond to that peptide, because of crosstolerance with different self peptides.

Secondary Responses

Immunization/vaccination should achieve two major goals. The first is the continuing presence of high affinity specific antibody which will generally neutralize most (>95%) of the challenge virus. Probably, vaccines rarely if ever give 'sterilizing' immunity (100% prevention of infection). If sufficient virus escapes neutralization by pre-existing antibody to infect enough antigen presenting cells (APCs) the second effect is an enhanced CMI response, particularly CTLs. *In vitro,* limit dilution analyses show that following priming, there is an increase in the frequency of T cells of the particular specificity. However, these memory cells are also more easily activated than naive cells, and this may be a more important reason why a more rapid and greater CTL response is seen.

If the antigenic specificity (for neutralizing antibody) of the challenge virus differs grossly from that of the virus used for vaccination, as happens when antigenic shift occurs with influenza, or between different clades of HIV, the control and recovery from the challenge infection will depend very largely on an enhanced CMI response.

Table 3 Some factors favoring or obstructing the development of an effective viral vaccine

Favoring
1. Infection by wild-type agent induces immunity which clears the infection
2. Few important serotypes (DNA viruses); little or no antigenic drift (RNA viruses)
3. Antigens that are a source of protective B cell epitopes or important T cell epitopes are readily identified
4. The virus is not highly infectious
5. Infection is confined to one or few organs, e.g. the lung with influenza virus
6. There is readily available a relatively inexpensive animal model that mimics the human infectious process with onset of characteristic disease
Obstructing
7. Marked antigenic shift or drift
8. Viral DNA/cDNA integrates into the host cell genome; latency occurs
9. Virus infects a variety of cells distributed widely throughout the body
10. A latent infection may be transmitted by infected cells
11. Protective immunity does not occur after natural infection
(a) infection persists due to suppression/evasion of CMI responses;
(b) escape mutants (T and B cells) occur over time
12. Crucial cells of the immune system are infected or affected
13. Antibodies may enhance infection of susceptible cells
14. Lack of a suitable animal model

Protection Following Immunization by Different Routes

The area of mucosal surface in mammals is far greater than the area of skin, and many viruses infect via this route. The main sites of entry are oral, rectal, respiratory, urogenital and ocular. Following vaccination via a mucosal route such as the gut, the first line of defense is s.IgA, and the CMI responses originate from local lymphoid tissues such as the Peyer's patches. For example, OPV induces both a mucosal and systemic response whereas IPV induces only the latter which, however, is sufficient to prevent infection of the central nervous system and poliomyelitis. Measles vaccine is given parenterally; viremia occurs so that some virus reaches the respiratory tract and a mucosal, as well as sytemic response, occurs. There is still interest in administering this vaccine intranasally to achieve a stronger mucosal response which might also be less affected by maternally derived antibody.

There is a 'common mucosal system' so that an immune response induced say in the gut will cause traffic of immune cells to other mucosal sites. An example is the adenovirus vaccine. This is given orally but induces significant protection in the respiratory tract where the natural infection occurs. In contrast, using this approach, it seems to be more effective to administer antigen intranasally rather than orally to achieve immunity in the urogenital tract. For reasons that are not yet well understood, mucosal immunity tends to be shortlived.

Immunological Requirements of a Vaccine

1. Activation of APCs to facilitate antigen processing and enhancement of costimulator and cytokine production;
2. Stimulation of both T and B cells so that there is a high yield of memory cells;
3. Generation of type 1 and 2 T cells to several epitopes, preferably in conserved regions, to overcome the variation in the immune response in the population due to MHC polymorphism;
4. Persistence of antigen in its natural conformation on follicular dendritic cells (FDCs) in lymphoid tissues, where B memory cells are formed and recruited to form antibody-secreting cells (ASCs) so that antibody of high affinity is continually present.

Factors Affecting the Feasibility of Vaccine Development

Table 3 lists some of the factors which make it more straightforward to develop a vaccine against a virus, and these can be contrasted with those which tend to increase the difficulty. It can be readily seen that most of the latter points apply to HIV.

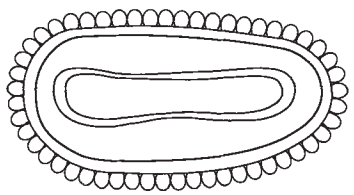
VACCINIA VIRUS (*POXVIRIDAE*)



Riccardo Wittek, Université de Lausanne, Lausanne, Switzerland

History

In 1980, the World Health Assembly announced that smallpox, once the most serious infectious disease of humankind, had been eradicated from all the countries of the world. Several factors were important in making the eradication campaign a unique success in the history of medicine. Among these was the active role played by WHO which organized the campaign and provided expertise in all relevant areas. Furthermore, variola virus, the agent of smallpox, had no animal reservoir and consequently, interrupting the chain of human-to-human transmission eliminated the virus. Finally, with vaccinia virus, an excellent vaccine for smallpox was available. The vaccine had a low production cost, could be freeze-dried and in this form was very heat stable obviating the need of a cold chain. In addition, the vaccine was easy to administer even by relatively untrained field workers and left a characteristic scar providing permanent evidence of vaccination which was important for WHO in assessing vaccination coverage.

It is not known when vaccinia virus was introduced as a smallpox vaccine. Edward Jenner, who was the first to demonstrate, at the end of the 18th century, that inoculation of a related poxvirus provided protection against challenge with variola virus, isolated his vaccine virus from a milkmaid infected with 'cowpox'. It is unclear what this virus was. Although, in modern times, vaccinia virus was occasionally isolated from skin lesions of infected cows, these cases were usually associated with contact with vaccinated humans and therefore, the cow does not seem to be the natural host of the virus. The origin of vaccinia virus thus remains a matter for speculation (see also: 'Evolution').

Taxonomy and Classification

Vaccinia virus is a member of the family *Poxviridae* which comprises a group of complex animal DNA viruses. The family is further subdivided into the two subfamilies, *Chordopoxvirinae* and *Entomopoxvirinae* whose representatives infect vertebrate and insect hosts, respectively. Within the subfamily, *Chordopoxvirinae* vaccinia virus belongs to the genus *Orthopoxvirus*.

Properties of the Virion

Poxviruses are among the largest and most complex viruses known. The particles have a typical brick-shape and measure about 300 × 250 nm. Two types of particles can be distinguished. Virions that are naturally released from the infected cells are surrounded by a Golgi-derived envelope. Virions that are released by experimental cell lysis lack this envelope, but are also infectious. Electron microscopy of negatively stained specimens reveals that the surface of nonenveloped particles is composed of tubular structures ('surface tubules'), which give the particles a characteristic appearance (**Fig. 1A**). However, more recent cryoelectron microscopy (**Fig. 1B**), which allows examination of hydrated virus particles, provided no evidence of surface tubules and it is conceivable that these structures represent a shrinkage artifact resulting from dehydration of particles prepared for electron microscopy by conventional procedures.

In thin sections of virions examined by conventional electron microscopy, the internal core structure can be visualized, which consists of an oval biconcave disk. The concavities of the core accommodate the two lateral bodies. Again, these structures are not

History

In 1980, the World Health Assembly announced that smallpox, once the most serious infectious disease of humankind, had been eradicated from all the countries of the world. Several factors were important in making the eradication campaign a unique success in the history of medicine. Among these was the active role played by WHO which organized the campaign and provided expertise in all relevant areas. Furthermore, variola virus, the agent of smallpox, had no animal reservoir and consequently, interrupting the chain of human-to-human transmission eliminated the virus. Finally, with vaccinia virus, an excellent vaccine for smallpox was available. The vaccine had a low production cost, could be freeze-dried and in this form was very heat stable obviating the need of a cold chain. In addition, the vaccine was easy to administer even by relatively untrained field workers and left a characteristic scar providing permanent evidence of vaccination which was important for WHO in assessing vaccination coverage.

It is not known when vaccinia virus was introduced as a smallpox vaccine. Edward Jenner, who was the first to demonstrate, at the end of the 18th century, that inoculation of a related poxvirus provided protection against challenge with variola virus, isolated his vaccine virus from a milkmaid infected with 'cowpox'. It is unclear what this virus was. Although, in modern times, vaccinia virus was occasionally isolated from skin lesions of infected cows, these cases were usually associated with contact with vaccinated humans and therefore, the cow does not seem to be the natural host of the virus. The origin of vaccinia virus thus remains a matter for speculation (see also: 'Evolution').

Taxonomy and Classification

Vaccinia virus is a member of the family *Poxviridae* which comprises a group of complex animal DNA viruses. The family is further subdivided into the two subfamilies, *Chordopoxvirinae* and *Entomopoxvirinae* whose representatives infect vertebrate and insect hosts, respectively. Within the subfamily, *Chordopoxvirinae* vaccinia virus belongs to the genus *Orthopoxvirus*.

Properties of the Virion

Poxviruses are among the largest and most complex viruses known. The particles have a typical brick-shape and measure about 300 × 250 nm. Two types of particles can be distinguished. Virions that are naturally released from the infected cells are surrounded by a Golgi-derived envelope. Virions that are released by experimental cell lysis lack this envelope, but are also infectious. Electron microscopy of negatively stained specimens reveals that the surface of nonenveloped particles is composed of tubular structures ('surface tubules'), which give the particles a characteristic appearance (**Fig. 1A**). However, more recent cryoelectron microscopy (**Fig. 1B**), which allows examination of hydrated virus particles, provided no evidence of surface tubules and it is conceivable that these structures represent a shrinkage artifact resulting from dehydration of particles prepared for electron microscopy by conventional procedures.

In thin sections of virions examined by conventional electron microscopy, the internal core structure can be visualized, which consists of an oval biconcave disk. The concavities of the core accommodate the two lateral bodies. Again, these structures are not

seen by cryoelectron microscopy and their significance remains to be established. Cores prepared by treatment of virions with 2-mercaptoethanol and a nonionic detergent have a similar appearance both by conventional and cryoelectron microscopy (**Fig. 1C**).

Properties of the Genome

Vaccinia virions contain a large double-stranded DNA genome which has been entirely sequenced in the Copenhagen strain and shown to consist of 191 636 base pairs. Characteristic features of the molecules are the crosslinks that join the two DNA strands at both ends. The terminal 100 nucleotides or so consist of single-stranded loops. The genome is further characterized by the presence of long inverted terminal repeats of about 10 kbp. The terminal 3.5 kbp of these are mainly composed of a tandemly repeated 70 bp sequence.

Properties of the Proteins

The DNA sequence of the viral genome provides evidence for the presence of about 200 potential protein-coding sequences, but only relatively few proteins have been assigned a function. The majority of polypeptides with known or suspected functions are enzymes involved in nucleic acid metabolism. Examples are the subunits of RNA polymerase, enzymes involved in capping and polyadenylation of mRNA, DNA polymerase, thymidine and thymidylate kinase, DNA ligase and several more. Other proteins are structural components of the virion. Together with some enzymes, which are also packaged in the virus particle, the total number of virion polypeptides may be as high as 100. The envelope of extracellular virions contains at least six proteins, five of which are glycosylated. The 37 kDa major envelope antigen is acylated.

Physical Properties

The development of a stable smallpox vaccine was greatly facilitated by the fact that the infectivity of vaccinia virus is relatively unaffected by environmental conditions which inactivate most other viruses. This property, together with the large particle size, was also the reason why vaccinia virus was the first

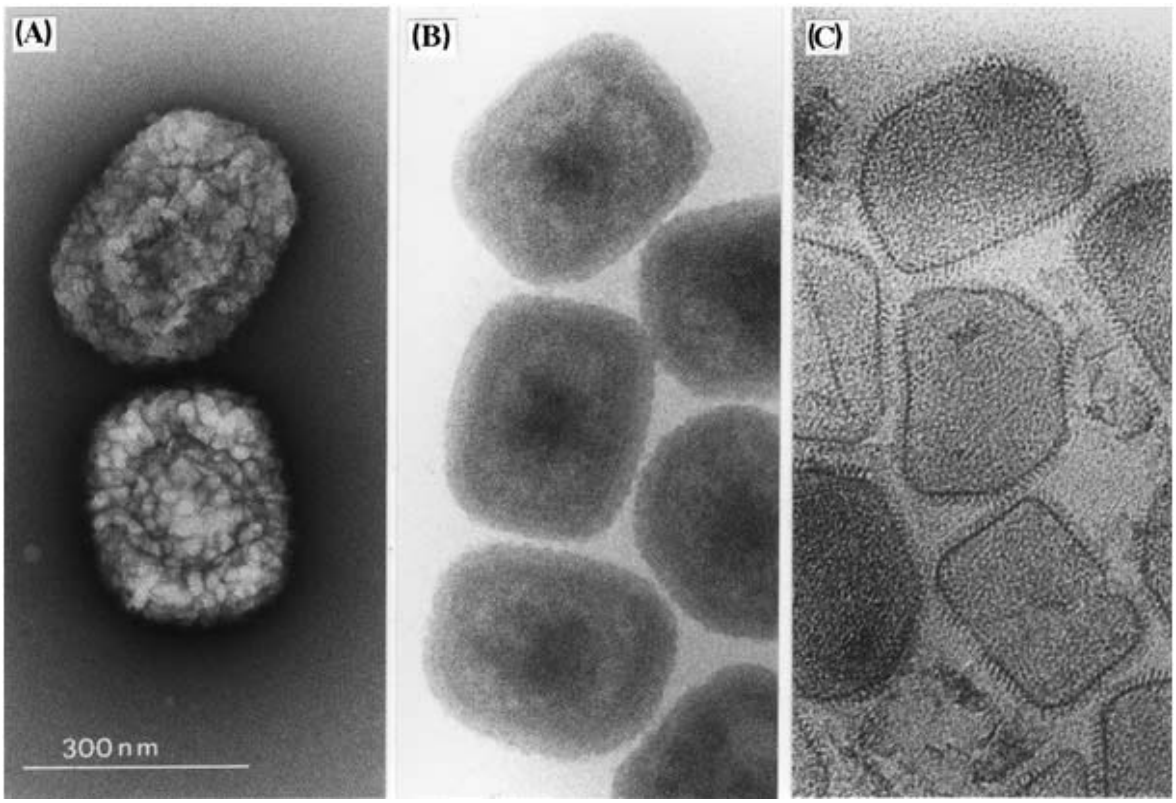

Figure 1 Structure of vaccinia virus including the viral core. (**A**) Conventional preparation of the virus by negative staining. (**B**) Vitrified sample observed by cryoelectron microscopy. The virus particles are in the native state and are floating in a thin layer of vitrified solution kept for observation at c. −160°C and are neither stained nor chemically fixed. animal virus to be purified extensively. Heating at 55°C for 60 min, or at 50°C for 90 min completely destroys infectivity. Other methods for destroying infectivity were tested in attempts to produce an inactivated smallpox vaccine. Ultraviolet irradiation, formaldehyde treatment, photodynamic inactivation with methylene blue and gamma irradiation were all found to inactivate vaccinia virus, but some of these procedures also resulted in a loss of antigenicity.

Complete solubilization of vaccinia virus is achieved by heating at 100°C in the presence of sodium dodecylsulfate and reducing agents.

Strategy of Replication of Nucleic Acid

Poxviruses are unusual among DNA viruses in that their replication cycle takes place in the cytoplasm of the infected host cell. Upon penetration, the virus sheds its outer protein layers resulting in the release of the viral core containing the DNA and enzymes involved in the synthesis and modification of mRNA. A first burst of RNA synthesis occurs. Following expression of the early genes, the DNA is released from the core and replicated. This allows expression of the intermediate genes, the transcription of which requires a naked DNA template. After transcription of intermediate genes, late genes, many of which encode structural proteins, are expressed.

Replication of the genome occurs through synthesis of long concatemeric intermediates which are subsequently resolved into unit-length genomes. Concatemer resolution is a highly specific process and depends on a 20 bp element located adjacent to the hairpin loop in the mature DNA molecule. For a long time DNA replication itself was not believed to require specific origins of replication since any DNA transfected into vaccinia virus-infected cells is replicated to some extent. More recently, however, it was shown that optimal replication efficiency depends on 200 bp of sequences from the viral telomere.

Characterization of Transcription

Transcription of the different temporal classes of vaccinia virus genes requires specific promoters, which are short, a multisubunit RNA polymerase and stage-specific transcription factors.

Transcription of early genes depends on early promoter elements, which are about 30 bp long. An early transcription factor binds to these regulatory sequences. Termination of early transcription requires the virus-encoded capping enzyme and occurs about 50 bp downstream of a UUUUUNU signal in the nascent RNA chain. Early mRNAs are capped and polyadenylated and typically contain short 5′ untranslated leader sequences.

Intermediate gene transcription requires the presence of the viral capping enzyme and two intermediate gene transcription factors which are able to activate intermediate gene transcription only after the DNA has been replicated. Interestingly, one of the intermediate gene transcription factors has also been purified from uninfected HeLa cells but not from nonpermissive cells. This finding challenges the dogma that exclusively virus-encoded proteins are used for transcription in vaccinia virus.

Late gene promoters also consist of about 30 bp and contain the highly conserved TAAAT motif in which transcription initiation occurs. Late mRNAs are heterogeneous in length, are polyadenylated and have a capped poly(A) leader sequence of about 35 Å residues. The leader is not encoded in the genome but is produced by stuttering of RNA polymerase in the TAAAT motif. In addition to RNA polymerase, four transcription factors are required for late gene transcription. Three of these are products of intermediate genes, the fourth is synthesized both before and after DNA replicaton.

Transcription in vaccinia virus is characterized by a cascade in which transcription of each temporal class of genes requires the presence of specific transcription factors which are made by the preceding temporal class of genes. Thus, early gene transcription factors are made late in infection, packaged in virions and used in the subsequent round of infection. Intermediate gene transcription factors are encoded by early genes, and late transcription factors by intermediate genes. The recent discovery of a cellular protein involved in intermediate gene transcription and the fact that one late gene transcription factor is made before and after DNA synthesis, requires some revision of the cascade model.

Characterization of Translation

Infection of cells by vaccinia virus results in rapid shut-off of host cell DNA, RNA and protein synthesis. Phosphorylation of ribosomal proteins and short polyadenylated viral RNAs has been implicated in the inhibition of cellular protein synthesis.

The preferential translation of temporal classes of mRNAs is probably a direct consequence of the half-life and abundance of mRNAs at a given time of infection.

Post-translational Processing

Several types of post-translational processing events occur in the maturation of viral proteins. The mature

brought in by a co-infecting virus. The gene to be expressed, under the control of the T3 or T7 promoter elements, is introduced into the cells either as an expression plasmid or as part of a vaccinia virus vector. These approaches allow for controlled expression, which is especially important when the protein product is cytotoxic.

Poxvirus expression systems have been used to express hundreds of proteins of biological and medical importance. The practical application of vaccinia virus vaccine candidates has been demonstrated in both the veterinary and human fields. Vaccinia was used successfully as a vaccine for the eradication of smallpox. Other examples of its use include vaccinia virus recombinants to protect raccoons against rabies, a capripoxvirus vector to protect cattle against rinderpest, a swinepox vector to protect pigs against pseudorabies, and fowlpox vectors to protect chickens against influenza virus, Newcastle disease virus and infectious bursal virus. Clinical trials with a vaccinia-based HIV-1(IIIB) *env* recombinant have been initiated in the USA. Results from these studies clearly demonstrated the ability of this recombinant to prime an immunological response in the recipients, although the response was suboptimal in some individuals. A vaccinia virus-based vector expressing the Epstein–Barr virus membrane glycoprotein has been used in China with some success in preventing natural infection.

New vectors have recently been developed that address some of the safety concerns of the original vectors. A strain of vaccinia virus with 18 genes implicated in the virulence and host range of the virus deleted has been developed. Another vector, based on a canarypoxvirus, replicates only in avian species. When this vector is introduced into nonavian cells, the transgene is expressed. Preliminary studies demonstrate that both are effective in generating high levels of transgene expression, and that in a vaccine setting they can both induce protective immunity. A canarypoxvirus-based vector expressing the rabies G glycoprotein has been assessed in phase I clinical trials in Europe and the USA, with encouraging results. In addition, vectors expressing the human cell surface protein CD80 are in clinical trials. This protein is involved in T cell recognition of target cells, so its expression in tumor cells potentially enhances the ability of the immune system to recognize cancer cells. This tumor vaccine approach is expanding, as poxvirus vectors encoding a variety of tumor antigens are currently undergoing preclinical testing. Given the large capacity of the vectors, genes encoding both tumor antigens and immune system recognition enhancing molecules could be inserted into a single virus.

Poxvirus vector-based systems have demonstrated their utility for expression of foreign genes for study in tissue culture, for use as a vaccine vehicle in both animals and humans, and they are beginning to be used for treating cancer. Because of the wide variety of available vectors, and the safety features that have been built into them, poxvirus vectors will increasingly become the vector of choice for a variety of applications.

Baculovirus Expression Vectors

Baculoviruses are pathogenic insect viruses that have been investigated for possible use as biological control agents for insect pests. Recently, these viruses have proven useful in the development of helper-independent vectors for overexpression of foreign genes in eucaryotic cells. Baculoviruses contain a double-stranded DNA genome of around 130 kb, and the DNA is infectious. The main attraction of this system is the ability to produce very large quantities of transgene protein, but until recently the system was limited to insect cells. Recent developments have considerably expanded the potential of the baculovirus vector system for use in mammalian cells.

Baculovirus vectors are generally produced by homologous recombination between a shuttle vector and a wild-type genome, using the viral polyhedrin gene as the recombination target. Shuttle vectors often contain the transgene of interest plus a selectable marker gene, although inactivation of the polyhedrin gene through transgene insertion gives rise to plaques that can be differentiated from those of wild-type virus. The polyhedrin gene of baculoviruses such as *Autographa californica* nuclear polyhedrosis virus (AcMNPV) is expressed at very late times of infection and produces a protein that surrounds the mature virus particle to form an occlusion body in insect larvae. Polyhedrin protein expression in infected tissue culture cells can continue for days following initial infection and often amounts to 50% of the total cell protein. The polyhedrin protein is not essential for replication of the virus in tissue culture, and transgenes placed under the control of its promoter can be expressed to levels approaching that of the polyhedrin itself. The virus has a rod-shaped capsid and has a large capacity for packaging foreign DNA. Baculoviruses do not productively infect vertebrate cells, but modifications to the system have allowed transgene expression in a variety of mammalian cell lines, further expanding the potential of the vector system.

Baculovirus vectors have found their greatest use in the production of large quantities of protein for purification. While insect cells can post-translation-

ally modify proteins correctly, there were concerns that they could not process high-mannose glycans like mammalian cells. However, recent reports on human plasminogen expressed in insect cells show that the enzymes necessary for processing high-mannose glycans can be activated with glycan processing identical to that found in the human-expressed protein. These are important considerations if baculovirus-expressed products are to have the same biological and immunological properties as that of the native protein. Baculovirus-expressed protein was used in the first human clinical trials for an acquired immune deficiency syndrome (AIDS) vaccine, using an HIV-1 (IIIB) *env* gene product purified from insect cells. Its general utility for production of purified proteins for clinical use remains to be demonstrated.

Herpesvirus Vectors

Two herpesviruses are emerging as alternatives for the development of gene transfer vectors: herpes simplex virus (HSV) and Epstein–Barr virus (EBV). HSV has a genome of approximately 155 kb in length, which is maintained as a concatemerized circular or linear episome in infected cells. It efficiently infects cells, including nondividing cells, from a wide variety of organisms, and is able to establish a persistent infection. Its genome can accommodate large amounts of foreign DNA, and a number of vector systems have been developed. The EBV-based systems have not been developed as extensively and currently employ replication-defective EBV strains. Unlike HSV, EBV vectors have a very limited tropism and their possible usefulness remains to be explored. The main difficulty using these two systems is the need for almost complete virus genomes that are very complex and large in size, making manipulations exceedingly difficult. The eventual usefulness of these systems will be dictated by further simplifications that render them more manageable in the laboratory and that facilitate vector production.

Helper-dependent and -independent systems have been developed for preclinical evaluation. The helper-independent systems have basically the complete viral genome with one or more transgenes substituted for nonessential viral genes. These vectors are rendered defective for growth by deletion of essential genes, permitting their growth only on complementing cell lines. So far these vectors have met with limited success in model systems because of leakiness in the system, which leads to cytotoxicity and cell death. The requirements for maintenance of gene expression during the latent state in neuronal cell types are also currently unknown, so prolonged transgene expression has been difficult to obtain. The second type of HSV vector is the helper-dependent system. The vectors contain only the sequences required for replication and packaging, but all the other functions must be supplied in *trans* from a helper virus. While such systems are capable of producing high-titer amplicon-containing virus, they are almost invariably contaminated with large quantities of the helper virus. Recent improvements in the amplicon system have allowed the generation of relatively high-titer amplicon preparations with much lower levels of contamination with helper virus. These systems hold promise for use in clinical situations, especially in gene transfer to neuronal cells, but further development of the system is required.

Retrovirus Vectors

Retroviruses are ubiquitous in nature and have a relatively simple RNA genome of around 9 kb in length. By reverse transcription, the RNA genome becomes a double-stranded DNA that integrates into the host chromosome and is stably transmitted to progeny cells. Specific aspects of the life cycle of retroviruses and their relatively simple genome have facilitated their development into gene transfer vectors. Most of the vectors currently used for basic science and for clinical applications are based on murine leukemia viruses. Because of the high efficiency with which retroviral vectors can transduce a variety of cell types from many different species, they have become a method of choice for gene transfer experiments.

Retrovirus vectors can be produced by either transient transfection of cells, or by the generation of stable producer cell lines. In both cases, the transcription units for the packaging functions for the virus particle and that for the transgene are on separate genetic elements. The packaging proteins are provided in *trans*, either by a co-transfected second plasmid that encodes the proteins needed for particle formation, reverse transcription and integration of the vector (transient production), or by a packaging cell line that contains these genes integrated into the chromosome (**Fig. 2**). Separation of the *trans* functions into several plasmids is important to minimize the chance that a wild-type replication competent virus may be generated by a recombination event. Packaging cell lines are able to generate large numbers of virus particles without a genome. These particles are empty because the packaging construct does not contain the information needed for specific incorporation of RNA into the virus particle. This is an important aspect of the system because it prevents the transmission of genomic information encoding virus proteins. The vector plasmid contains all of the *cis*

replication in cultured cells but that their presence confers a selective advantage for virus propagation in the organism.

Evolution

Several hypotheses for the origin of vaccinia virus have been advanced, but none is entirely convincing. According to some of these, vaccinia virus was either derived from variola or cowpox virus, or is a hybrid between the two. Other authors propose that vaccinia virus is a 'fossil' and represents the maintenance in the laboratory of a virus of a domestic or wild animal that has otherwise become extinct. This view is supported by the fact that with the exception of buffalopox virus all vaccinia virus strains form a homogeneous group of viruses both with respect to biological properties and genome structure and are not more closely related to cowpox virus or variola virus than to other orthopoxvirus species. Therefore, the virus that was introduced by Jenner for smallpox vaccination and subsequently distributed worldwide, may indeed have been vaccinia virus.

At the genome level, differences between vaccinia virus strains are mainly due to variability in the terminal regions of the molecule, whereas the central part is highly conserved. Comparison of protein-coding regions between different strains typically show greater than 99% identity in amino acid sequences.

Buffalopox virus is also considered as a vaccinia virus strain and was probably derived from smallpox vaccine. The virus appears to have evolved more rapidly and has become a separate subspecies which is maintained in buffalo herds in certain parts of India.

Serologic Relationships and Variability

All orthopoxviruses show extensive serological cross-reactivity which is even more marked between individual vaccinia virus strains. Strains cannot, therefore, be distinguished by serological means. Restriction enzyme analysis of the viral genome has become the most reliable method for differentiating between vaccinia virus strains, and has largely replaced methods based on biological criteria such as pock morphology on the chorioallantoic membrane, or ceiling temperature.

Epidemiology

Vaccinia virus was occasionally spread from newly vaccinated humans to nonvaccinated individuals. This could lead to serious complications in cases where contraindications for vaccination of the unvaccinated contact existed. Transmission also occurred to domestic animals, such as cows and pigs and these animals in turn, represented a source of infection for humans. Buffalopox virus which probably also originated from vaccinia virus, was spread between animals by farmers. According to recent reports from India, buffalopox virus has acquired considerable pathogenicity for humans. Most outbreaks of rabbitpox in colonies of laboratory rabbits were caused by a vaccinia virus strain which was accidentally transmitted to the animals by laboratory workers. In some outbreaks, the source of infection was not traced.

Transmission and Tissue Tropism

The smallpox vaccine was usually introduced into the epidermis over the deltoid muscle. Jenner inoculated human subjects by a light scratch of the skin through a drop of vaccine and variations of this technique were used for a very long time. During the smallpox eradication campaign, other techniques for delivering vaccine were developed. Jet injectors were widely used in West Africa and Brazil. The major advance was the development of the bifurcated needle which could easily be used even by inexperienced vaccinators and which required no special maintenance.

Accidental transmission of vaccinia virus between humans or between humans and animals occurred by direct contact through minute skin lesions. In most outbreaks of rabbitpox, spread appeared to occur by the respiratory route; direct contact between animals was not necessary.

After smallpox vaccination of humans, virus replicated in the epidermis and remained confined to the site of inoculation. Spread to other parts of the body was only observed in the rare cases of complications. After infection of rabbits with rabbitpox virus by the respiratory route, virus spread through the body in a stepwise manner and replication occurred in various tissues.

Pathogenicity

The frequency of the rare, but serious complications of smallpox vaccination was related to the use of particular vaccinia virus strains. For instance, after the Bern strain, once in Austria, Switzerland and West Germany, was replaced by the Lister strain in 1971, the occurrence of complications of the central nervous system declined. Other strains with a good safety record are the New York City Board of Health strain and the Japanese LC16m8 strain. Since the residual virulence of vaccinia virus is the major obstacle for the introduction of recombinant virus as live vaccines against other pathogens, considerable effort is being

made to make the virus a safer vector. Several nonessential genes have been deleted from the viral genome and in each case, the resulting mutant virus showed an attenuated phenotype in experimental animal models.

Rabbitpox virus is a highly virulent vaccinia virus strain for rabbits causing a rapidly lethal disease. Frequently death occurs before skin lesions have time to develop.

Clinical Features of Infection

After primary smallpox vaccination a papule developed in 3–5 days, rapidly became a vesicle and later became pustular, reaching its maximum size after 8–10 days. A scab then formed, which separated at 14–21 days leaving a typical vaccination scar. Vaccination produced a generalized infection with swelling and tenderness of the draining lymph nodes and mild fever. The vaccinees frequently felt miserable for a few days.

Apart from the 'normal' vaccination reactions, which were more intense than those seen with other human vaccines, a number of rare but serious complications occurred. These were of two kinds: those affecting the skin and those affecting the central nervous system. In the first group, progressive vaccinia was the least frequent, but most serious complication and was observed only in vaccinees with a deficient cell-mediated immune system. The clinical features of progressive vaccinia were a failure of the primary vaccination lesion to heal, appearance of lesions elsewhere on the body and progression of all lesions until the patient died. The fatality-rate was extremely high. Eczema vaccination was the second most serious skin affection and occurred among persons with eczema. This complication was characterized by the appearance of lesions on areas of the skin that were eczematous at the time or had previously been so. The fatality-rate was about 30%. Generalized vaccinia followed virus spread via the bloodstream. Lesions similar to the vaccination lesions appeared on many parts of the body. Generalized vaccinia had a good prognosis. Accidental infection occurred among laboratory workers in research facilities or vaccine production centers or in contacts of newly vaccinated persons and were most serious when they affected the eye. Complications affecting the central nervous system were encephalopathy, usually in children less than 2 years of age, and encephalomyelitis in older children and adults. These complications were of particular concern since they occurred in persons with no obvious contraindications for vaccination and had a high case-fatality rate.

Pathology and Histopathology

The pathology and histopathology of 'normal' skin lesions at various stages after smallpox vaccination were studied in biopsies. For more information, the reader is referred to the specialized literature which also deals with the pathology of the rare complications of vaccination.

Immune Response

Smallpox vaccination with vaccinia virus provided complete protection against smallpox for at least 5 years and some protection for over 30 years. Both humoral and cell-mediated immune responses were observed. Studies in mice indicated that cytotoxic T cells are more important for protection against mousepox than circulating antibodies. In humans, progressive vaccinia developed in patients with an impaired cell-mediated immune system, but normal humoral antibody responses, underlining the importance of cytotoxic T cells for limiting vaccinia virus spread and presumably also for providing protection against smallpox.

Evasion of the Host Immune Response

The recent discovery that poxviruses encode a whole arsenal of proteins whose functions are to counteract the host response to infection, has opened up a new field of exciting research. The list of such proteins includes a viral protein that blocks complement activation, thereby protecting intracellular virus from complement-mediated neutralization of infectivity. Other proteins target the host interferon response either by acting as soluble interferon receptors or by neutralizing the action of interferon-induced antiviral host proteins. Still other proteins interfere with the production of interleukin or compete for the binding of this cytokine to its cell surface receptor, or delay apoptosis. Some of these viral proteins exhibit unusual properties. For instance, in contrast to its cellular counterpart the virus-encoded secreted receptor for interleukin-1 binds only interleukin-1b but not interleukin-1a. The soluble viral interferon receptors on the other hand bind interferons from several different species. The study of these interesting viral proteins is expected to provide insight into the functions of host defense mechanisms which are particularly relevant for the control of infection by certain viruses.

Prevention and Control

After the eradication of smallpox, all countries have abandoned general, compulsory smallpox vaccina-

tion. Whether or not the staff in research institutes working with vaccinia virus should be vaccinated is a matter of controversy. Apart from the risk associated with smallpox vaccination, it will become increasingly more difficult in future to obtain vaccine and to find medical doctors proficient in the vaccination procedure.

Future Perspectives

Clearly, in future vaccinia virus vectors will continue to play an important role in basic and applied research. The future of vaccinia virus as a vaccine will depend on whether recombinant virus-expressing antigens of other pathogens will be accepted as live virus vaccines. The main argument against the introduction of such recombinants are the rare complications associated with the use of vaccinia virus as the smallpox vaccine. Considering the great potential of recombinant virus, the decision of whether or not to introduce such vaccines should only be made after a thorough risk–benefit evaluation and the development of safer vectors might influence the decision favorably.

VARICELLA-ZOSTER VIRUS (*HERPESVIRIDAE*)

Contents

General Features

Jeffrey I Cohen and **Stephen E Straus**, Medical Virology Section, Laboratory of Clinical Investigation, National Institutes of Health, Bethesda, Maryland, USA

History

Descriptions of vesicular rashes characteristic of chickenpox (varicella) date back to the ninth century. In 1875 Steiner showed that chickenpox was an infectious agent by transmitting the disease from chickenpox vesicle fluid to previously uninfected people. Shingles (zoster) has been recognized since ancient times. In 1909 Von Bokay suggested that chickenpox and shingles were related infections, an idea that was experimentally confirmed in the 1920s and 1930s when children inoculated with fluid from zoster vesicles were shown to contract chickenpox. By virtue of the remarkable dermatomal confinement of most zoster lesions, Garland suggested in 1943 that zoster was due to reactivation of varicella virus that had remained dormant or latent in sensory nerve ganglia.

The viral agents of varicella and zoster were first cultivated by Weller in 1952 and shown on morphologic, cytopathic and serologic criteria to be identical. In 1984 Straus and colleagues showed that viruses isolated during sequential episodes of chickenpox and zoster from the same patient had identical restriction endonuclease patterns, proving the concept of prolonged latent carriage of the virus. However, demonstration of latent virus within dorsal root ganglia awaited subsequent molecular studies using *in situ* hybridization and polymerase chain reaction (PCR) techniques.

Taxonomy and Classification

Varicella-zoster virus (VZV) is a member of the *Alphaherpesvirinae* subfamily, genus *Varicellovirus* of the family *Herpesviridae*. Other alphaherpesviruses that infect humans include herpes simplex viruses 1 and 2, and rarely cercopithicine herpesvirus (B virus). All of these agents exhibit relatively short

tion. Whether or not the staff in research institutes working with vaccinia virus should be vaccinated is a matter of controversy. Apart from the risk associated with smallpox vaccination, it will become increasingly more difficult in future to obtain vaccine and to find medical doctors proficient in the vaccination procedure.

Future Perspectives

Clearly, in future vaccinia virus vectors will continue to play an important role in basic and applied research. The future of vaccinia virus as a vaccine will depend on whether recombinant virus-expressing antigens of other pathogens will be accepted as live virus vaccines. The main argument against the introduction of such recombinants are the rare complications associated with the use of vaccinia virus as the smallpox vaccine. Considering the great potential of recombinant virus, the decision of whether or not to introduce such vaccines should only be made after a thorough risk–benefit evaluation and the development of safer vectors might influence the decision favorably.

VARICELLA-ZOSTER VIRUS (*HERPESVIRIDAE*)

Contents

General Features

Jeffrey I Cohen and **Stephen E Straus**, Medical Virology Section, Laboratory of Clinical Investigation, National Institutes of Health, Bethesda, Maryland, USA

History

Descriptions of vesicular rashes characteristic of chickenpox (varicella) date back to the ninth century. In 1875 Steiner showed that chickenpox was an infectious agent by transmitting the disease from chickenpox vesicle fluid to previously uninfected people. Shingles (zoster) has been recognized since ancient times. In 1909 Von Bokay suggested that chickenpox and shingles were related infections, an idea that was experimentally confirmed in the 1920s and 1930s when children inoculated with fluid from zoster vesicles were shown to contract chickenpox. By virtue of the remarkable dermatomal confinement of most zoster lesions, Garland suggested in 1943 that zoster was due to reactivation of varicella virus that had remained dormant or latent in sensory nerve ganglia.

The viral agents of varicella and zoster were first cultivated by Weller in 1952 and shown on morphologic, cytopathic and serologic criteria to be identical. In 1984 Straus and colleagues showed that viruses isolated during sequential episodes of chickenpox and zoster from the same patient had identical restriction endonuclease patterns, proving the concept of prolonged latent carriage of the virus. However, demonstration of latent virus within dorsal root ganglia awaited subsequent molecular studies using *in situ* hybridization and polymerase chain reaction (PCR) techniques.

Taxonomy and Classification

Varicella-zoster virus (VZV) is a member of the *Alphaherpesvirinae* subfamily, genus *Varicellovirus* of the family *Herpesviridae*. Other alphaherpesviruses that infect humans include herpes simplex viruses 1 and 2, and rarely cercopithicine herpesvirus (B virus). All of these agents exhibit relatively short

replicative cycles, destroy the infected cell and establish latent infection in sensory ganglia.

Three subgroups of simian viruses cause severe varicella-like illnesses in nonhuman primates. These include the delta herpesvirus, Medical Lake macaque virus and chimpanzee herpesvirus. While these simian viruses are antigenically related to VZV, they are more homologous to each other than to VZV and are not known to infect humans.

Geographic and Seasonal Distribution

Varicella and zoster infections occur worldwide. Over 90% of varicella occurs during childhood in industrialized countries located in the temperate zone, but infection is commonly delayed until adulthood in tropical regions. Zoster may occur less frequently in tropical areas because of later acquisition of primary infection.

Varicella infection is epidemic each winter and spring, while zoster occurs throughout the year, without a seasonal preference.

Host Range and Virus Propagation

The reservoir for VZV is limited to humans. The virus inherently grows poorly in nonhuman animals or cell lines. Myers and colleagues, however, developed a guinea pig animal model of VZV infection by adapting the virus for growth in guinea pig embryo cells *in vitro*. Inoculation of animals results in a self-limited viremic infection and the emergence of both humoral and cellular immunity. Virus replicates initially in the nasopharynx and can be transmitted to other guinea pigs. Latent VZV DNA has been demonstrated in dorsal root and trigeminal ganglia. The same investigators extended their animal model to congenitally hairless Hartley guinea pigs with the advantage that some animals develop a papular erythematous rash. Rats and mice inoculated with VZV develop latent infection of dorsal root ganglia. Inoculation of VZV into fetal thymus and liver implants in SCID mice results in virus replication in T cells; inoculation of virus into subcutaneous fetal skin implants reproduces many of the histopathologic features of varicella.

An alternative, but less ideal animal model involves the common marmoset (*Callithrix jacchus*). VZV replicates in the lungs with a mild pneumonia and a subsequent humoral immune response. Inoculation of chimpanzees with VZV results in a transient rash containing viral DNA and evokes a modest humoral immune response. None of these animal models has, as yet, reproduced the disease pattern seen in humans, namely a vesicular rash and spontaneous reactivation from latency.

VZV is usually cultured in human fetal diploid lung cells in clinical laboratories. The virus has been cultivated in numerous other human cells including melanoma cells, primary human thyroid cells, astrocytes, Schwann cells and neurons, and can be grown in some simian cells including African green monkey kidney cells and Vero cells, and in guinea pig embryo fibroblasts.

VZV is extremely cell-associated. The titer of virus released into the cell culture supernatant is very low, and preparation of cell-free virus, by sonication or freeze-thawing cells, usually results in a marked drop in the viral titer. Therefore, virus propagation is usually performed by passage of infected cells on to uninfected cell monolayers. VZV is detected by its cytopathic effect, with refractile rounded cells that gradually detach from the monolayer, or by staining with fluorescein-labelled antibody.

Genetics

Several markers can be used to distinguish different strains of the virus. These include temperature sensitivity, plaque size, different effects on host cell lipid metabolism, antiviral sensitivity and restriction endonuclease cleavage patterns. The molecular basis for most of these strain differences are unknown, but viruses that are resistant to acyclovir are usually found to have mutations in their thymidine kinase gene. Other resistant strains have mutations in the DNA polymerase gene.

The entire genome of one prototypical laboratory strain of VZV consists of 124 884 bp. The identification of some viral genes was made by analogy to herpes simplex virus type 1 genes with similar sequences, and by genetic complementation studies in which cell lines expressing selected VZV proteins were used to support the growth of temperature-sensitive mutants of herpes simplex type 1 viruses. Recombinant VZV containing Epstein–Barr virus, hepatitis B virus or herpes simplex virus antigens have been constructed. Recently, a versatile cosmid transfection system has been developed that has allowed targeted deletion, insertion or mutagenesis of a number of individual viral genes products. For example, deletion of the VZV ORF10 gene, the homologue of the essential herpes simplex virus gene VP16, resulted in a virus that was unimpaired for growth *in vitro*.

Evolution

Comparison of the nucleotide and predicted amino acid sequences of VZV with herpes simplex virus types 1 and 2 indicates that these viruses originated

from a common ancestor. They share similar gene arrangements and only five genes of VZV do not appear to have herpes simplex virus counterparts.

VZV is more distantly related to all other human herpesviruses, but many of the nonstructural proteins involved in viral replication have conserved elements and activities. Comparison of VZV, for example, with Epstein–Barr virus shows that the majority of VZV genes are homologous with Epstein–Barr virus. Three large blocks of genes are conserved, although rearranged within the two genomes.

Serologic Relationships and Variability

There is only one serotype of VZV. Antibodies detected by the complement fixation test and virus-specific IgM antibodies decline rapidly after convalescence from varicella. Other, more sensitive serologic tests recognize antibodies that persist for life, including immune adherence hemagglutination (IAHA), fluorescence antibody to membrane antigen (FAMA) and enzyme linked immunosorbent assay (ELISA). VZV-specific antibodies are boosted both by recrudescent infection (zoster) and by exposure to others with varicella.

Variability of VZV strains has been shown primarily by differences in restriction endonuclease patterns. Passage of individual strains *in vitro* eventually results in minor changes in restriction endonuclease patterns, predominantly through deletion or reiteration of small repeated elements scattered throughout the genome. Other than these sites, the genome sequence is remarkably stable. For example, the sequence of the thymidine kinase gene has been determined for several epidemiologically unrelated wild-type and acyclovir-resistant strains and found to possess >99% nucleotide and amino acid identity.

Epidemiology

Varicella may occur after exposure of susceptible persons to chickenpox or to herpes zoster. Over 95% of primary infections result in symptomatic chickenpox. Over 90% of individuals in temperate countries are infected with VZV before age 15.

Zoster is due to reactivation of VZV in patients who have previously had chickenpox; some of these patients may not recall the primary infection. Zoster is not clearly related to exposure to chickenpox or to other cases of zoster. About 10–20% of individuals ultimately develop herpes zoster; the risk of which rises steadily with age (**Fig. 1**). Severely immunocompromised patients, such as those with the acquired immune deficiency syndrome (AIDS), have a particularly high incidence of zoster. Recurrent zoster is uncommon; less than 4% of patients experience a second episode. Asymptomatic viremia has been detected in bone marrow transplant recipients and has been followed by recovery of cell-mediated immunity.

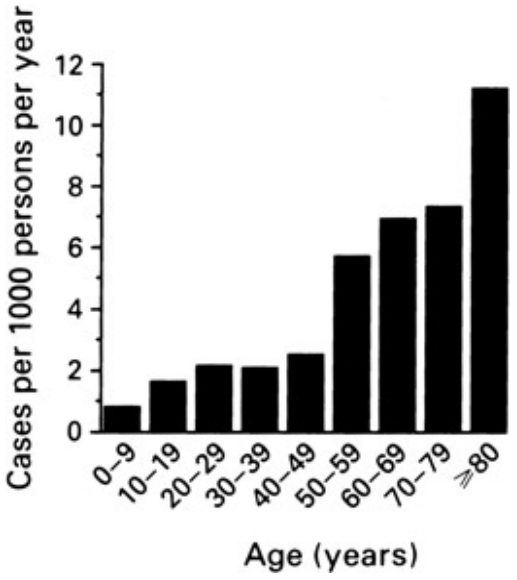

Figure 1 Incidence of herpes zoster per 1000 persons. (Reproduced with permission from Kost and Straus (1996).)

Transmission and Tissue Tropism

VZV is transmitted by the respiratory route. VZV has been detected by PCR in room air from patients with varicella or zoster. Intimate, rather than casual, contact is important for transmission. Chickenpox is highly contagious; about 60–90% of susceptible household contacts become infected. Herpes zoster is less contagious than chickenpox. Only 20–30% of susceptible contacts develop varicella. Patients with varicella are infectious from 2 days before the onset of the rash until all the lesions have crusted.

Primary infection with VZV results in viral replication in the upper respiratory tract and oropharynx, with lesions present on the respiratory mucosa. The infection subsequently spreads to the lymphatics and a mild viremia develops. Mononuclear cells are thought to support viral replication and convey the virus throughout the body. VZV DNA has been detected by PCR in the oropharynx, and virus has been cultured from the blood early during varicella. Further viral replication occurs in the reticuloendothelial system. A brisk secondary viremia results in spread to the periphery. Skin lesions begin with infection of the vascular endothelial cells and virus spreads to epithelial cells. At some time during the course of the infection the virus spreads to both

Med.* 108: 221–237.)

neurons and their surrounding satellite cells. During latency, VZV DNA can be detected in thoracic and trigeminal ganglia by PCR, but there are conflicting data regarding the cell types harboring the latent virus. Using *in situ* hybridization, VZV has been detected in neurons, in satellite cells, or in both cell types. During latency only about four of the 70 known viral genes remain expressed.

Zoster is due to reactivation of virus in the sensory ganglia. The factors leading to its reactivation are not known, but are associated with neural injury and cellular immune impairment. Reactivated virus spreads down the sensory nerve to the skin where the resulting vesicles are typically confined to a single dermatome. Viremia and subsequent cutaneous or visceral dissemination of lesions may occur in zoster, especially in immunocompromised patients.

Pathogenicity

Passage of wild-type VZV in cell culture by Takahashi in 1974 led to attenuation of the virus and changes in its temperature sensitivity and infectivity for certain cell lines. The resulting Oka vaccine strain has several differences in restriction endonuclease patterns from wild-type strains, but it is not known which of these differences contribute to attenuation.

Clinical Features of Infection

The incubation period for chickenpox is 2 weeks, with a range of 10–21 days. The disease begins with fever and malaise, followed by a generalized vesicular rash (**Fig. 2B**). Lesions tend to appear first on the head and trunk and then spread to the extremities. New lesions usually follow viremic waves for 3–5 days and, in the normal host, most lesions are crusted and healed by 2 weeks. Lesions in different stages coexist in an individual. The disease is usually self-limited in the normal host.

Complications of varicella are more common in neonates, in children with malnutrition, in immunocompromised patients (e.g. malignancy or immunosuppressive therapy), in pregnant women, and in

older adults. These complications include bacterial superinfection of the skin, pneumonia, hepatitis, encephalitis, thrombocytopenia and purpura fulminans. Reye syndrome occurs in rare children who take aspirin to treat varicella fevers. There are about 3–4 million cases of varicella each year in the USA, with about 100 deaths.

Zoster usually presents with pain and dysesthesias 1–4 days before the onset of the vesicular rash. The rash is usually painful and confined to a single dermatome (**Fig. 2C**), but may involve several adjacent dermatomes. Fever and malaise often accompany the rash. Vesicles are often pustular by day 4 and become crusted by day 10 in the normal host.

Postherpetic neuralgia, manifested by pain lasting for weeks to several years in the area of the initial rash, is the most common and disconcerting complication of zoster in the normal host. Less common complications include encephalitis, myelitis, the Ramsay Hunt syndrome (lesions in the ear canal, with auditory and facial nerve involvement), ophthalmoplegia, facial weakness and pneumonitis. Immunocompromised patients with zoster are more likely to develop disseminated disease with neurologic, ocular or visceral involvement (**Fig. 2D**). Patients with AIDS have a high frequency of zoster and may develop recurrent or chronic disease with verrucous, hyperkeratotic skin lesions.

Pathology and Histology

Varicella lesions are readily recognized in the skin and mucous membranes. However, similar lesions also occur in the mucosa of the respiratory and gastrointestinal tracts, liver, spleen and any tissue, and remain unrecognized except in severe cases. With severe disease there is inflammatory infiltration of the small vessels of most organs. Zoster causes inflammation and necrosis of the sensory ganglia and its nerves, and skin lesions which are histopathologically identical to those seen with varicella.

Cutaneous lesions due to VZV begin with infection of capillary endothelial cells, followed by direct spread to epidermal epithelial cells. The epidermis becomes edematous, with acantholysis and vesicle formation. Mononuclear cells infiltrate the small vessels of the dermis. Initially, vesicles contain clear fluid with cell-free virus, but later the vesicles become cloudy and contain neutrophils, macrophages, interferon and other cellular and humoral components of the inflammatory response pathways. Subsequently, the vesicles dry, leaving a crust that usually heals without scarring. Cells infected with VZV show eosinophilic intranuclear inclusions with multinucleate giant cell formation (**Fig. 2A**). These changes are not specific for VZV, as they are seen with herpes simplex and cytomegalovirus infections.

Immune Response

Infection with VZV elicits both a humoral and cellular immune response. The ability of VZV immune globulin (VZIG) to attenuate or prevent infection in exposed children (see Prevention and Control, below) indicates that virus-specific antibody is important in protection from primary infection. The presence of VZV-specific IgG does not correlate, however, with protection from zoster. Antibody to VZV is often present by the time the rash of varicella first appears. Virus-specific IgM, IgG and IgA are present within 5 days of symptomatic disease; however, only IgG persists for life. Antibodies to viral glycoproteins gE (gpI), gB (gpII), gH (gpIII) and the immediate early gene 62 product have been detected during acute infection, and the titers of antibodies to these proteins are boosted during recurrent infection. The mere presence of antibody to VZV glycoproteins in children with leukemia who had received live varicella vaccine was not adequate to prevent breakthrough varicella or zoster.

The cellular immune responses are thought to be more important in recovery from acute varicella infection and for prevention of, and recovery from, zoster. The level of cellular immunity correlates with disease severity during acute varicella. Cytotoxic T cells that lyse virus-infected cells are present by 2–3 days after the onset of the rash of varicella. Cell-mediated immunity, as measured by lymphocyte proliferative response, is directed against cells expressing glycoproteins gE, gB, gH, gI and gC (gpI–gpV, respectively), the immediate early genes 62 and 63, and presumably other gene products as well. Interferon is present in VZV vesicles.

Most varicella infections result in lifelong immunity to reinfection. Second episodes of varicella are rare; these individuals tend to have reduced humoral and cellular immunity to VZV at the time of the second infection. Zoster is associated with a reduction in cellular immunity to VZV that, in the normal host, is partially restored in response to this recurrent infection. Recurrent zoster is uncommon, except in severely immune deficient patients, such as those with AIDS.

Prevention and Control

Prevention of varicella can be achieved by restricting exposure or by resorting to either immunoglobulin prophylaxis or vaccination with live, attenuated virus. If given within 4 days of exposure to the virus,

VZIG prevents or attenuates varicella in seronegative persons. The preparation has no effect in modifying zoster. VZIG is recommended for individuals (1) with recent, close contact to patients with varicella or zoster, (2) who are susceptible to varicella, *and* (3) who fall in a high-risk category. The last group includes premature or certain newborn infants, pregnant women, and patients with congenital or acquired cellular immune deficiencies.

The live, attenuated varicella vaccine (Oka strain) was licensed in the USA in 1995 and is recommended for vaccination of all children and some susceptible adults. The vaccine protects normal children and adults, as well as children with malignancies, from clinical varicella. Most children develop adequate humoral and cellular immunity to varicella after a single dose of vaccine; additional doses enhance the degree of immunity and are recommended for adults. A rash may follow vaccination. It is usually mild, but can be severe if the vaccine is given to patients experiencing periods of profound cellular immune impairment. The live vaccine virus establishes neural latency and can reactivate. Thus, zoster has been reported in vaccinees, especially those who are immunocompromised, but the rate appears to be no higher than that following natural infection. Vaccination may be combined with VZIG for postexposure prophylaxis.

Patients with varicella or zoster should be isolated from susceptible persons until all lesions have crusted. This is particularly important for hospital workers and immune-deficient patients.

Acyclovir, vidarabine and leukocyte interferon have been used in the treatment of varicella and zoster in immunocompromised patients. Interferon proved to be an inadequate and impractical therapy. Vidarabine must be administered intravenously and is also less effective and more toxic than acyclovir. Acyclovir is the current treatment of choice for selected infections. It results in a shorter duration of symptoms and decreased visceral dissemination of varicella or zoster in the immunocompromised host. Acyclovir also prevents spread of trigeminal zoster to the eye and modestly shortens the duration of varicella and zoster symptoms in the normal host. Analogues of acyclovir, such as famciclovir and valaciclovir, result in higher levels of antiviral activity and have been licensed for oral therapy of zoster in the USA.

Acyclovir-resistant strains of VZV have been reported in patients with AIDS; these infections are best treated with foscarnet. Corticosteroids, when used early during zoster, reduce acute pain. Herpes zoster, particularly in elderly patients, may lead to prolonged and severe postherpetic neuralgia. Treatment of postherpetic neuralgia is difficult and often unsatisfactory, but many patients experience improvement with tricyclic antidepressant drugs like amitriptyline.

Future Perspectives

Widespread vaccination of children (both normal and immunocompromised) with the attenuated, live varicella vaccine should reduce the incidence and severity of varicella. The increase in humoral and cellular immunity after vaccination of elderly patients suggests that the vaccine might also reduce the frequency and severity of zoster and a large clinical trial is being planned to test this hypothesis. Because of the potential for the live vaccine to cause zoster, subunit vaccines (containing viral glycoproteins) may prove preferable.

Properties of the Virion

The morphology of the varicella-zoster virus (VZV) virion is similar to that of other herpesviruses. The virion is 180–200 nm in diameter and is made up of four structurally distinct elements. The linear duplex viral DNA genome is packaged in a central 75 nm core, contained within an icosahedral nucleocapsid 100 nm in diameter, with 5:3:2 axial symmetry. The nucleocapsid is composed of 162 hexameric and pentameric capsomeres with central hollows wider on the outside than the inside. A proteinaceous tegument surrounds the nucleocapsid and is, in turn, surrounded by a lipid bilayer potentially derived from a number of cellular membranes, including the nuclear membrane and Golgi membranes. This lipid coat contains at least six virus-encoded glycoproteins which are visualized by electron microscopy as spikes or studs approximately 8 nm in length.

A minimum of 30 proteins ranging in size from ~250 to 17 kDa have been identified as components of the VZV virion. The capsid is composed primarily of the 155 kDa VZV major capsid protein which makes up the capsomeres. In addition, some 8–10 other polypeptides are also present in purified nucleocapsids based on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS–PAGE) analysis. Thus the capsid proteins and the glycoproteins account for somewhat less than half the virion proteins. The remainder are, by a process of elimination, contained in the tegument of the virus. Our knowledge of the VZV tegument proteins is incomplete. Recent work, however, has shown that two of the tegument components (the ORF10 protein and the IE62 protein) are the VZV homologues of the herpes simplex virus (HSV) alpha-*trans*-inducing factor (alpha-TIF) and the major immediate early transcriptional regulatory protein ICP4 (IE175). In addition, the products of VZV gene 47 (a protein kinase), gene 9 and the IE4 and IE63 proteins (both gene regulatory proteins) also appear to be present in the virion. The significance of the presence of these proteins is discussed in subsequent sections.

Properties of the Genome

The genome of VZV is a linear duplex DNA molecule with a bouyant density of 1.706 g cm^{-3} and an overall G + C content of 46%. The genome of VZV strain Dumas has been sequenced in its entirety and contains a total of 124 884 base pairs. The size and organization of VZV DNA indicated by this sequence are in good agreement with experimental data derived from a number of different strains over the last decade and it has been taken as the paradigm by workers in the field. The VZV genome is composed of two covalently joined segments designated L (long segment) and S (short segment) and is subdivided into four distinct domains based on sequence redundancy. These include a long unique region, U_L, ~105 kilobase pairs (kbp) in length and a short unique region, U_S, ~5.2 kbp in length, both of which are composed primarily, although not exclusively, of single-copy sequences. The U_L region is bounded by a short, 88.5 bp element (R_L) which is present in inverted orientation at the external (TR_L) and internal (IR_L) termini of the L segment. The S segment is also bounded by a set of inverted repeats termed TR_S and IR_S. These repeat elements, however, are much larger, being ~7.3 kbp in size. Both repeat elements are considerably higher in G+C content than the U_L and U_S segments with average values of 59% and 68% for R_S and R_L, respectively, as compared to ~43% for the single copy sequences.

The VZV genome exists as two predominant isomeric forms which result from inversion of the S segment. These two isomers, which have been designated P (prototype) and I_S (inverted S), are present in equimolar amounts and represent 90–95% of packaged VZV DNA. The remaining two isomeric possibilities, involving inversion of the L segment (I_L) and of both L and S (I_{LS}) with respect to the prototype, are also present but represent only 5–10% of the viral DNA. The four isomeric forms of VZV DNA are believed to result from general recombination during viral DNA synthesis. Why only two isomers predominate, as opposed to the four equally present in HSV is not clear, and this finding could indicate a preferential recognition of specific L-S joints by the VZV cleavage apparatus. Finally, a small and variable percentage of molecules (0.1–5.0%) can be isolated from virions as full-sized circular genomes. The origin of these molecules, the modes of their packaging and circularization, and the role they may play in the infectious cycle of the virus are unknown.

Properties of Viral Proteins

The VZV genome has been shown to contain at least 69 genes, three of which are diploid, encoding proteins that range in size from 8079 to 306 325 Da. Currently, approximately one-third of these proteins and/or their associated activities have been identified

in VZV-infected cells. The functions of roughly another one-third have been inferred based on comparison of their genome location and predicted primary amino acid sequences with those of known HSV functions. Five of the open reading frames (ORFs) appear to be unique to VZV and one of these encodes a thymidylate synthetase activity. Not unexpectedly, several VZV proteins are not absolutely required for growth in cell culture; these include the products of ORFs 1, 8, 9A, 10, 13, 19, 36, 47 and 66. The VZV genes and their characteristics are given in **Table 1.**

Among the most extensively studied VZV protein species are the viral glycoproteins designated gB, gC, gE, gH, gI and gL (originally named gpII, gpV, gpI, gpIII, gpIV and gpVI). These glycoproteins are homologous to the HSV proteins of the same names, are incorporated into the lipid coat of the virion during maturation, and may appear on several cellular membranes in infected cells. Based on sequence homologies, there are likely to be several additional glycoprotein/membrane proteins that remain to be described. All of the known VZV glycoproteins appear to be heavily modified post-translationally.

Glycoprotein E (the most abundant VZV glycoprotein) and gI are believed to form an IgG Fc receptor and thus may have roles similar to that of their HSV counterparts. Glycoprotein B is assumed to be involved in viral attachment and fusion, whereas gH and gL form complexes that are transported to the cell surface, playing roles in cell fusion and cell-to-cell spread of VZV. Glycoprotein C varies considerably in size from strain to strain, has homology to the MHCII complex and may have a role in the pathogenesis of VZV in human tissue.

Homologues of all of the seven genes required for origin-dependent DNA synthesis in the HSV-1 system are present in the VZV genome. Of these seven predicted VZV gene products, only three have been characterized to any significant extent. These are the viral DNA polymerase, the major single-strand-binding protein and the origin-binding protein, that specifically recognizes DNA sequences at the VZV replication origin. The VZV DNA polymerase has been partially purified and is, like other herpesvirus enzymes, activated by monovalent cations with a peak activity at approximately 80 mM KCl. Finally, the VZV DNA polymerase is sensitive to phosphonoacetate and acyclovir, although to a lesser extent than the HSV-1 DNA polymerase. The VZV gene 29 single-stranded (ss) DNA binding protein is a major species in VZV-infected cells, contains a potential divalent metal binding site (zinc finger) and is present primarily in the nuclei of infected cells. The pattern observed is similar to the punctate and localized patchy staining seen with the HSV-1 major DNA-binding protein, suggesting a role in organization of proteins involved in DNA replication complexes, analogous to that of HSV ICP8. The remaining putative VZV origin-dependent replication genes (6, 16, 52 and 55) have not been examined in any detail.

VZV encodes proteins in ORFs 4, 61, 62 and 63 that are homologues of four of the five HSV immediate early genes. It is not yet clear that these are all 'immediate early' products in VZV, but three of them seem to be (IE4, IE62 and IE63); all are known to be involved in transactivation and transrepression of VZV transcription. VZV IE4 is homologous in genome location and, to a limited extent, in predicted amino acid sequence with the HSV U_L54 gene which encodes ICP27 (IE63). Based on transient expression assays, it is a potent transactivator of both homologous and heterologous promoters and can act synergistically with IE62 to enhance transcription. No evidence of a trans repressor activity has been identified, distinguishing IE4 from its HSV analogue, which acts both as a trans activator and a trans repressor. The ORF 61 product is phosphorylated and contains a RING finger domain, involved in metal binding and important for its functions. A similar region is found in the HSV-1 homologue (ICP0; IE110), a promiscuous trans activator of transcription. Used singly, the ORF 61 product can trans activate several VZV promoters and can further trans activate or repress the activating ability of both VZV IE4 and IE62; its activity appears to be cell type-specific. VZV IE62 is a phosphoprotein that both occurs in the virion tegument and will substantially enhance viral DNA infectivity. It is homologous to the HSV ICP4 (IE175) and is likely to be the major gene regulatory factor for VZV. It strongly trans activates VZV promoters of all kinetic classes through an N-terminal activation domain, reminiscent of a similar domain in HSV VP16. Thus, VZV IE62 may play some roles in VZV assigned to two proteins in HSV. IE62 is a sequence-specific DNA-binding protein, capable of regulating the activity of its own promoter. This promoter contains octamer-binding sites, as well as sites for CE/B and ATF binding. VZV IE63 is homologous to HSV ICP22 (IE68), and some evidence exists that it may, either singly, or in combination with IE62, play a role in VZV gene expression regulation. Also in the context of gene regulation, the ORF 10 tegument product (homologous to HSV VP16) is able to trans activate VZV promoters, but is much weaker than VP16 (or IE62).

Other VZV proteins that have been characterized include two protein kinases (from ORFs 47 and 66).

[a]Inferred from data with HSV.

The ORF 47 enzyme is found in the virion tegument, and can phosphorylate IE62, but not other VZV IE proteins. In addition, several enzymes of DNA metabolism are coded by VZV genes, including ribonucleotide reductase and thymidylate synthetase.

Physical Properties and Sensitivity to Environment

Due to the highly cell-associated nature of VZV and the relatively low yields of virus obtained from infected cells, very little work has been done on the physical properties and chemical composition of the virion. It is assumed that, based on its overall structural similiarity to other herpes virions, that the relative proportions of protein, nucleic acid and lipid are typical, as are the bouyant density and overall virion mass.

The VZV virion is highly sensitive to physical and chemical agents. The infectious particle is very labile, and cell-free virus preparations have very high particle:infectivity ratios. Virus from vesicle fluid appears to be more stable. VZV is temperature-sensitive and is inactivated rapidly and completely at 60°C and somewhat more slowly at lower temperatures. VZV is also sensitive to freezing, a property which contributes to difficulties in preparation and storage of high titer stocks. Quick freezing of the virus or infected cells and subsequent storage at −70°C, however, can result in less than 10% loss in titer. In contrast, the titer is rapidly lost on storage at −10°C. Recent reports indicate that lyophilization of both infected cells and cell-free virus in the presence of sugar followed by storage at temperatures as high as −20°C results in complete titer preservation.

VZV is sensitive to pH, with loss of infectivity occurring below pH 6.2 and above pH 7.8. It is also sensitive to UV irradiation, to an extent similar to HSV-1 and HSV-2. VZV is susceptible to mechanical disruption, with 80–99% of infectivity lost after 2 min of sonication. This property may be responsible for some of the loss of infectivity seen on purification of the virus by ultracentrifugation, when a large number of damaged cell-free virions are observed in the electron microscope. HSV virions treated in the same manner are largely intact. A likely explanation for at least part of this VZV property is that virus particles may mature through lysosomal vesicles, allowing digestion of virion components by glycosidases and peptidases.

Replication of Nucleic Acid

The replication of VZV DNA has not been subject to extensive analysis, primarily due to the difficulty in obtaining sufficient numbers of synchronously infected cells. Consideration of the relative proportions of isomeric forms of the viral DNA and the frequency of novel junctions has led to the following model. On entry into the infected cell, the viral genome circularizes and undergoes a limited number of rounds of bidirectional replication. This initiates at the viral

origin (ori) sequences (in the RS regions) consisting of an AT-rich palindrome and a CGTTCGCACTT sequence. During this phase, segment inversion may take place by intramolecular recombination between the inverted repeats. Replication, generating head-to-tail concatemers via a rolling circle mechanism, then accounts for the bulk of viral DNA synthesis. Finally, the newly synthesized DNA is cleaved into unit length molecules and packaged into preassembled capsids in the nucleus. The non-random proportions of isomeric DNA forms are postulated to result from a differential recognition of the normal and novel L-S joints by the viral cleavage system.

The full complement of viral and cellular proteins required for the complete replication of VZV DNA has not been identified. However, as indicated above and in **Table 1**, analogues of the seven genes required for origin-dependent replication of HSV have been identified in the VZV system and three of these have been partially characterized.

Characterization of Transcription

The enzyme responsible for transcription of VZV mRNAs is, presumably, the RNA polymerase II encoded by the host cell. As with other herpesviruses, no viral encoded RNA polymerase activity has been identified. Although 78 relatively abundant transcripts (reading from both strands) have actually been mapped to the VZV genome, as well as 33 less abundant and 29 large transcripts (6–11 kb), these numbers are underestimates of the true transcriptional capability of the genome.

Based on the extensive colinearity of the VZV and HSV genomes and the relatively high degree of functional homology predicted between VZV and HSV gene products, it is reasonable to assume that VZV transcription is regulated in the coordinated cascade scheme seen with other alphaherpesviruses. Direct experimental evidence for this scheme has been difficult to obtain due to the low titers of VZV obtained in cell culture. However, time course studies of protein synthesis have been carried out, which indicate that under conditions of near-synchronous infection, three major classes of VZV-specific proteins are apparent. They have been named immediate early (IE), early (E) and late (L) by analogy with HSV, and each temporal class contains proteins which are representative of such classes in other herpesvirus systems. For example, IE62 is synthesized in the IE phase, the gene 29 major DNA-binding protein is synthesized during the E phase, and the major capsid protein is synthesized at peak levels during the L phase of protein synthesis. Despite these similarities, though, VZV transcription is often different from that of HSV-1. For example, the VZV ORF 10 protein, corresponding to the HSV VP16 (virion trans activator) lacks the acidic carboxy-terminal region which is responsible for the trans inducing activity of that protein. VZV has apparently evolved a separate strategy for the efficient initial transcription of its immediate early genes, probably involving IE62.

Other general features of VZV transcription are apparent from studies of transcription from specific genes. As of this writing, detailed transcript mapping has been carried out on relatively few VZV genes. One finding from these studies is that VZV may use atypical *cis*-acting transcriptional control elements. For example, several consensus TATA box elements may be present upstream of transcriptional start sites but are not used, whereas nonconventional AT-rich regions function to initiate transcription. Similarly, transactivation of VZV promoters often occurs using unusual upstream sequences. Analysis of the 3′ends of VZV genes also reveals differences in the utilization of *cis*-acting polyadenylation sites. Canonical polyadenylation signals for transcripts are often ignored and atypical sequences are utilized preferentially, although GU-rich elements (as in HSV) are usually present. Generally, multiple transcripts are often derived from one gene sequence, but there is no documented evidence for splicing. Indeed, in some VZV genes with spliced mRNAs in their HSV counterparts, there is no spliced VZV mRNA; it is predicted from the genome sequence that ORFs 42/45 will be spliced, however.

Characterization of Translation

Little is known about the details of translation in VZV-infected cells. It is assumed that mRNAs are translated in a fashion similar to that seen in HSV-infected cells and that translation occurs both on free and membrane-bound polyribosomes. Following translation, the majority of viral proteins are efficiently transported to the nucleus where they carry out their roles in viral replication.

Post-translational Processing

Thus far, the most extensively studied post-translationally processed VZV proteins are the glycoproteins. All are N-linked glycosylated and the majority show additional modifications including O-linked glycosylation, sulfation and phosphorylation. For example, VZV gE contains both O-linked and N-linked glycans, and is heavily sulfated and phosphorylated, with phosphorylation occurring at the level of both the polypeptide chain and glycosyl residues. The phosphorylated amino acids are serine

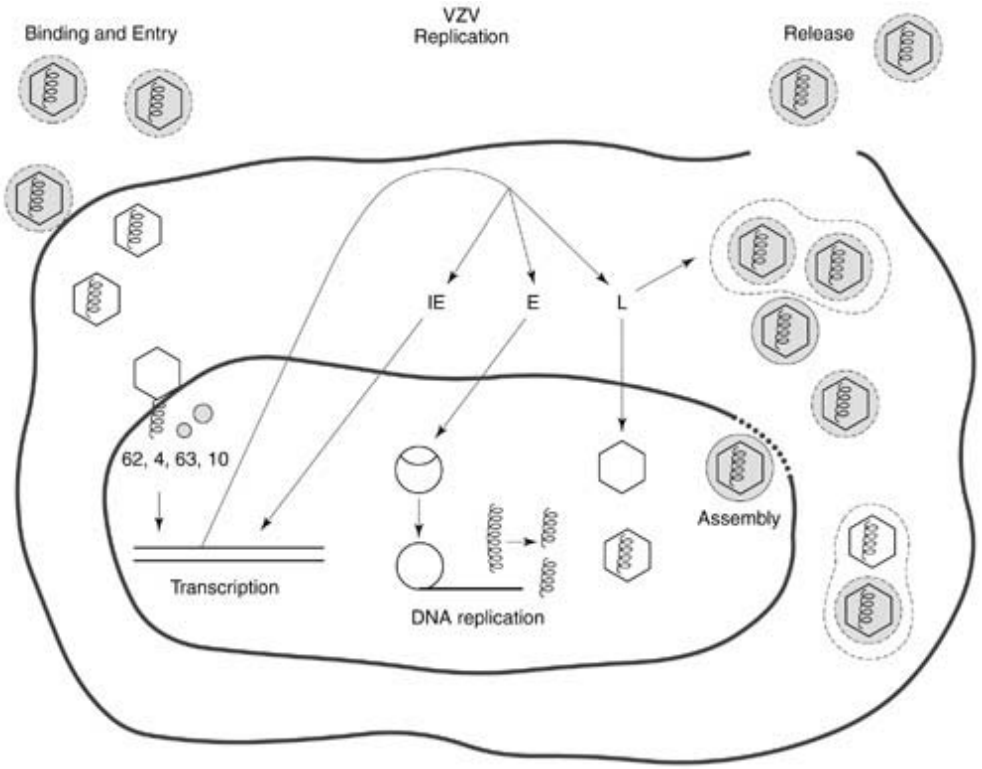

Figure 1 Schematic diagram of the proposed infectious cycle of VZV during lytic infection. Infection is initiated by binding of the virus to the plasma membrane of susceptible cells followed by fusion of the viral envelope and entry of the virus. Following uncoating, the viral DNA, along with tegument components, enters the nucleus where three temporal classes of proteins (IE, E and L) are produced. Transcription of IE mRNA may be enhanced by the IE62 protein which is carried into the cell as a major tegument component. DNA synthesis takes place during the E phase possibly utilizing both bidirectional and rolling circle mechanisms. During the L phase, progeny DNA are packaged into preformed capsids, in the nucleus. These may be enveloped by budding through the nuclear membrane. Enveloped particles acquire a second envelope by budding into cytoplasmic vesicles, which may fuse with lysosomal vesicle. Nucleocapsids may also cross the nuclear membrane and become enveloped in large cytoplasmic vesicles. The membranes surrounding all of these vesicles may ultimately fuse with the plasma membrane, resulting in release of the virus. In cell culture, much of this released virus may have damaged envelope structures.

and threonine but not tyrosine, and the enzymes involved are probably cellular casein kinases I and II. The enzyme responsible for the phosphorylation of the complex oligosaccharides has not been identified, nor has a specific role for the phosphorylated or sulfated residues.

Other viral proteins are modified, particularly by phosphorylation, including IE62 and the ORF 61 protein. IE62 has a predicted molecular weight of 140 kDa, but migrates at approximately 175 kDa on SDS–PAGE, showing evidence of differently phosphorylated forms. The functional significance of the phosphorylation of VZV proteins is unknown.

Assembly Site Uptake, Release, Cytopathology

Models for assembly and release of VZV virions are derived both from extensive, well-established electron microscopic studies and from analyses of VZV glycoprotein biosynthesis and trafficking in infected cells, but no consensus exists (**Fig. 1**). Fully assembled capsids containing unit length genomes comprising all four possible isomeric forms appear to be released from the nucleus, either naked, or having acquired a lipid envelope from the nuclear lamella. In the former case, nucleocapsids acquire their envelope by budding into large cytoplasmic vesicles into which viral glycoproteins have been inserted (via the Golgi), and are released from the cell through reverse endocytosis. In the latter case, vesicles with enveloped particles fuse with lysosomes, in which degradation of virions may take place. The involvement of lysosomes in this case is proposed to rest on their mannose-6-phosphate receptors binding this sugar on the surface of VZV particles. This apparently will not occur in the human host, since the cells in the superficial layers of the skin lack lysosomal vesicles. Perhaps this is also why vesicle fluid virus tends to have a higher and more stable titer.

In tissue culture, cells infected with VZV initially show increased refractility followed by rounding and swelling. Multinucleated cells are common, although the extent of syncytium formation is less than that seen with HSV strains of syncytial plaque morphology. Eventually, the infected cells detach from the support surface, producing readily discernible plaques. The nuclei of infected cells are larger than those of uninfected cells with marginally located chromatin and peripherally located nucleoli. Eosinophilic proteinaceous intranuclear inclusion bodies are present which occupy the sites of viral DNA replication. The nature and function of these inclusion bodies are unknown. Chromosomal aberrations and chromosome and chromatid breakage have also been observed.

Subjects for Further Investigation

A variety of interesting and fundamental questions remain to be answered concerning this important human herpesvirus. One of these is the cellular location and nature of latent VZV infection. Several early reports indicated that the sites of latency were neuronal cells within the dorsal root ganglia but later studies pointed to satellite cells surrounding the neuron. This has led to a model for reactivation of latency in which virus reactivating in satellite cells or neurons lytically infects the neuron resulting in cell destruction. This model is consistent both with the normally singular recrudescence of the virus, and with neuronal damage and postzoster neuralgia associated with reactivation of VZV. Another important feature of VZV latency is the state of expression from the viral genome. Unlike HSV, which appears to produce only a single transcript in the latent state known as the latency associated transcript (LAT), several messages are expressed in cells latently infected with VZV, corresponding to IE4, IE62, IE63, ORF 21 and ORF 29. Assuming translation of these mRNAs in latently infected cells, four of these 'latency proteins' have gene regulatory capacity, and may serve to control the latent state.

A second question involves the factors delineating VZV pathogenesis. Currently there are two obvious areas for investigation. The first involves the identification and understanding of both the *cis*- and *trans*-acting factors involved in the regulation of expression of VZV genes. Why, for example, has the virus evolved to use noncanonical transcription start and stop sites? Which specific viral polypeptides are involved in recognition of such sequences and how many cellular factors are involved? The roles of the known transcriptional regulatory proteins (IE4, IE62, IE63, ORF 61 and ORF 10) will have to be evaluated *in vivo*, in order to define their true roles during productive infection in the human host. Such an approach could also lead to the identification of host cell factors which influence the control of VZV expression. A second set of proteins for which we have only vague functional ideas are the glycoproteins. Some obvious questions are: why does VZV have fewer glycoproteins than HSV and how does this affect its pathogenesis? And do the VZV glycoproteins modulate tissue tropism of VZV?

These questions are all germane to the fact that an effective live attenuated vaccine strain (Oka) has been developed and is in widespread use in children in the industrialized world. However, the specific molecular nature of its attenuation is unknown. In recent studies in a SCID-hu model for VZV infection, it has been demonstrated that the Oka vaccine virus grows well in T-lymphocytes but not in skin cells, consistent with its antigenicity, as well as its relative inability to cause the typical varicella rash. In analogous experiments, VZV lacking gC has been shown to replicate poorly in skin cells, suggesting that this glycoprotein is a virulence factor for the virus. Now that we have a good animal model, as well as a reliable method for construction of viral mutants, we can anticipate substantial new data on VZV replication, both *in vivo* and *in vitro*.

sequences seem only to be beneficial with respect to biological containment, since viral vectors will not survive for long in nature. On the other hand, new functional viral genomes may arise from recombinational events involving (disarmed) RNA vectors, co-infecting (helper-) viruses and transgenes, which could lead to undesired spread of pathogens. Although so far no evidence has been obtained for such events, it is clear that critical risk-assessment analyses should be performed prior to possible release of viral vectors in agricultural practice.

Introduction

It has been nearly 100 years since a leafhopper was confirmed as the vector of rice dwarf virus. Several hundred plant viruses have since been identified, a majority of which are dependent upon a vector for transmission between, and inoculation into, plant hosts. The plant viruses have evolved many interesting and biologically complex associations with their vectors, which include arthropods, nematodes and fungi. Although there is a great deal known about the general biology of most virus–vector interactions, we are only beginning to understand the molecular and cellular mechanisms that regulate the transmission processes and determine the efficiency of transmission.

General Mechanisms of Virus Transmission by Arthropods and Nematodes

In the early years viruses were said to be either mechanically transmitted or biologically transmitted by their vectors. Biological transmission was the specific association of a virus with a particular arthropod species or genus and the virus replicated in the vector. Mechanical transmission referred to the nonspecific transmission of viruses, usually by multiple vector species. The viruses did not replicate in the vector and transmission was thought to occur by the simple contamination of vector mouthparts. Most plant viruses do not replicate in their vectors, but it

was quickly realized the transmission process involved more than just contaminated mouthparts.

The early work on plant virus–vector associations was related to timing events, e.g. acquisition and inoculation periods, retention periods and latent periods (the time between ingestion of the virus and the ability of the vector to inoculate a healthy host). Therefore, the terminology evolved to describe time events. Nonpersistent viruses are not retained by the vector for more than a few hours. Semipersistent viruses are retained for days or possibly weeks. Nonpersistent and semipersistent viruses are acquired and inoculated within seconds or minutes, and do not require a latent period, nor do they replicate in the vector. Persistent viruses are retained for the life of the vector. These viruses require longer acquisition and inoculation times (hours to days), and latent periods of one day to several weeks.

As additional data were generated on the mechanisms of transmission, other variations of the terminology evolved. The nonpersistent and semipersistent viruses were found to associate specifically with the epicuticle that lines the stylets (mouthparts) or foregut, respectively, of their arthropod and nematode vectors and were often referred to as stylet-borne or foregut-borne viruses.

All of the above terms were developed for use with aphid and leafhopper vectors and are applicable to many plant viruses. However, as additional arthropod, nematode and fungal vectors were discovered and their associations with viruses were studied, terminology problems arose, especially with regard to fungal vectors.

In recent times the terms circulative and noncirculative have been widely used. Circulative refers to the requirements that the virus be actively transported across cell membranes and internalized by the vector. These viruses, which would include the persistent viruses, can be further divided into propagative viruses, which replicate in their arthropod vector in addition to their plant hosts, and nonpropagative viruses which only replicate in their plant hosts. Noncirculative viruses do not cross vector cell membranes and are carried externally either on the vector surface or on the cuticle lining of the vector's mouthparts or foregut. These would include both the nonpersistent and semipersistent viruses.

The noncirculative and circulative classification is simple and can be used for all plant viruses that require a vector for optimal existence in nature. There is of course some loss of definition and categorization, but subgrouping, such as nonpersistent and semipersistent, can be added if they pertain to a particular vector taxa. There would, of course, be the paradoxical virus–vector associations that may not easily fit into the proposed scheme. For example, beetle-transmitted viruses and the myirid bug-transmitted velvet tobacco mottle virus may utilize both circulative and noncirculative transmission mechanisms. Additionally, these terms have not been adapted for use with viruses transmitted by fungal vectors (see below).

Vector Feeding Mechanics and Behavior

Plant viruses are incapable of penetrating the plant cell wall and require a wound to gain entrance. However, the cell they enter must be viable so the virus can replicate and translate movement proteins that enable it to move to neighboring unwounded cells. A majority of arthropod and nematode vectors of plant viruses have piercing–sucking mouthparts which are ideal for inoculating plant viruses into plant cells. The hollow needle-like mouthparts can penetrate the plant cell wall by mechanical force and with the help of salivary and gut enzymes. The cell membrane is easily breached by mechanical force, making the cell contents available as food. The most significant feature of this type of feeding is that it does not irreparably damage the plant cell.

The general feeding behavior of many arthropod and nematode vectors also aids in the inoculation process. The acceptance or rejection of a plant host is accomplished by a series of brief probes into multiple epidermal cells. These 'taste-tests' are sufficient to inoculate the noncirculative, nonpersistent viruses. This type of transmission mechanism does not require the plant to be a host of the vector for the virus to establish an infection. Accordingly, most of the noncirculative, nonpersistent plant viruses are transmitted by numerous species within one vector taxon. For example, individual potyviruses are transmitted by numerous aphid species, but are not transmitted by whiteflies or leafhoppers.

If the brief feeding probes indicate the plant is an acceptable host or food source then the vector is likely to initiate prolonged feeding. This may occur in numerous epidermal or mesophyll cells, or more often the insect will seek out its preferred feeding site, the carbohydrate-rich phloem sap. Prolonged feeding allows for the inoculation of the semipersistent, noncirculative viruses as well as the circulative viruses. The transmission strategy of these viruses is to associate with one, or at most a few, vector species for the life of the vector. The virus and the vector share overlapping host ranges and this ensures the virus will be delivered to a new host when the vector moves to a new host.

There are insect vectors (mainly beetles) of plant viruses that have chewing mouthparts and a more

indiscriminate feeding behavior than the piercing–sucking insects and nematodes. Inoculation by beetles was, until recently, considered to be a mechanical process; virus contaminating the mouthparts was deposited into the wound, or virus in the gut was regurgitated as the beetle fed. The process is now known to be extremely specific and biologically complex. Viruses are inoculated into a gross wound resulting from the chewing action of the beetle because the virus can rapidly translocate in xylem elements away from the site of inoculation and infect cells away from the feeding site. Several viruses that are not transmitted by beetles can be acquired and are present in the hemolymph and gut regurgitant that is deposited into and around the feeding sites. The nontransmissible virus is apparently inactivated at the wound site or unable to gain entrance to a functional plant cell capable of sustaining a virus infection.

The transmission of plant viruses has been found to be extremely complex even in situations where initially it may have appeared to be a simple, nonspecific mechanical inoculation. The details of many of these molecular and cellular mechanisms regulating the transmission of plant viruses are described in subsequent sections.

Noncirculative Transmission

The noncirculative method of transmission is not widely associated with animal virus transmission, but it is the method of choice for a majority of plant viruses (**Table 1**). The noncirculative viruses are transmitted by arthropod and nematode vectors and can be further subdivided into nonpersistent and semipersistent categories. Semipersistent viruses tend to be associated with the cuticle lining the foregut of the vector (**Fig. 1**) and are retained for several days or weeks (months or years in some). Transmission efficiency increases as the acquisition feeding time increases, which suggests that virus is stably bound and accumulates until binding sites are saturated. In contrast, the nonpersistent viruses are retained only for a few hours and are easily lost during feeding probes. Furthermore, transmission efficiency rapidly decreases as acquisition feeding time increases. This suggests that bound virus is easily dislodged during prolonged feeding and subsequently ingested virus cannot associate with sites along the stylets.

There are two current theories for the mechanics of noncirculative, nonpersistent transmission. The ingestion–egestion model suggests that transmissible virus adheres to the cuticle at the stylet tips or further inside the mouthparts or foregut during ingestion of plant material. Bound virus is subsequently released during periods of regurgitation and salivation. The ingestion–salivation model acknowledges that virus can bind at multiple sites along the anterior alimentary canal, but the transmitted virus is limited to that which is bound to the proximal tip of the maxillary stylet where the food and salivary canals are fused. Virus is released by the act of salivation rather than by regurgitation (**Fig. 1**).

The most complete understanding of the mechanisms of noncirculative virus transmission comes from work on the aphid-transmitted potyviruses and caulimoviruses, both of which are nonpersistent and require a nonstructural, virus-coded protein referred to as a helper component, or aphid transmission factor to be transmitted (**Table 1**). Although there are several hypotheses for the role of helper in virus–vector interactions, one is emerging as the most plausible. The 'bridge' hypothesis suggests that the helper acts to mediate the attachment of virus to the cuticle lining of the vector mouthparts. Purified virus is not transmissible, but if aphids are given access to a solution containing helper prior to or along with purified virus then transmission can occur. Ultrastructural and immunolabeling evidence indicates that potyvirus fed to aphids along with helper becomes embedded in a matrix material bound to the cuticle, and helper protein is a component of the matrix. If aphids are fed on virus without helper, the matrix material is absent and virus is not retained.

The potyvirus coat protein contains a DAG amino acid motif located near the N-terminus. Mutations within this domain or adjacent to this domain abolish transmission and also prevent accumulation of virus in the stylets. Additionally, all of the potyvirus helper factors studied to date contain two characteristic amino acid motifs, a KITC box and a PTK box. Mutations in or adjacent to these motifs render the virus nontransmissible by the natural vector. A specific mutation of the KITC sequence to EITC abolished transmission, but did not affect the *in vitro* binding of virus to the helper. Furthermore, the virus was not observed on the stylets when acquired with the EITC-mutant helper, but was observed when acquired along with wild-type helper. These data indicate that the KITC box functions in aphid–helper interactions rather than helper–virus interactions. In contrast, mutations in the PTK box abolished helper–virus interactions *in vitro*; therefore this domain may play a role in attachment of the virus to the helper. Alternatively, mutations in the PTK box may prevent dimerization of the helper, which is the active configuration of the helper protein.

Analysis of the cauliflower mosaic caulimovirus (CaMV) helper provides further evidence of the bridge hypothesis. The CaMV helper accumulates in paracrystals in the cytoplasm of infected plant cells

Table 1 Mechanism of transmission and the principal vectors of plant virus families

Virus taxa	*Number of members*[a]	*Principal vector taxa*[b]	*Transmission mechanism*[c]	*Helper required*[d]
Caulimovirus	17	Aphids	NC-NP	Yes
Fabavirus	2	Aphids	NC-NP	No
Potyvirus	186	Aphids	NC-NP	Yes
Carlavirus	55	Aphids	NC-NP	No
Cucumovirus	3	Aphids	NC-NP	No
Alfamovirus	1	Aphids	NC-NP	No
Machlomovirus	1	Thrips/beetle	NC-NP	No
Macluravirus	2	Aphids	NC-NP	No
Potexvirus	55	Aphids (7/10), mites (2/10),	NC-NP	No
Badnavirus	16	Mealybugs (3/6), leafhopper (1/6)	NC-SP	No
Closterovirus	25	Aphids (10/19), whiteflies (6/19), mealybugs (2/19)	NC-SP	No*
Nepovirus	39	Nematodes	NC-SP	No*
Sequivirus	2	Aphids	NC-SP	No
Tobravirus	4	Nematodes	NC-SP	No
Trichovirus	6	Aphids (1/3), mealybugs (1/3), mites (1/3)	NC-SP	No
Waikavirus	3	Aphids (1/3), leafhopper (2/3)	NC-SP	No
Necrovirus	3	Fungi	*in vitro*	No
Tombusvirus	12	Fungi (1/12)	*in vitro*	No
Varicosavirus	4	Fungi	*in vitro*	No
Enamovirus	1	Aphids	C-Npr	No
Geminivirus				
Bigeminivirus	41	Whiteflies	C-Npr	No*
Hybrigeminivirus	2	Treehoppers	C-Npr	No
Monogeminivirus	11	Leafhoppers	C-Npr	No
Luteovirus	27	Aphids	C-Npr	No
Nanavirus	5	Aphids	C-Npr	No
Umbravirus	10	Aphids	C-Npr	Yes
Bromovirus	6	Beetles	C-Npr*	No
Carmovirus	22	Beetles (3/10)	C-Npr*	No
Comovirus	14	Beetles	C-Npr*	No
Sobemovirus	17	Beetles (6/8)	C-Npr*	No
Tymovirus	21	Beetles	C-Npr*	No
Rymovirus	7	Mites	?	No
Bymovirus	6	Fungi	*in vivo*	No
Furovirus	12	Fungi	*in vivo*	No
Bunyaviridae				
Tospovirus	5	Thrips	C-Pr	No
Marafivirus	3	Leafhopper	C-Pr	No
Reoviridae				
Phytoreovirus	5	Leafhopper	C-Pr	No
Fijivirus	6	Planthopper	C-Pr	No
Oryzavirus	2	Planthopper	C-Pr	No
Rhabdoviridae				
Phytorhabdovirus	32	Aphid (1/3), leafhopper (1/3), planthopper (1/3)	C-Pr	No
Cytorhabdovirus	17	Aphid (3/7), planthopper (4/7)	C-Pr	No
Nucleorhabdovirus	38	Aphid (7/17), leafhopper (4/17), planthopper (6/17)	C-Pr	No
Tenuivirus	10	Planthopper	C-Pr	No

[a] The number of members of each group was obtained from Brunt AA *et al* (1996) *Viruses of Plants.* Cambridge: CAB International.

[b] Indicates the vector taxa that is commonly associated with the transmission of the members of the virus group. In cases where multiple vector taxa have been reported to vector members of the virus group, the number of viruses vectored by that insect

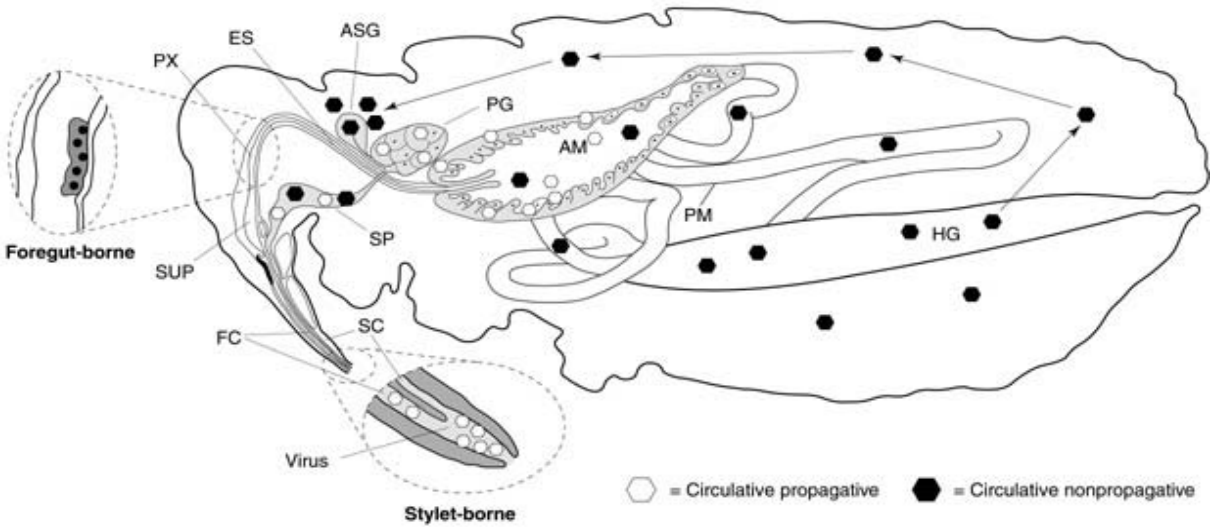

Figure 1 Mechanisms of transmission of plant viruses by arthropods with piercing–sucking mouthparts. The general anatomy of the alimentary system and the salivary system is shown; the areas relevant to virus transmission are labeled. One inset shows a detailed view of the distal end of the mouthparts where the food canal (FC) and salivary canal (SC) empty into a common space. The current model of transmission of stylet-borne (nonpersistent, noncirculative) viruses suggests that transmissible virus is retained at the distal tip of the stylets and then released by salivary secretions as the insect salivates during feeding. A second inset shows a detailed view of foregut-borne (semipersistent, noncirculative) viruses attached to the cuticle lining of the foregut, a region that would include the sucking pump (SUP), pharynx (PX) and esophagus (ES). Note the virus is embedded in a matrix material attached to the cuticle. The origin or composition of the matrix material is unknown. The circulative nonpropagative viruses will pass through the foregut into the anterior midgut (AM), posterior midgut (PM) and then into the hindgut (HG). They do not infect the gut cells but are transported through the posterior midgut or hindgut cells and released into the hemocele (body cavity). Current information indicates these viruses specifically associate with the accessory salivary glands (ASG) and are transported across the ASG cells and then released into the salivary canal (SC). The circulative propagative viruses will infect the midgut cells and subsequently infect other tissues. These viruses ultimately associate with the principal salivary glands (PG) and possibly ASG prior to their release into the SC. SP, salivary pump.

from which active helper can be solubilized. Mutations in the C-terminal domain of the CaMV helper abolish helper–virus binding *in vitro* and aphid transmission. Mutations in the N-terminus also abolish aphid transmission, but the helper retains its ability to bind to virions *in vitro*. These results suggest the C-terminus of the helper protein binds to virus particles, while the N-terminus of the helper protein is free to bind to sites in the aphid and bridge the indirect association of the virus particles to the insect cuticle.

Not all viruses transmitted in a noncirculative manner require a helper protein or helper virus (**Table 1**). Purified alfamoviruses, carlaviruses and cucumoviruses can be transmitted by aphids without helpers. Studies with cucumber mosaic cucumovirus have shown that transmission is regulated solely by the capsid protein. It is not known if these viruses are retained in similar locations in the vector.

The mechanisms of semipersistent transmission are not well studied. They may share some attributes with nonpersistent transmission but differences in sites of virus binding to the vector and times of retention indicate major differences in release of virus, if not in mechanisms of binding. There are few experimental data to explain how virus particles bound to the epicuticle substrate are released. The N-terminus of the potyvirus coat protein which binds the helper protein is often proteolytically cleaved *in vitro* without any deleterious effect on its infectivity.

taxa/the number of viruses tested for transmission is given. Information obtained from Brunt AA *et al* (1996) *Viruses of Plants.* Cambridge: CAB International.

[c] NC-NP, noncirculative, nonpersistent; NC-SP, noncirculative, nonpersistent; C-Npr, circulative, nonpropagative; C-Npr*, viruses transmitted by beetles do circulate in the insect hemolymph, but may also use a noncirculative mechanism of transmission as well; C-Pr, circulative, propagative. All mechanisms are defined in the text.

[d] Virus require a virus-encoded nonstructural helper protein or a helper virus for transmission; * indicates that there is some information that suggests a helper may be required for the transmission of some members of these virus families.

Similarly, the C-terminus of the nematode-transmitted tobacco rattle tobravirus can be cleaved from the particle without adversely affecting the virus. It is possible that proteases in the vector saliva or regurgitated gut secretions can act to cut the virus particle loose. Conformation differences in virus–helper–vector combinations and/or exposure to different enzymes and ionic conditions, depending on the site of retention, may account for differences between nonpersistent and semipersistent viruses and also for the differences in the specificity or transmission efficiency of vectors for the same virus.

Circulative Transmission

The mechanism of circulative transmission requires the virus to be internalized by the arthropod vector; there are no known circulative nematode transmitted plant viruses (**Table 1**). As previously mentioned, the circulative viruses are further divided into two subgroups: propagative viruses, those which replicate in their arthropod vectors (similar to the arboviruses); and the nonpropagative viruses.

Circulative, nonpropagative transmission

This type of transmission has been best studied with the luteoviruses and pea enation mosaic enamovirus (PEMV). The members of the luteovirus group and PEMV are each efficiently transmitted by one or, at most, a few aphid species. All the viruses share a common circulative pathway (**Fig. 1**) and biology within their aphid vectors. Ultrastructural studies have shown that ingested virus is not degraded or inactivated in the gut. Acquisition of virus into the aphid hemocele (body cavity) occurs either through the posterior midgut or hindgut epithelial cells by endocytosis. Virus is transported through the cell cytoplasm in vesicles that ultimately fuse with the basal plasmalemma, releasing particles into the space between the membrane and the basal lamina. Virus apparently moves rapidly across the basal lamina and into the hemocele. In most virus isolate–aphid species combinations, virus is acquired into the hemocele regardless if the aphid is a vector of that particular virus isolate. The gut does not appear to be a major barrier to luteovirus acquisition, although the process is specific for luteoviruses. Morphologically similar viruses can accumulate in the gut, but are not acquired into the hemocele.

Virus in the hemocele must pass through the salivary gland cells via an endocytosis pathway to be released by the vector into the plant. The salivary glands in aphids consist of two principal glands and two accessory salivary glands (ASG). Luteoviruses and PEMV associate exclusively with the ASG and more specifically with the anterior portion of these four celled glands. The ASG may function as an excretory organ in aphids and it is possible that luteoviruses have evolved to take advantage of specific excretory pathways to access the salivary ducts. An inability of luteovirus isolates to penetrate the ASG of nonvector aphids has long been known to contribute to the vector specificity. Recently it was shown that both the basal lamina and the basal plasmalemma function as independent barriers to transmission in different luteovirus isolate–aphid species combinations.

Studies of multiple luteovirus isolates in multiple nonvector aphid species has shown that the hindgut barrier or either of the two ASG associated barriers can function as the primary barrier of transmission for the same virus in different aphid species or in the same aphid for different virus isolates. This indicates that different membrane attachment sites (receptors) and/or different virus attachment protein domains are used at each transmission barrier by different virus isolate–aphid species combinations. Receptors on the aphid cell membranes have not been identified. However, the luteovirus and PEMV encoded proteins involved in aphid transmission have been studied and both virus groups share some structural features. The virus capsid contains a predominant coat protein (*c.* 22–24 kDa) and a minor amount of a larger protein translated via a readthrough of the coat protein stop codon. The full-length luteovirus coat protein readthrough is *c.* 72–74 kDa, but the C-terminal half of the 50 kDa readthrough domain is proteolytically processed to yield a 55–58 kDa coat protein readthrough commonly associated with purified virus preparations. It is not known if this type of processing actually occurs *in vivo*, but the C-terminal readthrough domain is not required for aphid transmission. The PEMV capsid also contains a coat protein readthrough, but the protein is inherently shorter than the luteovirus counterpart and does not undergo further processing.

The readthrough protein is not required for particle assembly or plant infection, and although particles containing only the 22–24 kDa coat protein are not aphid transmissible, ingested particles are found in the hemolymph. These results indicate that the coat protein regulates the uptake of the virus through the hindgut, and suggest the N-terminal portion of the readthrough domain regulates the virus–ASG associations. When luteovirus coat protein genes were expressed in insect cells using a baculovirus expression vector, virus-like particles (VLPs) were assembled. The readthrough-minus VLPs were purified and either fed to aphids through a Parafilm membrane or injected directly into the hemocele.

Ultrastructural examination of the aphids revealed the ingested particles were acquired through the gut into the hemocele, but, surprisingly, VLPs were observed in the accessory salivary gland cells and in the salivary ducts. These results are consistent with earlier studies showing that readthrough was not required for acquisition through the gut, but contrasted with the hypothesis that readthrough regulated the transport of virus through the accessory salivary gland. What then is the function of the readthrough domain, if any, in the aphid transmission process?

Aphids harbor endosymbiotic bacteria of the genus *Buchnera* in specialized cells located in the abdomen, called mycetocytes. Neither the aphid nor the bacteria are able to survive and reproduce without the other. All of the benefits that the bacteria provide for the aphid are unknown, but they are likely to provide essential amino acids the aphid is unable to synthesize. In addition, the bacteria produce copious amounts of a chaperonin protein named symbionin, a homologue of the *Escherichia coli* GroEL chaperonin protein.

Six luteoviruses and the related PEMV were all shown to bind specifically, but differentially, to *E. coli* GroEL and symbionin homologues from vector and nonvector aphids *in vitro*. The binding capacity was not correlated with transmission efficiency of the aphid, suggesting that if symbionin plays a role in transmission it does not play a role in vector specificity. A mutational analysis indicated the N-terminal portion of the readthrough domain contained the determinants for symbionin binding. Finally, virions that did not contain readthrough protein and did not bind symbionin *in vitro* were less persistent in the aphid hemolymph than wild-type virus. These studies provide convincing data that symbionin can interact specifically with luteoviruses and PEMV *in vitro* and may slow the degradation of virus in hemolymph. The mechanisms of degradation of virus in the hemolymph are unknown, nor is it known whether the attachment of symbionin to the virus protects the virus from targeting by the aphid immune system; alternatively, it may facilitate virus movement into the accessory salivary gland.

The coat protein readthrough appears to be a requirement for vector transmission of luteovirus and PEMV, but not for all circulative, nonpropagative viruses. Geminiviruses are single-stranded circular DNA viruses that have been divided into three taxonomic groups or genera (**Table 1**). The viruses within the monogeminivirus and hybrigeminivirus genera are each transmitted by a different species of leafhopper or treehopper. Viruses within the bigeminivirus genera are all transmitted by whiteflies. Geminiviruses have been observed in the gut epithelial cells and associated with salivary glands of whitefly vectors. They are assumed to follow a similar circulative route through the whitefly as the aphid transmitted luteoviruses, although no detailed ultrastructural studies have been published. Several lines of evidence suggest that the transmission mechanisms used by the geminiviruses differ from that of the luteoviruses.

The geminivirus coat protein has been shown to be the sole determinant of transmission of some whitefly-borne viruses, a property that was recently mapped to the N-terminus of the coat protein of abutilon mosaic bigeminivirus. The coat protein was also shown to be the sole determinant of whether a geminivirus was transmitted by a whitefly or a leafhopper. However, the coat protein does not solely determine the transmission phenotype of all geminiviruses. A genomic analysis of tomato golden mosaic bigeminivirus indicated that, although the coat protein was required for acquisition of the virus, both genomic components were required for transmission. DNA B was essential for the accumulation of virus in the whitefly, while DNA A was required for the successful inoculation of plants by viruliferous insects. It is not understood if either or both genomic sequences are directly influencing virus–insect interactions or plant–virus interactions that may indirectly influence transmission efficiency.

Studies of geminivirus titer over time in whiteflies have not been able to show conclusively an increase that would suggest virus replication, but the viral DNA does persist in the insect longer than its infectivity would suggest. No replicative forms of the viral DNA have been detected within the insect, which also argues against the replication of virus in the insect. However, squash leaf curl virus was observed in several whitefly tissues and the presence of virus was associated with cytopathological abnormalities in some tissues. Furthermore, the presence of the virus in the insect can have detrimental effects on the biology and reproduction of the vector. Both of these observations would suggest virus replication. Additionally, tomato yellow leaf curl virus was recently reported to be transmitted transovarily in its whitefly vector. This type of vertical transmission usually indicates the virus is replicating in the vector, but geminiviruses may have evolved a mechanism to cross the transovarial transmission barriers without replicating in that tissue, or perhaps there is some low level amount of infection of reproductive tissues. No cytopathological effects, deleterious reproductive effects or transovarial transmission have been documented for aphids fed on luteovirus-infected plants.

Circulative, propagative viruses

The plant-infecting viruses within this classification (**Table 1**) are those most closely related to the animal-infecting arboviruses. Indeed three of the five taxonomic groups considered here have animal infecting members: rhabdoviruses, reoviruses and bunyaviruses. The plant viruses within these groups could be considered as plant-infecting arboviruses or phytoarboviruses.

The phytoarboviruses, with few notable exceptions such as the tomato spotted wilt tospovirus, are not economically important and have not been intensively studied. Their genomes tend to be relatively large and complex and they have remained recalcitrant to many of the modern molecular biology techniques. In addition, it has been difficult to generate sufficient numbers of stable mutants with phenotypes related to vector transmission. These are problems that have also plagued arbovirus research but, on the other hand, arbovirus research has benefited tremendously from the establishment of cultured vector cell lines and the ability to conduct detailed genetic studies on vector populations. Both of these research strategies have been difficult to develop and apply to the insect vectors of the phytoarboviruses.

Similar to the circulative, nonpropagative viruses, the individual phytoarboviruses tend to be transmitted by only one or a limited number of closely related vector species. Furthermore, many of the individuals within a population of any given vector species are not able to transmit the virus, although many can support virus replication. Consequently much of the research on transmission has investigated the movement of virus in vectors and the mechanisms of vector specificity. The general pathway through the arthropod is similar for all these viruses (**Fig. 1**). Virus is imbibed along with the plant sap and attaches to and infects midgut cells, usually reaching high titers in these tissues. Virus is released into the hemocele and secondarily infects other tissues, including reproductive tissues from which the virus can spread vertically to offspring. Horizontal transmission to other plant or animal hosts occurs following infection of salivary tissues and subsequently release of infectious virus from the glands in the salivary secretions that are injected into the host during feeding.

Vector competence (ability to transmit) is determined not only by the ability of the virus to replicate in the various tissues of the vector, but also by the ability of the virus to successfully enter and exit the tissues. The cellular barriers to transmission have been extensively studied and include a midgut infection barrier, which was first demonstrated for eastern equine encephalomyelitis alphavirus and has subsequently been demonstrated for other animal- and plant-infecting viruses. An active midgut infection barrier will effectively render the arthropod immune to the virus. Other barriers allow infection of the arthropod, but virus is not transmitted. A midgut escape barrier has been demonstrated for tomato spotted wilt tospovirus (*Bunyaviradae*) in the adult stage of the thrip vector. Virus can infect and replicate in midgut cells of both larval and adult thrips, but virus can only disseminate from larval midgut cells into other thrip tissues, therefore it must be acquired by the larval thrips to be transmitted. Wound tumor reovirus and sowthistle yellow vein rhabdovirus, both phytoarboviruses, are able to invade and replicate in several tissues of their leafhopper or aphid vectors, respectively. However, in nontransmitting individuals the viruses were not associated with the salivary glands. This suggests the existence of a salivary gland infection barrier, but does not rule out the possibility that the virus is not able to survive in the hemolymph or hemolymph-associated cells that would come in contact with the salivary glands. A salivary gland escape barrier has also been demonstrated for some arboviruses in their mosquito vectors, but has not been demonstrated for any phytoarbovirus. Similar to the situation described earlier for the circulative, nonpropagative luteoviruses, the specific barrier may differ for any combination of virus and vector and no generalities seem to be applicable.

The molecular and physiological basis for virus–vector interactions at these various barriers that regulate transmission are not well understood, but it is clear that genetic elements of the vector ultimately decide if a particular species or individual within a species of arthropod is able to vector a particular virus strain. Environmental or abiotic factors also play a role in determining virus–vector interactions, but in general these factors seem to influence the efficiency of the interaction rather than to determine the ability of the interaction to take place.

Virus transmission by vectors is not controlled solely by the vector: the virus also contributes to the overall process. Limited progress has been made in understanding the phytoarbovirus genes and gene products that influence vector transmission. A lack of stable cell lines from insect vector species and a difficulty in developing stable mutants with a transmission-deficient phenotype have contributed to the slow progress, but recently cell lines have been established for leafhopper vectors of reoviruses as well as for thrip vectors of tomato spotted wilt tospovirus.

Despite an absence of vector cell lines, progress on the identification of virus genes whose function is related to transmission has been made by studying

virus associations with whole insects. The animal-infecting La Cross bunyavirus glycoproteins have long been implicated in vector transmission and recently it was shown that the tomato spotted wilt bunyavirus glycoproteins interact with two different thrip proteins, one of which was associated with midgut tissues. The tissue association of the other was not determined. The glycoproteins are likely involved with cell attachment and virus entry.

Studies on whole, virus-infected insects have also identified differences in virus RNA and protein accumulation between the plant and insect hosts. A nonstructural protein of maize stripe tenuivirus and rice grassy stunt tenuivirus accumulates in maize and rice, but not in the leafhopper vector. The function of the nonstructural protein is unknown. Perhaps it serves as a plant virus movement protein or aids in the initial uptake of virus by the vector, but would not subsequently be needed to be produced by the vector. In contrast to the aforementioned studies, the RNAs encoding the two maize stripe virus glycoproteins are abundant in both insect and plant host cells, and all serologically detectable rice dwarf reovirus proteins are present in both insect and plant hosts. Similar findings of no qualitative differences in viral RNAs or proteins have been reported for the alphaviruses. However, there were differences in the post-translational processing of the viral proteins between the mosquito and vertebrate hosts.

Another major problem in understanding phytoarbovirus–vector interactions has been in developing or identifying stable mutants that have altered vector transmission phenotypes. The viruses have all remained recalcitrant to many of the modern molecular biology techniques. Infectious DNA clones have not yet been produced and therefore a directed mutational strategy is not possible, nor is a reverse genetic approach to identifying gene function. A limited number of transmission mutants have been obtained by repeated mechanical inoculation of plant hosts without going through the insect host. A strain of the rice dwarf reovirus maintained for 12 years in vegetatively propagated rice plants had lost the P2 outer capsid protein due to a point mutation that introduced a termination codon in the open reading frame. The P2-minus virus was able to infect plants, but was unable to infect the leafhopper vector and be transmitted to plants.

Vegetative propagation of wound tumor reovirus-infected plants also resulted in leafhopper transmission-defective virus isolates. This was later found to result from the generation of defective RNAs of four of the 12 genomic sequences. These defective viruses were not able to infect the leafhopper vector cells, but were able to maintain a near wild-type infection of the plant host. Presumably all of the virus functions necessary to infect the plant host were contained on the eight remaining genomic segments, whereas one or more of the four defective segments provided for, as of yet, undefined functions specific for infection of the insect host. The data that have been generated thus far point to the conclusion that outer capsid proteins of the phytoarboviruses are, as would be predicted, involved in the infection of insect cells, i.e. attachment proteins. These would not be necessary for plant hosts because of the cell wall, which must be breached by totally different mechanisms than the cell membrane of insect hosts.

There is very limited reference to the continued serial passage of phytoarboviruses in their insect vector. Sowthistle yellow vein rhabdovirus was mechanically passaged by injecting virus into the hemocele of aphid vectors. Continuous serial passage did give rise to virus isolates that were difficult to transmit to plants and also more pathogenic to the vector. The reasons for the low probability of transmission was not determined and may have been a deficiency in systemic plant infection or an inability to move through all the transmission barriers in the aphid. With the advances in technologies that now allow further characterization of such mutants, there should be advances in our understanding of virus–vector interactions despite the difficulties with vector cell cultures and a lack of infectious clones of the viruses.

Viruses with Fungal Vectors

The terminologies and concepts described in the previous sections were all developed for multicellular organisms that feed on plant tissues. These are not easily adapted to virus transmission by fungal vectors. Although the fungi are multicellular, the vector is the unicellular zoospore. Furthermore, the acquisition of virus by the fungus does not involve feeding and ingestion comparable to the arthropod or nematode vectors discussed previously. Therefore, different terminology has been applied to the transmission of viruses by fungi.

Properties of Fungal Vectors

The fungally transmitted viruses belong to at least seven plant virus genera contained within at least four families (**Table 1**). The fungi known to be involved in vector transmission are zoosporic obligate parasites of plant roots and include two species of Chytridiomycetes (*Olpidium bornovanus* (formerly *O. radicale*) and *O. brassicae*) and three species of Plasmodiophoromycetes (*Polymyxa graminis, P. be-*

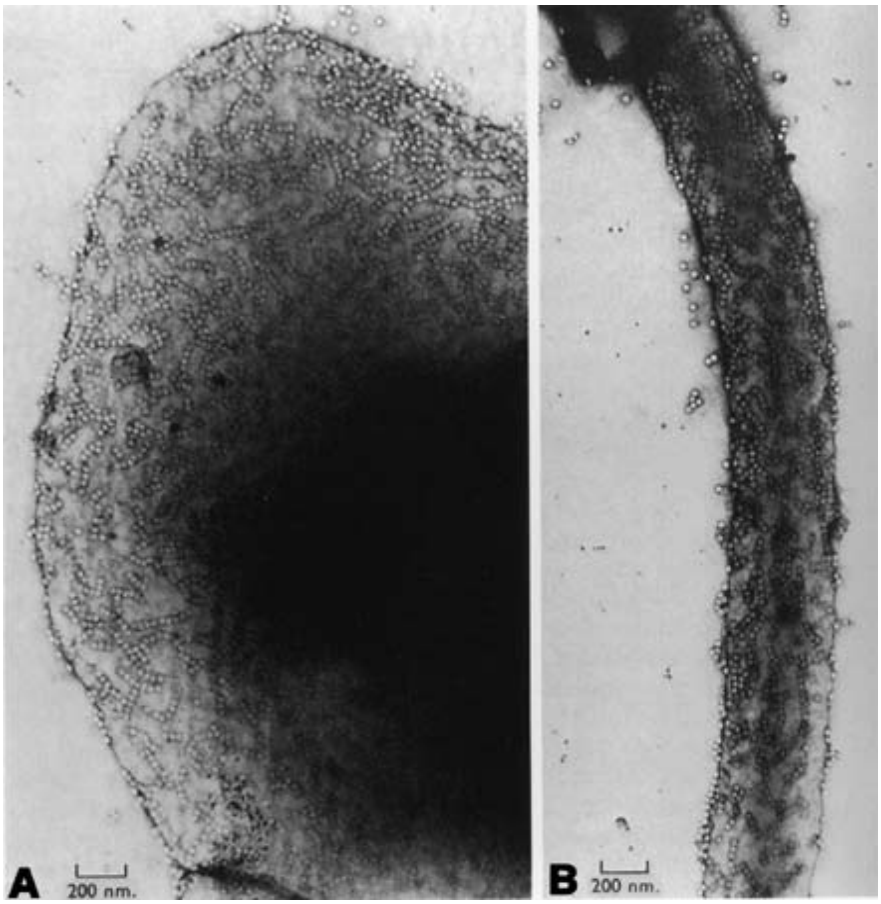

Figure 2 Electron micrograph showing binding of tobacco necrosis virus particles to the plasmalemma of the body (**A**) and to the axonemal sheath of the flagellum (**B**) of *Olpidium brassicae* zoospores. (Reprinted with permission from Temmink JHM, Campbell RM and Smith PR (1970) Specificity and site of *in vitro* acquisition of tobacco necrosis virus by zoospores of *Olpidium brassicae*. *J. Gen. Virol.* 9: 201–213.)

tae and *Spongospora subterannea*). The genera *Polymyxa* and *Olpidium* apparently cause little or no direct damage to crops but the viruses they vector can cause significant disease.

Most of the viruses vectored by *Olpidium* species are members of the family *Tombusviridae* and, as such, are small, spherical viruses containing single-stranded RNA genomes. Exceptions to this are the 'varicosaviruses' which are double-stranded RNA viruses with rod-shaped virus particles. Viruses with plasmodiophorid vectors are rod shaped and usually contain segmented single-stranded RNA genomes.

Olpidium spp. have zoospores which are uniflagellate, whereas *Polymyxa* and *Spongospora* spp. have biflagellate, heterokont zoospores. The developmental stages of these fungi are similar. Resting spores (or cystosori in the Plasmodiophoromycetes) produced in plant roots are released into the soil when roots decay. The resting spores germinate and produce motile zoospores which swim to roots and encyst when they encounter epidermal cells. Encystment involves withdrawal of the flagellum, attachment to root cell walls, and secretion of a thin cyst wall. The protoplasm of the zoospore is then released into the host cell and divides into a multinucleated plasmodium, which then develops into a sporangium. The sporangium liberates secondary zoospores, which are either released into the soil to infect other root cells, or which infect adjacent root cells. Vegetative sporangia produce the thick-walled resting spores. These are essential for survival of the fungus in the absence of a host and also permit survival of virus for extended lengths of time (>20 years for viruses transmitted in the *in vivo* fashion, see below).

Fungal Transmission Mechanisms

Two types of fungal–vector relationships are recognized: *in vitro* and *in vivo*. They are distinguished by the method of acquisition of the virus by the fungus and the location of the virus relative to the fungal resting spore (internal or external). In *in vitro*

transmission the virus is carried externally on the zoospores (**Fig. 2**) and virus is not found within resting spores. In *in vivo* transmission, virus is acquired during growth of the fungus in a virus-infected plant and is found within resting spores. The location of a virus particle relative to a resting spore can be determined by treating resting spores with strong chemicals that are known to inactivate virus exposed to them (e.g. 20% Na_3PO_4 or 5 mol l^{-1} HCl). A virus carried internally will remain transmissible following treatment, whereas a virus on the surface will not. Alternatively, mixing virus with zoospores obtained from virus-free plants in solution and then inoculating roots with the suspension can result in infection by *in vitro* transmitted viruses, but viruses transmitted *in vivo* will not be acquired by the zoospores in solution and cannot infect plants inoculated with the suspension. *Olpidium* spp. are the only vectors identified that transmit virus *in vitro*, whereas *in vivo* transmission occurs with *Olpidium* spp., *Polymyxa* and *Spongospora* vectors. There is no evidence for replication of fungally transmitted viruses in their vectors.

In vitro transmission

The mechanism of *in vitro* transmission has been best described using tobacco necrosis necrovirus (TNV) and its vector *O. brassicae*, but was also later demonstrated for cucumber necrosis tombusvirus (CNV) and *O. bornovanus*. The virus is adsorbed on to the surface of the zoospore (**Fig. 2**) as it moves through the soil following independent release of the fungus and virus into the soil. The source of zoospores can either be from vegetative sporangia or from resting spores. The source of virus can be from infected root material obtained during the growing season or from other decaying plant parts after the crop is harvested. The acquisition time is short, in the range of 5–15 min, and the virus is very stably adsorbed to the plasmalemma of the body and the axonemal sheath of the zoospore. Electron microscopy studies have shown that adsorption is very specific: TNV binds *O. brassicae* zoospores but not *O. bornovanus* zoospores; CNV binds *O. bornovanus* zoospores but not *O. brassicae* zoospores. In addition, there is intraspecific variation in transmission efficiency. Different *O. brassicae* isolates vary in their ability to transmit TNV and three categories of vector efficiency could be identified: efficient vectors, inefficient vectors and nonvectors. Virus is not absorbed on to zoospores of a nonvector isolate and inefficient vector isolates adsorb fewer particles than zoospores of efficient vectors. The ability or inability of particles to bind zoospores appears to play a major role in the specificity of transmission.

The manner in which bound virus enters a root cell following zoospore encystment has not been extensively studied. It has been suggested that virions enter the zoospore protoplasm as the flagellum is retracted during encystment. Virus then enters a root cell when the zoospore protoplasm is discharged.

The molecular basis of *in vitro* transmission is also not well understood. Work with CNV and its fungal vector *O. bornovanus* has shown that virus particles are required for transmission. Further work in which the coat protein (CP) gene of CNV was exchanged with that of the nontransmissible tomato bushy stunt virus showed that the CNV CP contains transmission-specificity determinants. Transmission-defective CNV mutants have been isolated by repeated mechanical passaging. The transmission deficiencies were found to be due to either a deleted CP gene, the inability to express CP or an altered CP. One characterized mutant contained a single amino acid substitution in the CP shell domain which decreased transmissibility to less than 20% that of wild-type virus without affecting particle stability, virus accumulation or infectivity. This mutant also showed a decreased ability to bind zoospores in an *in vitro* binding assay, providing further evidence that binding plays a critical role in the transmission process. In addition, binding of CNV to *O. bornovanus* zoospores has been found to be saturable, specific and pH dependent. These studies suggest that a specific zoospore receptor may be involved in mediating viral attachment.

In vivo transmission

Viruses such as beet necrotic yellow vein furovirus (BNYVV) and barley yellow mosaic bymovirus (BaYMV) are transmitted by the *in vivo* mechanism and have been visualized within zoospores and resting spores of their fungal vectors. The virus must be acquired by the fungus within an infected host plant, but the timing and mechanisms of acquisition are unknown. A majority of the research has focused on roles of virus-encoded proteins in the transmission process.

Similar to the luteoviruses described earlier, the furovirus capsid contains a predominant coat protein and lesser amounts of a coat protein readthrough. Repeated mechanical passage of BNYVV and soil-borne wheat mosaic furovirus (SBWMV) results in transmission-defective mutants, a trait that is associated with the accumulation of deletion mutations in the readthrough domain. These results suggest that the readthrough domain contains sequences which

can promote interactions between particles and fungus. Deletion analysis, along with alanine scanning mutagenesis, has identified a KTER amino acid motif near the C-terminus of the BNYVV readthrough as being important for the fungus transmission process. A similar sequence (KTEIR) is found in the readthrough domain of SBWMV.

Bymoviruses do not translate a coat protein readthrough. The repeated mechanical transfer of a BaYMV strain resulted in the loss of fungus transmission and a spontaneous approximate 1 kb deletion in RNA2. The deleted region is from a protein which is associated with crystalline inclusion bodies in infected tissue. Alignments of portions of the protein products of RNA2 of two bymoviruses and the readthrough portion of several furovirus capsids has revealed that certain amino acid combinations (ER or QR) are found consistently in all the viruses. These amino acids occur on the outside of the protein and therefore may be available for interaction with the fungus vector. In addition, certain conserved regions are absent in nontransmissible deletion mutants. These studies suggest that bymoviruses and furoviruses encode similar proteins for facilitating their transmission.

History

Vesicular stomatitis viruses (VSVs) are rhabdoviruses which infect a wide range of wild and domestic animals, and several groups of insects. VSVs are best known as the cause of vesicular stomatitis (VS), a disease characterized by vesicular lesions in the mouth, tongue, udder teats and hoof coronary bands of cattle, horses and pigs. Clinical disease occurs every year in farming areas from northern South America to

Introduction

Researchers have exploited knowledge of the structure of viral genomes to insert DNA from foreign sources (transgenes) for over 20 years. Vectors, as such recombinant molecules are known, were initially generated from the genomes of the smaller DNA viruses (papovavirus and papillomavirus families). Knowledge of the genome structure of the larger DNA viruses (adenovirus, herpesvirus, poxvirus and baculovirus) and RNA viruses has expanded the numbers and types of backbones available for generating vectors. Each virus family, and vector backbone, has its own set of advantages and disadvantages that identify the types of operations for which they can optimally be used. Scientists have used these vector systems: (1) to study gene regulation; (2) in mRNA processing; (3) to achieve high-level expression of biologically active proteins; (4) to address questions of the structure–function relationship of specific polypeptides; (5) to investigate the immunobiology of specific pathogens; (6) to develop recombinant vaccine candidates and serodiagnostic reagents; and (7) to understand and treat cancer and genetic diseases in the clinic.

The salient features of many, but not all, RNA and DNA virus-based vectors will be discussed here. Not included are some of the vectors used infrequently, including the original vectors derived from papova- and papillomaviruses.

Adeno-associated Virus Vectors

Adeno-associated viruses (AAV) belong to the family *Parvoviridae*, genus *Dependovirus*. As indicated in their name, these viruses are replication defective and depend on other viruses for factors required for replication. In the laboratory, the factors are generally supplied by adenovirus or herpesvirus co-infection. The AAV vector genome consists of a single-stranded DNA of 4.7 kb, with 150 bp palindromic sequences or inverted terminal repeat sequences (ITRs) at both ends. These two ITRs are all that is needed for packaging and integration into the host genome. AAV vectors can be constructed with up to 5 kb of exogenous DNA between the two ITRs. The transgene inserted between the ITRs must have its own promoter, as these sequences do not function as promoters. During infection, a low percentage of the viral genomes will integrate into the host chromosome. Wild-type AAV has a propensity to integrate at a specific site in human chromosome 19, but the currently available AAV vectors have lost this property and integrate randomly into the genome of the target cell.

A number of systems have been developed for using the AAV DNA backbone as a vector for gene transfer, with varying degrees of success. Despite the relatively simple genomic structure of AAV, vector systems require three components: one that supplies the AAV capsid proteins, the transgene containing vector and the helper virus. The need for helper virus results in contamination of vector preparations with helper virus particles or with denatured viral proteins, even after extensive purification and heat inactivation of vector stocks. This contamination is undesirable for the implementation of AAV vectors in clinical applications. Identification of the adenovirus genes required for complementation of AAV has allowed the development of new schemes that use a non-replicating adenovirus genomic plasmid as a helper. When co-transfected with the AAV vector and the AAV helper construct, vector preparations free of replication-competent adenovirus and wild-type AAV can be produced at relatively high titers. However, this system is based on transient transfection of cell lines, which would make large-scale clinical implementation of protocols using AAV vectors difficult. Efforts to develop stable cell lines for the production of AAV vectors are still at an early stage, but their availability is likely to facilitate evaluation of this potentially useful vector system.

AAV vectors are being developed almost exclusively as vehicles for gene transfer and gene therapy in a clinical setting. Several features of AAV make it attractive for these uses. The virus is nonpathogenic

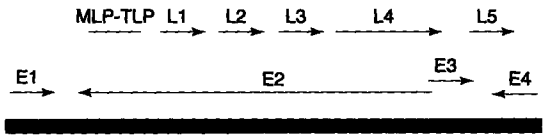

Figure 1 Adenovirus transcription map. Early (E) and late (L) transcription units are represented by solid lines relative to the 36 kb adenovirus genome. Arrowheads indicate direction of transcription. Each transcription unit gives rise to families of mRNAs derived by differential splicing events. The late mRNAs are generated by differential splicing and polyadenylation site utilization and all are initiated from the major late promoter (MLP) and contain the tripartite leader (TPL).

and has a broad host range and tissue tropism. A major advantage is its ability to infect nondividing cells, and its potential for targeted integration. In preclinical model systems the levels and duration of transgene expression have varied, so it is not entirely certain that therapeutic levels of expression can be achieved. Transduced cells do not elicit a cytotoxic T cell response, a common occurrence when using adenovirus vectors. Phase I clinical trials are underway to evaluate toxicity in humans.

Adenovirus Vectors

The human adenovirus (Ad) family consists of at least 49 members that have been classified into six subgroups based on a variety of biological and molecular characteristics. Two members of the subgroup C adenoviruses, Ad2 and Ad5, form the backbone for the majority of Ad vectors in use today. The viral genome is divided into five early and five late gene regions, with each region coding for a multiplicity of mRNAs and proteins (**Fig. 1**). All coding regions are by and large essential, with the exception of the early region 3 (E3), which is not necessary for growth in tissue culture. The viral genome is approximately 36 kb in length, and studies have shown that up to 105% of the viral genome can be packaged. High titer virus vector preparations are relatively easy to prepare and consequently they have found many uses, including the expression of large amounts of transgenes, in vaccine development, and especially in the area of gene therapy. Some of the types of adenovirus vectors used to date are discussed below.

There are two basic methods for inserting foreign genes (transgenes) into adenovirus vectors, methods that are also used for the larger DNA viruses. The first is through homologous recombination, which can be carried out in tissue culture cells, bacteria or yeast. The gene of interest is inserted into a shuttle vector containing about 2–4 kb of the viral genome, and it is co-transfected with DNA representing (at minimum) the remainder of the viral genome into the cells of choice. Recombinants can be selected by analyzing individual plaques, or by including marker genes in the shuttle plasmid that allow visual selection. The second method of construction of adenovirus vectors involves cloning of the whole genome in bacterial plasmids. An advantage of this method is that most of the characterization can be performed on the plasmid, and all plaques arising from transfection into human cells should contain the transgene. The maximal length of the transgene is directly dependent on the number of viral genes deleted. Most vectors are based on E1A- and E1B-deleted backbones, and can hold transgenes of up to 4 kb. Deletion of the nonessential E3 region brings the packaging capacity to about 7 kb, and deletion of additional early region genes further increases the packaging capacity. Every essential gene deleted has to be complemented, and cell lines expressing various complements of these genes are available. The promoter used to drive transgene expression will dictate the relative level of expression, and transgenes with and without introns are expressed equally well. With the exception of hematopoietic cells, adenovirus vectors efficiently infect most cell types.

Adenovirus vectors do not integrate, so expression of transgenes is limited to the time the vector DNA is maintained episomally in the cell. The viral episome is stable in cells, so when terminally differentiated cells are infected, the viral genome will last for essentially the life of the cell. *In vivo*, adenovirus causes significant immune responses, which is also true for adenovirus vectors, so this is potentially a limiting factor for their use in animals or humans.

Adenovirus, especially the attenuated virus produced when E1A and E1B are deleted, is generally innocuous for immunocompetent adults, and vaccines for a variety of human viruses are under development using Ad vectors for transgene delivery. Virus genes inserted into Ad vectors for vaccine development include genes from hepatitis B, human immunodeficiency virus (HIV), herpes simplex virus and pseudorabies, but to date no vaccine has come into common use. Humoral responses were elicited with the hepatitis B/Ad recombinant in chimpanzees, but they only partially protected against hepatitis B challenge. Other methods of gene delivery, including other viruses and direct injection of DNA, are finding their way into clinical trials, and it is likely that few adenovirus vectors will be used for vaccine development.

Adenovirus vectors have been used in numerous clinical trials to deliver therapeutic and/or toxic compound to cells. Use of Ad vectors for delivery of

therapeutic proteins has generally not been successful. The extent to which adults are already armed against adenovirus infections was underestimated in these trials. There are a number of physical and immunological barriers to adenovirus infection that diminish the duration and extent of transgene expression. These include: (1) physical barriers to infection; (2) virus removal from the blood through unknown mechanisms; and (3) the presence of a memory immune response to the virus. The initial failures with the subgroup C backbone-based Ad vectors has led to the development of a variety of vectors based on backbones from other subgroups to which the majority of the population has not been exposed. Vectors lacking all viral genes have also been developed, but have not yet been put to use in the clinic.

Adenovirus vectors that are potentially selectively toxic to tumor cells are now in clinical trials. Adenovirus mutants that replicate only in cells lacking p53 are being tested in clinical trials for their ability to specifically kill tumor cells (in combination with chemotherapy). Vectors carrying tumor suppressor genes such as p53 and Rb are being tested in numerous clinical trials for their efficacy in halting tumor growth. Vectors that carry transgenes for enzymes that convert prodrugs to their active forms are being developed. The transgene is expressed under the control of a promoter that is either tumor or tissue specific. Ad vectors with altered tropisms are being developed to target tumors or specific tissues. One problem with many of these approaches is that the virus is large and does not readily diffuse from the site of injection, and therefore killing can be quite localized. Thus, adenovirus vector-mediated therapy of cancer is likely to be an additional tool for the oncologist, to be worked into a regimen of more traditional chemotherapy and radiotherapy.

Adenovirus vectors are being developed for use in nonmalignant disease therapy. A vector containing the gene encoding vascular endothelial growth factor is being used to try to help ischemic hearts grow new blood vessels. Other vectors are being used to try to prevent the closure of blood vessels newly opened in angioplasty.

Adenovirus vectors are finding their way into many niches in medicine, but it is safe to say that researchers are still learning how to use the virus most effectively.

Poxvirus-based Vector Systems

Poxviruses are widespread in nature and tend to have a limited host range. They are large DNA viruses, with genomes of about 190 kb in length. They differ from other DNA viruses in that they replicate solely in the cytoplasm of cells. This requires the virus to encode nearly all of the enzymes involved in replication of the virus, many of which are found in the virus particle and enter a cell with the virus. Poxvirus particles can package DNA at least 25 kb larger than the wild-type genome, and deletion of nonessential genes can significantly increase the size of foreign DNA that can be inserted into the vector. Poxvirus vectors grow well in cells of the native host, and the virus can readily be purified to high titers. Vectors based on human, animal and avian poxviruses have been developed, each with a particular set of advantages for a given application.

Poxvirus DNA is not infectious because of the requirement for virus particle-associated enzymes, and the generation of recombinants requires the use of infectious virus. The favored technique is based on marker rescue, originally developed to map mutants in the viral genome. The technique is similar to the homologous recombination method used with adenovirus vectors, but cells are first infected with a virus whose genome is to be altered and then transfected with a plasmid containing the transgene between viral sequences normally contiguous in the genome. The relative level of homologous recombination is low, about 0.1%, so efficient selection methods have been developed. These include inactivating the viral thymidine kinase gene by insertion of the foreign gene within it, and the insertion of genes encoding visual marker proteins in the rescuing plasmid. Because poxvirus vectors replicate in the cytoplasm and use poxvirus-encoded enzymes, transgenes must be placed under the control of poxvirus promoters for expression (some exceptions are discussed below). There are three classes of poxvirus promoters, early, intermediate and late, and the timing and level of expression of any transgene can be regulated by the choice of promoter. Proteins produced in poxvirus expression systems are processed and transported normally, so relatively high levels of production of normal protein are possible in permissive and nonpermissive cell lines.

Vaccinia virus is the favored vector for a variety of applications. Many different variations on the straight transgene-containing vector have been developed. Systems are available for expression of proteins from recombinant plasmids introduced into vaccinia virus-infected cells. This type of transient expression system affords much higher levels of transgene expression than conventional transfection systems. Inducible expression systems based upon the bacteriophage T7 and T3 RNA polymerase promoter and the *Escherichia coli* lac operator–repressor systems have been developed. The RNA polymerase can either be constitutively expressed in the cell line, or be

brought in by a co-infecting virus. The gene to be expressed, under the control of the T3 or T7 promoter elements, is introduced into the cells either as an expression plasmid or as part of a vaccinia virus vector. These approaches allow for controlled expression, which is especially important when the protein product is cytotoxic.

Poxvirus expression systems have been used to express hundreds of proteins of biological and medical importance. The practical application of vaccinia virus vaccine candidates has been demonstrated in both the veterinary and human fields. Vaccinia was used successfully as a vaccine for the eradication of smallpox. Other examples of its use include vaccinia virus recombinants to protect raccoons against rabies, a capripoxvirus vector to protect cattle against rinderpest, a swinepox vector to protect pigs against pseudorabies, and fowlpox vectors to protect chickens against influenza virus, Newcastle disease virus and infectious bursal virus. Clinical trials with a vaccinia-based HIV-1(IIIB) *env* recombinant have been initiated in the USA. Results from these studies clearly demonstrated the ability of this recombinant to prime an immunological response in the recipients, although the response was suboptimal in some individuals. A vaccinia virus-based vector expressing the Epstein–Barr virus membrane glycoprotein has been used in China with some success in preventing natural infection.

New vectors have recently been developed that address some of the safety concerns of the original vectors. A strain of vaccinia virus with 18 genes implicated in the virulence and host range of the virus deleted has been developed. Another vector, based on a canarypoxvirus, replicates only in avian species. When this vector is introduced into nonavian cells, the transgene is expressed. Preliminary studies demonstrate that both are effective in generating high levels of transgene expression, and that in a vaccine setting they can both induce protective immunity. A canarypoxvirus-based vector expressing the rabies G glycoprotein has been assessed in phase I clinical trials in Europe and the USA, with encouraging results. In addition, vectors expressing the human cell surface protein CD80 are in clinical trials. This protein is involved in T cell recognition of target cells, so its expression in tumor cells potentially enhances the ability of the immune system to recognize cancer cells. This tumor vaccine approach is expanding, as poxvirus vectors encoding a variety of tumor antigens are currently undergoing preclinical testing. Given the large capacity of the vectors, genes encoding both tumor antigens and immune system recognition enhancing molecules could be inserted into a single virus.

Poxvirus vector-based systems have demonstrated their utility for expression of foreign genes for study in tissue culture, for use as a vaccine vehicle in both animals and humans, and they are beginning to be used for treating cancer. Because of the wide variety of available vectors, and the safety features that have been built into them, poxvirus vectors will increasingly become the vector of choice for a variety of applications.

Baculovirus Expression Vectors

Baculoviruses are pathogenic insect viruses that have been investigated for possible use as biological control agents for insect pests. Recently, these viruses have proven useful in the development of helper-independent vectors for overexpression of foreign genes in eucaryotic cells. Baculoviruses contain a double-stranded DNA genome of around 130 kb, and the DNA is infectious. The main attraction of this system is the ability to produce very large quantities of transgene protein, but until recently the system was limited to insect cells. Recent developments have considerably expanded the potential of the baculovirus vector system for use in mammalian cells.

Baculovirus vectors are generally produced by homologous recombination between a shuttle vector and a wild-type genome, using the viral polyhedrin gene as the recombination target. Shuttle vectors often contain the transgene of interest plus a selectable marker gene, although inactivation of the polyhedrin gene through transgene insertion gives rise to plaques that can be differentiated from those of wild-type virus. The polyhedrin gene of baculoviruses such as *Autographa californica* nuclear polyhedrosis virus (AcMNPV) is expressed at very late times of infection and produces a protein that surrounds the mature virus particle to form an occlusion body in insect larvae. Polyhedrin protein expression in infected tissue culture cells can continue for days following initial infection and often amounts to 50% of the total cell protein. The polyhedrin protein is not essential for replication of the virus in tissue culture, and transgenes placed under the control of its promoter can be expressed to levels approaching that of the polyhedrin itself. The virus has a rod-shaped capsid and has a large capacity for packaging foreign DNA. Baculoviruses do not productively infect vertebrate cells, but modifications to the system have allowed transgene expression in a variety of mammalian cell lines, further expanding the potential of the vector system.

Baculovirus vectors have found their greatest use in the production of large quantities of protein for purification. While insect cells can post-translation-

ally modify proteins correctly, there were concerns that they could not process high-mannose glycans like mammalian cells. However, recent reports on human plasminogen expressed in insect cells show that the enzymes necessary for processing high-mannose glycans can be activated with glycan processing identical to that found in the human-expressed protein. These are important considerations if baculovirus-expressed products are to have the same biological and immunological properties as that of the native protein. Baculovirus-expressed protein was used in the first human clinical trials for an acquired immune deficiency syndrome (AIDS) vaccine, using an HIV-1 (IIIB) *env* gene product purified from insect cells. Its general utility for production of purified proteins for clinical use remains to be demonstrated.

Herpesvirus Vectors

Two herpesviruses are emerging as alternatives for the development of gene transfer vectors: herpes simplex virus (HSV) and Epstein–Barr virus (EBV). HSV has a genome of approximately 155 kb in length, which is maintained as a concatemerized circular or linear episome in infected cells. It efficiently infects cells, including nondividing cells, from a wide variety of organisms, and is able to establish a persistent infection. Its genome can accommodate large amounts of foreign DNA, and a number of vector systems have been developed. The EBV-based systems have not been developed as extensively and currently employ replication-defective EBV strains. Unlike HSV, EBV vectors have a very limited tropism and their possible usefulness remains to be explored. The main difficulty using these two systems is the need for almost complete virus genomes that are very complex and large in size, making manipulations exceedingly difficult. The eventual usefulness of these systems will be dictated by further simplifications that render them more manageable in the laboratory and that facilitate vector production.

Helper-dependent and -independent systems have been developed for preclinical evaluation. The helper-independent systems have basically the complete viral genome with one or more transgenes substituted for nonessential viral genes. These vectors are rendered defective for growth by deletion of essential genes, permitting their growth only on complementing cell lines. So far these vectors have met with limited success in model systems because of leakiness in the system, which leads to cytotoxicity and cell death. The requirements for maintenance of gene expression during the latent state in neuronal cell types are also currently unknown, so prolonged transgene expression has been difficult to obtain. The second type of HSV vector is the helper-dependent system. The vectors contain only the sequences required for replication and packaging, but all the other functions must be supplied in *trans* from a helper virus. While such systems are capable of producing high-titer amplicon-containing virus, they are almost invariably contaminated with large quantities of the helper virus. Recent improvements in the amplicon system have allowed the generation of relatively high-titer amplicon preparations with much lower levels of contamination with helper virus. These systems hold promise for use in clinical situations, especially in gene transfer to neuronal cells, but further development of the system is required.

Retrovirus Vectors

Retroviruses are ubiquitous in nature and have a relatively simple RNA genome of around 9 kb in length. By reverse transcription, the RNA genome becomes a double-stranded DNA that integrates into the host chromosome and is stably transmitted to progeny cells. Specific aspects of the life cycle of retroviruses and their relatively simple genome have facilitated their development into gene transfer vectors. Most of the vectors currently used for basic science and for clinical applications are based on murine leukemia viruses. Because of the high efficiency with which retroviral vectors can transduce a variety of cell types from many different species, they have become a method of choice for gene transfer experiments.

Retrovirus vectors can be produced by either transient transfection of cells, or by the generation of stable producer cell lines. In both cases, the transcription units for the packaging functions for the virus particle and that for the transgene are on separate genetic elements. The packaging proteins are provided in *trans*, either by a co-transfected second plasmid that encodes the proteins needed for particle formation, reverse transcription and integration of the vector (transient production), or by a packaging cell line that contains these genes integrated into the chromosome (**Fig. 2**). Separation of the *trans* functions into several plasmids is important to minimize the chance that a wild-type replication competent virus may be generated by a recombination event. Packaging cell lines are able to generate large numbers of virus particles without a genome. These particles are empty because the packaging construct does not contain the information needed for specific incorporation of RNA into the virus particle. This is an important aspect of the system because it prevents the transmission of genomic information encoding virus proteins. The vector plasmid contains all of the *cis*

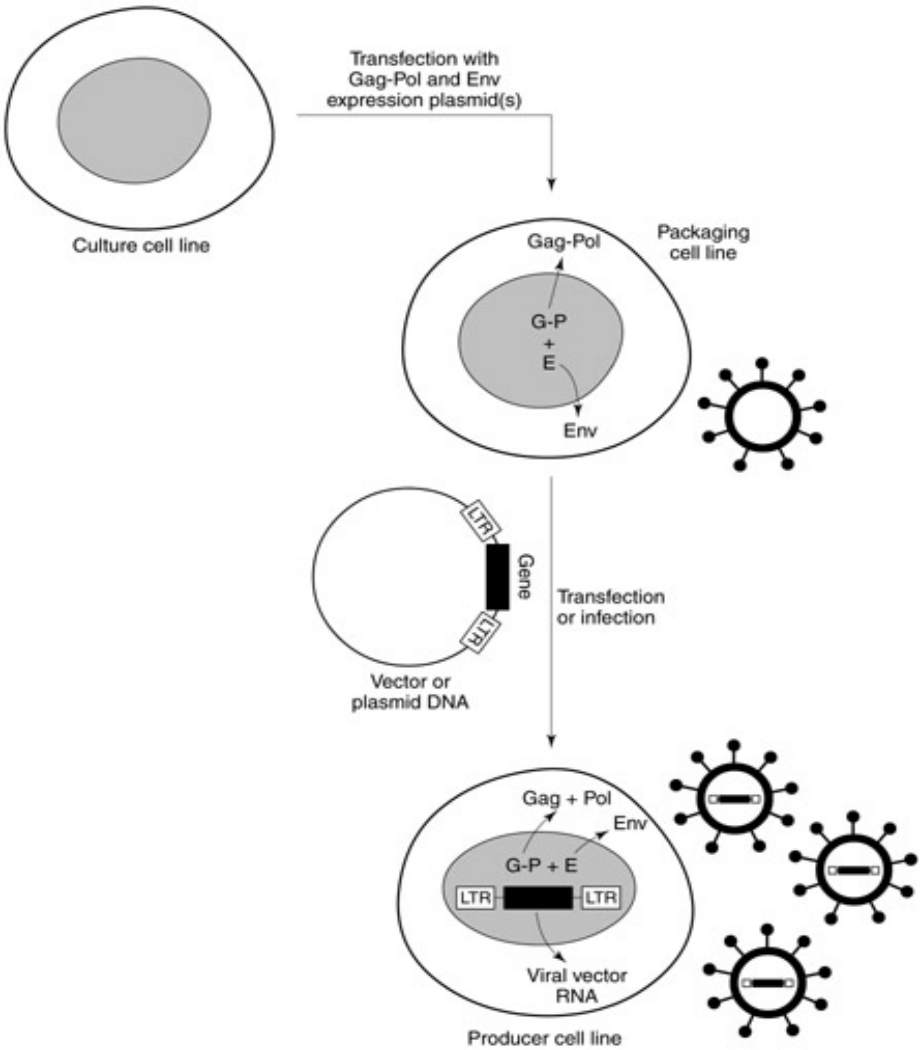

Figure 2 Construction of a retrovirus packaging cell line. Plasmids encoding the Gag-Pol polyprotein are transfected into cells. Clones expressing high levels of 'empty' virus particles in the supernatant are identified. An envelope expression construct is then transfected into the Gag-Pol-expressing clone and clones expressing high levels of both Gag-Pol and Env are identified. Finally, a retrovirus vector is introduced into the Gag-Pol-Env cell line and clones producing the highest levels of transducing particles are identified. Once cloned, these producer cell lines are stable and can be expanded to produce large amounts of vector for clinical or basic science experimentation. LTR, long terminal repeat.

elements necessary for transcription and polyadenylation of the transgene, and for reverse transcription and encapsidation (packaging) of the vector RNA. Once the vector that contains the packaging signal is introduced into the packaging cell, or cotransfected with a plasmid containing the genes for the packaging functions, particles are generated that contain the vector genome. The vector-containing particles are infectious and can introduce new genetic information into the genome of a target cell.

Producer cell lines can be made that express different envelope proteins, cell surface glycoproteins (*env*) needed for attachment and penetration into the target cell. By using *env* proteins from different retroviruses, the species specificity and tissue tropism of the vector can be altered. Recently, retrovirus vectors that use the vesicular stomatitis virus G protein in place of *env* have been produced. In addition to having a broad host range and tissue specificity, such vectors can be concentrated by centrifugation, which is not possible with *env*-containing vectors. Expression of the transgene in vectors can be under the control of the viral long terminal repeat promoter, or of an exogenous promoter such as the cytomegalovirus or SV40 early promoters. It is possible to express multiple genes under the control of a single promoter through the introduction of an element termed an internal ribosome entry site, which can be derived from an RNA virus such as encephalomyocarditis virus. Because

retrovirus vectors can be made free of wild-type virus, there is no expression of virus proteins in the transduced cell. Therefore, retrovirus vector-transduced cells do not induce virus-specific immune responses.

Advantages of the retrovirus gene transfer system include stable integration of the vector into the genome of target cells, the wide tropism of the available vectors, the relative ease of vector production, and the large number of vector and producer cell lines available for both basic research and clinical applications. Some disadvantages include: (1) integration of the vector into the genome of the host is random, which can potentially lead to gene mutation; (2) a limited packaging capacity; and (3) an inability to transduce nondiving cells. This last limitation has been resolved by using lentiviruses, such as HIV, instead of murine leukemia viruses to derive the packaging components and packaging cell lines. Lentivirus-based vectors have shown significant promise in early evaluations. Undoubtedly, lentivirus-based vectors are likely to complement the existing battery of vectors and possibly expand the usefulness of this system to nondividing targets such as liver, brain and the hematopoietic stem cell.

RNA Virus Vector Systems

Researchers are investigating the potential of RNA genome-containing viral vectors, such as poliovirus, alphaviruses, influenza virus and vesicular stomatitis virus (VSV). These viruses have the potential advantage of not having a DNA phase in their replication cycle, which provides a measure of safety for their use in humans. Negative-strand viruses such as influenza and VSV do not undergo measurable rates of homologous RNA recombination, which contributes to the stability and safety of these vectors. Expression of foreign proteins has now been shown for vectors derived from influenza, rabies, VSV, respiratory syncytial virus, SV5 and Sendai virus. The foreign proteins include antigens derived from other viruses, bacteria and parasites, and in general have represented attempts to derive vaccines for agents for which no adequate vaccine currently exists. The vectors produced thus far have coded for a single antigen, and we can expect that in the near future vectors encoding multiple antigens will become available. While the larger DNA viruses such as adenovirus, herpesvirus and the poxviruses code for proteins capable of downmodulating the immune response, no such proteins have been found in RNA viruses. Some of the RNA viruses have been shown to be excellent inducers of both cellular and humoral immune responses in humans.

Poliovirus, a positive-strand RNA virus, has been used to express a number of foreign genes. Poliovirus vectors expressing epitopes derived from hepatitis A virus, rhinovirus 14, human papillomavirus 16, foot-and-mouth disease virus and HIV have been produced. A poliovirus–HIV chimera has been shown to elicit anti-HIV antibodies in rabbits. Furthermore, this antiserum neutralized a wide range of American and African HIV-1 isolates. The major disadvantage of polio, relative to the negative-strand RNA virus vector systems, is that the systems that have been developed thus far have a limited capacity for foreign sequences.

Alphavirus (Sindbis virus and Semliki Forest virus)-based vector systems have also been introduced. The value of such systems is derived from the ability to use these vectors in a wide range of mammalian cells, as a plasmid, or a recombinant progeny virus. Noncytopathic Sindbis virus replicons that replicate in BHK cells and express large amounts of foreign protein have been produced. These vector systems are bipartite, contain a selectable marker for selection, and are capable of expressing the transgene protein at high levels for prolonged periods of time. They do not contain a complete complement of viral genes and thus no infectious particles can be produced. The vectors are probably minimally immunogenic for the parent viral components, as there is little of the parental viral RNA in the vector and structural proteins are not produced. Because of all of these features, the latest generation of alphavirus vectors have a number of safety advantages over some of the DNA virus-based vector systems, and could see applications soon not only in terms of vaccine development but also in the gene therapy arena. Since they replicate in the cytoplasm, and get distributed into the dividing cells without affecting the chromosomal make-up, many safety concerns could be satisfied. Use in the latter area is likely to be limited initially to the introduction of vectors into cells that can be grown in culture for periods of time to permit selection.

For vaccines, cytolytic virus vectors that stimulate an immune response to the virus infection may be useful in stimulating a response against a heterologous protein. Derivatives of Venezuelan equine encephalitis virus that show a self-limiting replication *in vivo* have been used to generate a protective immunity against influenza virus in animals.

Future Perspectives

Viral vectors have changed the way science is done, from the expression of single proteins in cells, to the generation of new vaccines and to the implementation

of new therapeutic strategies for the cure of genetic diseases and the treatment of cancer and other diseases. The variety of viral vectors continues to grow, and much is being learned about the advantages and disadvantages of each type. Practical application in the future will be based on extensive knowledge gained of the structures of viral genomes, their replication strategies and the response of immune systems to infection by such vectors. Such practical application will turn these causes of diseases into tools for curing disease.

Plant Viruses

Thomas Hohn, Friedrich Miescher Institute, Basel, Switzerland

Rob Goldbach, Agricultural University, Wageningen, The Netherlands

Introduction

Virus vectors have become useful tools for introducing genes into a variety of organisms. The first successful virus vectors were derivatives of the bacteriophage λ, with the help of which the first homologous and heterologous gene libraries were established in *Escherichia coli*. Likewise, a number of animal viruses were used to introduce foreign genes into animal cells where they replicated and were expressed. The two most important types are based on the double-stranded (ds)DNA papovaviruses, e.g. bovine papillomavirus, and those based on retroviruses. While papovavirus vectors replicate as circular dsDNA, retroviral vectors mediate the incorporation of the passenger gene into the host chromatin. All of the cases mentioned above lead to relative stability of the passenger gene in the transfected cell, since their replication as dsDNA involves a proofreading mechanism.

Neither true dsDNA viruses nor viruses mediating DNA integration have yet been found amongst the large variety of plant viruses. Accordingly, experiments with plant virus vectors are based on single-stranded (ss)DNA viruses, pararetroviruses and RNA viruses; replication in all these cases can lead to genome rearrangements, because single-strand intermediates are involved on which proofreading mechanisms do not apply and where template switching could occur. If the design and use of the virus vector interferes with viral replication, expression or other vital functions, the passenger gene will be removed from the vector population within a few generations. The passenger gene will in any case be finally eliminated unless it provides some selective advantage. This instability can be also looked upon as a benefit, since it provides biological containment: hybrid plant virus derivatives released purposely or accidentally into the environment are unlikely to maintain a nonselective gene. Stable transformation of plants, on the other hand, can be achieved either with the help of *Agrobacterium*-derived vectors, which mediate integration of passenger DNA into the plant chromatin, or by direct gene transfer.

Another peculiarity of plant viruses is their mechanism of spreading within the host tissue. Spreading usually makes use of the plasmodesmata (cytoplasmic connections between individual cells) which are

of new therapeutic strategies for the cure of genetic diseases and the treatment of cancer and other diseases. The variety of viral vectors continues to grow, and much is being learned about the advantages and disadvantages of each type. Practical application in the future will be based on extensive knowledge gained of the structures of viral genomes, their replication strategies and the response of immune systems to infection by such vectors. Such practical application will turn these causes of diseases into tools for curing disease.

Plant Viruses

Thomas Hohn, Friedrich Miescher Institute, Basel, Switzerland

Rob Goldbach, Agricultural University, Wageningen, The Netherlands

Introduction

Virus vectors have become useful tools for introducing genes into a variety of organisms. The first successful virus vectors were derivatives of the bacteriophage λ, with the help of which the first homologous and heterologous gene libraries were established in *Escherichia coli*. Likewise, a number of animal viruses were used to introduce foreign genes into animal cells where they replicated and were expressed. The two most important types are based on the double-stranded (ds)DNA papovaviruses, e.g. bovine papillomavirus, and those based on retroviruses. While papovavirus vectors replicate as circular dsDNA, retroviral vectors mediate the incorporation of the passenger gene into the host chromatin. All of the cases mentioned above lead to relative stability of the passenger gene in the transfected cell, since their replication as dsDNA involves a proofreading mechanism.

Neither true dsDNA viruses nor viruses mediating DNA integration have yet been found amongst the large variety of plant viruses. Accordingly, experiments with plant virus vectors are based on single-stranded (ss)DNA viruses, pararetroviruses and RNA viruses; replication in all these cases can lead to genome rearrangements, because single-strand intermediates are involved on which proofreading mechanisms do not apply and where template switching could occur. If the design and use of the virus vector interferes with viral replication, expression or other vital functions, the passenger gene will be removed from the vector population within a few generations. The passenger gene will in any case be finally eliminated unless it provides some selective advantage. This instability can be also looked upon as a benefit, since it provides biological containment: hybrid plant virus derivatives released purposely or accidentally into the environment are unlikely to maintain a nonselective gene. Stable transformation of plants, on the other hand, can be achieved either with the help of *Agrobacterium*-derived vectors, which mediate integration of passenger DNA into the plant chromatin, or by direct gene transfer.

Another peculiarity of plant viruses is their mechanism of spreading within the host tissue. Spreading usually makes use of the plasmodesmata (cytoplasmic connections between individual cells) which are

thought to become modified to allow passage of viral nucleic acid or particles. Since plant cells in culture lack these connections, their infection with viruses or viral genomes usually depends upon artificial methods, such as electroporation or polyethylene glycol (PEG) treatment, and further spread will not occur. In contrast, animal viruses have developed methods to both leave and enter cells, e.g. by exo- and endocytosis, and are, therefore, able to spread through host cell cultures after the initial infection.

Inoculation of Plants with Virus and Vectors

Many plant viruses, irrespective of whether their genome consists of DNA or RNA, can be inoculated mechanically on to plant leaves using an abrasive. In these cases, naked nucleic acid or manipulated derivatives can also usually be used as an inoculum. A further method is agroinoculation, which was first developed with CaMV (see **Table 1** for definitions of virus abbreviations) and potato spindle tuber viroid and makes use of the DNA-transfer machinery of *Agrobacterium tumefaciens*, the cause of crown gall disease in a number of dicotyledons. Using this method, multimers, or at least 'one-and-a-bit-mers', of the virus genome are cloned between the T-DNA borders of the *Agrobacterium tumefaciens* Ti-plasmid and this manipulated T-DNA is introduced into the plant upon bacterial infection. Once in the plant cell, probably in the nucleus, the viral genome can escape either by recombination or by the direct production of monomeric replicative intermediates, such as the CaMV 35S pregenomic RNA.

Table 1 Plant virus names and their abbreviations

Virus	*Abbreviation*	*Group*
African cassava mosaic[a]	ACMV	Bipartite gemini
Cassava latent[a]	CLV	
Alfalfa mosaic	AlMV	–
Beet curly top	BCTV	Monopartite gemini
Brome mosaic	BMV	Bromo
Beet necrotic yellow vein	BNYVV	Furo
Barley stripe mosaic	BSMV	Hordei
Barley yellow dwarf	BYDV	Luteo
Beet western yellows	BWYV	Luteo
Cauliflower mosaic	CaMV	Caulimo
Cowpea chlorotic mottle	CCMV	Bromo
Cucumber mosaic	CMV	Cucumo
Cucumber necrosis	CNV	Tombus
Cowpea mosaic	CPMV	Como
Cymbidium ringspot	CyRSV	Tombus
Digitaria streak	DSV	Monopartite gemini
Maize streak	MSV	Monopartite gemini
Odontoglossum ringspot	ORSV	Tobamo
Pea early browning	PEBV	Tobra
Plum pox	PPV	Poty
Potato X	PVX	Potex
Red clover necrotic mosaic	RCNMV	Diantho
Rice tungro bacilliform	RTBV	Badna
Tomato bushy stunt	TBSV	Tombus
Turnip crinkle	TCV	Carmo
Tomato golden mosaic	TGMV	Bipartite gemini
Tobacco mosaic	TMV	Tobamo

Tobacco vein mottling	TVMV	Poty
Turnip yellow mosaic	TYMV	Tymo
White clover mosaic	WCIMV	Potex
Wheat dwarf	WDV	Monopartite gemini

[a] The same virus.

Certain viruses and their nucleic acids are not infectious on mechanical inoculation. This group contains many viruses that are restricted to the phloem tissue, being directly introduced there by their insect vectors. Among these are many viruses that have members of the *Gramineae* as hosts, plants that are also not susceptible to crown gall disease. It was thus surprising that maize plants could be infected with MSV by agroinoculation. This success indicated that *Gramineae* are also susceptible to T-DNA transfer, and opened a route to the introduction of a number of different viruses that could not enter by other artificial means, e.g. WDV into wheat and RTBV into rice.

Pararetrovirus Vectors

Pararetroviruses, like retroviruses, use both the host nucleus and the cytoplasm for replication. In the nucleus, viral DNA is transcribed into terminally redundant RNA, in the cytoplasm the RNA is reverse transcribed into DNA, which is transported either directly or via new infections into the nucleus. Pararetrovirus DNA accumulates (but does not replicate) in the form of supercoiled circles, while retrovirus DNA is inserted in a terminally redundant form into the host chromatin. Plant pararetroviruses exist as two groups, the icosahedral caulimoviruses and the bacilliform badnaviruses. The genomes of these viruses are all around 8000 bp in length.

So far, only CaMV, a caulimovirus from this group, has been used as a vector. The seven open reading frames (ORFs) of this virus are arranged densely packed on the pregenomic 35S RNA, and it is thought that all but one of the ORFs are translated from this polycistronic messenger. Infection can be achieved in the laboratory by mechanical inoculation with virus particles or virus DNA and thus ORF 2, which codes for an aphid transmission factor, becomes dispensable. In view of this, an ORF-2-replacement vector was constructed and used to clone, express and spread systemically payloads through turnips. By this means, the ORFs for bacterial dihydrofolate reductase (DHFR; 240 bp), the Chinese hamster metallothionein (200 bp), human αD interferon (500 bp), and BNYVV ORF N (171 bp) were cloned, spread systemically and expressed in plants.

From these successful and other unsuccessful experiments, it was learned that sequences introduced into the CaMV genome are frequently lost, probably as a result of illegal template switching of the nascent minus or plus DNA strands as well as negative selection against the inserted DNA sequence. These recombination events could be minimized by avoiding homologies at the insertion site, and selection for the deletions could be minimized by avoiding whatever might interfere with the virus life cycle as follows:

1. The total size of the genome should not, or should only slightly, exceed the original viral genome length of 8000 bp. About 700 bp can be capitalized by deletion of ORF 2, as mentioned above, and ORF 7, which is also dispensable for virus growth. Allowing for overpackaging of 300 bp, a payload of about 1000 bp seems to be the upper limit. CaMV vectors to clone a larger payload might be developed from artificial bipartite CaMV genomes, which together contain all essential functions and lack recombination targets.
2. The tightly packed ORF organization should be maintained, probably because of the unusual CaMV translation mechanism. Experience has shown that noncoding sequences between CaMV and passenger ORFs diminish vector stability.
3. Inserted sequences should not interfere with CaMV gene expression and replication. For instance, the insertion of an RNA polyadenylation signal would interfere with the production of pregenomic RNA, insertion of a new promoter might occlude the original CaMV promoters and an intron would not survive the transcription/reverse transcription cycle for very long.
4. Sequences leading to gene products that interfere with virus replication either directly or by affecting the host cell must be avoided.

CaMV and its derived vectors do not proliferate efficiently in cell culture; while DNA replicative intermediates can be found in infected protoplasts, mature virus particles are absent or rare. This might be explained by developmental control of genome replication versus translation. Both processes depend on the same 35S RNA, and one can assume a control mechanism that switches between these two functions. In protoplasts and the derived cell cultures, the switch is apparently set to genome replication and particle formation is inhibited.

It is also likely that other plant pararetroviruses can be developed as gene vectors, collectively covering a large host range. This would also include the *Gramineae* if, e.g. RTBV is considered. Since this virus has a bacilliform capsid, overpackaging might be less of a problem.

Geminivirus Vectors

Geminiviruses (**Table 2**) contain 2.5–3 kb of circular ssDNA. They are characterized by twinned (geminate) icosahedral particles. Geminiviruses of dicotyledonous plants are usually, but not always, bipartite

Table 2 Geminivirus vectors

Virus	*Partite*	*Target*	*Host*	*Payload*
TGMV	Bi-	Plants	*Nicotiana tabacum*	CAT, GUS, NPT-II
ACMV	Bi-	Plants	*Nicotiana benthamiana*	CAT
MSV	Mono-	Protoplasts	*Zea mays*	NPT-II, GUS, DSI
WDV	Mono-	Protoplasts	*Triticum monococcum*	NPT-II, CAT, βGAL

and transmitted by white flies; geminiviruses of monocotyledonous plants are monopartite and transmitted by leafhoppers. Usually, component 'A' of the bipartite geminiviruses is sufficient for replication in single cells, while component B is required for systemic spread and needs component A for replication. With respect to their bidirectional expression strategy, geminiviruses resemble the animal polyomaviruses and simian virus 40 (SV40). Their intranuclear dsDNA forms contain two non-coding regions, one harboring the clockwise and counter-clockwise promoters and the other containing the two polyadenylators. Transcription in one direction (in consensus clockwise) produces RNAs coding for structural proteins, and transcription in the other direction gives RNAs required for DNA replication.

The coat proteins of geminiviruses are dispensable for genome replication but are required for insect transmission, and in the case of the monopartite viruses are also required for virus spread within the plant. Accordingly, mutants in the coat protein gene of bipartite geminiviruses can still replicate in single cells and spread through the host plant. Coat protein mutants of monopartite geminiviruses do not spread.

Geminivirus coat protein replacement vectors have been introduced into plants by either mechanical means or agroinoculation. Vectors based on component A DNA of bipartite geminiviruses can spread if component B is provided either as a transgene or as a co-inoculum. However, when transgenes of these vectors are used or transient expression in protoplasts or leaf disks is studied, component B is not required. Monopartite geminivirus vectors are so far restricted to transient expression experiments in localized patches of plant tissue disks, seed-derived embryos or cell cultures.

The following additional observations have been made.

1. In addition to the coat protein gene, the small ORF of unknown function located further upstream can also be replaced by the payload. Deletion or replacement mutants of the counter-clockwise coding regions, however, are defective in replication.
2. Systemically spreading vectors are unstable if they are either smaller or larger than wild-type virus; rearrangements occur which restore the original size. The reason for this size dependence in the absence of packaging is not known. Non-spreading vectors, on the other hand, can exceed normal genome size by up to 4 kb, for instance when they harbor the long β-glucuronidase (GUS) or neomycin phosphotransferase (NPT) II coding regions.
3. Geminivirus vectors also tolerate the insertion of additional promoters, e.g. the CaMV 35S promoter, which leads to a large increase in payload expression without affecting replication.
4. An *E. coli* replicon can also be incorporated into monopartite geminivirus genomes, creating shuttle vectors that replicate and express a payload gene in both bacteria and protoplasts of *Gramineae*.

RNA Viruses as Gene Vectors

Infectivity of cloned cDNA

To develop RNA viruses as gene vectors, it is essential that infectious RNA can be generated from cloned cDNA copies. This has been achieved for a growing number of plus-strand RNA viruses (but not minus-strand viruses) using four different approaches.

1. With a cDNA clone directly. Only limited results have been reported so far (excluding the viroids), namely for A1MV RNA3 and TMV RNA; in both cases, the cDNAs gave rise to virus at a very low level. The infectivity found here is probably due to transcription from unidentified promoters.
2. As cDNA fused to the CaMV 35S promoter. This results in more efficient production of progeny virus, as reported for BMV and BNYVV RNA 3 and RNA4.
3. By agroinoculation. This has been achieved for BWYV, a luteovirus, using a cDNA clone provided with a ribozyme sequence to enable *in vivo* run-off transcription.
4. As *in vitro* run-off transcripts, from linearized full-length cDNA clones, using phage SP6, T7, T3 or *E.*

coli RNA polymerase, in combination with their respective promoters. This is by far the most frequent approach, and infectious transcripts have been synthesized for more than 20 different RNA viruses belonging to 15 distinct taxonomic groups (**Table 3**). It is essential for infectivity that the transcripts are not only of full length but also (almost) identical to the natural viral RNAs. Some problems may arise here since most promoters extend into the transcribed region, resulting in transcripts that start with extra nonviral nucleotides. In general, it has been found that nonviral residues at the 3′ end are better tolerated than extra nucleotides at the 5′ end, which mostly lead to a significant drop in infectivity.

The best results have been obtained with *in vitro* transcription systems using SP6, T3 or T7 promoters and the corresponding specific polymerases. These systems are highly efficient (up to 20 μg of transcript from 1 μg of template) and can be designed to yield almost authentic termini. However, if the first viral nucleotide is not *a priori* a G residue, one extra G residue must be tolerated at the 5′ end. It should be noted that, in most cases studied, the extra nonviral nucleotides were deleted in progeny RNAs. In cases of virus with capped genomic RNAs, the addition of a cap structure at the 5′ end of the transcripts often enhances infectivity. For BSMV RNAs capping seems to be an absolute requirement. There is an additional complication with viruses belonging to the 'picornalike superfamily', e.g. the como-, nepo- and potyviruses. The genomic RNAs of these viruses possess a protein (denoted VPg) covalently linked to the 5′ end. Nevertheless, both capped and uncapped *in vitro* transcripts have been shown to be infectious.

Insertion and expression of foreign genes

Cloned full-length copies from which infectivity can be recovered by following one of the approaches discussed above provide a good starting point for constructing replicons that can be used as gene vectors (**Table 3**). Of course, insertion of foreign sequences should not interfere with any viral function or process (e.g. RNA replication, subgenomic mRNA synthesis, translation, encapsidation) required for (helper-independent) infectivity.

With respect to noncoding sequences, the terminal sequences should at least be retained for replication, while for some viral RNAs (e.g. BMV RNA3) internal noncoding sequences also appear to contain obligatory *cis*-acting replication signals.

With respect to the introduction of payloads into coding sequences ('replacement' vectors), the following points can be made.

Table 3 Plant viral cDNAs reported to generate infectious *in vitro* transcripts

Group	*Virus*
Alfalfa mosaic	A1MV (RNA3)
Bromo	BMV, CCMV (RNA1–3)
Carmo	TCV
Comovirus	CPMV (RNA1–2)
Cucumo	CMV (RNA1–3)
Diantho	RCNMV (RNA1–2)
Furo	BNYVV (RNA1–4)
Hordei	BSMV (RNA α, β, γ)
Luteo	BYDV, BWYV
Potex	PVX, WCIMV
Poty	PPV, TVMV
Tobamo	TMV
Tobra	PEBV, TRV (RNA1–2)
Tombus	CNV, CYRSV, TBSV
Tymo	TYMV

Genes encoding proteins involved in RNA replication

All plant RNA viruses so far studied possess one or more cistrons encoding replication proteins (e.g. putative helicase, viral polymerase). It is obvious that any manipulation of these genes will lead to non-replicating transcripts unless the functions can be provided in *trans*. This is feasible, e.g. by transformation of host plants with functional copies of the affected genes (transgenic tobacco plants expressing the RNA1 and RNA2 products of AIMV are able to support RNA3 replication) or by co-inoculation with helper virus (smaller TMV RNA-derived replicons co-replicate and spread systemically with TMV helper virus). In both cases, however, the viral vector has lost its truly independent character.

The movement protein gene(s)

A considerable number of plant RNA viruses encode a so-called 'movement protein' which is actively involved in cell-to-cell spread of the viral genome (e.g. tobamoviruses) or viral particle (e.g. comoviruses) through plasmodesmata. Its coding sequence should be retained if systemic spread of the viral vector is desired. This is true for TMV for the 30 kD protein, for BMV for the RNA3-encoded 32 kD protein and for CPMV for the M-RNA-encoded 58 kD/48 kD protein pair. For expression in protoplast systems or cultured cell suspensions, the movement protein cistron can be omitted and the site exploited.

Table 4 Heterologous gene expression from plant RNA viral genomes

Group	*Virus*	*Insertion site*	*Gene*	*Expression system*
Bromo	BMV	Coat protein gene	CAT	Protoplasts
Furo	BNYVV	25 kD gene (RNA3)	GUS	Inoculated leaf

[a] From inserted ORSV coat protein promoter.

The coat protein gene(s)

The viral coat protein gene can, in some instances, be manipulated in order to express foreign sequences, though it always leads to lower fitness in terms of systemic spread. Although for some viruses the coat protein is dispensable for cell-to-cell movement (e.g. TMV), this structural protein cannot be omitted for long-distance transport of the inoculated vector (via the vascular system) throughout the whole plant. Therefore, replacement of coat protein genes by reporter genes (e.g. CAT, **Table 4**) always leads to naked, infectious RNA which is confined to the inoculated leaf. Such replacement vectors can, however, be efficiently expressed in protoplast systems (**Table 4**). The problem of limited spread has recently been circumvented for TMV by creating a viral vector (TB2) which contained a duplicated subgenomic promoter of the coat protein gene, enabling the expression of both the coat protein and the payload gene (NPT II, DHFR). It was found that the duplicated promoter should be cloned from a different tobamovirus with enough sequence divergency (i.e. ORSV) to avoid removal by homologous recombination.

Miscellaneous genes

Further genes with potential for exploitation as vectors exist in some viruses. Their function has usually not been resolved, although some of them have been shown to be dispensable for both viral RNA replication and systemic spread. For example, in the quadripartite RNA virus BNYVV, both RNA3 (specifying a 25 kD protein) and RNA-4 (specifying a 31 kD protein) have been shown to be dispensable and are in fact lost after serial mechanical inoculation. Large internal parts of both these RNAs can be deleted without affecting replication. Insertions of the bacterial GUS gene in a deletion-containing RNA3 cDNA has been shown to give rise to detectable GUS activity in the inoculated leaf (**Table 3**) and amplification of the transcript. A further example of successful replacement, this time with BSMV, is insertion of the firefly luciferase (LUC) coding sequence into the βb gene (located on β-RNA and encoding a 58 kD protein with a helicase motif), which resulted in infectious virus expressing high-level luciferase activity in both tobacco and maize protoplasts. However, luciferase activity was not detected in extracts of whole plants inoculated with BSMV RNAs α, β or the LUC-gene-containing RNA, which is consistent with the replaced βb protein being essential for multiplication in whole plants.

Independent versus 'disarmed' vectors

From the previous paragraph, it is clear that viral RNA vectors able to replicate and spread independently through whole plants should contain all *cis*- and *trans*-acting factors involved in RNA replication, encapsidation and spread. Two approaches have been shown to be successful for the development of such helper-independent vectors, i.e. the insertion of a ('recombination-proof') extra promoter, as shown for TMV, and the replacement of non- or less essential genes (e.g. BNYVV 25 kD gene).

As an alternative, 'disarmed' viral vectors could be constructed for foreign gene expression in plants, which lack one or more essential functions and are able to multiply only in target plants transformed with the required gene(s). The properly constructed transgenic plant which is required provides a bonus in the form of control over the spread of field-released genetically engineered virus. This approach is indeed feasible, as shown by the replication of engineered AlMV RNA3 molecules in tobacco plants transformed with the AlMV replicase genes, and the complementation of spread-deficient TMV strains in transgenic plants expressing the TMV 30 kD movement protein.

Plant Viruses as Vectors for Studying DNA and RNA Rearrangements

Virus vectors have also been used for purposes other than expression of a payload ORF.

Splicing

Cloning of introns in virus vectors allows precise measurement of the efficiency and accuracy of splicing in monocotyledons and dicotyledons. The precise excision of an intron introduced into a CaMV vector verified the intron and was a proof for reverse transcription of CaMV.

Recombination

Experiments can be designed which make use of essentially nonviable virus hybrids which become viable upon specific genome rearrangements. The most obvious examples, already mentioned in the course of discussing agroinoculation, are given by 'one-and-a-bit-mer' of manipulated caulimo- and geminivirus genomes which release viable virus upon recombination. If the redundant portions of these constructs are derived from different viral strains, questions can be answered concerning the recombination mechanism, the presence of recombination hot spots, the degree of homology required, etc. Escape of pregenomic virus RNA by transcription was observed if the promoter/polyadenylator region of CaMV constituted the terminal redundancy. If transgenic *Brassica napus* plants were produced containing CaMV one-and-a-bit-mers arranged such that CaMV could not escape by simple transcription, true recombination events could be scored by appearance of viral symptoms. Sequence analysis of recombinant molecules suggested that mismatch repair was linked to the recombination process. Intermolecular recombination could also be studied, i.e. between transgenic CaMV ORF 4 and supertransfected complementary virus sequences.

Infectious transcripts from cloned RNA viruses have been very useful for studying RNA recombination, e.g. in bromoviruses, and for analyzing and understanding the *cis*- and *trans*-acting factors in RNA replication.

Agrobacterium T-DNA transfer

A CaMV-based system was used to analyze independent *Agrobacterium* transfer DNA (T-DNA) transfer events. The complete T-DNA without the border sequences was replaced by the virus genome such that a viable replicon could be produced by circularization upon transfection of plants. Analysis of this replicon revealed rather conserved right border remnants, while sequences remaining at the left border were more variable. The presence of small direct repeats between some of the joined ends showed that linear T-DNA had been transported to the plant.

Transposition

Using WDV and MSV vectors that contained the maize transposable element *Ac* or its defective *Ds* derivatives, excision of the transposable element could be studied in protoplasts and whole maize plants. Excision of the *Ds* element was dependent on the presence of *Ac*. The junction sequences left on the viral genomes after excision revealed the typical footprints.

Conclusions

Based on the limited and (sometimes) rather preliminary results obtained so far, it may be concluded that plant viruses can be engineered into gene vectors able to express desired genes. Systems are described that allow expression in single plant cells; others allow replication, expression and spread through the plant, either independently or as 'disarmed vectors' in the presence of a helper virus, or within a transgenic host carrying the missing functions.

The advantages of the viral vector transfection systems are ease of handling, the short time periods required to obtain results and the replication of the vectors to high copy numbers which can result in expression levels much higher than in transgenic plants.

Because of the lack of any proofreading mechanism and the large number of replication cycles (even in a single cell), one might imagine that payload genes in RNA virus and pararetrovirus vectors would rapidly accumulate point mutations, leading to inactivation of these nonessential inserts. The (limited) experimental data obtained so far, however, indicate that at least for the duration of a single protoplast batch or plant infection, functional proteins can be obtained in desirable amounts. It is not excluded that viral vectors eventually lose their capacity to encode a functional protein upon serial passage, although this would merely provide an advantage in view of biological containment.

A second issue of concern is the risk of recombination involving viral vectors. Indeed, it has now been well documented that viral genomes, including those of RNA viruses, are frequently the subject of recombinational events. One obvious mechanism for recombination in all classes of plant viral vectors relies on template switches of the nascent DNA and RNA strands. On the one hand, nonviral inserts in viral vectors might become lost by recombination because of the lack of selective pressure; the con-

sequences seem only to be beneficial with respect to biological containment, since viral vectors will not survive for long in nature. On the other hand, new functional viral genomes may arise from recombinational events involving (disarmed) RNA vectors, co-infecting (helper-) viruses and transgenes, which could lead to undesired spread of pathogens. Although so far no evidence has been obtained for such events, it is clear that critical risk-assessment analyses should be performed prior to possible release of viral vectors in agricultural practice.

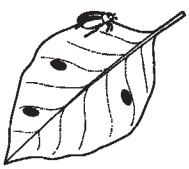
VECTOR TRANSMISSION OF PLANT VIRUSES



Stewart M Gray, USDA, ARS and Department of Plant Pathology, Cornell University, Ithaca, New York, USA

D'Ann Rochon, Agriculture and Agri-Food Canada, Pacific Agri-Food Research Centre, Summerland, British Columbia, Canada

Introduction

It has been nearly 100 years since a leafhopper was confirmed as the vector of rice dwarf virus. Several hundred plant viruses have since been identified, a majority of which are dependent upon a vector for transmission between, and inoculation into, plant hosts. The plant viruses have evolved many interesting and biologically complex associations with their vectors, which include arthropods, nematodes and fungi. Although there is a great deal known about the general biology of most virus–vector interactions, we are only beginning to understand the molecular and cellular mechanisms that regulate the transmission processes and determine the efficiency of transmission.

General Mechanisms of Virus Transmission by Arthropods and Nematodes

In the early years viruses were said to be either mechanically transmitted or biologically transmitted by their vectors. Biological transmission was the specific association of a virus with a particular arthropod species or genus and the virus replicated in the vector. Mechanical transmission referred to the nonspecific transmission of viruses, usually by multiple vector species. The viruses did not replicate in the vector and transmission was thought to occur by the simple contamination of vector mouthparts. Most plant viruses do not replicate in their vectors, but it

can promote interactions between particles and fungus. Deletion analysis, along with alanine scanning mutagenesis, has identified a KTER amino acid motif near the C-terminus of the BNYVV readthrough as being important for the fungus transmission process. A similar sequence (KTEIR) is found in the readthrough domain of SBWMV.

Bymoviruses do not translate a coat protein readthrough. The repeated mechanical transfer of a BaYMV strain resulted in the loss of fungus transmission and a spontaneous approximate 1 kb deletion in RNA2. The deleted region is from a protein which is associated with crystalline inclusion bodies in infected tissue. Alignments of portions of the protein products of RNA2 of two bymoviruses and the readthrough portion of several furovirus capsids has revealed that certain amino acid combinations (ER or QR) are found consistently in all the viruses. These amino acids occur on the outside of the protein and therefore may be available for interaction with the fungus vector. In addition, certain conserved regions are absent in nontransmissible deletion mutants. These studies suggest that bymoviruses and furoviruses encode similar proteins for facilitating their transmission.

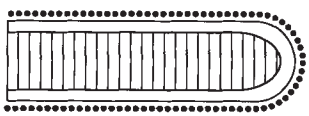
VESICULAR STOMATITIS VIRUSES (*RHABDOVIRIDAE*)



Luis L Rodriguez, Plum Island Animal Disease Center, Agricultural Research Service, United States Department of Agriculture, Greenport, New York, USA

Stuart T Nichol, Special Pathogens Branch, Division of Viral and Rickettsial Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia, USA

History

Vesicular stomatitis viruses (VSVs) are rhabdoviruses which infect a wide range of wild and domestic animals, and several groups of insects. VSVs are best known as the cause of vesicular stomatitis (VS), a disease characterized by vesicular lesions in the mouth, tongue, udder teats and hoof coronary bands of cattle, horses and pigs. Clinical disease occurs every year in farming areas from northern South America to

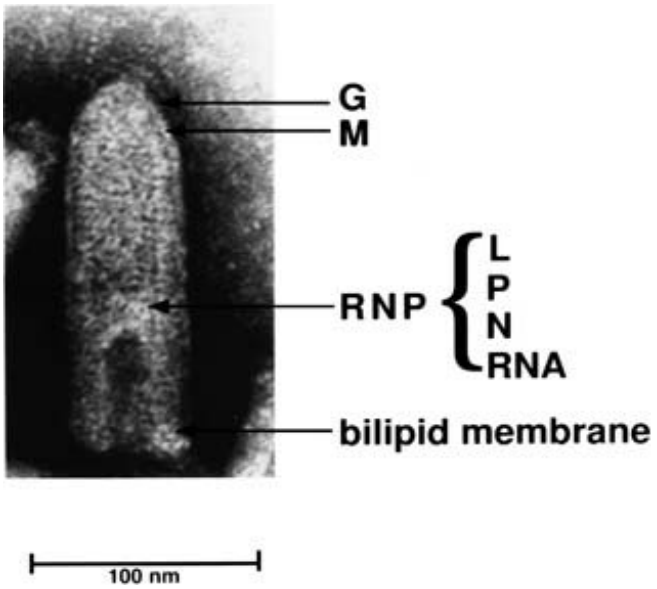


Figure 1 Electron micrograph of VSV-IN. Location of virion components is indicated. RNP is ribonucleoprotein.

southern Mexico where VSVs seem to have a stable natural cycle and are considered endemic. Humans living in these areas are often infected, and consequently develop flu-like symptoms. Early records of disease compatible with VS such as 'sore tongue' in pigs and 'hoof loss' in horses date back to the early 1800s in the Southeastern US and Central America. In 1862, a vesicular and febrile illness compatible with VS affected thousands of army horses in the US during the Civil War. The first large epizootic of VS to be described in detail occurred in 1916 in the US. The contagious, febrile and vesicular disease spread rapidly from Colorado to the East Coast, affecting large numbers of horses and mules and to a lesser extent cattle. Large epizootics have continued to occur in the US, on an approximately 10 year cycle, mostly in south western states.

Taxonomy and Classification

VSVs are classified in the order *Mononegavirales* (non-segmented-negative-sense RNA viruses), family *Rhabdoviridae*, genus *Vesiculovirus*. All rhabdoviruses share a characteristic bullet- or rod-shaped morphology and basic biochemical properties (**Fig. 1**). VSVs are grouped together on the basis of antigenic crossreactivity and genetic and biochemical relatedness. Two main serotypes, Indiana (IN) and New Jersey (NJ), have been defined based on cross-neutralization properties. The prototype strain of the IN serotype (VSV-IN1) was isolated in 1925 from an outbreak in cattle in Richmond, Indiana. A year later, the prototype virus strain of the NJ serotype (VSV-NJ) was isolated from cattle in New Jersey. Other VSVs serologically related to but distinct from VSV-IN1 have been found. Cocal virus, a virus isolated from mites in 1961 in Trinidad became the prototype strain of the VSV-IN type 2 (VSV-IN2). Another IN-related virus was isolated in 1964 from a mule in Alagoas, Brazil and became the prototype strain of VSV-IN type 3 (VSV-IN3). Many viruses serologically related to VSVs have been found, such as, Calchaqui in Argentina, Maraba and Carajas in Brazil, all isolated from insects, and Piry isolated from an opossum in Brazil.

Properties of the Virion

VSV particles are rod-shaped (hence the name rhabdo, from the Greek for rod) enveloped viruses of approximate dimensions 70 × 180 nm (**Fig. 1**). The virion core consists of a helical ribonucleoprotein (RNP) structure containing the RNA genome. The protein components of RNP cores consist of nucleocapsid (N) protein, the polymerase-associated phosphoprotein (P) and the large (L) polymerase protein. Based on studies using electron microscopy it has been estimated that there are 1258, 466 and 50 molecules of N, P and L, respectively, in each virion core of VSV-IN1. The matrix (M) protein is closely associated with the core structure, and provides structural support to the bullet-shaped helical RNP. The RNP is enveloped by a bilipid membrane derived from the host cell. Embedded in the membrane is the surface glycoprotein (G). The majority of the G molecule protrudes to the exterior of the viral particle and the short cytoplasmic tail contacts the underlying M protein.

Physical Properties

VS virions consist of approximately 74% protein, 20% lipid, 3% RNA and 3% carbohydrate. Infectivity is unstable at pH 3, but relatively stable in the pH range 5–10. It is rapidly inactivated at 56°C and by UV and X-ray irradiation. Infectivity is also sensitive to lipid solvents, detergents, formalin and various disinfectants such as bleach.

Properties of the Genome

The single-stranded non-segmented negative-sense RNA genome of VSV is approximately 11 kb in length. These linear RNA molecules possess 5′-phosphate and 3′-hydroxyl groups, and lack 5′ cap or 3′ poly(A) tail structures. The termini exhibit limited self-complementarity which may be involved in the circularization of the genome. The naked RNA

Table 1 Properties of proteins of vesicular stomatitis virus (NJ serotype)[a]

Protein	*Biochemical characteristics*	*Localization and function(s)*
Nucleocapsid (N)	422 aa; pI 5.8–6.3; 47–48 kDa	Encapsidates RNA to form nucleocapsid, essential component of transcription–replication complex
Phosphoprotein (P)	274 aa; acidic pI 4.2–4.3; 30–31 kDa; phosphorylated	Part of viral polymerase complex, mediates binding of L to nucleocapsid cores
Large (L)	2109 aa; basic pI 8.6–8.8; 241–242 kDa	Nucleocapsid, multifunctional enzyme, protein kinase, polymerase, capping, methylation and poly(A) addition
Matrix (M)	229 aa; highly basic pI 9.9; 26–27 kDa, phosphorylated	Forms scaffolding of nucleocapsids, promotes virus assembly, regulates genome transcription, inhibits host-cell gene expression, most abundant virion protein
Glycoprotein (G)	517 aa; 57–58 kDa class I membrane protein, N-glycosylated at 2 Asp residues	Major protein on viral envelope, attaches to cell receptor(s), mediates membrane fusion at low pH, induces cell toxicity, target of virus-neutralizing antibodies
C and C′	Coded in second ORF of P gene, 55 and 65 aa respectively, highly basic, arginine-rich	Nonstructural with unknown function

[a] Similar properties have been reported for VSV-IN1 proteins. aa, amino acids.

is not infectious. The nucleotide sequences of the complete genomes of VSV-IN1 and VSV-NJ have been determined. Furthermore, infectious virus has been recovered from plasmids containing the full-length genome of VSV-IN1. This has allowed extensive studies on the genome structure, transcription and replication strategies of VSV (see replication section).

Properties of the Proteins

VSV-NJ and VSV-IN1 code for seven proteins; five structural proteins (N, P, M, G, L) are coded in separate nonoverlapping open reading frames (ORFs) whereas two small highly basic nonstructural proteins (C and C′) are coded in a second ORF within the P gene. The following details relate to VSV-NJ proteins unless otherwise stated (for details see **Table 1**). The N protein encapsidates the viral RNA, it is an essential component of actively transcribing or replicating viral cores and functions in close association with the P protein. The P protein is a highly phosphorylated protein associated with viral polymerase activity. It mediates the binding of the L protein to the nucleocapsid core and facilitates access of the polymerase to the RNA template during transcription and replication. Phosphorylation of P protein seems to be necessary for optimal transcriptase activity of the RNP complex. C and C′ are nonstructural proteins of which the exact role in the life cycle of VSV is not clear. Engineered viruses that do not express C proteins are indistinguishable from wild-type virus in protein synthesis, virus production and host-protein synthesis shut off in tissue culture cells. The large L protein is a multifunctional enzyme required in only catalytic amounts and probably performs most of the polymerase-associated functions of the virus such as RNA synthesis, capping, methylation and poly(A) addition. It also has protein kinase activity which preferentially phosphorylates serine residues on the P protein. The matrix protein (M) is the most abundant protein of virions. M binds specifically to G protein monomers and promotes their trimerization, it also associates with the cellular lipid bilayer through the C-terminal domain to promote the condensation of viral RNP cores into tightly coiled helical structures that are subsequently enveloped and released as virions. The M protein, in tight association with RNPs, inhibits genome transcription and may play an important role in the correct regulation of viral genome transcription.

The G protein is a typical class I membrane-associated glycoprotein, with the N-terminal 90% of the molecule projecting from the surface of the virion or infected cell, a hydrophobic transmembrane domain anchoring the protein in the membrane, and a C-terminal 28-amino acid cytoplasmic domain projecting to the interior of the virion or infected cells. The G protein forms trimers that constitute the approximately 400 spikes on the virion envelope. The G protein plays a major role in attachment, penetration of VSV into susceptible cells and budding of virions from infected cells. It is the major target of VSV-specific neutralizing antibodies and is capable of inducing cell membrane fusion at low pH.

Replication Cycle

Unless otherwise stated, the following description of viral replication (**Fig. 2**) is that of VSV-IN1, although

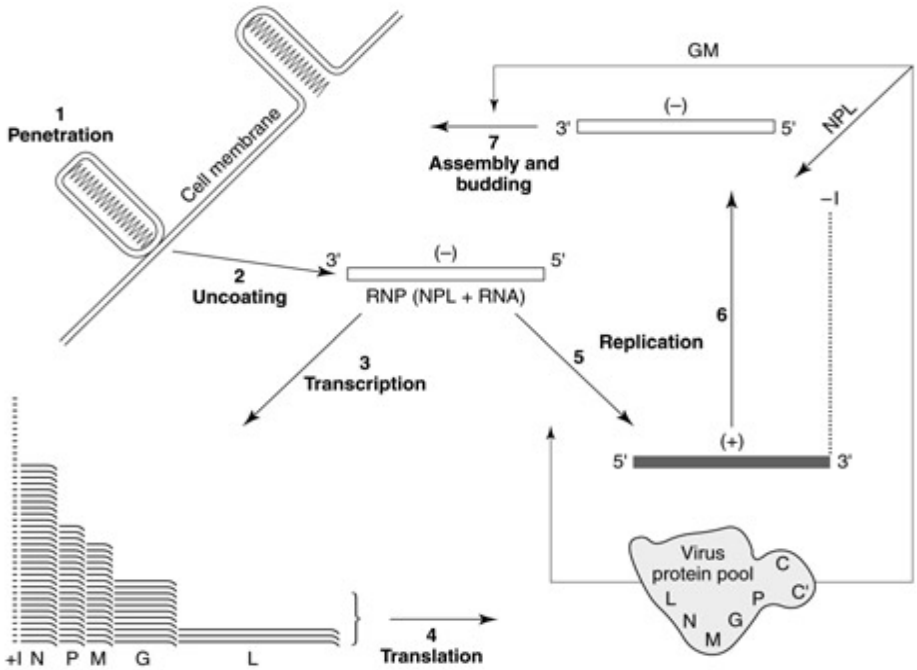

Figure 2 Model of VSV replication cycle. The major steps in the replication cycle of VSV are shown in diagram form. Open bars represent viral negative-sense RNA and closed bars represent viral positive-sense RNA. Refer to the text for discussion of steps 1–7.

it is likely to be representative of events occurring with the other VSVs. The infection cycle starts when the VSV G protein interacts with receptors on the host cell surface (such as phosphatidylserine). The virion penetrates by receptor-mediated endocytosis (**Fig. 2**, step 1). Once inside the cell, the G protein mediates the fusion of the cell and viral membranes under the low-pH conditions in the endosomes (**Fig. 2**, step 2). The viral ribonucleoprotein or nucleocapsid is released in the cytoplasm and the negative-sense viral RNA is transcribed by the virion-associated polymerase complex to produce six viral transcripts (**Fig. 2**, step 3). Active transcribing complexes consist of the template, made up of the RNA genome in tight association with the N protein, together with the polymerase, consisting of the phosphoprotein (P) and large (L) protein. The polymerase complex starts transcribing at a single entry site at the 3′ end of the genome and transcribes each gene in decreasing amounts as it moves away from the entry site. Therefore, the gene order provides an efficient way of regulating gene expression, where proteins necessary in larger amounts are located near the 3′ end and are transcribed in larger amounts and those needed in smaller amounts are located towards the 5′ end and are transcribed less frequently (i.e. 3′ N>P>M>G>L 5′). The complex initiates transcription by completing a 47-nucleotide transcript termed the leader RNA which is an exact copy of the genome 3′ end. This is followed by an untranscribed junctional sequence AAA (AAAA in VSV-NJ). The leader transcript which is neither capped nor polyadenylated, is transported to the nucleus where it inhibits host cell transcription. The leader transcript is followed by the N mRNA, which is capped during synthesis by the virion polymerase complex. At the end of the N gene, and indeed of all five viral genes, is the sequence 5′-AGUUUUUUUCAUA-3′ which signals the termination and polyadenylation of the mRNA. The mRNA poly(A) tract is probably synthesized by the viral polymerase slipping or chattering on the 7 U stretch. In an essentially identical manner, the polymerase completes the sequential synthesis of the remaining four mRNAs. Translation of the mRNAs is coupled to the transcription process and the protein amounts reflect the relative abundance of each mRNA (**Fig. 2**, step 4). Subsequently, after translation of viral proteins has occurred, a switch is made to synthesis of full-length positive-sense copies of the genome (**Fig. 2**, step 5). The switch mechanism is not fully understood but it requires protein synthesis and perhaps the participation of host cell factors. The critical step is the readthrough of the first junction encountered by the polymerase, i.e. the leader-N gene junction. The polymerase must be altered so as to no longer recognize the termination signal at this junction and continue down the full length of the genome. The

simplest model fitting most of the experimental data proposes that rising levels of encapsidation of the nascent positive-strand leader RNAs by N protein reaches a threshold whereby it prevents the polymerase complex from recognizing the termination signals. Once full-length positive-strand synthesis occurs, production of the virus negative-sense RNA genomes necessary for packaging into released virions commences (**Fig. 2**, step 6). A negative-sense leader RNA which represents a 46-nucleotide copy of the 3′ end of the positive-sense template can be found in infected cells. Its function is not known but it is probably synthesized in a manner similar to the positive sense leader RNA, i.e. in the presence of limiting levels of N protein the nascent negative-sense RNA synthesis terminates after the leader RNA transcript. In the presence of optimal levels of N protein the efficient encapsidation of the nascent strand pushes the polymerase through the termination signal and allows the polymerase complex to complete the synthesis of the entire negative-sense RNA genome. Such a proposed mechanism is attractive as it closely couples the production of virion RNA with the availability of viral proteins necessary for virion production.

The five viral mRNAs are transcribed in the cytoplasm of infected cells and their translation is directly coupled to the transcription process. Four of the viral mRNAs, N, P, M and L, are translated on free polysomes in a manner essentially analogous to cellular mRNAs. The G mRNA is translated on membrane-bound polysomes, the N-terminus of the newly emerging G protein has a 16 amino acid hydrophobic signal peptide which targets the protein to the rough endoplasmic reticulum (ER). The signal peptide is cleaved in the lumen of the ER. The protein is glycosylated as it is transported through the Golgi complex and is eventually expressed on the cell surface membrane in a trimeric form.

Assembly and Release

The glycoprotein forms patches on the surface of the infected cells. The M protein appears to form a bridge between the G protein membrane patches and virion RNP cores and promotes the tight condensation of the cores and their assembly into mature virion particles. These are then released by budding from the surface of the cell (**Fig. 2**, step 7). Considerable virus release occurs prior to the eventual disruption and death of the host cell. VSVs are generally highly cytopathic causing rapid cell death (in less than 12 h in some cases) in susceptible cells. Both M and G proteins and the viral inhibition of cell macromolecular synthesis have been shown to be involved in the cytotoxicity and death of infected cells.

Growth in Tissue Culture

The growth of VSVs is supported by a large number of vertebrate and insect tissue culture cells. VSV grows to high titers (8–9 $\log_{10}$) and produces dramatic cytopathic effect (CPE) in vertebrate cells such as cell lines and primary cultures of hamster, bovine and primate origin. In contrast, CPE is less obvious or absent and titers are lower in insect cells including several cell lines from mosquitoes (*Aedes albopictus* and *Aedes aegypti*).

Geographic and Seasonal Distribution

VSVs have been isolated almost exclusively from New World mammals and insects. Disease epizootics have been reported as far north as Canada, and as far south as Argentina. According to the intervals between outbreaks of clinical disease, there are areas of high, moderate or low VS activity with intervals of less than 1 year, 2–10 years or more than 10 years, respectively (**Fig. 3**). VSV-NJ infections are the most common, and have the widest distribution, with isolations as far north as Canada and as far south as Peru. VSV-IN1 has a similar wide geographical distribution but is less frequently encountered. VSV-IN2 (Cocal) viral infections have been detected in Trinidad, Brazil and

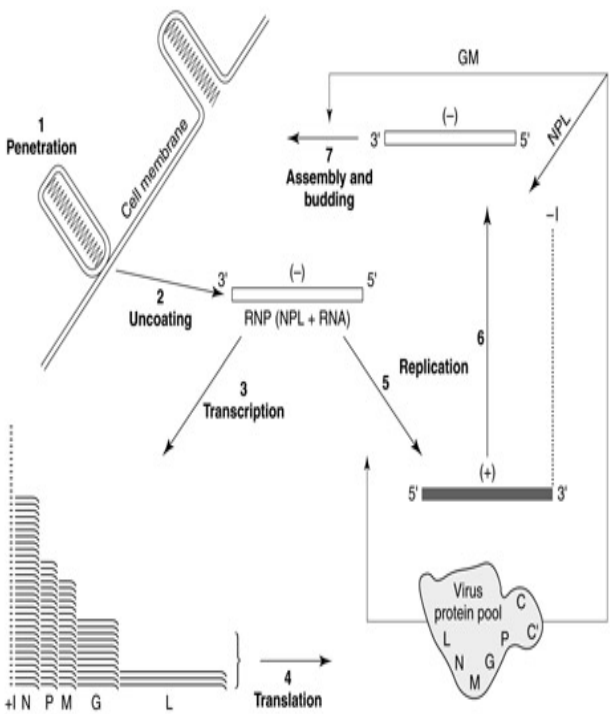

Figure 3 Geographical distribution of VSV serotypes. Areas are shaded according to the approximate interval between outbreaks of clinical vesicular stomatitis: □, never reported; ■, > 10 years; ■, 2–10 years; ■, 1 year.

Argentina. The last reported outbreaks caused by VSV-IN 2 date back to 1979 in Brazil. VSV-IN3 (Alagoas) is the main cause of VS outbreaks in Brazil. VS outbreaks often follow natural features of the land (e.g. spreading throughout river valley systems rather than along road systems or trucking routes) and tend to have a marked seasonality. In temperate regions, they begin in the late spring, peak in the late summer and cease with the first frosts of late fall/early winter. In more tropical regions, the epizootics frequently appear at the cessation of rainy seasons. In both regions, the seasons of high VSV activity tend to correlate with high insect population levels.

There are only two reports of suspected VS epizootics outside of the New World. The first was an apparent VS outbreak in horses and mules in Transvaal, South Africa in the late nineteenth century. The second was a VS outbreak in France during World War I which was initiated by a shipment of infected US army horses. There is no evidence of VSV activity persisting for prolonged periods in either of these continents. VS is a mandatory reportable disease in most countries, either because of it being exotic in those countries or for the similarity of its clinical signs to those caused by foot-and-mouth disease virus, a virus exotic or under eradication in most parts of the world.

Natural History

VSVs seem to infect a wide range of hosts in endemic areas, with evidence of viral infections in wild small mammals such as: cotton rats (*Sigmodon* spp.), rice rats (*Oryzomis* spp.) and field mice (*Peromyscus* spp. and *Reithrodontomys* spp.); arboreal mammals such as bats (many species) and howler monkeys (*Alloata palliatta*); and large wild mammals such as white tail deer (*Odocoileus virginianus*) and feral swine (*Sus scrofa*). Infections of wild animals seem to be asymptomatic. Insects are also infected by VSVs, with isolations reported from sand flies (*Lutzomyia* spp.), black flies (*Simulium* spp.), midges (*Culicoides* spp.), mosquitoes (*Culex* spp., *Aedes* spp.), eye gnats (*Hippelates* spp.), mites (*Gigantolaelaps* spp.) and domestic flies (*Musca domestica*). No disease symptoms are observed in insects and their importance in the maintenance and transmission of VS disease is unclear. However, the ability of VSVs to replicate and be transovarially transmitted in sand flies and black flies and the seasonal appearance of clinical disease, suggests a role for these insects in the natural cycle of VSV. Since transovarial transmission of VSV in insects is inefficient it has been proposed that natural reservoirs, in which the virus induces high titers in the blood, are necessary for hematophagous insects to maintain the virus in nature. However, to date such wild or domestic natural reservoir(s) remain elusive.

One of the best documented VSV endemic foci is on Ossabaw Island, a barrier island off the coast of Georgia in southeastern US. On this island, the local feral swine population is infected every year by VSV-NJ. Several lines of evidence indicate that the sand fly (*Lutzomyia shannoni*) is the vector responsible for VSV-NJ transmission to feral swine. First, *L. shannoni* is the only species of sand fly on the island. Second, VSV-NJ has been isolated not only from hematophagous females but also from nonhematophagous male sand flies which indicates that transovarial transmission must have occurred in these flies. Third, the population peak of sand flies on the island precedes by about a month the peak in seroconversion rates of sentinel pigs, and fourth, it was found that the virus is transmitted most often to sentinel pigs in those habitats of the island where the sand flies are abundant, such as maritime live oak forests. However, the reservoir that feeds this apparent insect–swine cycle in Ossabaw remains unknown, since neither deer nor feral swine from the island were capable of producing detectable viremias after experimental inoculation with the local strain of VSV-NJ. Other studies in well-documented endemic areas in Costa Rica have shown that the presence of clinical VS in dairy cattle is associated with the presence of forested areas near the affected farms, where wild animals including rodents, primates and bats have high antibody prevalence to VSV, and also where sand flies and black flies are present. The role of these wild animals and insects in the natural cycle of VSV is to be determined.

Evolution

RNA-dependent RNA-polymerase of VSVs has an estimated error rate of $1–4 \times 10^{-4}$ substitutions per base incorporated. As a consequence of this high error rate, every time the genome is replicated new variants arise producing a heterogeneous virus progeny referred to as a 'quasispecies'. VSV uses this genetic variability to adapt and persist in its natural niche. Despite the high mutation rate of VSV *in vitro*, naturally occurring VSVs show a clear pattern of genetic stability (**Fig. 4**). There is good correlation between viral phylogeny and the location of virus isolation, indicating that many lineages and sublineages are maintained in infection foci of limited geographical distribution (**Fig. 4**). There is no correlation between lineages and host species, i.e. there is not a distinct VSV of any particular host species. Viruses isolated from mammals and insects in the same endemic area usually have identical se-

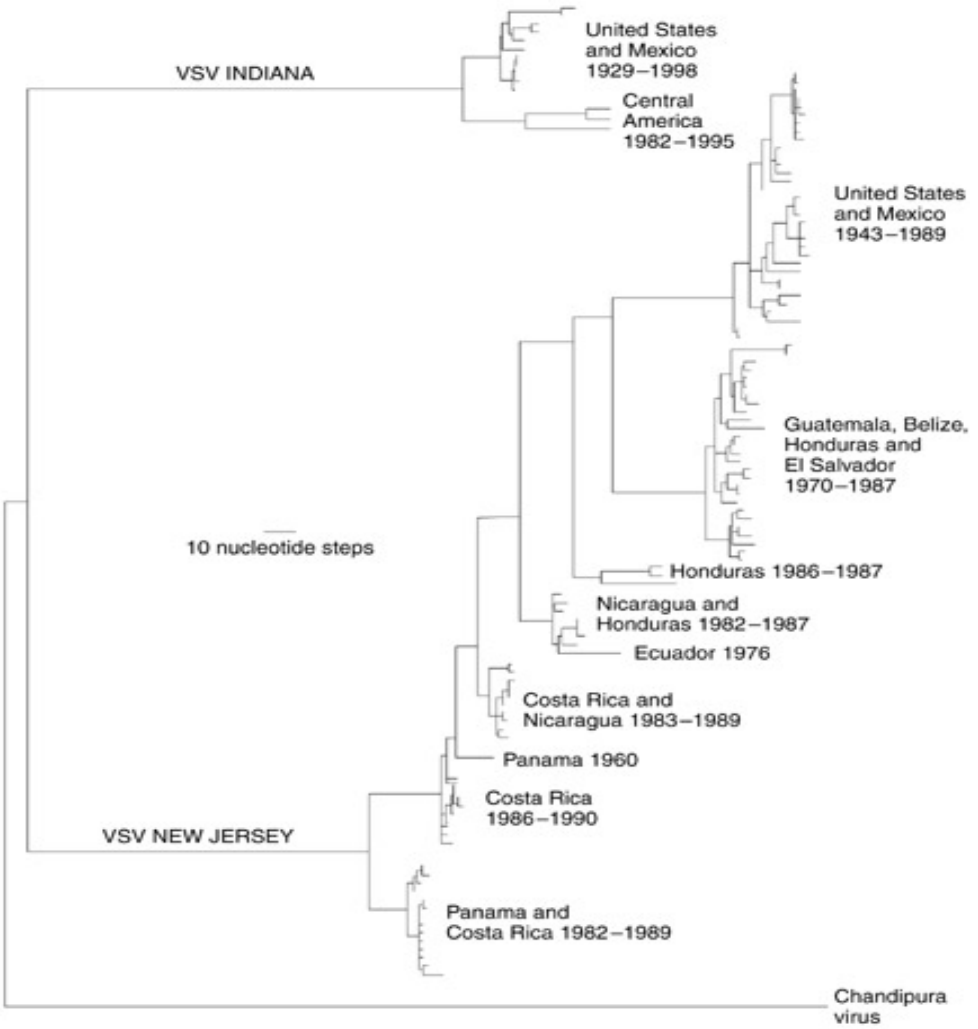

Figure 4 Evolutionary tree topology for VSV-NJ and VSV-IN1 from North and Central America, obtained by maximum parsimony analysis of partial phosphoprotein sequences from 122 VSV isolates. Genetic distance is proportional to the length of horizontal lines. Vertical distances are for graphic display only.

quence, furthermore, viruses isolated in these areas 30 years apart are more closely related than viruses from the same year but from different areas. The absence of a molecular clock contrasts with the evolutionary pattern of other RNA viruses such as human influenza A viruses which show a clear relationship between year of isolation and position within a phylogenetic tree. The evolutionary pattern of influenza virus A is driven mainly by the immune response of the infected hosts, where new antigenic variants capable of escaping the immune response have a selective advantage. In contrast, sequence analysis of VSVs causing clinical disease in Central and North America suggest that ecological factors rather than immune selection are the major forces driving VSV evolution (**Fig. 4**). For instance, viruses originating less than 25 km apart but from different ecological zones had different sequences, whereas viruses originating over 800 km apart but from areas of similar ecological characteristics had identical sequences. The ancestral origin of the VSVs is currently unclear. A relatively conserved gene order and limited sequence similarity with other nonsegmented negative-strand RNA animal viruses suggest a common, albeit very ancient, ancestor.

Serological Relationships and Variability

All VSVs share common N protein epitopes which are group specific and are usually detected by complement fixation assay. The two major VSV serotypes, IN and NJ, have been defined by crossneutralization assays using antibodies to the surface glycoprotein (G). Limited antigenic variation has been observed

among natural virus isolates of VSV-NJ. Greater antigenic diversity is seen among VSV-IN with at least three distinct types identified. Antisera raised to virus of one IN type will neutralize virus of another type but to a lesser degree. Although some antigenic variation can be found, there is no evidence of distinct antigenic drift of VSVs in nature (see Evolution section).

Epidemiology

The epidemiological characteristics of VS outbreaks depend to a large extent on whether the outbreak occurs in an endemic or a nonendemic area. Endemic areas are located in tropical and subtropical areas of the Americas where the interval between clinical outbreaks is less than one year. An epidemiologic study carried out in an endemic area of dairy production in Costa Rica reported clinical cases starting in November, peaking in December and January and continuing until March (the dry season in this area begins in November and continues through May). Most clinical cases occurred in adult lactating cattle (average age 5.4 years) and were caused by VSV-NJ (90%) and to a lesser extent IN 1 (10%). The majority of the adult population, including those that became clinically ill, had significant titers of neutralizing antibodies to VSV-NJ (93%) and VSV-IN1 (25%). Interestingly, there was no evidence for genetic drift in the viral glycoprotein gene in viruses recovered from these cases, despite the fact that clinically affected animals had high titers of neutralizing antibodies prior to clinical disease. In these endemic areas many animals, particularly young animals (less than 2 years) become seropositive to VSV during periods of clinical activity without showing any signs of clinical disease.

VSV causes periodic large-scale disease epizootics of cattle, horses and swine in non-endemic areas with peaks of activity approximately every 10 years. Clinical cases appear in many premises in a short period of time, generally during the summer months, and the disease disappears with the first frosts. However, in 1982–83 a large outbreak of VSV-NJ in western US persisted well into the winter months. After the 1982/83 outbreaks, VS has occurred in Southwestern US in 1995, 1997 and 1998. All cases in 1995 were caused by VSV-NJ, however, during the 1997 and 1998 outbreaks, VSV-IN1 was the major cause of clinical cases. Interestingly, this was the first report of VSV-IN1 in the US since 1966. It is not known what the sources of VSVs are for the US outbreaks. Nucleotide sequencing of virus isolates from US in 1982/83 showed that these viruses were very close to each other, they differed greatly from viruses from the only documented endemic focus in the US in Ossabaw Island, Georgia, but were related to VS strains circulating in Mexico during the same years. VSV-IN type 2 and type 3 cause outbreaks mainly in South America. Little is known regarding the epidemiology of these two virus types.

Transmission and Tissue Tropism

There is little information regarding transmission and tissue tropism of VSVs. Presumably domestic animals are infected by bites from insect vectors. Viral activity is most obvious in cattle, horses and pigs because of their clinical signs. However, it is likely that these animals play little or no role in the maintenance and transmission of the virus in nature, since infected animals do not show detectable viremias. There is no virus shedding in milk, feces or urine. Fluid from vesicular lesions contains large amounts of infectious virus ($>10^{10}$ PFU ml^{-1}) which can serve as a source for mechanical transmission from animal to animal. However, attempts to reproduce animal-to-animal transmission of VSV have met with only occasional success. Experimental data would suggest that the epidermal layer probably needs to be broken or abraded for successful direct viral transmission. Several lines of evidence suggest that VSVs are insect viruses and the infection of animals may be incidental. Tissue tropism of VSVs in insects has not been studied extensively, although the midgut and fat body have been shown to be major sites of VSV-NJ viral replication in sand flies. Serological surveys of humans in areas enzootic for VSVs suggest that human infection can be relatively common. Numerous cases of infection of laboratory workers, veterinarians and animal handlers have been reported. These are usually associated with viral entry through breaks in the skin or exposure to high virus titer aerosols such as infected animals sneezing in the faces of susceptible individuals. Human to human transmission has never been reported.

Tissue tropism of the virus in naturally infected animals is poorly understood. It seems likely that the majority of viral replication is found close to the site of entry of the virus and remains relatively localized. However, cases in which lesions appear in multiple sites (hoof, mouth and teats) in the same animal might suggest that generalization occurs through blood circulation. The localized nature of the vesicular lesions in the mouth (tongue, gum, lips), coronary band of the hoof and the skin of the teats or prepuce, suggest a tropism to tissues in these areas. It has been shown that the virus replicates in the *stratum spinosum* layer of the skin. However, the physiological basis of this tropism remains unknown.

Pathogenicity

The majority of VSV natural infections of domestic animals appear to be asymptomatic, as seroconversion in the absence of obvious clinical symptoms is frequently observed. Data from epidemiologic studies have showed that physiological state (e.g. lactation, pregnancy, age) are significant risk factors for clinical VS, suggesting that host, rather than viral factors likely determine the clinical outcome of infections. However, tissue-culture-grown virus appears to quickly lose the ability to produce clinical disease when reintroduced into animals. This might be related to loss in fitness of the viral quasi-species by repeated passage in tissue culture (see Evolution section).

Clinical Features of Infection

VS disease in cattle, horses and swine is characterized by the appearance of vesicular lesions on the mouth (tongue, lips, gums), teats, or hoof coronary band epithelium layer approximately 2–4 days after inoculation of the virus. Animals rarely exhibit lesions at more than one site, but when it happens it is usually in serologically naive animals introduced to endemic areas or infected during large epizootics. Depression, lameness, fever and excessive salivation are often seen before vesicles are detected. Alterations in hepatic enzyme levels suggest that VSV infection may also affect the liver in cattle and humans. In dairy cattle, milk production virtually ceases and weight loss can be as much as 300 pounds (140 kg) in beef cattle. This is especially true if mouth lesions become too sore for animals to eat, or they become too lame to get to food and water. Mastitis is a common consequence of the infection due to milk retention (caused by pain during milking) and secondary infections. In severe cases the udder can be lost to gangrenous mastitis. In most cases healing of lesions occurs within 7–10 days. Human VSV infections are characterized by an influenza-like illness after 24–48 h incubation. The majority of cases develop a biphasic fever accompanied by malaise, myalgia, headache, photophobia and chills. Vesicles appear on the tongue, oral and pharyngeal mucosa, lips or nose in a minority of cases. There is one report of VSV causing severe encephalitis in a child.

Pathology and Histopathology

The main lesions associated with clinical VSV infections are the vesicles that can appear in the tongue, the mouth, the hoof coronary bands or on the skin of the teat or prepuce. Vesicles begin as small blanched areas, the epithelium separates from the basal layer and forms a vesicle filled with clear-yellowish fluid. Vesicles rupture easily leaving a red surface which usually heals in 1–2 weeks if they are kept free of secondary bacterial infections. Necropsy reports of infected animals are rare since VSV does not cause mortality. No gross lesions of internal organs have been reported in experimentally infected animals. Histopathological examination of vesicular lesions reveals that lesions develop in the *stratum germinativum* where intercellular edema is observed. Cells become necrotic later which results in the separation of the epithelial layers above the *stratum basale* and accumulation of vesicular fluid.

Immune Response

Little is known about the immune response to VSV in domestic animals or wild natural hosts. However, VSV has been used extensively to study the immune response to viruses in laboratory animals, particularly mice. There are three major components in the immune response to VSV: the nonspecific immunity (interferon and nitric oxide); humoral immunity (antibodies); and cellular immunity (T cells). Interferon seems to play a role in survival of laboratory mice inoculated with VSV. Naturally occurring VSV strains differ in their capacity to induce interferon *in vitro*; in general VSV-NJ strains induce higher interferon responses than VSV-IN1. However, there is no clear correlation between interferon induction capacity of VSV strains and their pathogenesis *in vivo*. Neutralizing antibodies directed against VSV glycoprotein play an important role in protection of laboratory animals against VSV. The exact mechanism of protection is not clear, since virus–antibody complexes are still capable of binding to susceptible cells but do not initiate infection. The majority of cattle, horses and pigs living in endemic areas have neutralizing antibodies to VSV. However, it seems that the presence of neutralizing antibodies is not sufficient to prevent clinical disease in these animals. This may be explained by the majority of viral replication being localized in the epithelium.

Experiments in cattle and swine have demonstrated proliferative responses of peripheral blood mononuclear (PBM) cells to VSV antigens which could be detected at 3 weeks postinoculation in swine or postvaccination in cattle. In both cases, these responses could still be detected 6 months later. However, the role of the cellular immune response in protection against VSV is questionable since laboratory animals devoid of direct and indirect cytotoxicity, but capable of humoral response, survive VSV infections.

Prevention and Control of VSVs

The first step in controlling VS is rapid detection of clinical cases. Differential diagnosis particularly to distinguish VS from foot-and-mouth-disease is important. Diagnostic methods currently used include complement fixation, fluorescent antibody and isolation in cell culture. Other detection methods include antigen-capture ELISA and reverse-transcriptase-polymerase chain reaction (RT-PCR). Epithelium or vesicular fluid from fresh lesions are ideal samples for submission. In premises affected with VS in non-endemic areas, quarantine is usually established to avoid further spread of the disease. Within the affected premises, control measures include insect control and cleaning and disinfection with bleach of feed and water troughs, milking equipment and any utensils that could transfer the virus between animals. Since it has been suggested that scarification plays a role in virus entry, rough hay or overgrown pastures should be avoided.

Several inactivated vaccines containing both serotypes NJ and IN1 have been used in South and Central America. Although their effectiveness has not been rigorously tested, a recent report indicates that an oil-based bivalent vaccine decreased the incidence of clinical disease by as much as 25-fold among vaccinated cattle in endemic areas of Colombia. Other vaccine approaches including subunit vaccines and Vaccinia vectors containing G protein have had limited success in laboratory trials using domestic animals and have not been tested in the field. International control of VS is by means of import/export control on the movement of animals with significant neutralizing antibody titers to VSVs.

Future Perspectives

Despite significant efforts made during the last 30 years, many of the questions about the natural cycle of VSV remain unanswered. There is compelling evidence indicating that VSVs are transmitted to domestic animals by blood-sucking insects. However, despite the testing of many species of wild and domestic mammals, none has been found capable of producing the sustained viremias necessary to be a source of virus for insects. The genetic stability of VSV in endemic areas and the specific ecological characteristics associated with different VSV genotypes, indicate that there could be different natural cycles of VSV under different ecological conditions. The fact that VSV activity can be traced to very specific ecological conditions and even to specific forest types in endemic areas, should be taken into consideration in designing future studies on the natural cycle of VSV.

The ability to obtain infectious VSV-IN from cDNA clones has opened a new chapter in VSV research, since by using reverse genetics it is now possible to dissect the role that individual genes and genome sequences play in the life cycle of VSV, both within the cell and also within the animal and insect hosts. The availability of VSV cDNA clones has also made possible the inclusion of foreign genes in the VSV genome, which are expressed and incorporated in the virion along with other viral structural proteins, providing the potential to use VSV as a vector for vaccine delivery. One of the most interesting applications of this technology is the incorporation of the human immunodeficiency virus 1 (HIV-1) cell receptor CD4 and coreceptor CXCR4 in the VSV virion. This virus is unable to infect normal cells but infects and kills those expressing HIV-1 membrane fusion protein on their surface, making it a 'guided' killer for HIV-1-infected cells only.

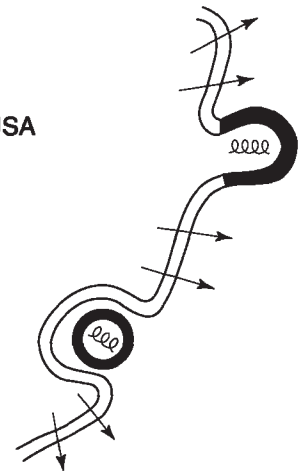
VIRAL MEMBRANES

John Lenard, Department of Physiology and Biophysics, Robert Wood Johnson Medical School, University of Medicine and Dentistry of New Jersey, Piscataway, USA



Introduction

Viruses of many kinds possess lipids as integral components of their structure. Lipid-containing, or enveloped, viruses include *Corona-*, *Orthymyxo-*, *Paramyxo-*, *Bunya-*, *Rhabdo-*, *Toga-*, *Retro-*, *Herpes-*, *Baculo-* and *Poxviridae*. Despite the great diversity of these viruses in regard to structure, replicative strategy, host range and pathogenicity, the function of the lipid is the same in all of them: to form a membrane surrounding the encapsidated viral genome. In all these viruses the lipids form a continuous bilayer that functions as a permeability barrier protecting the viral nucleocapsid from the external milieu. Embedded in the bilayer are numerous copies of a limited number (usually one or two) of virally encoded transmembrane proteins that are required for virus entry into a host cell. These proteins must mediate two essential functions: attachment of the virion to the cell surface; and fusion of the viral envelope with a cell membrane.

The membrane is acquired during viral assembly within an infected cell. Membrane acquisition generally occurs by budding of the viral nucleocapsid through a particular cellular membrane, which is characteristic for each enveloped virus. Many of the viruses mentioned above bud through the plasma membrane. However, bunyaviruses bud through the Golgi apparatus, coronaviruses take their membranes chiefly from the endoplasmic reticulum and herpesviruses bud from the nuclear membrane. Poxviruses, which are among the largest and most complex animal viruses, are unique in not acquiring membrane by simple budding. They acquire several membranes through a series of interactions with different elements of the intracellular membrane transport system.

Viruses that lack lipids often possess capsids or shells consisting only of viral protein. These structures perform the same functions as viral membranes, i.e. protection of the genome, attachment to a suitable host cell and facilitation of its entry into the host cell. Increasingly, the actions of these proteins are being shown to resemble those of the glycoproteins of enveloped viruses.

Viral Bilayer

Knowledge of the structure of viral membrane bilayers has come chiefly from the study of a few viruses that are easily grown in large quantities in the laboratory, namely the orthomyxo-, paramyxo-, rhabdo- and togaviruses. In these, the bilayer arrangement of the lipids has been directly demonstrated using physical methods, and the lipid composition of various viruses grown under different conditions has been described in detail. Since all of these viruses acquire their bilayer by budding through the host cell's plasma membrane, the viral membrane contains the lipids present there. Wide variations of lipid composition are tolerated, and most of the lipids display the properties characteristic of lipids in a bilayer, not those of protein-bound lipids. The precise content of each individual phospholipid or glycolipid in a viral membrane does not always reflect the bulk composition of the host cell membrane from which it was derived, however. This difference may arise from interactions of lipids with the viral membrane proteins, or from inhomogeneity in the host cell membrane.

Intact virions are impermeant to proteases and other enzymes. Indeed, virions can swell and shrink in response to changes in osmolarity, showing that the viral membrane is impermeant to small molecules and ions as well as large proteins. This property indicates that the viral membrane consists of an intact bilayer, completely surrounding the encapsidated viral gen-

ome. It is generally assumed that intact bilayers are characteristic of all enveloped viruses, and not just for those few for which this property has actually been demonstrated.

Viral Membrane Proteins

The proteins of viral membranes, like those of other membranes, may be classified as either integral or peripheral. Integral proteins are those that span the membrane one or more times, and thus cannot be solubilized without disrupting the bilayer, e.g. with detergents. Peripheral proteins do not cross the membrane, and can be removed from it and solubilized by treatment with aqueous salts or chaotropic agents, which do not destroy the bilayer.

Integral membrane proteins of enveloped viruses generally span the membrane only once; an exception is the E1 protein of coronavirus, which spans the membrane three times. Each membrane-spanning, or transmembrane, or anchoring, domain is a sequence of 18–27 predominantly hydrophobic amino acid residues. Transmembrane sequences are inherently insoluble in water, so that integral membrane proteins require the presence of detergents to be soluble. In the absence of detergents or lipids, membrane proteins tend to aggregate as rosettes, with the transmembrane sequences clustered together at the center of the rosette, in order to minimize contact with water. Viral membrane proteins can be reinserted into lipid bilayers of defined composition by mixing detergent-solubilized proteins and lipids together, then removing the detergent by dialysis or centrifugation. These reconstituted viral membranes often possess biological activity.

As much as 90% of the polypeptide chain of a viral membrane protein may be external to the bilayer, where it is accessible to degradation by added proteases. In some favorable cases, nearly the entire external domain can be recovered intact and correctly folded after limited proteolysis, facilitating crystallization and structural analysis. The best example is the influenza virus HA protein. The external portions of viral membrane proteins generally possess oligosaccharide side chains, identical to those of cellular proteins in attachment position and structure. Often, they also possess disulfide bonds. These post-translational modifications reflect the viral proteins' synthesis at, assembly within and translocation through, the cell's rough endoplasmic reticulum (see Membrane Synthesis below).

Peripheral proteins are attached to the viral membrane by a combination of electrostatic and hydrophobic interactions. Although they may penetrate the bilayer to some extent, they do not cross it as the integral proteins do. Viral peripheral proteins include the M1 protein of influenza, the M proteins of paramyxo- and rhabdoviruses, and the MA proteins of retroviruses.

Attachment of Viruses to Host Cells

The first step in infection, attachment of the virus to the outer surface of the host cell, is performed by the membranes of enveloped viruses. Each virus recognizes a unique feature of its host cell membrane. Thus, the nearly total specificity of human immunodeficiency virus (HIV)-1 for cells expressing CD4 protein is conferred by the affinity of the viral envelope protein gp120 for this cell surface 'receptor'. Other enveloped viruses bind to different specific cell surface proteins to initiate infection. An emerging generalization is that, even when viruses bind to true cell surface receptors that normally initiate complex intracellular responses such as phosphorylation cascades, these responses are not essential for viral infectivity. The virus is simply using a characteristic surface landmark to identify and attach to its appropriate host cell.

Orthomyxo- and paramyxoviruses have a broader receptor specificity than was discussed above. Their hemagglutinin (HA and HN, respectively) glycoproteins bind to sialic acid residues attached to various cell surface proteins and lipids. Sialic acids are bound to the host cell membrane through several different kinds of glycosidic linkages, and different virus strains show some preference for sialic acid residues in particular linkages. The most nonspecific of the enveloped viruses may be the rhabdoviruses, represented by vesicular stomatitis virus (VSV) and rabies, which bind indiscriminately to clusters of negative charges, whether created by lipids, proteins or oligosaccharides. This nonspecific binding property helps to account for the extremely broad host range of these viruses.

Viral Fusion

Before viral transcription and replication can commence, the viral genome must cross the barriers presented by both the viral envelope and the cell membrane. Fusion of the viral membrane with a cellular membrane accomplishes this, introducing the viral genome into the host cell cytoplasm. Fusion, like cell attachment, is a property conferred upon each virus by one (or perhaps, in some cases, more) envelope glycoprotein. In most well-studied cases (notably the orthomyxo-, paramyxo-, rhabdo- and togaviruses) fusion does not require the participation of cell proteins, as virions and reconstituted viral

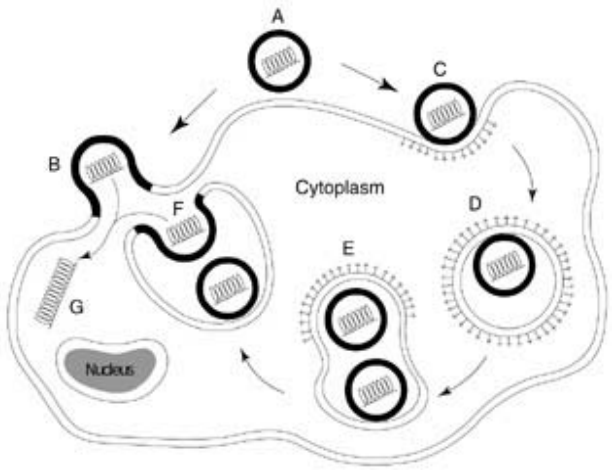


Figure 1 The two major pathways for cellular penetration and uncoating of enveloped viruses. Uncoating begins with attachment of the virion to the cell surface (A), through the binding of an integral viral membrane protein to a 'receptor' on the cell surface, which may be a specific cell protein, an oligosaccharide or a patch of charged lipids. Attachment is followed by fusion, mediated by a viral protein which may or may not be of the same type as the attachment protein. If the viral fusion protein is active at neutral pH, fusion can occur directly with the plasma membrane (B). Alternatively, if fusion requires an acidic pH, the virion must first be endocytosed via the coated pit–coated vesicle pathway (C,D). The viral fusion protein is activated in the acidic endosomes (E,F). Both pathways result in the introduction of the viral nucleocapsid, containing the viral genome, into the cytoplasm (G). For viruses that undergo transcription and replication in the nucleus (such as orthomyxoviruses and most DNA viruses), uncoating is followed by transport of the nucleocapsid through the nuclear pores into the nucleus by unrelated processes.

membranes (often called 'virosomes') fuse readily with protein-free liposomes and planar lipid bilayers.

The fusion proteins of the paramyxoviruses differ from those of the orthomyxo-, rhabdo- and togaviruses in regard to the pH at which they act. While the former are active at neutral pH, the latter require a more acidic environment, usually below pH 6, for fusion. This difference has profound consequences, as it reflects two distinctly different modes of viral entry (**Fig. 1**). The paramyxoviruses, and others capable of fusing at neutral pH, can fuse with the cells' plasma membranes under normal conditions, i.e. at the neutral pH of extracellular fluid or culture medium (**Fig. 1B,G**). Those viruses that fuse only at acidic pH, on the other hand, must first be internalized from the cell surface into specialized vacuoles, the endosomes. Although this process brings the virus inside the cell, the viral genome is still separated from the cell cytoplasm by the same two membranes as before. The endosomes are acidic, however, which activates the viral fusion protein and allows fusion between the viral and endosomal membranes (**Fig. 1C–G**). The pH dependence of viral fusion activity, which is conveniently measured as virus-induced hemolysis, or by a variety of direct fusion assays, serves to distinguish between viruses that enter the cell by the two distinct routes shown in **Fig. 1.**

The two different routes of cell entry shown in **Fig. 1** are differentially inhibitable by specific compounds. A variety of membrane-permeant or 'lysosomotropic' amines (notably chloroquine, ammonia and methylamine, but also including a variety of local anesthetics, tranquilizers and other commonly used pharmaceuticals) possess the property of being able to diffuse across membranes only in their unprotonated, uncharged form. The protonated, charged form of these compounds thus accumulates in acidic compartments such as the endosomes, raising the endosomal pH and preventing the activation of acid-dependent viral fusion proteins. Lysosomotropic amines generally have no effect on the entry of those enveloped viruses that fuse at neutral pH.

Viral fusion proteins are generally glycoproteins which possess a single transmembrane domain, and which assemble into multimers, usually homotrimers. In the last few years considerable progress has been made in understanding the molecular events that occur during viral fusion. Fusion mediated by the influenza fusion protein, HA, has been the most thoroughly studied and is the best understood, since the three-dimensional structure of its proteolytically derived extracellular portion has been determined by x-ray crystallography. The fusion-competent form of HA arises from proteolytic cleavage of an inactive precursor, HA0, to yield HA1 and HA2. The single transmembrane domain is in HA2, to which HA1 is attached by disulfide bonds. HA1 is primarily concerned with cell attachment, while HA2 chiefly mediates the fusion reaction, which relies on three structural features of the molecule:

1. *The fusion peptide,* situated at the N-terminus of HA2. This hydrophobic sequence was recognized early as a conserved feature between influenza and paramyxovirus fusion proteins. Its release from constraint by the proteolytic cleavage that creates HA2 is an essential element in the proteolytic activation of HA.
2. *The three-stranded coiled-coil* that comprises the stem of the HA trimer at neutral pH. The low pH-mediated activation of HA for fusion consists of a rearrangement and extension of this coiled-coil. This repositions the fusion peptide, from a sequestered location close to the viral membrane to an exposed position at the extreme end of the newly elongated coil. This enables the fusion

peptide to contact and penetrate the target membrane (**Fig. 2**).

3. *The transmembrane domain of HA2.* An essential role of this domain was demonstrated through the use of a mutant from which it had been deleted. When the entire external portion of HA was anchored through a lipid only into the outer leaflet of the membrane bilayer, it was no longer capable of mediating fusion. However, it could still catalyze half the reaction, or hemifusion, a process in which only the outer leaflets of the two membrane bilayers become mixed.

Using influenza HA protein as the model, viral fusion may be considered to occur in a series of discrete steps following virus-receptor binding (**Fig. 3**):

1. *Activation of the fusion protein* by conformational rearrangement. For influenza HA this is induced by acid, and consists of the extension of the coiled-coil stalk and exposure of the fusion peptide (**Fig. 2**). For fusion proteins that act at neutral pH, other activation processes operate. Some paramyxovirus fusion proteins (named F) may be activated by interaction with a partner viral protein, the cell attachment protein HN. For the HIV-1 fusion protein, activation is thought to occur by interaction with one of several chemokine receptors present on the surface of host cells (part of step 1, **Fig. 3**).
2. *Penetration of the fusion peptide* into the target bilayer, thus linking the viral bilayer with the target bilayer (step 1, **Fig. 3**).
3. *Relocation of the extended coiled coil stem* so as to bring the two linked membranes into close apposition (part of step 3, **Fig. 3**).
4. *Hemifusion* between the outer leaflets of the viral membrane and the target membrane. This may be mediated by the fusion peptide. Hemifusion is initiated by formation of a *stalk*, a lipid structure of very high negative curvature that provides continuity between the two outer leaflets. Mixing of outer leaflet lipids, but not those of the inner leaflet, characterizes hemifusion (step 3, **Fig. 3**).
5. *Formation of fusion pores.* The transition from the structure present in the hemifused state (the *hemifusion diaphragm*, a small area consisting of a single bilayer composed of the inner leaflets of the two reacting membranes; **Fig. 3**) to the fusion pore is energetically favorable. This transition requires participation of the transmembrane domain of the viral fusion protein (step 4, **Fig. 3**).
6. *Enlargement of the fusion pore.* Initially, fusion pores allow only flickering electrical contact between the aqueous compartments. The pore eventually widens out to permit transfer of the viral genome or other large molecules, thus completing the fusion process (step 5, **Fig. 3**).

It should be noted that the mechanism by which the viral fusion protein catalyzes (3)–(6) above is not yet understood. The major recognized fusion intermediates – the stalk, the hemifusion diaphragm and the fusion pore – are predominantly lipidic in nature, and have been defined in pure lipid systems. None the less, it has been estimated that HA-mediated fusion requires the concerted action of at least three HA trimers (step 2, **Fig. 3**). It seems likely that all viral fusion reactions proceed through a very similar series of steps. A more detailed understanding of the mechanisms of viral fusion would be of fundamental importance, and might also suggest new avenues for antiviral therapeutic intervention.

Membrane Synthesis

Viruses in general make maximal use of mechanisms already in place in the infected cell to perform their functions. Hence, viral protein synthesis is carried out on host cell ribosomes. Synthesis of viral membrane proteins occurs on membrane-bound ribosomes, from

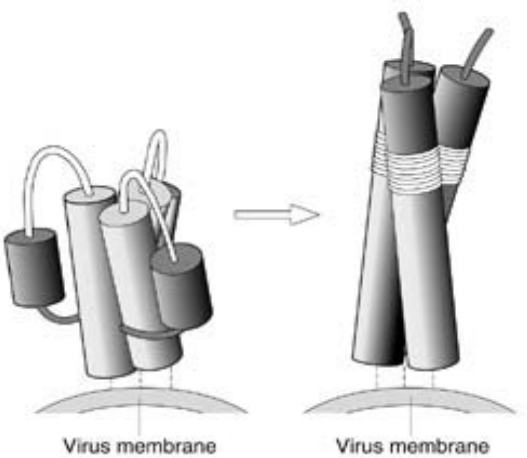

Figure 2 How influenza HA protein is activated for fusion by low pH. *Left:* A simplified representation of the trimeric structure of HA2 at neutral pH, as revealed by x-ray crystallography. Cylinders represent α helices; the light colored cylinders interact to form a three-stranded coiled-coil stem. The 'fusion peptide', which extends from the short, dark cylinders, is sequestered close to the viral membrane. *Right:* Upon exposure to low pH (e.g. inside an endosome), the previously unordered region shown in white becomes helical and extends the coiled-coils, which are still further extended by incorporation of the darkly colored region as shown. This repositions the fusion peptide to the end of the coiled-coils, enabling it to insert into a target membrane. (Modified with permission from Carr CM and Kim PS (1993) *Cell* 73: 823–832.)

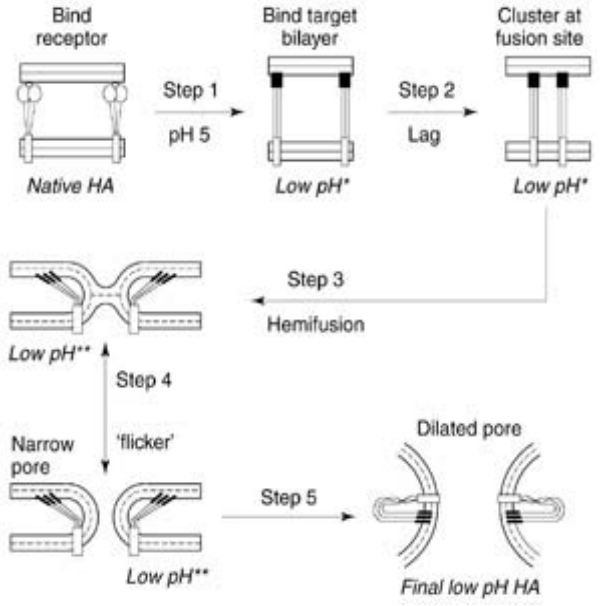

Figure 3 Sequence of events during HA-mediated virus fusion. See text for details. (Reproduced with permission from Hernandez *et al* (1996).) 'Low pH*' and 'Low pH**' are successive low pH-mediated conformations postulated by Hernandez *et al* (1996) to mediate the successive fusion events.

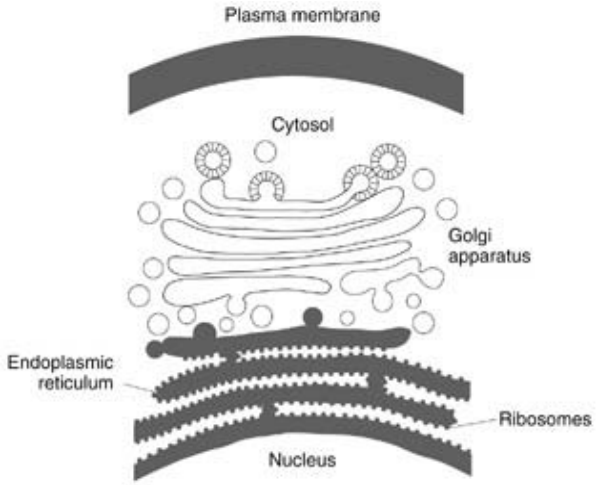

Figure 4 Endoplasmic reticulum–Golgi–plasma membrane system of a cell. All viral and cellular integral membrane proteins are synthesized by ribosomes bound to the endoplasmic reticulum membrane. Proteins destined for the plasma membrane then undergo vesicular transport to the nearest lamella of the Golgi apparatus (the *'cis'* face). A series of sequential vesicular transport steps then carries these proteins through the Golgi to the *'trans'* face and out to the plasma membrane. In polarized cells, further sorting steps target the viral protein to the apical or basolateral plasma membrane. Assembly and budding of different enveloped viruses occurs at characteristic points within this membrane system.

which they are inserted, always in the correct orientation, into the endoplasmic reticulum membrane. There they are glycosylated and assembled into multimeric form. The influenza HA protein, for example, is assembled into the trimers that form the 'spikes' seen in electron micrographs of the surface of influenza virions. The viral glycoproteins may then be further processed through the Golgi and on to the plasma membrane (**Fig. 4**). In fact, the membrane proteins of VSV, influenza, and several other enveloped viruses have provided valuable tools for the study of these transport processes. This is because many of these viruses possess only one major membrane protein, which is expressed in infected cells at very high levels. Further, host cell protein synthesis is inhibited by both VSV and influenza infection, so large amounts of a single membrane protein are produced and correctly processed in infected cells.

Viral proteins are targeted to specific cellular locations by the same mechanisms that cells use for their own membrane proteins. Viral proteins, in fact, are widely used in the study of these targeting mechanisms. Newly synthesized VSV G protein, for example, is targeted to the basolateral plasma membranes of polarized cells. Newly synthesized influenza HA protein, on the other hand, is delivered to the apical plasma membranes of the same polarized cells. Similarly, the retention of coronavirus glycoproteins by the endoplasmic reticulum, and of bunyavirus glycoproteins by the Golgi, are thought to reflect the operation of the same cellular mechanisms that retain resident cellular proteins in these organelles. The localization of viral membrane proteins is of particular importance, as it determines the location of viral assembly and budding.

As described above, the lipids of the viral membrane are taken from the host cell membrane during budding. No new lipids are specifically synthesized in response to viral infection, and viruses seem to tolerate wide variations in their lipid composition. Alterations in cellular lipid metabolism have been reported to result from some viral infections in cultured cells, but these are most likely secondary to other cytopathic effects; there is no indication that they play an important role in the progress of the infection.

Virus Assembly

The budding process consists of the wrapping of a specific piece of membrane around the previously assembled nucleocapsid, which contains the viral genome. The process is shown diagrammatically in **Fig. 5.** The specificity of the process is remarkable in

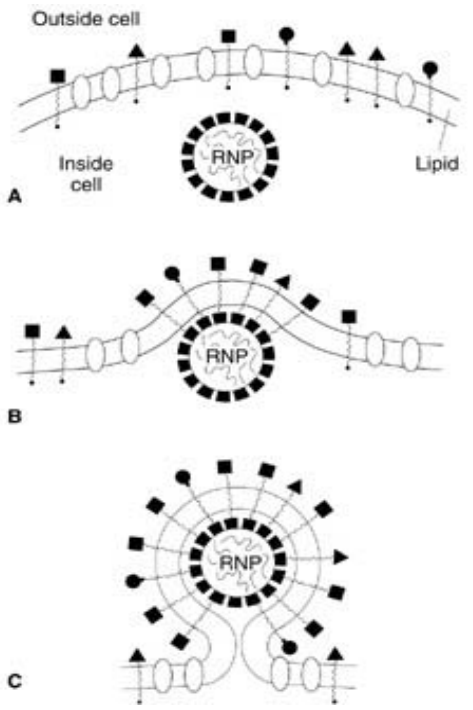

Figure 5 One kind of virus budding. Viral glycoproteins, inserted into the cellular membrane at the endoplasmic reticulum (**Fig. 4**), associate with the assembled viral nucleocapsid. The direct association pictured here is characteristic of togaviruses. For other viruses, possessing helical nucleocapsids, the association is mediated by a peripheral membrane protein. Cellular membrane proteins are excluded from the envelope of the mature virion. This may occur during assembly, as pictured, or by prior formation of a viral membrane patch, before the nucleocapsid arrives at the membrane.

that the completed viral envelope contains viral proteins and host cell lipids almost exclusively, with host cell membrane proteins being almost completely excluded.

Viruses can bud anywhere in the endoplasmic reticulum–Golgi–plasma membrane pathway shown in **Fig. 4.** While the parmyxo-, orthomyxo-, rhabdo- and togaviruses (and many others) generally bud from the plasma membrane, they have also been shown to bud intracellularly under certain conditions. Other viruses normally bud intracellularly, from the endoplasmic reticulum or Golgi apparatus, e.g. coronaviruses and bunyaviruses, respectively. In these cases the nucleocapsid, assembled in the cytoplasm, buds into the lumen of the appropriate organelle. The assembled virus is often seen inside vesicles in electron micrographs, producing a double-shelled appearance. Eventually, the newly formed virion may be secreted out of the cell through the normal secretory pathway, although this does not always occur efficiently.

In many cases viral assembly occurs at the plasma membrane. Some retroviruses assemble there, while others do not; this has provided a classical basis for distinguishing between different types of retroviruses. In orthomyxo-, paramyxo- and rhabdoviruses, budding is mediated by a peripheral membrane protein (called M). Surprisingly, this protein does not interact specifically with the corresponding viral membrane glycoproteins; in fact, successful budding has been observed in the complete absence of viral glycoproteins. This lack of specificity has made possible the creation of pseudotype viruses, possessing the encapsidated genome of one virus and the membrane glycoproteins of another. Since the membrane proteins determine host range and host cell specificity (see above), pseudotypes have proven useful in redirecting specific viral genomes to alternate host cells.

In contrast, togaviruses, which lack any M protein, possess an icosahedral nucleocapsid, which interacts directly with the viral membrane protein. Completed virions contain an equal number of nucleocapsid and membrane protein molecules. Both are in a similar geometric arrangement, so in this case specific interaction between the two proteins appears likely.

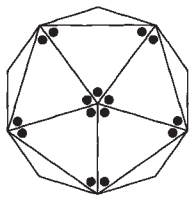
VIRAL RECEPTORS



Horacio U Saragovi, Gordon J Sauvé and **Mark I Greene**, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA

Introduction

Virus–host interactions are complex processes that span binding to cells, entry, dissemination and finally lytic or persistent infection. The first step, binding to host molecules that serve as viral receptors, is critical in all subsequent events. However, host cell alterations can occur in the virtual absence of entry and infection. These effects are due to viral binding to the cellular receptor and the activation of second messenger systems linked to the receptor.

Several viruses reportedly exploit cellular molecules for binding (see **Table 1**). Two interesting examples are the human immunodeficiency virus (HIV) and the vaccinia virus. HIV gp120 appears to bind to two distinct molecules, CD4 in T cells and galactosylceramide in brain. No homologies have been reported between gp120 and Class II major histocompatibility complex (MHC) molecules which are the biological ligand of CD4. Furthermore, it seems that the sites of CD4–Class II interaction are distinct from sites of CD4–gp120 interaction. This example emphasizes the evolution of the gp120 molecule as an effective binding agent for two completely different receptors. In contrast, the vaccinia VGF protein appears to bind to the epidermal growth factor (EGF) receptor. Vaccinia virus VGF is partially homologous to EGF which may explain its binding to EGF receptors. Therefore, some viruses may mimic the biological ligand of the cellular receptor.

Viruses have been proven to be invaluable tools in the molecular dissection of cellular processes and immune regulation. We have been studying the cellular receptor for reovirus type 3 and the role of this receptor in growth and development. Reoviruses provide an excellent model for the study of viral binding which includes biological effects. Furthermore, the as yet unknown structure of the reovirus receptor and its putative biological ligand provides an interesting system in which receptor biological function can be analyzed. In the following section we describe the role of reovirus type 3 cellular receptor in growth and differentiation of a variety of tissue types. New findings also point to the development of novel vaccines and drugs to treat viral infections.

Table 1 Cell surface molecules that serve as viral receptors

Virus	*Putative receptor*
Vaccinia	EGF receptor
Sendai	Gangliosides
Epstein–Barr	C3d receptor
Lactic dehydrogenase	Ia and Fc receptors
Rabies	Acetylcholine receptors
Rhinovirus	ICAM-I adhesion molecules
HIV (in T cells)	CD4
HIV (in brain)	Galactosylceramide

Abbreviations: EGF, epidermal growth factor; HIV, human immunodeficiency virus.

The Reovirus Type 3 Cellular Receptor (Reo3R)

Reo3R was initially analyzed by Fields and colleagues when mammalian lymphocytes and neurons were recognized to express a molecule utilized by the reovirus as its attachment site. Initially, cellular tropism by reovirus type 3 was linked to the expression of the viral hemagglutinin (HA) encoded by the $\sigma 1$ viral gene. Later, receptor-ligand assays using murine cells and labeled virus demonstrated that reovirus type 3 binds to lymphoid cells and fibroblasts with similar affinity. In contrast, reovirus type 1 or a recombinant construct of reovirus type 3 expressing type 1 HA was found to bind to fibroblast L cells but did not bind to lymphocytes (**Table 2**). The viral HA determines both the serotype specificity and the ability of reovirus to bind to cells. Thus, the HA type 1 (HA1) and HA type 3 (HA3) appear to recognize and bind to different and nonoverlapping structures on cell surfaces. These cell surface molecules bound by viral HA are exploited as cellular receptors for reovirus.

Table 2 Binding affinity of *Reoviridae* to murine cell lines

Cell type	*K_d for reovirus type 3 (nM)*	*K_d for reovirus type 1 (nM)*
R1.1 thymoma	0.6	Not detected
Fibroblast cells	0.8	0.4

The R1.1 murine thymoma cells express ~50 000 Reo3R molecules per cell and the murine L fibroblasts express ~100 000 Reo3R molecules per cell.

Table 3 Sequence comparison of MAb 87.92.6 variable heavy (V_H) and light (V_L) chains with HA3

87.92.6 V_H	43	**Q**	**G**	**L**	**E**	**W**	**I**	**G**	R	I	D	P	A	N	G			56
Reovirus HA3	317	**Q**	**S**	**M**	**-**	**W**	**I**	**G**	I	V	S	**Y**	**S**	**G**	**S**	**G**	**L**	N	332
87.92.6 V_L	39	K	P	G	K	T	N	K	L	L	I	**Y**	**S**	**G**	**S**	**T**	**L**	Q	55
									I			Reo3R binding						I	

Amino acid sequence similarity of the reovirus type 3 σ1 protein and MAb 87.92.6 light chain CDR2 is shown using the single-letter code. Amino acid numbers of the proteins are shown, and the regions within HA3 and V_L required for Reo3R binding are indicated. Bold letters indicate amino acid homology between viral protein and mAb.

To analyze Reo3R in detail, we obtained a murine monoclonal antibody (MAb) directed against the receptor. The anti-Reo3R MAb 87.92.6 was raised against MAb 9BG5 which binds and neutralizes HA3. Thus, the interactions of MAb 9BG5 with MAb 87.92.6 or HA3, and the interactions of HA3 and MAb 87.92.6 with the cellular receptor, can be studied. An important feature of this model is that binding to Reo3R is accomplished by a structure that is shared by MAb 87.92.6, the HA3 and their analogues. It has been demonstrated that the light chain variable region (V_L) of MAb 87.92.6 (specifically the complementarity determining region 2; CDR2) bears the internal image of HA3 (**Table 3**), emphasizing the relevance of structural domains in binding to Reo3R. Conversely, it has been hypothesized that Reo3R may bear the internal image of MAb 9BG5. Work in progress towards the molecular cloning of Reo3R cDNA will answer this question.

Given the primary sequence and structural similarity between HA3 and MAb 87.92.6, it is not surprising that the MAb prevents reovirus type 3 attachment to cells and primes mice to develop humoral or cellular immunity to the virus. Most importantly, binding of MAb 87.92.6 or its peptide analogues to Reo3R elicits receptor-mediated biological effects identical to those elicited by binding of inactivated virus to cells. Functional effects include the inhibition of mitogen-induced proliferation of T cells, maturation of oligodendrocytes and demyelination of neurons. Peptide analogues derived from V_L amino acids 45–55, as well as a synthetic nonamino-acid-based β-loop structure which mimics this region, also bind to Reo3R and elicit functional responses, indicating that receptor ligation generates the biological effects. Thus the technology developed using the Reo3R system might lead to the development of new drugs to modulate immune responses and affect neural development.

Effects mediated upon Reo3R binding are so profound and significant that an important role for the cellular receptor is suggested, resulting in an increased interest in understanding the cognate function of this surface molecule. Unlike other viral receptors the biological functions of which are known (e.g. CD4 is the HIV receptor and its biological ligands are Class II MHC gene products), it is not known whether Reo3R is also a true receptor with a true ligand. We will discuss evidence addressing this question in the next section.

Functional Studies of Reo3R

Reoviral infection takes place primarily in the gut epithelium, and can be spread to neutral tissue by an as yet unclear mechanism. The uncoupling of viral entry and replication processes is emphasized by the fact that, while productive infection occurs in the epithelium, latent chronic infection can take place in lymphoid cells. Obviously Reo3R must be expressed on epithelial, neural and lymphoid tissues for viral binding, and studies with MAb 87.92.6 have determined that the viral receptor is the same for these three cell types. However, the varied effects manifested upon receptor ligation suggest that expression of Reo3R has different repercussions for different tissues. Therefore, in order better to understand the function of Reo3R, we have studied its expression and the functional consequences of receptor engagement with the use of anti-Reo3R MAb 87.92.6.

Lymphoid cells

Most (80%) freshly isolated murine splenic B cells express Reo3R. In contrast, only a small proportion (5–15%) of resting splenic T cells and thymocytes express Reo3R. Interestingly, activation of T cells with concanavalinA (ConA) mitogen induces expression of Reo3R to detectable levels after 24h and optimally after 36h. Therefore, Reo3R is constitutively expressed in splenic B cells, but is inducible in T-cells, suggesting that differential regulation of transcription or translation occurs. The kinetics of expression in T cells parallel those of other inducible T-cell activation markers such as interleukin 2 (IL-2) receptor p55 (α) subunit and transferrin receptor, suggesting that Reo3R plays an important role in cellular immunity. After expression of Reo3R has been induced in T cells, binding by inactivated virus,

MAb 87.92.6, peptides derived for the MAb V_L domain or synthetic compounds that mimic these structures to the cell surface leads to a dramatic inhibition of proliferation even in the presence of the powerful stimulator ConA.

Litle is known about the mechanism of inhibition, but it does not involve cell death. Alternative possibilities include (i) blocking of an as yet unidentified biological ligand to the receptor or (ii) induction of receptor-mediated inhibitory signals. An exciting recent development has been the demonstration that inhibitory effects require ligation of Reo3R at the cell surface. In contrast to the negative growth regulation induced by Reo3R extracellular ligation, intracellular ligation has no effect on T cell proliferation. The data, however, do not clarify which of the possible mechanisms for inhibition may be operational.

Central nervous system (CNS)

The CNS is an important target of reovirus type 3 infection. Mature oligodendrocytes and both type 1 and 2 astrocytes, but not glial progenitor cells, express Reo3R. Surface Reo3R appears at an early stage of development prior to expression of myelin basic protein (MBP).

The effects of MAb 87.92.6 and its peptides in neural tissue have been tested *in vitro* and *in vivo*. In both systems neural tissue biology is altered and demyelination is induced, suggesting that Reo3R normally plays an important role in oligodendrocyte differentiation. Thus, it may be possible to create analogues of MAb 87.92.6 that stimulate myelin synthesis *in vivo* leading to the development of new drugs to modulate immune responses and affect neural development. A recent advance in this area has shown that synthetic analogues of MAb 87.92.6 bind Reo3R and induce functional effects, emphasizing the usefulness of viruses in analyzing receptor biology.

Future studies will reveal the structure and function of Reo3R, define the true physiological ligand(s) and provide insights into the signal transducing pathways by which this receptor exerts its important effects.

VIROIDS

Robert A Owens, Molecular Plant Pathology Laboratory, Beltsville Agricultural Research Center, Beltsville, Maryland, USA

Introduction

Viroids are the smallest known agents of infectious disease – small (246–375 nucleotides), highly structured, circular, single-stranded RNAs which lack both a protein capsid and detectable messenger RNA activity. Whereas viruses have been described as 'obligate parasites of the cell's translational system' and supply some or most of the genetic information required for their replication, viroids can be regarded as 'obligate parasites of the cell's transcriptional machinery'. Thus far, viroids are known to infect only plants.

History

While scientific investigation of plant diseases now known to be caused by plant viruses did not begin until the late nineteenth century, the earliest written records of plant viral disease date to the eighth century AD. The first viroid disease to be studied by

MAb 87.92.6, peptides derived for the MAb V_L domain or synthetic compounds that mimic these structures to the cell surface leads to a dramatic inhibition of proliferation even in the presence of the powerful stimulator ConA.

VIROIDS

Robert A Owens, Molecular Plant Pathology Laboratory, Beltsville Agricultural Research Center, Beltsville, Maryland, USA

Introduction

Viroids are the smallest known agents of infectious disease – small (246–375 nucleotides), highly structured, circular, single-stranded RNAs which lack both a protein capsid and detectable messenger RNA activity. Whereas viruses have been described as 'obligate parasites of the cell's translational system' and supply some or most of the genetic information required for their replication, viroids can be regarded as 'obligate parasites of the cell's transcriptional machinery'. Thus far, viroids are known to infect only plants.

History

While scientific investigation of plant diseases now known to be caused by plant viruses did not begin until the late nineteenth century, the earliest written records of plant viral disease date to the eighth century AD. The first viroid disease to be studied by

plant pathologists was potato spindle tuber disease. In 1923, its infectious nature and ability to spread in the field led Schultz and Folsom to group potato spindle tuber disease with several other 'degeneration diseases' of potatoes. These maladies, long attributed to senility, 'reversion', or loss of vigor caused by prolonged asexual reproduction, are now known to be caused by infection with conventional RNA viruses. Nearly 50 years were to elapse between the first published descriptions of potato spindle tuber disease and Diener's 1971 demonstration of the fundamental differences between the structure and properties of its causal agent, potato spindle tuber viroid (PSTVd), and those of conventional plant viruses.

Growers and plant pathologists are unlikely to have simply overlooked diseases with symptoms as severe as those of chrysanthemum stunt or cucumber pale fruit, two other viroid diseases first reported after World War II. Thus, certain aspects of modern agricultural practice seem to have favored the appearance of viroid diseases in the twentieth century. Large-scale monoculture of genetically identical crops and the commercial propagation/distribution of many cultivars are two comparatively modern developments which can facilitate the development of serious disease problems following the chance transfer of viroids from wild hosts to cultivated plants.

Genome Structure

Efforts to understand how viroids replicate and cause disease without the assistance of any viroid-encoded polypeptides have prompted detailed analysis of their structure. Viroids possess rather unusual properties for single-stranded RNAs (e.g. a pronounced resistance to digestion by ribonuclease and a highly cooperative thermal denaturation profile), leading to an early realization that they might have an unusual higher-order structure. Their small size also made viroids tempting objects for detailed structural investigation.

To date, the complete sequences of more than 20 distinct viroid species plus a large number of sequence variants have been determined (**Table 1**). All known viroids are single-stranded circular RNAs which contain 246–399 unmodified nucleotides and lack any unusual 2,′5′-phosphodiester bonds or 2′-phosphate moieties. Electron microscopy, optical melting and other physicochemical studies, and theoretical calculations of their lowest free-energy secondary structure all indicate that PSTVd and related viroids assume a highly base-paired, rod-like conformation *in vitro* (**Fig. 1**). Pairwise sequence comparisons of PSTVd with several related viroids suggest that the series of short double helices and small internal loops which comprise this so-called 'native' structure are organized into five domains whose boundaries are defined by sharp changes in sequence similarity.

As implied by its name, the 'conserved central domain' is the most highly conserved viroid domain and is believed to contain the site where multimeric viroid RNAs are cleaved and ligated to form circular progeny. The 'pathogenicity domain' contains one or more structural elements which modulate symptom expression, and the relatively small 'variable domain' exhibits the greatest sequence variability between otherwise closely-related viroids. The two 'terminal domains' appear to play an important role in viroid replication and evolution. Although these five domains were first identified in members of the PSTVd viroid group, ASSVd and related viroids also contain a similar domain arrangement. (See **Table 1** for explanation of abbreviations.) Certain viroids such as *Columnea* latent viroid appear to be 'mosaic molecules' formed by exchange of domains between two or more viroids infecting the same cell. Individual plants of the *Coleus blumei* cultivar 'Ruhm von Luxemburg' may contain as many as three viroid species, one of which (i.e. CbVd 2) represents a fusion product of the right half of CbVd 1 and the left half of CbVd 3. RNA rearrangement/recombination can also occur within individual domains, thereby leading, in the case of CCCVd, to duplication of the right terminal domain plus part of the variable domain, as disease progresses. The presence of domains in ASBVd and other ribozyme-containing viroids remains uncertain pending identification of additional group members.

Much less is currently known about viroid tertiary structure, especially *in vivo* where these molecules accumulate as ribonucleoprotein particles. Although the extended, rod-like nature of the 'native' structure might suggest that viroids lack significant tertiary structure, the ability of UV irradiation to crosslink certain nucleotides within the conserved central domain of PSTVd provided the first definitive evidence for such tertiary interactions. Similar UV-sensitive structural elements have also been discovered in a number of other RNAs, including 5S ribosomal RNA, adenovirus VAI RNA, and the viroid-like domain of the hepatitis delta virus genome. Studies of the spontaneous self-cleavage of various ASBVd-related RNAs as well as the nuclease-dependent conversion of multimeric PSTVd RNAs into monomers have provided additional evidence for the functional importance of viroid tertiary structure.

Classification

Viroids of known sequence have recently been assigned to one of two taxonomic families based

upon differences in the structural and functional properties of their genomes (**Table 1**). Members of the *Pospiviroidae* (type member, potato spindle tuber viroid) have a rod-like secondary structure that contains five structural–functional domains. Two members of the *Avsunviroidae* (type member, avocado sunblotch viroid), in contrast, appear to adopt a branched conformation, and multimeric RNAs of all three known family members undergo spontaneous self-cleavage *in vitro*. Groups of independently replicating sequence variants that show >90% sequence homology in pairwise comparisons have been arbitrarily defined as viroid species.

Phylogenetic evidence for an evolutionary link between viroids and other viroid-like subviral RNAs has been presented by Elena *et al* (**Fig. 2**). Among several subviral RNAs possibly related to viroids is carnation small viroid-like RNA, a 275 nt circular molecule with self-cleaving hammerhead structures in both its plus and minus strands. This novel retroviroid-like element shares certain features with both viroids and a small RNA transcript from newt.

Host Range and Transmission

All viroids are mechanically transmissible, and most are naturally transmitted from plant to plant by humans and their tools. Nevertheless, individual viroids vary greatly in their ability to infect and replicate in different plant species. PSTVd can replicate in about 160 primarily solanaceous hosts, while only two members of the Lauraceae are known

Table 1 Viroids of known nucleotide sequence (1998)

Family[a]	*Genus*[a]	*Name*	*Abbreviation*	*Nucleotides*[b]
Pospiviroidae	*Pospiviroid*	Chrysanthemum stunt	CSVd	354–356
		Citrus exocortis	CEVd	368–375 (463)
		Columnea latent	CLVd	370–373
		Iresine	IrVd	370
		Mexican papita	MPVd	359–360
		Potato spindle tuber	PSTVd	358–361 (341)
		Tomato apical stunt	TASVd	360–363
		Tomato planta macho	TPMVd	360
	Cocadviroid	Citrus viroid IV	CVd-IV	284
		Coconut cadang-cadang	CCCVd	246–247 (287–301)
		Coconut tinangaja	CTiVd	254
		Hop latent	HLVd	256
	Hostuviroid	Hop stunt[c]	HSVd	294–303
	Apscaviroid	Apple dimple fruit	ADFVd	306
		Apple scar skin[d]	ASSVd	329–334
		Australian grapevine	AGVd	369
		Citrus bent leaf	CBLVd	315, 318
		Citrus viroid III	CVd-III	294, 297
		Grapevine yellow speckle 1	GYSVd 1	336–388
		Grapevine yellow speckle 2	GYSVd 2	363
		Pear blister canker	PBCVd	315
	Coleviroid	*Coleus blumei* 1	CbVd 1	248–251
		Coleus blumei 2	CbVd 2	301
		Coleus blumei 3	CbVd 3	361–364
Avsunviroidae	*Avsunviroid*	Avocado sunblotch	ASBVd	246–251
	Pelamoviroid	Chrysanthemum chlorotic mottle	CChMVd	398, 399
		Peach latent mosaic	PLMVd	336–337

[a] Classification follows scheme proposed by Flores *et al* (see Seventh Report of the International Committee on Taxonomy of Viruses). The nucleotide sequences of apple fruit crinkle, burdock stunt, eggplant latent, *Nicotiana glutinosa* stunt, pigeon pea mosaic mottle and tomato bunchy top viroids are currently unknown; thus, these viroids have not been assigned to specific genera.

[b] Sizes of variants containing insertions or deletions arising *in vivo* are shown in parentheses.

[c] Includes cucumber pale fruit, citrus cachexia, peach dapple and plum dapple viroids.

[d] Includes pear rusty skin and dapple apple viroids.

[e] Formerly named grapevine viroid 1B.

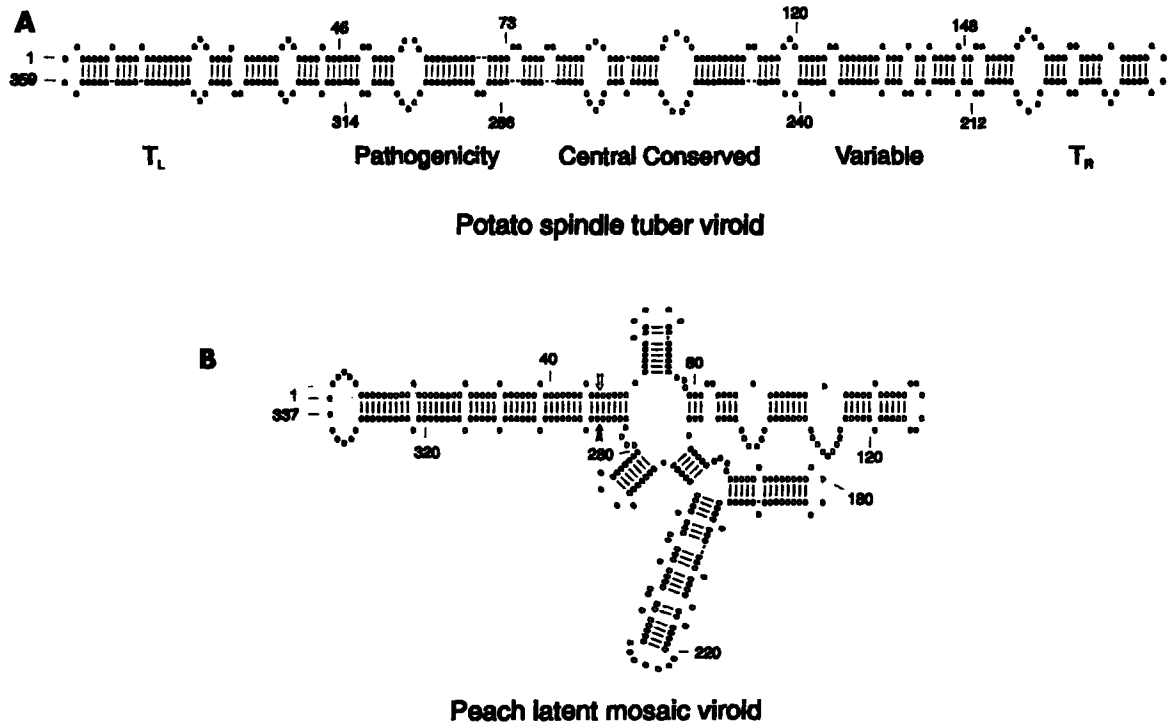

Figure 1 Secondary structures of potato spindle tuber and peach latent mosaic viroids. (**A**) A rod-like secondary structure for PSTVd is supported by a variety of physical studies as well as chemical and enzymatic mapping data. Boundaries of the terminal-left (T_L), pathogenicity, central conserved, variable and terminal-right (T_R) domains are indicated by vertical lines. (**B**) Proposed lowest-free-energy structure of PLMVd. Predicted self-cleavage sites in the plus and minus strands are indicated by filled and open arrows, respectively. (Redrawn from Hernandez and Flores (1991) *Proc. Natl. Acad. Sci. USA* 89: 3711.)

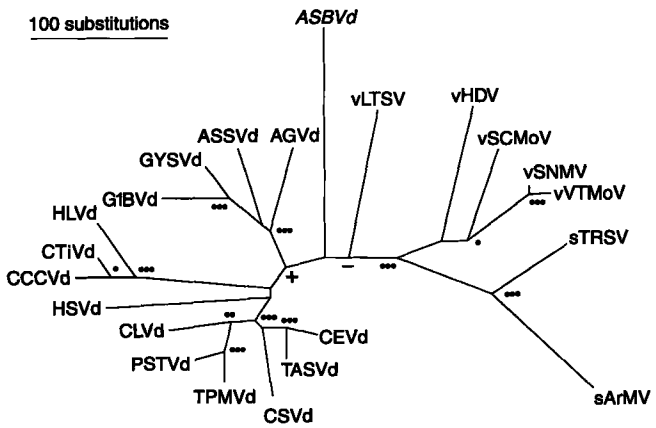

Figure 2 Consensus phylogenetic tree containing 22 viroids, viroid-like satellite RNAs and the viroid-like domain of hepatitis delta virus RNA. ASBVd has been taken as outgroup. ***, Group monophyletic in all 1000 bootstrap replicates; **, monophyletic in more than 99%; *, in more than 95%; +, in more than 90%; and −, in more than 80% of all replicates. From ASBVd to the left of the figure groups are considered as being within the viroid family, and from ASBVd to the right (including the viroid-like domain of HDV RNA) as within the satellite family. For example, satellite tobacco ringspot virus (sTRSV) and satellite *Arabis* mosaic virus (sArMV) (satellite family) or CCCVd, CTiVd and HLVd (viroid family) conformed to two well-defined monophyletic groups in all bootstrap replicates. G1BVd, grapevine viroid 1B; LTSV, Lucerne transient streak virus; ScMoV, subterranean clover mottle virus; SNMV, *Solanum nodiflorum* mosaic virus; VTMoV, velvet tobacco mottle virus. Other abbreviations as in **Table 1**. (From Elena SF *et al* (1991) *Proc. Natl. Acad. Sci. USA* 88: 5631, with permission.)

to support ASBVd replication. HSVd has a particularly wide host range which includes several herbaceous species as well as woody perennials (e.g. grapes, citrus and various *Prunus* spp.). Many natural hosts of viroids are either vegetatively propagated crops, such as potato and chrysanthemum, or those that are subjected to repeated grafting or pruning operations. PSTVd, ASBVd and CbVd can all be vertically transmitted through pollen and/or true seed, but the significance of this mode of transmission in the natural spread of disease is unclear. PSTVd can be encapsidated by potato leafroll luteovirus (PLRV) as well as velvet tobacco mottle sobemovirus, and epidemiological surveys suggest that PLRV can facilitate viroid spread under field conditions.

Commonly used techniques for the experimental transmission of viroids include the standard leaf abrasion methods developed for use with conventional viruses, various 'razor slashing' methods in which phloem tissue in the stem or petiole is inoculated via cuts made with a razor blade previously dipped into the inoculum, and, in the case of CCCVd, high-pressure injection into folded apical leaves. PSTVd and HSVd have also been experimentally transmitted by 'Agroinoculation', a technique in which a modified *Agrobacterium tumefaciens* Ti plasmid is used to introduce full-length viroid cDNA into the potential host cell. In both cases, Agroinoculation was able to overcome a marked host resistance to mechanical inoculation. Identification of the molecular mechanism(s) which determine host range remains an important research goal.

Symptomatology

Viroids and conventional plant viruses induce a very similar range of macroscopic symptoms (and presumably metabolic changes) in their hosts. Symptom expression is usually optimal at the same relatively high temperatures that promote viroid replication (i.e. 30–33°C). Prominent among metabolic changes are dramatic alterations in growth regulator levels. Stunting and leaf epinasty (a downward curling of the leaf lamina resulting from unbalanced growth within the various cell layers) are often considered the classic symptoms of viroid infection, and other commonly observed symptoms include vein clearing, veinal discoloration or necrosis, and the appearance of localized chlorotic/necrotic spots or mottling in the foliage. Viroid infections only rarely kill the host (**Figs 3** and **4**).

Viroid infections are also accompanied by a number of cytopathic effects – various chloroplast and cell wall abnormalities, the formation of membranous structures (so-called 'plasmalemmasomes' or 'paramural bodies') in the cytoplasm, and the accumulation of electron-dense deposits in both chloroplasts and cytoplasm. A combination of subcellular fractionation and *in situ* hybridization studies has shown that the plus and minus strands of PSTVd and related viroids both accumulate in the nucleolus. Precise partitioning between the nucleoplasm and nucleolus remains to be established, but this nucleolar localization may have important implications for replication and pathogenicity. ASBVd, in contrast, appears to be associated with chloroplast thalykoid membranes rather than the nucleoli of infected cells, thereby raisng the possibility that a host-encoded enzyme other than RNA polymerase II may be responsible for its replication (see below).

Geographic Distribution

Viroids such as PSTVd, HSVd, CEVd and ASBVd are widely distributed throughout the world, while others have never been detected outside the areas where they were first reported. Several factors may contribute to this variation in distribution pattern. Among the crops most affected by viroid diseases are a number of valuable woody perennials such as grapes, citrus, various pome and stone fruits, and hops. Propagation and distribution of improved cultivars is becoming increasingly commercialized, with the result that many are now grown worldwide. The international exchange of plant germplasm has also continued to increase at a rapid rate. In both instances, the large number of latent (asymptomatic) hosts facilitates viroid spread. Also, several newly-discovered viroids affect either tropical or subtropical crops. The combination of the generally high temperature optimum for viroid replication and an increased interest in diseases affecting tropical crops is likely to cause a continued shift in the known geographic distribution of viroid diseases.

Epidemiology and Control

While many viroids were first detected in ornamental or crop plants, most viroid diseases are thought to be the result of their chance transfer from endemically-infected wild species to susceptible cultivars. Several lines of circumstantial evidence are consistent with this hypothesis:

- The experimental host ranges of several viroids include many wild species, and these wild species often tolerate viroid replication without the appearance of recognizable disease symptoms.
- Although coevolution of host and pathogen is often accompanied by appearance of gene-for-gene ver-

Garnsey and L. Levy.)

tical resistance, no useful sources of resistance to PSTVd has been identified in the cultivated potato.

- Viroids and/or viroid-related RNAs closely related to TPMVd and CCCVd have been detected in weeds and other wild vegetation growing near fields containing viroid-infected plants.

Viroid diseases may also arise by transfer between cultivated crop species. Studies conducted in the People's Republic of China have shown that pears provide a latent reservoir for ASSVd; likewise, while there is no obvious correlation between disease status and the presence of HSVd in grapes, this viroid is known to cause severe disease in hops. In both instances, the two crops are often grown in close proximity.

All viroid diseases pose a potential threat to agriculture, and several are of considerable economic importance. Coconut cadang-cadang has killed over 30 million palms in the Philippines since it was first recognized in the early 1930s, and estimates of the resulting loss in copra production are in the range of US $80–100 per tree (1987 estimate). Ready transmission of PSTVd by vegetative propagation, foliar contact and true seed or pollen poses a potentially serious threat to potato production, germplasm collections and breeding programs. For many plant viruses, the preferred method of prevention involves incorporation of genetic resistance into the genomes of commercially desirable cultivars. Unfortunately, no useful sources of natural resistance to viroid disease are known, and thermotherapy and/or mer-

istem culture protocols have not been widely adopted. Thus, suitable diagnostic tests for the rapid, specific and reliable detection of viroids continue to play a prominent role in disease control efforts.

Tests based upon their unique physical or chemical properties have largely supplanted biological assays for viroid detection. Problems associated with viroid bioassays include the often extended period of time required for completion (weeks to months) and difficulties in detecting mild or latent strains of the pathogen. Several rapid (1–2 day) protocols involving two-dimensional or bidirectional polyacrylamide gel electrophoresis have been developed which take advantage of the circular nature of viroids. Using these protocols, subnanogram amounts of viroid can be unambiguously detected without the use of radioactive isotopes, but neither bioassay nor electrophoretic assays are well suited for the routine analysis of large numbers of samples. Because viroids lack a protein capsid, antibody-based diagnostic techniques are not applicable.

In recent years, diagnostic procedures based upon nucleic acid hybridization or the polymerase chain reaction have become widely used. The simplest methods involve the hybridization of a highly radioactive viroid-complementary DNA or RNA probe to viroid samples that have been bound to a solid support, followed by autoradiographic detection of the resulting DNA–RNA or RNA–RNA hybrids. Such conventional 'dot blot' assays can detect picogram amounts of viroids using clarified plant sap rather than purified nucleic acid as the viroid source, but sample preparation is often a significant stumbling block. Polymerase chain reaction-based protocols are finding increasing acceptance in those cases where either this level of sensitivity is inadequate or a number of closely-related viroids are present in the same sample.

Molecular Biology

Although apparently devoid of messenger RNA activity, viroids replicate autonomously and induce disease in a wide variety of plant species. The many gaps in our present understanding of the biological properties of these unusual molecules have been aptly summarized by Diener as a series of questions:

- What molecular signals do viroids possess (and cellular RNAs evidently lack) that induce certain host enzyme(s) to accept them as templates for the synthesis of complementary RNA molecules?
- What are the molecular mechanisms responsible for viroid replication? Are these mechanisms also operative in uninfected cells? If so, what are their functions?
- How do viroids induce disease? In the absence of viroid-specified proteins, disease must arise from direct interaction(s) of viroids (or their complementary RNA molecules) with as yet unidentified host cell constituents.
- What are the molecular determinants of viroid host range? Are viroids restricted to higher plants, or do they have counterparts in animals?
- How did viroids originate?

Over the past several years, considerable information has accumulated concerning the molecular biology of viroid replication, pathogenesis and host range determination. The precise nature of the molecular signals involved nevertheless remains elusive.

Replication

Viroid replication is believed to proceed via a 'rolling circle' mechanism involving the synthesis of a minus-strand RNA template. A variety of multimeric plus- and minus-strand viroid RNAs have been detected by nucleic acid hybridization. ASBVd replication appears to utilize a symmetric replication cycle in which the multimeric minus strand is first cleaved to unit-length molecules and circularized before serving as template for the synthesis of multimeric ASBV plus strands. PSTVd and related viroids appear to utilize an asymmetric cycle in which the multimeric minus strand is directly copied into a multimeric plus-strand precursor.

A variety of host-encoded enzymes have been implicated in different aspects of viroid replication. Low concentrations of α-amanitin specifically inhibit the synthesis of both PSTVd plus and minus strands in nuclei isolated from infected tomato, strongly suggesting the involvement of RNA-dependent RNA polymerase II in the replication of PSTVd and related viroids. Localization of both the mature viroid and the replicative intermediates within the nucleolus would seem to argue against the involvement of RNA polymerase II in their synthesis, but this contradiction may be more apparent than real. One or more host-encoded nuclease activities appear to be required for the specific cleavage of multimeric PSTVd plus strands, while both plus- and minus-strand ASBVd RNAs transcribed *in vitro* undergo a spontaneous self-cleavage to form linear monomers. The final step in viroid replication is the ligation of linear monomers to form mature circular progeny. Plant cells are known to contain RNA ligase activities which can act upon the 5′-hydroxyl and 2′,3′-cyclic phosphate termini formed during either cleavage pathway, and ribonuclease T1 is able to generate circular RNA molecules from PSTVd-specific RNA transcripts by cleavage and intramolecular ligation *in vitro*.

During replication, the rod-like native structure of PSTVd and related viroids must rearrange to assume one or more as-yet-undefined alternative conformations. How a viroid 'switches' between these different conformations remains to be determined. As shown in **Fig. 5**, there is compelling biochemical and molecular genetic evidence for the ability of dimeric ASBVd minus-strand RNA to undergo spontaneous *in vitro* cleavage via two different (but related) structures. The preferred pathway for enzymatic processing of longer-than-unit-length PSTVd plus-strand RNAs seems to involve a cleavage site formed by rearrangement of the conserved central domain, but other less efficient sites can also be used *in vivo*.

Pathogenicity

Both viroid cDNAs and their RNA transcripts are infectious when inoculated on to susceptible plants, a fact which provides a unique opportunity to relate sequence (and hence structural) variation to pathogenicity. Infectivity studies with chimeras constructed by exchanging the pathogenicity domains of naturally occurring mild and severe strains of CEVd have clearly shown that the pathogenicity domain contains important determinants of symptom expression. Sequence variation within the variable domain of CEVd also influenced viroid titer in infected plants. Application of a similar experimental strategy to TASVd revealed the presence of a third pathogenicity determinant located in the left terminal loop.

The ability of novel viroid chimeras to replicate and move normally from cell-to-cell implies certain basic similarities between their structures *in vitro* and *in vivo* but provides no information about the nature of the molecular interactions responsible for symptom development. Viroid infections are accompanied by quantitative changes in a variety of host-encoded

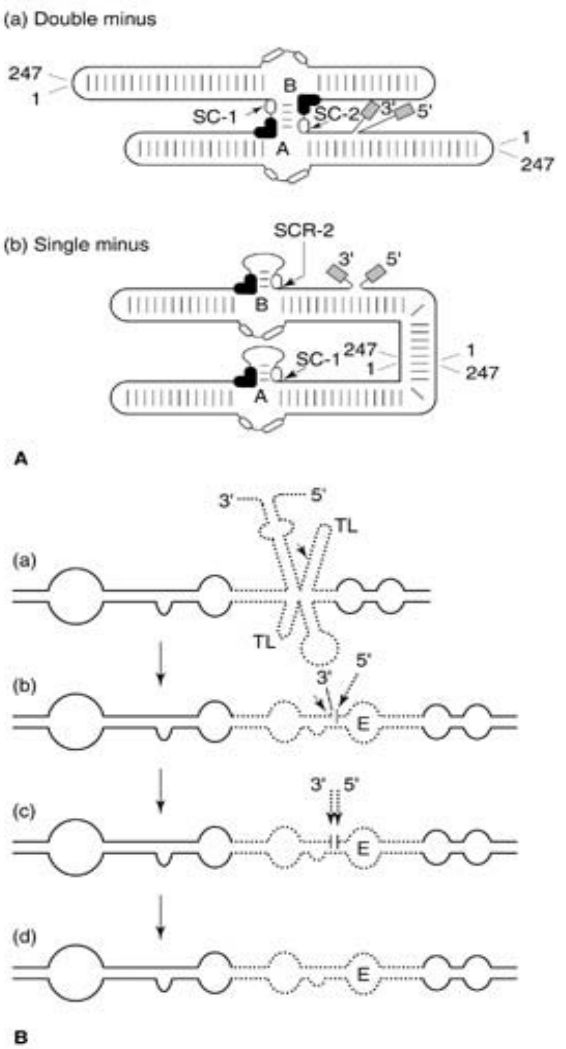

Figure 5 Cleavage of multimeric viroid RNAs requires rearrangement of the native structure. (**A**) A dimeric minus ASBVd RNA transcribed *in vitro* from a *Bst*NI dimeric cDNA clone can fold to produce a structure containing either a double- (**a**) or single- (**b**) hammerhead. Self-cleavage sites, labeled SC-1 and SC-2, are indicated by arrows; stippled boxes, vector sequences at 5′ and 3′ ends; closed boxes, conserved GAAAC sequences labeled A and B; open boxes, remaining conserved nucleotides. Base-pairing is represented by lines between RNA strands. (From Davies C *et al* (1991) *Nucl. Acids Res.* 19: 1893, with permission.) (**B**) Processing of a longer-than-unit-length plus PSTVd RNA transcript in a potato nuclear extract. The central conserved region of the substrate for the first cleavage reaction (**a**) contains a tetraloop (denoted TL). (**b**) After dissociation of the 5′ segment from the cleavage site, the new 5′ end refolds and is stabilized by formation of a UV-sensitive loop E, while the 3′ end partially base-pairs with the lower strand. Single-stranded nucleotides at the 3′ end are then cleaved between positions 95 and 96 (**c**), and ligation of the 5′ and 3′ termini (**d**) results in formation of mature circular progeny. (From Baumstark T *et al* (1997) *EMBO J.* 16: 599, with permission.)

proteins. Certain of these proteins may be 'pathogenesis-related' proteins whose synthesis or activation is part of a general host reaction to both biotic and abiotic stresses; others, such as a 140 kDa protein whose accumulation requires the presence of a replicating low molecular weight viroid or viral satellite RNA, may be more specific. In tobacco, PSTVd infection results in the preferential phosphorylation of a host-encoded 68 kDa protein that is immunologically related to an interferon-inducible, double-stranded RNA-dependent mammalian protein kinase of similar size. Diener and coworkers have presented evidence for the differential activation of the human kinase by PSTVd strains of varying pathogenicity. Although major differences have been reported in the overall three-dimensional conformations of the pathogenicity domain from a series of PSTVd strains, precise cause and effect relationships for the role of protein kinase(s) in viroid pathogenicity remain to be established.

Host range

Perhaps as a result of its involvement in the cleavage/ligation of multimeric plus-strand progeny RNA, a variety of evidence indicates that the central conserved region of PSTVd and related viroids also plays an important role in determining host range. For example, a severe isolate of PSTVd known as as KF 440-2 replicates very poorly in tobacco, but a single nucleotide substitution in the so-called 'loop E' portion of the central conserved region results in a dramatic increase in the rate of replication and systemic movement. The biological properties of Columnea latent viroid also suggest that this domain contains one or more host range determinants. As described above, CLVd appears to be a natural mosaic of sequences present in other viroids; phylogenetic analysis (**Fig. 2**) suggests that it can be considered to be a PSTVd-related viroid whose conserved central domain has been replaced by that of HSVd. Like HSVd (but unlike other PSTVd-related viroids), CLVd is able to replicate and cause disease in cucumber.

Origin and Evolution

As discussed by Matthews, available evidence suggests three possible origins for viruses: (1) descent from molecules present in a prebiotic RNA world; (2) descent from normal host RNAs; and (3) degeneration from simple obligate cellular parasites. Present-day plant viruses form four clusters (i.e. single-stranded positive-sense RNA viruses (three superfamilies); plant reoviruses, rhabdoviruses and bunyaviruses; caulimoviruses; and geminiviruses) and

the existence of these clusters may reflect their different origins. Much of the early speculation about viroid origin involved their possible origin as 'escaped introns' (i.e. descent from normal host RNAs). More recently, however, viroids have been proposed to represent 'living fossils' of a precellular RNA world that assumed an intracellular mode of existence sometime after the evolution of cellular organisms.

According to Diener, the chief proponent of this view, the inherent stability of viroids and viroid-like RNAs which arises from their small size and circularity would have enhanced the probability of their survival in primitive, error-prone RNA self-replicating systems and assured their complete replication without the need for initiation or termination signals. Most viroids (but not satellite RNAs or random sequences of the same base composition) also display structural periodicities with repeat units of 12, 60 or 80 nucleotides. The high error rate of prebiotic replication systems would be expected to have favored the evolution of polyploid genomes, and the mechanism of viroid replication (i.e. rolling-circle transcription of a circular template) provides an effective means of genome duplication.

Viroids and viroid-like satellite RNAs all possess efficient mechanisms for the precise cleavage of their oligomeric replication intermediates to form monomeric progeny. As discussed earlier, PSTVd and related viroids appear to require proteinaceous host factor(s) for cleavage, but others (the self-cleaving viroids and viroid-like satellite RNAs) function as self-cleaving RNA enzymes far smaller and simpler than those derived from introns. Thus, ASBVd and the other self-cleaving viroids may represent an evolutionary link between viroids and satellite RNAs. No viroid is known to code for protein, a fact that is consistent with the possibility that viroids are phylogenetically older than introns. It is conceivable that introns may be 'captured' viroids, rather than viroids 'escaped' introns.

Introduction

The question of what is a virus species is part of the general problem of how the diversified world of viruses should be organized to achieve a coherent scheme of distinct and easily recognizable viral entities. Virus taxonomy suffers from a bad image among virologists, the subject often being equated with arcane debates about proposed names for newly discovered viruses or theoretical discussions about possible phylogenetic relationships of little relevance to practising virologists. This is unfortunate since virus classification and the demarcation of virus species are subjects of fundamental importance for clarifying the nature and identity of the objects studied by virologists and for allowing virology to develop into a mature scientific discipline.

The first internationally organized attempt to introduce some order in the bewildering variety of viruses took place at the International Congress of Microbiology held in Moscow in 1966. A committee was created, later called the International Committee on Taxonomy of Viruses (ICTV) which was given the task of developing a single, universal taxonomic scheme for all the viruses infecting animals (vertebrates, invertebrates and protozoa), plants (higher

plants and algae), bacteria, fungi and archaea. Since 1971 the ICTV, operating on behalf of the world community of virologists, has produced six reports describing the current state of virus taxonomy; a seventh one is due for publication in 1999. The current system of virus classification uses the classical hierarchical levels of order, family, genus and species. At present 184 genera have been recognized and of these, 161 are classified in 54 families.

Although the species is the most fundamental unit in all biological classifications, it took many years before an internationally agreed definition of virus species applicable to all viruses became generally accepted and was ratified by the ICTV. The virologists who study viruses that infect plants had been particularly reluctant to admit that the species concept could be used in virology. Some of these virologists argued that the only legitimate definition of species was that of *biological species*, used for sexually reproducing organisms but which is clearly not applicable to entities such as viruses that replicate by clonal means. However, a great variety of species concepts exists and some of them may be applicable to viruses. Unfortunately, there is no general agreement among biologists on what counts as a good species concept. Before outlining the concept of virus species, it will be helpful, therefore, to define a few terms and to analyze some of the key concepts used in biological classification.

What is a Virus?

A virus is an elementary biosystem that possesses some of the properties of living systems such as having a genome and being able to adapt to changing environments. However, viruses cannot capture and store free energy and they are not functionally active outside their host cells. Although viruses are pathogens, they should not be equated with pathogenic microorganisms.

A virus has both *intrinsic properties* (e.g. its size) and *relational properties* (e.g. its host), the second type of property existing only by virtue of a relation with other objects. These properties are either *resultant properties* already possessed by the components of the virus (e.g. the mass of the virion equals the sum of the mass of its parts) or *emergent properties* that are only possessed by the system as a whole and are not present in its constituent parts (e.g. the viral replication cycle or the viral ecological niche). It should be stressed that only cells and multicellular systems possess the emergent property of being alive and that this property is not present in subcellular components or individual molecules. A virus becomes part of a living system only after its genome has been integrated in the host cell and viral replication is made possible through the metabolic activity of the cell. Viruses are thus not organisms and they lead only a kind of borrowed life.

It is also important to clearly distinguish between the entity called a virus and a single, discrete virus particle or virion. The virion possesses intrinsic biochemical and structural properties which, incidentally, include as one of the phenotypic characters the composition and sequence of the viral genome (although this is generally called the genotype). A virus, on the other hand, possesses in addition a number of relational and emergent properties that become actualized, for instance during the viral replication cycle, i.e. when the virus forms an integrated whole with its host cell. A virus can thus not be reduced to the physical constituents and chemical composition of a virion and it is necessary to include in its description the functional activity it possesses inside its host, as well as a variety of other biotic interactions. Furthermore, the hereditary material of a particular virus cannot be described in terms of the unique genomic sequence present in a single virion. The genome of a virus is not a single molecular species but must be viewed as a dynamic population consisting of the thousands of viral mutants that are always present in a given viral clone. This population, which is the target of selection, is referred to as a viral quasi-species (see below).

Classes, Fuzzy Sets and Species

One of the difficulties in defining species is that the term is used in many different ways which unfortunately are not always clearly distinguished. For instance, the term species is often used to designate groups of real organisms studied by taxonomists, in which case it refers to concrete objects, i.e. material things that are located in time and space. One popular taxonomic theory views species as concrete individuals in the sense that they correspond to historical entities related by common descent. The thesis that species should be regarded as individuals instead of classes has led to vigorous debate, but this has not solved the species problem in biology.

Classes

A second meaning of the term species is that of a class, i.e. a conceptual construct or abstraction that does not exist on its own in the absence of someone conceiving of the idea. Properties and classes are related abstract entities. Whatever is said about a thing is seen as ascribing a property to it, and the thing thereby becomes a member of a particular class. If a virus has a positive-strand RNA genome, it

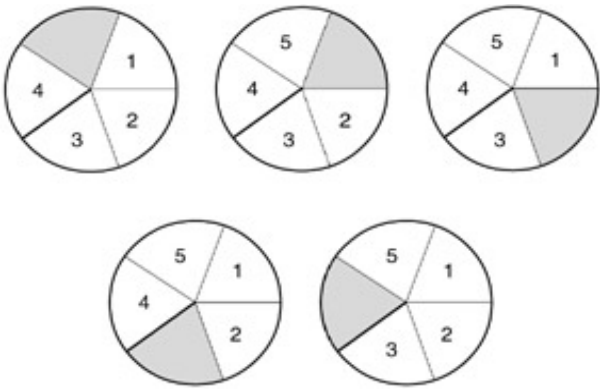

Figure 1 Five members of a polythetic class characterized by five properties, 1–5. Each member possesses several of these properties, but no single property is present in all the members of the class. The missing property in each case is represented by the hatched sector.

becomes automatically a member of the class of positive-strand RNA viruses. Such a class is called a universal class because it is defined by a single property, or a combination of properties, necessarily present in all the members of the class.

A biological classification is a conceptual construction made up of classes with a hierarchical structure, the ranks being the species, genus, family, order and phylum. It must be emphasized that the classes or taxonomic categories used for building up a classification are conceptual constructions that do not correspond to groups of real organisms with a spatiotemporal location. It is thus impossible for a biologist ever to encounter an abstract genus or species when handling organisms. It is odd that many biologists who readily accept that genera, families or orders are conceptual constructions of the mind, i.e. abstractions, insist that species have a real existence in space and time and are not abstract classes. It seems that species are more readily perceived as populations of real organisms rather than as abstractions. On the other hand, higher ranks such as genera and families, are more easily accepted as universal classes defined by one or more properties present in every member of the class. One problem with the species class is that its members, i.e. living organisms, undergo continuous developmental and evolutionary changes in time, and are therefore always endowed with intrinsic variability. This seems to contradict the notion that such organisms could belong to a universal class, seen as immutable and timeless. It also seems problematic to speak of the origin of species if one conceives of them as abstract concepts with neither beginning nor end in time. However, these difficulties disappear when species are viewed, not as classical, universal classes, but as polythetic classes, the members of which share only a certain number of characteristic attributes which can change with time. Whereas a traditional class is defined by the necessary presence of at least one property in all its members, the members of a polythetic class need not have a single defining property in common (**Fig. 1**). When species are viewed as polythetic classes, it is possible to accommodate individuals that lack one or other character normally considered typical for the species. The concept of polythetic species is thus particularly suited for dealing with replicating biological entities endowed with intrinsic variability and undergoing continual evolutionary changes. When viewed in this way, species correspond to fuzzy sets with hazy boundaries, and it is not possible to draw sharp boundaries between them as is done with classical sets and universal classes.

Fuzzy sets

The use of vagueness or fuzziness as a descriptor of reality has a long history in Western philosophy. Vagueness stems from a continuum with innumerable steps and is exemplified in the well-known sorites paradox of the heap described by Greek philosophers. This paradox arises because it is impossible to say how many grains of sand can be removed from a heap before it stops being a heap. This implies that the concept of heap cannot be defined in a precise manner. In a similar way, fuzzy sets have no sharp boundaries, and since the set is defined by a vague predicate, membership of a fuzzy set is not an all-or-nothing matter. This means that the law of excluded middle of classical logic (a swan is either white or nonwhite) does not apply, as in some cases it may not be possible to ascertain if an object is a member of the set or not. Handling fuzzy sets, therefore, falls outside the scope of classical, bivalent logic. In a biological classification, it may sometimes be necessary to allocate an organism to a particular species purely as a matter of convention or convenience rather than logical necessity.

Science is based on empirical observations, the precision of which is always limited. Scientific evidence, therefore, can never be assigned the absolute truth value possessed by certain types of statement in formal logic that lack factual reference. Scientific knowledge always remains approximate and incomplete and it would be counterproductive to look for certainty and for absolutely precise boundaries where none exist. When fuzziness is accepted as an unavoidable ingredient of species taxa, spurious problems of definition disappear and it becomes possible to describe species in terms of continuums devoid of artificial sharp edges. In a similar way, colors can be

distinguished conceptually in spite of the continuous nature of the spectrum of electromagnetic waves, and mountain peaks are given names although there are no sharp boundaries in geological rock formations.

Species

The traditional view of species is that they correspond to groups of similar organisms that can breed among themselves and produce fertile offspring. Mayr's classical definition of biological species states that 'species are groups of interbreeding natural populations that are reproductively isolated from other such species'. This definition has been criticized because if defines species as a population instead of a class; furthermore it applies only to organisms that reproduce sexually and it ignores the phenomenon of interspecies hybridization that is widespread in the plant kingdom. Since groups of plants lie on a continuum from completely interfertile to completely reproductively isolated, the criterion of infertility for demarcating species is very often inapplicable and the choice of what constitutes a significant breeding discontinuity is rather arbitrary. In order to make it applicable to asexual organisms, Mayr subsequently modified his definition and stated that 'a species is a reproductive community of populations, reproductively isolated from others, that occupies a specific niche in nature'.

As biologists became increasingly committed to evolutionary theory, several authors introduced the notion of evolutionary species corresponding to a time-slice in an evolving lineage. By including in the definition the idea of ancestry and descent, the concept of species acquired an internal cohesion which was absent when species were defined on a morphological or phenetic basis, i.e. only in terms of similarity. However, the evolutionary species concept remains a highly theoretical one as it gives no indication of how individual time-slices of evolving lineages segregate into separate species. Transition from one species to another during evolution occurs within an uninterrupted chain of replicating nucleic acid molecules and ancestral-descendant organisms and there are no criteria for deciding how far back in time a species can be traced. It is thus as difficult to demarcate boundaries in time in order to identify evolutionary species as it is to define clear-cut breeding discontinuities for identifying biological species.

For most practical purposes, biologists today still tend to distinguish between different species on a phenetic or morphological basis. As noted before, the genomic sequence of an organism is also a phenotypic trait and it seems that the overall degree of phenotypic difference observed between organisms, which also includes genomic divergence, is roughly proportional to the amount of evolutionary distance from a common ancestor. This is the reason why phenetic species defined only in terms of overall similarity are often very similar to the species defined as lineages of ancestral-descendant populations.

What is a Virus Species?

The rationale for using the species concept in viral taxonomy is that viruses are biological entities and not simply chemicals. Viruses possess genes, replicate, evolve and are adapted to particular biotic habitats and ecological niches. Like all biological entities that possess the ability to replicate and reproduce themselves, viruses are endowed with an intrinsic variability derived from the error-prone process of nucleic acid replication. Whereas the molecules of a compound studied by a chemist are all identical, the virus particles in a clone always include thousands of mutants which constitute a so-called quasi-species population. This built-in variability allows any biological system to become adapted through selection and in the end guarantees its survival.

In 1981, the ICTV proposed the following definition of virus species: 'A virus species is a concept that will normally be represented by a cluster of strains from a variety of sources, or a population of strains from a particular source, which have in common a set of correlating stable properties that separate the cluster from other clusters of strains.' This definition does not explain what a strain is and it proposes grouping viruses purely on a phenetic basis without considering the cohesive forces present in ancestral-descendant populations. In 1989, the author proposed a definition of virus species which took into account that a species is a polythetic class, the members of which are united by relational properties of descent and by occupation of a particular biotic niche. In 1991, the ICTV endorsed this definition, which states that: 'A virus species is a polythetic class of viruses constituting a replicating lineage and occupying a particular ecological niche.'

Virus species as polythetic class

As shown in **Fig. 1**, there is no single attribute in a polythetic class that can be used to indicate that a virus qualifies as a member of a particular species. A polythetic class consists of members that have several properties in common, although there is no single defining property which is present in all the members of a particular species and absent in the members of other species. A single discriminating character, for instance a particular host reaction or a certain degree

of genome sequence dissimilarity, cannot be used as an absolute criterion for differentiating two species within the same genus. Attempts to use a single discriminating character for distinguishing species would fail because of the inherent variability of members of the species, and furthermore it would contradict the notion that species are not universal classes definable by a single property. The situation is different with higher taxa, such as genera and families, which are universal classes and consist of members that share one or more defining properties that are both necessary and sufficient for class membership. As far as virus species are concerned, it is always a combination of statistically covariant properties that provides the rationale for deciding that a particular virus should be considered a member of a species.

Virus species as a replicating lineage

This part of the definition acknowledges that a virus species, in addition to being a polythetic class, is made up of members that represent an evolving lineage. The membership of a virus species varies over time but all its members share descent from a common ancestor. It should be noted that shared descent is a property that also links different species and different genera.

The genomic plasticity inherent in any viral replicating lineage leads to continual phenotypic variation that makes the virus species a polythetic rather than a universal class. It should be stressed that a single criterion, such as the degree of genome sequence divergence or the potential for genetic reassortment, cannot serve as a criterion for species demarcation. Classifying viral genomes should not be confused with classifying viruses. Genome comparisons cannot by themselves justify taxonomic placements that would disregard the biotic and phenotypic properties which are the main reason why virologists want to classify viruses.

Ecological niche occupancy

The ecological niche refers to biotic properties of members of a virus species, such as host range, tissue tropism, virulence, pathogenesis, host responses, vectors and habitat. The ecological niche does not simply refer to a location in three-dimensional space but is a functional concept based on relational properties of the virus. The niche is not a property of the environment but a property of the virus and there can therefore be no vacant or empty niches but only unoccupied habitats or geographical spaces. In the absence of the virus, its ecological niche property is also absent and the notion of a vacant niche is thus meaningless. A niche provides the needs that must be met for the virus to replicate and to survive and it is restricted to the relations that have a positive biological advantage for the virus.

Taxonomic Polythetic Species Versus Molecular Quasi-species

As mentioned above, the genome of a virus cannot be defined by a unique sequence corresponding to a so-called wild type but consists of a distribution of mutant sequences, each one differing in one or a few nucleotide positions from the consensus sequence of the clone. This consensus sequence, identified by sequencing a clone, may give the impression of a stable, unique structure, although it corresponds in fact to the average of a large number of different individual sequences. Since RNA viruses have genomes that replicate in the absence of repair mechanisms, they evolve very rapidly, with a mutation frequency per nucleotide site in the genome of 10^{-3}–10^{-5}. The genome of an RNA virus therefore consists of a master sequence corresponding to the most fit genome sequence under a given environment, together with thousands of competing mutants. Such a population is usually referred to as a quasi-species, a somewhat unfortunate term as it may seem to imply that the virus corresponds to some sort of imperfect species, as opposed to a 'true' or genuine species that would possess a single, invariant genome sequence. Such idealized species, of course, do not exist. The term quasi-species was introduced by Eigen and his colleagues to describe self-replicating RNA molecules which, because of mutation, do not consist of a unique molecular species. In this context, the term species refers to a purely chemical entity, i.e. a species of molecule, and not to the taxonomic concept of virus species as a variable biological entity. Whereas all the members of a chemical species are identical molecules, the members of a virus species are not. Taxonomic species are thus automatically quasi-species in the molecular sense.

Virus Species Demarcation

Although the acceptance of a definition of virus species by the international virological community was an important step for establishing a unified virus classification system based on the traditional taxonomic categories, it should be stressed that such a definition is of little use for deciding if a particular virus isolate is a member of a certain species or not. The reason for this is that definitions apply only to abstract concepts such as the notion of species taken as a category or class used in classification. Individual viruses located in time and space cannot be 'defined'

Table 1 Characters that would demarcate virus isolates as distinct species in the families *Potyviridae* and *Geminiviridae* (Van Regenmortel *et al*, 1997).

Character	*Potyviridae*	*Geminiviridae*
Genome features		
	—	Different numbers of genome components
	—	Different organization of genes in the genome
	—	No transcomplementation of gene products
	—	No pseudorecombination between components
Genome sequence		
	< *c.* 85% identical over whole sequence	< *c.* 90% identical in coat protein sequence
	< *c.* 75% identical in 3′ noncoding region	—
Protein features		
	Different polyprotein cleavage sites	—
	Virions react differently with key antibodies	Virions react differently with key antibodies
	< *c.* 90% identical in coat protein sequence	< *c.* 90% identical in coat protein sequence
Transmission		
	Different vector species	Different vector species
	Different seed transmissibility	—
Effects in infected tissue		
	Different inclusion body morphology	—
	No crossprotection effects	—
	—	Different tissue tropism
Host range		
	Different in key species	Different in key species

but can only be identified by means of so-called diagnostic properties. The difference between definition and identification can be clarified by the following analogy. It is possible to define the concept of a human family in terms of an ancestral-descendant population comprising parents, grandparents, children, siblings, etc., but such a definition of the family concept would be of no help whatsoever for recognizing the members of the Smith family who have gathered for the annual school concert and for distinguishing them from members of the Brown family. What is required is a set of characters and diagnostic properties that can be used for identifying individual members of a family or species. It is thus necessary to reach an agreement about which diagnostic properties are most useful for identifying the members of a virus species.

The identification of a virus isolate is a comparative process based on a number of different characters that will indicate the extent of relationship of the isolate with members of an established species. Since species are polythetic, the comparison must involve several characters rather than the presence or absence of a single key feature. For species diagnosis it is of course essential not to use characters that are present in all the members of a genus or family, as these obviously will not permit species demarcation within the group. Characters such as virion morphology, genome organization, method of replication and the number and size of structural and nonstructural viral proteins are family- or genus-defining properties that are of little value for identifying individual species. The following characters are useful for discriminating between virus species within the same genus:

- genome sequence relatedness,
- natural host range,
- cell and tissue tropism,
- pathogenicity and cytopathology,
- mode of transmission,
- physicochemical properties,
- antigenic properties.

A list of characters that have been used to decide if two virus isolates belonging to the plant virus families *Potyviridae* or *Geminiviridae* are different species or not are listed in **Table 1.** Some criteria are the same for the two families, others are qualitatively the same but quantitatively different and some criteria do not apply to viruses in both families. No one criterion has an absolute supremacy over others; some are more

informative and discriminatory than others, but it is the sum total of the information that is gathered which allows reliable species demarcation. Once different species have been established on this basis in the classification scheme, it may be sufficient to check for the presence of a few characters in a particular isolate to be able to allocate it to a particular species.

In each genus, one species for which considerable knowledge is available is designated as the type species. However, this designation does not imply that the properties of the type species are most typical and representative of the properties of all species in the genus.

Atomic Structure

Ming Luo, Center for Macromolecular Crystallography, The University of Alabama, Birmingham, Alabama, USA

Architecture of Viruses

Viruses have two essential components: protein and nucleic acid. A closed capsid may be formed by one type or a few types of proteins to encapsidate the nucleic acid genome. The protein capsid can have a helical (filamentous virus) or icosahedral (spherical virus) symmetry. The symmetry allows a small protein unit to assemble into a large particle. The helical symmetry is described by the diameter d, the pitch P, and the number of subunits per turn. There are as many capsid proteins as necessary for completely covering the nucleic acid genome. The icosahedral symmetry is defined by six fivefold axes, ten threefold axes, and 15 twofold axes. A number T, called the *triangulation number*, indicates how many quasisymmetrical subunit interactions there are within one asymmetrical region of the icosahedron. There are a total of $60T$ copies of proteins in one icosahedral capsid. In some viruses, there is a membrane envelope wrapped around the protein–nucleic acid core. There are proteins on the surface of the envelope.

Methods of Structure Determination

X-ray diffraction is the common technique used for studying the atomic structure of proteins and nucleic acids. When X-rays strike electrons of the atoms in a stationary specimen, a diffraction pattern of different intensities is generated and recorded. By analysis of the diffraction pattern and the intensities, a three-dimensional electron density map (EDM) can be calculated by Fourier transformation. A three-dimensional chemical structure could be built based on the interpretation of the EDM. Two types of X-ray diffraction experiments are useful for virus structure studies: fiber diffraction (for filamentous viruses) and

Architecture of Viruses

Viruses have two essential components: protein and nucleic acid. A closed capsid may be formed by one type or a few types of proteins to encapsidate the nucleic acid genome. The protein capsid can have a helical (filamentous virus) or icosahedral (spherical virus) symmetry. The symmetry allows a small protein unit to assemble into a large particle. The helical symmetry is described by the diameter d, the pitch P, and the number of subunits per turn. There are as many capsid proteins as necessary for completely covering the nucleic acid genome. The icosahedral symmetry is defined by six fivefold axes, ten threefold axes, and 15 twofold axes. A number T, called the *triangulation number*, indicates how many quasisymmetrical subunit interactions there are within one asymmetrical region of the icosahedron. There are a total of $60T$ copies of proteins in one icosahedral capsid. In some viruses, there is a membrane envelope wrapped around the protein–nucleic acid core. There are proteins on the surface of the envelope.

Methods of Structure Determination

X-ray diffraction is the common technique used for studying the atomic structure of proteins and nucleic acids. When X-rays strike electrons of the atoms in a stationary specimen, a diffraction pattern of different intensities is generated and recorded. By analysis of the diffraction pattern and the intensities, a three-dimensional electron density map (EDM) can be calculated by Fourier transformation. A three-dimensional chemical structure could be built based on the interpretation of the EDM. Two types of X-ray diffraction experiments are useful for virus structure studies: fiber diffraction (for filamentous viruses) and

crystallography (for spherical viruses and globular viral proteins).

Atomic Structure of Helical Viruses

The disc of the tobacco mosaic virus (TMV) coat protein has been crystallized and its atomic structure resolved by X-ray crystallography. The intact TMV structure containing the nucleic acid could only be determined by X-ray fiber diffraction experiments, as could that of Pf2 phage. The coat proteins of TMV and Pf2 contain mainly α-helices and the nucleic acid interacts with the coat protein with one base (Pf2) or three bases (TMV) per protein unit. The axis of the coat protein helix coincides with that of the nucleic acid. The coat proteins of TMV have many aggregation forms, depending on pH or ionic strength. The TMV RNA is inserted into the coat protein helix in the growing virus particle. The coat protein of Pf2 was added one by one to the DNA helix emerging from the membrane.

Atomic Structure of Spherical Viruses

Spherical viruses without a membrane envelope form large single crystals under proper conditions. Their atomic structure can be determined by X-ray crystallography with the aid of supercomputers and synchrotron X-ray sources. Since 1978, numerous atomic structures of viruses have been reported. These include the plant RNA viruses tomato bushy stunt virus (TBSV), southern bean mosaic virus (SBMV), satellite tobacco necrosis virus (STNV), bean pot mottle virus (BPMV), and cow pea mosaic virus (CPMV); the animal RNA viruses human rhinovirus, poliovirus, black beetle virus (BBV), Mengo virus, foot-and-mouth disease virus (FMDV), Theiler's murine encephalomyelitis virus (TMEV), coxsackievirus, and tetravirus; and the animal DNA viruses canine parvovirus (CPV), simian virus 40 (SV40), bluetongue virus and adenovirus hexon; as well as the bacteriophages MS2 and ϕx174.

Most capsid proteins of these viruses contain an antiparallel, eightstranded β-barrel folding motif. The motif has a wedge-shaped block with four β-strands (BIDG) on one side and another four (CHEF) on the other. There are also two conserved α-helices (A and B), one is between βC and βD, the other between βE and βF. In animal viruses, there are large loops inserted in between the β-strands. These loops form the surface features of individual viruses. The wedge shape is best suited to making a concealed icosahedral shell.

A virus capsid may contain multiple copies of the β-barrel fold with the same amino acid sequence (such as $T = 3$ TBSV or $T = 1$ CPV) or with different amino acid sequences (such as pseudo $T = 3$ rhinovirus). In some cases there are two β-barrel folds in a single polypeptide (such as CPMV and adenovirus hexon). Capsid proteins of spherical viruses can have other motifs such as plane β-sheet in MS2 and α-helices in bluetongue virus.

Atomic Structure of Viral Proteins

There are many functional viral proteins that do not have any symmetrical quaternary structure in virus particles. Therefore, their atomic structure has to be studied by crystallizing isolated proteins. Crystal structures have been determined for the hemagglutinin (HA) and the neuraminidase (NA) of enveloped influenza virus, and the protease and reverse transcriptase of human immunodeficiency virus (HIV) and other retrovirus, matrix and capsid proteins (influenza virus and HIV/SIV), a fragment of the HIV glycoprotein gp41, the protease of picornaviruses, the protease and the thymidine kinase of herpesvirus, the protease of hepatitis C virus, the receptor binding domain of adenovirus fiber and the envelope glycoprotein of tick-borne encephalitis virus.

The HA has two domains in the subunit and the functional molecule is a trimer. The domain extending from the membrane contains α-helices and β-sheets. This domain forms the base interacting with the membrane envelope. The distal domain has an eight-stranded β-barrel fold similar to that seen in the spherical viruses. This domain bears the binding site for sialic acid, the receptor for influenza virus on the cell surface. The membrane fusion peptide at the N terminus of HA_2 is located in the membrane-interacting domain.

The NA is a tetrametric molecule and its subunit contains six sheets of four β-strands each. The six β-sheets are arranged like the blades of a propeller. The enzymatic site is at a hydrophobic depression in the center of the β-sheets. The antibody recognition site has been defined on the external surface near the enzymatic site by the atomic structure of the NA complexed with Fab fragments.

The HIV protease is an aspartic acid protease with two β-sheets in each subunit. The enzyme has to dimerize before it becomes active. This activation mechanism has an important role in HIV assembly. The virus assembly complex attached to the membrane will not proceed during maturation until all the necessary components are present to initiate dimerization of the protease.

The matrix protein of influenza virus contains at least two α-helix domains and works as a dimer in the

virion. The N-terminal domain has a hydrophobic surface which can bind membrane, while the middle domain has a positively charged surface that interacts with the RNA. This bifunctional protein can simultaneously bind membrane and RNA. The matrix protein and the capsid protein of HIV have similar folds as the matrix protein of influenza virus when compared with each domain. In HIV, the two proteins are initially covalently linked, as are the two domains in the matrix protein of influenza virus. After being cleaved during maturation, the matrix protein remains bound to membrane and the capsid protein binds to the RNA nucleocomplex.

Nucleic Acid–Protein Interaction

The viral nucleic acid genome is always packaged inside the protein capsid. Usually the structure of the nucleic acid cannot be observed in a single crystal X-ray diffraction experiment because of the random orientation of the icosahedral particles in the crystal. However, in rare cases, the nucleic acid might assume icosahedral symmetry by interacting with the protein capsid. Fragments of the complete genome make the same conformation, although with different nucleotide sequences, at locations related by icosahedral symmetry. Such structures have been seen in BPMV (RNA virus) and CPV (DNA virus). The bases are stacked either as in A-type RNA helix (BPMV) or to form a coiled conformation to fit the interactions with the protein capsid. These viruses readily form empty virus particles and have a hydrophobic pocket on the interior surface of the capsid. The nucleic acid generally interacts nonspecifically with the protein.

Evolution

The highly conserved β-barrel motif of the viral capsid protein indicates that many viruses must have evolved from a single origin. The unique three-dimensional structure of this motif is required for capsid assembly and it is generally conserved over a longer period of time than the amino acid sequence. The superposition of the capsid proteins from different viruses can be used to estimate the branch point in the evolutionary tree for each virus group. The structural alignment not only relates plant viruses to animal viruses, RNA viruses to DNA viruses, but also viruses to other proteins like concanavalin A, which has a similar fold and competes with poliovirus for its cellular receptor. The evolutionary relationship of these viruses is supported by amino acid sequence alignment of more conserved viral proteins, such as the viral RNA polymerase. The structural similarities of the matrix and capsid proteins, as well as the surface glycoproteins of influenza virus and HIV, further support the idea of a common evolutionary origin among enveloped viruses.

Assembly

The icosahedral capsid is assembled from smaller units made of several protein subunits. In small animal RNA viruses, a protomeric unit is first formed with one copy of each polypeptide after translation. The termini of the subunits are intertwined with each other to hold the subunits together in the protomer. The protomers are then associated as pentamers, which in turn form the complete icosahedral virion while encapsidating the viral RNA. In $T = 3$ or $T = 1$ plant RNA viruses, the pentamers are formed by dimers of the capsid proteins. In adenovirus and SV40, the capsid proteins form hexon units (three polypeptides, each has two β-barrels) or pentamers before they assemble into an icosahedral shell. The assembly of enveloped viruses like influenza virus is directed by the matrix protein, which initiates the assembly at the cellular membrane.

Host Receptor Recognition Site

Animal viruses have to recognize a specific host cellular receptor for entry during infection. Host receptor binding is the initial step in the viral life cycle and could be an effective target for preventing viral infection. Based on the atomic structure of animal viruses, it was found that the receptor recognition site is located in an area surrounded by hypervariable regions of the antigenic sites. Usually the area is in a depression (called the 'canyon') on the viral surface that is protected from recognition by host antibodies. This structural feature is present in rhinovirus, and the active site of influenza virus NA. The receptor-binding site on influenza virus HA does not have a deep depression, but it is surrounded by antigenic sites.

Antigenic Sites

Antibodies are the first line of defense by the immune system against a viral infection. The epitopes combined with the neutralizing antibodies are mapped on a few isolated locations on the surface of viral proteins. The structure of the influenza virus NA complexed with Fab fragments showed that the antibody makes contact with an area about 6 nm^2 and the epitope spans four discontinuous polypeptides. Therefore, an effective vaccine usually needs to include a complete viral protein or a large fragment. The binding of the antibodies does not change the

structure of the antigen. The exact mechanism by which antibodies neutralize antigens is still unclear.

Antiviral Agents

Viral infectious diseases can be cured if an agent can be administered to stop viral infection. Such agents have been synthesized and shown to bind to the capsid of rhinovirus in the crystal structure. The compounds were inserted into the hydrophobic pocket within the β-barrel of the major capsid protein VP1. Binding of the compounds stops uncoating of the virion and the receptor binding, which results in the failure of release of the viral RNA into the cytoplasm. These compounds inhibit infections of several other RNA viruses and may be effective against other viruses after modification, as the β-barrel structure exists in many viruses.

The most successful antiviral drugs are the HIV protease inhibitors, which are developed based on the atomic structure of the protease. Through interactive cycles of computer modeling, chemical synthesis and structural studies of the protein–inhibitor complexes, a panel of clinically effective drugs has been brought to the market and shown benefits to patients. Inhibitors of influenza virus NA are also under development by the same method.

John E Johnson and **Jeffrey A Speir**, Department of Molecular Biology, The Scripps Research Institute, La Jolla, California, USA

Introduction

The virion is a nucleoprotein particle designed to move the viral genome between susceptible cells of a host and between susceptible hosts. An important limitation on the size of the viral genome is its container, the protein capsid. The virion has a variety of functions during the virus life cycle (**Table 1**); however, the principles dictating its architecture result from the need to provide a container of maximum size with a minimum amount of genetic information. The universal strategy evolved for the packaging of viral nucleic acid requires multiple copies of one or more protein subunit types arranged symmetrically about the genome. The assembly of these subunits into nucleoprotein particles is, in many cases, a spontaneous process that results in a minimum free energy structure under intracellular conditions. The two broad classes of symmetric virions are helical rods and spherical particles.

The nucleoprotein helix can, in principle, package a genome of any size. Extensive studies of tobacco mosaic virus (TMV) show that protein subunits will continue to add to the extending rod as long as there is exposed RNA. Protein transitions required to form the TMV helix from various aggregates of subunits are now understood at the atomic level. It is clear that subunits forming the helix display significant polymorphism in the course of assembly; however,

Table 1 Functions of the virus capsid in simple RNA viruses

Introduction

The virion is a nucleoprotein particle designed to move the viral genome between susceptible cells of a host and between susceptible hosts. An important limitation on the size of the viral genome is its container, the protein capsid. The virion has a variety of functions during the virus life cycle (**Table 1**); however, the principles dictating its architecture result from the need to provide a container of maximum size with a minimum amount of genetic information. The universal strategy evolved for the packaging of viral nucleic acid requires multiple copies of one or more protein subunit types arranged symmetrically about the genome. The assembly of these subunits into nucleoprotein particles is, in many cases, a spontaneous process that results in a minimum free energy structure under intracellular conditions. The two broad classes of symmetric virions are helical rods and spherical particles.

The nucleoprotein helix can, in principle, package a genome of any size. Extensive studies of tobacco mosaic virus (TMV) show that protein subunits will continue to add to the extending rod as long as there is exposed RNA. Protein transitions required to form the TMV helix from various aggregates of subunits are now understood at the atomic level. It is clear that subunits forming the helix display significant polymorphism in the course of assembly; however,

Table 1 Functions of the virus capsid in simple RNA viruses

Assembly	Subunits must assemble to form a protective shell for the RNA
Package	Subunits must specifically package the viral RNA
Infection	The capsid may actively participate in virus infection processes.
Binding to receptors	Binding to receptors and mediating cell entry (animal)
Transport	Virion transport within the host (plant)
Mutation	Capsid protein mutation to avoid the immune system
Replication	Some capsid proteins function as a primer for viral RNA replication

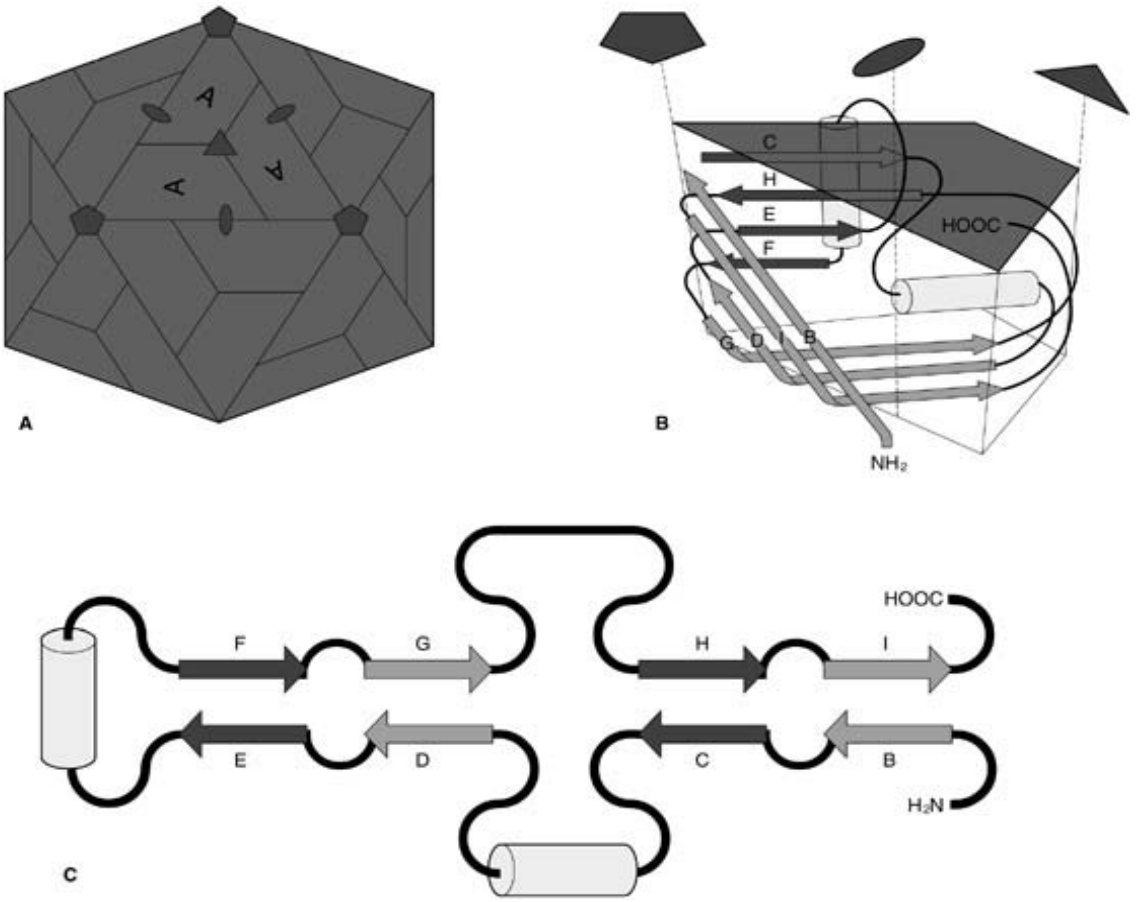

Figure 1 (**A**) The icosahedral capsid contains 60 identical copies of the protein subunit (blue) labeled A. These are related by fivefold (yellow pentagons at vertices), threefold (yellow triangles in faces) and twofold (yellow ellipses at edges) symmetry elements. For a given sized subunit this point group symmetry generates the largest possible assembly (60 subunits) in which every protein lies in an identical environment. (**B**) A schematic representation of the subunit building block found in many RNA and some DNA viral structures. Such subunits have complementary interfacial surfaces which, when they repeatedly interact, lead to the symmetry of the icosahedron. The tertiary structure of the subunit is an eight-stranded β-barrel with the topology of the jellyroll (see (**C**), β-strand and helix coloring is identical to (**B**). Subunit sizes generally range between 20 and 40 kDa with variation among different viruses occurring at the N-and C-termini and in the size of insertions between strands of the β-sheet. These insertions generally do not occur at the narrow end of the wedge (B–C, H–I, D–E and F–G turns). (**C**) The topology of viral β-barrel showing the connections between strands of the sheets (represented by yellow or red arrows) and positions of the insertions between strands. The green cylinders represent helices that are usually conserved. The C–D, E–F and G–H loops often contain large insertions. (**For color references see Color Plate 31.**)

excluding the two ends of the rod, all subunits are in identical environments in the mature helical virion. This is the ideal protein context for a minimum free energy structure. In spite of these packaging and structural attributes the helical virion must be deficient in functional requirements that are common for animal viruses because they are found only among plant and bacterial viruses. Even among plant viruses only seven of the 25 recognized groups are helical. The large majority of all viruses are roughly spherical in shape.

The architectural principles for constructing a 'spherical' virus were first articulated by Crick and Watson in 1956. They suggested that identical subunits were probably distributed with the symmetry of Platonic polyhedra (the tetrahedron, 12 equivalent positions; the octahedron, 24 equivalent positions; or the icosahedron, 60 equivalent positions). Subunits distributed with the symmetry of the icosahedron (**Fig. 1A**) provide the maximum sized particle in which all copies of a subunit will lie in identical positions. The repeated interaction of chemically complementary surfaces at the subunit interfaces leads naturally to such a symmetric particle. The 'instructions' required for assembly are contained in the tertiary structure of the subunit (**Fig. 1B, C**). The actual assembly of the protein capsids is a remarkably accurate process. The use of subunits for

the construction of organized complexes places strict control on the process and will naturally eliminate defective units. The reversible formation of noncovalent bonds between properly folded subunits leads naturally to error free assembly and a minimum free energy structure.

Crystallographic studies of more than 40 unique viruses have demonstrated that there are a limited number of folds utilized in forming viral capsids. **Figure 2** shows schematically the folds of subunits from viruses infecting vertebrates, insects and bacteria. By far the most common fold is the eight-stranded antiparallel β sandwich shown schematically in **Fig. 1B**. Other folds include one that is closely similar to the protease enzyme chymotrypsin.

Early ideas explaining spherical virus architecture were extended on the basis of physical studies of small spherical RNA plant viruses. The large yields and ease of preparation made them ideal subjects for investigations requiring substantial quantities of material. Protein subunits forming virus capsids of this type are usually 20–40 kDa. An example of a virus consistent with the Crick and Watson hypothesis is satellite tobacco necrosis virus (STNV) which is formed from 60 identical 25 kDa subunits. The particle outer radius is 80 Å and the radius of the internal cavity is 60 Å, providing a volume of 9×10^5 Å^3 for packaging RNA. A single hydrated ribonucleotide in a virion will occupy on average roughly 600 to 700 Å^3. The STNV volume is adequate to package a genome of only 1200–1300 nucleotides. STNV is a satellite virus and the packaged genome codes for only the coat protein. Proteins required for RNA replication are supplied by the 'helper virus', tobacco necrosis virus. Most simple ribovirus genomes contain coding capacity for at least two proteins, roughly 1200 nucleotides for the capsid protein and 2500 nucleotides for a RNA-directed RNA polymerase. The inner radius required to package a minimal genome is 90 Å. Consistent with this requirement were experimental studies showing that the vast majority of simple spherical viruses had outer radii of at least 125 Å which corresponds to inner radii of roughly 100 Å. Such particles had to be formed from more than 60 subunits, yet X-ray diffraction patterns of crystalline tomato bushy stunt virus (TBSV) and turnip yellow mosaic virus (TYMV) were consistent with icosahedral symmetry. Although a number of investigators developed hypotheses explaining the apparent inconsistent observations, in 1962 Caspar and Klug derived a general method for the construction of icosahedral capsids that contained multiples of 60 subunits. The method for systematically enumerating all possible quasi-equivalent structures was similar to that used by Buckminster Fuller in constructing geodesic domes. The quasi-equivalent theory of Caspar and Klug has explained the distribution of morphological units (features identifiable at low resolution by electron microscopy often corresponding to hexamer, pentamer, trimer or dimer aggregate of the subunits) on all structures observed to date, but the results from high resolution crystallographic studies have shown some remarkable inconsistencies with the microscopic principles upon which the theory is based.

Quasi-equivalence is best visualized graphically. Formally, subunits forming quasi-equivalent structures must be capable of assembling into both hexamers (which are conceptually viewed as planar) and pentamers (which are convex because one subunit has been removed from the planar hexamer and yet similar (quasi-equivalent) contacts are maintained). If subunits assembled as all hexamers, the result would be a sheet of hexamers and a closed shell could not form (**Fig. 3A**). The rules of quasi-equivalence described a systematic procedure for inserting pentamers into the hexagonal net in such a way as to form a closed shell with exact icosahedral symmetry. **Figure 3** illustrates this principle and the selection rules for inserting pentamers. **Figure 4** illustrates how the morphogenesis of such an assembly may occur using the crystallographic structure of cowpea chlorotic mottle virus (CCMV) as inspiration. CCMV, although solved only recently, was the first virus structure that agreed in detail with the predictions of Caspar and Klug.

The quasi-equivalence theory has been universally successful in describing surface morphology of spherical viruses observed in the electron microscope and, prior to the first high resolution crystallographic structure of a virus, it was assumed that the underlying assumptions of Caspar and Klug were essentially correct. The structure of TBSV determined at 2.9 Å resolution revealed an unexpected variation from the concept of quasi-equivalence which was defined as 'any small nonrandom variation in a regular bonding pattern that leads to a more stable structure than does strictly equivalent bonding'. Unlike CCMV, the structure of TBSV showed that differences occurring between pentamer interactions and hexamer interactions were not small variations in bonding patterns, but almost totally different bonding patterns. **Figure 5A** shows diagrammatically the subunit interactions in the shell of TBSV, southern bean mosaic virus (SBMV), BBV and TCV. These high resolution structures revealed that the mathematical concept of quasi-equivalence predicted surface lattices with high fidelity, but *not* for the reasons expected. Bonding contacts between quasi-threefold related subunits are maintained with little deviation

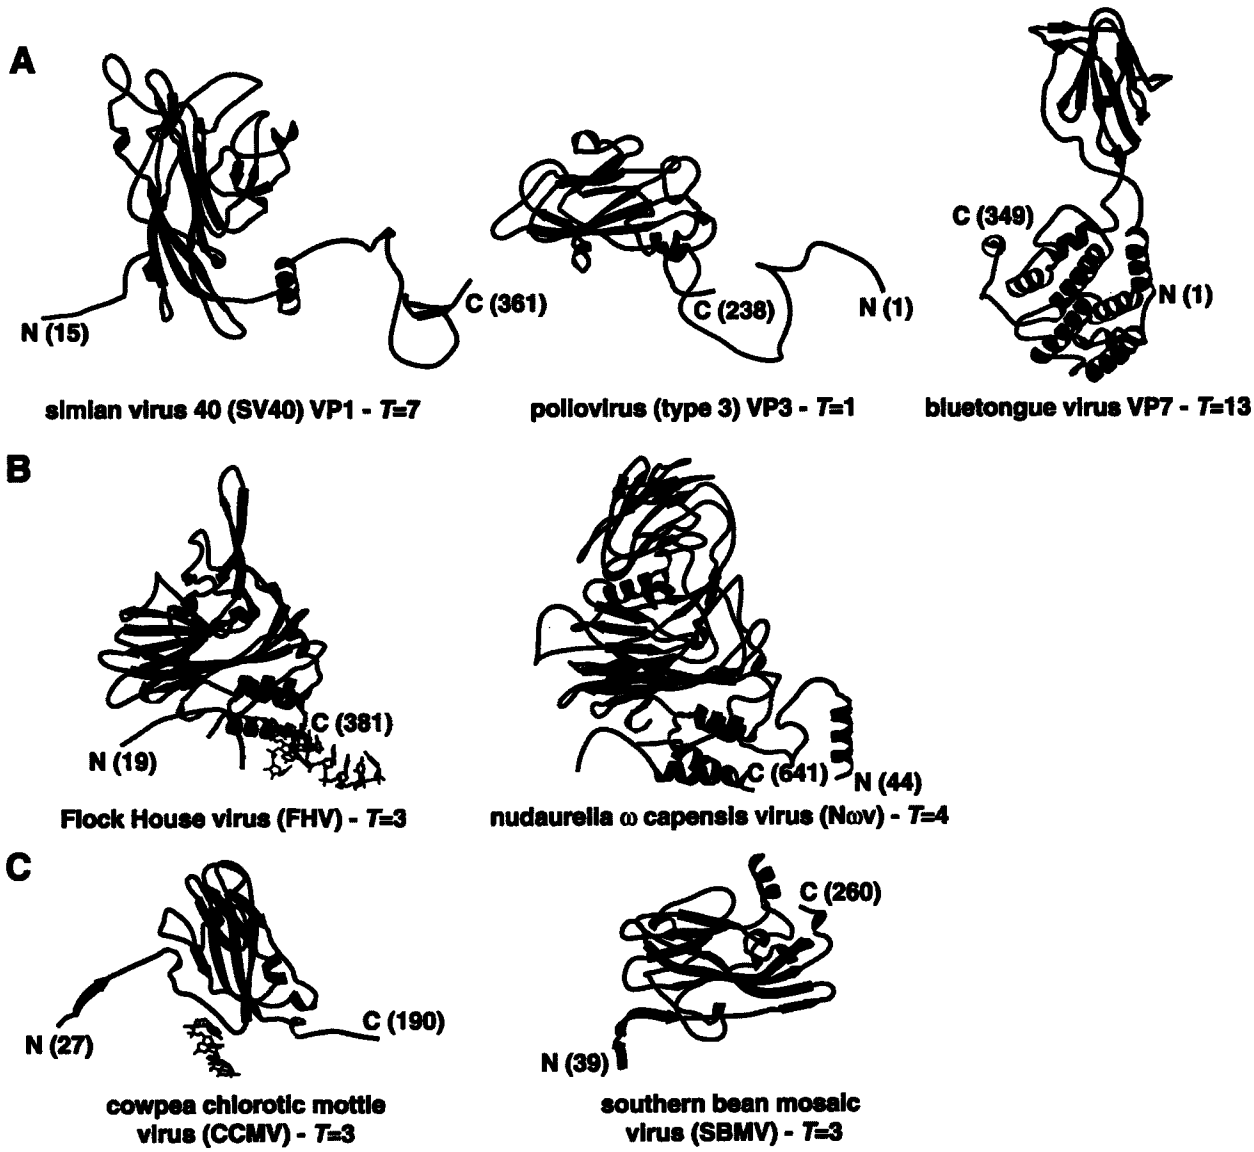

Figure 2 Structure of (**A**) vertebrate, (**B**) insect and (**C**) plant virus protein subunits that assemble into icosahedral shells. The name of the virus appears below the corresponding protein subunit along with the capsid triangulation number *T* (explained in **Fig. 3**). The N- and C-termini are labeled with the residue numbers in brackets. Many virus subunit structures determined to near atomic resolution have the β-barrel fold and/or insertions with nearly all β-secondary structure (colored red, see **Fig. 1B, C**). Multiple copies (from 180 to 780) of the single subunit shown for each virus, except for that of poliovirus, form the entire icosahedral protein shell. Assembly of icosahedral virus particles with more than 60 subunits (e.g. see **Fig. 1A**) requires quasi-symmetric interactions (nonidentical interactions between neighboring identical subunits, discussed in detail later in this chapter, see **Figs 3** and **4**) often involving subtle to extensive differences in structure at the subunit N- and C-termini. The subunit regions involved in quasi-symmetric interactions critical to virion structure and assembly are colored green (only a single variation is shown for each virus). The 'switch' in structure between identical subunits is a response to differences in the local chemical environment, defined the number of subunits forming the icosahedral shell, in order to maintain similar bonding between neighboring subunits. The structural variations include the presence or absence of highly ordered RNA structure (green stick models) in FHV and CCMV. Poliovirus utilizes multiple copies of two additional subunits highly similar to VP3 to form a complete virion. Thus, there is no quasi-symmetry in poliovirus (note the absence of any green highlights) since neighboring subunits are different proteins. **(For color references see Color Plate 32.)**

from exact symmetry, while quasi-twofold contacts and icosahedral twofold contacts (which are predicted to be very similar) are quite different. The hexamer quasi-symmetry is better described as a trimer of dimers in the TBSV and related structures. Unlike the conceptual model and the CCMV capsid

(Fig. 5B), the particle curvature in TBSV results from both pentamers and hexamers.

The high resolution $T = 3$ structures showed that the overall features of the quasi-equivalent theory were correct, but that the underlying concepts of quasi-equivalent bonding had to be revised. The first low (22.5 Å) resolution structure of a $T = 7$ virus required an even greater conceptual adjustment to the underlying principles of quasi-equivalence. Rayment, Baker and Caspar reported, in 1982, that the polyomavirus capsid contained 72 capsomeres, as previously reported from electron microscopy studies, but that all the capsomeres were pentamers of protein subunits even though they were located at hexavalent lattice points. The $T = 7$ surface lattice predicts 12 pentamers and 60 hexamers, thus the prediction of the number and position of the morphological units is correct, but the fine structure of the morphological units is incorrect. Although the result was highly controversial when first reported, additional electron microscopy studies and the 3.5 Å resolution X-ray structure of polyomavirus have fully confirmed the all-pentamer structure. This result clearly shows the limits of theory in predicting virus structure and indicates that further understanding of capsid structure will come only from experimental studies. The structure of the polyomavirus and its relatives illustrates an important concept when considering surface lattice formation. The important feature is not the symmetry of the morphological unit positioned on the hexamer sites, but only its ability to accommodate six neighbors (it is a hexavalent position). Normally this is accomplished by morphological units with sixfold symmetry, but here, rather acrobatic molecular switching has permitted a pentamer of subunits to accommodate six neighbors. Although the all-pentamer capsid has been observed for the $T = 7$ structure of papillomaviruses, cauli-

Figure 3 Geometric principles for generating icosahedral quasi-equivalent surface lattices. These four constructions show the relation between icosahedral symmetry axes and quasi-equivalent symmetry axes. The latter are symmetry elements that hold only in a local environment. (**A**) It is assumed in quasi-equivalence theory that hexamers and pentamers can be interchanged at a particular position in the surface lattice. Hexamers are initially considered planar (an array of hexamers forms a flat sheet as shown) and pentamers are considered convex, introducing curvature in the sheet of hexamers when they are inserted. Inserting 12 pentamers at appropriate positions in the hexamer net generates the closed icosahedral shell, composed of hexamers and pentamers. The positions at which hexamers are replaced by pentamers are defined by the indices **h** and **k** measured along the labeled axes. The values of (**h, k**) used in the following examples are labeled. To construct a model of a particular quasi-equivalent lattice, one face of an icosahedron (equilateral triangles colored orange in (**B–F**) is generated in the hexagonal net. The origin (0,0) is replaced with a pentamer, and the (**h,k**) hexamer is replaced by a pentamer. The third replaced hexamer is identified by threefold symmetry (i.e. complete the equilateral triangle). Each quasi-equivalent lattice is identified by a number $T = \mathbf{h}^2 + \mathbf{hk} + \mathbf{k}^2$ where **h** and **k** are the indices used above. T indicates the number of quasi-equivalent units in the icosahedral asymmetric unit (a hexamer contains six units and a pentamer contains five units). For the purpose of these constructions it is convenient to choose the icosahedral asymmetric unit as one-third of an icosahedral face defined by the triangle connecting a threefold axis to two adjacent fivefold axes. Other asymmetric units can be chosen such as the triangle connecting two adjacent threefold axes and an adjacent fivefold axis (see (**C**) and **Fig. 5**). The total number of units in the particle is $60T$, given the symmetry of the icosahedron. The number of pentamers must be 12 and the number of hexamers is $(60T - 60)/6 = 10(T - 1)$. (**B**) One face of the icosahedron for a $T = 3$ surface lattice is identified by the orange triangle with the bold outline (this corresponds to a face of the icosahedron in **Fig. 1A**). The yellow symmetry labels are the same as those defined in **Fig. 1**. The hexamer replaced has coordinates $\mathbf{h} = 1$, $\mathbf{k} = 1$. The icosahedral asymmetric unit is one-third of this face and it contains three quasi-equivalent units (two units from the hexamer coincident with the threefold axis and one unit from the pentamer). (**C**) Arranging 20 identical faces of the icosahedron as shown can generate the three-dimensional model of the quasi-equivalent lattice. Three quasiequivalent units labeled A (blue), B (red) and C (green) are shown. These correspond to the three quasi-equivalent units defined in **Figs 4** and **5** rather than the alternative definition used in (**A**) and (**B**). (**D**) The folded icosahedron is shown with hexamers and pentamers outlined. The orange face represents the triangle originally generated from the hexagonal net. The $T = 3$ surface lattice represented in this construction has the appearance of a soccer ball. The trapezoids labeled A, B and C identify quasi-equivalent units in one icosahedral asymmetric unit of the rhombic tri-icontahedron discussed in **Fig. 5**. (**E**) An example of a $T = 4$ icosahedral face ($\mathbf{h} = 2$, $\mathbf{k} = 0$). In this case the hexamers are coincident with icosahedral twofold axes. (**F**) A folded $T = 4$ icosahedron with the orange face corresponding to the face outlined in the hexagonal net. Note that folding the lattice has required that the hexamers have the curvature of the icosahedral edges. (**G**) A single icosahedral face generated from the hexagonal net for a $T = 7$ lattice. Note that there are two different $T = 7$ lattices ($\mathbf{h} = 2$, $\mathbf{k} = 1$ in bold outline; and $\mathbf{h} = 1$, $\mathbf{k} = 2$ in dashed outline). These lattices are the *mirror* images of each other. To fully define such a lattice, the arrangement of hexamers and pentamers must be established as well as the enantiomorph of the lattice. (**H**) A single icosahedral face for a $T = 13$ lattice is shown. The two enantiomorphs of the quasi-equivalent lattice ($\mathbf{h} = 3$, $\mathbf{k} = 1$ – bold; and $\mathbf{h} = 1$, $\mathbf{k} = 3$ – dashed) are outlined. The procedure for generating quasi-equivalent models described here does not exactly correspond to the one described by Caspar and Klug (1962). Caspar and Klug distinguish between different icosadeltahedra by a number $P = \mathbf{h}^2 + \mathbf{hk} + \mathbf{k}^2$ where **h** and **k** are integers that contain no common factors but 1. The deltahedra are triangulated to different degrees described by an integer f that can take on any value. In their definition $T = Pf^2$. The description in this figure has no restrictions on common factors between h and k, thus $T = \mathbf{h}^2 + \mathbf{hk} + \mathbf{k}^2$ for all positive integers. The final models are identical to those described by Caspar and Klug. **(For color references see Color Plate 33.)**

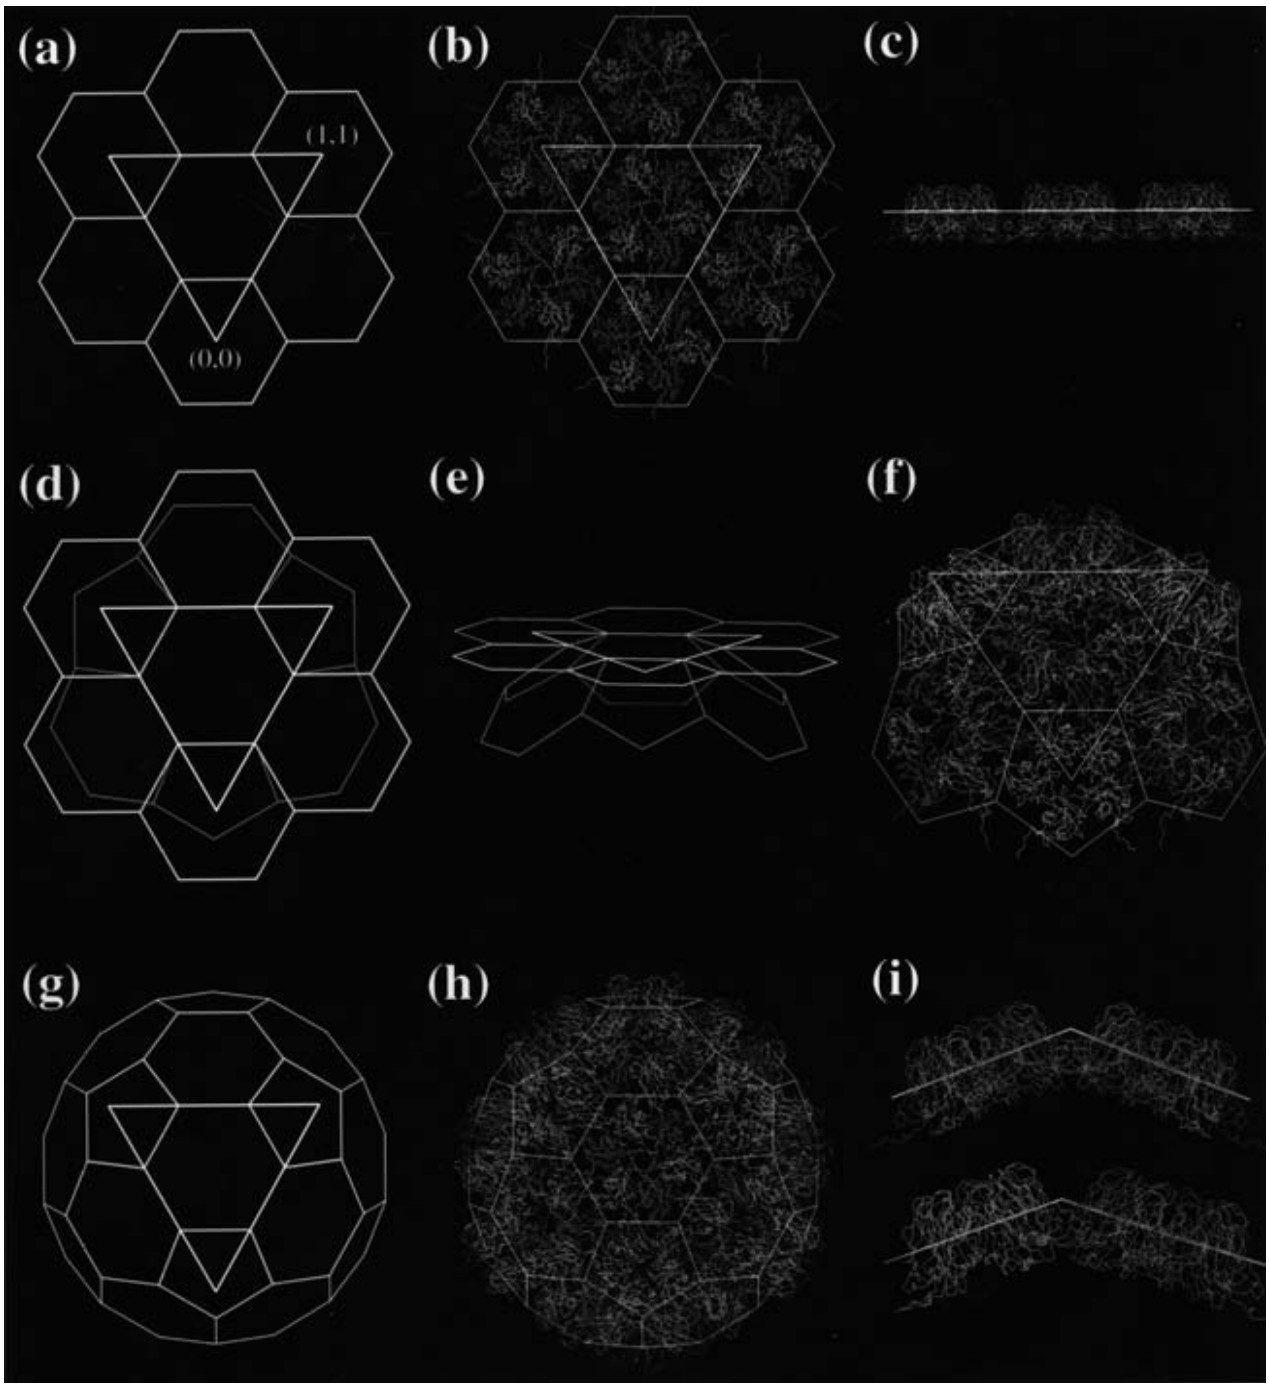

Figure 4 Molecular graphics construction of a $T = 3$ quasi-equivalent icosahedron. (**a**) Hexagonal sheet overlaid with the triangular coordinates (white) for a theoretical $T = 3$ quasi-equivalent icosahedron (**h** = 1, **k** = 1, see **Fig. 3B**). The sheet has true sixfold rotational symmetry about axes passing through the hexamer centers, which are normal to the sheet. (**b**) Copies of the hexamer coordinates from the CCMV X-ray structure (colored by asymmetric unit position, see **Fig. 5**) can be positioned in the sheet by simple translations. (**c**) A side view of the modeled sheet demonstrates its planarity. (**d**) Hexamers at the corners of the white (**h** = 1, **k** = 1) triangle become pentamers. The planar sheet (yellow model) takes on curvature to maintain contacts between the polygons (green model). (**e**) The magnitude of the pentamer-induced curvature is displayed in the side view of the partial polyhedron. (**f**) Coordinates of the CCMV X-ray structure fit this construction without any manipulation. (**g**) A completed $T = 3$ icosahedral model. The 12 pentamers generate curvature that closes the structure. This cage (a truncated icosahedron) accurately describes the geometric morphology of CCMV (**h**) which is composed of modular, planar pentamers (12) and hexamers (20). Angular pentamer–hexamer and hexamer–hexamer interfaces (**i**) stabilize curvature in the absence of convex pentamers used to construct the soccer ball of **Fig. 3D** (see also **Fig. 5**). (**For color references see Color Plate 34.**)

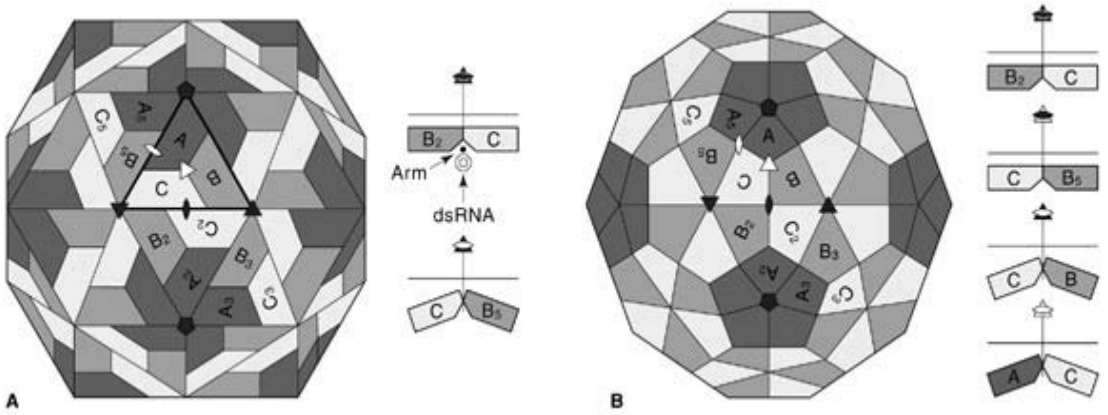

Figure 5 Although quasi-equivalence theory can predict, on geometrical principles, the organization of hexamers and pentamers in a viral capsid, the detailed arrangement of subunits can only be established empirically. High-resolution X-ray structures of $T = 3$ plant and insect viruses show that the particles are organized like the icosahedral rhombic tri-icontahedron or truncated icosahedron (**Fig. 4**). A convenient definition of the icosahedral asymmetric unit for both geometrical shapes is the wedge defined by icosahedral threefold axes left and right of the particle center and an icosahedral fivefold axis at the top. The icosahedral asymmetric unit contains three subunits labeled A (blue), B (red) and C (green) (see **Fig. 3C, D**). The asymmetric unit polygons represent chemically identical protein subunits that occupy slightly different geometrical (chemical) environments as indicated by differences in their coloring. Polygons with subscripts are related to A, B, and C by icosahedral symmetry (i.e. A to A_5 by fivefold rotation). The shapes of the $T = 3$ soccer ball model in **Fig. 3D**, truncated icosahedron in **Fig. 4** and rhombic tri-icontahedron are all different; however, the quasi-symmetric axes are in the same positions relative to the icosahedral symmetry axes for all three models. Quasi-threefold and quasi-twofold axes are represented by the white symbols. The quasi-sixfold axes are coincident with the icosahedral threefold axes in $T = 3$ particles as shown in **Figs 3B–D** and **4**. **(A)** The rhombic tri-icontahedron is constructed by placing rhombic faces perpendicular to icosahedral twofold symmetry axes (yellow ellipse). Thus, the A, B and C polygons are coplanar within each asymmetric unit. The shape of the subunit in $T = 3$ plant and insect viruses is nearly identical to the shape of the subunit in the $T = 1$ virus and they pack in a very similar fashion. The $T = 1$ subunits in one face (**Fig. 1A**) are related by an icosahedral threefold axis, while the $T = 3$ subunits in one face are related by a quasi-threefold axis. The dihedral angle between subunits C and B_5 (juxtaposed across quasi-twofold axes) is 144° and is referred to as a bent contact (bottom right image), while the dihedral angle between subunits C and B_2 (juxtaposed across icosahedral twofold axes) is 180° and is referred to as a flat contact (top right image). Two dramatically different contacts between subunits with identical amino acid sequences are generated by the insertion of an extra polypeptide from the N-terminal portion of the C subunit into the groove formed at the flat contact. This polypeptide is called an 'arm'. The flat contact can also be upheld by insertion of nucleic acid structure into the same groove. The N-terminal arms of the A and B subunits are disordered, and nucleic acid structure has not been observed in the groove across the quasi-twofold axis; thus, C and B_5 are in direct contact as in, for example, the X-ray structure of FHV. **(B)** A truncated icosahedron achieves curvature at different interfaces compared to the rhombic tri-icontahedron. Interactions between B_2–C and between C–B_5 polygons are both defined by 180° dihedral angles (side view at top right) whereas bends similar in magnitude occur within the asymmetric unit at the B–C and C–A polygon interfaces (138° and 142°, respectively; side view at bottom right). This creates the planar pentamer and hexamer morphological units characteristic of the truncated icosahedron and the CCMV X-ray structure (**Fig. 4h**). **(For color references see Color Plate 35.)**

flower mosaic virus appears to have the hexamer/pentamer distribution predicted by quasi-equivalent theory, as do the $T = 7$ capsids of the λ-like bacteriophage, HK97. A substantial number of complex virus structures have been determined by cryoelectronmicroscopy and the surface lattices agree well with the predictions of quasi-equivalence. Thus there is considerable confidence in the lattice assignments, but the capsomere and therefore number of subunits must be carefully confirmed.

A number of viral capsids are constructed with pseudo $T = 3$ symmetry. These structures contain β-barrel subunits (**Fig. 1B**) in the quasi-equivalent environments formed in $T = 3$ structures, but each of the three β-barrels in the asymmetric unit has a unique amino acid sequence. Rather than 180 identical subunits, the $P = 3$ particles contain 60 copies each of three different subunits (**Fig. 6**). These structures do not require quasi-equivalent bonding because each unique interface will have different amino acids interacting, rather than the same subunits forming different contacts. The animal picornaviruses have capsids of this type. Animal virus capsids undergo rapid mutation to avoid recognition by the circulating immune system. Capsids composed of three subunit types could mutate in one subunit without affecting the other two. This would be less likely to affect assembly or other functions of the particle in $P = 3$ shells than it would in $T = 3$ shells. At least one plant virus group displays $P = 3$ shells,

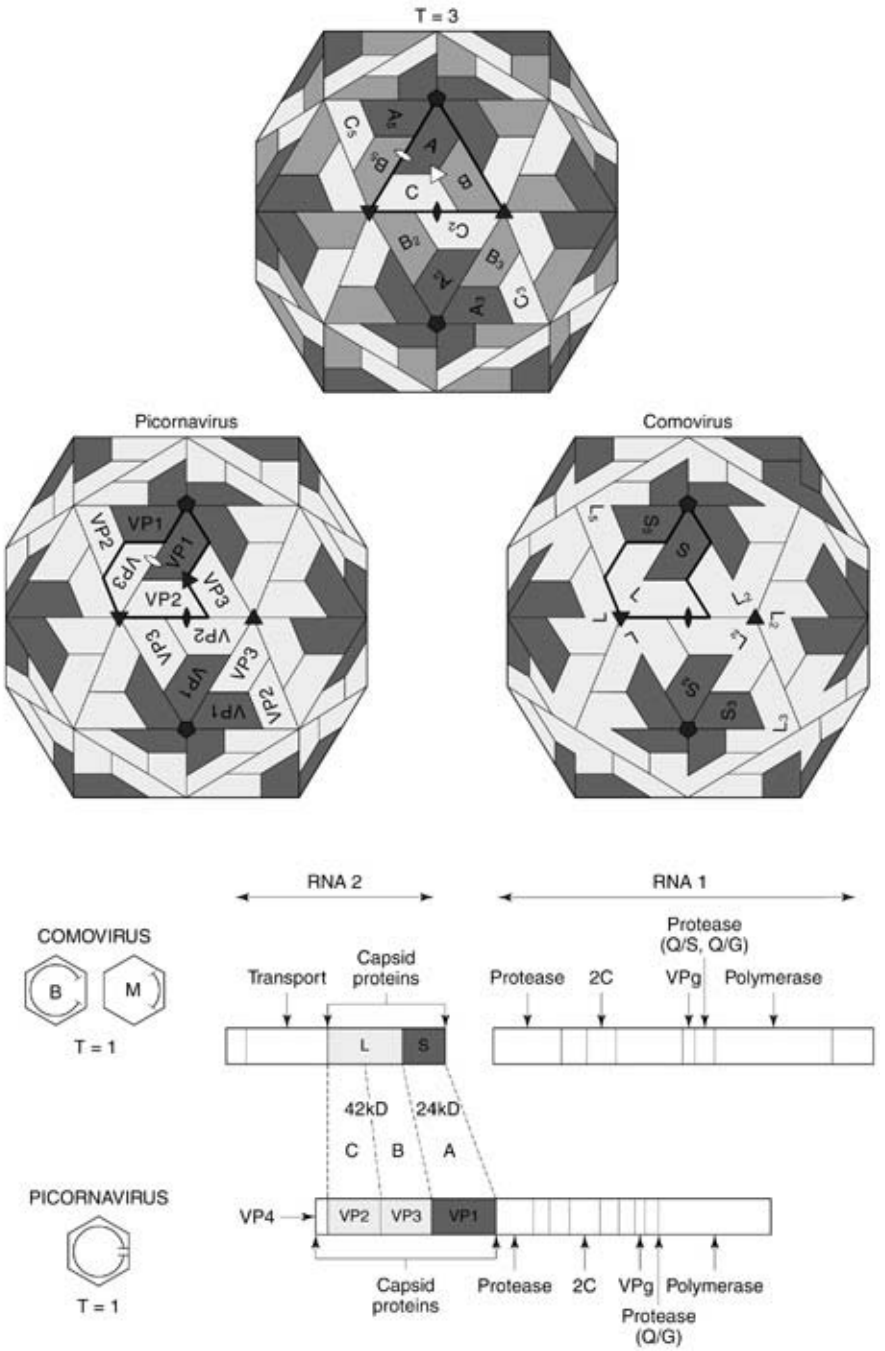

Figure 6 A comparison of $T = 3$, picornavirus and comovirus capsids. In each case, one trapezoid represents a β-barrel and the icosahedral asymmetric units are outlined in bold. The icosahedral asymmetric unit of the $T = 3$ shell contains three identical subunits labeled A, B and C (see **Fig. 5**). The asymmetric unit of the picornavirus capsid contains three β-barrels, but each has a characteristic amino acid sequence labeled VP1, VP2 and VP3. The comovirus capsid is similar to the picornavirus capsid except that two of the β-barrels (corresponding to the green VP2 and VP3 units) are covalently linked to form a single polypeptide, the large protein subunit (L), while the small protein subunit (S) corresponds to VP1 (note the similar color shading). The individual subunits of the comovirus and picornavirus capsids are in identical geometrical (chemical) environments (e.g. VP1 and S are always pentamers) making these $T = 1$ capsids. Comoviruses and picornaviruses have a similar gene order, and the nonstructural 2C and polymerase genes display significant sequence homology. The relationship between the capsid subunit positions in these viruses and their location in the genes is indicated by color coding and the labels A, B and C in the gene diagram. **(For color references see Color Plate 36.)**

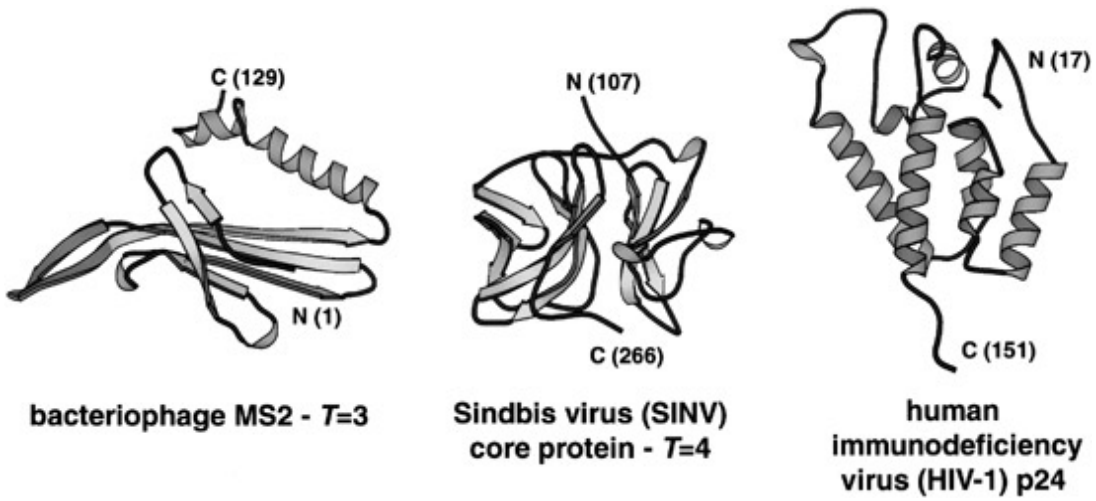

Figure 7 Viral capsid subunits having a fold other than the β-barrel. The MS2 and SINV subunits assemble into icosahedral shells with the *T* numbers shown. The SINV core is further surrounded by a lipid bilayer and glycoprotein spikes to form the complete virus particle. HIV-1 p24 does not form a capsid with icosahedral symmetry. Together with other products from Gag protein cleavage by the viral protease, p24 forms a conical core structure that encloses the HIV nucleocapsid protein–RNA complex.

the comoviruses. An interesting variation occurs in these capsids when compared with the picornaviruses. Two of the domains forming the shell are contained in a single polypeptide chain. This phenomenon is readily understood in the context of the synthesis of the subunits in picornaviruses and comoviruses. In both cases the proteins are synthesized as a polyprotein that is subsequently cleaved into functional proteins by a virally encoded protease. Clearly one of the cleavage sites in picornaviruses is missing in the comoviruses, resulting in these two domains being still a 'polyprotein'.

Other icosahedral shells containing more than one type of protein subunit have been investigated by high resolution electron microscopy and X-ray crystallography.

Subunit Tertiary Structure

The dominant tertiary fold observed in high resolution X-ray structures determined to date is the eight-stranded β-barrel illustrated in **Fig. 1B**. This fold has been observed in a wide range of viruses. The wedge shape is ideally suited to form pentamers and hexamers, as it does in $T = 3$ virus and $P = 3$ viruses. In other viruses, however, the wedge is not found in this favorable geometric environment. Canine parvovirus, the phage ϕX174, the DNA tumor virus SV40 and adenovirus hexons have the β-barrel fold, but its geometrical environment in each of these viruses is very different from that observed in the $T = 3$ and $P = 3$ viruses.

In all cases the residues in the β-barrel form most of the contiguous shell, while insertions between strands of the barrel project outward. In some cases these insertions can be up to 100 residues or more, creating additional domains of the protein. Extensions at the N-terminus are generally on the interior of the shell, and in many plant and some animal viruses this portion will be extremely basic. These regions are generally not visible in X-ray structures because they are assuming different structures and do not obey icosahedral symmetry. Extensions at the C-terminus are generally external. In the case of TBSV and TCV an entire protruding domain is created by the 90 residues following the polypeptide that forms the contiguous shell (**Fig. 2**).

Although infrequent, other tertiary structures have been seen in viral capsid subunits (**Fig. 7**). The RNA phage MS2 was found to have an entirely different fold than the β-barrels observed in other $T = 3$ structures. What is more, like CCMV, the quaternary structure of MS2 is more closely related to the quasi-equivalence of subunit interactions originally envisioned by Caspar and Klug. The difference between quasi and icosahedral twofold axes are extremely small and the difference in contacts at the pentamers and hexamers seems to be regulated by a loop between two strands that is extended at hexamer axes and folded down at pentamer contacts.

Another tertiary structure found is in the core protein of Sindbis virus. In this case subunits were purified and crystallized because the intact nucleoprotein core was not stable enough to crystallize. The fold found was that of chymotrypsin. It was

previously known that this subunit functions as an enzyme because it cuts itself out of a polyprotein after synthesis. Generally the structure has shorter loops than found in chymotrypsin, but the topology and active site are conserved. The C-terminal tryptophane, where the cleavage occurs, is still in the active site of the subunit. These subunits form $T = 4$ shells with the viral RNA. In this case a protein fold with a totally different function has been adapted to form shells. The N-terminal region of this protein (residues 1–100) is composed predominately of basic residues and is not visible in the crystal structure.

The principles of virus structure discussed reflect the level of current understanding for a few relatively simple virus systems. More than 40 unique virus structures have been determined at moderate to high resolution (35 nm or higher) by X-ray crystallography and coordinates are available for these capsids in the Brookhaven Protein Data Bank. This structural information has allowed an understanding of virus assembly and disassembly at the chemical level and this has led to the rational design of antiviral agents that effect particle stability. Approximately 30 virus structures, many with dimensions greater than 80 nm, have been determined at moderate resolution (~2 nm) with cryo-electron microscopy and image reconstruction and these structures have revealed organizational principles of exceptional complexity. The large icosahedral viruses extend the principles of quasiequivalence to multisubunit capsid types, but it remains a unifying theme over a remarkable range of virus particle size.

Complex Virus Structures

Many viruses are composed of complex particles with specific functions associated with different structural elements. Complex bacteriophages, for example, have been a subject of study for decades, and the details of their morphogenesis and low resolution structure have been determined. A variety of viruses contain multiple copies of different subunits in their capsids, and the structural roles of each subunit type are still being determined. In most cases these particles are too large to be analyzed by crystallography, but some have been successfully examined by high resolution electron microscopy. Many viruses of medical importance are enveloped by a membrane that contains functionally important proteins. Usually a quasi-symmetric nucleoprotein particle assembles in the cytoplasm and the membrane and associated proteins are acquired when the particle buds through the plasma membrane of the host cell. In the paramyxoviruses, two proteins in the membrane (neuraminidase and hemagglutinin) have been purified, crystallized and analyzed at high resolution. There are a number of examples in which envelopes have been removed and nucleoprotein cores have been analyzed by cryoelectronmicroscopy and image analysis. Their structures display a variety of T numbers, and they are not significantly different from nonenveloped protein capsids. The largest structure ever determined by crystallography is the core of the nonenveloped, double-stranded RNA bluetongue virus that is delivered to the cytoplasm of infected cells. The particle is over 600 Å in diameter, has a $T = 13$ outer capsid and an inner capsid with $T = 1$ symmetry formed of 120 copies of the same gene product. The subunit that forms the outer $T = 13$ shell is shown in **Fig. 2**.

The continued rapid development of single crystal X-ray diffraction, cryo-electron microscopy and associated image processing techniques virtually guarantees rapid progress in understanding the structure and function of large complex viruses. These complex structures will certainly provide insights for broader biological mechanisms as well.

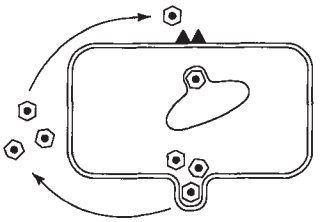
VIRUS–HOST CELL INTERACTIONS



Patricia Whitaker-Dowling and **Julius S Youngner**, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA

Introduction

The topic of virus–host cell interactions spans all of virology and provides some of the most important insights into this field. Since viruses are intracellular parasites, they rely on their host cells for the energy, macromolecular synthesis machinery and the work benches for genome replication and particle assembly. Because of this dependence, viruses have evolved a myriad of mechanisms for exploiting normal host cell functions. Often this exploitation is associated with damage to the host cell which may be one of the major factors in the pathology and disease caused by viruses. The material in this entry is confined to model systems of virus–host cell interactions that involve the infection by animal viruses of cells in culture.

The past few decades have witnessed a dramatic expansion of our knowledge of animal viruses. These advances have provided a detailed understanding of the structure and composition of the viral genome and the virus particle as well as insight into the replication strategies used by viruses and the regulation of viral gene expression during infection. Development of an understanding of the virus growth cycle has proved easier than a clear comprehension of the interaction of the virus with the host cell. Owing to the complexity of the cell, many of the effects of virus infection on the host occur by mechanisms yet to be determined.

Types of Virus Infections

When a virus infects a cell, the outcomes that may occur can be grouped into several general categories which are determined by the particular virus involved, as well as by the type of cell and its functional state. Productive infections result in the formation of progeny virus and usually cause the destruction of the host cell. In some cases the host cells are not all destroyed, leading to persistent infections in which the surviving cells multiply and continue to produce progeny viruses. When persistent infections occur in which the viral genome is present but no infectious virus is produced, these infections are referred to as latent infections. In such infections some level of viral gene expression is usually detectable although virions are not produced. When genetic information of the virus is integrated as DNA into the host cell genome or is carried as episomal DNA, transforming infections may take place. Such infections can cause an oncogenic alteration of the growth properties of the cell. Abortive infections occur when viruses infect cells that are nonpermissive or only partially permissive. In this instance, the virus is able to enter the cell but because some step essential for viral replication is absent, the replication cycle does not go to completion and no progeny are produced. Such abortive infections may or may not cause cell death.

A few examples follow which demonstrate that different outcomes of infection are dependent on the particular virus and host cell involved, as well as on the state of the host cell. For example, influenza A virus causes a productive, cytolytic infection of a line of canine kidney cells (MDCK). However, when the same virus infects the L cell line of mouse fibroblasts an abortive infection occurs because of a block at the level of virion RNA replication. The same mouse L cell line supports a productive, cytolytic infection by vesicular stomatitis virus (VSV). However, if the L cells are pretreated with interferon, the functional state of the cells is altered; the VSV replication cycle is blocked at the level of protein synthesis and an abortive infection results. When VSV infects insect cell lines derived from *Aedes* or *Drosophila*, productive noncytolytic infections occur. Continuous passage of the insect cell lines reveals that they have become persistently infected and continuously produce infective virus without any signs of cytopathology. Adeno-associated virus (AAV), a parvovirus, is capable of a productive or a latent infection depending upon whether or not the host cells are co-infected with a helper virus such as adenovirus. In some host cells, AAV can cause a latent infection by integrating its DNA into the host cell genome.

There are instances in which infection with a second unrelated virus can dramatically alter the type of infection produced by certain viruses. As mentioned in the preceding paragraph, adeno-associated viruses are capable of productive, cytolytic infections only in cells co-infected with adenovirus. Human adeno-viruses can multiply in monkey cells only in the presence of SV40, a simian papovavirus that supplies a helper function that permits translation of adenovirus mRNAs. In rabbit corneal cells, co-infection with vaccinia or some other poxviruses can convert nonproductive infections with VSV into cytolytic infections.

Effects of Virus Infection on the Host Cell

Effects on host cell morphology and viability

The most readily recognized effects of viruses on host cells are those that involve morphologic changes or cell death. Enders defined viral cytopathogenicity as 'the capacity to induce any demonstrable departure from the normal either in the morphological or functional properties of cells'. The space available for this entry precludes a comprehensive survey of all the cytopathic effects induced by infection with the various families of animal viruses. However, one of the most striking observations that emerges from an overview of the effects of viruses on host cells is how little is known of the mechanisms by which viruses induce cytopathology. The production of cytopathic effects has been observed with most families of viruses and in many cases the viral gene(s) involved or implicated in these morphological changes has been defined. However, in most cases the mechanisms responsible for cell destruction have not been identified. It is fair to say that one of the most fundamental questions of virology, namely, how viruses kill cells, remains for the most part unanswered.

Effects on host cell macromolecular synthesis

Many of the investigations of the effect of virus infection on the host cell have centered on virus-induced alterations of host cell macromolecular synthesis. While these studies are important to an understanding of the viral growth cycle and have yielded significant insights into the control of host cell gene expression, there is no direct evidence that inhibition at this level is the direct cause of visible cytopathology or cell death. In fact, treatment of host cells with drugs such as actinomycin D and cycloheximide, which inhibit nucleic acid and protein synthesis, does not mimic the morphological changes produced by virus infection. Nevertheless, viruses do employ a variety of strategies to affect the host cell at the level of gene expression.

Effects on host cell DNA and RNA synthesis A variety of DNA and RNA viruses are capable of affecting gene expression by directly altering the host cell genome. For example, the host cell DNA is degraded after infection with poxviruses. Herpes-, picorna- and reoviruses cause a displacement of the cellular chromatin, while an inhibition of host DNA synthesis has been reported following infection with herpes-, pox-, adeno-, picorna-, reo-, alpha- and rhabdoviruses. This inhibition of host DNA synthesis may be a direct effect of a virus factor in the nucleus or a secondary consequence of the inhibition of host cell protein synthesis.

Viral products can directly affect the activity of cellular RNA polymerases and cause an inhibition of host RNA synthesis. Such an inhibition has been seen with VSV and polioviruses. In the case of VSV, both a small viral-encoded RNA molecule (leader RNA) and a viral protein (the matrix M protein) have been implicated in the inhibition of the cellular polymerases at the level of RNA synthesis initiation. Another mechanism to inhibit host RNA synthesis is employed by polioviruses. These agents encode a protease that is capable of cleaving transcription factors required by host RNA polymerases II and III. Reo- and alphaviruses also block host RNA synthesis but the mechanism of this inhibition is not known. Synthesis is not the only level at which viruses can affect host mRNA. Infection with herpes- and poxviruses increases the rate of host mRNA degradation. A unique effect on host cell mRNA is produced by influenza viruses. These agents cleave the cap structure and the first 10–13 nucleotides from the 5′ ends of newly synthesized host mRNAs, and utilize this oligomer as a primer for viral mRNA synthesis. Another mechanism that affects host RNA is seen with adenoviruses; in this instance, infection inhibits the transport of host mRNA out of the nucleus.

Effects on host cell protein synthesis Although much effort has been directed at understanding the effect of virus infection on host protein synthesis, it is unlikely that an inhibition of host protein synthesis is required for successful virus replication. Many viruses, such as paramyxo-, papova- and retroviruses do not normally inhibit host protein synthesis during their replication. Furthermore, mutant viruses that are defective in their ability to shut down host protein synthesis are not necessarily defective for virus growth. In fact, VSV mutants selected during a persistent infection have a reduced ability to inhibit the host's translational machinery; nevertheless, these mutants grow to higher titer during a lytic growth cycle than the parental wild-type virus. With several virus families, infection causes a selective inhibition of the translation of host cell mRNA. Such viruses include picorna-, pox-, herpes-, adeno-, rhabdo-, reo- and orthomyxoviruses. In many cases this inhibition is accompanied by a decrease in the overall rate of protein synthesis in the infected cell. It is likely that this overall inhibition occurs at the level of initiation of protein synthesis since, where it has been examined, the average size of the polysomes in the infected cells is reduced.

The most clearly defined case of virus-induced damage to the translational machinery of the host cell

is the effect of poliovirus on one of the translation initiation factors. Following infection with poliovirus, the cap binding complex responsible for recognition of the capped 5′ end of cellular mRNA is inactivated by a proteolytic cleavage of the p220 component of the complex. It has been speculated that the destruction of the p220 protein confers a selective advantage on the translation of poliovirus messages which are uncapped. Infection with poliovirus also causes the release of host mRNA from the cytoskeleton.

Virus-mediated inactivation of other initiation factors for protein synthesis has also been reported. Translational extracts prepared from VSV-infected cells are deficient in eucaryotic initiation factor 2 (eIF-2) activity in one report and eIF-3 in another, while infection with reoviruses impairs the function of eIF-2. It has recently been shown that vaccinia virus, a poxvirus, encodes a small protein which has significant homology to the α subunit of eIF-2. This protein may function as a replacement initiation factor since there is evidence that it may be important in making the virus resistant to inhibition by interferon.

Another viral strategy to inhibit host protein synthesis involves a direct competition of viral and host RNAs. VSV and reoviruses compete successfully with the host for the translational machinery through sheer abundance of viral transcripts. Mengovirus, a picornavirus, produces mRNA which initiates translation more efficiently than the bulk of the host message and, in addition, synthesizes a factor that causes an overall inhibition of protein synthesis in infected cells.

It has been suggested that selective translation of viral mRNA may also occur following changes in intracellular ion concentrations during infection. Increased plasma membrane permeability is a common cytopathic effect of virus infection which can alter the intracellular levels of sodium and potassium ions. Under conditions that cause increased intracellular sodium ion concentrations, the translation of viral mRNAs may be unimpaired while the translation of host mRNAs is severely reduced. Such a differential effect on virus and host protein synthesis has been reported for cells infected with poliovirus, encephalomyocarditis virus, VSV, reovirus and Sindbis virus. In the case of Sindbis virus, the shutdown of host protein synthesis following infection has been correlated temporally with an increase in permeability of the plasma membrane.

Effects on host cell membranes and cytoskeleton

In addition to altering membrane permeability, virus infection can cause other changes in the membranes of the host cell. Insertion of viral proteins into the plasma membrane can induce syncytia formation by fusing infected cells with neighboring uninfected cells. This fusion can be induced either from without by input virions or from within by newly synthesized viral fusion protein made during infection. The ability to fuse cells, which is characteristic of the paramyxovirus family, is also seen with herpes-, flavi-, lenti-, pox- and coronaviruses. Flaviviruses can also affect internal membranes by causing the proliferation of the rough endoplasmic reticulum, a site associated with the assembly of viral particles. Reo-, picorna- and alphavirus infections frequently produce a significant increase in vesicle formation in the cytoplasm.

Cytolytic virus infections generally cause a progressive loss of integrity of the lysosomal membranes. Two phases of damage are recognized. In the first phase, which in some cases is reversible, the lysosomes become permeable to small molecules and are able to concentrate dyes such as neutral red. Visible evidence of this phenomenon is seen with a mutant strain of Newcastle disease virus, a paramyxovirus, which produces red plaques when assayed using an agar overlay containing neutral red. Concentration of this vital stain in lysosomes can also be detected in cells infected with certain strains of influenza A virus. In this instance a ring of darkly staining cells surrounds a clear area of unstained dead cells. In the second phase of lysosomal damage the membrane becomes so permeable that lysosomal enzymes are released into the cytoplasm. As a rule, this release occurs late in the replicative cycle. The release of lysosomal enzymes into the cytoplasm has been described for a wide variety of viruses such as picorna-, pox-, herpes-, orthomyxo-, paramyxo-, corona-, adeno- and papovaviruses. The mechanism responsible for this type of virus-induced cytopathology and the role it plays in cell death have not been clearly defined.

One of the most common signs of virus-induced cytopathology is cell rounding, a morphological change which has been correlated with alterations in the cytoskeleton. Disruption of one or more of the elements of the cytoskeleton has been described after infection with several viruses. Early gene products of herpes, vaccinia and SV40 viruses produce a disassembly of the actin-containing microfilaments, while infection with polio- and reoviruses causes an alteration and reorganization of the virimentin-containing intermediate filaments of the cytoskeleton. Microtubules, another element of the cytoskeleton, are depolymerized following infection with herpes simplex virus 1 (HSV-1), canine distemper virus and frog virus-3. It has been reported that infection with VSV causes a sequential disassembly of all three filament

components of the cytoskeleton. The mechanisms by which virus infections disrupt the cytoskeleton are not known and it is not clear whether these morphologic changes are a direct effect of some virus product or a secondary consequence of some other aspect of virus-induced cytopathology. It is interesting to note that in normal cells polyribosomes are closely associated with the cytoskeleton, and on the basis of this association it is possible to speculate that some of the effects of virus infection on the host translational apparatus may be caused by virus-induced changes in the integrity of the cytoskeleton.

Viruses also use the structural elements of the cytoskeleton as the work benches for virion assembly and for transport of viral products within the cell. Examples of this function of the cytoskeleton include adenoviruses which appear to use the microtubules for movement within the infected cell; Newcastle disease virus, the viral products of which are associated with actin filaments; and reoviruses which produce inclusion bodies found in association with microtubules and are the site of viral RNA synthesis and virion assembly. It has also been suggested that, in VSV infections, assembly of nucleocapsids occurs in close association with the cytoskeleton.

Inclusion bodies

Another commonly recognized form of virus-induced alteration of the infected host cell is the formation of intracellular masses called inclusion bodies. It should be noted that at the beginning of this century the discovery of a characteristic cytoplasmic inclusion, the Negri body, in cells infected with rabies virus provided an effective diagnostic test for this disease. Depending upon the virus, these intracellular masses may consist of either virions or unassembled viral products. Inclusion bodies may occur in the cytoplasm, as in cells infected with pox-, paramyxo-, orthomyo-, reo-, rubella or rabies viruses, or may be found in the nucleus in cells infected with adeno- and herpesviruses.

Transformation of host cells

In addition to producing various forms of cell destruction, some families of animal viruses are capable of inducing cell transformation. In most cases, transformation is associated with integration of the viral genome into the host cell DNA or maintenance of viral DNA in an episomal state. Only one family of RNA viruses, the retroviruses, is capable of transforming cells. This family of viruses induces transformation through the action of a variety of oncogenes that are cellular in origin and that are not part of or necessary to the virus replicative cycle. There are several families of DNA viruses that are the cause of or are associated with tumor induction in animals and cell transformation in cultured cells. These include polyoma-, adeno-, herpes-, papilloma-, hepadna- and poxviruses. In contrast to the RNA viruses, the genes of DNA viruses responsible for transformation are viral in origin and required for virus replication.

Is It Murder or Suicide?

It is clear from the information reviewed above that the mechanisms responsible for cell death following virus infection have not been clearly defined. Perhaps the reason it has been so difficult to explain how viruses kill cells is that they do not do this directly. An alternative to a direct cell killing is the induction by viruses of a suicide function in infected cells. It would be advantageous for a cell, as part of a metazoan, to induce an apoptosis-like function in response to viral infection rather than to continue on as a factory producing a constant stream of progeny virus. Some recent evidence has appeared that lends support to this possibility. The cytopathic effect of human immunodeficiency virus (HIV) infection has been associated with apoptosis; and in another report, a noncytopathic latent infection of B cells with Epstein–Barr virus (EBV) has been associated with an inhibition of the apoptosis function. In this connection, it is interesting to note that latent infection with EBV blocks the killing of B cells by VSV with little or no effect on the replicative ability of this RNA virus. These observations provide some basis for suggesting that virus-associated cell killing may involve the induction of apoptosis or some other suicide function in the infected cell.

Resistance of Cells to Virus Infection

The major determining factor of the susceptibility of a cell to a particular virus is the ability of the viral attachment proteins to recognize and interact with specific receptors on the cell surface. In many cases, cells are resistant to infection by a particular virus simply because of the lack of appropriate surface receptors. A dramatic example of this type of resistance is seen when chicken fibroblast cells, which lack specific receptor molecules on their plasma membranes, are exposed to poliovirus. Infection does not take place because the viruses cannot adsorb to the cell membrane. However, the avian cells are fully able to support the growth of poliovirus if transfected with the virion RNA rather than infected with intact virions. In addition to cell surface viral receptors, the host range of some viruses can be determined by other

factors such as host cell transcriptional regulators. There is evidence that suggests that viruses from the herpes-, polyoma-, retro- and hepadnavirus families can replicate only in cells that express the appropriate factors that permit recognition of the viral enhancers.

Although viruses have an adaptive advantage in terms of genetic plasticity, cells are not totally powerless to mount a defensive response to viral infection. The best characterized defense that cells have evolved for protection against viral infection is the interferon system. The interferon family of proteins that is produced in response to viral infection promotes the development of an antiviral state through the induction of a second group of proteins. Two of these proteins, the 2′-5′ A synthetase and the protein kinase, have been well characterized and evidence has accumulated that demonstrates their role in the development of the interferon-mediated antiviral state. Perhaps the best evidence to suggest that these proteins are actually involved in the interferon-induced antiviral state comes from the fact that several families of viruses have evolved factors that are capable of blocking the activity of the 2′-5′ A synthetase (herpes- and poxviruses) and the protein kinase (herpes-, pox-, adeno-, reo- and orthomyxoviruses).

Viruses as Tools for Probing the Host Cell

Many of the crucial discoveries concerning cellular processes were offshoots of investigations into the replication cycle of viruses or derived from the use of viruses as model systems. This is particularly true for understanding the mechanisms involved in gene expression. It is apparent that all viruses must use the host cell translational apparatus for the synthesis of viral proteins and that many DNA viruses depend on the host transcriptional and DNA replication machinery as well. Consequently, investigation of the intricacies of viral gene expression has led to the discovery of nearly all identified host factors involved in host genome replication, RNA splicing, enhancer sequences, the scanning model for the initiation of protein synthesis, the use of translational frameshifting for gene expression, and the manner in which proteins are targeted within the cell. This list, which is far from exhaustive, will surely be expanded in the future.

It would be difficult to overestimate the impact of the study of tumor viruses on our understanding of the mechanisms involved in transformation and the nature of the cancer cell. In spite of the fact that most naturally occurring cancers of humans and animals are not caused by viruses, investigation of transforming viruses, and retroviruses in particular, has led to an understanding of the major mechanisms and cellular genes responsible for transformation. A detailed review of this subject can be found elsewhere in this volume.

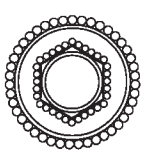
VISNA-MAEDI VIRUSES (*RETROVIRIDAE*)



Opendra Narayan, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

History

Visna and maedi are Icelandic terms for two sheep diseases characterized by wasting paralysis and progressive labored breathing respectively. These diseases broke out in epizootic proportions among Icelandic sheep following introduction of European sheep into the local flocks. The newly introduced

Karakul rams had gone through a long pre-importation quarantine period and had come from flocks with no history of the type of disease that broke out in Iceland. These animals were intended to provide a new gene pool for native Icelandic animals which had been maintained in isolation on the island for several centuries. The new diseases spread rapidly among the Icelandic sheep, involving as many as 50% of the animals in some flocks. Maedi was the predominant disease with visna occurring mainly as a complication. The disease complex was finally eradicated from the islands during the 1960s by slaughter of all sheep on the farms that had affected animals. The farms were then restocked with sheep from other parts of the island that had had no contact with the foreign sheep or local sheep with the disease syndromes. Virus obtained from sick animals was the origin of the prototype visna-maedi virus. In 1974, a virus genetically and serologically related to visna-maedi virus was obtained from goats affected with arthritis and encephalitis in Washington State. This virus was named caprine arthritis encephalitis virus (CAEV).

Clinical and Pathological Criteria

Clinical signs of visna are gradual weight loss and gradual weakening of the hind legs followed by ataxia. These signs progress slowly during a period of months to cachexia and paralysis of the hindlimbs. Rarely, forelimbs are also involved in the paralytic syndrome. Signs of maedi are characterized by weight loss, labored breathing, a dry cough and inability to keep up with the rest of the flock. Both of these diseases occur in adult animals, 2–3 years old, and the disease syndromes last 6–8 months. Arthritis synovitis also occurs in some sheep and is the hallmark of the infection in goats. Similar to visna-maedi, this disease appears in adult life of the animals. Clinically, signs of swelling of the carpal joints ('knees') appear first and this progresses to arthritis and eventual lameness. The encephalitis in goats is confined to kids and becomes apparent a few weeks after birth. This progresses to paralysis and eventually death. In all cases, the animals have normal blood counts. They do not develop fever and all have normal appetites. They do not succumb to opportunistic infections.

Pathology

Histologically, all of the lesions in sheep and goats are characterized by infiltration and proliferation of mononuclear cells consisting of macrophages, B lymphocytes and T lymphocytes in the affected tissues. In the brain, this inflammation is accompanied by demyelination and necrotizing changes in the neural parenchyma. In the lungs, these mononuclear cells infiltrate into the interalveolar interstitial areas of the lung causing consolidation of the organ and physical obliteration of the alveoli. The arthritis consists of thickening and infiltration of mononuclear cells into the synovial lining of the joint and accumulation of large amounts of synovial fluid. This is followed later by degeneration and calcification of the articular facets of the joint and eventually degeneration in the bone. Massive lymphadenopathy accompanies these organ-specific diseases.

There are only a few reports of visna from other parts of the world but pulmonary lesions in sheep similar to maedi had been described previously in the USA and subsequently in several other countries except Australia and New Zealand. In the Netherlands the disease was called Zwoegerziekte, in South Africa, Graaf Reinet, in France, La Bouhite, in the USA, Montana lung disease and/or progressive pneumonia, etc. This provides a clear indication at the pathological level that visna-maedi viruses are present in sheep throughout the world. Modern diagnostic procedures have confirmed this, but unlike the experience in Iceland, the disease in most sheep populations occurs mainly sporadically and usually only in adult animals. The caprine disease complex has also been reported in most of the industrialized countries of the world, including New Zealand and Australia. The infection is rare in most underdeveloped countries where herds are small and isolated.

Host Range and Epizootiology

Visna-maedi virus replicates best in sheep and CAEV in goats. However, reciprocal infection has been documented. Further, some strains of ovine virus such as those found in the USA are biologically more similar to CAEV than Icelandic visna-maedi virus. These viruses are infectious for other small ruminant animal species. Such cross-over infections have been documented in zoos. The viruses are spread mainly by colostrum, milk and respiratory exudates. Under field conditions, viral transmission from mother to offspring is very efficient but localized unless the milk is used for feeding other animals. Virus is also disseminated by poor management practices and this has led to local epizootics. A high rate of transmission occurs in poorly ventilated barns during winter months and this is exacerbated further during intercurrent respiratory infections (caused by other agents) that cause increased production of respiratory exudates. Minimal spread occurs during summer months while animals are on pasture. Infected macrophages in colostrum milk and respiratory exudates are a source of the infection. Intercurrent mastitis causes

increased numbers of infected macrophages in the milk and this increases the efficiency of transmission. The major mechanism of dissemination of CAEV has been the dairy husbandry practice by which all kids were fed pooled milk. This guaranteed infection in all kids when only a single infected lactating female may have been present in the herd.

Taxonomy and Classification

By the early 1960s, Icelandic investigators had established that the visna-maedi syndrome was caused by a new virus which replicated productively in stationary ovine cell cultures and caused acute cytopathic effects characterized by fusion of the cells into multinucleated giant cells. Paradoxically, sheep inoculated with the virus at that time remained clinically well for several months. Onset of clinical disease occurred insidiously and progressed slowly but inexorably, leading to death. These findings led to the definition of the viruses as 'slow viruses', the forerunner of the present term, lentiviruses. CAEV had similar biological properties. Some 10 years after the discovery of reverse transcriptase in retroviruses by Temin and Baltimore, the ovine and caprine viruses were both shown to be retroviruses. As lenti-retroviruses, these new agents were distinct from the oncogenic retroviruses which require dividing cells for replication and the oncogenic and transforming properties of which are associated with defective helper virus-dependent replication. The viruses also differ from spuma retroviruses which are not associated with disease. This new ungulate lentivirus, visna, was shown to share similar genetic and biological properties with the lentiviruses of horses, cattle, cats, macaques and humans. Its genome has approximately 9.5 kb of nucleotide sequences and its reverse transcriptase enzyme requires Mg^{2+} instead of Mn^{2+} to catalyze transcription of viral RNA to DNA. In addition to the long terminal repeat (LTR)-gag-pol-env-LTR arrangement of the proviral DNA of retroviruses, visna virus and other lentiviruses also have open reading frames that encode regulatory genes important for replication of the virus. *Tat* and *rev* are examples of these genes.

Variability

The lentiviruses of sheep are genetically and biologically highly heterogeneous. The high mutation rate of the virus has been attributed in part to mistake-prone reverse transcription of viral RNA to DNA. The high mutation rate may be more apparent than real, however, because many mutations in the *env* gene of the virus are viable and viruses with distinct biological properties can be selected by various host systems. Mutant viruses with slow and fast replication rates have been selected by various tissues. Virus-neutralizing antibodies select for neutralization-escape variants (antigenic drift viruses) and macrophages in various tissues such as the brain, lung, synovium and mammary glands select for specific viral phenotypes that replicate optimally in these tissues.

Immune Responses

The envelope proteins of the lentivirus elicit biological responses of greatest importance in the infection. Neutralization epitopes in the envelope consist of either linear peptides or conformational structures and induce antibodies that inhibit replication of the virus. Other epitopes in the viral envelope induce antibodies that bind viral particles but do not neutralize infectivity. These antibodies thus bind to viral particles and enhance entry into target macrophages by Fc receptor-mediated endocytosis. Such antibodies comprise the so-called enhancing antibodies. Cytotoxic CD8 T lymphocytes are also induced by the virus. While these cells, along with neutralizing antibodies, probably lower the virus load *in vivo*, they are incapable of curing the infection, because the virus usually persists for the lifetime of the animal. Part of the failure of the immune responses to eliminate the virus may be due to the integrated unexpressed viral genome in precursor cells in the animal.

Cell Biology and Pathogenesis

The main cell type that supports visna replication *in vivo* is the macrophage-lineage cell, and virus-laden macrophages can be found in all tissues with lesions such as the encephalitic brain, the pneumonic lung, the arthritic joint and mastitic mammary gland. Intense viral replication in local macrophage populations along with local overproduction of cytokines lead to worsening of the inflammatory lesion and more viral replication. Hence, the progressive nature of the lesion and the disease. In animals with organ-specific disease, there is also a high level of infection in precursor cells in bone marrow and in dendritic cells in the blood. In subclinically infected animals that do not have organ-specific lesions, the virus is found at a low rate in the bone marrow and in rare cells in blood but not in tissues. Factors causing the upregulation of viral replication in specific macrophages in tissues have not yet been identified. Studies on viral replication in monocytes (immature macrophages) and in mature macrophages have shown that the viral life

cycle is incomplete in the monocytes and mature viral particle formation occurs only in the mature macrophages. The linkage between the life cycle of the virus to that of the cell is probably due in part to the requirement for DNA binding proteins c-Fos and c-Jun (present only in mature cells) to activate viral transcription in the virus LTR. The LTR of the proviral DNA has AP-1 and AP-4 sites which specifically interact with these proteins in mature cells and result in increased transcription of viral RNA. Linkage of the viral life cycle to the physiology of the macrophage as the cell begins its life cycle in the bone marrow and ends in the tissues has relevance in both the disease state in the animals and the mechanism of transmission of the virus in body fluids to other animals.

Prevention and Control

The most effective mechanism for control of lentiviruses in sheep and goats has been the prevention of infection. This has been achieved by removal of infected animals and their young from flocks, prevention of consumption of colostrum and correction of management practices that facilitate enhancement of the spread of virus in respiratory exudates and milk. The sexual route is not a major mechanism for transmission of these viruses. Lentivirus proteins are poor at inducing protective immunity, and such mechanisms have not been investigated thoroughly.

Future Perspectives

These viruses are agricultural pathogens with effects that are in general too subtle to grasp the attention of regulatory agencies. They provide excellent models of human immunodeficiency virus (HIV) infection since they represent an example of natural lentivirus infection in which the host usually wins the battle. More studies in the future may be directed to investigations on mechanisms by which these hosts keep their viruses in check and mechanisms by which virulent strains of these viruses cause disease.

W

WAIKAVIRUSES (*SEQUIVIRIDAE*)

Donald T. Gordon, The Ohio State University, Wooster, Ohio, USA

History

Maize chlorotic dwarf was first recognized in the early 1960s in the southeastern USA. Initially, the disease was thought to be incited by the maize dwarf mosaic potyvirus, and in the late 1960s by the Ohio corn stunt agent (CSA-OH). The maize chlorotic dwarf virus (MCDV) was initially characterized in 1972. MCDV and CSA-OH were subsequently shown to be identical. MCDV infections were also frequently associated with symptoms of another similar disease, the Mississippi corn stunt.

Tungro, Philippine for 'degenerated growth', was similarly first recognized in the early 1960s. It was observed at the International Rice Research Institute (IRRI) in the Philippines. The disease was known by other names in countries of South and Southeast Asia and as early as 1859 in Indonesia. Initially, spherical or isometric particles, 30 nm in diameter, were associated with the tungro disease and the virus was named rice tungro virus (RTV). Later, small bacilliform virus particles were also associated with the disease and both spherical and bacilliform particles were observed frequently in rice (*Oryza sativa*) plants expressing tungro symptoms. The virus with the isometric particles was renamed rice tungro spherical virus (RTSV), and the second virus rice tungro bacilliform virus (RTBV). RTSV is also named rice tungro waikavirus. The rice waika disease was discovered in 1971 in southwestern Japan. Initially, the disease was known as the 'waisei' or stunting phenomenon in Japanese. In 1973, the disease became known as 'rice waika' (stunting) and the virus was named the rice waika virus (RWV). RWV is confined to Japan.

Anthriscus yellows virus (AYV) was first isolated in 1968 from *Anthriscus sylvestris*. AYV is the least agriculturally important of the waikaviruses and has been the least studied. Interest in AYV comes from its role as a helper virus in the transmission of parsnip yellow fleck *sequivirus* (PYFV). In the following sections, where nothing is known for AYV reference to the virus is omitted.

Taxonomy and Classification

The genus *Waikavirus* was approved in 1995 by the International Committee on Taxonomy of Viruses (ICTV). Previously, the genus was referred to as the maize chlorotic dwarf virus group by the ICTV (1993). Species of the *Waikavirus* include the RTSV, which is the type species, MCDV, RWV and AYV. The genus is classified in the family *Sequiviridae*. The latter is not classified at upper taxonomic levels of class and order.

The waikaviruses are differentiated from the sequiviruses, the other genus of the *Sequiviridae*, by genome organization and size with the genome of PYFV, the *Sequivirus* type species, being smaller, about 10 kb in length, and lacking a 3′ poly(A) tract. The amino acid sequences of the conserved motifs of the waikavirus polyprotein most closely resemble those of the *Comoviridae* and *Picornaviridae*, and the genome organization that of the *Picornaviridae*. The waikaviruses belong to the picornavirus superfamily.

Geographic and Seasonal Distribution

The geographical distributions of MCDV and RTSV are the western and eastern hemispheres, respectively, where they occur in temperate and subtropical regions. MCDV occurs in 18 states in the southeastern quadrant of the USA, from the east coast to eastern Texas and north to southern Missouri and the Ohio river valley and in Pennsylvania and Arizona and Mexico. MCDV occurrences are delimited by the overlapping distributions of Johnson grass (*Sorghum halepense*), the overwintering host, and the principal vector, *Graminella nigrifrons*.

Tungro, and presumably RTSV, occurs in the Philippines, Malaysia, Indonesia, Thailand, India, Bangladesh, China, Nepal, Pakistan, Sri Lanka and

Vietnam and RWV in Japan. AYV occurs in Scotland and possibly England and other northern European countries where the transmission-dependent PYFV occurs.

During the growing season, MCDV occurs in maize (*Zea mays*) and a few crop and weed grass species. Over winter, when maize is not present, the virus survives in perennial grass species, most notably in the rhizomes of Johnson grass. For RTSV seasonal occurrence is principally in rice, during the growing season, and rice stubble, ratoons and volunteer plants between rice crops. RTSV infects various weed grass species. When long rice-free periods occur between rice plantings, the virus may occur primarily in weed hosts. RWV occurs in rice and in several wild rice species during the growing season. Between seasons the virus survives in rice ratoons and in the roots of rice stubble.

Host Range and Virus Propagation

Hosts of MCDV, RTSV and RWV are species within the *Poaceae*. The principal cultivated host of MCDV is maize, in which economic yield loss occurs. Several other cultivated species including sorghum (*Sorghum bicolor*) are susceptible but no important disease caused by MCDV has been recorded for these species. The principal natural host is Johnson grass, a perennial grass species and the overwintering host of MCDV. Other perennial and grass hosts are known but have no known role in the epidemiology of the virus. Maize is the principal propagation host.

Rice is the principal host of RTSV. In addition to cultivated rice, wild rice, weed grasses and other crop plants are alternate hosts of the tungro viruses. Hosts of RWV include rice and wild rice species. Rice is the propagation host of RTSV and RWV.

Hosts of AYV are *Anthriscus sylvestris* (anthriscus), *A. cerefolium* (chervil) and *Corandrum sativium* (coriander). Coriander is the preferred propagation host.

Genetics

The genomes of MCDV and RTSV contain a large single component, single-stranded (ss), linear, positive-sense, 3′ polyadenylated RNA consisting of one major open reading frame (ORF) which encodes a large polyprotein. The latter is presumably cleaved by a self-encoded protease(s) to yield individual functional proteins, the total number of which is unknown. Further, it is not known whether the 5′ end of the genome has a 7-methylguanosine or a VPg, although a VPg is probable. The sizes of the sequenced genomes are 11 786 nt (MCDV-OH), 11 813 nt (MCDV-TN) and 12 433 nt (RTSV-PH1). The genomes of other RTSV isolates may be 253 nt shorter. The 5′ untranslated leader sequence ranges in length from 435 to 514 nt and is followed by a large ORF which encodes a polyprotein of 3342–3473 amino acids. The 5′ leader contains extensive secondary structure and multiple AUG triplets before the large ORF internal initiation AUG. Immediately downstream of the noncoding 5′ leader is P1, a putative polypeptide of *c.* 78 kDa or 644 amino acids in length. Downstream of the putative P1 protein are the encoding sequences of the capsid proteins CP2, CP3 and CP1 of MCDV or CP1, CP2 and CP3 of RTSV. Electrophoretically estimated M_rs for CP1 (MCDV) and CP3 (RTSV), which are equivalent, are 30–35 kDa; CP2 (MCDV)/CP1 (RTSV), 22.5–27.1 kDa; and CP3 (MCDV)/CP2 (RTSV), 18–24.5 kDa. The three CPs of each virus are immunologically distinct. Polyprotein sequences downstream of the structural proteins contain domains characteristic of proteins with nucleoside triphosphate (NTP) binding, picornaviral serine-like 3C protease and RNA-dependent RNA polymerase (RdRP) domains. A serine-like proteinase, with similarity to the cysteine proteinase of cowpea mosaic *comovirus*, appears to be involved in the cleavage of the individual proteins from the polyprotein. The C-terminal portion of the RTSV polyprotein is processed into a penultimate 35 kDa protease and a C-terminal 68 kDa RdRP. The protein(s) between the C-terminus of CP3 and the C-terminal protease and RdRP has not been identified but contains the NTP-binding domain. The 3′ terminal noncoding region (NCR) sequence ranges from 956 to 1240 nt in length, which is unusually long for a plant virus genome and is a distinctive characteristic of the waikavirus genome. A small ORF (ORF 1) occurs in the 5′ NCR of MCDV-TN and another (ORF 3) in the 3′ NCR. Two small ORFs (ORF 2 and 3) occur in 3′ NCR of RTSV. Subgenomic RNAs but not proteins have been detected for the RTSV small ORFs, whereas neither have been detected for MCDV-TN.

The AYV genome is a single species of RNA with an electrophoretically estimated $10\,600 \pm 70$ nt. Virions contain four electrophoretic CP species of M_rs 35.0, 28.4, 24.3 and 22.3 kDa, respectively.

Evolution

Waikaviruses appear to have an evolutionary relationship with the plant and animal picornaviruses. Waikaviruses resemble the animal picornaviruses in having: (1) a large polyadenylated unsegmented (+)-sense ssRNA genome with a 3′ poly(A) tract; (2) an isometric virion containing three similarly sized CPs;

Table 1 Predicted amino acid sequence identities between portions and the entire polyprotein of MCDV-TN and of other waikaviruses, a sequivirus and plant and animal picornaviruses

Virus	*CP1*	*CP2*	*CP3*	*NTP-binding*	*Proteinase*	*Replicase*	*Entire polyprotein*

(3) location of the CP encoding sequences upstream of the putative genome replication proteins; (4) polyprotein expression; and (5) a polyprotein processing involving a 3C-type virus-encoded protease. Preliminary comparisons of the waikavirus sequences, principally the amino acid sequences of the CP2, NTP-binding region and replicase, with those of the plant and animal picornaviruses support an evolutionary relationship. The greater similarity of the genome organization of the waikaviruses with that of the animal picornaviruses suggests a closer evolutionary relationship between the waikaviruses and the animal picornaviruses than between the latter and the other plant picornaviruses of the *Comoviridae* and *Potyviridae*. This greater similarity suggests that the waikaviruses may be more closely related to the ancestral virus of the plant picornaviruses that may have evolved from the animal picornaviruses.

Serologic Relationships and Variability

MCDV strains include the severe, white stripe (WS), type (T) or Ohio (OH), and M1. MCDV-M1 differs from MCDV-T in that its CP2 and CP3 are slightly larger. Also full, partially full and empty virus particles occur *in situ* and *in vitro* for M1, whereas for T and WS mainly full particles occur. Also, the CP1s of M1 and T show no serological relationship, whereas T and WS are serologically indistinguishable. Infection of maize by individual strains causes only mild symptoms, with M1 causing the mildest symptoms, whereas co-infection by T and M1 incites severe symptoms. MCDV-M1 and MCDV-T show a 54% sequence similarity for a corresponding region of 839 nt at the 3′ end of their genomes. Based on predicted amino acid sequences of the polyprotein, MCDV-TN has a sequence identity of 60% to MCDV-OH. It is less closely related to other picornaviruses (**Table 1**).

The waikaviruses share many characteristics with the animal picornaviruses (see Evolution). Differences include the putative P1 protein, which is larger than the leader (L) proteins of the two *Picornaviridae* genera with L proteins and which is absent for the remaining three genera. Also, MCDV and RTSV lack a CP equivalent to the *Picornaviridae* VP4.

Like MCDV, some RTSV isolates show symptomatological differences. A virulent RTSV strain from the Philippines, Vt6, readily infects rice cultivar TKM6, which is highly resistant to the IRRI strain A. RTSV isolates from India also show differences in virulence on TKM6. RTSV isolates from Thailand, Malaysia and India are serologically indistinguishable from the Philippines isolate when tested with antisera to the individual CPs of the latter. However, CP3 of the Indian RTSV isolate has a slightly higher electrophoretic mobility, which allows it to be differentiated from Southeast Asian isolates. Nucleotide and predicted amino acid sequences of part of the CP1 gene also show that Indian and Bangladeshi RTSV isolates are different from the Philippine and Malaysian isolates, suggesting the existence of two strain groups. Isolates from Thailand and Nepal may be mixtures of the two groups.

RTSV isolates also show variability in their sequences and organization in the 3′ terminus downstream of the large ORF. Significant sequence differences exist in ORF 2 of isolates from the Philippines (RTSV-PH-2), Thailand and India compared to ORF 2 of RTSV-PH-1. Also, a repeating nucleotide sequence in the 3′ NCR of RTSV-PH-1 is absent in the sequences of the other isolates. Because RTSV causes indistinct symptoms on many rice varieties and antisera to the virion or individual CPs

do not differentiate isolates, sequence analysis will be required to differentiate additional RTSV variants.

In Japan two strains of RWV occur: the common or C strain and a more virulent strain S. Since RWV or RTSV assists in the transmission of RTBV by the leafhopper *Nephotettix virescens* and symptoms incited by RWV in combination with RTBV are similar to those of the tungro virus complex (RTBV + RTSV), RWV is believed to be identical or closely related to RTSV.

Epidemiology

The epidemiology of the waikaviruses depends principally on virus and vector sources for early infections. MCDV survives winters in the USA in the rhizomes of infected Johnson grass. Its principal leafhopper vector, *G. nigrifrons*, is one of the most common leafhopper species in the eastern half of the USA and frequently the most abundant leafhopper on maize. In the southern USA, *G. nigrifrons* overwinters as adults and eggs on winter grasses, grains and grazing crops which allow survival in the absence of maize. Most of these overwintering hosts are not virus hosts. In the northern USA, where winter temperatures are probably too low for leafhopper survival, *G. nigrifrons* may be introduced at the beginning of each growing season by migration from the southern overwintering areas. *G. nigrifrons* presumably acquires MCDV from virus-infected Johnson grass early in the season and initiates the disease anew in seedling maize.

Outbreaks of tungro are unpredictable and appear suddenly over large areas, frequently followed by disease disappearance in the next season. Virus sources for these outbreaks include infected rice stubble and volunteer rice ratoons, which may act as vector sources as well, especially in asynchronously planted areas. Weed grasses generally are relatively poor virus sources. Rice nursery beds may also serve as a virus source. In single-crop areas with a long rice-free period, virus may be introduced by long distance migration of viruliferous leafhoppers from virus endemic areas and locally by leafhoppers from infected weeds in and near rice plantings. *N. virescens*, the dominant and most efficient vector, is monophagous and prefers rice, whereas the relatively inefficient *N. nigropictus* prefers weeds. In areas of overlapping rice plantings, *N. virescens* may be of greater importance in virus spread and survival, whereas in single-cropping areas, *N. nigropictus* may be important in transmitting the virus among weed hosts in fallow fields.

The primary source of RWV for leafhopper acquisition is infected rice plants, rice stubble and spring ratoons. Winter host plants of *N. cincticeps*, the principal vector, are restricted to several grass species that are not virus hosts. Since rice plants do not survive over winter in most areas of Japan where RWV occurs owing to cold temperatures, migration of *N. virescens* from the disease-free islands, where it overwinters, to the areas of virus occurrence and then to areas where the virus does not overwinter may perpetuate RWV in the latter.

Transmission and Tissue Tropism

The waikaviruses are obligately vector transmitted in nature. The principal vectors of MCDV, RTSV and RWV are the leafhopper species *G. nigrifrons, N. virescens* and *N. cincticeps*, respectively. AYV is transmitted by the aphid *Cavariella aegopodii*. These vectors acquire and inoculate the viruses following a 10–15 min to 2 h acquisition access period and a 2 min to 2 h inoculation access period, respectively, and usually lose inoculativity within up to 4 days following acquisition and always following a molt. Preacquisition starvation has no effect on transmission efficiency and there is no detectable latent period in vectors. The viruses are not transovarially transmitted in their vectors. Leafhopper nymphal instars as well as adults transmit the viruses with similar efficiencies. The virus–vector relationship is semipersistent and transmission presumably involves a virus-encoded helper component (HC) protein.

RTSV is required for transmission of RTBV, which occurs only when the leafhopper has previously or simultaneously fed on RTSV-infected plants from which it acquires the putative RTSV HC. RTSV can be transmitted independently. AYV also acts as a helper virus for the transmission of PYFV, presumably by providing an HC for the transmission of PYFV.

Vectors acquire the viruses while ingesting from phloem cells and retain the viruses at sites on the lining of the vector's foregut. The particles are surrounded by a lightly or densely staining matrix, which in turn is embedded in a lightly staining material (M material) overlying the lining of the foregut. The matrix presumably allows virus retention within the vector for transmission. The viruses are released from these sites to infect phloem cells when the vectors extravasate during subsequent phloem feeding. The viruses are mainly phloem limited in infected plants and presumably move cell-to-cell via plasmodesmata.

Pathogenicity

Maize chlorotic dwarf and rice tungro are incited by

co-infections of MCDV and RTSV plus other viruses, respectively. For maize chlorotic dwarf, the severe symptoms are caused by synergistic co-infections of MCDV-T and MCDV-M1, which individually cause mild symptoms. However, not all field occurrences of the disease involve co-infections by isolates of the two viruses, making the disease etiology problematic.

Rice tungro is caused by co-infections of RTSV and RTBV. RTBV alone causes symptoms of moderate stunting and dark green and transitory yellow-orange discoloration of leaves, whereas RTSV alone causes no conspicuous symptoms. RWV occurs alone unassociated with RTBV.

AYV may occur alone or with PYFV.

Clinical Features and Infection

The principal symptoms incited by MCDV on susceptible maize are a reduction in plant height, chlorotic clearing or banding of tertiary veins and red or yellow discoloration of upper leaves. Symptoms of plant stunting or dwarfing and red or yellow leaf discoloration are often associated with infections of maize by the corn stunt spiroplasma or maize bushy stunt phytoplasma. MCDV infections can be differentiated from infections by the latter two pathogens by the diagnostic chlorotic vein clearing or banding of tertiary veins.

RTSV incites almost no symptoms and infected plants appear green with only mild stunting. Moderately resistant cultivars may exhibit recovery from tungro symptoms incited by RTSV plus RTBV, whereas stunting and leaf discoloration persist on susceptible cultivars. Tungro symptoms may show similarity to feeding damage caused by *N. virescens*, vector of both viruses, and symptoms caused by leafhopper feeding may be mistaken for those caused by the viruses and *vice versa*. Both the tungro virus (RTSV plus RTBV) and *N. virescens* cause foliar discoloration (orange or reddish-brown), reduction in tiller numbers, plant stunting and plant death when large numbers of leafhoppers feed on rice plants during tillering. Plants recover from leafhopper- but not virus-caused stunting.

RWV causes stunting and yellowing of leaves, but symptoms are less severe than those of RTSV plus RTBV. Leaf discoloration ranges from green to yellow and is transitory, not appearing on subsequently emerging leaves. Stunting symptoms persist.

AYV is associated with no conspicuous symptoms for infections of *Anthriscus sylvestris*, its principal host, but causes stunting and reddish purple leaf discoloration on *A. cerefolium*.

Pathology and Histopathology

Waikaviruses, which have 30 nm diameter isometric particles, are mostly phloem-limited in sieve tubes, companion cells and phloem parenchyma and cause distinctive inclusions detected by both light and electron microscopy. For MCDV, these inclusions include electron-dense granular and fibrous, fibriform or striated sheet inclusions. The former resemble the currant-bun inclusions of AYV and the viroplasms of RTSV and RWV. The fibrous inclusions are unique to MCDV infections. For the M1 and WS strains of MCDV, accumulations of virus-like particles occur within the dense granular inclusions, whereas with type strain isolates most of these inclusions contain no or very few virus-like particles. Individual virus-like particles are rarely found in the surrounding cytoplasm. In maize leaf cells infected with the WS isolate, the chloroplasts are deformed; and in stunted plants doubly infected with MCDV-T and MCDV-M1, some phloem cells degenerate. Histological changes include plugging of xylem but not phloem, reduced thickness of the leaf cuticular layer, and reduction of the diameter of the sieve elements in the rachis.

In RTSV-infected cells, inclusions include amorphous X bodies and lattice or tubular structures as well as viroplasms. Viroplasms are not membrane bound and appear as masses of electron-dense bodies. Virus particles are mostly scattered in the cytoplasm or vacuoles. Small vesicles, containing fibers and occasionally RTSV particles, are found in the cytoplasm, usually along the cell wall. RWV particles present in vacuoles are often in crystalline arrays. Phloem necrosis is observed with RWV infection. AYV-infected chervil petioles show phloem cells containing clusters of isometric virus-like particles embedded in amorphous densely staining material.

Prevention and Control

The recommended control for MCDV, RTSV and RWV is the cultivation of virus-resistant or -tolerant cultivars. For MCDV, no maize hybrids are immune and only a few are highly resistant. Other means of MCDV control include early planting, herbicide eradication of Johnson grass, and leafhopper vector control using the systemic insecticide carbofuran. Of these, widespread Johnson grass eradication and vector control are effective but problematic, being costly and potentially harmful to the environment. Cultivation of resistant or tolerant hybrids in combination with Johnson grass eradication and early planting is sufficient to limit yield loss due to the virus.

While RTSV causes only mild to inconspicuous

symptoms and presumably little or no yield loss, its control is important because of its role in RTBV transmission by the leafhopper vector and in inciting the severe symptoms of tungro when co-infecting with RTBV. While control of tungro is possible by use of vector resistance, the latter has been short-lived due to its breakdown after a few seasons. Resistance in rice is available for RTSV, but not for RTBV, and can provide an effective control of tungro in large fields, as plants infected with RTBV do not serve as sources for secondary spread of the virus in the absence of RTSV. However, RTSV resistance may be ineffective in small plots where high numbers of viruliferous vectors migrate from neighboring fields. Other means of tungro control include: (1) eradication of rice stubble and volunteer seedlings; (2) early transplanting; (3) large scale synchronous rice planting followed by a sustained fallow period; and (4) application of insecticides, especially carbofuran, for vector control. Control of RWV involves use of insecticides and cultivation of resistant varieties.

Future Perspectives

To complete knowledge of the waikavirus genome organization and protein functions, determination of the function(s) and the numbers and sizes of proteins is needed for the following portions of the polyprotein: the putative P1 protein downstream of the 5′ leader sequence and the sequences downstream of the structural proteins which contain an NTP-binding domain. Information is also needed on whether an RTSV-like C-terminal protease and RdRP are also present in the C-terminus of the MCDV polyprotein. Also, it is not known whether the cysteine-like C-terminal protease alone cleaves the viral polyproteins to release all the functional proteins. Functions are also unknown for the unusually long 5′- and 3′-terminal NCR and the small ORFs of the terminal NCRs of several waikavirus genomes. The designations of the three CPs (CP1, CP2 and CP3) need to be uniform among the waikaviruses. Finally, the relationship of the encapsidated small RNAs, found in slower sedimenting particles of some waikaviruses, to their associated viruses is unresolved.

Among the unresolved taxonomic questions is the relationship between MCDV-OH and MCDV-TN, which seem sufficiently distinct based on sequence identities to consider them as distinct waikaviruses. MCDV-M1 may also be a distinct species, but the similarity of its sequence to that of MCDV-TN is unknown. Also, nucleotide sequence information for the RWV genome would resolve its relationship with RTSV.

Other matters concerning the waikaviruses in need of demonstration are the HC protein, the role of MCDV-OH and -M1 in inciting the severe symptoms of maize chlorotic dwarf, and biological differences among waikavirus isolates differentiated by sequence and sometimes serological characteristics.

Finally, several characteristics of AYV raise the question of whether it is properly classified as a waikavirus. These characteristics are its apparent smaller genome, the presence of four rather than three CP species, an aphid rather than a leafhopper vector, and a dicot rather than monocot host range. The sequence of the AYV genome is needed to resolve this question.

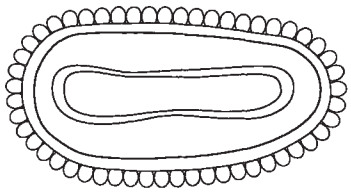
Y

YABAPOX AND TANAPOX VIRUSES (*POXVIRIDAE*)



HA Rouhandeh, Torrey Pines Cancer/Aids Research Institute, San Diego, California, USA

History

The disease produced by Yabapox virus is characterized by formation of tumors that regress slowly. The disease was first observed in 1958 in captive Rhesus monkeys housed in open pens in Yaba, Nigeria. At first the disease was confined to Asian monkeys and one baboon. Later one species of African monkey (*Cercopithecus aethiops tantalus*) became infected with the virus. In 1969 a spontaneous outbreak of the disease occurred in monkeys housed in Roswell Park Memorial Institute in Buffalo, New York. Infection of a laboratory worker reported in 1963 showed the virus to be pathogenic for humans.

The disease produced by Tanapox virus is characterized by a mild febrile illness in humans with one or two pock-like lesions developing on the upper part of the body. Two outbreaks occurred in 1957 and 1962 among the indigenous population living in the Tana River Valley in Kenya. In 1966 outbreaks occurred in monkey colonies in the USA and in humans having contact with the animals. Although Tanapox virus was first isolated from humans during an outbreak of the disease, it, like Yabapox virus, primarily causes a disease of macaque monkeys.

Taxonomy and Classification

The International Committee for Taxonomy of Viruses (ICTV) has proposed a classification of *Yatapoxviruses* as the genus name for Yabapox virus and Tanapox virus (as well as Yabavirus-like disease) within the *Poxviridae*.

Evolution

Both Tanapox and Yabapox viruses have been identified within the last 40 years. As far as is known, both viruses originated in monkeys. Human infections of Tanapox are believed to have originated from monkeys through the mosquito as a vector.

Properties of the Virion

Yabapox virus measures 250–280 μm in the long axis. The surface consists of thread-like structures which are randomly formed around the viral particle. Both Yabapox and Tanapox viruses are symmetrical and dumbbell-shaped; both contain a core with lateral bodies in the concavities and a double lipoprotein bilayer envelope comparable to other poxviruses.

Properties of the Genome

Yabapox and Tanapox viruses contain linear double-stranded DNA; the number of segments of 3′ terminal poly(A) tracts present or absent is presently unknown for these viruses. The size of both DNAs is estimated to be approximately 145 kbp with a molecular mass of 119×10^3 kD. The G+C content is $32.5 \pm 0.5\%$.

Properties of Virus Proteins

Tanapox virus contains approximately 55 proteins ranging in size from about 200 to 11 kDa. Yabapox virus contains approximately 44 proteins of which 21 are core-associated, ranging in molecular mass from 220 to 10 kDa. Four enzymatic activities have been identified with purified Yaba virions: DNase with pH optimum at 5.0; DNase with pH optimum at 7.8; RNA polymerase; and nucleotide phosphohydrolase.

Physical Properties

Yabapox viral DNA has a density of 1.6905 g ml^{-1} in CsCl and its T_m value in 0.015 M citrate in saline is 82.3°C.

Replication of Yabapox Virus

Nucleic acid

Viral DNA is detected 3 h after infection. At 6 h postinfection 7–10S RNA is detected which increases in amount after 12 h. At 24 h after infection, 14–15S RNA as well as 7–10S RNA is detected. The first and largest peak of mRNA synthesis occurs between 11 and 12 h postinfection and a second slightly smaller peak occurs between 21 and 23 h after infection. Late in the infection cycle, viral DNA is present in the host cell nucleus.

Protein synthesis

Yabapox viral proteins are synthesized at different times after infection and can be grouped into two classes, early and late. Early proteins are synthesized before the onset of viral DNA replication (3 h postinfection). Some of the proteins in this group are structural and continue to be synthesized in the presence of DNA inhibitor. Late viral proteins are detected at 6 h postinfection and continue to increase in number during the infection period. Viral infection does not inhibit host protein synthesis.

Virus synthesis

Yabapox virus is synthesized in the cytoplasm. At 35°C, the minimum length of replicative cycle is 35 h; however, maximum virus yields are not obtained until 75 h postinfection. Synthesis of at least two viral structural antigens occurs in the presence of the DNA inhibitor, cytosine arabinofuranoside, indicating potential transcription and translation of these antigens from parental DNA. The first progeny DNA is completed after 20 h postinfection, but is not detected in infectious form until 35 h postinfection. The maximum rate of progeny DNA synthesis occurs between 20 and 30 h postinfection. Viral DNA synthesis continues until 45–50 h after infection.

Morphogenesis

Within 3 h postinfection, the adsorption and phagocytosis of Yabapox virus particles by the cells can be seen by electron microscopy. This is followed by the disruption of the phagocytic vacuole membrane, with the release of viral DNA into the cytoplasm. At 24 h postinfection, large cytoplasmic inclusions termed 'factories' are observed. A typical factory contains a large number of viral particles, particulate glycogen, DNA-containing electron dense material, and small membranous spherical structures (40 nm in diameter) designated as 'micelles'.

Transformation

Various cell lines of monkey kidney cells have been transformed with UV-irradiated Yabapox virus. Two different cloned restriction enzyme fragments can also transform CV-1 monkey kidney cells. Transformed cells do not produce virus but exhibit biological characteristics typical of transformed cells. These include increased saturation density, reduced serum requirements for growth, and ability to grow in soft agar. The morphological alterations of transformed cells are similar to Yabapox virus-induced tumor cells and are characterized by loss of contact inhibition, multinucleated cells, and cytoplasmic lipid droplets. Southern blot hybridization showed that sequences homologous to low molecular weight viral DNA (5.1, 4.8 and 3.9 kbp) are present in transformed cells. Virus-specific antigens detected by immunofluorescence assays are found in the cytoplasm of transformed cells. Four virus-specific proteins, with molecular masses of 160, 140, 108 and 74 kD, are contained in transformed cells immunoprecipitated with sera from tumor-bearing monkeys.

Serological Relationships and Variability

Serologically Tanapox and Yabapox viruses show minimal to moderate cross-reactivity. The presence of type-common and type-specific antigens has been demonstrated. Yabapox viral infection fully protects primates against Tanapox virus challenges. In monkeys infected with Tanapox virus then challenged with Yabapox virus, symptoms were delayed in developing, and histiocytomas were smaller.

Complement fixing (CF) and complement fixing inhibiting (CFI) antibodies were demonstrated in the clinical and convalescent stages, respectively, of Rhesus monkeys infected with either Tanapox or Yabapox viruses. The persistence of CF antibody in monkeys infected with Tanapox virus is from 10 to 12 weeks; in monkeys infected with Yabapox virus CF antibody persists up to 35 weeks postinfection.

Epidemiology

The epidemiology of Tanapox virus is believed to be a reservoir of monkeys in the wild in Kenya from which the natives of the Tana River Valley are occasionally infected as a result of mosquito transmission of the virus. An outbreak occurred in monkey colonies in California, Oregon and Texas in 1965 and 1966 and spread to men in contact with the housed diseased animals. Tanapox of man is essentially a zoonosis. Yabapox is believed to be epidemic in scope in African and Asian monkeys. Infection in man occurs only through injection of the virus.

Transmission and Tissue Tropism

Yabapox and Tanapox viruses are both believed to be transmitted by insect vectors. Yabapox virus transforms fibrocytes of the dermis and subcutaneous cells to pleomorphic polygonal cells. The histiocyte gives rise to the tumor. In monkeys inoculated with Yabapox virus, histiocytes migrate into the infected area by 48 h postinoculation. After 3–5 days, the histiocytes undergo striking morphologic alterations and proliferate rapidly, leading to tumor formation. Intravenous inoculation results in many tumors in the heart, lungs, muscles and subcutaneous tissues of susceptible monkeys.

Tanapox viral infection is histiologically distinct from Yabapox. It affects the epidermis almost exclusively, resulting in hypertrophy and thickening of the epithelial layers of the skin with swelling and ballooning of the deeper epithelial cells; there is little cellular infiltration into the underlying dermis.

Pathogenicity

Because of the lack of studies on the prevalence of either Yabapox or Tanapox disease in the population of monkeys in the wild, little is know about pathogenicity. However, both viruses are of low pathogenicity in housed monkey populations. Pathogenicity from monkeys to humans is probably nonexistent in the case of both viruses in that each depends upon a vector or artificial means of transmission.

Clinical Features of Infection

In humans, Tanapox starts with a short febrile illness lasting 3–4 days and sometimes a severe headache, backache and pronounced prostration also occur. During the course of the febrile illness, one or two pock-like lesions appear on the upper part of the body, usually on the upper arm, face, neck and trunk. The lesion resembles a modified smallpox lesion in a vaccinated individual, except there is no pustulation in the Tanapox lesion. The illness is nonfatal and of short duration.

In monkeys, Yabapox is characterized by tumors on the hairless areas of the face, on the palms and interdigital areas and on the mucosal surfaces of the nostrils, sinuses, lips and palate. The benign tumors develop 5 days after inoculation, grow to 25–45 mm in diameter and project up to 25 mm in diameter. Tumor growth proceeds steadily, reaching a maximum in 6 weeks, after which regression occurs and is completed by 12 weeks postinoculation.

Pathology and Histopathology

In Yabapox infection tumor cells which develop are characterized by the appearance of multinucleated cells, cytoplasmic granulation, nuclear enlargement, nucleolar hypertrophy and the formulation of numerous lipid vacuoles in the cytoplasm. Granular inclusions in the cytoplasm stain positively for DNA with acridine orange.

Tanapox virus infection is characterized by hypertrophy and thickening of the epithelial layers with swelling and ballooning of the deeper epithelial cells, which show vacuolation of cell nuclei and eosinophilic cytoplasmic inclusions.

Immune Response

In Yabapox, circulating neutralizing antibody is ineffective in preventing growth of established tumors. Immunity to superinfection is present when tumors are present or regressing, but after total regression of tumors, re-infection results in new tumor formation.

In Tanapox infection immunity persists in monkeys for at least nine months following healing of the skin lesions.

Prevention and Control

Prevention of Tanapox in the human population is thought to be controllable by controlling the mosquito population and avoidance of mosquito-infested areas where the disease is epidemic in monkeys. Control of both diseases in housed monkeys has been accomplished by control of insects and by strict isolation of infected animals.

Future Perspectives

The control of Tanapox in the human population presents a serious problem because of the highly isolated and rare epidemiology of the disease and its non-serious nature. More studies of wild monkey populations where the disease is epidemic are needed in order to determine for certain how the disease is spread. If both diseases are spread by mosquitoes as postulated, complete control is unlikely to be achieved.

YEAST RNA VIRUSES (*TOTIVIRIDAE*)

Lionel Benard, Herman Edskes, Juan Carlos Ribas and **Reed B Wickner**, Laboratory of Biochemistry and Genetics, National Institutes of Health, Bethesda, Maryland, USA

History

Some strains of the yeast *Saccharomyces cerevisiae* secrete a protein toxin that kills other strains, but to which the secreting strain is itself immune. Toxin production ability is inherited as a non-mendelian trait. This finding (in 1963) by Makower and Bevan led to the discovery of viral particles containing various double-stranded RNAs (dsRNAs), one of which, called M, was correlated with the killer phenomenon. Studies of this area have taken two directions, one concerned with the virology of the system, and the other with the processing, secretion and action of the toxin and the mechanism of immunity.

Classification

Yeast RNA viruses belong to the genus *Totivirus* of the *Totiviridae* family. Other genera in the family are *Giardiavirus* and *Leishmaniavirus*.

Yeast RNA Replicons

Four completely distinct RNA to RNA replication systems have been found in various strains of *S. cerevisiae*: L-A and its satellites (including M), L-BC, 20S RNA and 23S RNA. The L-A and L-BC systems are encapsidated, whereas the 20S and 23S RNAs apparently replicate naked in the cells (**Table 1**). None of the viruses are known to have a natural extracellular infectious cycle, although they can be introduced into spheroplasts along with transforming DNA plasmids. All are efficiently transmitted from cell to cell by the cytoplasmic mixing that occurs on mating. Perhaps because mating is a very frequent event for yeasts in nature, these viruses are widespread and most strains have more than one. The best studied is the L-A virus (**Fig. 1**) and its satellite viruses, M_1, M_2, M_3 and M_{28}, encoding different killer toxins and immunity functions. Defective interfering deletion mutants of L-A and M_1 have been described. Yeast strains also contain at least four families of retroviruses. Recently, brome mosaic virus and flockhouse virus have been found able to replicate in yeast, a result that promises further

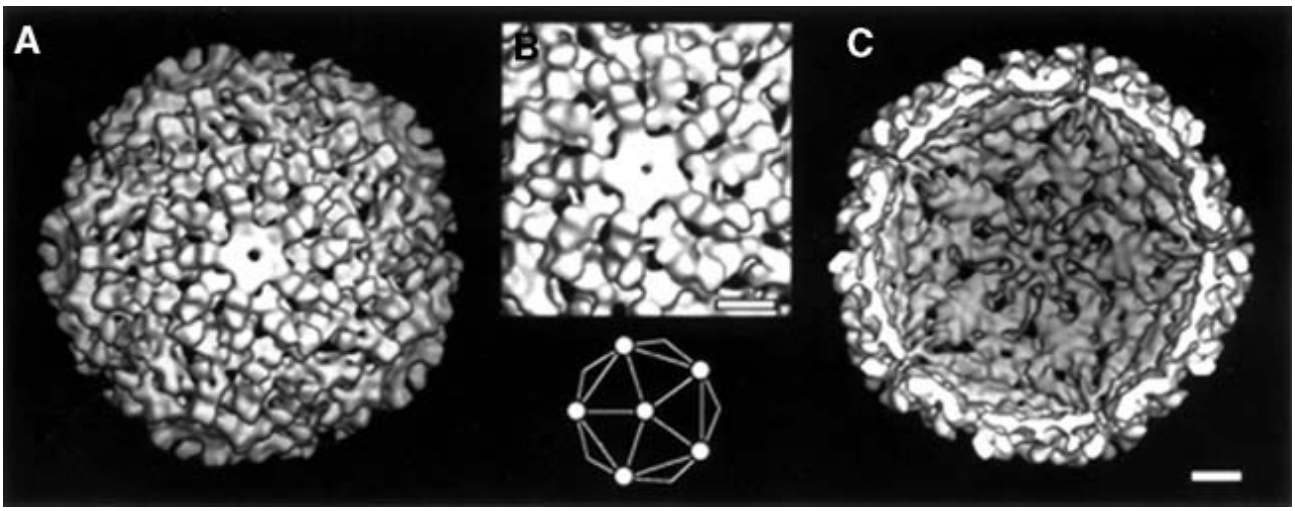

Figure 1 Cryo-electron microscopic reconstruction of L-A viral particles shows them to have icosahedral symmetry with a T=1 triangulation number. Each particle is composed of 120 Gag molecules, 60 pairs of Gag molecules with the members of a pair in two different environments. The outer (**A**, **B**) and inner (**C**) surfaces are shown at 20 Å resolution. Scale bar, 50 Å. (Reproduced with permission from Steven AC, Trus BL, Booy FP *et al* (1997) The making and breaking of symmetry in virus capsid assembly: glimpses of capsid biology from cryoelectron microscopy. *FASEB J.* 11: 733.)

widening of the scope of application of yeast studies to virology. Yeast RNA replicons are summarized in **Table 1**.

L-A Replication Cycle

L-A is a dsRNA virus that has a single 4.6 kb segment, and viral particles contain a single molecule of L-A dsRNA. The viral particles have a 76 kDa major coat protein (Gag) and a minor 170 kDa protein (Gag-Pol) whose N-terminal portion is a Gag monomer and whose C-terminal portion binds ssRNA and is the RNA polymerase. A conservative transcriptase activity of the particles produces viral plus-strands and extrudes them from the particles. The plus ssRNA is translated to form viral particle proteins (see below) and is also the species packaged to form new viral particles. These particles then make the minus-strand on the plus-strand template to form L-A dsRNA-containing particles and complete the cycle (**Fig. 2**).

Satellite viruses of L-A, such as M_1, use the L-A-encoded coat proteins. Again, a single viral plus-strand is packaged to form new particles, but after replication and transcription, the new transcripts often remain inside the viral particle where a second (or more) dsRNA molecule is formed by a second replication event. This is called 'headful replication' to distinguish it from the 'headful packaging' phenomena seen in many bacteriophages. In the case of L-A and its satellites, a single viral plus-strand is packaged and then it replicates inside the particle until the head is full. Then all new transcripts are extruded from the particle.

The *cis* signals responsible for packaging and replication have been defined on L-A (**Fig. 3**) and M_1. The packaging proteins recognize a stem–loop structure located about 400 nucleotides from the 3′ end of either L-A or M_1. The sequence of the stem is not important, only that it is a stem, but an A residue that protrudes on the 5′ side of the stem is critical, as is the loop sequence. The replication reaction requires that the template has both an internal site that largely overlaps with the packaging site (and may be identical to it) and a specific 3′-terminal sequence and structure.

The packaging of viral (+) strands involves recognition of the packaging site by residues 67–213 of the Pol domain of the Gag-Pol fusion protein. There are two copies of the fusion protein per particle.

L-A Expression: Ribosomal Frameshifting in a dsRNA Virus

L-A plus-strands encode the 76 kDa viral major coat protein (called Gag in analogy with retroviruses) and a 170 kDa Gag-Pol fusion protein, formed, as in the case of retroviruses, by a −1 ribosomal frameshift (**Fig. 3**). The structure responsible for the frameshifting is a slippery site, GGGUUUA, followed by an RNA pseudoknot, both located in the region of overlap of the *gag* and *pol* open reading frames. The efficiency of frameshifting appears to be critical for viral propagation, suggesting that the balance of Gag and Gag-Pol fusion proteins may be important in the assembly process. Since no eukaryotic cellular gene is known to use −1 ribosomal frameshifting as part of its expression strategy, these results suggest that drugs affecting this process may be useful for antiviral therapy.

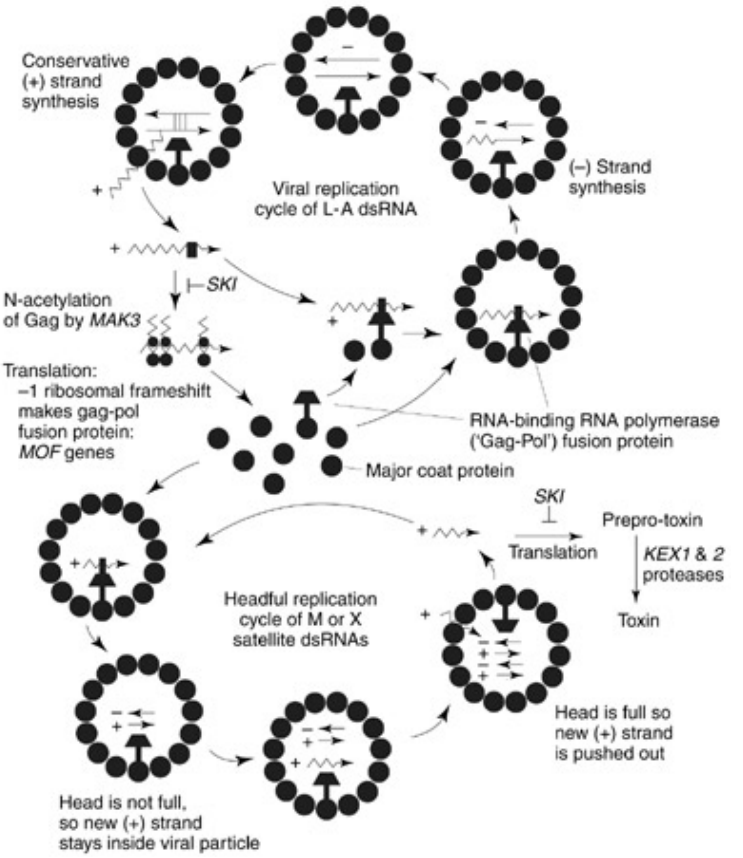

Figure 2 Replication cycles of L-A and its satellites.

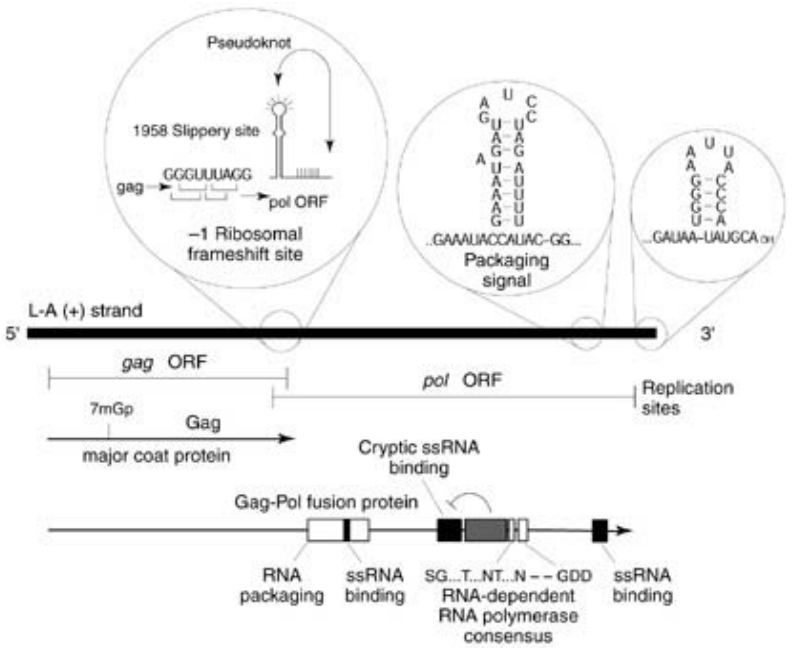

Figure 3 Expression of L-A-encoded information. The two L-A ORFs encode a chimeric RNA polymerase-RNA binding protein with a major coat protein domain. ORF 1 (Gag) is the major coat protein, whereas ORF 2 (Pol) encodes a region with the consensus sequence patterns for the RNA-dependent RNA polymerases of plus ssRNA viruses and dsRNA viruses. Pol also has three ssRNA binding domains, the N-terminal one of which is necessary for packaging viral (+) strands.

Table 2 Chromosomal genes affecting yeast RNA viruses

Gene(s)	*Encodes*	*RNA affected*	*Mechanism*
MAK3	*N*-Acetyltransferase	L-A, M	Viral assembly
*MAK*1, 7, 8, 11, 16, 18, 27, ...	60S ribosomal subunit proteins and assembly factors	L-A, M	Expression of viral poly(A)-mRNA
SKI1/XRN1	5′-exoribonuclease	L-A, M	Viral mRNA stability
*SKI*2, 3, 8	System blocking translation of nonpoly(A) mRNA	L-A, M, L-BC, 20S	Blocks viral translation
*SKI*6	3′-exoribonuclease required for 60S ribosomal subunit assembly	L-A, M	Blocks viral translation
porin, *NUC*1	Mitochondrial functions	L-A	?
*CLO*1	?	L-BC	?

The structure of the Gag-Pol fusion protein suggested a packaging mechanism for L-A in which the Pol part of the fusion protein captures a viral (+) strand and the Gag part primes polymerization of the coat by association with Gag molecules. This results in the natural packaging of one viral (+) strand per particle.

Why do L-A, retroviruses and a number of plus single-stranded (ss) RNA viruses use ribosomal frameshifting and readthrough of termination codons to make Gag-Pol and other fusion proteins? dsRNA viruses, plus ssRNA viruses and retroviruses all use their plus-strands as mRNA, as the form of the genome that is packaged to make new particles and as a template for replication. If they were to use splicing or RNA editing for the purpose of fusing open reading frames, they would be generating mutants unless the spliced out region contained a site essential for packaging or replicating the genome. Retroviruses often splice, but they remove the packaging site in so doing so that the spliced mRNAs will not be packaged. Insofar as is known, plus ssRNA viruses and dsRNA viruses do not splice, perhaps for this reason. Minus ssRNA viruses do splice and edit their RNAs.

Host Functions

Over 40 chromosomal genes affecting the propagation and expression of the L-A or M dsRNA genomes in yeast have been defined and a single gene is needed for L-BC (**Table 2**). Chromosomal (host) mutants that lose the M_1 genome are generally called *mak* mutants (for maintenance of killer). Among the 30 genes of this type are three, *MAK*3, *MAK*10 and *MAK*31, which are necessary for the propagation of L-A. *MAK*3 is now known to encode an *N*-acetyltransferase responsible for acetylating the N-terminus of the major coat protein (Gag) encoded by L-A. This acetylation appears to be necessary for the assembly of viral particles. This parallels the N-terminal myristylation necessary for proper assembly of poliovirus and proper localization of retrovirus Gag protein assembly.

Over 20 *MAK* genes encode proteins of the 60S ribosomal subunit or other factors necessary for 60S ribosomal subunit assembly. Deficiency of 60S subunits leads to loss or decreased copy number of L-A and M dsRNAs. The mechanism of this effect may be due to inefficient translation of the viral mRNA, which lacks 3′ poly(A). It has been suggested that the mRNA 3′ poly(A) structure facilitates the joining of the 60S subunit to the 40S subunit waiting at the initiator AUG. A deficiency of 60S subunits should therefore adversely affect translation of nonpoly(A) mRNAs (e.g. viral mRNA) more than the poly(A)$^+$ cellular mRNA.

Mutations of any of seven genes, called *SKI* genes (for superkiller, the phenotype of the mutants), result in elevated copy number of L-A, M, L-BC and 20S RNA (23S RNA has not been tested). *SKI*1 (= *XRN*1) encodes a 5′-exoribonuclease specific for uncapped RNAs (such as viral (+) strands) and known to be the major enzyme degrading cellular mRNAs. The L-A Gag protein can decap cellular mRNAs, probably as a means to distract the *SKI1* exoribonuclease from degrading viral mRNAs by providing other substrates to engage its attention.

Mutations in *SKI*2, 3, 6 or 8 result in derepressed translation of mRNAs lacking a 3′-poly(A) structure. It has been suggested that they act by affecting 60S ribosome biogenesis, but so far only *ski6* mutants have been proven to have altered 60S subunits. Ski3p is also known to be a nuclear protein, and Ski2p is highly homologous to a mammalian nucleolar protein. In strains carrying M dsRNA, *ski* mutants are cold-sensitive, temperature-sensitive or unable to grow at any temperature, depending on the presence of other nonchromosomal factors. The SKI system acts on L-A, M, L-BC and 20S RNA (see below), to lower their copy numbers in the cell.

A distinct system, affecting only L-A, is defined by mutations in the mitochondrial outer membrane

porin and the major mitochondrial nuclease (*NUC1*). Growth on nonfermentable carbon sources is also known to elevate the copy number of L-A, indicating that a complex relationship exists between these viruses and mitochondrial functions.

Killer Toxin Processing and Mammalian Prohormone Processing

The killer toxin is encoded by M_1 as a precursor protein which apparently gives immunity to cells carrying M_1. The toxin has two subunits which, in close analogy to insulin, are processed from the preproprotein by removal of a signal sequence and a peptide between the subunits (**Fig. 4**). This analogy with mammalian prohormone processing is more than superficial. The *kex*1 and *kex*2 mutations were originally isolated based on their inability to secrete K_1 killer toxin and the yeast α mating pheromone. The *KEX2* product was then found to be a protease cleaving specifically C-terminal pairs of basic residues, and *KEX1* is another protease that removes the two basic residues. This is just like the processing of insulin, pro-opiomelanocortin and other mammalian hormones. Indeed, using sequence information from *KEX2* or functional complementation of *kex*2 mutants, several mammalian protease genes have been isolated which are candidates for the physiological prohormone processing enzymes. Moreover, the yeast *KEX2* gene can substitute for the mammalian proteases in processing prohormones.

Toxin Action

The K_1 killer toxin must bind first to (1 → 6) β-D-glucan, a major structural component of yeast cell walls. The K_{28} toxin binds first to cell wall mannans. However, since spheroplasts remain sensitive to these toxins, there must be a receptor further downstream in the process. The K_1 toxin acts by creating proton pores in the membrane.

20S RNA Replicon and T and W dsRNA

20S RNA was discovered in 1971 as a species whose synthesis is induced when cells are transferred to the media that are used to induce meiosis and sporulation in yeast (potassium acetate medium). Subsequent studies showed that some strains were unable to produce 20S RNA under these conditions, and that there was no role for 20S RNA in sporulation. Thus, some strains that could sporulate made no 20S RNA and some that could not sporulate could make 20S RNA. It was also shown that the ability to induce 20S RNA synthesis was inherited as a non-mendelian factor.

Recently, most of 20S RNA has been cloned and

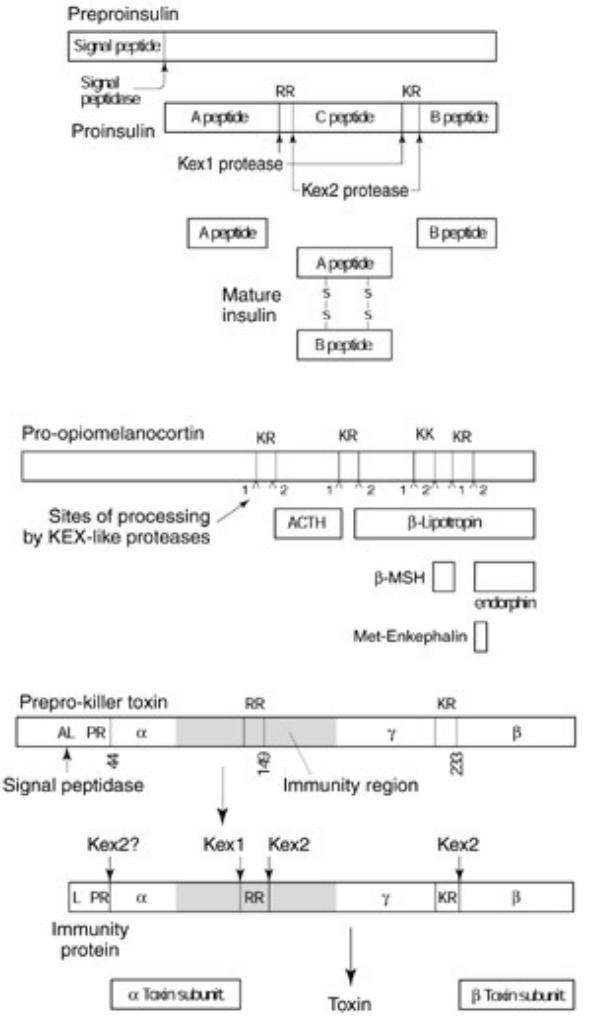

Figure 4 Preprotoxin processing resembles mammalian hormone processing. The two subunits of both insulin and killer toxin are cleaved out of their precursor hormones by Kex-like proteases. These enzymes were first discovered in the killer system and this led to their discovery in mammalian cells.

sequenced. 20S RNA is not encoded by any cellular DNA (chromosomal or otherwise). It replicates via an RNA to RNA mechanism. Electron microscopy of 20S RNA coated with T4 gene 32 protein and cross-linked with glutaraldehyde showed mostly circles, and dimer length molecules of both plus and minus polarity have also been detected *in vivo*, consistent with a rolling circle mode of replication. However, the inability to clone all the way around the 20S RNA circle suggests that either there is unusual structure at the uncloneable site, or a fundamentally linear molecule whose ends are held together by some structure. A linear structure is also indicated by biochemical experiments. At this time the structure of 20S RNA remains unclear.

Two low copy number dsRNAs, called T and W,

were described in 1984. Neither was homologous to cellular DNAs and the copy number of both was induced by growth at elevated temperatures. W was recently cloned and sequenced and was found to be identical to 20S RNA. Indeed, 20S RNA copy number is also induced at high temperature. Since the copy number of 20S RNA is always 10-fold or more that of W, W may be viewed as a replicative form of 20S RNA. Their sequence shows a single long open reading frame encoding a protein of about 90 kDa with some homology to the RNA-dependent RNA polymerases of plus-strand RNA viruses. T dsRNA encodes a similar putative RNA-dependent RNA polymerase. These proteins are found in extracts specifically associated with their respective templates, and the 20S RNA polymerase activity has actually been demonstrated *in vitro*.

Applications

Since killer strains kill nonkiller strains when cocultivated, brewing strains have been modified to include a killer virus so that strains present in the grapes (barley, hops, etc.) will not spoil the brewing process. This application is in use today. Vectors based on the toxin secretion signals have also been developed.

Future Perspectives

The ease with which yeast is manipulated genetically and the high yields of L-A virus that can be easily obtained from engineered strains have made possible extensive characterization of the genetics of this virus and its satellites and their relationship with their host. The *in vitro* replication, packaging and transcription systems were the first developed among the dsRNA viruses of eukaryotes, and few such systems have been developed for any RNA viruses. It is likely that the mechanisms found for L-A will not be unique to this system. Among the important problems to be solved are (1) development of an RNA transfection system so that the L-A virus may be used as a vector, (2) further pursuit of the mechanisms of transcription, replication and packaging and application of this information to viruses of higher systems, (3) further elucidation of the mechanisms by which the *SKI* genes control virus propagation, (4) further understanding of the role of host genes that the virus uses for its propagation, and (5) study of the role of various host components in ribosomal frameshifting and search for pharmacologic agents affecting this process – a new approach to antivirals.

The 20S RNA system (and the related T dsRNA system) have only begun to be studied. The question of the nature of the circularity of 20S RNA and the mechanism by which its propagation is controlled, including the massive 10 000-fold amplification on acetate medium, are of great interest. If it is a true circle of RNA, it is likely to self-cleave and self-ligate as do related viroid systems.

YELLOW FEVER VIRUS (*FLAVIVIRIDAE*)

Thomas P Monath, OraVax Inc., Cambridge, Massachusetts, USA

History

Yellow fever was first described as a disease entity in 1648 in Mexico. The origins of the disease are in doubt, but the susceptibility of New World – but not African – monkey species to lethal infection (suggesting contact with the virus in relatively recent times) indicates an African origin of the virus. Whether or

were described in 1984. Neither was homologous to cellular DNAs and the copy number of both was induced by growth at elevated temperatures. W was recently cloned and sequenced and was found to be identical to 20S RNA. Indeed, 20S RNA copy number is also induced at high temperature. Since the copy number of 20S RNA is always 10-fold or more that of W, W may be viewed as a replicative form of 20S RNA. Their sequence shows a single long open reading frame encoding a protein of about 90 kDa with some homology to the RNA-dependent RNA polymerases of plus-strand RNA viruses. T dsRNA encodes a similar putative RNA-dependent RNA polymerase. These proteins are found in extracts specifically associated with their respective templates, and the 20S RNA polymerase activity has actually been demonstrated *in vitro*.

The question of the nature of the circularity of 20S RNA and the mechanism by which its propagation is controlled, including the massive 10 000-fold amplification on acetate medium, are of great interest. If it is a true circle of RNA, it is likely to self-cleave and self-ligate as do related viroid systems.

YELLOW FEVER VIRUS (*FLAVIVIRIDAE*)

Thomas P Monath, OraVax Inc., Cambridge, Massachusetts, USA

History

Yellow fever was first described as a disease entity in 1648 in Mexico. The origins of the disease are in doubt, but the susceptibility of New World – but not African – monkey species to lethal infection (suggesting contact with the virus in relatively recent times) indicates an African origin of the virus. Whether or

not yellow fever in its enzootic form (transmitted between monkeys and sylvan mosquito species) predated the Spanish Conquest in tropical America, it was the slave trade that led to the introduction from Africa of the domestic mosquito vector, *Aedes aegypti* and the emergence of epidemic (urban) yellow fever. Yellow fever was one of the great scourges of mankind during the eighteenth and nineteenth centuries, with epidemics affecting coastal cities in the Americas, Europe and West Africa. The mode of spread of the disease was the subject of great debate. Mosquito transmission was suggested as early as 1848, was emphasized by the Cuban physician, Carlos Finlay in 1881, and finally was proven by Walter Reed and his colleagues in 1900. Reed *et al* also demonstrated that yellow fever was a filterable 'virus', although the etiology of the disease remained in dispute until isolation of the virus in 1927. In the decade that followed, quantitative virological and serological methods were established, allowing precise diagnostic, epidemiological and pathogenesis studies as well as the development and evaluation of live, attenuated vaccines.

Taxonomy and Classification

Yellow fever virus is the prototype member of the family *Flaviviridae*, genus *Flavivirus*, and the virus after which the family and genus were named (*flavus*, Lat. yellow). The genus consists of at least 68 viruses grouped on the basis of shared antigenic determinants and physicochemical properties (see below). The relatively specific neutralization test using polyclonal antisera has been used to distinguish at least eight antigenic complexes to which closely-related flaviviruses are assigned. Neutralization epitopes of yellow fever virus are sufficiently different from other flaviviruses to preclude assignment to a complex.

Properties of the Virion

Virions are spherical, 40–50 nm in diameter, and have short surface projections. The nucleocapsid has icosahedral symmetry, contains the RNA genome and a single core protein, and is surrounded by a lipid bilayer envelope. Approximately 66% of the virion is composed of protein, 12% carbohydrate and 17% lipid. Viral infectivity is rapidly inactivated by heat (56°C for 30 min), ultraviolet radiation and lipid detergents.

Morphogenesis of yellow fever virus occurs at intracellular (endoplasmic reticular, ER) membranes. Mature virions accumulate in these membranes, are transported to the cell surface, and released by exocytosis. Budding of virions into the lumen of the ER is rarely observed and may be an extremely rapid event. In secretory cells (such as the mosquito salivary gland and a variety of exocrine and endocrine glands infected in mammals), virion assembly occurs in concert with host cell secretory components and virions are released in secretory granules. Flavivirus infection often proceeds without markedly disturbing host cell function or macromolecular synthesis.

Properties of the Genome

The viral genome is composed of a single linear strand of infectious (positive polarity) RNA, 10 862 nucleotides in length, with a mass of 3750 kDa. The 5′ terminus has a type 1 cap, and the 3′ terminus is not polyadenylated. The GC content is 49.7%. The viral genome contains a single long open reading frame 10 233 nucleotides in length, encoding 11 viral proteins (**Fig. 1**). The remainder of the genome comprises short 5′ (118 nucleotides) and 3′ (511 nucleotides) noncoding regions. Nucleotide conservation is seen between the 5′ terminus of the plus strand and the 3′ terminus of the minus strand, serving as common recognition sequences for the viral polymerase. The 3′ terminus forms a stable hairpin loop involved in binding to the capsid protein.

Viral Proteins

The three virion structural proteins are encoded by the 5′ one-fourth of the genome, in the sequence C (capsid), prM (precursor to the mature membrane (M) protein) and E (envelope) (**Fig. 1**). The remainder of the open reading frame encodes eight nonstructural proteins, in the order illustrated. Translation begins at the 5′ terminus of the viral genome, and the individual proteins are produced after translation by a series of enzymatic cleavages. The C protein (12–14 kDa) interacts with RNA in the virion nucleocapsid; its hydrophobic C terminus anchors nucleocapsids to ER membranes, and provides signal sequence for prM. The prM glycoprotein (18–19 kDa), present intracellularly, is cleaved by a furin-like protease at the time of virus maturation to form M in the extracellular virion. The M protein spans the viral membrane, and has exposed antigenic domains that may play a minor role in the induction of protective immunity. However, the E glycoprotein (53–54 kDa) is the major surface structure and subserves many biological functions, including cell attachment, hemagglutination and neutralization. Important to these functions is the three-dimensional configuration of E protein, determined by disulfide bonding. Epitopes with strain-specific, type-specific and flavivirus group-reactive specificities are present in the E glycoprotein. As is the case for similar proteins, the C

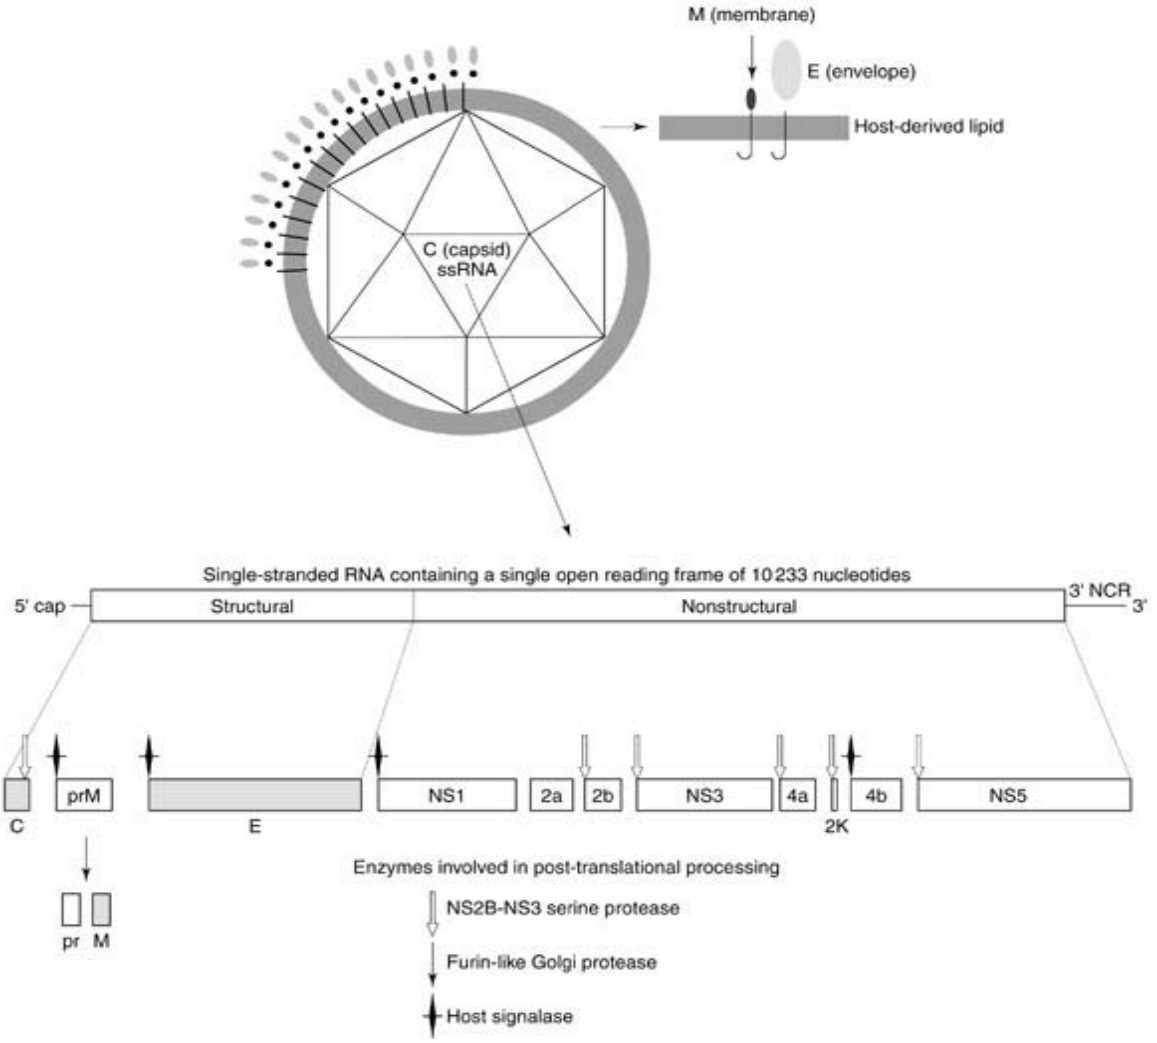

Figure 1 Yellow fever (flavivirus) virion and genome, showing the structural and nonstructural protein coding regions. The genome is characterized by type 1 5′ cap structure, followed by a short noncoding region and a long open reading frame of over 10 000 nucleotides encoding the structural (C-prM-E) and nonstructural (NS1–NS5) proteins. The genome lacks a 3′ poly(A) tail.

terminus contains hydrophobic sequences forming the protein anchor in the lipid membrane. The crystallographic structure of the E glycoprotein reveals a head-to-tail dimer composed of a 170 Å long rod anchored to the membrane at its basal end, with its long axis parallel to the virion surface. The C-terminus resembles an immunoglobulin constant domain and is connected by a flexible region to the central part of the molecule (domain I) with up-and-down topology having eight antiparallel β strands and containing the N-terminus. Two long loops (domain II) extending laterally are responsible for dimerization. A conserved stretch of 14 amino acids at the tip of one of the domain II loops constitutes the fusion domain responsible for internalization of nucleocapsids from endosomes into the cytoplasm of the infected cell. Domain III contains ligands involved in binding cell receptors. Neutralization determinants are conformational, and are scattered on the outer surface of all three flavivirus structural domains. The nonstructural NS1 glycoprotein is found both within infected cells and extracellularly (as circulating antigen with complement-fixing properties). Expressed on the cell surface, NS1 is a target for antibodies involved in clearance of virus infection. The highly conserved NS3 protein (68–70 kDa) has helicase, protease and RNA triphosphatase functions. NS5 (103–105 kDa) is the RNA polymerase. The functions of NS2A, NS2B, NS4A and NS4B are not clear.

Replication

After gaining entry to the cell, genomic, plus-strand RNA is translated and RNA replication proceeds by

Table 1 Amino acid differences between Asibi virus and attenuated 17D vaccines

Nucleotide	*Gene*	*Amino acid*	*Asibi*	*17D-204 and 17DD vaccines*
854	M	36	Leu	Phe
1127	E	52	Gly	Arg

synthesis of complementary minus strands. New plus strands are transcribed from genome-length minus-strand templates. Duplex RNA molecules (replicative forms) are thus formed in the infected cell. New genome-length plus strands serve as mRNAs for translation of structural and nonstructural proteins, as templates for transcription of new minus strands for replication, and as genomes for inclusion into nucleocapsids for production of mature virus particles.

Variation and Evolution

Nucleotide sequence analysis of the E gene revealed that yellow fever virus evolved early in the lineage of mosquito-borne flaviviruses, approximately 3000 years ago.

Yellow fever virus is distantly related to other flaviviruses by serologic tests and in terms of homology in RNA sequences. Strains of yellow fever virus from different geographic regions can be distinguished by RNA fingerprinting and are presently classified into three genotypes, one from West Africa, one from Central and East Africa, and one from South America. A high degree of homology has been noted between strains belonging to one topotype.

Molecular Basis of Virulence

The genomes of the attenuated 17D and the French neurotropic vaccines and their wild-type parents, Asibi and the French viscerotropic virus have been compared. The 17D and Asibi viruses differ at 20 amino acids, and four nucleotides in the 3′ noncoding region (**Table 1**). Because of the functional importance of the E protein in attachment and entry to cells, one or more of the seven amino acid differences that separate Asibi and the vaccine strains are likely to play a role in attenuation. The role of the E glycoprotein in neurovirulence of flaviviruses has been established by studies in which the E gene of a nonneurovirulent virus has been replaced by the corresponding gene of a virulent virus, resulting in a conversion to neurovirulent phenotype. Four of the seven amino acid differences in the E gene are nonconservative ($52^{Gly \rightarrow Arg}$; $200^{Lys \rightarrow Thr}$; $305^{Ser \rightarrow Phe}$; and $380^{Thr \rightarrow Arg}$). At least three wild yellow fever virus strains with different passage histories or geographic origins are identical at these codons, suggesting that the

mutations in 17D vaccine are in part responsible for attenuation. Residues 52 and 200 are located at the base of domain II, where mutations might affect acid-dependent conformational change in the endosome required for entry. The conservative change at position $173^{Thr \rightarrow Ile}$ corresponds to a site in tick-borne encephalitis virus at which a neutralization escape mutant had reduced neuroinvasiveness in mice. Residue 173 encodes an epitope recognized by wild-type specific monoclonal antibody and reversion at this site is correlated with the neurovirulence phenotype of a plaque variant recovered from a 17D vaccine. The non-conservative changes at E-305 and E-380 are located in domain III, which contains the determinants involved in tropism and cell attachment. Residue 305 is located on the outer surface of domain III and residue 380 is located in a highly conserved region in mosquito-borne flaviviruses implicated in cell receptor interactions. Sequence analysis of virus recovered from the brain of a 3-year-old child in the USA, who died of encephalitis following 17D immunization, revealed a mutation near the E-305 residue (at $303^{Glu \rightarrow Lys}$); the mutant had increased neurovirulence for mice and monkeys. Other studies emphasize the multigenic nature of virulence and suggest that one or more of the 10 amino acid changes in the nonstructural proteins or the changes in the 3′ noncoding region of the virus may contribute to the attenuation of 17D vaccine.

Little is known about the molecular basis of viscerotropism (the ability of wild-type yellow fever virus to replicate and damage nonneural tissue, particularly the liver), or the mutations responsible for loss of this trait in 17D vaccine. Sequence comparison of the French viscerotropic strain with that of the French neurotropic vaccine (FNV) revealed 77 (0.7%) nucleotide and 35 (1%) amino acid changes scattered throughout the genome, with the highest frequency of mutations in the C, M, E, NS2a, 2K and NS4b proteins. The large number of differences and lack of biological data on the role of these mutations preclude speculations on the genetic basis of viscerotropism. Sequence comparison of FNV with 17D vaccines (which also have attenuated viscerotropism) revealed only two shared differences from the parental and other wild-type yellow fever viruses. These common differences, which evolved during the development of vaccine strains by completely distinct processes, were at positions in the M protein ($35^{Leu \rightarrow Phe}$) and NS4b ($95^{Ile \rightarrow Met}$). It is unclear whether these mutations are involved in loss of viscerotropism.

Host Range and Virus Propagation

A highly conserved region in domain III of the E glycoprotein incorporates an RGD motif and is the probable site of virus–cell attachment. Cell membrane receptors also remain to be elucidated. Because of the broad host range of the flaviviruses, cell receptors may be molecules with conserved structure across the chordate and arthropod phyla. Yellow fever and other flaviviruses enter cells by typical receptor-mediated endocytosis.

Yellow fever virus replicates and produces cytopathic effects and plaque formation in a wide variety of cell cultures, including: primary chick and duck embryo cells; continuous porcine, hamster, rabbit and monkey kidney cell lines; and cells of human origin (e.g. HeLa, KB, Chang liver, SW-13 cells). The virus replicates in Fc-receptor bearing macrophages and macrophage cell lines, and replication is enhanced by antibody. Mosquito cell lines, especially *Ae. pseudoscutellaris* (AP-61) cells, are highly susceptible and are often used for primary isolation or efficient laboratory propagation of virus.

The most sensitive method for virus isolation and assay is the intrathoracic inoculation of mosquitoes, such as *Toxorhynchites* spp. or *Ae. aegypti*. Infected mosquitoes show no signs of illness, and the presence of virus must be demonstrated by immunofluorescence or subpassage to a susceptible host. Infant mice succumb within 6–8 days to encephalitis; at about 8 days of age, mice become resistant to lethal infection by the peripheral route, while remaining susceptible to intracerebral challenge. After parenteral virus infection, a number of subhuman primate species develop fatal hepatitis resembling the human disease. The only nonprimate species that develops lethal hepatitis in response to yellow fever infection is the European hedgehog, *Erinaceus europaeus*. Antibodies have been found in a wide variety of wild vertebrates collected in the field. Wild animals have also been experimentally infected with yellow fever virus, including rodents, bats and marsupials. With the possible exception of opossums in South America, the data do not support a role for nonprimate species in transmission cycles.

Geographic and Seasonal Distribution

Yellow fever virus presently occurs in tropical areas of South America and Africa. *Ae. aegypti*-infested regions of North and Central America, the Caribbean and southern Europe were intermittently invaded by the disease until the early part of this century and are still considered at risk, should the virus be introduced. Despite the prevalence of *Ae. aegypti* in tropical Asia, yellow fever has never reached that continent, possibly because transmission in Africa and South America occurs in relatively inaccessible areas and because crossprotection is afforded by immunity to dengue

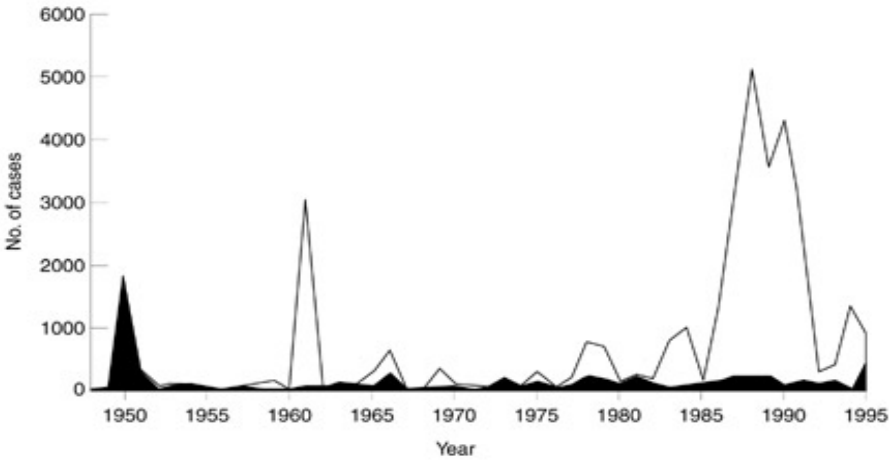

Figure 2 Officially reported incidence of yellow fever cases in South America (■) and Africa (□). The recent upsurge in incidence is due to a series of severe epidemics in Nigeria. Official reports greatly underestimate the true morbidity due to this disease.

viruses; dengue immunity is nearly universal in many parts of Asia. Asian populations of *Ae. aegypti* are relatively inefficient vectors; thus, vector competence may also provide a partial barrier to the spread of yellow fever in Asia.

The breeding of many mosquito species engaged in yellow fever transmission occurs in tree-holes and is highly dependent on rainfall. Transmission waxes during the tropical rainy season and wanes or ceases during the dry season. Breeding of the domestic mosquito, *Ae. aegypti*, occurs in manmade containers used for water storage and is thus less influenced by seasonal rainfall; where this species becomes involved in virus transmission, outbreaks may occur during the dry season.

Disease Incidence

Official notifications underestimate the true incidence of the disease by 10- to 250-fold. The number of cases officially reported annually from South America and Africa is shown in **Fig. 2**, and their geographic distribution in **Fig. 3**. The incidence in Africa has increased dramatically in recent years, due principally to a series of epidemics in Nigeria. Some epidemics in Nigeria and elsewhere in Africa have been very large, involving 100 000 or more cases, with case-fatality rates of over 20%.

Epidemiology and Transmission

Yellow fever virus is present in the blood of infected, susceptible hosts (humans and subhuman primates) for several days, during which mosquito vectors taking a blood-meal may become infected. The virus undergoes sequential replication in the midgut epithelium, body and salivary glands of the mosquito, a temperature-dependent process that takes a week or more to complete – the so-called extrinsic incubation period – before the vector is capable of transmitting virus by refeeding on a second host.

Two cycles of transmission are distinguished by the hosts and vectors involved. The urban cycle involves humans as the viremic host and *Ae. aegypti* mosquitoes, breeding in manmade containers. The forest cycle involves virus transmission between subhuman primates and tree-hole breeding mosquito vectors. The rate of transmission of yellow fever virus in the forest cycle can vary greatly, depending on the density of vectors and the available population of immunologically susceptible monkeys. In South America, some primate species succumb to fatal disease, and die-offs of these animals may provide a clue to yellow fever activity; in Africa, monkeys generally develop subclinical infections. Humans exposed in the forest to infected tree-hole mosquitoes may acquire yellow fever. In South America, this form (so-called jungle yellow fever) accounts for all cases in the last 50 years. Jungle yellow fever strikes mainly young adult males engaged in timbering and agricultural pursuits in the Amazon and Orinoco river basins. The principal mosquito vectors are species of the genus *Haemagogus*. The disappearance in the early 1940s of urban yellow fever, once a major endemic and epidemic disease in South American towns and cities, was attributed to successful programs to control the domestic vector, *Ae. aegypti*. However, in the last 10–15 years, *Ae. aegypti* has reinvaded much of the territory in South America from which it had formerly been eliminated, raising the spectre of urban epidemics in the future. Although

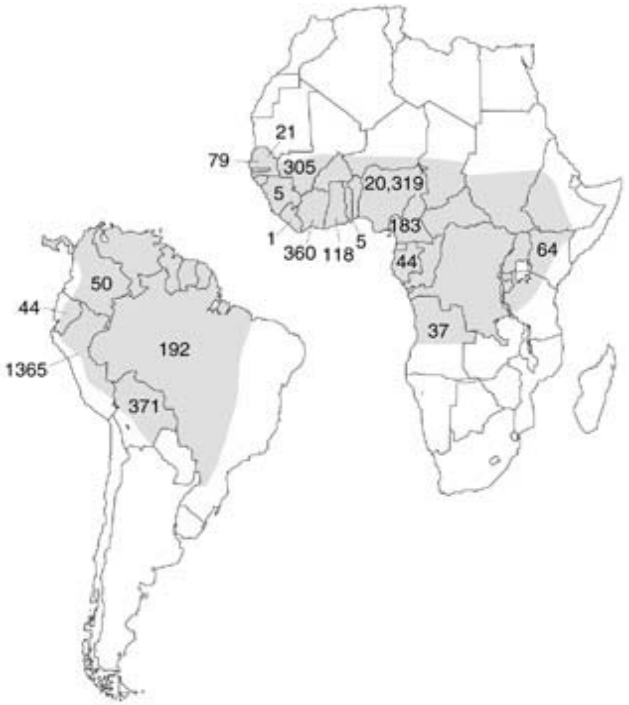

Figure 3 Geographic distribution of yellow fever cases, 1985–1996.

vaccine-induced immunity provides a degree of protection against such outbreaks, the level of coverage is presently incomplete.

The epidemiology of yellow fever in Africa is more complex than in the New World. The virus is present in a vast area of tropical Africa. Sporadic cases of jungle yellow fever occur in the rainforest zone, where the virus is maintained in a cycle involving monkeys and *Ae. africanus* mosquitoes, but such cases are rarely recognized because of inadequate surveillance. Unlike South America, tree-hole breeding *Aedes* spp. are also involved in epidemic transmission. Amplification of the virus transmission cycle occurs in moist savanna and forest-savanna transition zones, where the density of tree-hole *Aedes* reaches high levels during the rainy season. In these circumstances, humans are frequently infected. In urban areas or areas of low rainfall, where water storage practices favor breeding of domestic *Ae. aegypti*, this vector may be involved in epidemic spread, with humans serving as the viremic host.

Clinical Features

Subclinical or abortive infections occur more frequently than full-blown yellow fever. In its classical form, the disease begins suddenly, 3–6 days after the bite of an infected mosquito, with fever, headache, low back pain, muscle aches, loss of appetite and nausea. This period of infection is clinically nonspecific, and corresponds to the viremic phase when the patient is infectious for feeding mosquitoes. It may be followed by a brief period of remission, during which signs and symptoms abate. The patient then becomes increasingly ill, entering the period of intoxication, with reappearance of fever, vomiting, dehydration, abdominal pain, and the appearance of jaundice, protein in the urine, signs of renal failure, and hemorrhages, most notably the vomiting of blood. Virus is no longer present in the blood. Approximately 20 to 50% of patients who progress to this stage die between the 7th and 10th day after onset, with deepening renal and hepatic failure, shock, delirium and convulsions.

Pathology and Pathogenesis

In humans, pathologic changes in the liver include swelling and necrosis of hepatocytes in the midzone of the liver lobule, with sparing of cells in the portal area and surrounding the central veins. Viral antigen and RNA are demonstrable by immunocytochemistry and nucleic acid hybridization in cells undergoing these pathologic changes, and cytopathology is mediated by direct viral injury. Hepatocytes may undergo apoptosis. Inflammatory changes are absent or minimal, and patients with hepatitis who recover do not develop residual scarring or cirrhosis. The kidneys show acute tubular necrosis, probably the result of reduced perfusion of blood rather than direct viral

injury. Focal degeneration of muscle cells may be present in the heart. Spleen and lymph nodes show necrosis of B cell areas. The brain shows edema and petechial hemorrhages, but viral invasion and encephalitis are very rare events. Hemorrhage results principally from decreased synthesis of clotting factors by the liver. The mediators of hypotension and shock remain to be elucidated.

The pathogenesis of yellow fever has been studied in subhuman primates and mice, but our level of understanding is at the descriptive rather than the mechanistic level. Susceptible monkeys develop an illness similar to humans. Initial sites of virus replication have not been clearly defined, but probably include lymphatic tissue draining the site of virus inoculation. Viremia follows, with infection of the liver. Early virus replication occurs in fixed macrophages (Kupffer cells) in the liver, which undergo necrosis. The virus then invades hepatocytes, which develop accelerated cytopathologic changes during the 24 hours before death. Yellow fever virus demonstrates both viscerotropism (infection of liver, lymphoid and other visceral tissues) and neurotropism (infection and inflammation of the brain). In primates, viscerotropic infection is the rule; animals inoculated intracerebrally replicate virus in brain tissue and develop histopathologic evidence of encephalitis, but die of hepatitis. In contrast, mice develop brain infection without evidence of hepatitis.

Immune Response

Antibodies of both IgM and IgG subclass measurable by binding assays (immunofluorescence, ELISA), hemagglutination inhibition and neutralization appear 5–7 days after onset of illness (8–14 days after infection). IgM antibodies tend to wane to low or undetectable levels between 6 and 12 months after infection, although, in one study IgM neutralizing antibodies were still detectable several years after yellow fever immunization. Complement-fixing antibodies appear in the second week after infection, wane between 3–6 months later, provide a reliable indicator of recent wild-type yellow fever infection, and are rarely demonstrable after yellow fever vaccination. IgG neutralizing antibodies persist for at least 35 years, probably for life, and provide solid protection against reinfection. Antibodies to heterologous flaviviruses, such as Zika, dengue and Wesselsbron viruses, provide partial crossprotection against yellow fever. Complement-dependent antibody-mediated cytolysis of cells with exposed NS1 protein sequences may play a role in virus clearance and recovery, as well as in protection in the previously-immunized host. Little is known about cell-mediated responses in yellow fever. Limited studies in mice suggest that nonspecific resistance is mediated by interferon, NK cells and macrophages, and that cytotoxic T cells are important in clearance of yellow fever infection.

Prevention and Control

The control of domestic *Ae. aegypti* mosquitoes is an important measure, but has proven difficult to sustain. The most effective approach to prevention is immunization of the human population in endemic areas. Yellow fever 17D is a live, attenuated vaccine produced in embryonated eggs. Over 300 million people have been immunized with this inexpensive product, which has proven safe and highly effective. Recent efforts have focused on the production of a new vaccine derived from a full-length cDNA clone that generates infectious transcripts. By this approach it may ultimately be possible to produce chimeric vaccines with heterologous cassette genes incorporated into the 17D yellow fever vaccine backbone.

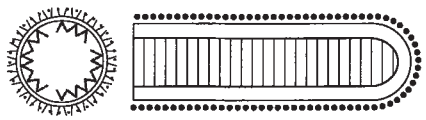
ZOONOSES



Thomas M Yuill, Institute for Environmental Studies, University of Wisconsin, Madison, Wisconsin, USA

Introduction

Zoonoses are diseases transmissible from vertebrate animals, other than humans, to people. Hundreds of viruses in a wide range of families are zoonotic. Mammals, birds, reptiles and probably amphibians are reservoir or amplifier hosts for these viral zoonoses. Frequently, these viruses cause little or no overt disease in their nonhuman vertebrate hosts. Some zoonotic viruses have very limited host ranges, others may infect a wide range of vertebrates. Human infection may vary from unapparent to fatal disease. Some viral zoonoses have been recognized since ancient times, others have become public health problems recently. Both new and old viral zoonoses are especially important in emerging and re-emerging virus diseases.

Transmission

Transmission of zoonotic viruses may occur by a variety of routes. Rabies is transmitted by *direct contact* through the bite of an infected animal. *Indirect contact* transmission of other zoonoses occurs by ingestion of contaminated food and water, as is the case with the hantaviral and arenaviral hemorrhagic fevers. *Nosocomial* arenavirus and filovirus infections have been problems in hospitals caring for patients where isolation has not been adequate. *Aerosol transmission* of Venezuelan equine encephalitis virus has occasionally been a problem in the laboratory, where virus-bearing microdroplets have been widely circulated, with many resulting human cases. *Vertical (in utero)* transmission of arenaviruses results in persistent virus infection in the offspring. A large number of viral zoonoses throughout the world are *vector-* or *arthropod-borne*.

Some Common Zoonotic Viruses Around the World

Viral zoonotic diseases occur on every continent except, perhaps, Antarctica. Some are found around the world, in a variety of ecological settings. Others are found only in very limited ecologic and geographic foci. The panorama of viral zoonotic diseases is constantly changing. Although hundreds of viruses have been shown to infect both humans and animals, the importance of many of these viruses, as agents of either human or animal disease, has not yet been established. Some of the more important viral zoonoses will be discussed briefly.

Rabies virus

Rabies is one of the oldest reported zoonoses. Rabies virus infection causes nervous system disease that ends in death. Animals can become infected without nervous system involvement or disease, develop antibodies, and survive, but play no role in transmission. Classical rabies is found all around the world except in Antarctica, Britain, the Hawaiian Islands, Australia and New Zealand. Transmission occurs by the bite of an infected mammal that has virus in its saliva. Aerosol (droplet) transmission to humans has been reported, although rarely. Dogs and cats are the main reservoirs, especially in the tropical developing countries where more than 99% of all human deaths due to rabies occur. In the industrialized countries, wild mammals are the main reservoirs and the species involved vary from region to region. Translocation of rabid wild animals by hunting groups has been a cause of rabies spread in the USA. The principal species are: in North America, skunks, raccoons and foxes; in Europe, foxes; and in the Caribbean, mongooses. Bats in all enzootic regions harbor rabies, with vampire bats especially important in the Neotropics. Rabies virus is classified in the *Lyssavirus* genus of the family *Rhabdoviridae*. Genetic relationships between rabies isolates from different species and geographic areas have been established by genomic sequence analysis. Rabies-related viruses have been found in bats in Australia (Australian bat lyssavirus) and Britain and other European countries

(European bat lyssaviruses). Still more distantly-related lyssaviruses, some zoonotic, are found in Africa. Diagnosis is based on characteristic altered behavior of infected mammals, confirmed by isolation of virus or demonstration of intracellular antigen by immunofluorescence or of virus genomic sequences by nested reverse transcription–polymerase chain reaction (RT-PCR) confirmed by Southern blot hybridization. Postexposure treatment is accomplished by thorough washing of the bite wound, administration of hyperimmune serum or globulin, and administration of antirabies vaccine (prepared in human diploid cells, purified chick embryos or purified Vero cells). Dogs and cats in enzootic areas should be vaccinated. Other domestic animals and humans at high risk should be also vaccinated. Vaccination campaigns of free-ranging red fox populations in Europe and raccoons and coyotes in the USA have been carried out by oral administration of recombinant vaccinia-vectored vaccines in bait.

Hantavirus hemorrhagic fevers and pulmonary syndrome viruses

Hantaviruses are a newly-recognized complex of public health importance. These viruses belong to the *Hantavirus* genus of the *Bunyaviridae* family. Hantaan virus causes Korean hemorrhagic fever, and occurs in east Asia, especially in Korea, China and eastern Russia. Closely related rodent-associated hantaviruses cause milder hemorrhagic fever with renal syndrome in humans and have been reported from Scandinavia, Europe and Russia (Puumala virus), The Balkans (Dobrava-Belgrade virus), Russia and Asia as well as port areas around the world (Seoul virus). The similarity of many *Rattus* spp.-associated viruses globally suggests that movement of rats through commercial shipping has spread the virus as well. Seoul virus has been found in laboratory rats, with transmission to personnel there. Direct transmission of these viruses among rodents or from rodents to humans may occur by bite. A group of hantaviruses have been newly recognized with the appearance of highly fatal hantavirus pulmonary syndrome (HPS) in humans. As of June, 1998, 183 cases of HPS from 29 states and 24 cases from three Canadian provinces have been reported. Western hemisphere rodent-maintained hantaviruses that cause HPS include Sin Nombre (Alaska, across Canada, the USA except the southeast, south to central Mexico), New York (eastern USA, Canada and Mexico), Black Creek Canal (eastern Canada, USA; northern South America), Bayou (south central and southeast USA), Andes (southern South America) and Laguna Negra from a vesper mouse (southern South America). Lechiguanas and Oran viruses have also been associated with HPS cases in Argentina. There is evidence of direct human-to-human transmission of Andes virus. Several other rodent hantaviruses newly discovered in Europe, Asia and the Americas have not been associated with human disease. Hantaviruses are harbored by wild rodents which often live in close association with humans. Virus is shed in urine and other excreta. Outbreaks of HPS have been associated with ecological changes and invasion of human habitations by expanding rodent populations. Diagnosis has been complicated by the lack of efficient and sensitive isolation and serological methods, which explains why these 'new' viruses have only recently been isolated and characterized. Cell cultures, immunofluorescence or RT-PCR are used to isolate or detect virus, or to test for antibody. Because some of these agents are highly pathogenic to humans, work with them must be carried out in facilities that provide a high degree of biocontainment. Rodent control and avoidance of exposure to rodent excreta, especially in dust, are the only methods available currently for prevention of transmission to humans.

Arenavirus hemorrhagic fever viruses

Arenavirus hemorrhagic fever (HF) viruses, like the hantaviruses, are rodent associated, and can also cause severe disease in humans. Lymphocytic choriomeningitis (LCM) virus, the first arenavirus isolated, came from a person with encephalitis residing in the USA. Junin virus occurs in Argentina, Machupo virus in Bolivia, Guanarito virus in Venezuela, Sabia virus in Brazil and Lassa virus in West Africa. A complex of related arenaviruses that do not cause human disease occur in the Americas and Africa. These pathogenic arenaviruses establish persistent infection in their rodent hosts, and virus is shed in urine, infecting humans who live in close contact with these contaminated environments. Transmission may occur when people are in contact with blood or fresh carcasses of infected rodents. Lassa fever is also transmitted in rural hospitals to other people in contact with blood from viremic patients. Diagnosis is accomplished by virus isolation in cell culture, but detection of virus may require use of specific antibody and immunofluorescent or enzyme labeling. These techniques, as well as cDNA hybridization probes, are also used to detect viral products in tissues of infected humans or rodents. Diagnosis may also be established serologically by a diagnostic rise of specific IgG, or detection of IgM antibodies. Except for LCM virus, isolation of HF viruses pathogenic for humans requires the use of biosafety level 4 facilities. Serological tests such as ELISA can be done reliably

with inactivated antigen at a lower level of biosafety. Control of these diseases is attempted mainly by reduction of rodent populations, as was done successfully with Bolivian HF, and by avoidance of dust containing rodent excreta. Prevention of human disease by vaccination is possible. A live attenuated vaccine has been developed for Argentine HF, and a vaccinia-vectored vaccine has been developed for Lassa fever. Ribivirin is effective for treating arenavirus infection if administered early in the course of infection.

Yellow fever virus

Yellow fever (YF), first recognized clinically in the Neotropics in the sixteenth century, periodically ravaged human populations in the Americas, Europe and Africa until as recently as the beginning of the twentieth century. Infection causes hemorrhagic disease with severe liver damage and death in up to half of the most acute cases. Presently, the virus is maintained enzootically in Africa and the tropical Americas in primates and arboreal mosquitoes. Humans or primates transport the virus from its sylvan cycle in forested areas to rural or urban areas, where other vector mosquitoes transmit it. YF may be a public health time bomb: there has been an alarming increase in human cases in West Africa in recent years, and, for the first time in history, in Kenya in 1992–1993. Although the number of 'jungle' YF cases in the American tropics has not increased as dramatically, re-establishment of the major urban vector, *Aedes aegypti*, and the recent appearance and spread of a potential YF mosquito vector, the Asian tiger mosquito (*Ae. albopictus*), in the hemisphere is a cause for serious concern. The risk of introduction of YF into cities is real. There have been recent instances of individuals infected acutely with sylvan yellow fever traveling to four South American urban centers infested with *Ae. aegypti*, but, fortunately, without subsequent transmission. YF virus is a flavivirus in the *Togaviridae* family. Diagnosis is by virus isolation in cell culture or in inoculated mosquitoes, detection of circulating antigens, demonstration of a significant raise in specific YF virus antibodies, or by observing viral inclusion bodies or antigen in tissues taken at postmortem examination. Insecticide spraying and elimination of breeding sites in homes can be used for vector control in epidemic situations. Disease can be prevented in humans by vaccination. Unfortunately, many countries have not been able to maintain an adequate level of immunity in populations in areas of risk and have to resort to emergency immunization programs when cases are detected. Because cases often occur in remote areas, it is difficult for many national health services to provide adequate vaccination coverage quickly in the face of YF outbreaks.

West Nile virus

West Nile (WN) virus, a close relative of Japanese encephalitis virus, occurs from India and Pakistan westward through the Middle East and into Africa, and northward into Europe and the republics of the former USSR. Mild infection to acute febrile disease with rash, and occasional encephalitis (mainly in the elderly), is produced in humans. *Culex* spp. are the main vectors, and birds are the vertebrate hosts. Diagnosis is by virus isolation and serological means. Unlike the related flavivirus encephalitides, WN virus can be isolated from the blood of human patients relatively commonly.

Chikungunya virus

Chikungunya (CHIK) virus has been responsible for acute febrile disease with rash and severe arthralgia in people in Africa and Asia. The epidemiology in Africa is similar to yellow fever; CHIK virus is maintained in sylvan or savanna cycles involving wild primates and arboreal *Aedes* mosquitoes. In both Africa and Asia, the virus also has an urban cycle involving humans and *Ae. aegypti* mosquitoes. Two outbreaks in Thailand in 1995 also involved *Ae. albopictus* mosquitoes. Virus can be recovered frequently from the blood of acute phase patients. The virus is an alphavirus of the *Togaviridae* family. The virus can be isolated in mammalian or mosquito cell cultures, although suckling mouse and mosquito inoculation are also sensitive systems. The virus has been transmitted to laboratory workers in the laboratory via aerosols created during virus isolation and passage. Serologic tests (neutralizing antibody or IgM capture ELISA test) are useful for diagnosis. Control of the sylvan and savanna enzootic cycles is not feasible. The urban cycle can be controlled by reduction of *Ae. aegypti* breeding sites and adult populations. No vaccine is available.

Sindbis virus

Sindbis (SIN) virus is one of the most widely distributed arthropod-borne viruses in the world, being found in Africa, Europe, Asia and Australia. Disease in humans is usually mild, and is characterized by acute fever, with arthralgia and rash. SIN virus is maintained in wild bird populations, with transmission by *Culex* spp. mosquitoes. In Africa and the Middle East, WN is often found in the same ecosystems where WN virus is being transmitted. The virus is an alphavirus of the *Togaviridae*. Phylogenetic analysis indicates that there is one major genetic

cluster of western SIN virus strains in Africa and another in Australia and Asia. There is evidence of some geographic mixing western strains of SIN virus that suggests long-distance transport via migrating birds. Diagnosis is accomplished by virus isolation, demonstration of virus genomic sequences by RT-PCR or by serological means. There is no vaccine available. Since many of the mosquito vectors breed in extensive rice fields, large-scale control would be expensive.

Crimean–Congo hemorrhagic fever virus

Crimean–Congo hemorrhagic fever (CCHF) virus is very widely distributed, and is found from eastern Europe and the Crimean, eastward through the Middle East to western China, and southward through Africa to South Africa. CCHF is characterized by severe hemorrhagic fever with hepatitis, with case mortality of 10–50%. Asymptomatic infections also occur. Maintenance of CCHF virus involves horizontal transmission from *Hyalomma* ticks to mammals, and vertical transmission in ticks through the eggs. Immature ticks feed on small mammals, and the adult ticks feed on cattle and other large mammals. *Hyalomma* ticks have also been found on birds migrating between Europe and Africa – a mechanism for long-distance dispersal of the virus. Recent human CCHF cases in workers handling livestock and their products in Saudi Arabia and the United Arab Emirates have been attributed to importation of infected cattle and their ticks from Somalia and the Sudan. Diagnosis is by virus isolation, demonstration of viral nucleic acid sequences by RT-PCR, *in situ* hybridization or immunohistochemistry or by serological techniques. There are no vaccine or tick control measures available.

Sandfly fever viruses

Sandfly fever (Sicilian, Naples and Toscana) viruses are endemic in the Mediterranean area (southern Europe, North Africa and Southwest Asia). They cause acute febrile disease in humans, with occasional aseptic meningitis. In central Italy, Toscana virus caused one-third of previously undiagnosed cases of aseptic meningitis. The viruses are members of the *Phlebovirus* genus of the *Bunyaviridae*. They are transovarially and horizontally transmitted by phlebotomine sandflies. Wild mammals are presumed reservoirs.

Viruses Occurring in the Americas

Encephalitis viruses

Venezuelan equine encephalitis (VEE) has been a major public and animal health problem in tropical and subtropical areas of the Americas. VEE virus is made up of a closely related complex of subtypes with several varieties, which have differing epidemiologies, geographic distributions and disease importance. The epizootic/epidemic (VEE IAB and IC) virus variants are of greatest concern. In equine animals, the virus causes acute encephalitis, and case fatality may approach 80%. Survivors may have serious neurological deficits. Although the case fatality rate in humans is low (less than 1%), the large numbers of acutely infected people that occur during an epidemic may completely overwhelm the local health care system. VEE IAB and IC viruses are maintained in northern South America, where they have periodically swept through Venezuela and Colombia in epidemic waves, with occasional extension into Ecuador and massively through Central America into Mexico and South Texas. Epidemic spread depends on the availability of susceptible equine populations (the amplifying host) and abundant mosquito vectors of several species. Although the interepidemic maintenance systems remain undefined, there is some recent evidence that the epidemic form may be enzootic in Central America, causing sporadic cases in equine animals there. There is other evidence that the epizootic strains may arise by mutation of subtype ID enzootic virus. The enzootic strains are maintained in limited foci involving rodents and *Culex* (*Melanconion*) spp. mosquitoes from Florida to Argentina. With the exception of subtype IE, which caused epizootics in horses in 1993 in Chiapas and in 1996 in Oaxaca State, Mexico, these virus strains do not cause disease in equine animals, but can cause acute febrile illness in humans. The VEE complex viruses are in the *Alphavirus* genus of the *Togaviridae*. Diagnosis is usually done by antibody detection (IgG or IgM ELISA test) because virus isolation from clinical cases is difficult (except from the blood of early febrile cases in infected herds of equine animals), although RT-PCR may detect viral genomic sequences. Viruses are subtyped with monoclonal antibodies in plaque-reduction neutralization or ELISA tests. There is an effective live, attenuated vaccine for both human and equine use. Because the maintenance of equine herd immunity is costly, most animal health agencies do not carry out ongoing, intensive vaccination campaigns. Thus, the risk of reoccurrence of explosive outbreaks remains.

Eastern (EEE) and western (WEE) equine encephalitis viruses occur in epidemic form in North America, but have also been found in Central and South America. Generally, EEE is maintained in eastern North America but has caused scattered epizootics and cases in the Caribbean, and in Central and South America. EEE virus can be divided into a North

American–Caribbean clade, an Amazon Basin clade, and a Trinidad, Venezuela, Guyana, Ecuador and Argentina clade. WEE occurs in western and prairie states and provinces and along the west coast. WEE has caused sporadic cases of encephalitis in equine animals, but not humans, in Argentina and Uruguay. Both involve wild birds and mosquito vectors, with spillover into equine populations and humans, causing clinical encephalitis and death. Central nervous sequelae may occur among survivors. Diagnosis is by isolation of the virus in mice or cell cultures, by demonstration of viral RNA by RT-PCR or of viral antigen by capture ELISA. Isolation from brain tissue of clinical encephalitis cases is difficult. Demonstration of IgG antibody by a variety of tests, or IgM antibody by capture ELISA, is of diagnostic value. Effective vaccines are available commercially for equine animals, and experimental vaccines are used for laboratory personnel. Effective mosquito abatement to control vector populations has been carried out in the West for many years. Insecticide application is used for vector control in epidemic situations.

St Louis encephalitis (SLE) virus occurs from Canada to Argentina and causes sporadic but extensive epidemics in the USA, with most epidemics occurring in the west, down the Ohio and Mississippi valleys into Texas, and in Florida. Wild passerine birds are amplifying hosts in North America, but in the Southeastern USA and the Neotropics mammals may play an epidemiologic role in virus maintenance and transmission. SLE virus is transmitted by *Culex* spp. mosquitoes in the USA. SLE virus is a flavivirus of the *Togaviridae*, and is closely related to Japanese encephalitis virus. RNA oligonucleotide fingerprint patterns indicate that the virus varies by geographic region. In humans, SLE is characterized by febrile disease, with subsequent encephalitis or aseptic meningitis, and strikes older people more often than the young. Diagnosis is accomplished by virus isolation, demonstration of viral genomic sequences by RT-PCR or antigens by ELISA capture. Serological diagnosis is made by demonstration of rising titer of IgG by standard techniques, or presence of specific IgM by ELISA tests. Since no vaccine is available, SLE prevention and control relies on surveillance, vector control and screening of dwelling windows and doors.

Powassan (POW) virus is a North American member of the flavivirus tick-borne encephalitis complex. Although POW virus is widely distributed across the USA and Canada, and westward into far eastern Russia, disease (febrile, with encephalitis) has only been detected in the eastern states and provinces of North America. The transmission cycle involves small mammals and *Ixodes* ticks.

La Crosse (LAC) and other California serogroup encephalitides are human pathogens in North America. LAC encephalitis is the most common arthropod-borne virus disease in this region, affecting mainly preschool-aged children. It is endemic in the Upper Midwest, but occasional cases occur elsewhere. Although fatality is uncommon, the disease is severe enough to cause prolonged hospitalization. LAC virus is maintained transovarially in treehole breeding *Ae. triseriatus* mosquitoes with horizontal transmission to small forest mammal reservoirs and to humans. The other California group viruses affecting people have similar epidemiologies, but do not cause disease as commonly. California encephalitis virus was isolated in California, and has occasionally caused human disease there. Snowshoe hare (SSH) virus occurs in the Northern USA and across Canada, and has caused human encephalitis in the eastern provinces. Jamestown Canyon (JC) virus is widely distributed across the USA, and has been shown to cause human disease, mainly in adults in the Midwest, and to infect deer. Like LAC virus, these other viruses have the same close epidemiological relationship with their *Aedes* vectors. These viruses are members of the California serogroup of the *Bunyavirus* genus of the *Bunyaviridae* family. SSH virus is an antigenic variant of LAC virus. Oligonucleotide analysis has shown differences in LAC viruses from the eastern and the western parts of its geographic range in the Midwest. Diagnosis is nearly always by serological means, with demonstration of an antibody rise during illness. There are no vaccines for the LAC group viruses. LAC has been controlled in a few places by eliminating vector breeding sites through filling treeholes and removing discarded rubber tires.

Colorado tick fever virus

Colorado tick fever (CTF) is endemic in sagebrush–pine–juniper habitats of the higher elevations (over 1200 meters) in the mountains of the western states and provinces of North America. Although seldom fatal, CTF can cause serious disease in humans, with prolonged convalescence. CTF may present as hemorrhagic or central nervous system disease, and is most severe in preadolescent children. Males are infected over twice as frequently as are females. The virus is transmitted by and overwinters in *Dermacentor andersoni*. Wild rodents are the vertebrate hosts, and develop a prolonged viremia. CTF virus is classified in the *Coltivirus* genus of the family *Reoviridae* and is serologically related to Eyach virus from Germany. Diagnosis is by virus isolation from erythrocytes, or demonstration of CTF viral antigen by immunofluorescence, during the long viremia.

Serologic diagnosis may be problematic because antibodies develop late in the course of infection. Avoidance of tick bites is the main preventive measure available, but control of rodents and the ticks that inhabit their burrows can be applied in foci of virus maintenance in the field.

Vesicular stomatitis virus

Vesicular stomatitis (VS) virus is of major economic concern as a cause of acute, febrile vesicular disease in cattle, mainly in Central and northern South America and in the USA. Both of the major serotypes, VS-Indiana and VS-New Jersey, cause influenza-like illness in humans and are an occupational hazard to people handling cattle. The VS viruses comprise a complex of related serotypes and subtypes in the Americas, with related vesiculoviruses (*Rhabdoviridae* family) viruses in Africa and Asia. Many of these viruses are transmitted horizontally and transovarially by phlebotomine sandflies, with evidence for infection of wild rodents and other small mammals. However, the role of these mammals in the epidemiology of VS viruses is unclear because they do not develop viremia. Thus, the host and vector transmission cycles of VS viruses in the Americas are not well understood. Diagnosis is established by isolation of the virus in cell cultures, demonstration of antigen in vesicular fluid or tissues of infected animals, or demonstration of specific RNA sequences by RT-PCR. Serological diagnosis may be complicated by lack of specificity of tests and by normal fluctuations of antibody titers. The experimental vaccines developed for use in domestic animals have not yet been commercialized.

Other Neotropical viruses

Oropouche virus, a Simbu serogroup bunyavirus, causes epidemics, occasionally severe, of acute febrile disease with arthralgia and occasional aseptic meningitis in humans in the Brazilian and Peruvian Amazon as well as Panama. During rainy season epidemics, the virus is transmitted by *Culicoides paraensis* biting midges. Enzootic maintenance cycles are believed to involve forest mammals and arboreal mosquitoes.

Mayaro (MAY) virus occurs epidemically in the Brazilian and Bolivian Amazon Basin, and has also been associated with human disease in Surinam and Trinidad. In humans, the acute, nonfatal, febrile disease with rash is clinically similar to CHIK, an alphavirus to which it is antigenically and taxonomically related. MAY virus appears to be maintained in nature in a cycle similar to that of yellow fever, with arboreal mosquito vectors and primate hosts, but also involving other mammals and birds.

Rocio virus was first isolated from fatal human encephalitis cases during an explosive outbreak of acute febrile disease in coastal Sao Paulo State, Brazil in 1975, after which time sporadic outbreaks have continued. This virus is an ungrouped flavivirus in the *Togaviridae*, and is serologically related to Murray Valley encephalitis virus from Australia. The epidemiology is unclear but probably involves wild birds, and several mosquito species are suspected vectors.

Viruses Occurring in Europe

Tahyna (TAH) virus is widely distributed in Europe, and has been reported in Africa. TAH virus produces an influenza-like febrile disease, with occasional central nervous system involvement. The virus is a bunyavirus of the California serogroup, in the *Bunyaviridae*. Like La Crosse virus, small forest mammals are TAH virus reservoirs, and the virus is horizontally and transovarially transmitted by *Aedes* mosquitoes. There are no effective control measures.

Omsk hemorrhagic fever occurs in a localized area of western Siberia. Disease can be severe, with up to 3% case fatality, and sequelae are common. This virus is a member of the tick-borne encephalitis (TBE) complex of the flaviviruses. The virus is epizootic in wild muskrats, which had been introduced into the area, and is associated with ixodid ticks. Muskrat handlers are at highest risk of infection. Water voles and other rodents are also vertebrate hosts of the virus. TBE virus vaccine is used in high-risk individuals to provide protection.

Central European tick-borne encephalitis (CETBE) virus is also a member of the TBE complex of flaviviruses. Because recreation in wooded areas has increased in recent years, CETBE has become the most frequent arthropod-borne disease in Europe. The virus occurs in deciduous forests in western Europe from the Mediterranean countries, westward to France, and northward to the Scandinavian countries. It is maintained in a transmission cycle involving small mammals and *Ixodes* spp. ticks. Human infection also occurs through the consumption of unpasteurized milk from infected cows. Infection can be prevented by an inactivated vaccine and avoidance of tick bites.

Cowpox virus is an orthopoxvirus in the *Poxviridae*. It has a wide host range. Domestic cats are the most important source of human infection, transmitting the virus from wild rodent reservoirs to people. In addition to cattle, this virus has produced severe, generalized infections in a variety of incidental animal hosts in zoos and circuses, including elephants and large cats, which may die. Humans develop typical poxvirus lesions (vesicle and pustule formation),

usually on the hands. Laboratory diagnosis (characterization of isolated virus) is required to differentiate cowpox from other nodule-forming zoonotic poxviruses such as orf virus, bovine papular stomatitis virus and pseudopoxvirus, which are worldwide in distribution.

Viruses Occurring in Africa

Rift Valley fever virus

Rift Valley fever (RVF) is among the most serious arbovirus infections in Africa today. Repeated RVF epidemics in sub-Saharan Africa cause serious disease in small ruminant animals and humans. RVF disease has expanded its historical geographic range in the livestock-raising areas of eastern and southern Africa over the past 25 years, causing a massive epidemic in Egypt in 1977–1978, appearing in epidemic form along the Mauritania–Senegal border 10 years later and in Madagascar in 1990–1991. Cattle, sheep and humans are affected. Abortion storms with febrile disease and bloody diarrhea occur in ruminant animals, and mortality may be heavy in young stock. Most infected humans develop febrile disease, with prolonged convalescence. A few individuals develop more severe disease, with liver necrosis, hemorrhagic pneumonia, meningoencephalitis and retinitis with vision loss. The human case fatality rate is less than 1%. RVF virus is in the *Phlebovirus* genus of the *Bunyaviridae*. In sub-Saharan Africa, RVF virus is closely tied to its *Aedes* mosquito vectors. RVF vectors transmit the virus transovarially and horizontally. The virus persists in mosquito eggs laid around seasonally flooded pools and depressions called 'dambos'. When the rains come and dambos flood, the eggs hatch and infected mosquitoes emerge and begin transmission. The vertebrate reservoir hosts of RVF virus are unknown. Agricultural development projects in Africa must take into account that creation of larval habitats (artificial dambos) may lead to epidemics of RVF, as happened in West Africa. Diagnosis depends on virus isolation and serologic testing. Field and laboratory workers need to exercise caution to avoid becoming infected by exposure to the virus during postmortem examination of animals or processing materials in the laboratory. A high level of biosecurity is required. Both live attenuated and inactivated vaccines are available for animals, but the unpredictability of scattered, sporadic RVF outbreaks across sub-Saharan Africa is a major obstacle for implementation of extensive, cost-effective vaccination programs. An inactivated vaccine is available for laboratory and field workers at high risk of infection.

Marburg and Ebola viruses

The reappearance of epidemic Ebola disease in Kikwit, Democratic Republic of the Congo (formerly Zaire) in 1995 and Makokou, Gabon in 1996 again focused international attention on this hemorrhagic disease. Marburg and Ebola viruses have sporadically caused severe hemorrhagic fever in humans. Marburg virus, although of African origin, first appeared in laboratory workers in Germany who had handled cell cultures originating from African primates. Later, epidemics of severe hemorrhagic fever occurred in the Sudan and in Zaire, and Ebola virus was isolated. These viruses produce hemorrhagic shock syndrome and visceral organ necrosis, and have the highest case fatality rate (30–90%) of the hemorrhagic fevers. These viruses, with their bizarre filamentous, pleomorphic morphology, belong to the *Filoviridae* family. They are presumed to be zoonotic, but their hosts in nature and mechanisms of transmission in the field have not been determined. Most of the Makokou, Gabon patients had very recently butchered chimpanzees. A variant of Ebola virus has been isolated from chimpanzees from Côte D'Ivoire, but since wild primates suffer severe disease, they are unlikely to be maintenance reservoirs. Nosocomial transmission of Marburg and Ebola viruses has occurred frequently; a high level of patient isolation and biosafety containment are essential to avoid hospital- and laboratory-acquired infection. An outbreak of simian hemorrhagic disease, caused by a Marburg/Ebola-like filovirus, occurred in a primate-holding facility, but without evidence of related human disease among animal care personnel. The virus can be detected by electron microscopic examination of tissue or isolation of the virus in cell culture. Serologic diagnosis is accomplished by means of indirect immunofluorescence or ELISA test, with antigen specificity confirmed by western blot. No vaccines or control measures are available.

Monkeypox virus

The largest epidemic of human monkeypox ever documented occurred in the Katako-Kombe area of the Democratic Republic of the Congo (formerly Zaire) in 1996–1997, with over 500 people becoming ill and five deaths. Primary monkey-to-human transmission occurred, as did subsequent secondary human-to-human spread. Human monkeypox is a severe, smallpox-like illness. Monkeypox belongs to the *Orthopoxvirus* genus of the *Poxviridae*. The virus is enzootic in wild primates and squirrels in the rainforests of West and Central Africa. Vaccinia is protective against infection, but its use has been discontinued with the eradication of smallpox. A new

drug, cidofovir, has been reported to be effective in preventing overt disease and death in monkeys infected experimentally.

O'nyong-nyong virus

O'nyong-nyong virus disease initially occurred in 1959 in Uganda and spread to Kenya, Tanzania, Malawi and Senegal, infecting 2 million people. O'nyong-nyong virus is considered a subtype of Chikungunya virus, and is widespread in eastern sub-Saharan Africa. The disease it produces and its epidemiology are similar to CHIK, with *Anopheles* spp. as the main mosquito vector. Igbo Ora virus is also antigenically related to CHIK virus, and has been isolated from humans in West Africa.

Semliki Forest virus

Semliki Forest (SF) virus caused an extensive epidemic of human disease in Bangui, Central African Republic, in 1987. SF virus is an alphavirus in the *Togaviridae*. It occurs across East, Central and West Africa, and has been isolated from various mosquitoes and from wild birds. Antibodies have been also found in wild mammals. The SF virus maintenance cycle probably involves *Ae. africanus* mosquitoes and vervet monkeys.

Orungo virus

Orungo (ORU) virus caused mild epidemic disease (fever, nausea, headache and rash) in Nigeria. The virus occurs in a band across Africa from Uganda to Sierra Leone. It is an orbivirus in the *Reoviridae*. ORU is probably mosquito transmitted, but the species that transmit it in nature are not known. Although the vertebrate reservoir hosts are unknown, wild primates have antibody and are suspected to be involved in virus maintenance.

Viruses Occurring in Asia

Kyasanur Forest disease (KFD) was first recognized in India in 1957, when an acute hemorrhagic disease appeared in wild monkeys and people frequenting forested areas. KFD has been slowly spreading in India. KFD virus is a member of the tick-borne encephalitis complex of flaviviruses. The basic virus maintenance cycle involves forest mammals (primates, rodents, bats and insectivores) and ixodid ticks, mainly *Haemaphysalis spinigera*. The virus can be isolated in mice and cell cultures, including tick cells. An inactivated vaccine provides some protection to people at risk of infection.

Japanese encephalitis virus

Japanese encephalitis (JE) is found in a broad area from far eastern Russia, northeastern Asia through China and Southeast Asia to Papua New Guinea and the Torres Strait Islands of Australia and westward into India. One of the world's arthropod-borne encephalitides, JE causes the greatest number of clinical human cases – thousands annually – predominantly in children. It produces encephalitis in humans and horses, and acute febrile disease with abortion in swine, an amplifying host. Herons and egrets are wildlife amplifying hosts. The virus is transmitted by *Culex* spp. mosquitoes. The overwintering mechanism in temperate Asia is unknown. JE virus is a member of a complex of four related flaviviruses in the *Togaviridae* family. RNA oligonucleotide analysis indicates that there are differences in JE virus isolates from different vertebrate species, and between strains from different geographic areas. Diagnosis is by means of virus isolation or demonstration of JE virus genomic sequences by RT-PCR, IgG antibody rise, or of specific IgM in acute sera. Prevention of disease is mainly through vaccination of humans, horses and swine. A bivalent vaccine is used that incorporates the two recognized antigenic variants. Insecticides and integrated pest control measures that include natural compounds (*Bacillus thurengiensis* toxins), larvicidal fish, and larval habitat modification have been successfully used in China. Use of pyrethroid-impregnated bed netting can also prevent transmission.

Viruses Occurring in Australia

Murray Valley encephalitis virus

Murray Valley encephalitis (MVE) occurs primarily in southeastern Australia, with cases appearing occasionally in other parts of the country and in Papua New Guinea. Febrile disease leads to encephalitis and, in severe cases, death. Neurologic sequelae are common in survivors. Children are predominantly affected. Large water birds are the main vertebrate amplifying hosts, but mammals are also reservoirs. The virus is transmitted mainly by *Culex annulirostris* mosquitoes. It is maintained in northern Australia and New Guinea and is believed to be introduced into southern Australia in years of high rainfall. MVE virus is a flavivirus of the *Togaviridae* and is closely related to Japanese encephalitis. RNA sequencing indicates that the Australian strains of MVE virus are similar to, but different from Papua New Guinea isolates. Like JE, MVE diagnosis depends on virus isolation and serological testing. No vaccine is

available. Control is achieved through application of larvicides.

Ross River virus

Ross River (RR) virus has caused annual epidemics of febrile disease with polyarthritis and rash in tropical and temperate eastern Australia. Within the past two decades, RR virus has spread through several Pacific islands in epidemic form and appears to have become endemic in New Caledonia. Convalescence can be long. RR virus is an alphavirus of the *Togaviridae* family. The enzootic maintenance cycles of RR virus in Australia are not well defined, but wild and domestic mammals appear to be the reservoir hosts, and the principal mosquito vectors are salt marsh *Aedes* spp. and freshwater *Culex* spp. In the Pacific Islands, the virus was probably transmitted from person to person by *Aedes* mosquitoes.

Kunjin virus

Kunjin virus has caused scattered cases of fever, myalgia and polyarthralgia across Australia and in clusters in central Queensland and northern Western Australia. Kunjin virus is a flavivirus of the *Togaviridae*, and is related to WN and MVE viruses. The virus is believed to be maintained in wild bird–*Cx annulirostris* transmission cycles similar to MVE virus.

Burmah Forest virus

Burmah Forest virus causes subclinical and clinical infections in humans, including fever, myalgia, polyarthalgia and rash. It is an alphavirus in the *Togaviridae*. The virus appears to be endemic in eastern Australia, and its mosquito vectors and vertebrate hosts have not been established.

Control

Control of zoonotic virus diseases is accomplished by breaking the cycle of transmission. This is usually achieved by eliminating or immunizing vertebrate hosts, and reducing vector populations. Reduction of reservoir host populations is usually not accomplished because it is too expensive, not environmentally safe, and not technically or logistically feasible. However, there have been some notable exceptions. Bolivian hemorrhagic fever, caused by Machupo virus, was controlled by reduction of its rodent hosts through intensive rodenticiding. The principal vampire bat reservoir of rabies, *Desmodus rotundus*, is being controlled by the application of warfarin-type anticoagulants, either directly to the bats themselves or to the cattle upon which they feed (with no harm to the cattle). Control programs like these have to be continuous to be effective. Their reduction or discontinuation results in host population recovery through reproduction and immigration, which may result in re-emergence of disease sweeping through the increasing, susceptible cohort.

Immunization of hosts is both promising and discouraging. After decades of research, safe and effective rabies vaccines are being used for immunization of humans, domesticated animals and some wildlife species. The human diploid cell vaccine is extremely effective, free of adverse effects and widely available but at a cost too high for use in many developing countries. Safe, effective animal vaccines of cell culture origin are on the market. After some initial public resistance, raccoon populations in the eastern USA and wild foxes in Europe are being successfully immunized by means of an oral, vaccinia-vectored recombinant vaccine. This experience illustrates the need for public understanding, in order to counteract fear of the unknown – in this case, field use of a genetically engineered virus. Other vectored rabies vaccines are under development for control of mongoose-transmitted rabies in the Caribbean. Vaccines will not be developed for many zoonotic viral diseases that affect relatively few people and are of very limited concern geographically. With limited markets for new vaccines, there is no economic incentive to justify the several millions of dollars for the research and testing required for licensure and commercialization of these products.

Vector control is another promising but difficult area of zoonoses reduction or elimination. Insecticide application has become more problematic because both vectors themselves, as well as public opinion, have become more resistant to their use. Integrated pest management techniques, well developed for the control of many crop insects, along with the use of natural pesticides such as *Bacillus thurengiensis* toxin, offers promise for the effective, environmentally safe control of dipterous vectors. Control of tick vectors is likely to remain a problem for some time to come.

Emerging and Reemerging Zoonoses

Ecological change

Human disturbance has become a feature of nearly every part of the planet. All too often these disturbances create habitats that favor increases in populations of key hosts and vectors, with subsequent increased transmission of viral zoonoses. Nowhere are ecological changes happening more rapidly and

profoundly than in the world's tropics. Conversion of tropical forests to agricultural ecosystems simplifies diverse ecosystems and provides either native or introduced host or vector species the conditions necessary to become more abundant, and sustain intensified virus transmission in areas where people live and work. In Africa, recent yellow fever epidemics have been increasing dramatically in agricultural areas. Some agricultural irrigation development projects have created extensive vector breeding habitats, with an increase in mosquito-transmitted disease. The extensive dams constructed in Senegal were followed by epidemics of Rift Valley fever, with numerous cases of disease in humans and small ruminant animals. The public health consequences of development projects must never be overlooked.

Global climate change will also bring ecological changes and shifts of human populations that will affect the occurrence of viral zoonoses. Although experts debate the geography, severity and rapidity of the oncoming greenhouse effect, there is general consensus that changes in the global climate will happen with unprecedented speed. With those changes will come alterations in the geography of natural and agricultural ecosystems, with corresponding changes in the distribution of zoonotic diseases and the intensity of their transmission. It is clear that El Niño–southern oscillation phenomena have increased rainfall, with resulting increases in rodent populations and occurrence of hantavirus pulmonary syndrome in the Southwestern USA, and increased breeding sites for mosquito vectors of Rift Valley fever virus in Africa. While it is not possible to predict accurately what the world will be like in 100 years, nor what zoonotic diseases are likely to be most troublesome, it is certain that things will be different, and constant surveillance will be essential to avoid serious problems or deal promptly and effectively with the ones that arise.

Movement of zoonotic viruses can result from the displacement of infected animals, contaminated animal products and virus-carrying arthropod vectors. It is clear that illegal translocation of wild raccoons for hunting purposes, with inadvertent movement of rabies-infected animals, was responsible for initiating the recent rabies epizootic in the Middle Atlantic states. Pets, sport, laboratory and agricultural animals are moving around the world as never before. Although international and national regulations have been established to prevent movement of infected individuals, it is not possible to test for all possible zoonotic viruses, and prevent them from crossing international boundaries. Moreover, significant numbers of animals of high commercial value move illegally. Psittacine and other exotic birds worth hundreds to thousands of dollars each cross illegally into the USA, despite intensive government efforts to halt this smuggling. The importation of highly virulent Newcastle disease (ND) virus has been occasionally linked to smuggled birds. The costly ND outbreak (more than $50 million to control) in southern California in the early 1970s was linked to the importation of an infected pet bird from Asia. Subsequently, highly lethal ND virus has been found in smuggled parrots. Although not a serious infection in humans, ND is highly transmissible and can be extremely lethal in poultry and costly to that industry.

Zoonotic viruses may be transported by movement of arthropod vectors, too. Just as the yellow fever mosquito, *Ae. aegypti*, moved around the world in water casks aboard sailing vessels, mosquitoes are transported around the world in international commerce. Ships still transport mosquito vectors. The Asian tiger mosquito, *Ae. albopictus*, has become established in the Western Hemisphere after multiple introductions in eggs deposited in used tires. This mosquito is capable of transmitting yellow fever, Venezuelan equine encephalitis, Jamestown Canyon (JC) and La Crosse (LAC) encephalitis viruses. It remains to be seen if this highly competitive exotic vector, with its peridomestic habits, will carry yellow fever virus from its jungle cycle to the urban, human amplified cycle in the American tropics, increase the numbers of La Crosse encephalitis cases in south temperate or subtropical areas of the USA, or facilitate emergence of LACV × JCV recombinants. Perhaps of greater concern, modern transport aircraft have been shown to move vector mosquitoes internationally. Nature can move vectors as well. For example, windblown biting insects, such as culicoid midges, have been shown to account for the spread of some arthropod-borne virus diseases of animals, in some cases over long distances. There is no reason to believe that vectors of human diseases cannot move similarly.

Human activity alters animal populations, contact between wild and domestic animals, and human–animal interactions, changing the occurrence of zoonotic diseases and the risk of infection to humans. For example, emergence of new influenza strains is related to the interaction of populations of people, pigs and aquatic birds. It is hypothesized that the emergence of the new H5N1 influenza strain in Hong Kong in 1997 was the result of a chain of events resulting in transmission from migrating shorebirds to ducks, to chickens, and finally to humans. Fortunately, this pathogenic strain was not easily transmitted from human to human, or a serious pandemic could have resulted.

Social change

Increasing human populations place great demands on the public health and other government services, especially in developing countries where needs for zoonosis diagnosis, control and prevention are greatest and resources are most limited. Some preventive measures could be implemented by the people who live in the affected areas themselves, and at minimal cost, if they knew why and how they needed to do it. Public education and information is essential for control and prevention of zoonotic diseases; however, it takes more than civic action to deal with them. Delivery of public education, disease surveillance and diagnosis and the technical materials and logistical support for control or preventive programs depend on national or international scientific and financial support. Because serious zoonotic viral diseases, such as rabies, yellow fever, Venezuelan equine encephalitis and the hemorrhagic fevers, know nothing of international boundaries, international technical cooperation and financial support are imperative.

APPENDIX

This appendix lists the updated ICTV virus name index published in the 1999 Seventh ICTV Report.[1] It lists all virus names, with nomenclature based on the ICTV code of 1999. Because of differences in publication schedules, some virus names in *Encyclopedia* entries may differ form those listed in the Appendix. While not all viruses listed are addressed by the *Encyclopedia*, the list provides a ready reference source for all viruses, from the most recognized to the most obscure.

Species names are in italics; names not in italics indicate synonym, strain, serotype, genotype, and clade or isolate names. Abbreviation virus names are enclosed in parenthesis. The family name is also indicated for each virus name.

10924 virus, *Arenaviridae*
12056 virus, *Arenaviridae*
1324Cg/79 virus, *Bunyaviridae*
3076 virus, *Arenaviridae*
3099 virus, *Arenaviridae*
3739 virus, *Arenaviridae*
63U-11 virus, (63UV), *Bunyaviridae*
75V 2374 virus, (V2374V), *Bunyaviridae*
75V 2621 virus, (V2621V), *Bunyaviridae*
78V 2441 virus, (V2441V), *Bunyaviridae*

Gallid herpesvirus 3, (GaHV-3), *Herpesviridae*
Gamboa virus, (GAMV), *Bunyaviridae*
Gan Gan virus, (GGV), *Bunyaviridae*
Ganjam virus, *Bunyaviridae*
Garba virus, (GARV), *Rhabdoviridae*
Gardner-Arnstein feline sarcoma virus, (GAFeSV), *Retroviridae*
Garland chrysanthemum temperate virus, (GCTV), *Partitiviridae*
Garlic common latent virus, (GarCLV), *Carlavirus*
Garlic dwarf virus, (GDV), *Reoviridae*
Garlic latent virus, (GarLV), *Carlavirus*
Garlic mite-borne filamentous virus, (GarMbFV), *Allexivirus*
Garlic mite-borne latent virus, (GarMbLV), *Allexivirus*
Garlic mosaic virus, (GarMV), *Carlavirus*
Garlic virus 2, *Potyviridae*
Garlic virus A, (GarV-A), *Allexivirus*
Garlic virus B, (GarV-B), *Allexivirus*
Garlic virus C, (GarV-C), *Allexivirus*
Garlic virus D, (GarV-D), *Allexivirus*
Garlic virus X, (GarV-X), *Allexivirus*
Garlic virus, *Potyviridae*
Gazelle herpesvirus, *Herpesviridae*

GB virus A, (GBV-A), *Flaviviridae*
GB virus B, (GBV-B), *Flaviviridae*
GB virus C, (GBV-C), *Flaviviridae*
GBV-A-like agents, (GBV-A-like), *Flaviviridae*
Gentiana latent virus, (GenLV), *Carlavirus*
Geotrupes sylvaticus entomopoxvirus, (GSEV), *Poxviridae*
Gerbera symptomless virus, (GeSLV), *Rhabdoviridae*
Germiston virus, (GERV), *Bunyaviridae*
Getah virus, (GETV), *Togaviridae*
Giardia lamblia virus, (GLV), *Totiviridae*
Gibbon ape leukemia virus, (GALV), *Retroviridae*
Ginger chlorotic fleck virus, (GCFV), *Sobemovirus*
Gloriosa stripe mosaic virus, (GSMV), *Potyviridae*
Glycine mosaic virus, (GMV), *Comoviridae*
Glycine mottle virus, (GMoV), *Tombusviridae*
Glypta fumiferanae ichnovirus, (GfIV), *Polydnaviridae*
Glypta sp. *ichnovirus*, (GspIV), *Polydnaviridae*
Glyptapanteles flavicoxis bracovirus, (GflBV), *Polydnaviridae*
Glyptapanteles indiensis bracovirus, (GiBV), *Polydnaviridae*
Glyptapanteles liparidis bracovirus, (GlBV), *Polydnaviridae*
Goat adenovirus 1, 2, (GAdV-1, 2), *Adenoviridae*
Goat herpesvirus, *Herpesviridae*
Goatpox virus, (GTPV), *Poxviridae*
Goeldichironomus haloprasimus entomopoxvirus, (GHEV), *Poxviridae*
Golden shiner reovirus, (GSV), *Reoviridae*
Goldfish herpesvirus, *Herpesviridae*
Goldfish virus 1, (GFV-1), *Iridoviridae*
Gomoka virus, *Reoviridae*
Gomphrena virus, (GoV), *Rhabdoviridae*
Gonometa podocarpi virus, (GpV), Unassigned
Gonometa rufibrunnea cypovirus 3, (GrCPV-3), *Reoviridae*
Goose adenovirus 1 to 3, (GoAdV-1 to 3), *Adenoviridae*
Goose adenovirus, (GoAdV), *Adenoviridae*
Goose parvovirus, (GPV), *Parvoviridae*
Gordil virus, (GORV), *Bunyaviridae*
Gorilla herpesvirus, *Herpesviridae*
Gossas virus, (GOSV), *Rhabdoviridae*
Grand Arbaud virus, (GAV), *Bunyaviridae*
Grapevine Algerian latent virus, (GALV), *Tombusviridae*
Grapevine berry inner necrosis virus, (GINV), *Trichovirus*
Grapevine Bulgarian latent virus satellite RNA, Satellite
Grapevine Bulgarian latent virus, (GBLV), *Comoviridae*
Grapevine chrome mosaic virus, (GCMV), *Comoviridae*
Grapevine fanleaf virus satellite RNA, Satellite
Grapevine fanleaf virus, (GFLV), *Comoviridae*
Grapevine fleck virus, (GFkV), Unassigned
Grapevine leafroll-associated virus 1, (GLRaV-1), *Closteroviridae*
Grapevine leafroll-associated virus 2, (GLRaV-2), *Closteroviridae*
Grapevine leafroll-associated virus 3, (GLRaV-3), *Closteroviridae*
Grapevine leafroll-associated virus 4, (GLRaV-4), *Closteroviridae*
Grapevine leafroll-associated virus 5, (GLRaV-5), *Closteroviridae*
Grapevine leafroll-associated virus 6, (GLRaV-6), *Closteroviridae*
Grapevine leafroll-associated virus 7, (GLRaV-7), *Closteroviridae*
Grapevine Tunisian ringspot virus, (GTRSV), *Comoviridae*
Grapevine virus A, (GVA), *Vitivirus*
Grapevine virus B, (GVB), *Vitivirus*
Grapevine virus C, (GVC), *Vitivirus*
Grapevine virus D, (GVD), *Vitivirus*
Grapevine yellow speckle viroid 1, (GYSVd-1), *Pospiviroidae*
Grapevine yellow speckle viroid 2, (GYSVd-2), *Pospiviroidae*
Grass carp reovirus, (GCRV), *Reoviridae*
Grass carp rhabdovirus, *Rhabdoviridae*
Gray Lodge virus, (GLOV), *Rhabdoviridae*
Great Island virus, (GIV), *Reoviridae*
Great Island virus, (GIV), *Reoviridae*
Great Saltee Island virus, (GSIV), *Reoviridae*
Great Saltee virus, (GRSV), *Bunyaviridae*
Green lizard herpesvirus, *Herpesviridae*
Grey kangaroo poxvirus, (KXV), *Poxviridae*
Grey patch disease of turtles, *Herpesviridae*
Grimsey virus, (GSYV), *Reoviridae*
Ground squirrel hepatitis virus, (GSHV), *Hepadnaviridae*
Groundnut bud necrosis virus, (GBNV), *Bunyaviridae*
Groundnut chlorotic fan-spot virus, (GCFSV), *Bunyaviridae*
Groundnut crinkle virus, *Carlavirus*
Groundnut eyespot virus, (GEV), *Potyviridae*
Groundnut ringspot virus, (GRSV), *Bunyaviridae*
Groundnut rosette assistor virus, (GRAV), *Luteoviridae*
Groundnut rosette virus satellite RNA, Satellite
Groundnut rosette virus, (GRV), *Umbravirus*
Groundnut yellow spot virus, (GYSV), *Bunyaviridae*
Gruid herpesvirus 1, (GrHV-1), *Herpesviridae*

GU71U 344 virus, (GU344V), *Bunyaviridae*
GU71U 350 virus, (GU350V), *Bunyaviridae*
Guajara virus, (GJAV), *Bunyaviridae*
Guama virus, (GMAV), *Bunyaviridae*
Guanarito virus, (GTOV), *Arenaviridae*
Guar green sterile virus, *Potyviridae*
Guar symptomless virus, (GSLV), *Potyviridae*
Guaratuba virus, (GTBV), *Bunyaviridae*
Guaroa virus, (GROV), *Bunyaviridae*
Guinea grass mosaic virus, (GGMV), *Potyviridae*
Guinea pig adenovirus 1, (GPAdV-1), *Adenoviridae*
Guinea pig adenovirus, (GPAdV), *Adenoviridae*
Guinea pig Chlamydia phage, (GPCh), *Microviridae*
Guinea pig cytomegalovirus, *Herpesviridae*
Guinea pig herpesvirus 3, *Herpesviridae*
Guinea pig herpesvirus, *Herpesviridae*
Guinea pig type-C oncovirus, (GPCOV), *Retroviridae*
Guineafowl transmissible enteritis virus, (GTEV), *Picornaviridae*
Gumbo Limbo virus, (GLV), *Bunyaviridae*
Guppy virus 6, (GV6), *Iridoviridae*
Gurupi virus, (GURV), *Reoviridae*
Gynura latent virus, (GyLV), *Carlavirus*
Gypsy moth virus, (GMV), *Nodaviridae*

H-1 virus, (H-1PV), *Parvoviridae*
H-32580 virus, (H32580V), *Bunyaviridae*
Habenaria mosaic virus, (HaMV), *Potyviridae*
Haematopoietic necrosis herpesvirus of goldfish, *Herpesviridae*
Haemophilus phage HP1, (HP1), *Myoviridae*
Haemophilus phage S2, (S2), *Myoviridae*
Halobacterium phage Hs1, (Hs1), *Myoviridae*
Halobacterium phage ϕH, (ϕH), *Myoviridae*
Hamster herpesvirus, *Herpesviridae*
Hamster polyomavirus, (HaPyV), *Polyomaviridae*
Hantaan 76-118 virus, *Bunyaviridae*
Hantaan virus, (HTNV), *Bunyaviridae*
Harbour seal herpesvirus, *Herpesviridae*
Harbour seals picorna-like virus, (SPLV), *Picornaviridae*
Hard clam reovirus, (HCRV), *Reoviridae*
Hardy-Zuckerman feline sarcoma virus, (HZFeSV), *Retroviridae*
Hare fibroma virus, (FIBV), *Poxviridae*
Hart Park virus, (HPV), *Rhabdoviridae*
Hartebeest malignant catarrhal fever virus, *Herpesviridae*
Hart's tongue fern mottle virus, (HTFMoV), Unassigned
Harvey murine sarcoma virus, (HaMSV), *Retroviridae*
Hawaii virus, (HV), *Caliciviridae*
Hazara virus, (HAZV), *Bunyaviridae*
HB virus, (HBPV), *Parvoviridae*
HB55 virus, *Bunyaviridae*
HCV cluster 1, (HCV-1), *Flaviviridae*
HCV cluster 2, (HCV-J6), *Flaviviridae*
HCV cluster 3, (HCV-NZL1), *Flaviviridae*
HCV cluster 4, (HCV-ED43), *Flaviviridae*
HCV cluster 5, (HCV-EVH1480), *Flaviviridae*
HCV cluster 6, (HCV-EUHK2), *Flaviviridae*
Helenium virus S, (HVS), *Carlavirus*
Helenium virus Y, (HVY), *Potyviridae*
Helicoverpa armigera stunt virus, (HaSV) *Tetraviridae*
Helicoverpa zea SNPV, (HzSNPV), *Baculoviridae*
Heliothis armigera cypovirus ('B' strain), *Reoviridae*
Heliothis armigera cypovirus 11, (HaCPV-11), *Reoviridae*
Heliothis armigera cypovirus 14 ('A' strain), (HaCPV-14), *Reoviridae*
Heliothis armigera cypovirus 5, (HaCPV-5), *Reoviridae*
Heliothis armigera cypovirus 8, (HaCPV-8), *Reoviridae*
Heliothis armigera entomopoxvirus 'L', (HAVE), *Poxviridae*
Heliothis armigera iridescent virus, *Iridoviridae*
Heliothis virescens ascovirus 1a, (HvAV-1a), *Ascoviridae*
Heliothis zea cypovirus 11, (HzCPV-11), *Reoviridae*
Heliothis zea virus 1, (HzV-1), Unassigned
Heliothis/Helicoverpa zea iridescent virus, *Iridoviridae*
Helleborus mosaic virus, (HeMV), *Carlavirus*
Helminthosporium maydis virus, (HMV), Unassigned
Helminthosporium victoriae virus 145S, (HvV-145S), *Partitiviridae*
Helminthosporium victoriae virus 190S, (HvV-190S), *Totiviridae*
Henbane mosaic virus, (HMV), *Potyviridae*
Hepatitis A virus, (HAV), *Picornaviridae*
Hepatitis B virus, (HBV), *Hepadnaviridae*
Hepatitis C virus, (HCV), *Flaviviridae*
Hepatitis delta virus, (HDV), *Deltavirus*
Hepatitis E virus, (HEV), "HEV-like viruses"
Hepatitis G virus, (HGV-1), *Flaviviridae*
Hepatopancreatic parvo-like virus of shrimps, *Parvoviridae*
Heracleum latent virus, (HLV), *Vitivirus*
Heracleum virus 6, (HV-6), *Closteroviridae*
Heron hepatitis B virus, (HHBV), *Hepadnaviridae*
Herpes simplex virus 1, *Herpesviridae*
Herpes simplex virus 2, *Herpesviridae*
Herpesvirus aotus 1, *Herpesviridae*
Herpesvirus aotus 3, *Herpesviridae*
Herpesvirus ateles strain 73, *Herpesviridae*

Herpesvirus ateles, *Herpesviridae*
Herpesvirus cuniculi, *Herpesviridae*
Herpesvirus cyclopsis, *Herpesviridae*
Herpesvirus marmota, *Herpesviridae*
Herpesvirus pan, *Herpesviridae*
Herpesvirus papio 2, *Herpesviridae*
Herpesvirus papio, *Herpesviridae*
Herpesvirus pottos, *Herpesviridae*
Herpesvirus saimiri, *Herpesviridae*
Herpesvirus salmonis, *Herpesviridae*
Herpesvirus sanguinus, *Herpesviridae*
Herpesvirus scophthalmus, *Herpesviridae*
Herpesvirus simiae, *Herpesviridae*
Herpesvirus sylvilagus, *Herpesviridae*
Herpesvirus tamarinus, *Herpesviridae*
Heteronychus arator iridescent virus, *Iridoviridae*
Hibiscus chlorotic ringspot virus, (HCRSV), *Tombusviridae*
Hibiscus latent ringspot virus, (HLRSV), *Comoviridae*
Highlands J virus, (HJV), *Togaviridae*
Himetobi P virus, (HiPV), "CrPV-like viruses"
Hincksia hinckiae virus a, (HhV-a), *Phycodnaviridae*
Hippeastrum latent virus, *Carlavirus*
Hippeastrum mosaic virus, (HiMV), *Potyviridae*
Hippotragine herpesvirus 18, (HiHV-1), *Herpesviridae*
Hirame rhabdovirus, (HIRRV), *Rhabdoviridae*
Hog cholera virus, *Flaviviridae*
HoJo virus, *Bunyaviridae*
Holcus lanatus yellowing virus, (HLYV), *Rhabdoviridae*
Holcus streak virus, (HSV), *Potyviridae*
Hollyhock leaf curl virus, (HLCV), *Geminiviridae*
Honeysuckle latent virus, (HnLV), *Carlavirus*
Honeysuckle yellow vein mosaic virus, (HYVMV), *Geminiviridae*
Hop latent viroid, (HpLVd), *Pospiviroidae*
Hop latent virus, (HpLV), *Carlavirus*
Hop mosaic virus, (HpMV), *Carlavirus*
Hop stunt viroid, (HSVd), *Pospiviroidae*
Hop trefoil cryptic virus 1, (HTCV-1), *Partitiviridae*
Hop trefoil cryptic virus 2, (HTCV-2), *Partitiviridae*
Hop trefoil cryptic virus 3, (HTCV-3), *Partitiviridae*
Hordeum mosaic virus, (HoMV), *Potyviridae*
Hordeum vulgare BARE-1 virus, (HvuBar1V), *Pseudoviridae*
Horsegram yellow mosaic virus, (HgYMV), *Geminiviridae*
Horseradish curly top virus, (HrCTV), *Geminiviridae*
Horseradish latent virus, (HRLV), *Caulimoviridae*
Hosta virus X, (HVX), *Potexvirus*
HR80-39, *Bunyaviridae*
Hsiung kaplow herpesvirus, *Herpesviridae*
Hughes virus, (HUGV), *Bunyaviridae*
Human adenovirus 1, 2, 5, 6, (HAdV-1, 2, 5, 6), *Adenoviridae*
Human adenovirus 12, 18, 31, (HAdV-12, 18, 31), *Adenoviridae*
Human adenovirus 16, 21, 34, 35, 50, (HAdV-16, 21, 34, 35, 50), *Adenoviridae*
Human adenovirus 20, 22–30, 32, 33, (HAdV-20, 22–30, 32, 33), *Adenoviridae*
Human adenovirus 3, 7, 11, 14, (HAdV-3, 7, 11, 14), *Adenoviridae*
Human adenovirus 36-39, 42–49, 51, (HAdV-36–39, 42-49, 51), *Adenoviridae*
Human adenovirus 4, (HAdV-4), *Adenoviridae*
Human adenovirus 40, 41, (HAdV-40, 41), *Adenoviridae*
Human adenovirus 8–10, 13, 15, 17, 19, (HAdV-8–10, 13, 15, 17, 19), *Adenoviridae*
Human adenovirus A, (HAdV-A), *Adenoviridae*
Human adenovirus B, (HAdV-B), *Adenoviridae*
Human adenovirus C, (HAdV-C), *Adenoviridae*
Human adenovirus D, (HAdV-D), *Adenoviridae*
Human adenovirus E, (HAdV-E), *Adenoviridae*
Human adenovirus F, (HAdV-F), *Adenoviridae*
Human astrovirus 1, (HAstV-1), *Astroviridae*
Human astrovirus 2, (HAstV-2), *Astroviridae*
Human astrovirus 3, (HAstV-3), *Astroviridae*
Human astrovirus 4, (HAstV-4), *Astroviride*
Human astrovirus 5, (HAstV-5), *Astroviridae*
Human astrovirus 6, (HAstV-6), *Astroviridae*
Human astrovirus 7, (HAstV-7), *Astroviridae*
Human astrovirus 8, (HAstV-8), *Astroviridae*
Human astrovirus, (HAstV), *Astroviridae*
Human coronavirus 229E, (HCoV-229E), *Coronaviridae*
Human coronavirus OC43, (HCoV-OC43), *Coronaviridae*
Human coxsackievirus A1, (CV-A1), *Picornaviridae*
Human coxsackievirus A10, (CV-A10), *Picornaviridae*
Human coxsackievirus A11, (CV-A11), *Picornaviridae*
Human coxsackievirus A12, (CV-A12), *Picornaviridae*
Human coxsackievirus A13, (CV-A13), *Picornaviridae*
Human coxsackievirus A14, (CV-A14), *Picornaviridae*
Human coxsackievirus A15, (CV-A15), *Picornaviridae*
Human coxsackievirus A16, (CV-A16), *Picornaviridae*
Human coxsackievirus A17, (CV-A17), *Picornaviridae*
Human coxsackievirus A18, (CV-A18), *Picornaviridae*

Human coxsackievirus A19, (CV-A19), *Picornaviridae*
Human coxsackievirus A2, (CV-A2), *Picornaviridae*
Human coxsackievirus A20, (CV-A20), *Picornaviridae*
Human coxsackievirus A21, (CV-A21), *Picornaviridae*
Human coxsackievirus A22, (CV-A22), *Picornaviridae*
Human coxsackievirus A24, (CV-A24), *Picornaviridae*
Human coxsackievirus A3, (CV-A3), *Picornaviridae*
Human coxsackievirus A4, (CV-A4), *Picornaviridae*
Human coxsackievirus A5, (CV-A5), *Picornaviridae*
Human coxsackievirus A6, (CV-A6), *Picornaviridae*
Human coxsackievirus A7, (CV-A7), *Picornaviridae*
Human coxsackievirus A8, (CV-A8), *Picornaviridae*
Human coxsackievirus A9, (CV-A9), *Picornaviridae*
Human coxsackievirus B1, (CV-B1), *Picornaviridae*
Human coxsackievirus B2, (CV-B2), *Picornaviridae*
Human coxsackievirus B3, (CV-B3), *Picornaviridae*
Human coxsackievirus B4, (CV-B4), *Picornaviridae*
Human coxsackievirus B5, (CV-B5), *Picornaviridae*
Human coxsackievirus B6, (CV-B6), *Picornaviridae*
Human cytomegalovirus, *Herpesviridae*
Human echovirus 1, (E-1), *Picornaviridae*

Marigold mottle virus, (MaMoV), *Potyviridae*
Marituba virus, (MTBV), *Bunyaviridae*
Marmomid herpesvirus 1, (MarHV-1), *Herpesviridae*
Marmoset cytomegalovirus, *Herpesviridae*
Marmoset herpesvirus, *Herpesviridae*
Marmosetpox virus, (MPV), *Poxviridae*
Marrakai virus, (MARV), *Reoviridae*
MARU 10962 virus, (GAMV), *Bunyaviridae*
Mason-Pfizer monkey virus, (MPMV), *Retroviridae*
Masou salmon reovirus MSV, (MSRV), *Reoviridae*
Matruh virus, (MTRV), *Bunyaviridae*
Matucare virus, (MATV), *Reoviridae*
Maus Elberfeld virus, *Picornaviridae*
Mayaro virus, (MAYV), *Togaviridae*
Mboke virus, (MBOV), *Bunyaviridae*
MC2 virus, *Arenaviridae*
Meaban virus, (MEAV), *Flaviviridae*
Measles virus, (MeV), *Paramyxoviridae*
Medical lake macaque herpesvirus, *Herpesviridae*
Megakepasma mosaic virus, (MegMV), *Closteroviridae*
Melandrium yellow fleck virus, (MYFV), *Bromoviridae*
Melanoplus sanguinipes entomopoxvirus 'O', (MSEV), *Poxviridae*
Melao virus, (MELV), *Bunyaviridae*
Meleagrid herpesvirus 1, (MeHV-1), *Herpesviridae*
Melilotus latent virus, (MeLV), *Rhabdoviridae*
Melilotus mosaic virus, (MeMV), *Potyviridae*
Melolontha melolontha entomopoxvirus, (MMEV), *Poxviridae*
Melon leaf curl virus, (MLCV), *Geminiviridae*
Melon necrotic spot virus, (MNSV), *Tombusviridae*
Melon rugose mosaic virus, (MRMV), *Tymovirus*
Melon variegation virus, (MVV), *Rhabdoviridae*
Melon vein-banding mosaic virus, (MVBMV), *Potyviridae*
Mengovirus, *Picornaviridae*
Mermet virus, (MERV), *Bunyaviridae*
Methanobacterium phage ΦF3, (ΦF3), *Siphoviridae*
Methanobacterium phage ΨM1, (ΨM1), *Siphoviridae*
Methanobrevibacter phage PG, (PG), *Siphoviridae*
Mexican papita viroid, (MPVd), *Pospiviroidae*
Mexico virus, (MXV), *Caliciviridae*
Mibuna temperate virus, (MTV), *Partitiviridae*
Mice minute virus, (MMV), *Parvoviridae*
Michigan alfalfa virus, *Luteoviridae*
Micrococcus phage N1, (N1), *Siphoviridae*
Micrococcus phage N5, (N5), *Siphoviridae*
Micromonas pusilla virus GM1, (MpV-GM1), *Phycodnaviridae*
Micromonas pusilla virus PB6, (MpV-PB6), *Phycodnaviridae*
Micromonas pusilla virus PB7, (MpV-PB7), *Phycodnaviridae*
Micromonas pusilla virus PB8, (MpV-PB8), *Phycodnaviridae*

Micromonas pusilla virus PL1, (MpV-PL1), *Phycodnaviridae*
Micromonas pusilla virus SG1, (MpV-SG1), *Phycodnaviridae*
Micromonas pusilla virus SP1, (MpV-SP1), *Phycodnaviridae*
Micromonas pusilla virus SP2, (MpV-SP2), *Phycodnaviridae*
Microplitis croceipes bracovirus, (McBV), *Polydnaviridae*
Microplitis demolitor bracovirus, (MdBV), *Polydnaviridae*
Microtus pennyslvanicus herpesvirus, *Herpesviridae*
Middelburg virus, (MIDV), *Togaviridae*
Milk vetch dwarf virus, (MDV), *Nanovirus*
Milker's nodule virus, *Poxviridae*
Mill Door virus, (MDRV), *Reoviridae*
Mimosa bacilliform virus, (MBV), *Caulimoviridae*
Minatitlan virus, (MNTV), *Bunyaviridae*
Mink calicivirus, (MCV), *Caliciviridae*
Mink enteritis virus, (MEV), *Parvoviridae*
Minnal virus, (MINV), *Reoviridae*
Mirabilis mosaic virus, (MiMV), *Caulimoviridae*
Mirim virus, (MIRV), *Bunyaviridae*
Miscanthus streak virus, (MiSV), *Geminiviridae*
Mitchell river virus, (MRV), *Reoviridae*
MM-2325 virus, (BAKV), *Bunyaviridae*
Mobala virus, (MOBV), *Arenaviridae*
Modoc virus, (MODV), *Flaviviridae*
Moju virus, (MOJUV), *Bunyaviridae*
Mojui Dos Campos virus, (MDCV), *Bunyaviridae*
Mokola virus, (MOKV), *Rhabdoviridae*
Molinia streak virus, (MoSV), *Tombusviridae*
Mollicutes phage Br1, (Br1), *Myoviridae*
Mollicutes phage C3, (C3), *Podoviridae*
Mollicutes phage L3, (L3), *Podoviridae*
Molluscum contagiosum virus, (MOCV), *Poxviridae*
Molluscum-like poxvirus, (MOV), *Poxviridae*
Moloney murine leukemia virus, (MoMLV), *Retroviridae*
Moloney murine sarcoma virus, (MoMSV), *Retroviridae*
Monkeypox virus, (MPXV), *Poxviridae*
Mono Lake virus, (MLV), *Reoviridae*
Monongahela virus, *Bunyaviridae*
Montana myotis leukoencephalitis virus, (MMLV), *Flaviviridae*
Monte Dourado virus, (MDOV), *Reoviridae*
Mopeia virus, (MOPV), *Arenaviridae*
Moravia/Ma5302V virus, *Bunyaviridae*
Moriche virus, (MORV), *Bunyaviridae*
Moroccan pepper virus, (MPV), *Tombusviridae*
Moroccan watermelon mosaic virus, (MWMV), *Potyviridae*
Mosqueiro virus, (MQOV), *Rhabdoviridae*
Mosquito iridescent virus, *Iridoviridae*
Mossuril virus, (MOSV), *Rhabdoviridae*
Mount Elgon bat virus, (MEBV), *Rhabdoviridae*
Mouse cytomegalovirus, *Herpesviridae*
Mouse herpesvirus strain 68, *Herpesviridae*
Mouse mammary tumor virus, (MMTV), *Retroviridae*
Mouse parvovirus 1, (MPV), *Parvoviridae*
Mouse thymic herpesvirus, *Herpesviridae*
Movar virus, *Herpesviridae*
MP 401 virus, (NDV), *Bunyaviridae*
MRM31 virus, (KOOV), *Bunyaviridae*
Mucambo virus, (MUCV), *Togaviridae*
Mudjinbarry virus, (MUDV), *Reoviridae*
Muir Springs virus, (MSV), *Rhabdoviridae*
Mulberry latent virus, (MLV), *Carlavirus*
Mulberry ringspot virus, (MRSV), *Comoviridae*
Mule deer poxvirus, (DPV), *Poxviridae*
Muleshoe virus, (MULV), *Bunyaviridae*
Mumps virus, (MuV), *Paramyxoviridae*
Mungbean mosaic virus, (MbMV), *Potyviridae*
Mungbean mottle virus, (MMoV), *Potyviridae*
Mungbean yellow mosaic virus, (MYMV), *Geminiviridae*
Munguba virus, (MUNV), *Bunyaviridae*
Murid herpesvirus 1, (MuHV-1), *Herpesviridae*
Murid herpesvirus 2, (MuHV-2), *Herpesviridae*
Murid herpesvirus 3, (MuHV-3), *Herpesviridae*
Murid herpesvirus 4, (MuHV-4), *Herpesviridae*
Murid herpesvirus 5, (MuHV-5), *Herpesviridae*
Murid herpesvirus 6, (MuHV-6), *Herpesviridae*
Murine adenovirus 1, (MAdV-1), *Adenoviridae*
Murine adenovirus 2, (MAdV-2), *Adenoviridae*
Murine adenovirus A, (MAdV-A), *Adenoviridae*
Murine adenovirus B, (MAdV-B), *Adenoviridae*
Murine hepatitis virus, (MHV), *Coronaviridae*
Murine leukemia virus, (MLV), *Retroviridae*
Murine parainfluenza virus 1, *Paramyxoviridae*
Murine pneumonia virus, (MPV), *Paramyxoviridae*
Murine pneumotropic virus, (MPtV), *Polyomaviridae*
Murine polyomavirus, (MPyV), *Polyomaviridae*
Murray Valley encephalitis virus, (MVEV), *Flaviviridae*
Murre virus, (MURV), *Bunyaviridae*
Murutucu virus, (MURV), *Bunyaviridae*
Musca domestica reovirus, (MdRV), *Reoviridae*
Muscovy duck parvovirus, (MDPV), *Parvoviridae*
Mushroom bacilliform virus, (MBV), *Barnaviridae*
Mushroom virus 4, *Partitiviridae*
Muskmelon vein necrosis virus, (MuVNV), *Carlavirus*
Mycobacterium phage I3, (I3), *Myoviridae*
Mycobacterium phage L5, (L5), *Siphoviridae*
Mycobacterium phage lacticola, (lacticola), *Siphoviridae*

Mycobacterium phage Leo, (Leo), *Siphoviridae*
Mycobacterium phage minetti, (minetti), *Siphoviridae*
Mycobacterium phage phlei, (GS4E), *Siphoviridae*
Mycobacterium phage R1-Myb, (R1-Myb), *Siphoviridae*
Mycobacterium phage ϕ17, (ϕ17), *Podoviridae*
Mycogone perniciosa virus, (MpV), *Totiviridae*
Mykines virus, (MYKV), *Reoviridae*
Mynahpox virus, (MYPV), *Poxviridae*
Myriotrichia clavaeformis virus a, (McV-a), *Phycodnaviridae*
Myrobalan latent ringspot virus (160), (MLRSV), *Comoviridae*
Myrobalan latent ringspot virus satellite RNA, Satellite
Myxoma virus, (MYXV), *Poxviridae*

Nairobi sheep disease virus, (NSDV), *Bunyaviridae*
Nandina mosaic virus, (NaMV), *Potexvirus*
Nandina stem pitting virus, (NSPV), *Capillovirus*
Naranjal virus, (NJLV), *Flaviviridae*
Narcissus degeneration virus, (NDV), *Potyviridae*
Narcissus late season yellows virus, (NLSYV), *Potyviridae*
Narcissus latent virus, (NLV), *Potyviridae*
Narcissus mosaic virus, (NMV), *Potexvirus*
Narcissus tip necrosis virus, (NTNV), *Tombusviridae*
Narcissus yellow stripe virus, (NYSV), *Potyviridae*
Nasoule virus, (NASV), *Rhabdoviridae*
Nasturtium mosaic virus, *Potyviridae*
Navarro virus, (NAVV), *Rhabdoviridae*
Ndelle virus, (NDEV), *Reoviridae*
Ndumu virus, (NDUV), *Togaviridae*
Neckar river virus, (NRV), *Tombusviridae*
Negro coffee mosaic virus, (NeCMV), *Potexvirus*
Nelson Bay orthoreovirus, (NBV), *Reoviridae*
Neodiprion sertifer NPV, (NeseNPV), *Baculoviridae*
Nepuyo virus, (NEPV), *Bunyaviridae*
Nerine latent virus, (NeLV), *Carlavirus*
Nerine virus X, (NVX), *Potexvirus*
Nerine virus Y, (NVY), *Potyviridae*
Nerine virus, (NV), *Potyviridae*
Nerine yellow stripe virus, (NeYSV), *Potyviridae*
Netivot virus, (NETV), *Reoviridae*
New Minto virus, (NMV), *Rhabdoviridae*
New York virus, (NYV), *Bunyaviridae*
New Zealand virus, (NZV), *Nodaviridae*
Newcastle disease virus, (NDV), *Paramyxoviridae*
Nezara viridula virus-1, (NVV-1), Unassigned
Ngaingan virus, (NGAV), *Rhabdoviridae*
Ngari virus, (NRIV), *Bunyaviridae*
Ngoupe virus, (NGOV), *Reoviridae*
Nicotiana glutinosa stunt viroid, (NGSVd), *Avsunviroidae*
Nicotiana tabacum Tnt1 virus, (NtaTnt1V), *Pseudoviridae*
Nicotiana tabacum Tto1 virus, (NtaTto1V), *Pseudoviridae*
Nicotiana velutina mosaic virus, (NVMV), Unassigned
Nilaparvata lugens reovirus, (NLRV), *Reoviridae*
Nile crocodile poxvirus, (CRV), *Poxviridae*
Nique virus, (NIQV), *Bunyaviridae*
Nkolbisson virus, (NKOV), *Rhabdoviridae*
NMH10 virus, *Bunyaviridae*
NMR-11 virus, *Bunyaviridae*
Noctua pronuba cypovirus 7, (NpCPV-7), *Reoviridae*
Nodamura virus, (NoV), *Nodaviridae*
Nola virus, (NOLAV), *Bunyaviridae*
North Clett virus, (NCLV), *Reoviridae*
North End virus, (NEDV), *Reoviridae*
Northern cereal mosaic virus, (NCMV), *Rhabdoviridae*
Northern pike herpesvirus, *Herpesviridae*
Northway virus, (NORV), *Bunyaviridae*
Norwalk virus, (NV), *Caliciviridae*
Norwalk virus, (NV), *Caliciviridae*
Nothoscordum mosaic virus, (NoMV), *Potyviridae*
Ntaya virus, (NTAV), *Flaviviridae*
Nudaurelia capensis β virus, (NβV) *Tetraviridae*
Nudaurelia capensis ε virusa, (NεV), *Tetraviridae*
Nudaurelia capensis ω virus, (NωV), *Tetraviridae*
Nudaurelia cytherea cypovirus 8, (NcCPV-8), *Reoviridae*
Nugget virus, (NUGV), *Reoviridae*
Nyabira virus, (NYAV), *Reoviridae*
Nyamanini virus, (NYMV), Unassigned
Nyando virus, (NDV), *Bunyaviridae*

O'nyong-nyong virus, (ONNV), *Togaviridae*
Oak-Vale virus, (OVRV), *Rhabdoviridae*
Oat blue dwarf virus, (OBDV), *Marafivirus*
Oat chlorotic stunt virus, (OCSV), *Tombusviridae*
Oat golden stripe virus, *Furovirus*
Oat mosaic virus, (OMV), *Potyviridae*
Oat necrotic mottle virus, (ONMV), *Potyviridae*
Oat sterile dwarf virus, (OSDV), *Reoviridae*
Oat striate mosaic virus, (OSMV), *Rhabdoviridae*
Obodhiang virus, (OBOV), *Rhabdoviridae*
Obuda pepper virus, (ObPV), *Tobamovirus*
Oceanside virus, (OCV), *Bunyaviridae*
Ockelbo virus, *Togaviridae*
Odontoglossum ringspot virus, (ORSV), *Tobamovirus*
Odrenisrou virus, (ODRV), *Bunyaviridae*

Oedaleus senigalensis entomopoxvirus 'O', (OSEV), *Poxviridae*
Oilseed rape mosaic virus, *Tobamovirus*
Oita virus, (OITAV), *Rhabdoviridae*
Okhotskiy virus, (OKHV), *Reoviridae*
Okola virus, (OKOV), *Bunyaviridae*
Okra leaf curl virus, (OLCV), *Geminiviridae*
Okra mosaic virus, (OkMV), *Tymovirus*
Olesicampe benefactor ichnovirus, (ObIV), *Polydnaviridae*
Olesicampe geniculatae ichnovirus, (OgIV), *Polydnaviridae*
Olifantsvlei virus, (OLIV), *Bunyaviridae*
Olive latent ringspot virus, (OLRSV), *Comoviridae*
Olive latent virus 1, (OLV-1), *Tombusviridae*
Olive latent virus 2, (OLV-2), *Bromoviridae*
Oliveros virus, (OLVV), *Arenaviridae*
Omo virus, (OMOV), *Bunyaviridae*
Omsk hemorrhagic fever virus, (OHFV), *Flaviviridae*
Oncorhynchus masou herpesvirus, *Herpesviridae*
Onion mite-borne latent virus, (OMbLV), *Allexivirus*
Onion yellow dwarf virus, (OYDV), *Potyviridae*
Ononis yellow mosaic virus, (OYMV), *Tymovirus*
Operophtera brumata cypovirus 2, (ObCPV-2), *Reoviridae*
Operophtera brumata cypovirus 3, (ObCPV-3), *Reoviridae*
Operophtera brumata entomopoxvirus 'L', (OBEV), *Poxviridae*
Opogonia iridescent virus, *Iridoviridae*
Oran virus, *Bunyaviridae*
Orangutan herpesvirus, *Herpesviridae*
Orchid fleck virus, (OFV), Unassigned
Orf virus, (ORFV), *Poxviridae*
Orgyia pseudosugata cypovirus 5, (OpCPV-5), *Reoviridae*
Orgyia pseudotsugata MNPV, (OpMNPV), *Baculoviridae*
Orgyia pseudotsugata SNPV, (OpSNPV), *Baculoviridae*
Oriboca virus, (ORIV), *Bunyaviridae*
Oriximina virus, (ORXV), *Bunyaviridae*
Ornithogalum mosaic virus, (OrMV), *Potyviridae*
Oropouche virus, (OROV), *Bunyaviridae*
Orungo virus 1 to 4, (ORUV-1 to 4), *Reoviridae*
Orungo virus, (ORUV), *Reoviridae*
Oryctes rhinoceros virus, (OrV), Unassigned
Ossa virus, (OSSAV), *Bunyaviridae*
Ostreid herpesvirus 1, (OsHV-1), *Herpesviridae*
Ouango virus, (OUAV), *Rhabdoviridae*
Oubi virus, (OUBIV), *Bunyaviridae*
Ourem virus, (OURV), *Reoviridae*
Ourmia melon virus, (OuMV), *Ourmiavirus*
Ovine adeno-associated virus, (OAAV), *Parvoviridae*
Ovine adenovirus 1, (OAdV-1), *Adenoviridae*
Ovine adenovirus 2-5, (OAdV-2 to 5), *Adenoviridae*
Ovine adenovirus 6, (OAdV-6), *Adenoviridae*
Ovine adenovirus A, (OAdV-A), *Adenoviridae*
Ovine adenovirus B, (OAdV-B), *Adenoviridae*
Ovine adenovirus C, (OAdV-C), *Adenoviridae*
Ovine adenovirus isolate 287, (OAdV-287), *Adenoviridae*
Ovine astrovirus 1, (OAstV-1), *Astroviridae*
Ovine astrovirus, (OAstV), *Astroviridae*
Ovine herpesvirus 1, (OvHV-1), *Herpesviridae*
Ovine herpesvirus 2, (OvHV-2), *Herpesviridae*
Ovine papillomavirus 1, (OPV-1), *Papillomaviridae*
Ovine papillomavirus 2, (OPV-2), *Papillomaviridae*
Ovine papillomavirus, (OPV), *Papillomaviridae*
Ovine pulmonary adenocarcinoma virus, *Retroviridae*
Owl hepatosplenitis herpesvirus, *Herpesviridae*

p2b-2 virus, *Arenaviridae*
p360 virus, *Bunyaviridae*
Pacific oyster herpesvirus, *Herpesviridae*
Pacific pond turtle herpesvirus, *Herpesviridae*
Pacora virus, (PCAV), *Bunyaviridae*
Pacui virus, (PACV), *Bunyaviridae*
Pahayokee virus, (PAHV), *Bunyaviridae*
Painted turtle herpesvirus, *Herpesviridae*
Pakistani cotton leaf curl virus, (PCLCuV), *Geminiviridae*
Palestina virus, (PLSV), *Bunyaviridae*
Palm mosaic virus, (PalMV), *Potyviridae*
Palyam virus, (PALV), *Reoviridae*
Palyam virus, (PALV), *Reoviridae*
Pampa virus, (PAMV), *Arenaviridae*
PAn 18400 virus, *Arenaviridae*
Pangola stunt virus, (PaSV), *Reoviridae*
Panicum mosaic satellite virus, Satellite
Panicum mosaic virus satellite RNA, Satellite
Panicum mosaic virus, (PMV), *Tombusviridae*
Panicum streak virus, (PanSV), *Geminiviridae*
Panolis flammea NPV, (PaflNPV), *Baculoviridae*
Papaya leaf curl virus, (PaLCV), *Geminiviridae*
Papaya leaf distortion mosaic virus, (PLDMV), *Potyviridae*
Papaya mosaic virus, (PapMV), *Potexvirus*
Papaya ringspot virus, (PRSV), *Potyviridae*
Papilio machaon cypovirus 2, (PmCPV-2), *Reoviridae*
Paprika mild mottle virus, (PaMMV), *Tobamovirus*

Peanut yellow spot virus, *Bunyaviridae*
Pear blister canker viroid, (PBCVd), *Pospiviroidae*
Pear rusty skin viroid, *Pospiviroidae*
Pear vein yellows virus, *Foveavirus*
Peaton virus, (PEAV), *Bunyaviridae*
Pecteilis mosaic virus, (PcMV), *Potyviridae*
Pectinophora gossypiella cypovirus 11, (PgCPV-11), *Reoviridae*
Pectinophora gossypiella virus, (PgV), Unassigned
Pelargonium flower break virus, (PFBV), *Tombusviridae*
Pelargonium leaf curl virus, (PLCV), *Tombusviridae*
Pelargonium vein clearing virus, (PVCV), *Rhabdoviridae*
Pelargonium zonate spot virus, (PZSV), Unassigned
Penaeus monodon NPV, (PemoNPV), *Baculoviridae*
Penguinpox virus, (PEPV), *Poxviridae*
Penicillium brevicompactum virus, (PbV), *Partitiviridae*
Penicillium chrysogenum virus, (PcV), *Partitiviridae*
Penicillium cyaneo-fulvum virus, (Pc-fV), *Partitiviridae*
Penicillium stoloniferum virus F, (PsV-F), *Partitiviridae*
Penicillium stoloniferum virus S, (PsV-S), *Partitiviridae*
Pepino latent virus, *Carlavirus*
Pepino mosaic virus, (PepMV), *Potexvirus*
Pepper huasteco virus, (PHV), *Geminiviridae*
Pepper leaf curl virus, (PepLCV), *Geminiviridae*
Pepper mild mosaic virus, (PMMV), *Potyviridae*
Pepper mild mottle virus, (PMMoV), *Tobamovirus*
Pepper mild tigré virus, (PepMTV), *Geminiviridae*
Pepper mottle virus, (PepMoV), *Potyviridae*
Pepper ringspot virus, (PepRSV), *Tobravirus*
Pepper severe mosaic virus, (PepSMV), *Potyviridae*
Pepper vein banding virus, (PVBV), *Potyviridae*
Pepper veinal mottle virus, (PVMV), *Potyviridae*
Perch hyperplasia virus, (PHV), *Retroviridae*
Percid herpesvirus 1, (PeHV-1), *Herpesviridae*
Perconia circinata virus, (PeCV), Unassigned
Perdicid herpesvirus 1, (PdHV-1), *Herpesviridae*
Pergamino virus, *Bunyaviridae*
Perilla mottle virus, (PerMoV, *Potyviridae*
Perinet virus, (PERV), *Rhabdoviridae*
Periplanata fuliginosa densovirus, (PfDNV), *Parvoviridae*
Peru tomato mosaic virus, (PTV), *Potyviridae*
Peste-des-petits-ruminants virus, (PPRV), *Paramyxoviridae*
Pestivirus of giraffe, *Flaviviridae*
Petevo virus, (PETV), *Reoviridae*
Petuluma, (FIV-P), *Retroviridae*
Petunia asteroid mosaic virus, (PetAMV), *Tombusviridae*
Petunia flower mottle virus, (PetFMV), *Potyviridae*
Petunia vein clearing virus, (PVCV), *Caulimoviridae*
Phalacrocoracid herpesvirus 1, (PhHV-1), *Herpesviridae*
Phalaenopsis chlorotic spot virus, (PhCSV), *Rhabdoviridae*
Phalera bucephala cypovirus 2, (PbCPV-2), *Reoviridae*
Phanerotoma flavitestacea bracovirus, (PfBV), *Polydnaviridae*
Pheasant adenovirus, (PhAdV-1), *Adenoviridae*

Phialophora radicicola virus 2-2-A, (PrV-2-2-A), *Partitiviridae*
Philosamia cynthia x ricini virus, (PxV), *Tetraviridae*
Phlogophera meticulosa cypovirus 3, (PmCPV-3), Reoviridae
Phlogophora meticulosa cypovirus 8, (PmCPV-8), *Reoviridae*
Phnom Penh bat virus, (PPBV), *Flaviviridae*
Phocid herpesvirus 1, (PhoHV-1), *Herpesviridae*
Phocine distemper virus, (PDV), *Paramyxoviridae*
Pholetesor ornigis bracovirus, (PoBV), *Polydnaviridae*
Physalis mottle virus, (PhyMV), *Tymovirus*
Physalis severe mottle virus, (PhySMV), *Bunyaviridae*
Physarum polycephalum Tp1 virus, (PpoTp1V), *Pseudoviridae*
Pichinde virus, (PICV), *Arenaviridae*
Picola virus, (PIAV), *Reoviridae*
Pieris brassicae granulovirus, (PbGV, ArGV-1), *Baculoviridae*
Pieris rapae cypovirus 12, (PrCPV-12), *Reoviridae*
Pieris rapae cypovirus 2, (PrCPV-2), *Reoviridae*
Pieris rapae cypovirus 3, (PrCPV-3), *Reoviridae*
Pieris rapae densovirus, (PrDNV), *Parvoviridae*
Pigeon adenovirus, (PiAdV), *Adenoviridae*
Pigeon circovirus, (PiCV), *Circoviridae*
Pigeon herpesvirus, *Herpesviridae*
Pigeon pea mosaic mottle viroid, (PPMMoVd), *Avsunviroidae*
Pigeon pea proliferation virus, (PPPV), *Rhabdoviridae*
Pigeonpox virus, (PGPV), *Poxviridae*
Pike fry rhabdovirus, (PFRV), *Rhabdoviridae*
Pineapple bacilliform virus, (PBV), *Caulimoviridae*
Pineapple chlorotic leaf streak virus, (PCLSV), *Rhabdoviridae*
Pineapple mealybug wilt-associated virus 1, (PMWaV-1), *Closteroviridae*
Pineapple mealybug wilt-associated virus 2, (PMWaV-2), *Closteroviridae*
Piper yellow mottle virus, (PYMoV), *Caulimoviridae*
Pirital virus, (PIRV), *Arenaviridae*
Piry virus, (PIRYV), *Rhabdoviridae*
Pisum virus, (PisV), *Rhabdoviridae*
Pittosporum vein yellowing virus, (PVYV), *Rhabdoviridae*
Pixuna virus, (PIXV), *Togaviridae*
Plantago asiatica mosaic virus, (PlAMV), *Potexvirus*
Plantago mottle virus, (PlMoV), *Tymovirus*
Plantago severe mottle virus, (PlSMoV), *Potexvirus*
Plantago virus 4, (PlV-4), *Caulimoviridae*
Plantain mottle virus, (PlMV), *Rhabdoviridae*
Plantain virus 6, (PlV-6), *Tombusviridae*
Plantain virus 7, (PlV-7), *Potyviridae*
Plantain virus 8, (PlV-8), *Carlavirus*
Plantain virus X, (PlVX), *Potexvirus*
Plautia stali intestine virus, (PSIV), "CrPV-like viruses"
Playas virus, (PLAV), *Bunyaviridae*
Pleioblastus mosaic virus, (PleMV), *Potyviridae*
Pleuronectid herpesvirus 1, (PlHV-1), *Herpesviridae*
Plodia interpunctella granulovirus, (PiGV), *Baculoviridae*
Plum dapple viroid, *Pospiviroidae*
Plum pox virus, (PPV), *Potyviridae*
Poa semilatent virus, (PSLV), *Hordeivirus*
Poinsettia cryptic virus, (PnCV), *Partitiviridae*
Poinsettia mosaic virus, (PnMV), *Tymovirus*
Pokeweed mosaic virus, (PkMV), *Potyviridae*
Poliovirus, (PV), *Picornaviridae*
Polistes hebraeus cypovirus 13, (PhCPV-13), *Reoviridae*
Pongine herpesvirus 1, (PoHV-1), *Herpesviridae*
Pongine herpesvirus 2, (PoHV-2), *Herpesviridae*
Pongine herpesvirus 3, (PoHV-3), *Herpesviridae*
Pongola virus, (PGAV), *Bunyaviridae*
Ponteves virus, (PTVV), *Bunyaviridae*
Poovoot virus, (POOV), *Reoviridae*
Poplar mosaic virus, (PopMV), *Carlavirus*
Populus virus, (PV), *Potyviridae*
Porcelio dilatatus reovirus, (PdRV), *Reoviridae*
Porcelio dilatatus iridescent virus, *Iridoviridae*
Porcine adenovirus 1-3, (PAdV-1 to 3), *Adenoviridae*
Porcine adenovirus 4, (PAdV-4), *Adenoviridae*
Porcine adenovirus 5, (PAdV-5), *Adenoviridae*
Porcine adenovirus A, (PAdV-B), *Adenoviridae*
Porcine adenovirus B, (PAdV-B), *Adenoviridae*
Porcine adenovirus C, (PAdV-C), *Adenoviridae*
Porcine astrovirus 1, (PAstV-1), *Astroviridae*
Porcine astrovirus, (PAstV), *Astroviridae*
Porcine circovirus, (PCV), *Circoviridae*
Porcine enteric calicivirus, (PECV), *Caliciviridae*
Porcine enterovirus 1, *Picornaviridae*
Porcine enterovirus 10, (PEV-10), *Picornaviridae*
Porcine enterovirus 11-13, (PEV-11 to 13), *Picornaviridae*
Porcine enterovirus 2-7, (PEV-2 to 7), *Picornaviridae*
Porcine enterovirus 8, (PEV-8), *Picornaviridae*
Porcine enterovirus 9, (PEV-9), *Picornaviridae*
Porcine enterovirus A, (PEV-A), *Picornaviridae*
Porcine enterovirus B, (PEV-B), *Picornaviridae*
Porcine epidemic diarrhea virus, (PEDV), *Coronaviridae*
Porcine hemagglutinating encephalomyelitis virus, (HEV), *Coronaviridae*
Porcine parvovirus, (PPV), *Parvoviridae*
Porcine respiratory and reproductive syndrome virus, *Arteriviridae*
Porcine respiratory coronavirus, (PRCoV), *Coronaviridae*

Porcine rotavirus Cowden, (PoRV-C/Cowden), *Reoviridae*
Porcine rotavirus DC-9, (PoRV-E/DC9), *Reoviridae*
Porcine rubulavirus, (PoRV), *Paramyxoviridae*
Porcine teschovirus 1, (PTV-1), *Picornaviridae*
Porcine teschovirus, (PTV), *Picornaviridae*
Porcine torovirus, (PoTV), *Coronaviridae*
Porcine type-C oncovirus, (PCOV), *Retroviridae*
Porton virus, (PORV), *Rhabdoviridae*
Potato aucuba mosaic virus, (PAMV), *Potexvirus*
Potato black ringspot virus, (PBRSV), *Comoviridae*
Potato leafroll virus, (PLRV), *Luteoviridae*
Potato mop-top virus, (PMTV), *Pomovirus*
Potato spindle tuber viroid, (PSTVd), *Pospiviroidae*
Potato virus A, (PVA), *Potyviridae*
Potato virus M, (PVM), *Carlavirus*
Potato virus S, (PVS), *Carlavirus*
Potato virus T, (PVT), *Trichovirus*
Potato virus U, (PVU), *Comoviridae*
Potato virus V, (PVV), *Potyviridae*
Potato virus X, (PVX), *Potexvirus*
Potato virus Y, (PVY), *Potyviridae*
Potato yellow dwarf virus, (PYDV), *Rhabdoviridae*
Potato yellow mosaic virus, (PYMV), *Geminiviridae*
Pothos latent virus, (PoLV) *Tombusviridae*
Potiskum virus, (POTV), *Flaviviridae*
Potosi virus, (POTV), *Bunyaviridae*
Powassan virus, (POWV), *Flaviviridae*
Precarious Point virus, (PPV), *Bunyaviridae*
Pretoria virus, (PREV), *Bunyaviridae*
Primate calicivirus, (VESV/Pan-1), *Caliciviridae*
Primate T-lymphotropic virus 1, (PTLV-1), *Retroviridae*
Primate T-lymphotropic virus 2, (PTLV-2), *Retroviridae*
Primate T-lymphotropic virus 3, (PTLV-3), *Retroviridae*
Primula mosaic virus, (PrMV), *Potyviridae*
Primula mottle virus, (PrMoV), *Potyviridae*
Prospect Hill virus, (PHV), *Bunyaviridae*
Protapanteles paleacritae bracovirus, (PpBV), *Polydnaviridae*
Prune dwarf virus, (PDV), *Bromoviridae*
Prunus necrotic ringspot virus, (PNRSV), *Bromoviridae*
Prunus virus S, (PruVS), *Carlavirus*
Pseudaletia includens densovirus, (PiDNV), *Parvoviridae*
Pseudaletia unipuncta cypovirus 11, (PuCPV-11), *Reoviridae*
Pseuderanthemum yellow vein virus, (PYVV), *Geminiviridae*
Pseudocowpox virus, (PCPV), *Poxviridae*
Pseudomonas phage 12S, (12S), *Myoviridae*
Pseudomonas phage 42, (42), *Myoviridae*
Pseudomonas phage 525, (525), *Podoviridae*
Pseudomonas phage 7s, (7s), *Leviviridae*
Pseudomonas phage D3, (D3), *Siphoviridae*
Pseudomonas phage F116, (F116), *Podoviridae*
Pseudomonas phage gh-1, (gh-1), *Podoviridae*
Pseudomonas phage Kf1, (Kf1), *Siphoviridae*
Pseudomonas phage M6, (M6), *Siphoviridae*
Pseudomonas phage PB-1, (PB-1), *Myoviridae*
Pseudomonas phage Pf1, (Pf1), *Inoviridae*
Pseudomonas phage Pf2, (Pf2), *Inoviridae*
Pseudomonas phage Pf3, (Pf3), *Inoviridae*
Pseudomonas phage PP7, (PP7), *Leviviridae*
Pseudomonas phage PP8, (PP8), *Myoviridae*
Pseudomonas phage PRR1, (PRR1), *Leviviridae*
Pseudomonas phage PS17, (PS17), *Myoviridae*
Pseudomonas phage PS4, (PS4), *Siphoviridae*
Pseudomonas phage PsP3, (PsP3), *Myoviridae*
Pseudomonas phage Pssy9220, (Psy9220), *Podoviridae*
Pseudomonas phage SD1, (SD1), *Siphoviridae*
Pseudomonas phage ϕ6, (ϕ6), *Cystoviridae*
Pseudomonas phage ϕCTX, (ϕCTX), *Myoviridae*
Pseudomonas phage ϕKZ, (ϕKZ), *Myoviridae*
Pseudomonas phage ϕPLS27, (ϕPLS27), *Podoviridae*
Pseudomonas phage ϕPLS743, (ϕPLS743), *Podoviridae*
Pseudomonas phage ϕW-14, (ϕW-14), *Myoviridae*
Pseudoplusia includens virus, (PiV), *Tetraviridae*
Pseudorabies virus, *Herpesviridae*
Psittacid herpesvirus 1, (PsHV-1), *Herpesviridae*
Psittacinepox virus, (PSPV), *Poxviridae*
Psophocarpus necrotic mosaic virus, *Carlavirus*
Pteroteinon laufella virus-1, (PlV-1), Unassigned
Puchong virus, (PUCV), *Rhabdoviridae*
Pueblo Viejo virus, (PVV), *Bunyaviridae*
Puffin Island virus, (PIV), *Bunyaviridae*
Puma lentivirus (PLV-14), (PLV), *Retroviridae*
Punta Salinas virus, (PSV), *Bunyaviridae*
Punta Toro virus D-4021A, (PTV), *Bunyaviridae*
Punta Toro virus, (PTV), *Bunyaviridae*
Purus virus, (PURV), *Reoviridae*
Puumala virus, (PUUV), *Bunyaviridae*
Python orthoreovirus, (PRV), *Reoviridae*

Qalyub virus, (QYBV), *Bunyaviridae*
Quail pea mosaic virus, (QPMV), *Comoviridae*
Quailpox virus, (QUPV), *Poxviridae*
Quaranfil virus, (QRFV), Unassigned
Queensland fruit fly virus, (QFFV), Unassigned
Quokka poxvirus, (QPV), *Poxviridae*

R22 virus, *Bunyaviridae*
Rabbit calicivirus, (RCV), *Caliciviridae*
Rabbit coronavirus, (RbCoV), *Coronaviridae*

Rabbit fibroma virus, (SFV), *Poxviridae*
Rabbit hemorrhagic disease virus, (RHDV), *Caliciviridae*
Rabbit hemorrhagic disease virus-AST89, (RHDV-AST89), *Caliciviridae*
Rabbit hemorrhagic disease virus-BS89, (RHDV-BS89), *Caliciviridae*
Rabbit hemorrhagic disease virus-FRG, (RHDV-FRG), *Caliciviridae*
Rabbit hemorrhagic disease virus-SD, (RHDV-SD), *Caliciviridae*
Rabbit hemorrhagic disease virus-V351, (RHDV-V351), *Caliciviridae*
Rabbit kidney vacuolating virus, (RKV), *Polyomaviridae*
Rabbitpox virus, (RPXV), *Poxviridae*
Rabies virus, (RABV), *Rhabdoviridae*
Raccoon parvovirus, (RPV), *Parvoviridae*
Raccoonpox virus, (RCNV), *Poxviridae*
Rachiplusia ou MNPV, (RoMNPV), *Baculoviridae*
Radi virus, (RADIV), *Rhabdoviridae*
Radish mosaic virus, (RaMV), *Comoviridae*
Radish vein clearing virus, (RaVCV), *Potyviridae*
Radish yellow edge virus, (RYEV), *Partitiviridae*
Rainbow trout virus, (RTV), *Iridoviridae*
Ranid herpesvirus 1, (RaHV-1), *Herpesviridae*
Ranid herpesvirus 2, (RaHV-2), *Herpesviridae*
Ranunculus mottle virus, (RanMoV), *Potyviridae*
Ranunculus repens symptomless virus, (RaRSV), *Rhabdoviridae*
Ranunculus white mottle virus, (RWMV), *Ophiovirus*
Raphanus virus, (RaV), *Rhabdoviridae*
Raspberry bushy dwarf virus, (RBDV), *Idaeovirus*
Raspberry ringspot virus, (RpRSV), *Comoviridae*
Raspberry vein chlorosis virus, (RVCV), *Rhabdoviridae*
Rat coronavirus, (RtCoV), *Coronaviridae*
Rat cytomegalovirus, *Herpesviridae*
Rat encephalomyelitis virus, (REV), *Picornaviridae*
Rat virus, *Parvoviridae*
Rattlesnake orthoreovirus, (RRV), *Reoviridae*
Raza virus, (RAZAV), *Bunyaviridae*
Razdan virus, (RAZV), *Bunyaviridae*
Red clover cryptic virus 2, (RCCV-2), *Partitiviridae*
Red clover mosaic virus, (RCIMV), *Rhabdoviridae*
Red clover mottle virus, (RCMV), *Comoviridae*
Red clover necrotic mosaic virus, (RCNMV), *Tombusviridae*
Red clover vein mosaic virus, (RCVMV), *Carlavirus*
Red deer herpesvirus, *Herpesviridae*
Red kangaroo poxvirus, (KPV), *Poxviridae*
Red pepper cryptic virus 1, (RPCV-1), *Partitiviridae*
Red pepper cryptic virus 2, (RPCV-2), *Partitiviridae*
Redfin perch virus, (RFPV), *Iridoviridae*
Redspotted grouper nervous necrosis virus, (RGNNV), *Nodaviridae*
Redwood Park virus, (RPV), *Iridoviridae*
Reed Ranch virus, (RRV), *Rhabdoviridae*
Regina ranavirus, (RRV), *Iridoviridae*
Reindeer herpesvirus, *Herpesviridae*
Rembrandt tulip breaking virus, (ReTBV), *Potyviridae*
Reptile calicivirus, (VESV/Cro-1), *Caliciviridae*
Resistencia virus, (RTAV), *Bunyaviridae*
Restan virus, (RESV), *Bunyaviridae*
Reston Ebola virus Philippines, *Filoviridae*
Reston Ebola virus Reston, *Filoviridae*
Reston Ebola virus Siena, *Filoviridae*
Reston Ebola virus Texas, *Filoviridae*
Reston Ebola virus, (REBOV), *Filoviridae*
Reticuloendotheliosis virus (strain T, A), (REV), *Retroviridae*
Rhesus EBV-like herpesvirus, *Herpesviridae*
Rhesus leukocyte associated herpesvirus strain 1, *Herpesviridae*
Rhesus monkey cytomegalovirus, *Herpesviridae*
Rhesus rhadinovirus, *Herpesviridae*
Rheumatoid arthritis virus, (RAV-1), *Parvoviridae*
Rhizidiomyces virus, (RZV), *Rhizidiovirus*
Rhizobium phage 16-2-12, (16-2-12), *Siphoviridae*

Plate 1

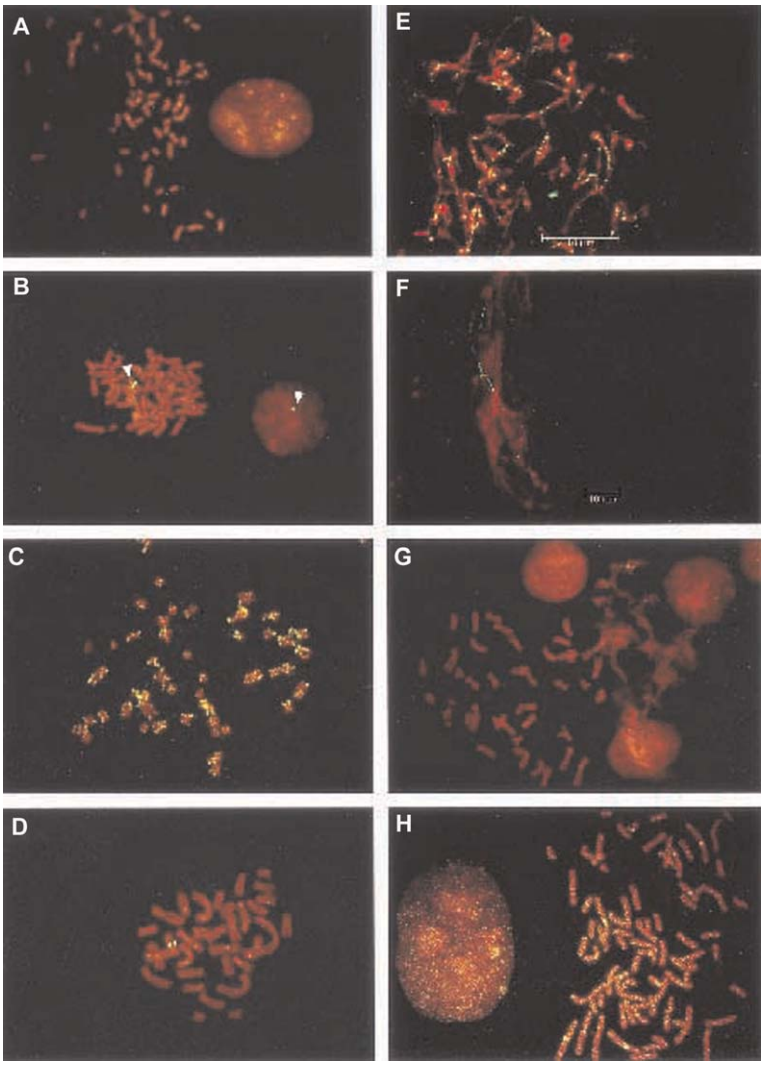

Plate 1 Association of Ad12 DNA with host cell chromosomes.(**A**) Human HeLa cells, uninfected control. (**B**) T637 cells, uninfected: arrowhead points to chromosomally integrated Ad12 genomes. (**C**) Productively Ad12-infected HeLa cells, 6 h p.i. (**D**) Abortively Ad12-superinfected T637 cells, 6 h p.i. (**E**) Productively Ad12-infected HeLa cells, 6 h p.i. (stretched chromosome preparation). (**F**) Ad12-transformed T637 cells (stretched chromosome preparation). (**G**) BHK21 cells, Ad12 DNA added to the medium. (**H**) BHK21, Ad12-DNA-TP added to the medium. Original magnification $\times$ 1250 (**A**–**D**, **G**, **H**); (**E**, **F**) see bar. (Reproduced with permission from Schröer *et al* (1997).) See article (**Adenoviruses *Adenoviridae*): Molecular Biology** for more information.

Plate 2

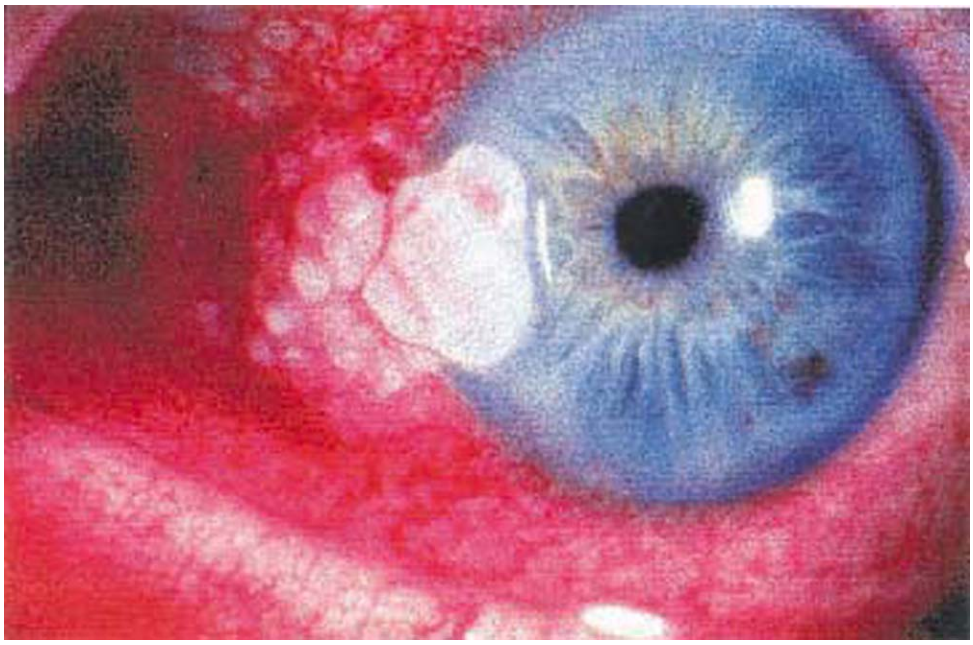

Plate 2 Squamous cell carcinoma of the corneal limbus is associated with infection by human papilloma virus types 16 and 18. See article **Eye Infections** for more information.

Plate 3

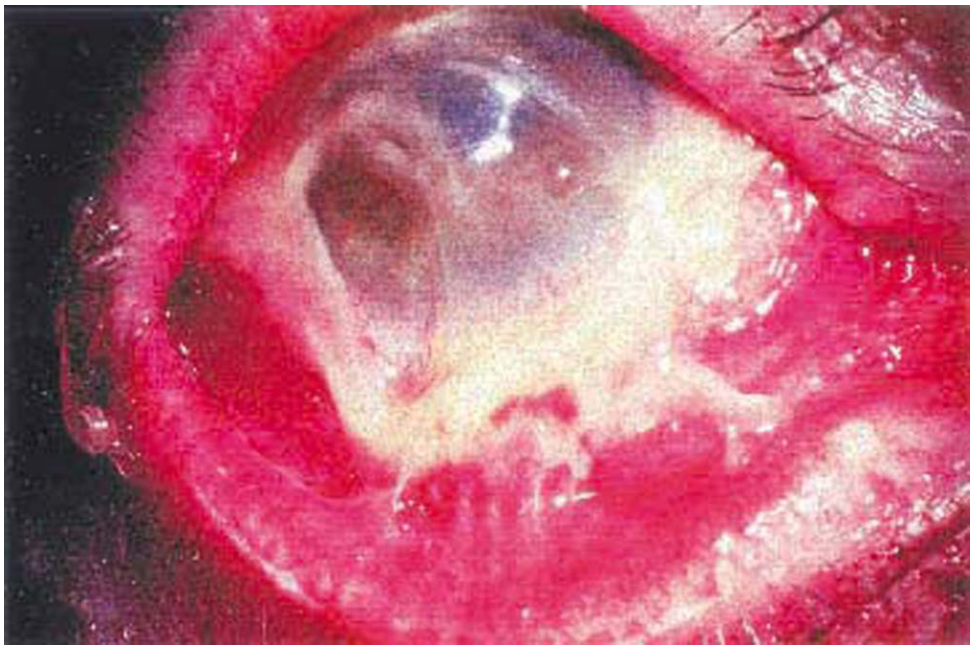

Plate 3 Epidemic keratoconjunctivitis. Infection with adenovirus serotype 19 has resulted in severe ocular surface inflammation. See article **Eye Infections** for more information.

Plate 4

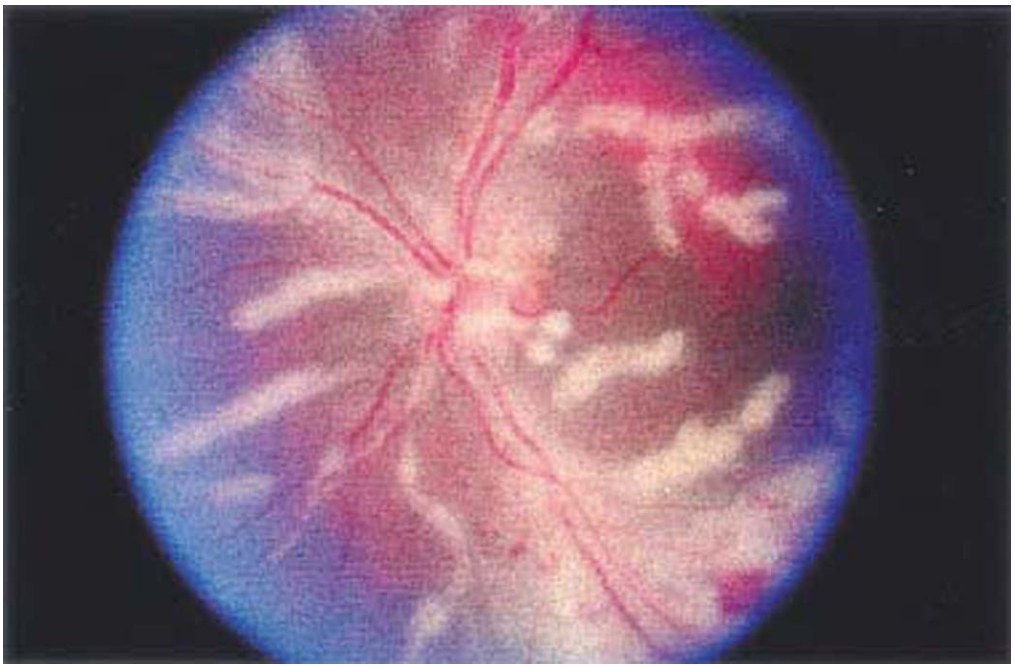

Plate 4 Cytomegalovirus retinitis. Discrete areas of perivascular necrosis and hemorrhage are typical. See article **Eye Infections** for more information.

Plate 5

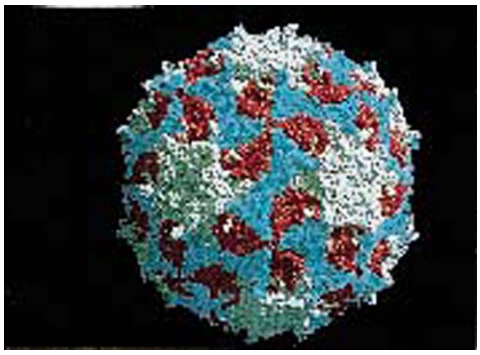

Plate 5 Computer graphics representation of the Mengo virion at a resolution of 3. ϕ 0 (Luo et al., 1987). Each small ball represents a single amino acid residue. The VP1 polypeptides are colored white, VP2 polypeptides are blue and VP3 polypeptides are red. See article **Cardioviruses** (*Picornaviridae*) for more information.

Plate 6

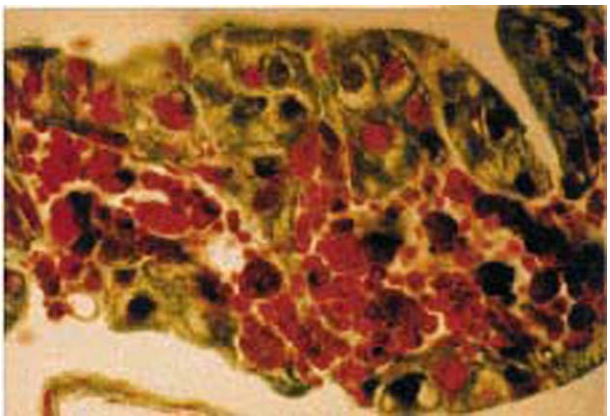

Plate 6 Section through the fat body tissue of the caterpillar, Spodoptera frugiperda, infected with an ascovirus. The green areas are uninfected cells or cells in early stages of infection. The red cells are infected cells and clusters of spherical virion-containing vesicles eventually disseminate into the hemolymph (blood) through ruptures in the basal lamina of the fat body tissue. See article **Ascoviruses (*Ascoviridae*)** for more information.

Plate 7

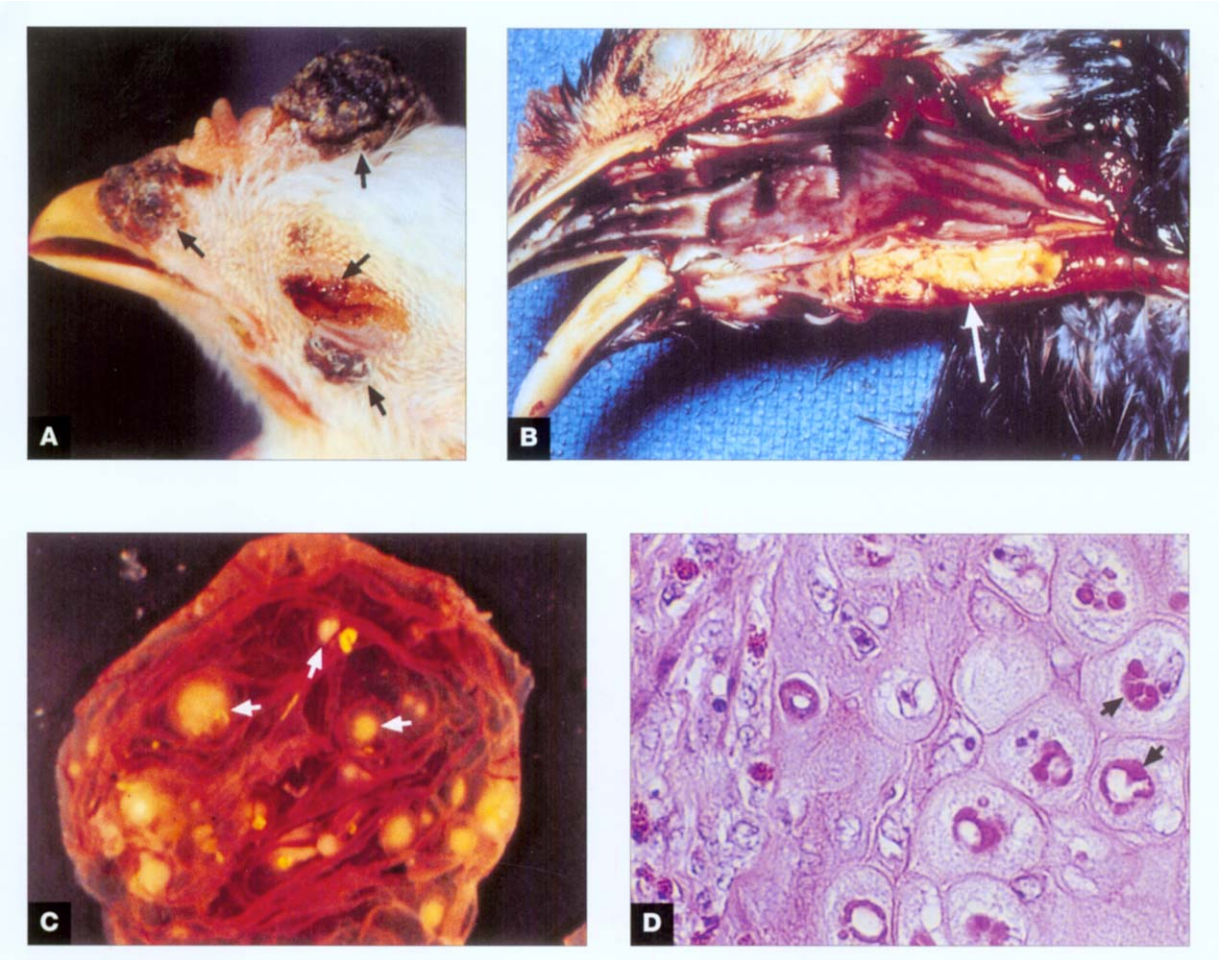

Plate 7 (**A**) Cutaneous lesions of fowlpox. (**B**) Diphtheritic fowlpox – tracheal plug. (**C**) Fowlpox virus lesions (pocks) in the chorioallantoic membrane of a developing chicken embryo. (**D**) Cells infected with fowlpox virus are enlarged and contain cytoplasmic inclusion bodies (arrows). Parts B and D are part of Fowlpox Slide Study Set prepared by Dr Tripathy for American Association of Avian Pathologists. See article **Fowlpox Viruses (*Poxviridae*)** for more information.

Plate 8

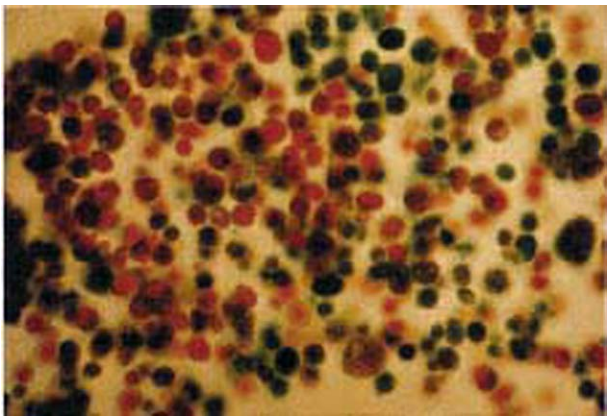

Plate 8 Hemolymph (blood) of the caterpillar, Spodoptera frugiperda, infected with an ascovirus. The green spherical vesicles are hemocytes and virion-containing vesicles in which virion assembly is at an early stage. The red vesicles contain large numbers of fully mature virions. Paraffin section stained with Hamm's strain. 900X. See article **Ascoviruses (*Ascoviridae*)** for more information.

Plate 9

Plate 9 A child with dengue hemorrhagic fever. See article **Dengue Viruses (*Flaviviridae*)** for more information.

Plate 10

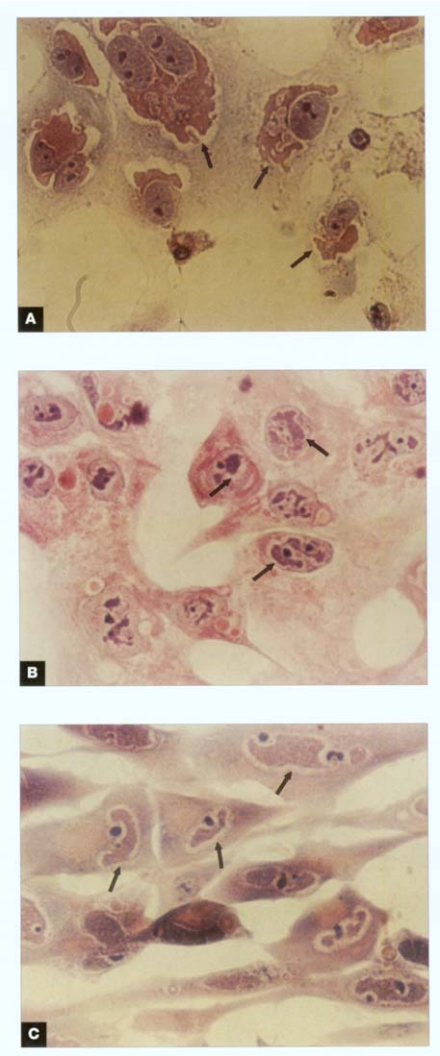

Plate 10 (**A**) Reovirus type 3 infected rhesus monkey kidney cells showing eosinophilic cytoplasmic inclusions (arrows) (H & E, 400X). (**B**) Adenovirus type 2 infected human embryonic kidney cells showing basophilic intranuclear inclusions (arrows) (H & E, 400X). (**C**) Human cytomegalovirus infected human diploid fibroblastic cells showing eosinophilic intranuclear inclusions (arrows) (H & E, 400X). See article **Diagnostic Techniques: Isolation and Identification by Culture and Microscopy** for more information.

Plate 11

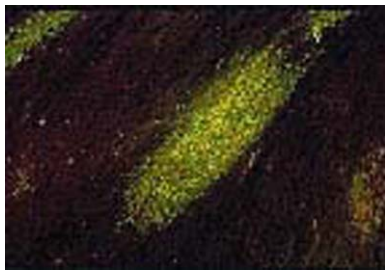

Plate 11 Shell vial culture stained 16 h postinoculation showing CMV immediate early antigens detected in the nuclei of infected human fibroblast cells (immunofluorescence test). See article **Diagnostic Techniques: Isolation and Identification by Culture and Microscopy** for more information.

Plate 12

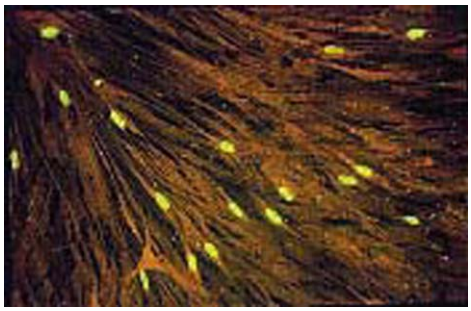

Plate 12 Shell vial culture stained 2 days postinoculation showing foci of varicella zoster virus-infected human fibroblast cells (immunofluorescence test). See article **Diagnostic Techniques: Isolation and Identification by Culture and Microscopy** for more information.

Plate 13

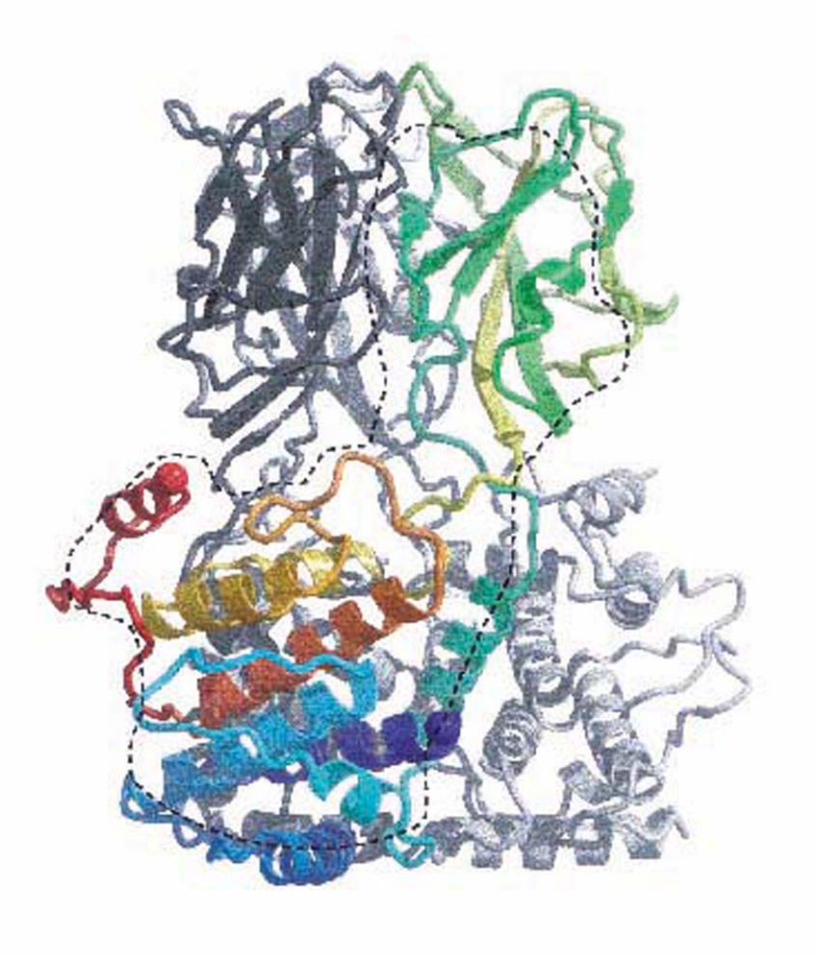

Plate 13 The structure of VP7 trimer rendered from x-ray crystallographic analysis. The threefold symmetry axis of the trimer is disposed vertically so that the flat base at the bottom of the image forms the inner surface of the outer VP7 layer of the core, which adheres to the VP3 subcore. Note the clear division into two domains, the upper domain contains mainly β-strands (shown as arrows), whereas the lower domain is constructed of a number of closely packed helices. (Reproduced from Grimes *et al* (1995) *Nature* 373: 167.) One subunit is outlined with a dashed line to clarify the twist of the subunit trimer with respect to the molecular 3-fold axis. See article **Orbiviruses and Coltiviruses (*Reoviridae*): Molecular Biology** for more information.

Plate 14

Plate 14 Colorized electron microscopy picture of the human immunodeficiency virus (HIV) showing, from right to left, the budding of a viral particle from the membrane of an infected CD4 lymphocyte, an immature particle and two mature virions; note the characteristic cone-shaped core of the upper mature virion. **Human Immunodeficiency Viruses (*Retroviridae*): Antiretroviral Agents** for more information.

Plate 15

Plate 15 Surface representation of the three-dimensional structure of BTV cores (deduced by electron cryo-microscopy at 25Å resolution) showing the trieric configuration of VP7 molecules. See article **Diagnostic Techniques: Isolation and Identification by Culture and Microscopy** for more information.

Plate 16

Plate 16 Symptoms of tobacco mosaic virus (TMV) on tobacco leaf leaves. Center-healthy. Right-leaf of a susceptible cultivar showing the typical mosaic symptoms of systemic TMV infection. Left-leaf of a cultivar containing the N-gene for TMV resistance showing the necrotic local lesions which form around each site of infection and to which the virus is restricted. See article **Plant Resistence to Viruses: Natural Resistence** for more information.

Plate 17

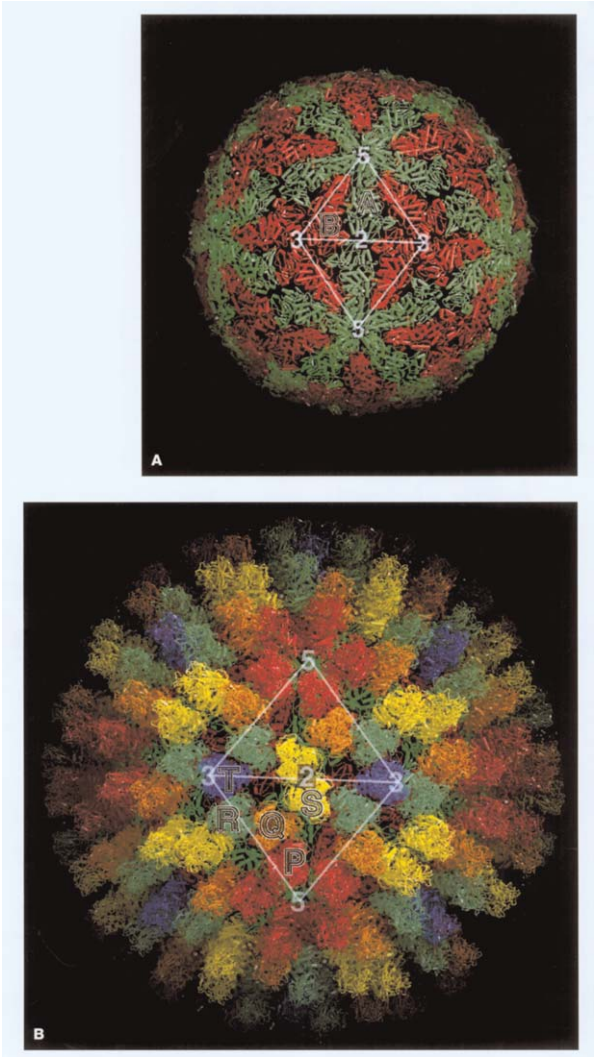

Plate 17 The essential features of the architecture of the native BTV core as determined by x-ray crystallography and cryoelectron microscopy. The icosahedral asymmetric unit is the triangular area defined (as marked) by the symmetric axes of the icosahedron. (**B**) The core surface layer composed of 780 copies of VP7, arranged as 260 trimers with $T = 13$ symmetry. The asymmetric unit contains 13 copies of VP7, arranged as five trimers P, Q, R, S and T: colored red, orange, green, yellow and blue, respectively. Trimer 'T' sits on the icosahedral threefold axis, and thus contributes only a monomer to the unique portion of the capsid. (**A**) The inner capsid layer of the BTV core (the subcore) composed of 120 molecules of VP3, arranged with $T = 2$ symmetry according to the principles of 'geometrical quasi-equivalence'. The icosahedrally unique molecules, of VP3 A and B, are colored in red and green, respectively. Note the completely different structural environment of the A and B molecules. (Reproduced from Grimes *et al* (1998) *Nature* 395: 470–478. Copyright 1998, Macmillan Magazines Ltd. See article **Orbiviruses and Coltiviruses (*Reoviridae*): Molecular Biology** for more information.

Plate 18

Plate 18 A representation of the VP3 B molecule, color-coded by domain. The 'apical' domain is shown in blue (residue 297–588), the 'carapace' domain in green (residues 7–297, 588–698 and 855–901) and the 'dimerization' domain in red (residue 698–855). (With acknowledgement to J. Grimes and D. Stuart for provision of the image.) See article **Orbiviruses and Coltiviruses (*Reoviridae*): Molecular Biology** for more information.

Plate 19

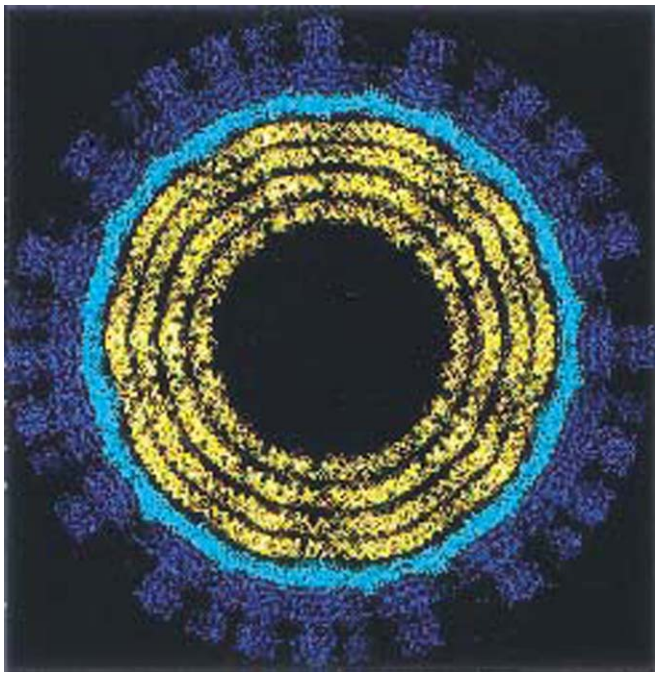

Plate 19 Thin section through the structure of the core of BTV (as determined by x-ray crystallography of native cores of BTV1 and BTV10). The VP7 outer layer of the core is shown in dark blue, the thin VP3 subcore layer in pale blue and the four layers of the genomic dsRNA are predominantly yellow. (Reproduced from Stuart *et al.* (1998) African Horse Sickness Virus. *Arch. Virol. Suppl.* 14: 235–250.) See article **Orbiviruses and Coltiviruses (*Reoviridae*): Molecular Biology** for more information.

Plate 20

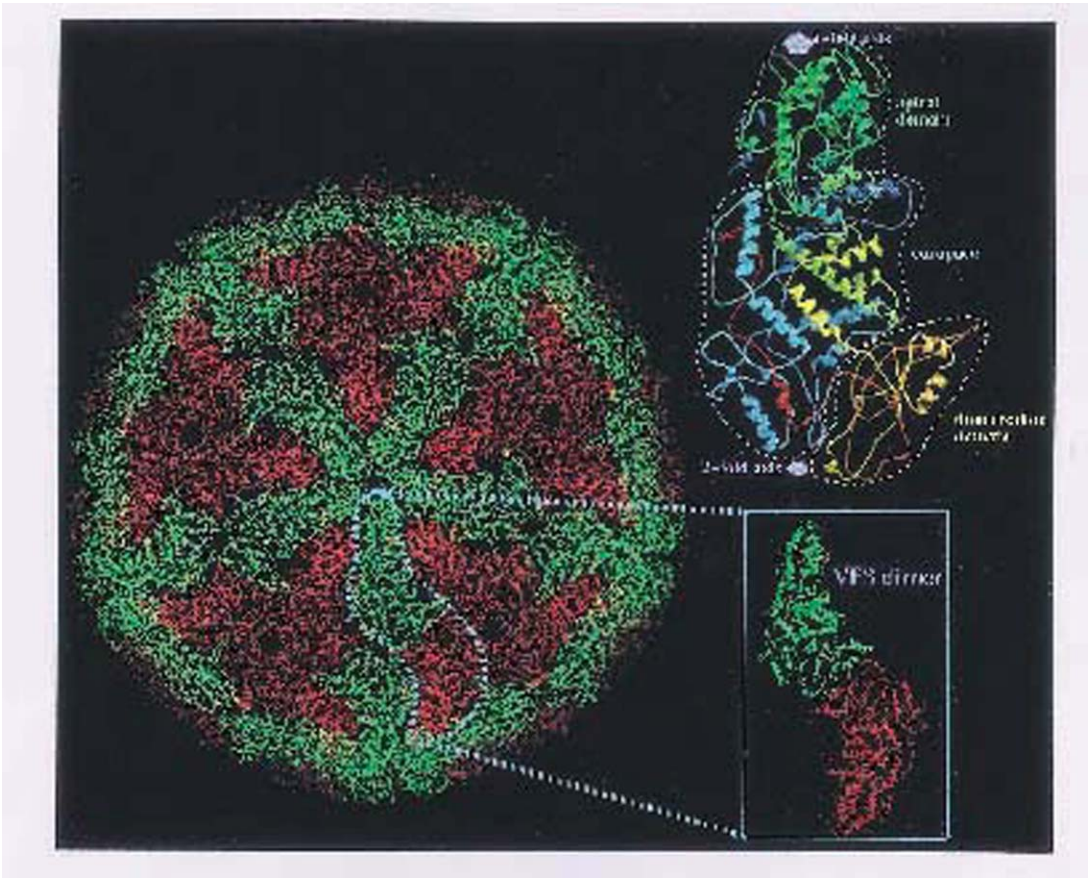

Plate 20 Overall structure and architecture of the VP3 layer of the BTV subcore. Each of 120 molecules has a structure similar to that illustrated on the right of the image. (Reproduced from Stuart *et al* (1998) African Horse Sickness Virus. *Arch. Virol. Suppl.* 14: 235–250.) See article **Orbiviruses and Coltiviruses (*Reoviridae*): Molecular Biology** for more information.

Plate 21

Plate 21 Paralysis of the legs in Marek's disease. See article **Marek's Disease Virus (*Herpesviridae*)** for more information.

Plate 22

Plate 22 Enlarged brachial and sciatic nerves (arrows) in Marek's disease. See article **Marek's Disease Virus (*Herpesviridae*)** for more information.

Plate 23

Plate 23 Ovarian lymphoma (arrow) in Marek's disease. See article **Marek's Disease Virus (*Herpesviridae*)** for more information.

Plate 24

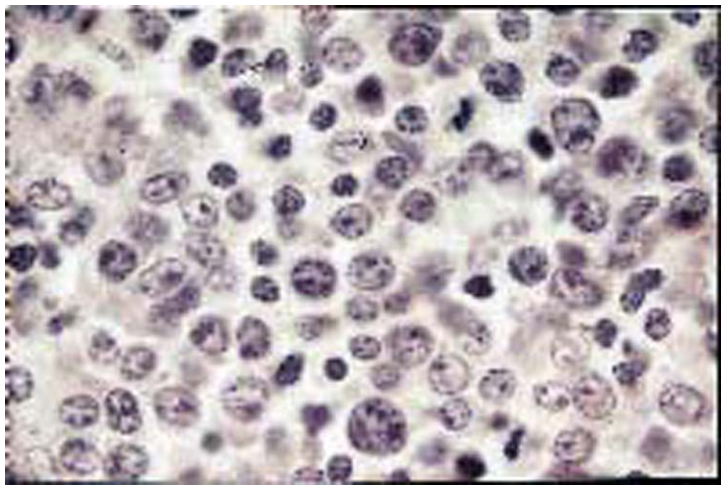

Plate 24 Neural lymphoma in Marek's disease showing varying morphology of lymphoid cells. See article **Marek's Disease Virus (*Herpesviridae*)** for more information.

Plate 25

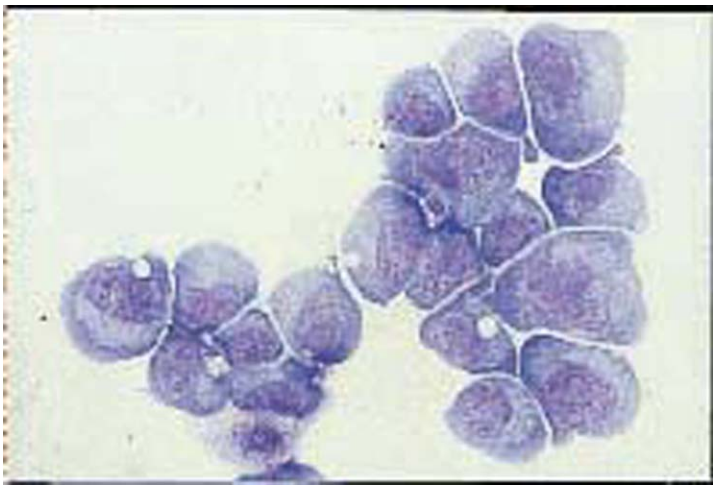

Plate 25 Impression smear of lymphoblastoid cell line derived from a Marek's disease lymphoma. See article **Marek's Disease Virus (*Herpesviridae*)** for more information.

Plate 26

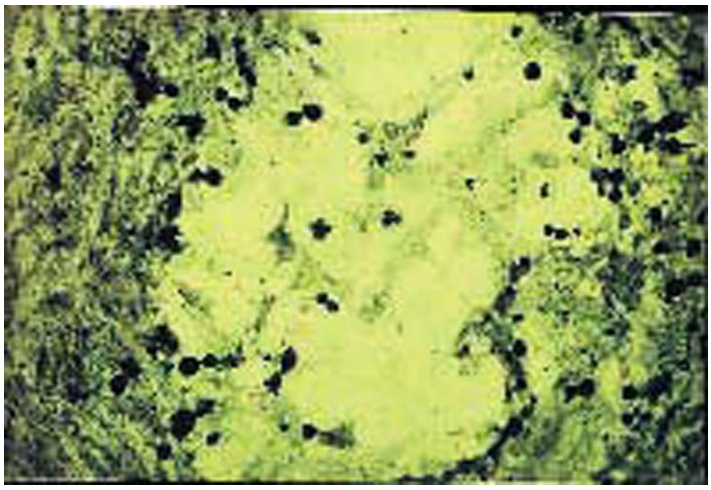

Plate 26 Cytopathic plaque induced in chick kidney cell monolayer culture by Marek's disease virus. See article **Marek's Disease Virus (*Herpesviridae*)** for more information.

Plate 27

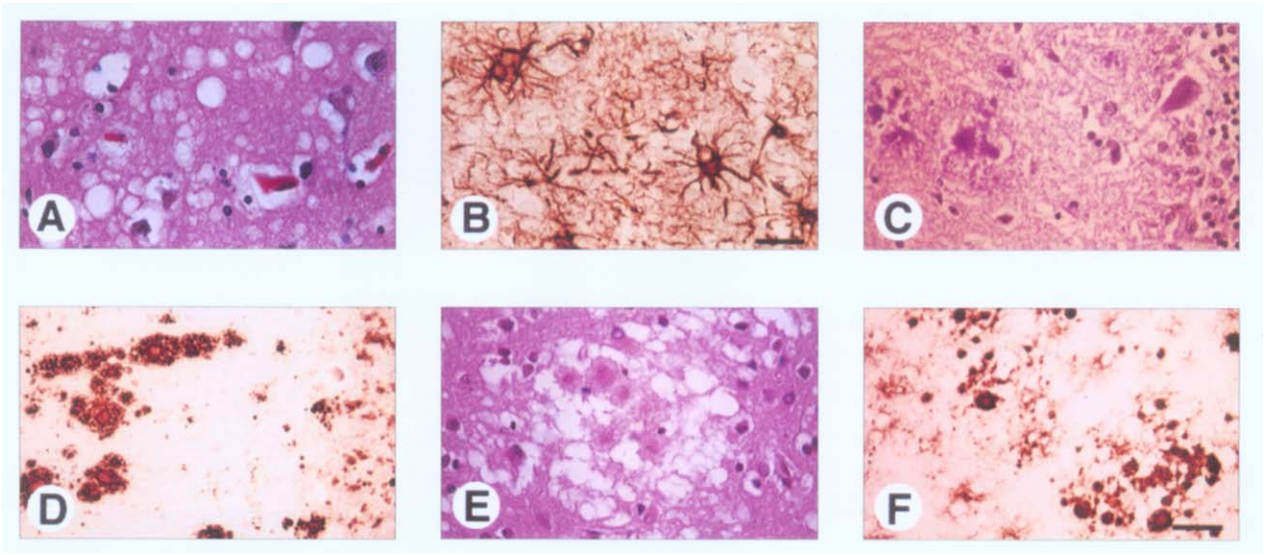

Plate 27 Neuropathology of human prion diseases. Sporadic CJD is characterized by vacuolation of the neuropil of the gray matter, by exuberant reactive astrocytic gliosis, the intensity of which is proportional to the degree of nerve cell loss, and, rarely, by PrP amyloid plaque formation (not shown). The neuropathology of familial CJD is similar. GSS (P102L), as well as other inherited forms of GSS (not shown), is characterized by numerous deposits of PrP amyloid throughout the CNS. New variant CJD (vCJD) has clinical and epidemiological features that suggest it was acquired by infection with prions. The neuropathological features of vCJD are unique among CJD cases because of the abundance of PrP amyloid plaques that are often surrounded by a halo of intense vacuolation. (**A**) Sporadic CJD, cerebral cortex stained with hematoxylin and eosin showing widespread spongiform degeneration. (**B**) Sporadic CJD, cerebral cortex immunostained with anti-GFAP antibodies demonstrating the widespread reactive gliosis. (**C**) GSS, cerebellum with most of the GSS-plaques in the molecular layer (left 80% of micrograph) and many but not all are periodic acid Schiff (PAS) reaction positive. Granule cells and a single Purkinje cell are seen in the right 20% of the panel. (**D**) GSS, cerebellum at the same location as panel C with PrP immunohistochemistry after the hydrolytic autoclaving reveals more PrP plaques than seen with the PAS reaction. (**E**) Variant CJD, cerebral cortex stained with hematoxylin and eosin shows that the plaque deposits are uniquely located within vacuoles. With this histology, these amyloid deposits have been referred to as 'florid plaques'. (**F**) Variant CJD, cerebral cortex stained with PrP immunohistochemistry after hydrolytic autoclaving reveals numerous PrP plaques often occurring in clusters as well as minute PrP deposits surrounding many cortical neurons and their proximal processes. Bar in B = 50 μm and applies also to panels A, C, and D. Bar in F = 100 mu;m and applies also to panel D. See article **Prions: Human and Animal** for more information.

Plate 28

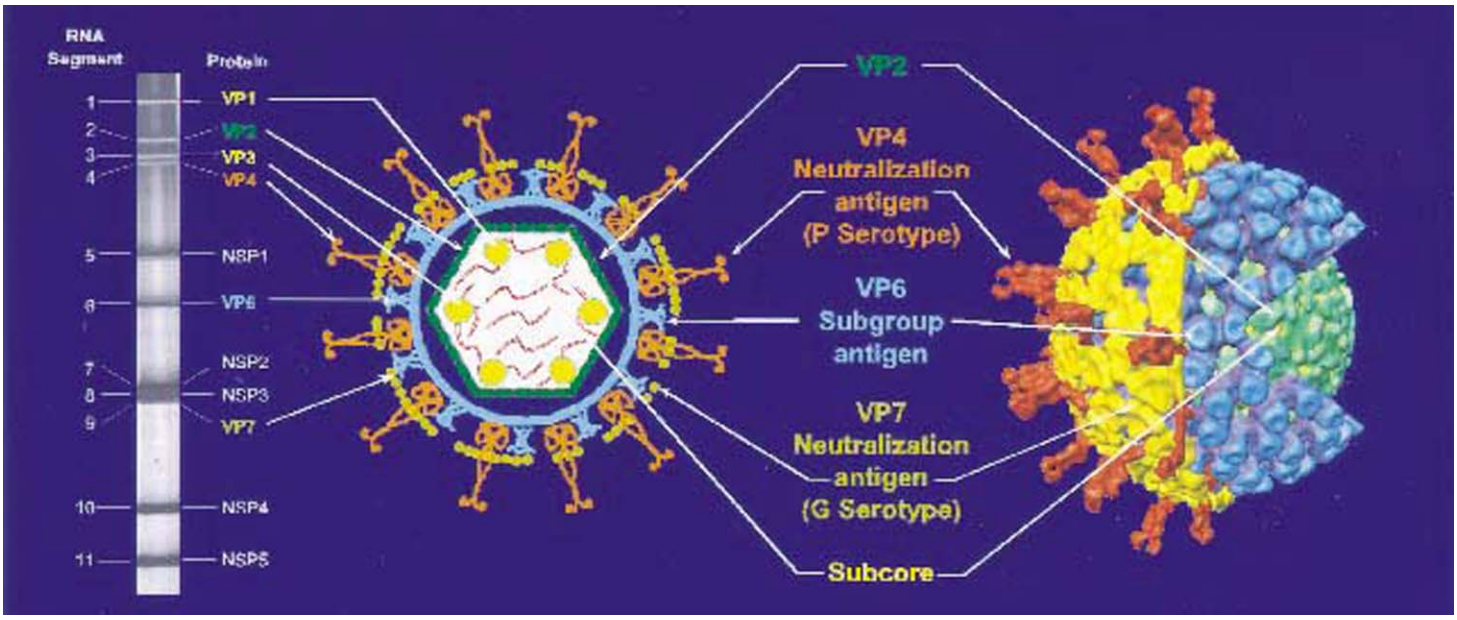

Plate 28 Rotavirus genes, proteins and structure. The left panel shows the RNA segments and the gene coding assignments for the simian rotavirus SA011. See **Table 1** (p. 1586) for details on the genes and proteins. The location of the viral structural proteins in the different shells of the virus particles is shown in the schematic in the center. The major structural proteins that make up the outer shell of particles (VP4 and VP7), the intermediate shell (VP6), the inner shell (VP2) and the subcore region composed of ordered viral RNA are illustrated in the 25 Å three-dimensional structure of particles shown in the right panel. (This reconstruction was kindly provided by B.V.V. Prasad.) See article **Rotaviruses (*Reoviridae*): Molecular Biology** for more information.

Plate 29

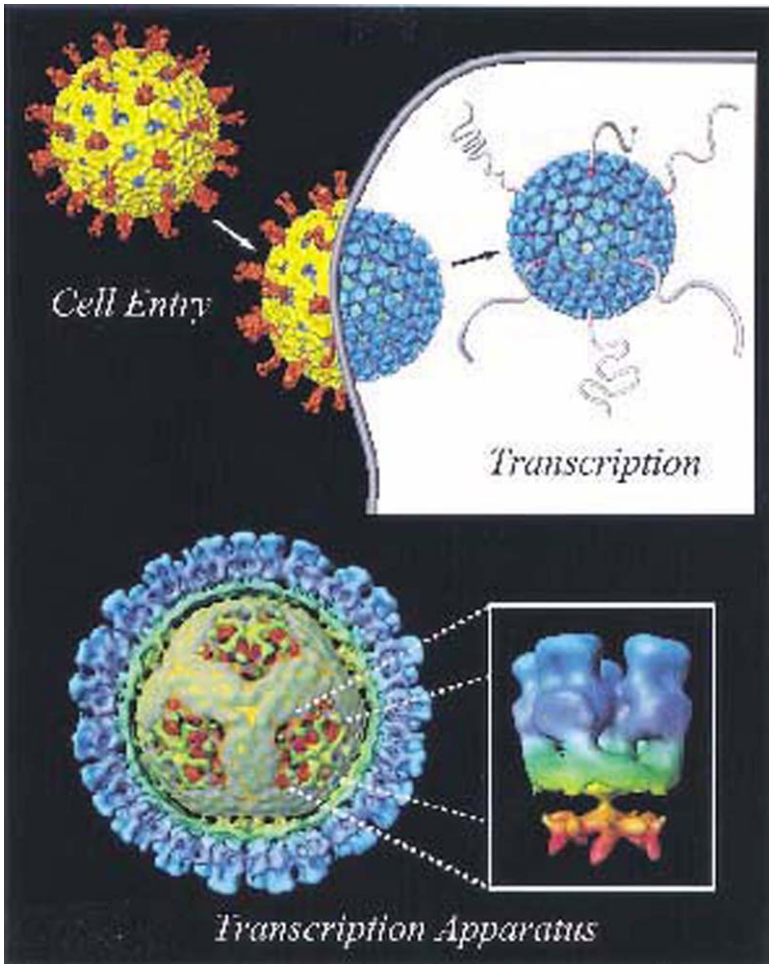

Plate 29 Rotavirus transcription. The top panel illustrates the early changes in rotavirus structure that lead to transcription and release of the mRNA molecules from the double-layered particles. The bottom panel shows the internal structure of rotavirus double-layered particles that are surrounded by trimers of the intermediate shell protein VP6 (blue). The double-stranded RNA genome is organized as a dodecahedral shell inside the particles and the minor internal proteins VP1 and VP3 are organized in a flower-shaped structure at the fivefold axes. The right-hand insert shows a side view of this structure highlighting VP6 (blue), VP2 (green) and the complex of VP1 and VP3 (orange). The newly made transcripts are extruded from these complexes at the fivefold axes (see top panel). (Figure kindly provided by J. Lawton.) See article **Rotaviruses (*Reoviridae*): Molecular Biology** for more information.

Plate 30

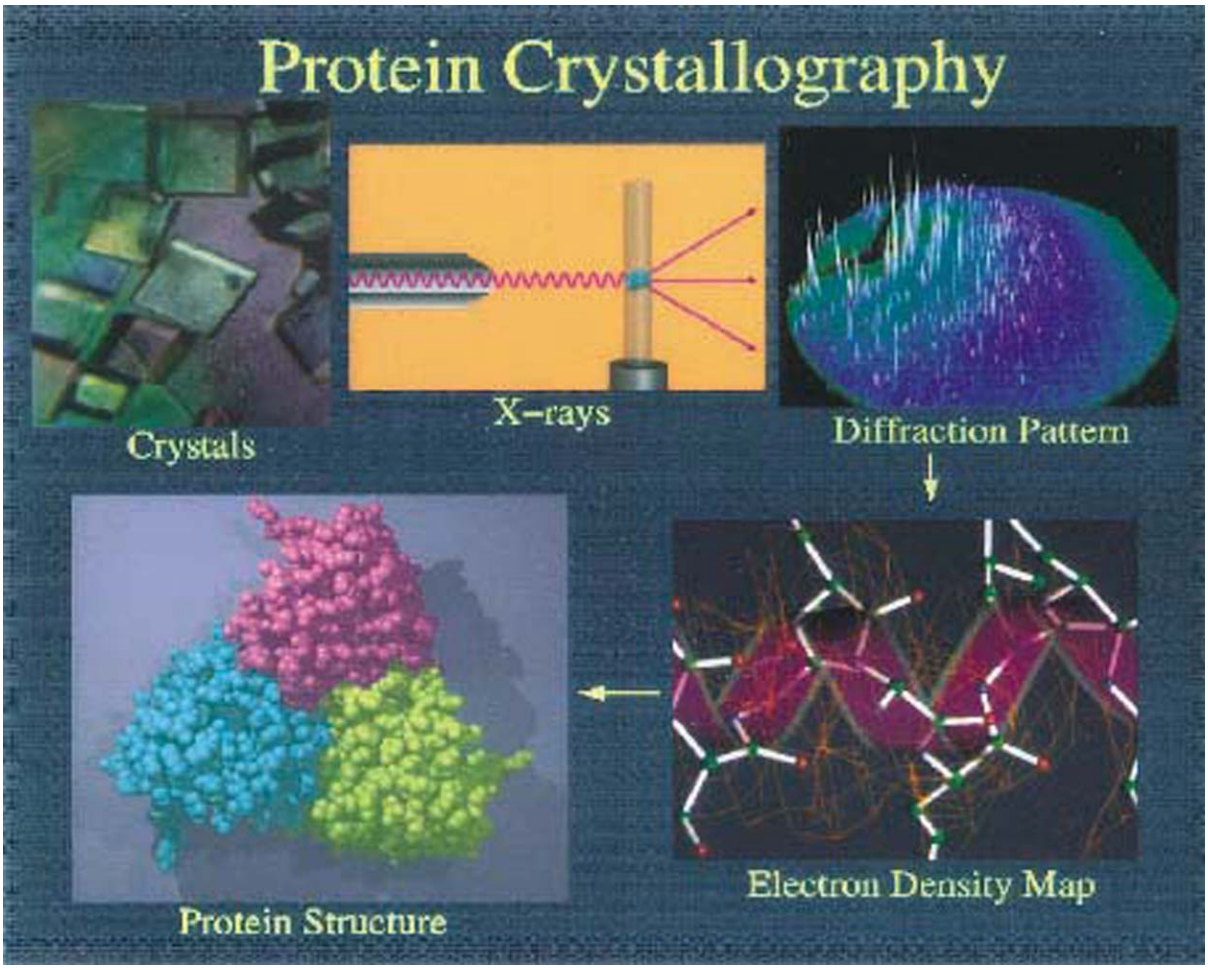

Plate 30 An illustration of protein crystallography used to determine protein structure. See article **Virus Structure: Atomic Structure** for more information.

Plate 31

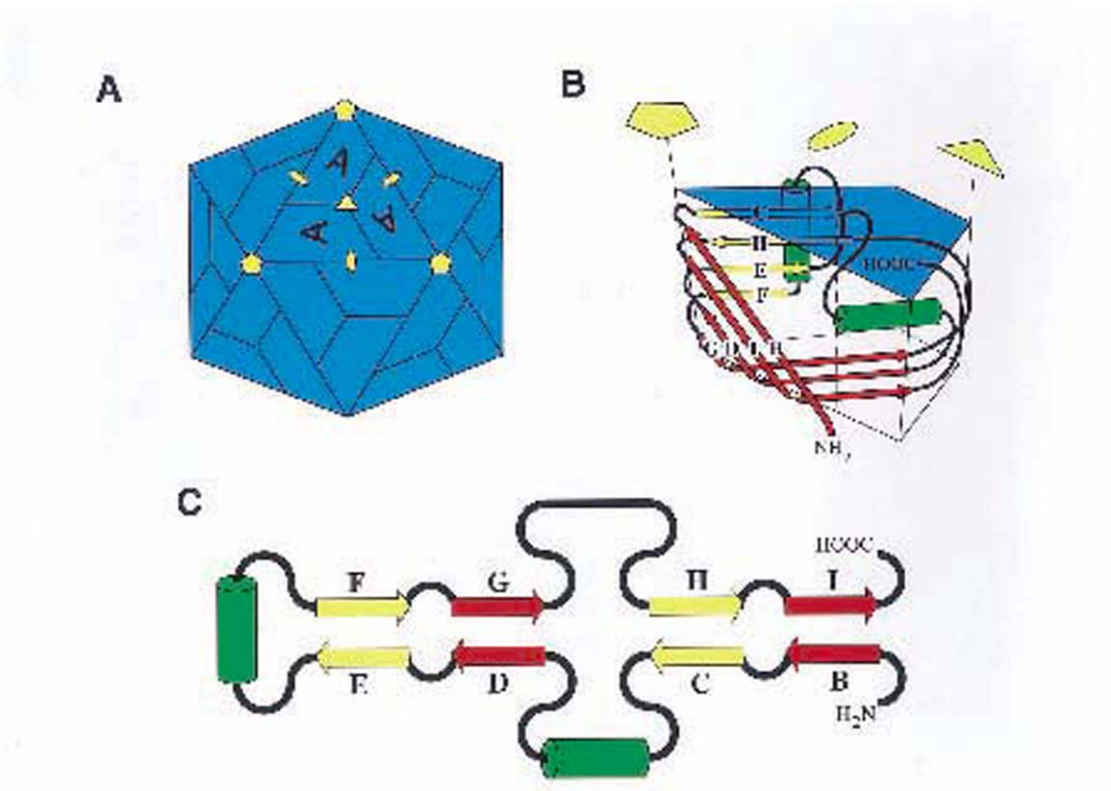

Plate 31 (**A**)The icosahedral capsid contains 60 identical copies of the protein subunit (blue) labeled A. These are related by fivefold (yellow pentagons at vertices), threefold (yellow triangles in faces) and twofold (yellow ellipses at edges) symmetry elements. For a given sized subunit this point group symmetry generates the largest possible assembly (60 subunits) in which every protein lies in an identical environment. (**B**) A schematic representation of the subunit building block found in many RNA and some DNA viral structures. Such subunits have complementary interfacial surfaces which, when they repeatedly interact, lead to the symmetry of the icosahedron. The tertiary structure of the subunit is an eight-stranded β-barrel with the topology of the jellyroll (see (**C**), β-strand and helix coloring is identical to (**B**). Subunit sizes generally range between 20 and 40 kDa with variation among different viruses occurring at the N-and C-termini and in the size of insertions between strands of the β-sheet. These insertions generally do not occur at the narrow end of the wedge (B–C, H–I, D–E and F–G turns). (**C**) The topology of viral β-barrel showing the connections between strands of the sheets (represented by yellow or red arrows) and positions of the insertions between strands. The green cylinders represent helices that are usually conserved. The C–D, E–F and G–H loops often contain large insertions. See article **Virus Structure: Principles of Virus Structure** for more information.

Plate 32

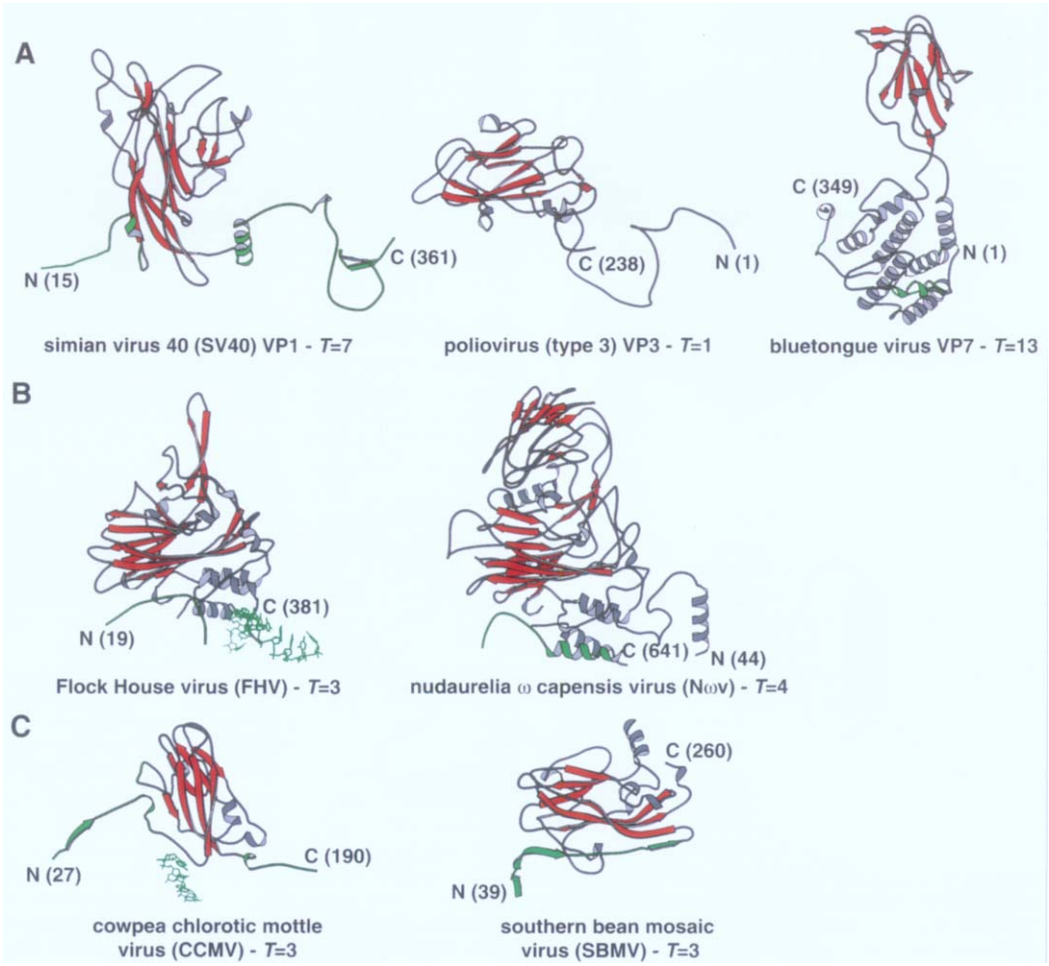

Plate 32 Structure of (**A**) vertebrate, (**B**) insect and (**C**) plant virus protein subunits that assemble into icosahedral shells. The name of the virus appears below the corresponding protein subunit along with the capsid triangulation number *T* (explained in **Plate 33**). The N- and C-termini are labeled with the residue numbers in brackets. Many virus subunit structures determined to near atomic resolution have the β-barrel fold and/or insertions with nearly all β-secondary structure (colored red, see **Plate 31B, C**). Multiple copies (from 180 to 780) of the single subunit shown for each virus, except for that of poliovirus, form the entire icosahedral protein shell. Assembly of icosahedral virus particles with more than 60 subunits (e.g. see **Plate 31A**) requires quasi-symmetric interactions (nonidentical interactions between neighboring identical subunits, discussed in detail later in this chapter, see **Plate 33 and Plate 34**) often involving subtle to extensive differences in structure at the subunit N- and C-termini. The subunit regions involved in quasi-symmetric interactions critical to virion structure and assembly are colored green (only a single variation is shown for each virus). The 'switch' in structure between identical subunits is a response to differences in the local chemical environment, defined the number of subunits forming the icosahedral shell, in order to maintain similar bonding between neighboring subunits. The structural variations include the presence or absence of highly ordered RNA structure (green stick models) in FHV and CCMV. Poliovirus utilizes multiple copies of two additional subunits highly similar to VP3 to form a complete virion. Thus, there is no quasi-symmetry in poliovirus (note the absence of any green highlights) since neighboring subunits are different proteins. See article **Virus Structure: Principles of Virus Structure** for more information.

Plate 33

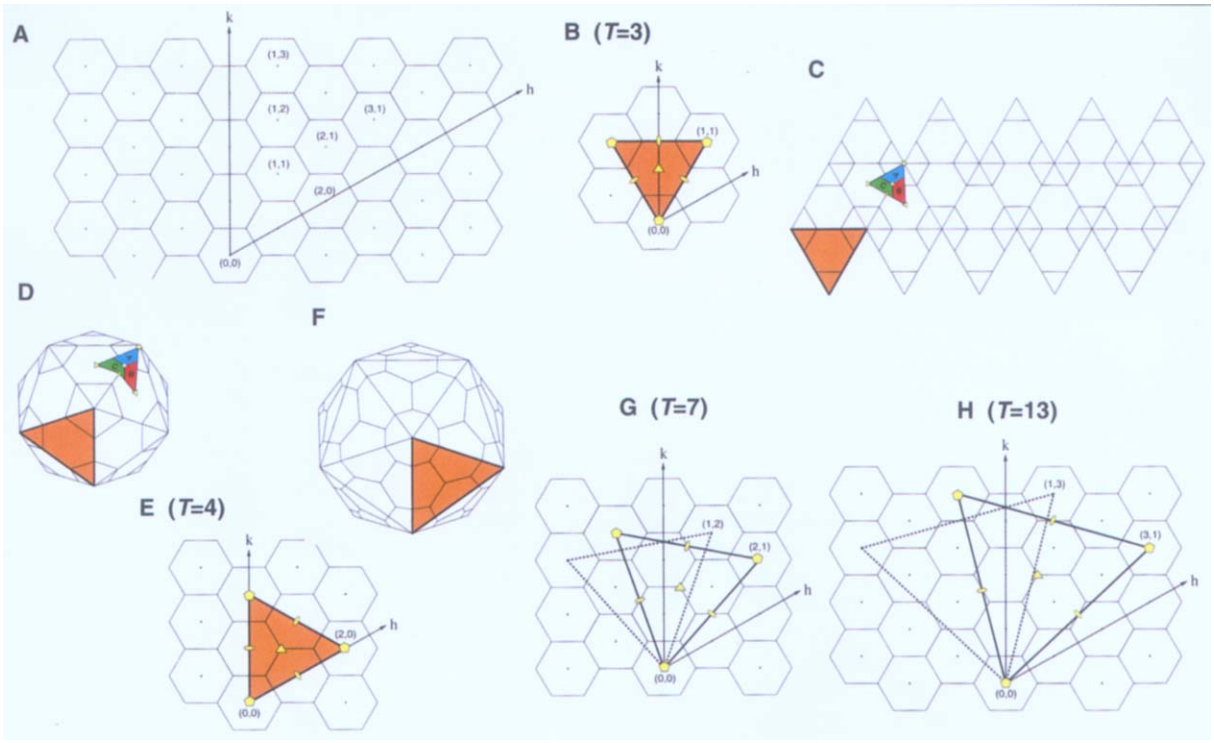

Plate 33 Geometric principles for generating icosahedral quasi-equivalent surface lattices. These four constructions show the relation between icosahedral symmetry axes and quasi-equivalent symmetry axes. The latter are symmetry elements that hold only in a local environment. (**A**) It is assumed in quasi-equivalence theory that hexamers and pentamers can be interchanged at a particular position in the surface lattice. Hexamers are initially considered planar (an array of hexamers forms a flat sheet as shown) and pentamers are considered convex, introducing curvature in the sheet of hexamers when they are inserted. Inserting 12 pentamers at appropriate positions in the hexamer net generates the closed icosahedral shell, composed of hexamers and pentamers. The positions at which hexamers are replaced by pentamers are defined by the indices **h** and **k** measured along the labeled axes. The values of (**h, k**) used in the following examples are labeled. To construct a model of a particular quasi-equivalent lattice, one face of an icosahedron (equilateral triangles colored orange in (**B–F**) is generated in the hexagonal net. The origin (0,0) is replaced with a pentamer, and the (**h,k**) hexamer is replaced by a pentamer. The third replaced hexamer is identified by threefold symmetry (i.e. complete the equilateral triangle). Each quasi-equivalent lattice is identified by a number $T = \mathbf{h^2 + hk + k^2}$ where **h** and **k** are the indices used above. T indicates the number of quasi-equivalent units in the icosahedral asymmetric unit (a hexamer contains six units and a pentamer contains five units). For the purpose of these constructions it is convenient to choose the icosahedral asymmetric unit as one-third of an icosahedral face defined by the triangle connecting a threefold axis to two adjacent fivefold axes. Other asymmetric units can be chosen such as the triangle connecting two adjacent threefold axes and an adjacent fivefold axis (see (**C**) and **plate 35**). The total number of units in the particle is $60T$, given the symmetry of the icosahedron. The number of pentamers must be 12 and the number of hexamers is $(60T - 60)/6 = 10\ (T - 1)$. (**B**) One face of the icosahedron for a $T = 3$ surface lattice is identified by the orange triangle with the bold outline (this corresponds to a face of the icosahedron in **plate 31A**). The yellow symmetry labels are the same as those defined in **plate 31**. The hexamer replaced has coordinates $\mathbf{h} = 1$, $\mathbf{k} = 1$. The icosahedral asymmetric unit is one-third of this face and it contains three quasi-equivalent units (two units from the hexamer coincident with the threefold axis and one unit from the pentamer). (**C**) Arranging 20 identical faces of the icosahedron as shown can generate the three-dimensional model of the quasi-equivalent lattice. Three quasiequivalent units labeled A (blue), B (red) and C (green) are shown. These correspond to the three quasi-equivalent units defined in **plate 44** and **35** rather than the alternative definition used in (**A**) and (**B**). (**D**) The folded icosahedron is shown with hexamers and pentamers outlined. The orange face represents the triangle originally generated from the hexagonal net. The $T = 3$ surface lattice represented in this construction has the appearance of a soccer ball. The trapezoids labeled A, B and C identify quasi-equivalent units in one icosahedral asymmetric unit of the rhombic tri-icontahedron discussed in **plate 35**. (**E**) An example of a $T = 4$ icosahedral face ($\mathbf{h} = 2, \mathbf{k} = 0$). In this case the hexamers are coincident with icosahedral twofold axes. (**F**) A folded $T = 4$ icosahedron with the orange face corresponding to the face outlined in the hexagonal net. Note that folding the lattice has required that the hexamers have the curvature of the icosahedral edges. (**G**) A single icosahedral face generated from the hexagonal net for a $T = 7$ lattice. Note that there are two different $T = 7$ lattices ($\mathbf{h} = 2, \mathbf{k} = 1$ in bold outline; and $\mathbf{h} = 1, \mathbf{k} = 2$ in dashed outline). These lattices are the mirror images of each other. To fully define such a lattice, the arrangement of hexamers and pentamers must be established as well as the enantiomorph of the lattice. (**H**) A single icosahedral face for a $T = 13$ lattice is shown. The two enantiomorphs of the quasi-equivalent lattice ($\mathbf{h} = 3, \mathbf{k} = 1$ – bold; and $\mathbf{h} = 1, \mathbf{k} = 3$ – dashed) are outlined. The procedure for generating quasi-equivalent models described here does not exactly correspond to the one described by Caspar and Klug (1962). Caspar and Klug distinguish between different icosadeltahedra by a number $P = \mathbf{h^2 + hk + k^2}$ where **h** and **k** are integers that contain no common factors but 1. The deltahedra are triangulated to different degrees described by an integer f that can take on any value. In their definition $T = Pf^2$. The description in this figure has no restrictions on common factors between h and k, thus $T = \mathbf{h^2 + hk + k^2}$ for all positive integers. The final models are identical to those described by Caspar and Klug. See article **Virus Structure: Principles of Virus Structure** for more information.

Plate 34

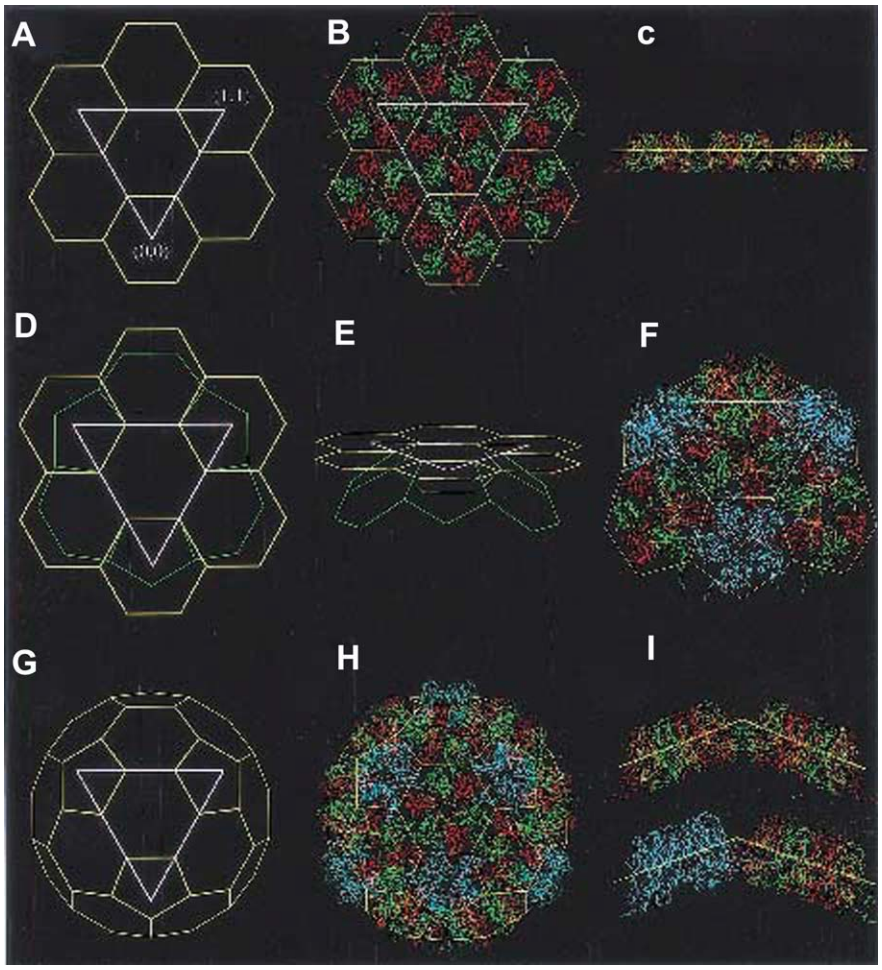

Plate 34 Molecular graphics construction of a $T = 3$ quasi-equivalent icosahedron. (**A**) Hexagonal sheet overlaid with the triangular coordinates (white) for a theoretical $T = 3$ quasi-equivalent icosahedron (**h** = 1, **k** = 1, see **plate 33B**). The sheet has true sixfold rotational symmetry about axes passing through the hexamer centers, which are normal to the sheet. (**B**) Copies of the hexamer coordinates from the CCMV X-ray structure (colored by asymmetric unit position, see **plate 35**) can be positioned in the sheet by simple translations. (**C**) A side view of the modeled sheet demonstrates its planarity. (**D**) Hexamers at the corners of the white (**h** = 1, **k** = 1) triangle become pentamers. The planar sheet (yellow model) takes on curvature to maintain contacts between the polygons (green model). (**E**) The magnitude of the pentamer-induced curvature is displayed in the side view of the partial polyhedron. (**F**) Coordinates of the CCMV X-ray structure fit this construction without any manipulation. (**G**) A completed $T = 3$ icosahedral model. The 12 pentamers generate curvature that closes the structure. This cage (a truncated icosahedron) accurately describes the geometric morphology of CCMV (**H**) which is composed of modular, planar pentamers (12) and hexamers (20). Angular pentamer–hexamer and hexamer–hexamer interfaces (**I**) stabilize curvature in the absence of convex pentamers used to construct the soccer ball of **plate 33D** (see also **plate 35**). See article **Virus Structure: Principles of Virus Structure** for more information.

Plate 35

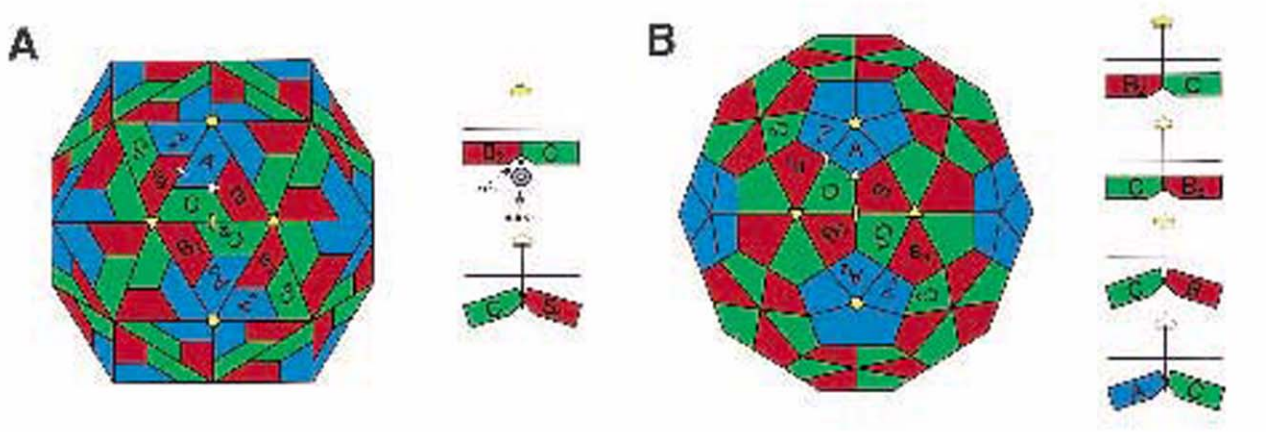

Plate 35 Although quasi-equivalence theory can predict, on geometrical principles, the organization of hexamers and pentamers in a viral capsid, the detailed arrangement of subunits can only be established empirically. High-resolution X-ray structures of $T = 3$ plant and insect viruses show that the particles are organized like the icosahedral rhombic tri-icontahedron or truncated icosahedron **plate 34**). A convenient definition of the icosahedral asymmetric unit for both geometrical shapes is the wedge defined by icosahedral threefold axes left and right of the particle center and an icosahedral fivefold axis at the top. The icosahedral asymmetric unit contains three subunits labeled A (blue), B (red) and C (green) (see **plate 33C, D**). The asymmetric unit polygons represent chemically identical protein subunits that occupy slightly different geometrical (chemical) environments as indicated by differences in their coloring. Polygons with subipts are related to A, B, and C by icosahedral symmetry (i.e. A to A_5 by fivefold rotation). The shapes of the $T = 3$ soccer ball model in **plate 33D**, truncated icosahedron in **plate 34** and rhombic tri-icontahedron are all different; however, the quasi-symmetric axes are in the same positions relative to the icosahedral symmetry axes for all three models. Quasi-threefold and quasi-twofold axes are represented by the white symbols. The quasi-sixfold axes are coincident with the icosahedral threefold axes in $T = 3$ particles as shown in **plate 33B-D** and **34**. (**A**) The rhombic tri-icontahedron is constructed by placing rhombic faces perpendicular to icosahedral twofold symmetry axes (yellow ellipse). Thus, the A, B and C polygons are coplanar within each asymmetric unit. The shape of the subunit in $T = 3$ plant and insect viruses is nearly identical to the shape of the subunit in the $T = 1$ virus and they pack in a very similar fashion. The $T = 1$ subunits in one face **plate 31A**) are related by an icosahedral threefold axis, while the $T = 3$ subunits in one face are related by a quasi-threefold axis. The dihedral angle between subunits C and B_5 (juxtaposed across quasi-twofold axes) is 144° and is referred to as a bent contact (bottom right image), while the dihedral angle between subunits C and B_2 (juxtaposed across icosahedral twofold axes) is 180° and is referred to as a flat contact (top right image). Two dramatically different contacts between subunits with identical amino acid sequences are generated by the insertion of an extra polypeptide from the N-terminal portion of the C subunit into the groove formed at the flat contact. This polypeptide is called an 'arm'. The flat contact can also be upheld by insertion of nucleic acid structure into the same groove. The N-terminal arms of the A and B subunits are disordered, and nucleic acid structure has not been observed in the groove across the quasi-twofold axis; thus, C and B_5 are in direct contact as in, for example, the X-ray structure of FHV. (**B**) A truncated icosahedron achieves curvature at different interfaces compared to the rhombic tri-icontahedron. Interactions between B_2–C and between C–B_5 polygons are both defined by 180° dihedral angles (side view at top right) whereas bends similar in magnitude occur within the asymmetric unit at the B–C and C–A polygon interfaces (138° and 142°, respectively; side view at bottom right). This creates the planar pentamer and hexamer morphological units characteristic of the truncated icosahedron and the CCMV X-ray structure **plate 34H**). See article **Virus Structure: Principles of Virus Structure** for more information.

Plate 36

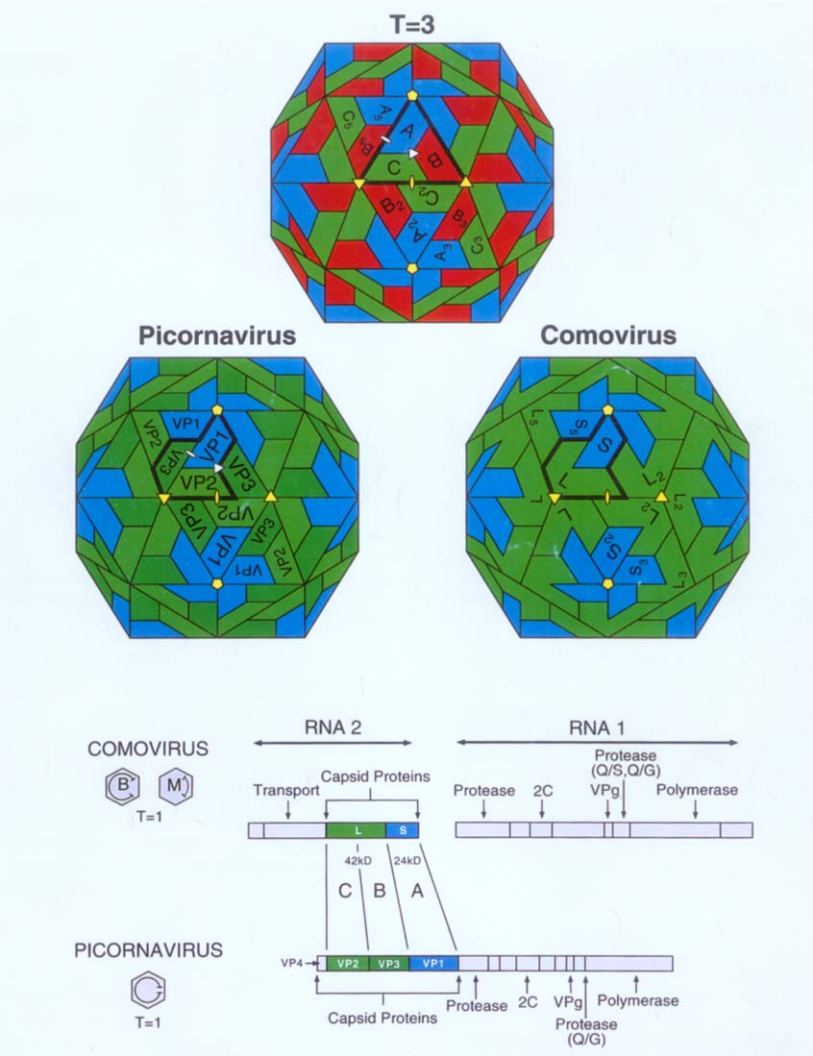

Plate 36 A comparison of $T = 3$, picornavirus and comovirus capsids. In each case, one trapezoid represents a β-barrel and the icosahedral asymmetric units are outlined in bold. The icosahedral asymmetric unit of the $T = 3$ shell contains three identical subunits labeled A, B and C (see **plate 35**). The asymmetric unit of the picornavirus capsid contains three β-barrels, but each has a characteristic amino acid sequence labeled VP1, VP2 and VP3. The comovirus capsid is similar to the picornavirus capsid except that two of the β-barrels (corresponding to the green VP2 and VP3 units) are covalently linked to form a single polypeptide, the large protein subunit (L), while the small protein subunit (S) corresponds to VP1 (note the similar color shading). The individual subunits of the comovirus and picornavirus capsids are in identical geometrical (chemical) environments (e.g. VP1 and S are always pentamers) making these $T = 1$ capsids. Comoviruses and picornaviruses have a similar gene order, and the nonstructural 2C and polymerase genes display significant sequence homology. The relationship between the capsid subunit positions in these viruses and their location in the genes is indicated by color coding and the labels A, B and C in the gene diagram. See article **Virus Structure: Principles of Virus Structure** for more information.
